where c_i^0 is the concentration of the component i in the original solution, are compiled. If the correction for pressure is small, and the sedimentation of one component does not influence the sedimentation of the other, then $p_i = 1$. It has been shown experimentally, however, that in all cases $p_1 > 1$, and $p_2 < 1$ [7,14,27–29,71] (see Fig. 2).

The experimentally observed picture of the movement of the components of the mixture is as follows. At the initial moment of time, the slow first component "remains in its position", since for this component the medium containing the fast (high-molecular-weight) second component represents a medium with an increased hydrodynamic resistance, whereas for the second component, the first (low-molecular-weight) component represents a medium with a lowered hydrodynamic resistance. In the region left by the fast component, there is a relative increase in the rate of movement of the slow component; the moving boundary then acts as a kind of "dam", and the concentration of the first component increases, leading to a relative decrease in the concentration of the second component. Thus the physical factor responsible for the JOE is the increase (fast) or decrease (slow) in the rate of movement of one component in the presence of the other.

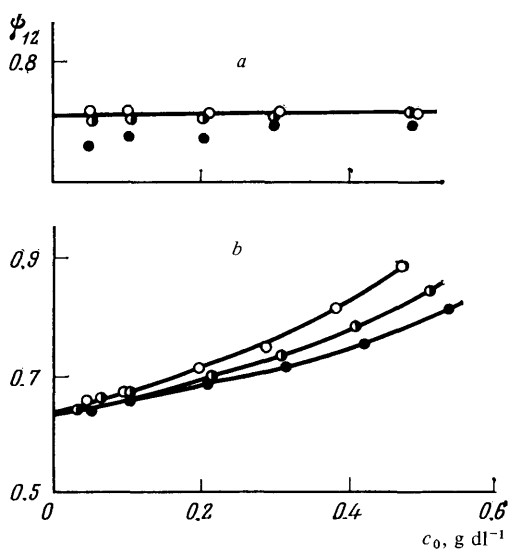

Figure 4. Concentration dependence of ψ_{12}: the symbols are the same as in Fig. 2; solvents: *a*) CH, *b*) toluene; the points of intersection of the curves with the ordinate correspond to the values $S_S^0/S_F^0 = S_{01}/S_{02}$.

In the theory of Trautman and coworkers[29], the changes in the concentrations of the components are taken into account by means of the parameter ψ_{12} (see Fig. 3):

$$c_1^\gamma/c_1^0 = (x_0/x_2)^{2\psi_{12}} = r_2^{-\psi_{12}}, \tag{10}$$

where the index γ refers to the values of the quantities in the region of the γ-plateau. It can be shown that the value of ψ_{12} is determined by the difference in the values of the sedimentation coefficients of the first and second components in the region of the γ-plateau:

$$\psi_{12} = \int_0^t S_1^\gamma \,dt \Big/ \int_0^t S_2^\gamma \,dt. \tag{11}$$

The experimental data[71] indicate that the concentration dependence of the sedimentation coefficients of the components of the mixture satisfies the relationship

$$S_i = S_{0i}/(1 + k_i c_i + k_{ji} c_j), \tag{12}$$

where the coefficient k_{ji} reflects the influence of the jth component on the sedimentation of the ith component. In a θ-solvent (CH for PαMS), $k_{ji} = k_i$, but in a good solvent, only the approximate relationship $k_{ji} \simeq k_i$ holds. Application of Eqn. (12) to the sedimentation of the components in the region of the γ-plateau gives:

$$\psi_{12} = S_{01}/S_{02}. \tag{13}$$

The original concentrations of the components c_1^0 and c_2^0 are related to the parameter ψ_{12} as follows:

$$c_1^0 = c_1^* (r_2 - r_1)/[r_2^{1-\psi_{12}} - 1], \tag{14a}$$

$$c_2^0 = c_1^* r_1 + c_2^* r_2 - c_1^0. \tag{14b}$$

By measuring the areas under the peaks c_i^* (see Fig. 1), it is possible to use Eqns. (14a) and (14b) to determine the parameter ψ_{12}. Fig. 4 gives the concentration dependence of this parameter[71]. For the θ-system PαMS–CH, relationship (13) is fulfilled, whereas in a good solvent (toluene), the value of ψ_{12} increases with increase in concentration.

Undoubtedly, the most important feature is that in the limit, as $c \to 0$, the parameter ψ_{12} does not tend to unity, which would correspond to the widely held view that the JOE decreases with decrease in the concentrations of the components, but becomes equal to the limiting value corresponding to Eqn. (13) in the case of the PS–CH system, or approaches it in the case of the PS–toluene system (PS = polystyrene). This in turn leads to the important conclusion that it is impossible to eliminate the influence of the Johnston–Ogston effect by extrapolating the experimental data to zero concentration.

If the influence of hydrostatic pressure is taken into account from the generalised dilution law (7), the following equations are obtained instead of Eqns. (14a) and (14b):

$$c_1^0 = c_1^* (y_2 - y_1)/[y_2^{1-\psi_{12}} - 1];\ y_i = r_i/[1 + m(r_i - 1)]; \tag{15a}$$

$$c_2^0 = c_1^* y_1 + c_2^* y_2 - c_1^0. \tag{15b}$$

IV. SEDIMENTATION OF POLYDISPERSE POLYMERS

1. CHARACTERISTICS OF THE EXTRAPOLATION METHOD

The graphical–analytical procedure widely adopted at present[2-4] for determining the distribution curves with respect to sedimentation coefficients (and also the MMD) of polymers is based on the assumption of simple additivity of the movement of the components and the factors operating in the system. It is assumed that the effects of pressure, diffusion, and the concentration dependence of the sedimentation coefficients are independent and additive and can be considered in turn. The apparent distributions $g^*(S, t)$, not corrected for diffusion broadening, are calculated from Eqns. (5), (5a), and (6) and the relationship

$$g^*(S, t) = zrx/[1 + m(r-1)]^2, \tag{16}$$

where the displacement $z \sim dc/dx$. Extrapolation of the $g^*(S, t)$ curves for a number of concentrations to infinite time (that is $1/t \to 0$) eliminates the diffusion factor, after

which the $g(S)$ distributions are extrapolated to zero concentration, which makes it possible to take account of the $S(c)$ relationship. It is assumed that these extrapolations simultaneously eliminate the influence of cross-term interactions; as shown in the previous section, however, the JOE cannot be eliminated by extrapolating the data to zero concentration. It is apparently not accidental that research experience[23] shows that there are considerable complications in carrying out the extrapolations. Moreover, the final distribution loses "fine" details (small or poorly resolved maxima, a "tail"), and are too narrow.

It is possible to distinguish three types of polymer, differing from one another in the width of the distribution curves $g(S)$: 1) highly polydisperse polymers contain high-molecular-weight fractions (a "tail"), which reach the foot of the cell, whereas the low-molecular-weight components do not leave the meniscus; 2) for polymers of medium polydispersity, the boundary occupies almost the entire column of solution, that is the boundary leaves the meniscus, but the "tail" of the distribution does not reach the foot; and 3) the boundary for weakly polydisperse polymers occupies approximately half (or less) of the height of the column of solution in the cell.

This division is of course to some extent arbitrary, since a given specimen in a thermodynamically ideal solvent and in a good solvent, or with a considerable variation in concentration, may correspond to different types of polydispersity with respect to $g(S)$. As will be shown subsequently, however, polymers of the second and third types differ considerably from one another in the relative roles of diffusion and the JOE. The sedimentation of highly polydisperse polymers (the first type) has already been examined[37].

The practical realisation of the extrapolation of distributions sometimes encounters difficulties even in making allowance for diffusion[23,73]. Thus the sedimentation of an industrial specimen of polystyrene (its characteristics will be given below) at $c \leq 0.3$ g dl^{-1} gives $g^*(S, t)$ curves which do not change in the same sense, and the height at the distribution maximum decreases with time. The introduction, with fairly crude assumptions, of corrections for dilution leads to $g^*(S, t)$ distributions for which the ordinates at the maximum increase with increase in t, and it is possible to eliminate the influence of diffusion[73]. The example given illustrates a characteristic unsatisfactory feature of calculations using Eqns. (5), (5a), (6), and (16)—the neglect of sector dilution. For a polymer which is non-uniform with respect to mass, this problem is not so simple, since different components of the mixture are diluted in different ways, both from purely geometric considerations and because they are situated in regions with different local concentrations.

Another unsatisfactory feature of the above widely adopted method of treating sedimentation diagrams is that the treatment is implicitly based on the concept of plateau concentration. In fact, all polymers are characterised by a $S = S(c)$ relationship, so that it is possible to relate a distribution $g^*(S, t)$ to a specific concentration c without additional corrections only if the concentration remains unchanged during sedimentation. The concentration remains practically unchanged in the region of the plateau, whereas along the boundary it increases from zero to the plateau concentration. Thus Eqns. (5), (5a), (6), and (16) are inseparable from the assumption that a decisive role in the sedimentation of a polydisperse polymer is played by the concentration in the region of the plateau. This concept is directly contradicted by the above results of the study of the sedimentation of two-component systems. This leads to the consideration of another fundamental problem.

On the basis of Fujita's equation (8),[13,14] relationships have been obtained[74] for calculating $g^*(S, t)$ with allowance for the $S(t)$ relationship and the change in the concentration along the boundary. Fig. 5 gives the $g^*(S, t)$ curves for a polystyrene specimen PS-1 (data on this specimen are given below) in CH at 34°C, calculated from the published equations[74]. The distributions with respect to sedimentation coefficients change in different senses to such an extent that it is not possible to eliminate diffusion broadening. The error in this case[74] is that for the intermediate range, the simple concentration c is used throughout, with no indication of its constituent components.

2. ROLE OF THE DIFFUSION FACTOR IN THE SEDIMENTATION OF POLYDISPERSE POLYMERS

a) The use of Fujita's theory[75] to estimate the diffusion broadening of the boundary

Allowance for diffusion broadening of the boundary is usually made[2-4] for each concentration with extrapolation of the distributions $g^*(S, t)$ or $G^*(S, t)$ (where $G^*(S, t)$ is the integral curve) to infinite time (that is $1/t = 0$). It is necessary, however, not only to eliminate the diffusion broadening of the distributions but also to determine quantitatively the role of diffusion and to determine the dependence of the diffusion factor on the molecular mass, polydispersity, and nature of the MMD curves of the polymers. This last feature is important in itself, and also in the development of single-point (single-recording) methods for calculating the MMD of polymers.

Fujita's theory[14,75] makes it possible to determine the role of diffusion in the sedimentation of polydisperse polymers[26,66,76]. This theory examines the sedimentation, in an "ideal sedimentation solvent"[14] in a rectangular cell, of a polymer of medium or low polydispersity, which does not contain appreciable quantities of low-molecular-weight fractions, that is $g(S)|_{x=x_0} = g'(S)|_{x=x_0} = 0$, and which does not contain high-molecular-weight fractions, that is a distribution "tail" which rapidly reaches the foot of the cell. Thermodynamically ideal behaviour is included as a necessary condition in the concept of an "ideal sedimentation solvent". Another important condition is the absence of all hydrodynamic interactions or the absence of concentration dependences $S(c)$ and $D(c)$ (D is the diffusion coefficient) and cross-term interactions. In addition, the following approximate relationship is used:

$$x - x_0 = x_0\omega^2 tS.$$

Since the sedimentation is ideal, the parameter K is constant:

$$K = SD = S_0D_0 = \text{const.} \qquad (17)$$

Subsequently, the interpretation of the experimental data will be related chiefly to this parameter. Using familiar relationships[3], it is possible to express K in terms of molecular parameters

$$K_0 = S_0D_0 = \frac{RT(1-\bar{v}\rho_0)}{N_A^2P^2\eta_0^2}\left(\frac{M}{\bar{h}_0^2}\right) = K_0^{\text{theor}}, \qquad (18)$$

where R is the universal gas constant, T the temperature, N_A Avogadro's number, P the frictional constant ($P = 5.1$

was used in the calculations), η_0 the viscosity of the solvent, $\overline{h_0^2}$ the dimensions of the coiled molecule in the ideal solvent, and $\overline{v}$ the partial specific volume of the polymer.

Despite these restrictions, Fujita's theory was the first to deal simultaneously with the sedimentation and diffusion of polymers of medium polydispersity, since Gosting's relationships[77] were derived with the condition that D = const for all components, that is, strictly speaking, for polymers (fractions) with low polydispersity. Analysis of the published expressions[66] for the dispersion of the displacements $\overline{\xi}^2$ from the theories of Fujita and Gosting shows that they are identical, but the former theory has the advantage of being general. Fujita's theory shows that Gosting's relationships are also inapplicable to the sedimentation of polymers of medium polydispersity if the weighted-mean diffusion coefficient is used. After allowance for the effect of self-contraction, the experimental data[66,78,79] on the dependence of $\overline{\xi}^2$ on t show qualitative agreement with theory.

**The equation is applicable for a concentration of 0.4 g dl^{-1}.

As noted above, allowance for the diffusion broadening of the boundary for polydisperse polymers is made difficult by the fact that the distributions $g^*(S, t)$ do not change in the same sense (see Fig. 5). By modifying slightly the correction for dilution[73], it is possible to improve considerably the extent to which the $g^*(S, t)$ curves change in the same sense and to carry out the extrapolation to $1/t = 0$ for specimens of PS and polyvinyl acetate (PVA) (see Table 2). For polymers with a low polydispersity—poly(*m*-phenylene)isophthalamide (PPhIA), polyacrylonitrile (PAN), and polyvinyl chloride (PVC)—calculation using Eqn. (5), (6a), (6), and (16) gave distributions $g^*(S, t)$ which changed satisfactorily in the same sence[76].

The asymptotic solution of the equation describing the broadening of the boundary in the sedimentation of a polydisperse substance has the following form[75]:

$$g^*(S, t) = g(S) - \frac{1}{4\tau}\frac{d}{dS}\left[\frac{g(S)}{S^2} - \frac{g'(S)}{S}\right] - \ldots ; \quad (19)$$

$$G^*(S, t) = G(S) - \frac{1}{4\tau}\left[\frac{g(S)}{S^2} - \frac{g'(S)}{S}\right] - \ldots ; \quad (20)$$

$$\tau = \omega^2 x_0^2 t/4K. \quad (21)$$

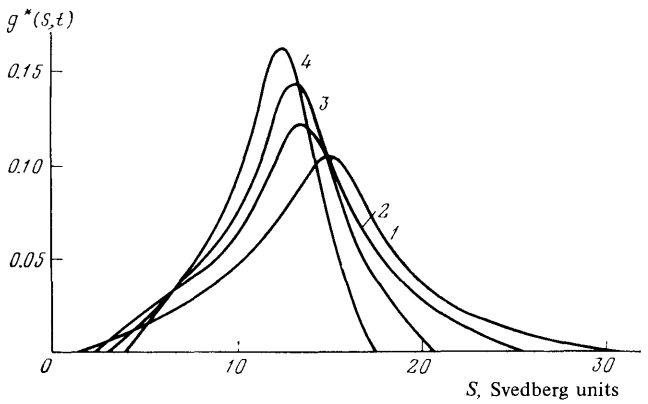

Figure 5. Normalised $g^*(S, t)$ curves for the specimen PS-1 (c = 0.3016 g dl^{-1}, ω = 40 000 r.p.m.), calculated from published equations[74]; time, s: *1*) 887, *2*) 1487, *3*) 2387, *4*) 3287.

In accordance with Eqn. (20), by plotting the sedimentation coefficients S^* against $1/t$ for constant G, it is possible from the magnitude of the intercept to find the values of $S = S^*_{t=\infty}$, and finally to obtain the distribution $G(S)$ corrected with allowance for diffusion.

The time dependence of S^* at constant G^* is given by the equation

$$S^* = a_0 + a_1/\tau + \ldots ; \quad (22)$$

$$a_0 = S, \; a_1 = \frac{1}{4}\left[\frac{1}{S^2} - \frac{g'(S)}{Sg(S)}\right]. \quad (22a)$$

The slope of this relationship $Y(S)$ is given by[75]:

$$Y(S) = -\left[\frac{K}{\omega^4 x_0^2 g(S)}\right]\frac{d}{dS}\left[\frac{g(S)}{S}\right]. \quad (23)$$

Since $dG = g(S)dS$,

$$\int_{G^0}^{1} Y(S)\,dS = \Xi = \frac{K}{\omega^4 x_0^2}\left[\frac{g(S^0)}{S^0}\right], \quad (24)$$

where Ξ is the area under the plot of Y against G, and the quantities G^0, $g(S^0)$, and S^0 correspond to the value $Y(S^0) = 0$. Thus K can be calculated from the experimentally determined values of Ξ, $g(S^0)$, and S^0 using Eqn. (24).

If the $g^*(S, t)$ distributions are extrapolated, it is possible to determine K as follows[86]. The slope $W(S)$ of the plot of $g^*(S, t)$ against $1/t$ for constant S, in accordance with Eqn. (19), is given by

$$W(S) = -\frac{K}{\omega^4 x_0^2}\frac{d}{dS}\left[\frac{g(S)}{S^2} - \frac{g'(S)}{S}\right]. \quad (25)$$

Integration of this expression with respect to S gives the basic relationship for determining K:

$$\int_{S_A}^{S_B} W(S)\,dS = -\frac{K}{\omega^4 x_0^2}\left[\frac{g(S)}{S^2} - \frac{g'(S)}{S}\right]_{S_A}^{S_B}. \quad (26)$$

The limits of integration S_A and S_B correspond to the value $Y(S_{A,B}) = 0$. For a Gaussian function, that is for

$$g(S) = \frac{1}{\sigma\sqrt{2\pi}}\exp\left\{-\frac{(S-S_m)^2}{2\sigma^2}\right\}, \quad (27)$$

the values of $S_{A,B}$ are found from the obvious condition $g^*(S_{A,B}) = g(S_{A,B})$, which leads to the following equation:

$$\frac{1}{\sigma\sqrt{2\pi}}\exp\left[-\frac{(S-S_m)^2}{2\sigma^2}\right]_{S_A}^{S_B} = \frac{1}{\sigma^*\sqrt{2\pi}}\exp\left[-\frac{(S-S_m)^2}{2(\sigma^*)^2}\right]_{S_A}^{S_B},$$

where $\sigma^* = \sigma + \Delta\sigma$ is the dispersion of the distribution $g^*(S, t)$. If it is assumed that $\Delta\sigma \ll \sigma$, then

$$S_{A,B} = S_m \pm \sigma, \quad (28)$$

$$\left[\frac{g(S)}{S^2} - \frac{g'(S)}{S}\right]_{S_m-\sigma}^{S_m+\sigma} = \frac{2S_m(S_m^2 - 3\sigma^2)}{\sqrt{2\pi e}\,\sigma^2(S_m^2-\sigma^2)^2}. \quad (29)$$

The value of the integral in the left-hand side of Eqn. (26) is determined from experimental data, so that K can be calculated from Eqns. (26) and (29). If the $g^*(S, t)$ curves are symmetrical and similar to a Gaussian distribution function, and if there is no removal of the distributions from the meniscus, it is better to use this method for determining K.[86]

Both methods for determining K have been verified using a large amount of experimental material; thus the calculations for all concentrations of the systems PS–CH and PPhIA–DMF–0.25% LiCl have been duplicated. Since the two methods gave practically identical results, the values of K are subsequently given without an indication of the method of determination. Fig. 6 gives the concentration dependence of the parameter K for the systems studied. The extrapolated values of K and the values calculated from Eqn. (18) are given in Table 3; the relationship $(\bar{h}_0^2/M) = bA/M_0$ was used (b is the length of the monomeric unit, M_0 the molecular mass of the monomeric unit, and A the length of the Kuhn segment). The data in Table 3 show that for the first two θ-systems, the experimentally determined values of K_0 are much greater than the theoretical values K_0^{theor}, calculated from Eqn. (18). For polymers in good solvents, these values are similar; in their comparison it must be borne in mind that K_0^{theor} is in fact the limiting value, since for non-ideal solutions it is necessary in Eqn. (18) to take account of the dimensions $\bar{h}^2$ of the coiled molecules in the good solvent.

From the experimental relationships $D(c)$ [88] and $S(c)$ for PS in CH, it is possible to calculate $K^{calc}(c)$ directly from Eqn. (17) (see Fig. 6*a*). Extrapolation gives for PS-1 the value $K_0^{calc} = 1.8\times10^{-19}$ and for PS-2, $K_0^{calc} = 2.0\times10^{-19}$, that is there is a very large difference between the experimental and calculated values of K_0. In addition, the published illustrations[21] can be used to determine the values of K for various PS specimens: the specimen with $\bar{M}_w = 3.16\times10^5$, $\bar{M}_w/\bar{M}_n = 1.02$, and $c = 0.3180$ has $K = 2.0\times10^{-19}$, and the specimen with $\bar{M}_w = 3.52\times10^5$, $\bar{M}_w/\bar{M}_n = 1.53$, and $c = 0.3253$ has $K = 2.3\times10^{-19}$. For PS-2 at $c = 0.3050$, $K = 17\times10^{-19}$, and for PS-1 at $c = 0.3016$, $K = 41\times10^{-19}$.

These examples show that there is a definite relationship between K and the polydispersity and average molecular mass. Comparison of the values of $\bar{D}_0$, calculated from the values of K_0 and K_0^{theor} (see Table 3) shows that the excess broadening (that is the broadening which is not due to the polydispersity) of the boundary of the solutions of specimens of PS in CH and of PVA in BEK is due chiefly not to diffusion but to other factors.

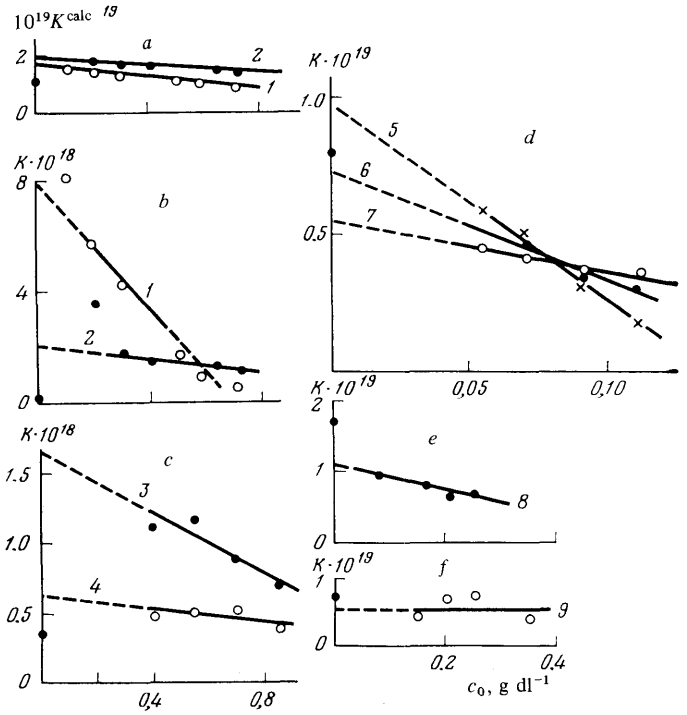

Figure 6. Concentration dependence of the parameter K for the systems: PS–CH, 34° (*a*, *b*); PVA–BEK, 29° (*c*); PPhIA–(DMF–0.25% LiCl), 25° (*d*); PAN–DMF : THF (1 : 1), 25° (*e*); PVC–THF, 25° (*f*). The points on the ordinate correspond to the values of K_0 calculated from Eqn. (18), and the figures give the numbering of the specimens in Tables 2 and 3.

* Symbols: M_0 is the molecular mass of the monomeric unit; b the length of the monomeric unit; A the length of the statistical segment; and σ_0 the dispersion of the distribution $g(S_0)$.

The values of $\bar{D}_0$ determined from K_0 and K_0^{theor} for PPhIA in DMF–0.25% LiCl do not differ so markedly, but they show the opposite dependence on the average molecular mass (or on $\bar{S}_0$ from Table 3): the value of D_0 decreases with increase in the average molecular mass of the specimen in the first case, and decreases in the second case, so that the excess broadening of the boundary for this system is not due entirely to diffusion.

An important role is apparently played by the hydrodynamic interactions of the components of the mixture (that is the JOE). The cross-term interactions of the flow of the individual components of a polydisperse polymer should lead to a decrease in the rate of sedimentation for the low-molecular-weight fractions and to an increase in this rate for the high-molecular-weight fractions, and this leads to broadening of the $g^*(S, t)$ curves, similar to diffusion broadening. Extrapolation to $1/t = 0$ apparently takes partial or complete account of this broadening, and leads to an increase in the values of K_0 and $\bar{D}_0$ (see Table 3).

b) The use of model functions to take account of the diffusion broadening of distribution curves with respect to sedimentation coefficients in a single recording

In real systems, the correction for diffusion in the sedimentation of polymers with medium and low polydispersity is comparatively small (10–30%), and the second term in the right-hand side of Eqns. (19) and (20) has the character of a correction, and this makes it possible to take it into account by means of model functions[26,66,89]. This can be done most simply on the basis of the Gaussian function (27) by an iteration method[26,66].

The distribution $g(S)$ in the second term in the right-hand side of Eqn. (19) is replaced by the distribution $g^*(S, t)$, and this in turn is replaced by the function (27), with parameters $S_m = \bar{S}^*$ and $\sigma = \sigma^*$,

$$(\sigma^*)^2 = \int_0^\infty (S^* - \bar{S}^*)^2 g^*(S, t)\, dS \Big/ \int_0^\infty g^*(S, t)\, dS. \qquad (30)$$

The following equations are obtained in place of Eqns. (19) and (22):

$$g(S) = g^*(S, t) \Big/ \left\{1 - \frac{1}{4\tau S}\left[\frac{1}{(\sigma^*)^2} - \frac{1}{S^2} - \left(\frac{S - \bar{S}^*}{(\sigma^*)^2} + \frac{1}{S}\right)^2\right]\right\}, \qquad (31)$$

$$S^* = S + \frac{1}{4\tau}\left[\frac{1}{S^2} + \frac{S - \bar{S}^*}{S(\sigma^*)^2}\right]. \qquad (32)$$

The distribution $g(S)$ obtained can be used again to refine the parameters S_m and σ of the Gaussian curve, after which the calculation from Eqns. (31) or (32) is repeated, etc. It should be noted that this procedure involves not the replacement of the real distribution by a model function[23,90–92] but the determination of the law corresponding to the deformation of this distribution (the denominator in Eqn. (31)).

By proceeding analogously, it is possible to obtain expressions[89] for taking account of the diffusion broadening of the boundary by means of the functions of Schulz[93] and Beasley[94]. Fig. 7*b*, for the specimen PPhIA-5, compares the extrapolation distribution $g(S)$ with the distributions calculated from one sedimentation diagram on the basis of the model functions of Gauss, Schulz, and Beasley[89]. The calculation based on the functions of Gauss and Schulz led to good agreement between the calculated and extrapolation curves $g(S)$, since the models coincide fairly closely with the distribution $g^*(S, t)$ (Fig. 7*a*). At the same time, in spite of the fact that the model based on the Beasley function had nothing in common with the distribution $g^*(S, t)$, the $g(S)$ curve calculated on the basis of this function did not differ greatly from the extrapolation distribution.

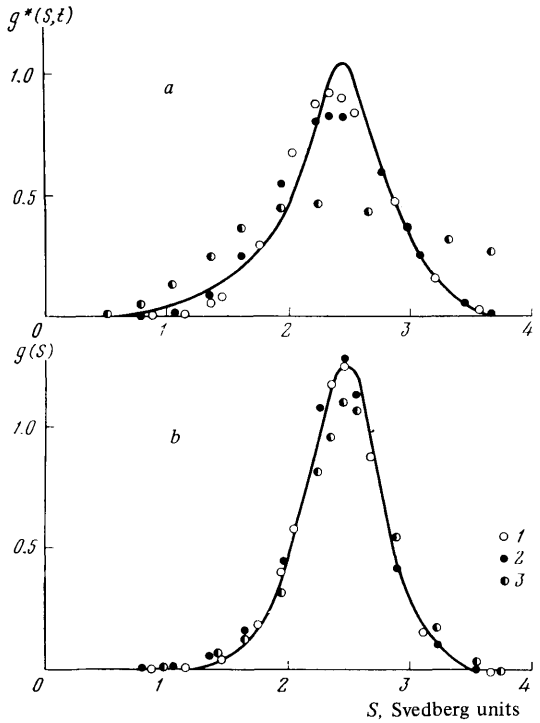

Figure 7. Comparison of the distribution $g^*(S, t)$ for specimen PPhIA-5 ($c = 0.11$ g dl^{-1}) in DMF–0.25% LiCl, $t = 4953$ s (continuous line) with model functions (*a*), and comparison of the extrapolation curve $g(S)$ (continuous line) with the distributions calculated from one recording, based on model functions (*b*): *1*) Gauss; *2*) Schulz; and *3*) Beasley.

Thus when allowance is made for diffusion from a single recording, the slight lack of agreement between the model curve and the real curve $g^*(S, t)$ does not play a significant role, but when the model is completely "separated" from the real distribution $g^*(S, t)$, allowance for diffusion from a single recording leads to distortion of the form of the $g(S)$ curves. Naturally, in real situations, the form of the sedimentation diagrams, the nature of the process by which the polymer is obtained, etc. should influence the type of model function which will make it possible to take account of the diffusion broadening of the distributions $g(S)$.

3. CONCENTRATION DEPENDENCE OF THE SEDIMENTATION COEFFICIENTS OF POLYDISPERSE POLYMERS

For a number of systems (see Table 2), the treatment of the $S(c)$ relationships in the extrapolation of the distributions $G(S)$ to $c = 0$ is carried out in accordance with

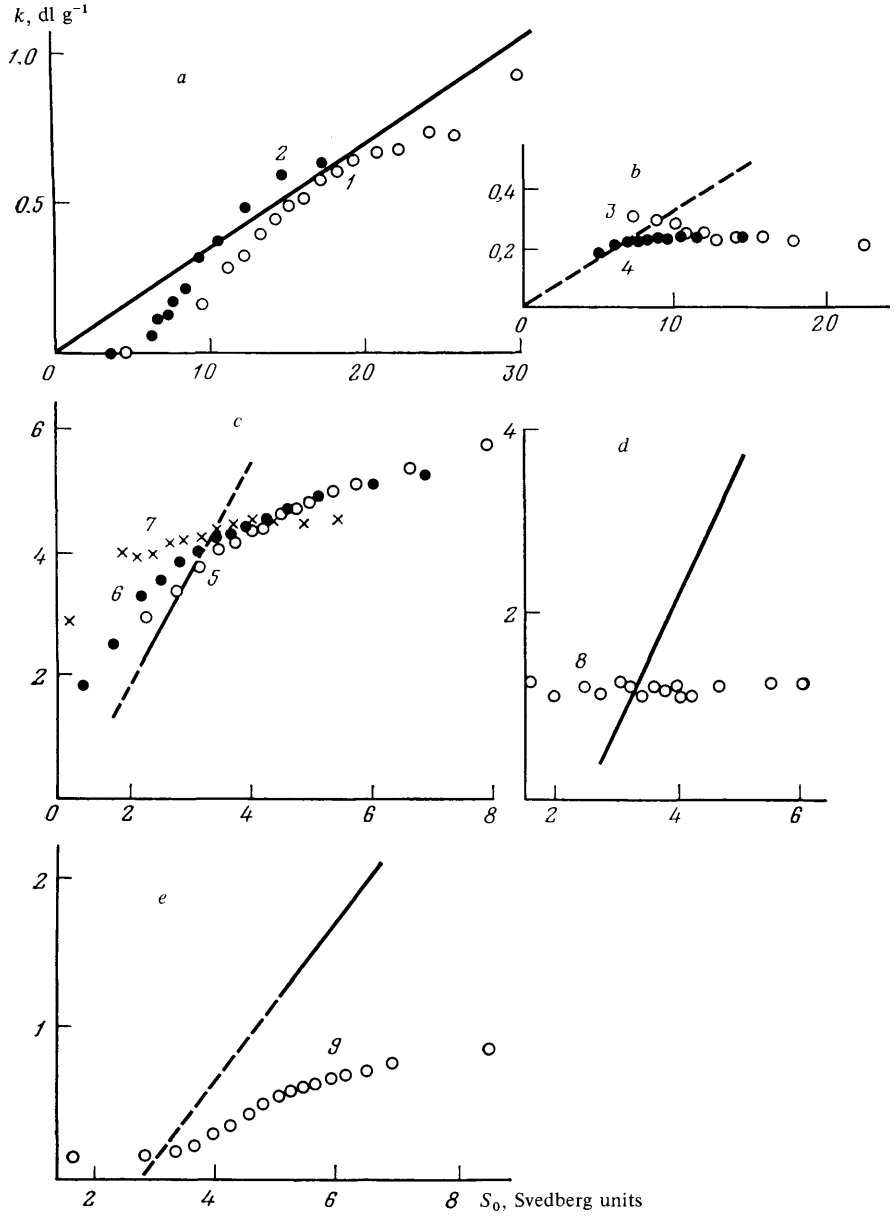

Figure 8. Dependence of k on S_0 for the systems: *a*) PS–CH, 34°; *b*) PVA–BEK, 29°; *c*) PPhIA–(DMF–0.25% LiCl), 25°; *d*) PAN–(DMF : THF = 1 : 1), 25°; *e*) PVC–THF, 25°; the numbers next to the symbols correspond to the numbering of the specimens in Table 2; the continuous and broken lines represent the functions $k(S_0)$ for the fractions.

Eqn. (3). In Fig. 8, the functions $k = k(S_0)$ obtained from these relationships are compared with the same functions for the fractions. The data in Fig. 8 show that polydisperse polymers in good solvents (Figs. 8*c*, 8*d*, and 8*e*) are characterised by a marked weakening of the concentration dependence of the sedimentation coefficients for the high-molecular-weight components, and an intensification of the concentration dependence of the sedimentation coefficients for the low-molecular-weight components. In the system PS–CH (Fig. 8*a*), there is a relatively poor correspondence between the functions for the polydisperse specimens and the fractions.

The following points should be noted regarding the θ-system PVA–BEK (Fig. 8*b*). For this system, a $S(c)$ relationship was not detected[82], but this relationship appeared when a correction was introduced for the pressure μ. The cross-term interactions in the polydisperse polymer compensate one another about the centre of gravity ($\overline{S}$) of the distribution $g(S)$, so that the $\overline{S} = \overline{S}(c)$ relationship (or the analogous functions found from the maxima of the gradient curves) should not be distorted by Johnston–Ogston effects. On the other hand, both theory[50] and experiment[21,54] give a linear dependence of k on S_0 for the case of flexible-chain polymers in a θ-solvent, although

for rigid-chain macromolecules this relationship is apparently more complex[61,62]. In view of these features, the function $k(S_0)$ for the fractions of the system PVA–BEK was estimated from the $\bar{S} = \bar{S}(c)$ relationship for two non-fractionated specimens, and is given by the broken line in Fig. 8*b*. In this system, as in the case of polymers in good solvents, marked differences are observed between the $k(S_0)$ relationships for polydisperse polymers and the analogous functions for homogeneous polymers (fractions).

If it is assumed that diffusion extrapolation does not eliminate completely the broadening of the distributions $g(S)$ due to cross-term interactions, there arises the question of how these interactions influence the concentration dependence of the sedimentation coefficients. The scheme in Fig. 9 can be examined in this connection. The hypothetical distribution with identical relative concentrations of all the components undergoes the usual self-contraction (straight lines *AB* and *CD*) and additional broadening due to cross-term interactions (straight lines *A'B'* and *C'D'*). The concentration dependence $S(c)$ is determined by the difference in the values of S for corresponding points of these straight lines for a given G = const. For the extreme points of the distributions, $A'C' > AC$ and $B'D' < BD$, indicating an increase for low-molecular-weight components, and a decrease for high-molecular-weight components, in the value of the function $\kappa(S_0)$ for polydisperse polymers compared with the same function for the fractions.

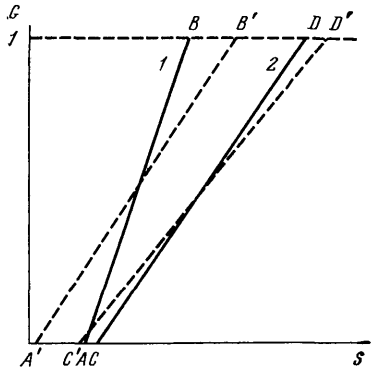

Figure 9. Schematic representation of the influence of effects of the Johnston–Ogston type on the integral distributions $G(S)$; the continuous lines correspond to distributions not perturbed by these effects, and the broken lines represent distributions influenced by these effects. The numbers 1 and 2 correspond to the distributions at concentrations c_1 and c_2 ($c_1 > c_2$).

In the examination of the data in the PS–CH system, it is necessary to take account of the difference by a power of ten between K_0 and K_0^{theor} and K_0^{calc} (see Table 3). It may be assumed that in this system, complete allowance is made for the Johnston–Ogston effects in the extrapolation of $g^*(S, t)$ to $1/t = 0$, so that the functions $k(S_0)$ are similar for the fractions and the polydisperse polymers.

Finally, it should be noted that the interpretation of the concentration dependence of S for polydisperse polymers by means of the scheme in Fig. 9 is inseparable from the concept of local concentration. Thus the concentration dependence of the high-molecular-weight components disappears (the value of k is small), since for these components, the components with higher and lower molecular weights represent a medium with a lower hydrodynamic resistance. Similarly, the accumulation of low-molecular-weight fractions in the sedimentation process may lead to a slight increase in the value of κ.

4. CROSS-TERM HYDRODYNAMIC INTERACTIONS OF THE COMPONENTS IN THE SEDIMENTATION OF POLYDISPERSE POLYMERS

a) Allowance for the JOE of polydisperse polymers

The experimental facts described above leave no doubt that local concentration plays a part in the sedimentation of a polydisperse polymer. Thus in the region of the boundary, the value of the sedimentation coefficient of the ith component will be determined by the concentrations and the interactions of the components with numbers from 1 to i, and in the region of the plateau it will be determined by the concentrations and interactions of all the components. In the general case, it is possible to determine phenomenologically the sedimentation coefficient of the ith component in a solution of q components of a polydisperse polymer as follows[8,95]:

$$S_i = S_{0i} \Big/ \left(1 + k_i c_i + \sum_{j=1}^{q} k_{ij} c_j\right); \; j \neq i; \; i = 1, 2, \ldots, q, \qquad (33)$$

where S_{0i} is the sedimentation constant of the ith component, and the coefficients k_i and k_{ij} were defined earlier. Eqn. (33) represents a generalisation of Eqns. (3) and (12), and is applicable for sufficiently dilute solutions, since in the denominator of the right-hand side the terms with the products (squares) of the concentrations have been discarded. If the concentrations c_i are taken as the concentrations in the region of the plateau, Eqn. (33) gives the values of the sedimentation coefficients in the region of the plateau.

As already noted, for an ideal solvent, $k_{ij} = k_j$, and the following equation is obtained in place of Eqn. (33):

$$S_i = S_{0i} \Big/ \left(1 + \sum_{j=1}^{q} k_j c_j\right), \qquad (34)$$

and for the intermediate region (see Fig. 10):

$$S_i = S_{0i} \Big/ \left(1 + \sum_{j=1}^{i} k_j c_j^*\right). \qquad (35)$$

A slightly different argument may be used. It may be assumed that the solvent for the ith component is the solution of the components from 1 to $i - 1$ (Fig. 10), and the influence of these components on the sedimentation of the ith component reduces to a decrease in the rate of its movement as a result of the viscosity of the medium. Neglecting quadratic terms, the following relationships are obtained for the viscosity η of the solution of the $i - 1$ components:

$$\frac{\eta - \eta_0}{\eta_0 c} \simeq [\eta]; \; c = \sum_{j=1}^{i-1} c_j^*; \; [\eta] = \sum_{j=1}^{i-1} [\eta]_j,$$

where $[\eta]_j$ is the characteristic viscosity of the jth component. The obvious relationship $S_1\eta_1 = S_2\eta_2$ (the indices 1

and 2 here correspond to different solvents) and Eqn. (3) give:

$$S_i = S_{0i}\Big/\left[1+\left(\sum_{j=1}^{i-1} c_j^*\right)\left(\sum_{n=1}^{i-1}[\eta]_n\right)\right](1+k_ic_i^*).$$

Rejection of the "cross-terms" $c_j[\eta]_n$, $j \neq n$, gives:

$$S_i = S_{0i}\Big/\left(1+\sum_{j=1}^{i-1} c_j^*[\eta]_j\right)(1+k_ic_i^*). \quad (36)$$

For flexible-chain polymers, $k_j = A[\eta]_j$, where A is a constant for a given polymer–solvent system[3, 61, 62]. Using this relationship, Eqn. (36) can be transformed to

$$S_i = S_{0i}\Big/\left(1+\sum_{j=1}^{i-1} k_jc_j^*/A\right)(1+k_ic_i^*).$$

In the particular case where $A = 1$, Eqn. (36a) becomes Eqn. (35).

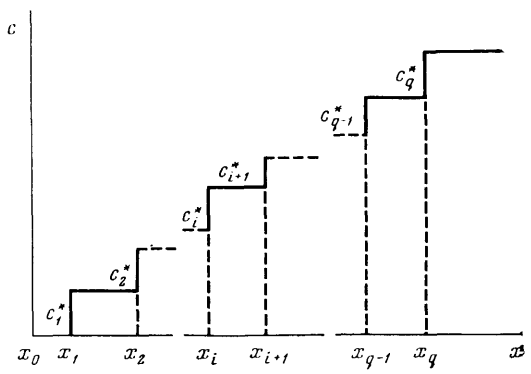

Figure 10. Schematic representation of the dependence of the concentration c on the coordinate x in the centrifuge cell in the sedimentation of a polydisperse polymer consisting of q components.

In the calculation of the true concentrations of the components c_i^0, the idea of additivity of the paired interactions is used, that is it is assumed that for an arbitrary pair of components i and j, by analogy with Eqns. (13), (15a), and (15b), the following relationships are applicable:

$$\psi_{ij} = S_{0i}/S_{0j},\ i = 1, 2, \ldots q; \quad (37)$$

$$c_{ij}^0 = c_i^*(y_j - y_i)/[y_j^{1-\psi_{ij}} - 1],\ i < j; \quad (38a)$$

$$c_{ji}^0 = c_i^*y_i + c_j^*y_j - c_{ij}^0, \quad (38b)$$

where c_{ij}^0 is the concentration of the ith component in the original mixture, calculated from c_i^* with allowance for the interaction with the jth component, neglecting the influence of the other components of the mixture. The sedimentation constants S_{0i} are determined from Eqns. (34), (35), and (36a). Averaging with respect to the interactions with all the components gives finally:

$$c_{i0} = \sum_{j=1}^{q} c_{ij}/(q-1),\ j \neq i. \quad (39)$$

The change to the distribution $g_i(S_{0i})$ is brought about by means of the relationship:

$$g_i(S_{0i}) = c_{i0}x_i/[1 + m(r_i - 1)]. \quad (40)$$

For centrifuges fitted with the usual refractometric optics, the experiment gives the distributions of the displacements $z_i(x_i)$. Since the calculations require the values of the concentrations throughout, it is necessary either to carry out a separate diffusion experiment or to make use of the relationship[48, 65]:

$$R\Delta x\sum_{i=1}^{q} z_iy_i = c_0, \quad (41)$$

where R is the refractometric coefficient, and $\Delta x = x_i - x_{i-1}$. By determining $R\Delta x$, it is possible to find c_i^*:

$$c_i^* = z_iR\Delta x\,. \quad (42)$$

In addition, it is necessary to know the function $k_i = k_i(S_{0i})$, preferably determined in experiments with narrow fractions. In the case of the linear relationship

$$k_i = \pm a + bS_{0i} \quad (43)$$

Eqn. (35) gives:

$$S_{0i} = S_i^*\left(1+\sum_{j=1}^{i-1} k_jc_j^* \pm ac_i^*\right)\Big/(1 - S_i^*bc_i^*). \quad (44)$$

The system of equations (43) and (44) is solved successively, beginning from $i = 1$.

Thus the theory takes account of the following factors influencing the form of the sedimentation curves: the hydrostatic pressure, the concentration dependence of the sedimentation coefficients, the sector form of the cell, and the hydrodynamic interaction of the components (JOE). Only the part played by diffusion is not taken into account. The last section will deal with the characteristic features of the application of this theory to specific systems, and in particular, methods of eliminating the diffusion broadening of the distributions $g(S)$.

b) Determination of the distributions $g(S_0)$

Allowance for the JOE not only gives a new series of equations for calculating $g_i(S_{i0})$ but also makes it possible to take a fresh look at various problems of sedimentation analysis[96]. The disappearance of the high-molecular-weight "tails" of the MMD of a number of PS and PE specimens during sedimentation was first detected by Belyaev[97]. It is obviously incorrect to attribute this fact to dilution or to a decrease in concentration in the region of the plateau[98, 99]. The concept of the JOE provides a comparatively simple explanation of this phenomenon. As a result of cross-term interactions in the sedimentation process, there is an accumulation of the low-molecular-weight components and a relative decrease in the concentration of the high-molecular-weight components. With the passage of time, this leads to a displacement of the maximum towards smaller values of S and to disappearance of the "tail" of the distribution.

In the determination of the MMD of highly polydisperse polymers by the coordinate method[37], an increase in the height of the maximum on the $g(S, t)$ curves of polyethylene (PE) in α-bromonaphthalene at 110°C with increase in the distance between the fixed coordinate and the line corresponding to the start of sedimentation was detected. The displacements (and concentrations) for different fixed coordinates in fact correspond to different stages of the sedimentation process. The farther the coordinate from

the line corresponding to the start of sedimentation, the stronger the manifestation of the cross-term interactions (see Eqn. (38a)) and the higher the maxima on the $g(S, t)$ curves for PE, corresponding to fairly low-molecular-weight components. These results show that the JOE is marked in the sedimentation of strongly polydisperse polymers, and it is for this reason that it is hardly possible to determine correctly the concentration of low-molecular-weight compounds in a polymer without allowance for this effect[41].

* For PS-1, the values for $c = 0.711$ and the values for the first recording $c = 0.3016$ were not included in the averaging (for explanation see text); for PPhIA-5, the values for $c = 0.11$ and the values for the second recording ($t = 2.493 \times 10^3$ s) $c = 0.09$ g dl^{-1} were not included.
** The first recordings for all concentrations of PPhIA served only for the determination of the end of the $g(S)$ curve (see text).

Table 4 gives the characteristics of the distributions $g(S_0)$ for specimens of PS-1 in CH at 34°C and of PPhIA-5 in a DMF–0.25% LiCl mixture at 25°C, calculated from a single recording using the theory taking account of the JOE or by a method[26,66] based on the mathematical formalisation of the extrapolation procedures, that is on the empirical values of the diffusion parameter K and the empirical functions (43).[76] In the calculations by the first method, the distributions $g_i^*(S_i)$ are first corrected with allowance for the concentration dependence of the sedimentation coefficients, pressure, the JOE, and dilution, after which (for $c = 0$) a correction is introduced for diffusion from the theoretical value of the parameter K.[76] For polystyrene, the correction for the $S(c)$ dependence was introduced from Eqn. (43) ($a = 0$, $b = 0.036$ dl g^{-1}) for both methods. The algorithms for the calculations were naturally different in these cases, since the original concepts are diametrically opposed (local concentration and plateau concentration). The sedimentation coefficients of PPhIA were corrected for the concentration dependence using different relationships: the first method (with allowance for the JOE) was based on data for fractions: $k_i = 0$ for $S_i \leq 0.75$; $k_i = -1.11 + 1.48\, S_{i0}$ for $S_i > 0.75$ (Svedberg unit); the second method was based on data for non-fractionated specimens $k_i = 2.12\sqrt{S_{0i}}$.

As already noted, the cross-term interactions of the components of a specimen non-uniform with respect to mass lead to the loss of the distribution "tail". Theory[95] provides a somewhat unusual method for reconstructing the end of the $g_i(S_{i0})$ curve. It is assumed that the true end of the distribution is the point obtained for short ultracentrifuging times. To supplement q graphical fractions (with concentrations $c_i^* > 0$), n "correction" components (with concentrations $c_j^* = 0$, $j > q$) are introduced into the computer store. Here it should be noted that the calculations are carried out by computer, and the complexity of the mathematical treatment is no obstacle to the determination of $g_i(S_{i0})$. The calculations using Eqns. (37)–(39) give non-zero concentrations for the "corrected" components.

Fig. 11 gives the distributions $g(S_0)$ for PS-1 in CH, $c = 0.3016$ g dl^{-1}, calculated by the first method with allowance for the JOE (circles). One of the curves was calculated with restoration of the "tail" for the values $q = 26$ and $n = 6$ (empty circles) and differs little from the curve obtained without restoration of the "tail" (filled circles). The calculation by the second method[26,66] gives a distribution which is very much sharper (crosses), and which differs considerably from the distribution determined by the first method. It is possible to point to three reasons for this sharpening. Firstly, the loss of the "tail" in the calculation by the second method[26,66] is irreversible. Secondly, the diffusion contribution to the broadening of the boundary is greatly over-estimated as a consequence of the JOE.[76] Thirdly, when there is appreciable diffusion, there is significant distortion of the $g(S_0)$ curves as a consequence of the difference between the model (Gaussian function) and the real distribution $g^*(S, t)$, whereas when there is little diffusion, these differences are not significant[89].

The generally accepted extrapolation procedures[2-4] lead to the following characteristics of the $g(S_0)$ distributions for the specimens studied: for PS-1, $\bar{S}_0 = 15.7$ and $\sigma_0 = 3.80$ Svedberg unit; for PPhIA-5, $\bar{S}_0 = 3.6$ and $\sigma_0 = 0.98$ Svedberg unit. Comparison of these parameters with the data in Table 4 confirms the familiar fact that extrapolation of the $g(S)$ curves in the case of polymers (PS) of medium polydispersity leads to a loss of the fine details of the distributions (for example, poorly resolved maxima) and the "tail", and to sharpening of the distributions (compare the values of σ_0).

The data obtained by different methods for the polymer PPhIA-5 with a low polydispersity show better agreement with one another (Table 4), but it was not possible, by the second method, to determine $g(S_0)$ for all recordings at $c = 0.11$ g dl^{-1} and for the first recording at $c = 0.09$ g dl^{-1}, whereas the calculations using the theory of Ref. 95 can be carried out for all values of c and t.

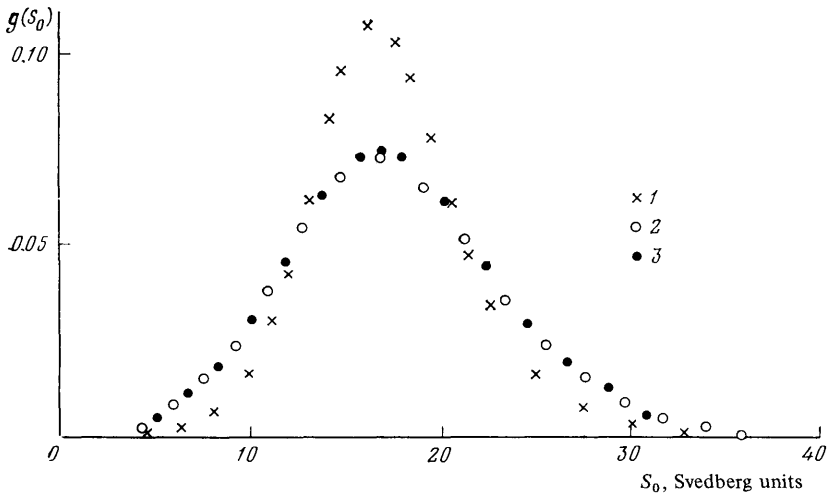

Figure 11. Distributions $g(S_0)$ for PS-1 in CH, 34°, $c = 0.3016$ g dl^{-1}, calculated from one recording for $t = 3287$ s by the published method[26,66] (*1*) and from theory, with allowance for the JOE, with (*2*) and without (*3*) additional components.

The slight decrease in the value of $\bar{S}_0$ in the calculations by the first method is apparently due to two features. Firstly, the theory[95], strictly speaking, refers to ideal systems. The results of the study of the JOE of binary mixtures in a good solvent indicate that the theory of Ref. 29 in this case is confirmed quantitatively only in the limit as $c \to 0$.[71] For PPhIA-5, the calculation algorithm should be based not on Eqn. (35) but on Eqn. (36). Secondly, the first recording was carried out too late, and part of the "tail" was lost. This applies particularly to the data for $c = 0.11$ g dl^{-1}.

A characteristic feature is that the parameters of the distributions $g(S_0)$ calculated by the first method have a much smaller scatter than the analogous values calculated by the second method. All the results obtained using Eqns. (35)–(44) must be regarded as preliminary—they can be improved considerably—whereas it is practically impossible to improve the calculation by the procedure of Refs. 26 and 66. The last approach preserves some of the unsatisfactory features characteristic as a whole of the extrapolation of the distributions, which is based on a number of arbitrary assumptions: simple additivity of the factors operating and the movement of the components, neglect of the cross-term interactions of the components, and the concept of plateau concentration. The approach based on allowance for the JOE and the concept of local concentration appears more correct[95,96].

V. CONCLUSION

Detailed analysis of the experimental data leaves no doubt that the cross-term hydrodynamic interactions of the components—the Johnston—Ogston effect (JOE)—play an important part in the sedimentation of polymers of high and medium polydispersity, and can be observed in the sedimentation of polymers of low polydispersity. Such phenomena as the displacement of the maxima, the loss of the "tail", the increase in the height of the maximum of the distribution $g^*(S, t)$ with increase in the distance between the fixed coordinate and the line corresponding to the start of the sedimentation, the non-diffusion broadening of the $g(S)$ curves, the decrease in the effect of the $S(c)$ dependence for the high-molecular-weight components of a mixture, and the increase in its effect for the low-molecular-weight components, can be explained only on the basis of the JOE and the concept of local concentration.

The distinctive feature of the situation is that no method has been found for making rigorous allowance—via the equations of motion—for the cross-term interactions of the components undergoing sedimentation, even for a binary mixture; the expectation of an exact theory of the sedimentation of many-component systems is therefore illusory. Thus at present the only possible approach is that based on the principle of additivity of the paired interactions[95].

The fact that the problem of the sedimentation of polydisperse polymers is insoluble theoretically, and decades of the preferred application of the extrapolation method, the concept of plateau concentration, unjustified single-recording and single-concentration approximations, and the view that different effects are "compensated" on the one hand have not stimulated serious experimental-methodological studies and on the other have effectively "immunised" research workers against theoretical work. This is the only possible explanation for the fact that very important work[48,75] has remained neglected, although the first of the works cited provides a theoretical basis for the treatment of sedimentation measurements on fractions, and the second makes it possible to carry out a quantitative estimation and allowance for the role of the diffusion factor in the sedimentation of polydisperse polymers[26,66,76,86,89].

The natural failure of the concept of plateau concentration and the development, on a new basis, of the concept of local concentration[95] indicates not only the usefulness but also the necessity of determining $g(S_0)$ from a single concentration, since for polymers of medium polydispersity, the extrapolation of the $g(S)$ distributions to $c = 0$ has no physical foundation. Using Fujita's theory[75], it is possible from a single recording to take account of the diffusion broadening of the $g^*(S, t)$ curves[26,66,89]; thus the required $g(S_0)$ distribution is obtained by computer

calculation from a single sedimentation diagram. Preliminary data[96] indicate that this method of determining $g(S_0)$ is promising.

In conclusion, the calculation procedure should be mentioned: it is not simple, and can only be carried out by computer. Eqns. (8) and (16) are first used to find the distribution $g^*(S, t)$ for which it is possible to introduce a correction for diffusion broadening (see Part III); the choice of the values of K is discussed below.

As already noted, for polymers of high and medium polydispersity, the required distribution $g(S_0)$ (or $g(M)$) is distorted by the loss of the "tail". The first recording must therefore be fixed at different times of ultracentrifuging. The time of ultracentrifuging should not be so short that the introduction of a correction for dispersal by the formal rule has no influence on the values of the sedimentation coefficients.

Using the parameter of the distribution $g(S)$, the diffusion problem is solved for the end of the distribution of the displacements, obtained in the first recording. In this case it is not strictly necessary to determine the entire distribution; it is sufficient to determine only the position of the end of the curve. The overall result gives the value of the sedimentation coefficient for the end of the distribution S_{end}, from which the number of components "lost" is subsequently determined.

Eqns. (41) and (42) are used to calculate c_i^*; the values of the sedimentation constants of the components S'_{i0} are then found in a first approximation from Eqns. (43) and (44), and this makes it possible to take account of the JOE from Eqns. (37), (38a), (38b), and (39). The corrected concentrations of the components c_{i0} can then be used to obtain more accurate values of the sedimentation constants S_{i0} and the functions $g_i(S_{i0}, t)$ from Eqn. (4). Since the concentration effects are eliminated, the diffusion broadening can be taken into account from the theoretical value of the parameter K (see Eqn. (18)). Alternatively, the values of K obtained from diffusion experiments can be used.

Identification of Substances in Gas Chromatography

A.A.Andersons and M.V.Shimanskaya

Methods for the qualitative analysis of substances separated chromatographically have been examined. Particular attention has been paid to methods which have been intensively developed in recent years for identifying substances from their chromatographic characteristics without the use of a standard. The bibliography contains 265 references.

CONTENTS

I. Introduction 714
II. Methods of identification using standards 714
III. Methods of identification without the use of standards 716

I. INTRODUCTION

One of the central problems with which research workers have been concerned throughout all stages of the development of the gas chromatographic method is the identification of substances separated chromatographically. In almost all monographs on gas chromatography, chapters have been devoted to qualitative analysis, and this question has also been dealt with in a number of review articles. In most of the latter, attention has been concentrated chiefly on one aspect of the problem. Monographs and reviews on this subject do not deal with recent work. In the most detailed review devoted to the contribution of gas chromatography to identification [1], published material up to only 1969 was reviewed. The most significant progress in this field, however, which has made it possible to reach conclusions regarding the structure of a substance from its gas chromatographic behaviour and to predict the chromatographic behaviour of a substance from its structure and physicochemical properties, has been made in recent years.

The present review deals with data on qualitative gas chromatographic analysis published up to and including 1974. Since zone identification based on additional operations with the components of mixtures before and after gas chromatographic separation has been dealt with in sufficient detail in reviews and monographs, for example in Ref. 2, the present review was restricted to an examination of methods which use only gas chromatographic data for identification. In addition to a discussion of methods of identification using standards, particular attention has been paid to the latest achievements in the development of correlation methods and methods based on predictive retention calculations, not involving the use of standards.

II. METHODS OF IDENTIFICATION USING STANDARDS

In these methods, the qualitative analysis of a mixture is carried out by comparing the chromatogram of the specimen being studied with the chromatograms of standard substances or with tabulated data. The identity criterion is the coincidence of the retention data of the substance being analysed and the standard, since under identical and correctly chosen experimental conditions, the retention values should be physicochemical constants of the substances, characterising their distribution in the gas–sorbent system [3-5].

In the first version, which is very frequently used in practice, the identification is carried out by comparing the retention values, measured under identical conditions, of the components of the mixture being analysed and standard substances, the presence of which in the material being studied is assumed. It is concluded that a substance is present in a mixture when the retention times coincide (for the analysis of standard directly before or after the chromatographic study of the specimen) or from the increase in the corresponding peak on the chromatogram (in the case where the assumed standard substance is added to the mixture being studied) [3]. The probability of correct identification depends on the number of substances eluted close to one another and on the accuracy of the measurement of the retention volume, and was characterised quantitatively by Klein and Tyler [4] by the magnitude of the "peak density" (the ratio of the total number of peaks to the total number of possible separations in a given interval). The reliability of the identification is increased if the chromatographic separation is carried out on two stationary phases of different polarity [3-5], since components having identical solubilities in one stationary phase in most cases have different solubilities in another. According to Brown [6] it is best to use a combination of non-polar, electron-donor, and electron-acceptor phases. Super-selective sorbents are effective for this purpose.

If the analysis is carried out in parallel on several columns operating under identical conditions, it is possible to obtain the so-called chromatographic spectra of substances. This method was first proposed by Klouwen and Ter Heide [7], who showed for the case of aliphatic compounds and monocyclic and bicyclic terpenes that each class of substance is characterised by a strictly definite form of the curves representing the retention on five stationary phases. Chromatographic spectra have been used for the qualitative analysis of organic substances by a number of workers [8-11]. Franc and Michajlova [8,9] showed that if the same specimen volatiliser and the same detector are used, the chromatographic spectra, like optical spectra, are specific for each individual substance. The possibilities for the identification of the components of mixtures are extended considerably by switching four columns with different stationary phases in pairs in the same apparatus; in this way, eight different versions of the analysis are carried out [11].

The method of standards is widely used in laboratories, but it requires on a priori knowledge of the possible composition of the mixture being analysed and the availability of standard substances for comparison.

In the second version, the components of a mixture are identified by comparing their retention data with data previously obtained by other workers and summarised in tables. Primary gas chromatographic data—retention

times t_R or retention volumes V_R—cannot be used, since they depend on the conditions of their determination. To eliminate this influence, either absolute or relative retention values are used.

Absolute retention characteristics—the specific retention volumes V_g and the distribution coefficients K [12-14] (reference tables [15-19])—are sufficiently reliable criteria for identification if they are accurately determined [20]. This last feature is responsible for the fact that these characteristics are not very widely used, since the accurate reproduction of the conditions of analysis, particularly the quantity of stationary phase in the column, is an extremely tedious task. For the identification of substances, it is preferable to use relative retention characteristics [3]. When the analysis is carried out at the appropriate temperature using the column and standard substance given in the literature, the retention times or volumes related to the corresponding values for the standard are free from the influence of the other conditions of the experiment and can be used to identify the components of the mixture being separated. The relative retention characteristics are given in general form by the equation [21]

$$R^{rel} = p\left(k + \frac{R_x - R_1}{R_2 - R_1}\right), \quad (1)$$

where R_X, R_1, and R_2 are the reduced retention values for the substance being studied and two standard substances respectively; and p and k are constants characteristic of the chosen system of coordinates. In the simplest case when $p = 1$, and $k = R_1 = 0$, the relative retention volume V_R^{rel} (or retention time t_R^{rel}) are obtained.

The relative retention volumes of representatives of the principal classes of organic substance have been tabulated [15-18,22-29]. Of particular interest are the tables of Schupp and Lewis [16], in which retention data are collected for 209 stationary phases and 26 carriers at different temperatures. An edition of tables of retention values has been planned in the USSR Committee of Standards.

An unsatisfactory feature of the method is that a large number of varied compounds are used as standard substances. In spite of an IUPAC recommendation [30], in which it was proposed that the choice of standards be restricted to several substances readily available in pure form (n-butane, 2,2,4-trimethylpentane, benzene, *p*-xylene, naphthalene, butan-2-one, cyclohexanol, and cyclohexanone), different research workers continue to determine V_R relative to any substance which they regard as convenient.

In 1960, Smith [31] proposed that a single substance—"theoretical nonane"—be used as standard. The retention values of "theoretical nonane" are obtained from an analysis of a mixture of n-hydrocarbons by extrapolating the linear relationship between the logarithms of the retention times and the number of carbon atoms in the molecules. To determine the retention relative to "theoretical nonane" R_{X9}, any alkane is added to the mixture being studied, and the retention volume relative to it is calculated. The above linear relationship is then used to determine the retention volume of the hydrocarbon used relative to n-nonane, and the two quantities obtained are multiplied. If the use of an n-alkane is difficult for any reason (analysis on columns containing polar sorbents), the use of the retention value relative to "theoretical n-pentanol", defined analogously, is proposed [31].

The "theoretical nonane" system was further developed by Smith and Evans [32-36]. For high column temperatures, an analytical method was proposed instead of graphical extrapolation [35]. Other retention values can also be recalculated to R_{X9} units, so long as V_R for four n-hydrocarbons are known [34]. The possibility of using a system of secondary standards [36] and of predicting retention values for compounds from the molecular formulas has also been examined [37-39]. The accuracy of the determination of the R_{X9} values, however, depends on how far the primary standard is separated from n-nonane.

A more general solution of the problem of the choice of standards was proposed by Kovats', who recommended the determination of relative retention data using the homologous series of n-alkanes as standards [40,41]. The choice of this series is most natural, since the n-alkanes represent as it were a "zero structure", on the basis of which it is possible to reproduce the structure of all organic substances. Kovats called the new parameter the "retention index". The data are expressed on a logarithmic scale; the retention indices are determined from Eqn.(1) for $p = 100$, $k = n$, $R_1 = \lg R_n$, $R_2 = \lg R_{n+1}$, $R_X = \lg R_X$ (n and $n + 1$ are the numbers of carbon atoms of the n-alkanes diluted immediately before and after the substance being determined). Since for n-alkanes, $\lg R$ is a linear function of the number of carbon atoms in the molecule, the denominator in Eqn.(1) is replaced by b—the slope of the straight line obtained by plotting $\lg R$ against n (b is determined for n-alkanes having $n \geq 6$).

Kovats' system of retention indices is now generally accepted. According to the Recommendation of The Data Sub-Committee For The Publication Of Retention Data [42], and the well-founded opinion of a number of research workers [20,43-53], it provides the most convenient and promising method of characterising retention in gas chromatography. When the retention times are measured accurately, and the temperature of the column is maintained to within 0.1°, [54,55] the retention indices have a high reproducibility, which reaches $\pm(0.03-0.05)$ units [52,56]; the reproducibility of the indices in different laboratories often lies in a range of ± 1 unit [51,52]. A detailed review [57] has been devoted to the problem of applying Kovats' indices in gas chromatography.

In addition to its indisputable advantages, Kovats' system of indices also has some unsatisfactory features. These include the comparatively tedious calculations and the fact that the n-alkanes are not always the most convenient reference substances. Thus in analysis on polar stationary phases, the characterisation of low-boiling polar substances requires the use of high-boiling n-alkanes, because of the weak retention of the latter on polar phases. The simultaneous analysis of high- and low-boiling substances under identical conditions is inaccurate.

The subsequent improvement of Kovats' system of indices has taken place in two directions: 1) simplifcation and an increase in the speed of the calculations, and 2) the use of other series of standard substances instead of n-alkanes and the development of systems similar to Kovats' system. Graphical methods have been proposed in order to increase the speed of calculations [58-60]. The accuracy of the values obtained is low, however. In place of Kovats' logarithmic index, an arithmetic index (also linear) was introduced ($p = 100$, $k = n$, $R_1 = R_n$, $R_2 = R_{n+1}$). [61-65] The problem of calculations is now being solved by the use of computers and special programs for calculating retention indices [66-69].

To avoid the difficulties in the identification of polar and high-boiling substances in Kovats' system, some workers propose that the use of n-alkanes as standards be

replaced by the use of other homologous series: androstane and cholestane for the characterisation of the gas chromatographic retention of steroids (the "steroid number" of Vanden Heuvel and Horning)[70,71]; linear polyphenyls for polyphenyl compounds (the "phenyl number" of Habgood and Harris)[72]; polyacenes for condensed aromatic and heterocyclic systems[73]; dimethylsiloxanes for methylpolysiloxanes ("dimethylsiloxane number")[74-76]; n-alcohols[77]; n-propyl esters[78]; and methyl n-alkyl ketones[79]. For the analysis of lipids, the methyl esters of saturated[80-82] or monounsaturated[83,84] normal acids have been recommended as standards ("equivalent chain length system"). Thus there is a danger of an increase in the number of proposed series of standards, and the problem of standardising retention data may arise again.

The above systems of standards are mainly applicable only for the characterisation of definite groups of substances, and often show poor agreement with one another[85]. For the recalculation of data to Kovats' system, if the indices of the standards I_1 and I_2 are known, the following equation can be used[86]:

$$I = (I_2 - I_1)\frac{\lg R_x - \lg R_1}{\lg R_2 - \lg R_1} + I_1. \qquad (2)$$

The logical conclusion of improvements to the system of retention indices is the introduction of a generalised retention index I_a,[87] which provides for the use, as fixed points, of any homologous series of substances with functional group X_a. The change from one scale of standards to another is brought about using the equation

$$I_a = I_b - I_b(a) + 100\,n(a), \qquad (3)$$

where I_a and I_b are the retention indices of the substances on the scales of the standards a and b respectively; and $I_b(a)$ is the retention index of the substance a with number of carbon atoms $n(a)$ on the scale of standards b.

Systems of expressing gas chromatographic data with an altered scale, such as the "carbon numbers"[80,81], the "methylene unit"[88,89], and the "standardised retention energies"[90,91] must be regarded merely as particular cases of Kovats' system; their adequacy has been demonstrated[92].

There are at present several systematic reference tables of retention indices[19,40,93]. The reference tables of McReynolds[19] are particularly extensive, and give the retention indices of substances on 26 stationary phases for rigorously standardised conditions. In addition to the quantities mentioned, Walraven and Berezkin[21] proposed another two quantities—the relative index ($p = 1$, $k = 100\,n$, $R_1 = 0$, $R_2 = R_n$) and the retention exponent ($p = 100$, $k = 1$, $R_1 = R_A$, $R_2 = R_B$).

The relative retention values are characterised by approximately equal accuracy (equivalent quadratic deviations 0.50–0.75%). For systems with two standards, the increase in the error resulting from the error of the measurement of the retention of the second standard is compensated by the significant of the correlation coefficients. The retention indices give more accurate results than the relative retention volumes only when the substance being analysed and both n-alkanes are introduced simultaneously on to the column[21]. The retention times of the n-alkanes should be measured as accurately as possible, since it has been shown from Erdey's equation[94,95] that these measurements introduce the greatest errors into the value of the retention index.

What has been said above applies chiefly to the accuracy of determinations in a given laboratory. The accuracy and the reproducibility of relative retention values in different laboratories are much lower. One of the chief reasons for the poor reproducibility of retention data between laboratories is the adsorption of substances at gas–liquid and liquid–solid carrier interfaces. The adsorption properties of these interfaces depend on the conditions of preparation of the sorbent[96,97].

To obtain constants which are independent of the conditions of the experiment and the method of preparing the sorbent, it is necessary to take account of the adsorption on the surfaces between the phases and to determine the relative retention values using the equations proposed by Berezkin and coworkers[98]:

$$\frac{V_N}{V_{N_{st}}} = \frac{K_L}{K_{L_{st}}} + \lambda\frac{1}{v_{L_S}};$$

$$\lambda_1 = \frac{(K_{GL}K_{L_{st}} - K_{GL}\cdot K_L)S_{L_S} + (K_S - K_{S_{st}})K_L K_{L_{st}} S_{S_S}}{K^2_{L_{st}}}, \qquad (4)$$

where V_N and $V_{N_{st}}$ are the pure retention volumes of the substance and the standard respectively; K_L and $K_{L_{st}}$ the distribution coefficients of the substance and the standard between the gaseous phase and the stationary liquid phase; K_{GL} and $K_{GL_{st}}$ the distribution coefficients of the substance and the standard in the system formed by the gas and the surface of the stationary liquid phase; K_S and $K_{S_{st}}$ the distribution coefficients of the substance and the standard in the stationary liquid phase–solid carrier system; v_{L_S} the volume of the stationary liquid phase corresponding to 1 g of carrier; S_{L_S} the area of the surface of separation between the gas and the stationary liquid phase, corresponding to 1 g of carrier; and S_{S_S} the specific surface of the solid carrier. If the substance chosen as standard is one for which the retention in the column is determined chiefly by solution, $K_{GL_{st}} = K_{S_{st}} = 0$ and Eqn.(4) is simplified.

The following equation has been proposed for the retention indices[98]:

$$I = 100n + 100\frac{\lg K_L - \lg K_{L_n}}{\lg K_{L_{n+1}} - \lg K_{L_n}} + \frac{43\lambda_2}{\lg K_{L_{n+1}} - \lg K_{L_n}}\cdot\frac{1}{v_{L_S}}, \qquad (5)$$

where $\lambda_2 = \lambda_1 K_{L_n}/K_L$; and K_{L_n} and $K_{L_{n+1}}$ are the distribution coefficients of the n-alkanes with n and $n+1$ carbon atoms between the gaseous and liquid phases. An analogous equation was proposed for the case where capillary columns are used[99].

Allowance for adsorption factors is necessary to obtain reliable results in qualitative analysis using tabulated retention values. This is particularly important in cases where the polarities of the substances being analysed and the stationary phases differ considerably.

III. METHODS OF IDENTIFICATION WITHOUT THE USE OF STANDARDS

From the initial development of gas chromatography, the inconvenience and disadvantage of the use of standard substances have directed research workers to the search for other methods of identification. Considerable progress in this field has been achieved by studying the relationship of the molecular characteristics and structures of substances to their gas chromatographic behaviour, with generalisation and transfer of the observed relationships to other series of compounds. The methods to be examined do not involve the use of standards in the

sense that they do not require the availability of the assumed components of the unknown mixture or the corresponding tabulated data.

The chief methods of identification without the use of standards are as follows: 1) the use of linear correlations between the physicochemical characteristics of substances and the retention values; and 2) calculation to predict retention by summation of the contributions made to it by the individual structural elements of a molecule.

1. Linear Correlations between the Retention Values of Substances and their Molecular Characteristics

An extremely widespread method for the qualitative analysis of substances is the method of homologue identification, in which use is made of linear correlations between the retention of substances and the size of their molecules. This method is based on the linear dependence of the logarithm of the distribution coefficient of the molecules of the substance being studied on the free energy of their reaction with stationary phases. The logarithm of the distribution coefficient of a substance $CH_3(CH_2)X$ is given by [87]

$$\ln K = -\frac{N\Delta G(CH_2)}{RT} - \left[\frac{\Delta G(CH_3)}{RT} + \frac{\Delta G(X)}{RT} + \ln\frac{M_L}{RTd_L}\right], \qquad (6)$$

where $\Delta G(CH_2)$, $\Delta G(CH_3)$, and $\Delta G(X)$ are the standard molar Gibbs free energies of sorption for the transfer of the pure sorbate between states of unit fugacity (gaseous phase) and infinite dilution in the sorbent (stationary phase) for the groups CH_2, CH_3, and X respectively; M_L the molecular weight of the stationary phase; N the number of methylene groups in the molecule of the substance; T the absolute temperature of the experiment, K; R the universal gas constant; and d_L the density of the stationary phase. Since homologues differ from one another only in the values of N, the existence of a linear correlation between $\ln K$ and N in homologous series is obvious.

In the qualitative analysis of homologues, use is made of a logarithmic relationship of the general form:

$$\lg R = a \cdot n + b, \qquad (7)$$

where R is the corrected retention time or volume, or specific or relative retention volumes (the equation remains applicable if the retention index is taken instead of $\lg R$); a a constant characterising the energy of the interaction of the CH_2 group with the sorbent; b a constant characterising the energy of the interaction of the functional groups with the sorbent†; and n the number of carbon atoms in the molecule.

Attention was first drawn to the existence of this correlation by James and Martin[3] for the case of carboxylic acids. The linear relationship naturally still holds if in Eqn.(7) the number of carbon atoms n is replaced by the number of CH_2 groups [101-103] or the molecular weight [104,105]. The retention index of the higher members of homologous series increase by 100 units for every CH_2 group [40,93,106]. The correlation was subsequently confirmed by many workers for various homologous series (the literature has been reviewed [1]).

† Hoshikawa, Kuriyama, and Yamabe [100] give the detailed significance of the constants for the case where the retention is expressed in the form of Kovats' logarithmic indices.

The linearity of the correlation is observed most accurately in the case of non-polar stationary phases, where a decisive factor in the interaction is the dispersion forces, which increase with increase in the size of the molecule. Some deviations from linearity are observed for the first members of the homologous series, particularly on polar stationary phases. Thus the increment in the retention indices, corresponding to one $-CH_2$ group, is rigorously equal to 100 for hydrocarbons only beginning from the seventh member of the series [107]. On polar stationary phases, this increment is lowered, as a consequence of the increase in the contribution to the total energy of the interaction from the partial excess free energy of mixing, which changes in the opposite direction to the molar free energy of condensation [108].

The distortion of the linearity of Eqn.(7) is also influenced slightly by the odd or even character of the number of carbon atoms; the magnitude of this influence can be taken into account [109].

The linear correlation between the free energy of solution and the molecular characteristics is universal, and can be extended to the dependence of the free energy on the number of other atoms or repeating structural units in the molecules of the substances in homologous series—silicon [110], sulphur [111], nitrogen, and oxygen [112,113] atoms, benzene rings [114], $-CH_2-CH_2-NH$ groups [112,113], double bonds [115,116], etc. The relationships between the retention values and the numbers of atoms or groups of the same kind in molecules are justified from the viewpoint of set theory, since both variables take denumerable sets of rational values [117]. Mathematically, these relationships are expressed in the most general form by linear-fractional equations (as revealed in the deviation from linearity of the correlation observed for more accurate measurements over a sufficiently wide range of values [107,118]), which are readily transformed into linear equations. The straight lines obtained for individual classes of substances form a pencil of lines.

Methods related to the group being considered are those based on the correlation between the energy of intermolecular interaction and the molar volume or polarisability of the substance. The energy of the dispersion interaction of an atom i of a substance with a stationary phase U_i can be calculated from the equation [119]

$$U_i = 0.9\pi h\nu \frac{\alpha\rho}{(r+r_f)^3}, \qquad (8)$$

where ν is an average frequency characterising the atom i and the stationary phase; α the polarisability of the atom i of the substance being analysed; ρ the density of the polarisability of the stationary phase; and r and r_f the average van der Waals radii of the atoms of the substances being analysed and the functional groups of the stationary phase respectively.

Since the volume of a molecule is proportional to the cube of its van der Waals radius, and the ratio of the polarisability to the molecular volume is in turn a function of the coefficient of refraction, the energy of the intermolecular interaction, and hence the retention value of the substance in the stationary phase, show a correlation with such physicochemical characteristics of the molecules as the parachor, density, coefficient of refraction, molar refraction, dipole moment, etc.

In fact, a number of authors have demonstrated and used for qualitative analysis the relationship between the retention parameters on the one hand and the dipole moments [120,121], density [122,123], coefficient of refraction or

molar refraction[124,125,126], the parachor[127], heat of formation[128], and other molecular characteristics[122] on the other. The existence of correlations with other physicochemical characteristics which take denumerable sets of rational values is to be expected.

For example, one group of identification methods is based on the relationship between the retention values and the saturated vapour pressures or boiling points of substances. Since there is a logarithmic relationship between V_g and the saturated vapour pressure p^0,[129,130] a correlation should also be expected between the boiling points $t_{b.p.}$ and the logarithms of the retention values of substances. This correlation cannot be strictly linear, since the dependence of the boiling points on the numbers of carbon atoms in a homologous series is non-linear, but the relationship for I or $\lg V_g$ is close to linear. The correlation is closer to linearity, the greater the similarity in the nature of the forces of intermolecular attraction which are responsible for the interaction between the molecules of the pure substance and between the molecules of the substance and the molecules of the stationary phase[131]. This requirement is satisfied most frequently when the substances being analysed and the stationary phase are similar in character. The relationship

$$\lg R = a(t_{b.p.} + b) \qquad (9)$$

is most frequently used in analyses on non-polar stationary phases, but the linearity is also preserved on polar columns[132,133]. In general, the linearity of the correlation is improved if a term including the activity coefficients of the substances being separated is included in Eqn.(9).[134]

In addition to the correlation (9), other equations including the boiling point have been proposed. Thus Zhukhovitskii and coworkers[135] and Sen[136] proposed the use of the independent parameter $T_{b.p.}/T_{col}$ for the identification of substances. The linear relationship between V_R and $T_{b.p.}/T_{col}$ makes it possible not only to determine the boiling point but also to estimate, from the slope of the straight line, the series to which a given substance belongs[137]. Another dimensionless parameter for the identification of related compounds, independent of the temperature of the analysis and the stationary phase, has been introduced[138]:

$$\varphi_T = \frac{\lg V^0_{R_i} - \lg V^0_{R_1}}{\lg V^0_{R_2} - \lg V^0_{R_1}} = \frac{T_{b.p._i} - T_{b.p._1}}{T_{b.p._2} - T_{b.p._1}}; \qquad (10)$$

where V^0_{Ri}, $V^0_{R_1}$, and $V^0_{R_2}$ are the corrected retention volumes; and $T_{b.p.i}$, $T_{b.p._1}$, and $T_{b.p._2}$ the boiling points of the unknown substance and two known substances respectively. A series of empirical equations for determining boiling points from retention data has been proposed by Japanese workers[139-142].

Bach and coworkers[143], from the dependence of t_R on the vapour pressures of substances, introduced the "retention boiling point" to supplement Kovats' system of retention indices. For correctly chosen operating conditions, this boiling point is fairly close to the true boiling point. All the above correlations make it possible to use the retention value to determine approximately the boiling point of a substance and hence to use tables of the boiling points of substances for identification.

Some authors ascribe considerable importance to the dependence of the retention values on the temperature of analysis T. The relationship between $\lg V$ and the reciprocal of the absolute temperature is linear[12]

$$\lg V = A + B/T. \qquad (11)$$

An analogous relationship holds for the relative retention characteristics[144]. It was later found that the correlation between I and $\lg V$ or I [145,148] is given more accurately by an equation which is analogous to the Antoine equation, describing the temperature dependence of the saturated vapour pressure of a substance:

$$\lg V_g \text{ or } \lg I = A' + \frac{B'}{T + C'}. \qquad (12)$$

In the temperature range characteristic of gas chromatography, the almost linear part of the hyperbola is used[144,146]. The coefficient A is directly related to the entropy, and the constants B [in Eqn.(12)] and also B' and C' are related to the enthalpy of solution. Since the thermodynamic functions of solution are characteristic for each substance and are different for different homologous series, the correlations (11) and (12) can be widely used for the identification of substances. The $\lg R - 1/T$ straight lines for the members of a given homologous series intersect at a characteristic point, the position of which is independent of the nature of the stationary phase[149].

Various non-linear equations characterising the temperature dependence of the retention indices have also been proposed[150,151]. The fruitful application of this method for the qualitative analysis of compounds of different classes has been demonstrated by a number of workers[12,103,126,149,150,152-155].

A characteristic parameter for the identification of substances is the temperature coefficient of the retention indices dI/dT. The values of this coefficient are different for groups of substances having different degrees of saturation or branching and also for cyclic compounds[156-158]. Saha and Mitra[159-161] showed that dI/dT for each series of hydrocarbons is constant and decreases in the order: aromatic hydrocarbons > cyclo-alkanes > tetra- and trialkylalkanes > di- and monoalkylalkanes. The temperature coefficients of the retention indices are linearly related to the mean square radii of the molecules of isomeric alkanes[162]. A thermodynamic treatment of the temperature coefficients of the retention indices has been given by Hammers and de Ligny[163].

Thus a number of correlations have been proposed for the gas chromatographic identification of separated substances using a single column. They have been widely used up to the present, but since the constants of the correlation equations are empirical, the validity of the correlations for individual classes of substance must be proved experimentally. To construct the corresponding curves, it is necessary to have at least three representatives of a series. After the construction of the correlation graphs, the identification of homologues does not present serious difficulty.

In addition to correlations between the physicochemical characteristics of substances and the retention values on a single stationary phase, corresponding correlations determined on two or several columns of different polarity are widely used in qualitative analysis. The values of $\lg R$ obtained on several columns show a correlation with one another. The graphs for substances belonging to different homologous series lie in different regions of the corresponding diagrams. Thus the values of $\lg R$ obtained on two columns of different polarity for each homologous series of substances lie on straight lines parallel to one another[164]. If R is plotted directly on the graph instead of $\lg R$, the homologues lie on straight lines having a characteristic slope. A correlation of this kind was

first used for the identification of primary, secondary, and tertiary alkylamines[165]. The method was subsequently widely recommended for the identification of organic substances of different classes[4,29,111,164,166-170]. Since many pairs of columns, for series of substances, give straight lines which are situated extremely close of one another on the graph, the identification requires a careful choice of sorbents[169,170].

A significant discovery was the detection[171] of the "roofing tile effect", that is that the values of $\lg V_R$ or I for isomeric compounds, obtained on two columns of different polarity, lie on parallel lines, forming "roofing tile groups" in accordance with the number of primary, secondary, tertiary, and quaternary carbon atoms in the molecules. This effect makes it possible to use gas chromatographic retention data on two columns to determine the fine structure of organic molecules. Moreover, the difference in the retention indices on two columns having sorbents with different polarities gives information on the nature of the functional groups[40,45].

Brown[6] proposed the measurement of the retention of substances on three columns, containing stationary phases with different electronic characteristics—non-polar, electron-donor, electron-acceptor. If the data are expressed as retention fractions ("affinity fractions") and plotted on a triangular diagram, each substance is represented by a point, according to its donor-acceptor properties. The points corresponding to substances in a given homologous series lie on straight lines, which are directed towards the apex corresponding to the non-polar column. This method has been used to identify steroids[172], ethers, nitriles, and aldehydes[173], alcohols and esters[174,175], aromatic hydrocarbons and ketones[175], and nitrogen-containing bases[176,177]. Brown's method can also be used to estimate the donor–acceptor properties of stationary phases[172] and to determine the optimum composition of binary stationary phases[178].

Ladon and Sandler[179] put forward an equation for determining the number of carbon atoms in a substance being analysed from its retention times on three carefully selected phases; the coefficients of the equations were found by regression analysis. The correlation is based on the use of one or several columns, depending on the complexity of the problem. Correlations using several columns are employed more frequently for the group analysis of substances.

2. Calculations for Predicting Retention Values

The subsequent development of the method using the correlation between gas chromatographic data and the structures of substances has involved the development of the so-called predictive calculation, in which the retention values on a given column or pair of columns are predicted from an assumed structural formula, and the qualitative analysis is carried out by comparing the calculated value with the experimental value for the component of the mixture being studied. Calculations for predicting retention form the subject of a large number of original papers and several reviews[47,180-182].

a) Calculation of the retention values from the physicochemical properties of the sorbates and stationary phases

The retention of a substance in a chromatographic column is determined by the free energy of the intermolecular interaction in the sorbent–sorbate system; it is therefore possible to predict retention values from empirical relationships between this energy and the physicochemical characteristics of the substances being analysed and the stationary phases.

The distribution coefficient and specific retention volume are inversely proportional to the product of the saturated vapour pressure of the substance being analysed at the temperature of the column and the activity coefficient[183]; a knowledge of these quantities makes it possible to predict the retention. The empirical calculation of activity coefficients from the general theory of solutions has been described[184]. This calculation is tedious, however, and makes it possible to estimate the activity coefficient only approximately. It is more convenient to use the relative values based on the following equation[185]:

$$\frac{\lg V_{R_2}}{\lg V_{R_1}} = \lg\left(\frac{p_1^0}{p_2^0}\right) + \lg\left(\frac{\gamma_1^0}{\gamma_2^0}\right), \qquad (13)$$

where γ_1^0 and γ_2^0 are the activity coefficients of substances 1 and 2 dissolved in the stationary phase. If the substances belong to the same series, $\gamma_1^0 = \gamma_2^0$ and Eqn.(13) is simplified[186].

The retention index of hydrocarbons on hydrocarbon stationary phases is given by[187]:

$$I = 100\,\frac{\lg\left(p_n^0 \cdot V_{\mathrm{mol}_n}/p_x^0 V_{\mathrm{mol}_x}\right)}{\lg\left(p_n^0 \cdot V_{\mathrm{mol}_n} p_{n+1}^0 V_{\mathrm{mol}_{n+1}}\right)}, \qquad (14)$$

where p_x^0, p_n^0, and p_{n+1}^0 are the saturated vapour pressures of the substance being studied and n-alkanes containing n and $n+1$ carbon atoms; and V_{mol_x}, V_{mol_n}, and $V_{\mathrm{mol}_{n+1}}$ the molar volumes of the substance and n-alkanes containing n and $n+1$ carbon atoms.

Several equations have been proposed for the theoretical calculation of the heats (or free energies) of solution. Sakharov[119] showed that the heat of formation ΔH_S of a solution at infinite dilution is made up of the energy of interaction of the sorbate with the sorbent (equal to the difference in the energies of the dispersion interaction of the atoms of the substance with the stationary phase, U_i, and the dispersion interaction of the atoms of the substance with the molecules of the stationary phase which might have occupied the space blocked by the other atoms of the molecules of the substance, E_i) and the energy of formation, in the stationary phase, of cavities having shapes and sizes corresponding to those of the sorbate molecule (this energy is proportional to the surface area of the molecule of the substance S and the surface tension of the solvent σ):

$$\Delta H_s = -\sigma S + \Sigma U_i - \Sigma E_i. \qquad (15)$$

The value of U_i for spherical molecules is determined from Eqn.(8), and ΣE_i, if the polarisability densities of the stationary phase and the sorbate are similar, can be replaced by twice the energy of the dispersion interaction between the atoms of the molecule of the sorbate $2E_S$ (that is by the magnitude of the steric effect)[119]. The method has been used successfully to calculate the retention of acyclic saturated[119], unsaturated[124], and aromatic[118] hydrocarbons, and also amino-substituted pyridines, quinolines, and thiophenes[188] on non-polar or weakly polar stationary phases.

Various modifications of the general Eqn.(15) have been proposed, with more accurate allowance for the energy of formation of a hole in the case of planar molecules of the stationary phase[189] or with an expression for

the energy of the London dispersion interaction [190-192]. These equations [190-192], together with the interaction of non-polar substances, have also been used to estimate the interaction of polar sorbates with non-polar stationary phases. The identification of substances reduces to the theoretical calculation of the heats of solution and comparison of the results with the experimental values found from the temperature dependence of $\lg V_R$.

The proportion of polar interactions in a column is also characterised by the dielectric constant of the stationary phase ϵ. A method has been proposed for predicting the retention of a substance on any stationary phase, based on the linear relationship between $\lg V_g$ and $1/\epsilon$. [193] If the substance being analysed and the stationary phases are polar, the retention volumes in the general case can be written as the sum [194]:

$$\lg V_R = \lg V_R^A + pP, \quad (16)$$

where V_R^A is the retention volume of the substance on the non-polar stationary phase, p the polarity of the substance being analysed, and P the polarity of the stationary phase.

The value of V_R^A can be calculated from the above equations, or determined experimentally; the polarities p and P can also either be estimated from the dipole moments, dielectric constants, or other physical quantities, or found experimentally from gas chromatographic data.

A procedure for predicting the retention from the gas chromatographic characteristics of sorbates and stationary phases was developed by Rohrschneider [195-199], who used a so-called linear combination of forms of interaction, based on the additivity of the free energy of solution [197]:

$$\Delta G = \Delta G_A + \Delta G_B + \ldots + \Delta G_Z, \quad (17)$$

where ΔG is the total free energy of solution; and $\Delta G_A \ldots \Delta G_Z$ the proportions of the free energy of solution corresponding to the different forms of intermolecular interaction from A to Z. The proportions of the free energy of solution represent the product of a factor characterising the ability of the stationary phase to undergo interaction of a definite type and a factor characterising the ability of the substance to undergo the same type of interaction.

Initially, Rohrschneider took account of only the dispersion interaction with the π-electrons of the aromatic ring, donor–acceptor interaction with the formation of a hydrogen bond, and the orientation of dipoles [195,196]. Subsequently, the calculation was improved by taking account of electron-acceptor and proton-donor interactions [197-199]. The retention of a substance, in the form of the relative retention volumes or times, is obtained by taking account of six types of interaction, or in the form of I or ΔI by taking account of five types of interaction [195,198]. For any substance on an arbitrary stationary phase

$$\Delta I = ax + by + cz + du + es, \quad (18)$$

where ΔI is the difference in the retention indices on polar and non-polar stationary phases; a, b, c, d, e, are constants characterising the substance being separated; and x, y, z, u, and s are constants characterising the stationary phases. The constants x, y, z, u, and s are determined from the difference in the retention indices, on the column being studied and on squalane, of substances characterising the types of interaction listed above (benzene, ethanol, butan-2-one, nitromethane, and pyridine) [198, 199], and the constants a, b, c, d, and e from the difference in the retention indices of the substance being studied on a non-polar sorbent and on stationary phases characterising the principal types of intermolecular interaction [199].

The subsequent development of Rohrschneider's method has involved an increase in the number of standard substances for characterising stationary phases and sorbates in order to make more detailed allowance for the interactions [200], and also a decrease in the number of standard substances by combining standards characterising similar types of interaction [201-203]. Appropriate mathematical methods have been developed for each of these approaches. Weiner and Howery [204,205] showed by factorial analysis that for an adequate description of a sorbate–sorbent system it is sufficient to have eight terms in an equation of type (18) to the five types of interaction it is necessary to add the Lewis acidity, the Lewis basicity, and the entropy [206]. Lowry and coworkers [207], using the "nearest neighbour" method, showed that satisfactory results in the prediction of retention can be obtained using four functional tests characterising the principal types of interaction.

The above methods are semi-empirical, and require a fairly large expenditure of time for the determination of the corresponding constants. In addition, the values found are not completely unambiguous.

b) Calculation of retention values from structural element increments

An extremely fruitful approach in qualitative analysis by predictive calculations is the development of methods based on the additivity of the enthalpies and free energies of solution of a substance in stationary phases. The interaction of any substance with a sorbent, determining its retention, represents the sum of the interactions of the separate parts of the molecule. By determining the increments in the retention values for all the structural elements of a molecule, it is possible to predict the chromatographic behaviour of the molecule as a whole. Since the enthalpy of solution is linearly related to $\lg V_R$, [12] additivity of the increments can be expected only if the retention data are expressed on a logarithmic scale. The identification of homologues from linear correlations, based on this principle, was examined in the previous section.

The additivity of the increments in retention values characteristic of the structural elements of molecules was first demonstrated on the basis of Kovats' system of retention indices [40,93,106,208]. In addition to the fact that the contribution of the $-CH_2-$ group to the retention value is constant, which formed the basis of the linear correlation methods examined above, it was established that the introduction of a given group of atoms into the molecules of compounds having analogous structures changes the value of the retention indices by the same amount. Assuming that the dispersion interactions of parts of molecules with different stationary phases are equal, Kovats proposed that the specific interactions of the molecules with a sorbent be characterised by increments ΔI, calculated from the difference in the values of the retention indices of the substances on polar and non-polar stationary phases. The increments ΔI consist of a principal term taking account of the influence of the "characteristic zone" (functional group, double bond, ring, etc.), and corrections taking account of the influence of the surroundings of this zone. Unknown compounds are identified by comparing the experimentally determined value with the values of ΔI calculated from several assumed structural formulae.

In 1962, Swoboda [209] suggested that the chromatographic behaviour of substances could be characterised more effectively by subtracting from their retention indices the

retention indices of the n-alkanes making up the main framework of the molecule. Since the difference obtained characterises the contribution of the functional groups to the retention, Swoboda called it the "functional retention index".

These ideas were later developed by Schomburg [47,52,210-217], who suggested that the difference between the retention indices of the substance and the alkane having an analogous carbon framework (the homomorph) be called the homomorphic factor H. [211] The homomorphic factors are extremely sensitive to changes in the geometry of a molecule—branching, the position of a double bond, and configuration—whereas the values of ΔI are not very characteristic in this respect [212,213]. The difference in the homomorphic factors on polar and non-polar columns ΔH, characterises the influence of the specific forces of intermolecular interaction [47,213]. The values of H, ΔI, and ΔH are additive, but the additivity breaks down if two characteristic structural elements are in close proximity. In these cases, Schomburg proposes the introduction of a correction in the form of increments of second order [215,216], which, like the corrections of Kovats and Wehrli [40,93,208], take account of the interaction of groups and the steric and other effects of the environment. The applicability of the principle of additivity of the increments in the retention indices for predicting the chromatographic behaviour of substances [210-217] has been confirmed by a number of workers for various classes of compound [103,218-224].

Since I and ΔI depend on temperature, they must be compared for identical temperatures, or recalculated [147]. A number of authors [147,225,226] have suggested that ΔI values be related to 0 K. At the absolute zero, when the thermal energy of a substance is equal to zero, the factors corresponding to the interaction between substances and stationary phases are more rigorous characteristics, depending only on the structural characteristics of the substances.

If the retention indices are expressed on the molecular weight scale (so-called effective molecular weights), substances in homologous series can be identified using the constancy and additivity of the increments in the molecular weights ΔM_e (the difference between the true and effective molecular weights) [37,39], as in the case of ΔI. Finally, instead of using ΔI, ΔH, and ΔM_e, retention values can be predicted by using directly the increments in the partial molar standard enthalpy $\Delta\bar{H}^0_S$ and entropy $\Delta\bar{S}^0_S$ of solution, characteristic of the individual structural elements of molecules [227]. They are less dependent on temperature than the increments ΔI, ΔH, and ΔM_e, and this makes it possible to calculate V_g over a wide temperature range, using the values of $\Delta\bar{H}^0_S$ and $\Delta\bar{S}^0_S$ measured at a given temperature.

Most of the works cited demonstrate that ΔI, ΔH, and ΔM_e are constant in homologous series, but more accurate measurements of these quantities over a sufficiently wide range show that they depend slightly on the number of carbon atoms in the group. The dependence is described effectively by the equation of a linear-fractional function

$$\Delta I = \frac{n}{an+b}, \qquad (19)$$

which can be transformed into the straight line equation [117]

$$Y = an + b \quad \text{for} \quad Y = n/\Delta I.$$

The principle of additivity of ΔI, H, ΔH, and ΔM_e, and its use for the identification of substances, are also justified by set theory.

The identification of substances by predicting retention from molecular structure is also possible using logarithmic interpolation. This method was developed by Evans and Smith [32], who showed that the retention time $t_{R_{1,2}}$ of unsymmetrical compounds of the type RXR′ can be determined if the retention times $t_{R_{1,1}}$ and $t_{R_{2,2}}$ for the symmetrical substances RXR and R′XR′ respectively are known. The equation which they proposed,

$$\lg t_{R_{1,2}} = \frac{1}{2}(\lg t_{R_{1,1}} + \lg t_{R_{2,2}}) \qquad (20)$$

is applicable if the active group X is not sterically shielded and is not included in a conjugated system of multiple bonds, and if the other parts of the molecule R and R′ are not highly polar.

The linear-fractional dependence of $\lg V_R$ on the molar refraction of the stationary phase has been made the basis of a method for predicting retention for substances of a given homologous series on any stationary phase if the values of V_R for this series on two stationary phases are known [228].

A general approach to the problem of predicting retention by calculation based on the additivity of the contributions of structural elements was developed by Berezkin [229-233], who showed that all the above relationships are particular cases of the general relationship [229,230]

$$\lg R = \sum_{i,j}^{k} n_{ij} P_{ij}, \qquad (21)$$

where P_{ij} is the contribution of a given structural element to $\lg R$; and n_{ij} the number of structural elements in the molecule of the substance. The structural elements on which the calculation is based may be either atoms or bonds, since the accuracy of the calculations depends not on the fundamental differences between the atoms and the bonds, but on the detail with which they are classified [234,235]. As the structural elements for the calculations, Berezkin took the bonds, with allowance for the first-order environment. If allowance is made for a larger environment, it is possible in principle to obtain more accurate results, but the error in the determination of the experimental data makes this calculation inappropriate. It is more justified and convenient in practice to carry out the predictive calculation of t_R^{rel} from an equation which contains an additional constant P_0, which depends on the choice of standard substance [233]:

$$\lg t_R^{rel} = P_0 + \sum_{i,j}^{k} n_{ij} P_{ij}. \qquad (22)$$

Relative or absolute values of R have been calculated for alkanes [229,230], alkenes [232], esters [230], amines [233], alcohols, ketones, sulphides, and various oxygen- and nitrogen-containing heterocyclic compounds [236].

Berezkin's approach has been made the basis of a predictive calculation of the retention indices of substances [237]. The influence of the environment is taken into account [237] not as different versions of the bonds [232] but as a separate component Π:

$$I = \sum_{i,j} I_{ij}^{(1)} + \Pi, \qquad (23)$$

where $I_{ij}^{(1)}$ represents the contributions of the individual bonds and structural elements to the retention indices of

the mono-functional compounds, and $\Pi = \sum_{ij}\pi_{ij}$ is the contribution of the interaction, which takes maximum values for 1,2-substitution.

It has also been shown that it is necessary and possible to take account of the inductive effect, which is estimated in the form of the coefficients of a multiple regression equation [238]. The dependence of the contributions of the structural elements and their sensitivity to the inductive effect on the nature of the structural elements and on the dielectric constant of the stationary phase has been studied [239,240].

In a series of papers [241-249] devoted to the predictive calculation of retention indices from the additivity of the contributions of the structural elements of molecules, the latter were dealt with in even more detail. The retention index of a substance was represented as the sum of three components [241-243]:

$$I = I_a + I_b + I_i = I_M + I_i, \qquad (24)$$

where I_a, I_b, and I_i represent respectively the contributions made to the retention index by the atoms, the bonds, and the interaction between the substance and the stationary phase. The atomic component of the retention index I_a is found as the sum of the indices of all the atoms of the molecule, which in turn are approximately equal to the atomic weight of the element divided by 10. [242,243] The component I_b is equal to the sum of the contributions from all the bonds of the molecule; the contributions of the bonds are determined with allowance for the immediate environment, by iteration. These two terms make up the part of the retention index which is characteristic of the given substance and independent of the nature of the stationary phase and temperature. This part of the retention index, called the molecular component I_M, can be calculated from the structural formula of a substance.

The interaction of a substance with a stationary phase, and its dependence on the temperature of the analysis, are taken into account by the component I_i. Experimental data [243] show that for homologous series of substances on squalane, $I_i = 4.97\,yI$ (y is a coefficient characteristic of a given class of substance; for example, for alkanes, $y = 0.15$ [241]). For other stationary phases, it is suggested that the component of the interaction I_i (or the interaction factor $F_i = I_M/I$) be further divided into two parts: I_{ia}, the contribution of the average interaction, and I_{ii}, the contribution of the individual interaction [242,244]. I_{ia} characterises the dispersion interactions, and I_{ii} the specific interactions between the molecules of the substance being analysed and the stationary phase. $I_{ia} = 0.7455.I$, [244] but I_{ii} must be determined by the methods of Rohrschneider [197-199,244] or McReynolds [200,245,246] (on a non-polar sorbent, $I_{ii} = 0$, $I_i = I_{ia} = 0.7455.I$ [249]). The method is also applicable when corrected retention volumes are used instead of the retention index [248].

The predictive calculation system developed by Takacs represents a theoretical approach to the separate determination of all the factors making up the retention index. This approach makes it possible to understand more deeply the nature of the retention of substances in chromatography and to distinguish the factors responsible for the gas chromatographic behaviour of substances in specific examples of analysis. Although the method is undoubtedly of considerable value, the determination of such important components of the retention index as I_b and I_{ii} is still semi-empirical. Moreover, the method for determining I_b is not given, so that the calculation is not reproducible [250], particularly for cyclic compounds. For practical purposes, it is much more convenient to use the method of calculation proposed by Berezkin, which, although it does not contain the details of P_{ij}, makes it possible to use definite experimental material to find unambiguous values of the contributions of the structural elements for the predictive calculation of the retention of other substances.

Thus the methods of incremental calculation provide theoretically justified and extremely promising methods for the qualitative gas chromatographic analysis of organic substances. Their use facilitates to a considerable extent the solution of problems arising when gas chromatography is used as an analytical method.

c) Prediction of retention values from a molecular-statistical calculation

The most general solution of the problem of predicting retention values by calculation is the theoretical molecular-statistical calculation of the specific retention volumes and Henry coefficients. This quantitative approach is being successfully developed in the USSR by Kiselev, Poshkus, and Afreimovich [251-259] for the gas-adsorption chromatographic characteristics obtained at sufficiently high temperatures with the assumption that the intramolecular vibrations of the adsorbent remain unchanged on adsorption [257]. Henry's coefficient K_1 (the specific retention volume for zero degree of covering of the surface of the adsorbent V_ρ) for three-dimensional quasi-rigid molecules is given by the following equation [256, 259]:

$$(V_\rho)\,K_1 = \frac{1}{8\pi^2 S}\int \{\exp[-\Phi(x, y, z, \vartheta, \varphi, \psi)/kT] - 1\}\sin\vartheta\, dx\, dy\, dz\, d\vartheta\, d\varphi\, d\psi, \qquad (25)$$

where S is the surface area of the adsorbent; Φ the potential energy of the adsorbate–adsorbent intermolecular interaction, which depends on the coordinates of the centre of mass of the molecule x, y, z and the angles of its orientation relative to the surface of the adsorbent θ, φ, ψ; and k the Boltzmann constant.

The potential energy of the intermolecular interaction is determined as the sum of the energies of the paired interactions over all interacting atoms, expressed in terms of the atom–atom potential functions of intermolecular interaction $\varphi_{C\ldots A}$ (or the atom–group potential functions in the case of the study of complex molecules). The atom–atom potential functions are calculated using the familiar semi-empirical equations for the Buckingham–Korner or Lennard-Jones potentials; the constants of the equations are calculated by the method of Kirkwood and Miller [260,261]. This method has been used to calculate the Henry coefficients for the noble gases and nitrogen for adsorption on graphitised thermal carbon black [251,253,258] and various cationic forms of zeolite A. [262,263] The molecular-statistical calculation of the Henry coefficients for adsorption on graphitised thermal carbon black was carried out for the C_1–C_6 n-alkanes [255-259]; the effective atom–atom potentials of the intermolecular interaction $\varphi_{C\ldots C}$ and $\varphi_{C\ldots H}$ were calculated using a special constant factor [256,259]. Using the effective potential functions of the atom–atom interaction and taking account of the differences in the adsorption of the rotational isomers of the n-alkanes, the authors cited obtained the values of V_ρ, K_1, and $\lg K_1$, and the dependence of the latter on the reciprocal of the absolute temperature, in good agreement

with experimental data. In the case unsaturated and aromatic hydrocarbons, it was necessary to introduce into the potential functions $\varphi_{C...C}$ additional factors taking account of the stronger interaction between the graphitised carbon black and carbon in other valency states (compared with the n-alkanes and cycloparaffins). In principle, by taking account of the differences in the valency states of carbon in molecules, it is possible to calculate the Henry coefficients or retention volumes for any hydrocarbons on graphite.

Molecular-statistical calculations have also been carried out for the adsorption of neopentane by NaX zeolite[264] and the adsorption of ethane by the zeolites NaX and NaY.[265]

The molecular-statistical calculation of retention values using semi-empirical potential functions is at present the most well-founded theoretical approach to the solution of the problems of qualitative analysis in gas chromatography. The chief disadvantage of the method is the tedious character of the calculations, and also the semi-empirical character of various constants in the equations used; the calculation of these constants requires many assumptions. This disadvantage can be overcome, however, using modern computing techniques. Unfortunately, at the present time the possibilities provided by molecular-statistical calculations are restricted to several examples of gas-adsorption chromatography on the fairly uniform surfaces of crystalline adsorbents. Since the structure of liquids has not yet been sufficiently fully studied, molecular-statistical calculations in gas-liquid chromatography represent a task for the future.

The Use of Spin-trapping in the Study of the Mechanisms of Radical Processes

V.E.Zubarev, V.N.Belevskii, and L.T.Bugaenko

The review is devoted to the spin-trapping method developed in recent years and used to identify short-lived radicals (mainly in liquid phase) and to investigate the mechanisms of their reactions. Unstable radicals are accepted by a spin-trapping agent with formation of a fairly stable free radical which carries information about its short-lived precursor. The EPR spectra of the resulting spin adducts can be recorded in the liquid phase and are as a rule well resolved. The properties of various spin-trapping agents are described in detail and tables of the parameters of the EPR spectra of the adducts of spin-trapping agents with the trapped radicals are presented. The application of the spin-trapping method in the study of the mechanisms of radical processes in various fields of chemistry is considered.
The bibliography includes 161 references.

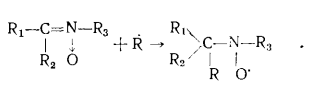
I. INTRODUCTION

The free radicals arising in the course of chemical reactions usually have very short lifetimes, which precludes their detection in the chemical reaction zone by the usual EPR method, since the steady-state concentrations of the radicals are below the sensitivity of modern EPR spectrometers. In order to detect short-lived radicals, special research techniques have therefore been developed: (1) stabilisation of radicals in the solid phase at low temperatures; (2) flow methods in the liquid phase with the radicals generated by means of Fenton's reagent or the titanium reagent in an acid medium; (3) recording of EPR spectra (or optical absorption spectra) under continuous irradiation by an electron beam or light in the liquid phase directly in the resonator; (4) stabilisation of radicals on the surface; (5) the method of chemically induced dynamic nuclear polarisation (CIDNP). These methods yielded much information about the radicals and the mechanisms of radical reactions. However, they suffer from many significant limitations. Owing to the high rate of radical reactions, it is usually impossible to detect the primary radicals. Analysis of the EPR spectra of solid specimens is in most cases difficult because of the broadening of the lines and the superposition of the spectra of several radicals. Flow methods are suitable only for a limited number of chemical reactions and involve the consumption of a large amount of reagents. Considerable technical and methodological difficulties arise also when the CIDNP method or a spectrometer irradiated by an electron beam are used. The majority of radical reactions occurring in the liquid phase cannot be investigated by the methods enumerated above.

The spin-trapping method, developed in recent years, has significantly greater possibilities and permits the investigation of short-lived radicals in liquid, solid, and gaseous phases. It is based on the acceptance by compounds (spin-trapping agents) of short-lived radicals with formation of fairly stable radical adducts having a characteristic EPR spectrum. Extensive information about short-lived radicals arising in photolysis, radiolysis, electrolysis, gas discharge, oxidation, thermal decomposition, rearrangement, and polymerisation has been obtained with the aid of the spin-trapping method. The aim of the present review is to demonstrate the possibilities of the method and the prospects for its utilisation in the study of the mechanisms of radical reactions. Earlier reviews[1-3] present data published up to 1971†. Since then the number of studies involving the use of spin trapping agents has greatly increased, new spin-trapping agents have become available, and new fields of their application have arisen.



II. SPIN-TRAPPING AGENTS

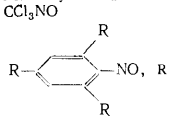
Mainly nitroso-compounds and nitrones are used as spin-trapping agents. In the study of the mechanism of the photolysis of 't-nitrosobutane' and nitrosobenzene it was observed[4] that these compounds react with the intermediate radicals arising as a result of the photolysis of the nitroso-compounds, forming stable nitroxy-radicals. Iwamura and Inamoto[5,6] were the first to use nitrones for the synthesis of stable radicals. It was shown subsequently that many nitroso-compounds and nitrones combine with unstable radicals, forming long-lived radicals. Table 1 presents a list of the main spin-trapping agents.

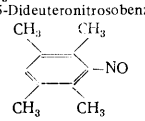
Nitroso-t-butane and *C*-phenyl-*N*-t-butylnitrone are most frequently employed. The unstable radical adds to the N–O fragment of the nitroso-compound:

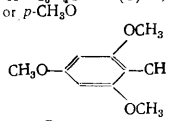
$$R_1{-}NO + \dot{R} \rightarrow R_1{-}N(\dot{O}){-}R \quad .$$

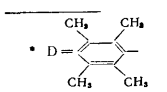
Radicals add to the double bond of nitrones:

Nitroxy-radicals, which belong to the large class of stable radicals whose properties have been thoroughly investigated[7,8], are formed in both cases.

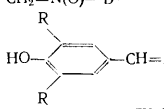


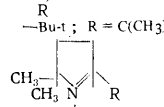


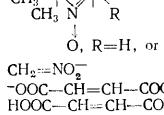


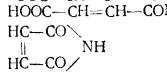


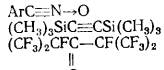
Apart from nitroso-compounds and nitrones, certain other compounds containing multiple bonds or heteroatoms are used as spin-trapping agents (see Table 1).

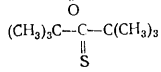


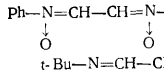


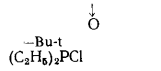












1. Nitrosoalkanes

The majority of nitroso-compounds exist in the forms of dimers which dissociate into monomers in solution. Only the monomeric form reacts with radicals. Mainly t-nitrosobutane and related compounds are used as spin trapping agents.

t-Nitrosobutane (TNB, t-BuNO). The simplest and most convenient method of synthesising TNB has been described by Stowell[9] (oxidation of t-$BuNH_2$ with hydrogen peroxide in the presence of Na_2WO_4), but other methods of synthesis are also available[10]. Solid TNB is a colourless dimer, which dissociates in solution with the appearance of a characteristic blue colour. The dimer–monomer equilibrium constants in CCl_4, methanol, heptane, and toluene have been determined[9,11-14].

The monomeric form of TNB in solution has an optical absorption maximum at 667 nm (ϵ = 18.2 litre $mole^{-1}$ s^{-1} in methanol[12]), while the dimer absorbs at 294 nm ($\epsilon = 5.7 \times 10^3$ litre $mole^{-1}$ s^{-1} in heptane[14]). The photolysis of liquid TNB solutions by visible light results in the formation of stable t-Bu_2NO radicals[4,15] and the solution cannot therefore be stored in the light. These radicals are also formed on heating TNB solutions[16]. In frozen solutions the monomeric form of TNB is resistant to the action of light[17], while the dimer dissociates under these conditions to the monomer under the influence of light[17,18]. It has been suggested that the photolysis of TNB in solution proceeds via the following mechanism:

$$\text{t-BuNO} \xrightarrow{h\nu} \text{t-BuNO}^* \rightarrow \text{t-Bu}^\cdot + \text{NO}, \quad (1)$$

$$\text{t-Bu}^\cdot + \text{t-BuNO} \rightarrow \text{t-Bu}_2\text{NO}^\cdot, \quad (2)$$

†See also the review by R. Kh. Freidlina, I. I. Kandror, and R. G. Gasanov, Uspekhi. Khim., 47, 508 (1978) [Russian Chemical Reviews, 47, No. 3 (1978)].

or

$$t\text{-BuNO}^* + t\text{-BuNO} \rightarrow t\text{-Bu}_2\dot{N}O + NO. \quad (3)$$

t-$Bu_2\dot{N}O$ radicals are also formed in the radiolysis of TNB solutions in benzene and toluene at 20°C as a result of the transfer of excitation energy from aromatic compounds to TNB.[13]

It has been shown[18] that TNB is stable in the presence of oxidants such as $Pb(AcO)_4$ and Ce^{4+} and over a wide pH range[18]. However, it was later observed[19] that alkyl hydroperoxides and dimethyl sulphoxides react with nitroso-compounds to form nitroxy-radicals:

$$R'OOH + R''NO \rightarrow \underset{\underset{OOR'}{|}}{R''\text{—}N\text{—}OH} \rightarrow R'\dot{O} + \underset{\underset{O\cdot}{|}}{R''\text{—}N\text{—}OH} \xrightarrow{+R''NO} \underset{\underset{O\cdot}{|}}{R'\text{—}O\text{—}N\text{—}R''}. \quad (4)$$

Nitroso-compounds react readily with certain anions [polystyrene, poly(methyl methacrylate), nitromethane, acetate, and cyanide anions][20], forming amino-oxyanions, which are oxidised either by the nitroso-compound itself or by "traces" of O_2 to nitroxy-radicals:

$$R^- + t\text{-BuNO} \rightarrow t\text{-Bu}\underset{\underset{O^-}{|}}{\text{—}N\text{—}R} \xrightarrow{t\text{-BuNO}} R\text{—}\underset{\underset{O\cdot}{|}}{N\text{—}}Bu\text{-}t. \quad (5)$$

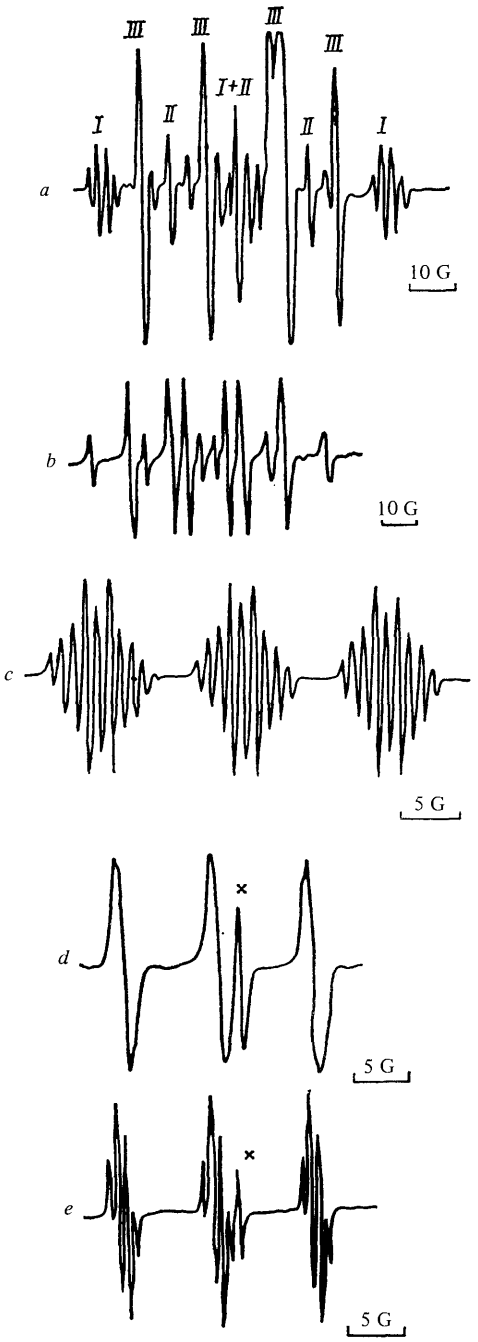
The interpretation of data on the trapping of TNB radicals in the presence of oxidants and in electron-donating media must therefore be approached with caution.

2-Methyl-2-nitroso-3-butanone is similar to TNB as regards its chemical properties and the EPR spectra of radical adducts[2,18] and is sometimes a more effective radical acceptor. When this compound is acted upon by ultraviolet light, acyl radicals are formed and then trapped.

Fully fluorinated t-nitrosobutane is also used to trap unstable radicals[21,22].



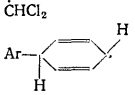
The EPR spectra of the radical adducts of TNB and 2-methyl-2-nitroso-3-butanone have a triplet due to splitting by the nitrogen atom of the nitroso-group and additional hyperfine structure arising as a result of the interaction with the magnetic nuclei of the trapped radical. Splitting by the t-butyl group is not observed. The trapped radical can be identified on the basis of the nature of the additional hyperfine structure, the constants for splitting by nitrogen atoms (a_N) or β-hydrogen (a^H_β), and in certain cases γ-hydrogen (or heteroatoms). Table 2 presents the splitting constants for the most characteristic TNB radical adducts. The values of a_N are different for different classes of organic radicals: a_N = 26–29 G for RO· radicals, 14–16 G for alkyl radicals, and 7–8 G for acyl radicals. Definite regularities in the variation of the constants for splitting by hydrogen and heteroatoms, associated with the structure of the trapped radical, have been observed. In polar solvents, the splitting constants can increase by 1–2 G relative to non-polar solvents and comparative measurements must therefore be performed in identical solvents. One must note that, owing to the broadening of the EPR lines due to the influence of the t-butyl group, a splitting smaller than 0.3 G is not resolved in the spectra.

An appreciable improvement of the resolution of the EPR spectra can be achieved by employing fully deuterated t-nitrosobutane $(CD_3)_3CNO$, whose synthesis has already been described[24]. The adducts of this trapping agent give rise to very narrow lines in EPR spectra, which makes it possible to observe additional splitting due to γ-protons or radicals with heteroatoms, which cannot be resolved in the case of the usual TNB. In addition, the signal to noise ratio is improved[23–26]. For example, splitting by the protons of the CH_3 group due to the hyperfine (HF) interaction via the carboxy-group has been observed for the adduct of $(CD_3)_3CNO$ with the radical $CH_3O\dot{C}O$ (Figs. *d* and *e*)

2. AROMATIC NITROSO-COMPOUNDS

(a) Nitrosobenzene

The disadvantages of TNB described above (sensitivity to light, oxidants, strong acids, and certain anions as well as instability of many adducts) limit the application of this trapping agent. Nitrosobenzene has some advantages compared with TNB[19]. It is readily available, exists in solution largely in the active monomeric form, and is not sensitive to light at wavelengths in excess of 360 nm. Only ultraviolet light with $\lambda < 310$ nm leads to the formation of the diphenylnitroxy-radical. Spin adducts with nitrosobenzene are usually stable at 20°C and their EPR spectra contain very narrow lines, so that very small splittings are resolved in the latter. The main disadvantage of nitrosobenzene is difficulty of analysing its EPR spectra, because addition HFS lines due to the benzene ring protons arise ($a^H_o = a_p = 2.5$ G, $a^H_m = 0.9$ G). The spectra simplify when 3,5-dideuteronitrosobenzene is used instead of nitrosobenzene, but the replacement itself leads to a broadening of the lines due to an unresolved HFS caused



EPR spectra of the adducts of t-nitrosobutane (TNB) with trapped radicals: *a*) irradiation of methanol with electrons having an energy of 3 MeV at −45°C directly in the resonator[30] [I) $CH_3O-N(\dot{O})-t\text{-}Bu$: II) $HOCH_2-N(\dot{O})-Bu\text{-}t$; III) $H-N(\dot{O})-Bu\text{-}t$]; *b*) adducts of TNB with the $\dot{C}H_3$ radical in benzene, obtained on decomposition of acetyl peroxide[15,33]; *c*) adduct of TNB with the phenyl radical in benzene at 20°C (thermal decomposition of benzoyl peroxide)[147]; *d*) adduct of TNB with the $CH_3O\dot{C}O$ radical; *e*) adduct of perdeutero-t-nitrosobutane with the $CH_3O\dot{C}O$ radical (in contrast to case *d*, the lines due to the CH_3 group are evidently resolved); the cross denotes one of the lines due to the adduct with the t-BuO· radical.

by the influence of the deuterium nuclei[19]. Substituted nitrosobenzene derivatives, which are free from the disadvantages of nitrosobenzene, have been used as spin-trapping agents[41-43].

(b) Nitrosodurene (2,3,5,6-tetramethylnitrosobenzene)[41]

Nitrosodurene (ND), synthesised by the method of Smith and Taylor[44], is a colourless dimer in the crystalline state; even in solutions it exists largely in the dimeric form. On heating, the degree of dissociation of the dimer increases and a greenish colour appears. Nitrosodurene is appreciably soluble in $CHCl_3$ and methylene chloride; in aromatic hydrocarbons its solubility is about 0.003 M and in other solvents it is even smaller. However, in consequence of the high trapping rate constants, such nitrosodurene concentrations are sufficient to trap short-lived radicals. The main advantages of nitrosodurene as a spin-trapping agent are simplicity of the EPR spectra of its spin adducts and the large amount of information contained in them, insensitivity to ultraviolet light, and high stability of radical adducts at 20°C. The EPR spectra exhibit hyperfine splitting by the nitrogen atom of the NO group and by the protons of the trapped radical.

Table 3. Parameters of the EPR spectra of the adducts formed as a result of the capture of radicals by nitrosodurene in benzene at 20°C.[41]

	—	13.5	8—14	161

The splitting by the *para*-protons and the protons of the CH_3 groups is not resolved, but the lines are broadened owing to the interaction with these protons. The HFS lines of the radical adducts of deuterated nitrosodurene [2,3,5,6-tetrakis(trideuteromethyl)nitrosobenzene] are appreciably narrowed, but splitting by the *para*-protons is manifested (a = 0.34 G).[41] The parameters of the EPR spectra of the nitrosodurene adducts are presented in Table 3. All alkyl radicals, including tertiary radicals, add to nitrosodurene via the nitrogen atom and do not form anilino-radicals. The presence of electronegative groups reduces a_N and increases the g-factors. The values of

a_{β}^{H} depend greatly on the structure of the trapped radical. The disadvantages of nitrosodurene include poor solubility in many compounds, the broadening of the lines, and lability of adducts with RO· radicals.

(c) 2,4,6-tri-t-butylnitrosobenzene (BNB)[42,43,45]

Compared with other spin-trapping agents, BNB has a number of advantages. 1. It dissolves readily in many solvents and exists in the active monomeric form in both the solid state and in solution. 2. The spin adducts of BNB have simple, satisfactorily resolved EPR spectra, but the latter show splitting due to *meta*-protons. 3. BNB is a bifunctional trapping agent: radicals can add both to the nitrogen atom, forming nitroxy-radicals, and to the oxygen atom of the nitroso-group with formation of *N*-alkoxy-anilino-radicals (the reaction pathway is determined by the structure of the precursor radical):

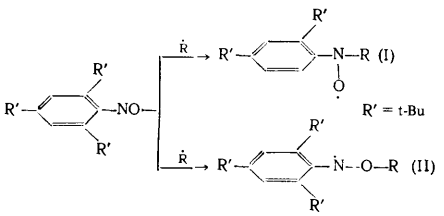

Table 4. Parameters of the EPR spectra of the radical adducts of 2,4,6-tri-t-butylnitrosobenzene.

*Here I = nitroxy-radical and II = anilino-radical.

The EPR spectra of *N*-alkoxyanilino-radicals can be readily distinguished from the spectra of nitroxy-radicals, because their *g*-factor and the constant for splitting by the nitrogen atom (Table 4) are smaller and the line width is greater than for nitroxy-radicals. 4. The majority of BNB adducts are stable in non-polar solvents at 20°C. 5. BNB is not photolysed in solution, which makes it possible to use it in the study of photochemical reactions.

Primary alkyl radicals react with BNB, forming exclusively nitroxy-radicals. Tertiary alkyl radicals add only to the O atom with formation of anilino-radicals. Secondary alkyl radicals add to both N and O atoms. Like tertiary alkyl radicals, triethylsilyl and triethylstannyl add to the oxygen atom. Certain radicals with heteroatoms (t-BuO·, the phenoxy-radical, ĊCl$_3$, the *N*-methylanilino-radical, Ṡ–Ph, etc.) are either ineffectively trapped or do not form stable adducts with BNB. However, BNB is perhaps the best spin-trapping agent for alkyl radicals, since the EPR spectra of their spin adducts are the most sensitive to changes in the structure of the radicals. Among other substituted nitrosobenzenes, the following compounds may be noted.

2,4,6-Trimethoxycarbonylnitrosobenzene[41] is a colourless dimer in the solid state, but dissociates almost completely in solution. In terms of the nature of the spin adducts, this nitroso-compound resembles nitrosodurene, but is a more convenient spin-trapping agent because of its high solubility and the very small width of the lines due to the spin adducts.

2,4,6-Trimethoxynitrosobenzene[41] has properties similar to those of nitrosodurene and the spectra of the spin adducts are simple and have narrow HFS lines. The compound itself is resistant to photolysis but is poorly soluble in many solvents.

2,4,6-Trichloronitrosobenzene[41] largely dissociates in solution but is not photolysed.

Pentafluoronitrosobenzene[41] is a monomer even in the crystalline state, is not photolysed in solution, but has been little investigated as a spin-trapping agent.

3. NITRONES

When the radicals Ṙ are trapped by nitrones having the general formula R′–CH=N(O)–R″, the products are the nitroxy-radicals R′–$\underset{\text{R}}{\text{CH}}$–$\underset{\text{O}}{\text{N}}$–R″, whose EPR spectra consist in most cases of a triplet of doublets (splitting by the nitrogen atoms and β-hydrogen atoms). The HFS due to the trapped radicals is usually not resolved and special mention shall be made of the exceptions to this rule. Nitrones can be used conveniently as spin-trapping agents, because of their high reactivity, ready solubility in many compounds, the simplicity of their EPR spectra, and the stability of the spin adducts.

(a) *C*-Phenyl-*N*-t-butylnitrone (PBN)

The majority of workers have synthesised PBN by Emmons' method[46]. The spectrum of PBN in solution in ethanol has an absorption band with a maximum at 294 nm (ϵ_{294} = 16 700 litre mole^{-1} s^{-1}) at 20°C.[46] The compound is stable and relatively insensitive to light, O_2, and water vapour, and dissolves readily in the majority of solvents (its solubility ranges from 0.1 to 1.0 M). Many adducts with PBN are stable at room temperature. In a highly acidic medium PBN hydrolyses with formation of hydroxylamine and benzaldehyde[46]. In the presence of oxidants [Cl_2, Br_2, NO_2, nitrosyl chloride, t-butyl nitrite, $KMnO_4$, and $Pb(AcO)_4$] the stable benzoyl-t-butylnitroxy-radical is formed[47–50] (triplet with a_N = 7.5–8 G).

The data concerning the resistance of PBN to ultraviolet light are contradictory. After prolonged photolysis of solid PBN, the formation of an unidentified radical (triplet in EPR spectra with a_N = 15.2 G) was noted[51]. However, radicals were not detected after ultraviolet irradiation of PBN solutions in methanol, ethanol, and benzene. On the other hand, photolysis of methanol in the presence of PBN led to the observation of the EPR spectrum of an adduct with $\dot{C}H_2OH$ radicals, while irradiation through a filter containing 0.5 M PBN does not lead to the appearance of radicals[55]. It is believed that the photoexcited PBN molecule is capable of abstracting a hydrogen atom from the solvent molecule.

The formation of the radical Ph–C(O)–N(Ȯ)–Bu-t was observed after intense ultraviolet irradiation of PBN solutions in benzene. A possible mechanism of the formation of this radical is based on the intermediate formation of the oxazirane Ph–C(O)(H)–N–Bu-t.[52,53] The contradictory nature of the data of different workers on the photochemical stability of PBN can be attributed not only to the complexity of the processes taking place but also to the purity of the reagent as well as the presence of oxygen in solution. It is noteworthy that no stable radicals are formed during the preparation of PBN solutions in daylight in alcohols and hydrocarbons.

Like other nitrones, PBN is an effective trapping agent not only for radicals but also for certain anions (nitromethane, phthalimide, benzyl cyanide, and styrene anions), the trapping process resulting in the formation of the corresponding nitroxy-radicals. The presence of traces of air increases the yield of these radicals[20,56]. Nitrones readily enter into the 1,3-dipolar addition reaction, which limits their use as spin-trapping agents. Examples of this are provided by the addition of HCN[20] and acetates[47]. At 20°C in the absence of light both $Pb(AcO)_4$ in benzene solution and CH_3COOK in acetic acid[20,47] react with PBN to form a spin adduct (a_N = 12.8 G, a_β^H = 1.73 G) indistinguishable from the adducts of PBN with the radical $CH_3C\dot{O}O$:

$$Ph{-}CH{=}\overset{+}{N}{-}Bu\text{-}t + Pb(OAc)_4 \rightarrow Ph{-}CH(O^-){-}N{-}Bu\text{-}t$$

$$\rightarrow Ph{-}CH(AcO){-}N(OPb(OAc)_3){-}Bu\text{-}t \xrightarrow{em} Ph{-}CH(AcO){-}N(O\cdot){-}Bu\text{-}t .$$

Slow oxidation of this adduct with air leads to the appearance of the benzoyl-t-butylnitroxy-radical.

Caution is necessary in the interpretation of the mechanism of the formation of the spin adducts of PBN with the radicals $CH_3C\dot{O}O$ and $PhC\dot{O}O$, arising in the thermal decomposition of acetates and benzoates, since the same spin adducts can appear also in the nucleophilic addition of acetate and benzoate ions to PBN[20,49].

PBN reacts readily with Grignard reagents and organometallic compounds of sodium, potassium, etc., the process being accompanied by the intermediate formation of the hydroxyamide anion, which oxidises in air to the corresponding nitroxy-radical[47,56]:

$$LiR + PhCH{=}N(O){-}Bu\text{-}t \rightarrow Ph{-}CH(R){-}N(OLi){-}Bu\text{-}t \xrightarrow{O_2} Ph{-}CH(R){-}N(O\cdot){-}Bu\text{-}t .$$

This property of nitrones is used for the "specific synthesis" of nitroxy-radicals in order to identify them.

The EPR spectra of the PBN radical adducts Ph–CHR–N(O·)–Bu-t consist of a triplet of doublets (as a result of splitting by the nitrogen atom and the β-proton) with small differences in the splitting constants a_N and a_β^H. As stated above, splitting by the nuclei of the trapped radical $\dot{R}$ is not manifested with the exception of adducts with H atoms and inorganic radicals (Table 5). In order to identify the trapped radicals, a very accurate (to within 0.03G) measurement of the hyperfine splitting constants is necessary (for comparison with the available literature data). The solvent has an appreciable influence on the splitting constants: they increase in more polar systems. The "specific synthesis" of nitroxy-radicals in the same solvent is necessary for identification in many instances. The measurement of the width of the line due to adducts may be of some assistance in identification. For example, the adducts of PBN with the radicals $CH_3\dot{O}$ and $\dot{C}H_2OH$ have lines with widths of 0.5 and 1.2 G respectively[57,58]. This difference is associated with the unresolved HFS due to the protons of the $\dot{C}H_2OH$ radical. Thus the EPR spectra of PBN adducts with trapped radicals contain much less information about the nature of the trapped radicals than in the case of nitroso-compounds.

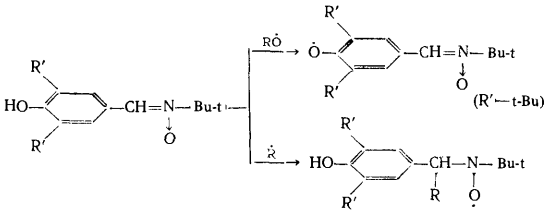

Table 5. Parameters of the EPR spectra of the radical adducts of *C*-phenyl-*N*-t-butylnitrone (PBN).

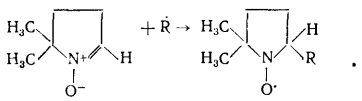
(b) Bifunctional Trapping Agents

Among other nitrones, the attention of investigators has been drawn to bifunctional trapping agents. α-(3,5-Di-t-butyl-4-hydroxyphenyl)-N-t-butyl-nitrone has been described[62]. Oxygen-containing radicals ($R\dot{O}$, $Ac\dot{O}$, $PhC\dot{O}O$, etc.) react with the nitrone by abstracting the phenolic hydrogen with formation of stable phenoxy-radicals; the solution is then coloured blue. Radicals with the unpaired electron at a carbon atom add to the β-carbon

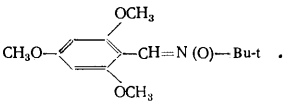
atom of the nitrone, forming nitroxy-radicals, which colour the solution yellow-orange. The EPR spectrum of the phenoxy-radical (a_N = 5.05 G, a_β^H = 2.1 G, a_m^H = 1.7 G) differs strongly from the spectrum of the nitroxy-radical (a_N = 13.5–15.5 G, a_β^H = 2.3–4.2 G). The formation of oxygen-containing radicals in the system can be readily established on the basis of EPR and optical absorption spectra[62]:



Together with this nitrone, an equimolar mixture of more readily available substances, PBN and 2,4,6-tri-t-butylphenol, can be used with equal success as a bifunctional trapping agent[63]. The PBN and phenol concentrations can be varied, the EPR spectral line of the phenoxy-radical formed is narrower than in the case of the preceding trapping agent, and the satellites due to the 13C atom of the phenoxy-radical are not superimposed on the weaker lines of the nitroxy-radicals:

(c) Cyclic Nitrones

The addition of short-lived radicals to five-membered nitrones of the pyrrolidine series has been studied[64–68]. Among them, 5,5-dimethylpyrroline 1-oxide (DMPO) is of greatest interest[64–68]:



All radicals with the unpaired electron localised mainly at a carbon atom react with DMPO to form adducts whose EPR spectra consist of a triplet of doublets but the splittings by the β-proton are significantly greater than by nitrogen (in contrast to PBN). For adducts with hydroxyalkyl radicals (with the exception of $\dot{C}H_2OH$), the splitting by β-protons is greater by 2–3 G than in the case of alkyl radicals, while for adducts with acyl, benzoyl, and $\dot{C}F_3$ radicals, it is smaller by several gauss.

In the EPR spectra of DMPO adducts with oxy-radicals (RȮ, AcȮ, BzȮ, etc.) there is additional splitting due to one of the γ-protons and the splitting by β-protons is smaller almost by a factor of 3 than for adducts with alkyl radicals (Table 6). The EPR lines of the adducts with RȮ radicals can therefore be readily distinguished from the spectra of other adducts.

The spin adducts of DMPO are stable at 20°C, have narrow lines in the EPR spectra, and the trapping agent itself exhibits a high efficiency in the trapping of radicals (Table 7) and can be conveniently used to trap oxy-radicals.

N-(2,3,5,6-Tetramethylphenyl)nitrone and methyl-*N*-(2,3,5,6-tetramethylphenyl)nitrone[41] as well as 2,4,6-trimethoxy-PBN[156] have been proposed for the trapping of oxy-radicals:

The adducts of these nitrones with oxy-radicals are stable and have EPR parameters which differ markedly from those of other radicals.

(d) t-Butylmethylenenitrone

t-Butylmethylenenitrone (MN) CH_2=N(O)=Bu-t has been proposed[33,69] as a spin-trapping agent and its application in radiation chemistry has been described[40,70]: MN is synthesised by the reaction of TNB with diazomethane[71,72].

This nitrone is readily soluble in water, alcohols, and many organic solvents. It is not photolysed by light with a wavelength in excess of 300 nm, but light with shorter wavelengths leads to the formation of the radical t-Bu–CH_2–N(Ȯ)–Bu-t (a_N = 13.1 G, a^H_β = 7.0 G). The splitting by β-protons in the spectra of radical adducts of MN depends greatly on the nature of the trapped radical and there is also splitting by the nuclei of the added radical $\dot{R}$. The EPR spectra of the adduct of MN with the radical $\dot{R}$ have the same parameters as the spectra of the adducts of TNB with the radicals $R\dot{C}H_2$ (where R is an H atom or a radical group):

$$\dot{H} + CH_2{=}N(O){-}Bu\text{-}t \rightarrow CH_3{-}N(\dot{O}){-}Bu\text{-}t \leftarrow t\text{-}BuNO + \dot{C}H_3 ,$$
$$\dot{C}_6H_5 + CH_2{=}N(O){-}Bu\text{-}t \rightarrow C_6H_5CH_2{-}N(\dot{O}){-}Bu\text{-}t \leftarrow t\text{-}BuNO + C_6H_5\dot{C}H_2 .$$

4. OTHER SPIN-TRAPPING AGENTS

Apart from nitroso-compounds and nitrones, organic compounds of other classes have been used as spin-trapping agents (Table 1). The *N*-oxides of aromatic nitriles trap unstable radicals, forming fairly stable iminoxy-radicals[73], and no less information is obtained about the structure of the trapped radical than in the case where nitroso-compounds are used:

$$Ar{-}C{\equiv}N{\rightarrow}O + \dot{R} \rightarrow \begin{matrix} Ar \\ R \end{matrix}\!\!>\!C{=}N{-}\dot{O} .$$

For example, the spectra of adducts with the radicals $R{-}\dot{C}O$ show splitting by the group R.[73] A deficiency of these trapping agents is that the geometrical isomers of the same iminoxy-radical have different EPR spectra, which complicates analysis.

The formation of adducts of certain organophosphorus compounds with radicals t-BuȮ has been observed.[80] The formation of radicals of this type can be of interest for organophosphorus chemistry:

$$t\text{-}Bu\dot{O} + (C_6H_5O)_2PCl \rightarrow (C_6H_5O)_2\dot{P}Cl(O{-}Bu\text{-}t) .$$

Substituted acetylenes[81] (for example, $CF_3{-}C{\equiv}C{-}CF_3$, $C_6H_5{-}C{\equiv}C{-}C_6H_5$) can be used as spin-trapping agents. The trapping process involves the formation of 1,2-disubstituted or trisubstituted vinyl radicals, the lifetimes of certain radicals at 20°C exceeding 1 h.

The ability to trap unstable radicals with formation of stable radical adducts is also possessed by perfluoroketones $(CF_3)_2CF{-}\underset{\underset{O}{|}}{C}{-}CF(CF_3)_2$[82] and di-t-butyl selenoketone[151].

5. SPIN-TRAPPING AGENTS IN AQUEOUS SOLUTIONS

Poor solubility frequently limits the application of spin-trapping agents in aqueous solutions. For example, DMPO, PBN, and TNB dissolved in water to an extent less than 0.1 M.[66] An exception is MN, which readily dissolves in water (see above).

In order to investigate the radicals arising in aqueous solutions, maleate and fumarate anions[74] as well as the amides and imides of maleic acid have been used[75]. These trapping agents can be employed particularly to trap ȮH radicals and H atoms.

Many inorganic and aromatic radicals arising in the radiolysis of aqueous solutions and in the reactions of ȮH radicals and $SO_4^{\dot{-}}$ radical-ions (generated, for example, in the photolysis of H_2O_2 and persulphate) with inorganic anions and aromatic compounds[83-86] have been identified[76-79] with the aid of nitromethane in the *aci*-form $CH_2{=}NO_2^-$ in an alkaline medium. Two types of reaction take place with the nitromethane anion: the addition of the inorganic radical $\dot{X}$ to the C=N bond with formation of the adduct $X\dot{C}H_2\dot{N}O_2^-$ and electron transfer from $CH_2{=}NO_2^-$ to the inorganic anion with formation of $\dot{C}H_2NO_2$, which also adds to the nitromethane anion. The constants for hyperfine splitting by the nitrogen atom and methylene protons in the radical-anion $X\dot{C}H_2\dot{N}O_2^-$ depend greatly on the nature of the trapped radicals; splitting due to the trapped radicals sometimes appears in the spectrum (X = CN, HPO_2^-).

The radical adducts with the nitromethane anion have short lifetimes (less than a second) and their detection requires the continual generation of radicals in the resonator (under an electron beam or with the aid of a flow technique). Direct detection of the majority of inorganic radicals in aqueous solution under an electron beam (without spin-trapping agents) is impossible[86], because the radicals themselves have shorter lifetimes by several orders of magnitude.

6. STABILITY OF RADICAL ADDUCTS AND THEIR SECONDARY REACTIONS

The stability of nitroxy-radicals is determined by the possibility of tautomeric transformations[7,8], the type of substituent at the nitrogen atom, temperature, and the solvent. Certain nitroxy-radicals can react with one another to form diamagnetic compounds[87-89]. It has been shown in the study of the reactions of dialkyl- and diaryl-nitroxy-radicals that the rate constants for the destruction of these radicals depend on the nature of the solvent[87]. For example, in isopentane the rate constant for the destruction of nitroxy-radicals is 40 times greater than in water. The formation of hydrogen bonds and complexes of nitroxy-radicals with a polar solvent is well known[8]. The solvation of the radical centre as well as other groups (for example, OH groups) alters the reactivity of the radical. For example, the adducts of TNB and PBN with the radicals RȮ are appreciably less stable than the adducts with the radicals $R\dot{C}HOH$.[12,57,58] The increased stability of the adducts of $R\dot{C}HOH$ has been explained by the formation of a hydrogen bond with the solvent and also an intramolecular hydrogen bond[12,58,70].

The PBN adducts are much more stable than the TNB adducts with the analogous radicals, which is due to the stabilising influence of the phenyl groups. For example, the adducts of TNB with alkyl radicals can be observed in the liquid phase either at a low temperature or under the conditions of continuous generation of radicals[18,27,32,33,90], while the analogous adducts with PBN are observed under steady-state conditions at 20°C (including the adduct with H atoms)[57,58,91,92].

In order to avoid an error in the interpretation of the mechanisms of the formation of radicals, account must be taken of the possibility of rapid secondary reactions of spin adducts with one another and with the spin-trapping agent. For example, the adduct of TNB with the radical $\dot{C}Cl_3$ is transformed as a result of secondary reactions into an adduct of TNB with the radical $Cl\dot{C}O$.[38] The absence of an adduct of TNB with the radical $\dot{C}H_2OH$ in γ-irradiated methanol has been explained[35] by the fact that $\dot{C}H_2OH$ is a secondary radical and appears in the reaction of $CH_3\dot{O}$ with methanol. The use of another trapping agent (PBN) showed that in radiolysis both radicals are primary species[57,58,92].

Nitroxy-radicals with a mobile β-hydrogen atom disproportionate with formation of hydroxylamine and a nitrone[87,88,93]:

$$2\left(\text{—CH}_2\text{—N—R}\right) \rightarrow \text{—CH=N—R} + \text{—CH}_2\text{—N—R}$$

(O· on the left; O on the nitrone; OH on the hydroxylamine)

The reaction between the adducts of TNB with H atoms and the radicals $\dot{C}H_2OH$ proceeds via the same mechanisms[12]:

$$\text{t-BuN(}\dot{\text{O}}\text{)H} + \text{HOCH}_2\text{—N(}\dot{\text{O}}\text{)—Bu-t} \rightarrow$$
$$\rightarrow \text{t-BuN(OH)H} + \text{HOCH=N(O)—Bu-t}\ .$$

Both radical adducts are detected with the aid of EPR spectra only under an electron beam and rapidly disappear after the beam is switched off, although the TNB adduct with the $\dot{C}H_2OH$ radical is itself stable at 20°C.[12,94]

The adduct of TNB with the radicals t-Bu$\dot{O}$ decomposes (the decomposition rate constant in benzene[95] at 40°C is 1.1×10^{-3} s^{-1}) with formation of the radicals t-$\dot{B}$u, which add to the TNB molecule, forming the stable radical t-$Bu_2N\dot{O}$:[95]

$$\text{t-BuON(}\dot{\text{O}}\text{)—Bu-t} \rightarrow \text{t-BuNO}_2 + \text{t-}\dot{\text{B}}\text{u} \xrightarrow{\text{t-BuNO}} \text{t-Bu}_2\text{N}\dot{\text{O}}\ .$$

The adducts of t-Bu$\dot{O}$ radicals with nitrosodurene[40] and probably with other trapping agents decompose analogously.

The nitroxy-radicals arising in the trapping of unstable radicals by nitrones and nitroso-compounds can trap yet another radical with formation of a diamagnetic compound:

$$\dot{\text{R}} + \text{R—NO} \rightarrow \text{R—N(O}\cdot\text{)—R} \xrightarrow{\dot{\text{R}}} \text{R—N(OR)—R}\ .$$

The rate constants for the reactions of nitroxy-radicals with solvated electrons, H atoms, and the radicals $\dot{O}H$ and $\dot{C}H_3$ reach 10^9–10^{10} litre $mole^{-1}$ s^{-1} [8,96,158] and those for the reactions with R$\dot{C}$HOH radicals reach 10^8 litre $mole^{-1}$ s^{-1}. This property of nitroxy-radicals has served as a basis for their employment as radical counting agents[8,97], which must be taken into account in the determination of the amount of unstable radicals captured by the spin-trapping agent, because one molecule of the spin-trapping agent can capture two radicals. In the case of nitrones the first radical adds to the carbon atom of the nitrone group and the second adds to the oxygen atom[98].

In addition, it has been noted[1,99,100] that, as a result of the trapping of unstable radicals by nitrones, the hydrogen atom in the radical adduct becomes readily mobile and can be abstracted by certain radicals and the nitrone formed in this case can capture radicals:

$$\text{Ph—CH(R)—N(O}\cdot\text{)—Bu-t} \xrightarrow{\dot{\text{R}}} \text{Ph—C(R)=N(O)—Bu-t} + \text{RH}\ .$$

For example, in the study of the radical adducts of PBN with chlorine and fluorine atoms, two types of nitroxy-radicals were detected in the EPR spectra[1,101]: Ph–CH(Cl)–N(Ö)–Bu-t and Ph–CCl_2–N(Ö)–Bu-t.

III. THE APPLICATION OF SPIN-TRAPPING AGENTS IN THE STUDY OF RADICAL PROCESSES

1. THE MECHANISMS OF ORGANIC REACTIONS

(a) Oxidation of Organic Compounds

In the majority of studies carried out with the aid of spin-trapping agents, the formation of radicals in the interaction of various oxidants with organic compounds of many classes has been investigated. Nitrosobenzene and TNB have been used to study the mechanism of the oxidation of aromatic compounds by nickel peroxide dispersed in benzene[19,102]. The aromatic hydrocarbons $ArCHR_2$ or Ar_2CHR with mobile methylene hydrogen atoms are oxidised with formation of radicals of the benzyl type if the substituents R are phenyl, cyano-, acyl, acyloxy-, alkoxy-, or allyl groups. The radicals formed in the oxidation of aromatic amines and phenols[19], diphenylacetonitrile, carbazole, acetonylacetone, and acetamide[102] by nickel peroxide have also been investigated.

Lead tetraacetate and Ce^{4+} ions oxidise 1,3-dicarbonyl compounds, for example acetylacetone and it is suggested that the first stage of the process is electron transfer from the ketone to the oxidant cation. Adducts with radicals of the type R–CO–$\dot{C}$H–CO–R have been observed in the presence of TNB.[18,32] On excitation with ultraviolet light $Pb(AcO)_4$ and thallium(III) ions give rise to the oxidative decarboxylation of carboxylic acids. When TNB and 2-methyl-2-nitroso-3-butanone in CH_2Cl_2 were used at a low temperature (–40°C), adducts with primary alkyl radicals were detected[18,31] and ultraviolet irradiation at 20°C led to the formation of adducts with the secondary radicals R$\dot{C}$HCOOH.

Most attention has been devoted to the mechanisms of the oxidation of alcohols. It has been established with the aid of spin-trapping agents that the mechanisms of the action of various oxidants are not the same. Uranyl nitrate, the radicals t-Bu$\dot{O}$ and $\dot{O}H$, and benzophenone in the triplet state abstract an α-hydrogen atom from the alcohol molecule and the EPR spectra show lines due to the adducts of hydroxyalkyl radicals with TNB, PBN, and DMPO[1,2,33,55,59,103].

In the photochemical oxidation of isopropyl and diphenylmethyl alcohols by benzophenone in the triplet state, the adduct of an H atom was detected together with the TNB adducts of the radical $(CH_3)_2\dot{C}OH$ under the conditions of continuous generation of radicals[30,33]. The appearance of the adduct with atomic hydrogen was explained[1,30,33] by electron transfer from the radical $(CH_3)_2\dot{C}OH$ to the TNB molecule with subsequent protonation of the radical-anion t-$BuNO^{\cdot-}$:

$$(CH_3)_2\dot{C}OH + \text{t-BuNO} \rightarrow (CH_3)_2CO + \text{t-BuNO}^{\cdot-} + H^+$$
$$\text{t-BuNO}^{\cdot-} + (CH_3)_2CHOH \rightarrow \text{t-BuN(}\dot{\text{O}}\text{)H} + (CH_3)_2CHO^-\ .$$

However, one should note that the adducts of TNB with H atoms can be formed not only via electron transfer but also as a result of secondary reactions: (1) the disproportionation of the adducts of TNB with the radicals $(CH_3)_2\dot{C}OH$ involving the formation of the hydroxylamine derivative R–N(OH)–Bu-t; (2) the reaction of t-butylhydroxylamine with a TNB molecule to form an adduct with an H atom. These reversible reactions have been observed[28,29]:

$$\text{t-Bu—N(H)—OH} + \text{t-BuNO} \rightleftarrows 2\,\text{t-Bu—N(O}\cdot\text{)—H}\ .$$

The abstraction of an α-hydrogen atom from the alcohol molecule had been suggested earlier also when variable-valence metal ions[104] and persulphate ions[105] are used as oxidants, although such powerful oxidants can convert alcohols into alkoxy-radicals. R$\dot{O}$ radicals could not be detected by EPR in the thermal and photochemical oxidation of alcohols even when a flow technique was used[106–108]. Owing to their high reactivity, R$\dot{O}$ radicals reacted with the alcohol, forming the radicals R$\dot{C}$HOH, which were detected by EPR. Only the use of spin-trapping agents made it possible to show that the oxidation of alcohols (methanol, ethanol, propanols, butanols, 2-phenylethanol, and cyclohexanone) by oxidants such as lead tetraacetate,

silver nitrate, and potassium persulphate leads to the formation of alkoxy-radicals [18,55,59].

The reactions of ȮH and t-BuȮ radicals have been studied in a number of investigations. The t-BuȮ radicals were generated by the photolysis of alkyl nitrites and also in the thermal decomposition of t-butyl peroxalates and t-butyl hydroperoxide. The oxidation of aldehydes has been investigated with the aid of TNB, nitrosobenzene, and the *N*-oxides of aromatic nitriles [34,39,73]. In the absence of aldehydes the adducts of t-BuȮ radicals are formed and in the presence of aldehydes the spin-trapping agent captures the acyl radicals R–Ċ=O. In addition TNB has been used to study the reactions of t-BuȮ radicals with sulphides, $CHCl_3$, acetate and malonate esters, toluene, ethylbenzene, and isopropylbenzene. The abstraction of the most mobile hydrogen atom was observed in all cases [16,33,34]. The reactions of ȮH radicals with ketones [31] and with sulphoxides and sulphones [32] have been studied with the aid of TNB. The ȮH radicals were generated by the photolysis of H_2O_2 solutions. In the reaction with ketones, mainly the adducts of TNB with the radicals formed by the abstraction of an α-hydrogen atom relative to the carbonyl group were observed. The reactions of ȮH radicals with sulphoxides and sulphones result in the formation of various alkyl and aryl radicals.

Photochemical oxidation by benzophenone in the triplet state was studied with the aid of TNB. Not only alcohols but also amines, phenols, sulphides, thiols, ethers, and hydrocarbons have been investigated under the conditions of the continuous generation of radicals in the resonator [30]. In some cases the spin-trapping agents themselves were involved in photochemical oxidation. The oxidation of alkenes in photolysis by red light in solution in the presence of TNB and oxygen proceeds via the following mechanism according to the authors [10]:

$$t\text{-BuNO} \xrightarrow{h\nu} t\text{-BuNO}^* \xrightarrow{O_2} t\text{-Bu}(\dot{O})\text{N}(\dot{O})\text{O}\cdot$$

$$t\text{-Bu}(\dot{O})\text{N}(\dot{O})\text{O}\cdot + PhCH{=}CH_2 \rightarrow t\text{-Bu}(\dot{O})\text{N}(\dot{O})\text{O}\text{–}CH(Ph)\text{–}\dot{C}H_2$$

$$\rightarrow t\text{-BuNO} + PhC(=O)H + CH_2O \ .$$

Benzaldehyde and formaldehyde were indeed detected in the reaction products. However, one cannot rule out the possibility of the formation of excited singlet oxygen which behaves as an oxidising agent:

$$t\text{-BuNO}^* + O_2 \rightarrow t\text{-BuNO} + O_2^*(^1S) \ .$$

(b) Photolysis of Organic Compounds

It has been shown that the photolysis of aryl iodides in the presence of TNB leads to the formation of aryl radicals which react with TNB to form adducts stable at room temperature. This method is convenient for the synthesis of aromatic nitroxy-radicals [31].

In the photolysis of halogenomethanes of the type CX_4, CHX_3, and CH_2X_2 (where X is a halogen atom) the radicals are formed as a result of the homolytic dissociation of the C–X bond [22,23,25,38,101,109]. The adducts with the $\dot{C}Cl_3$ and $\dot{C}HCl_2$ radicals can be conveniently detected when perfluoro-t-nitroso-butane is used [22,109]. In the presence of TNB, adducts with the X–Ċ=O radicals were detected together with the adducts of $\dot{C}X_3$ radicals [22–25,38,109]. The formation of the former is indicated by secondary reactions of the TNB radical adducts [23,25,38]. The study of the mechanism of the formation of the adducts of TNB with the radicals X–Ċ=O showed that, in the presence of an alcohol or dimethylamine, the nitroxy-radicals X–C(=O)–N(·)–Bu-t (X = Cl or Br) are transformed into the radicals RO–C(=O)–N(·)–Bu-t, whose structure has been established with the aid of nitrosoperdeutero-t-butane [23–25] and also by means of independent synthesis.

Photolysis of organometallic compounds of lead, tin, and mercury in the presence of PBN leads to the formation of adducts with radicals of the alkyl, phenyl, or benzyl types, depending on the nature of the substituents. It was found that the capacity for dissociation of the bond with the metal diminishes in the sequence phenyl > alkyl > acetate (or halogen) [1,47]. Adducts with the short-lived radicals $CH_3C(=O)\dot{O}$ and $PhC(=O)\dot{O}$ were detected in the photolysis of lead acetate and mercury benzoate, but the same adducts can arise also as a result of the addition of acetate and benzoate ions to PBN (see Section II, subsection 3).

Adducts with phenyl radicals were detected in the photolysis of organometallic compounds of the type Ph_3M (M = N, As, Sb, or Bi) in the presence of PBN, but the adducts of radicals containing a metal atom (Ph_2M) [100], which should have appeared if the decomposition proceeds via the mechanism

$$Ph_3M \xrightarrow{h\nu} Ph\cdot + Ph_2M \ ,$$

were absent.

Adducts with radicals of the acyl type RO–Ċ=O were detected in the photolysis of R–Hg–C(O)OR in the presence of BNB. [111] Adducts with ȮH radicals [67] were found in the photolysis of dilute H_2O_2 solutions in the presence of PBN and DMPO [67], while in concentrated H_2O_2 solutions adducts of $H\dot{O}_2$ radicals were detected. One cannot rule out the possibility that the latter appear as a result of the chemical reaction of H_2O_2 with the trapping agent.

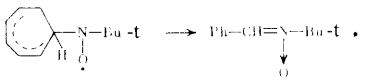
The radical products of the photochemical and thermal decomposition of *p*-tolyl arylazosulphones were investigated with the aid of TNB and PBN. [50] It has been suggested that these compounds decompose via the mechanism

$$Ar\text{–}N{=}N\text{–}S(=O)(=O)\text{–}C_6H_4\text{–}CH_3 \rightarrow Ar\cdot + N_2 + \dot{S}O_2\text{–}C_6H_4\text{–}CH_3 \ .$$

The adducts with aryl radicals was identified [50] with the aid of PBN but the adducts with the radicals $H_3C\text{–}C_6H_4\text{–}\dot{S}O_2$ were not detected. In the presence of TNB a triplet was observed in the EPR spectra, which the authors attributed to the adduct of TNB with the radicals $H_3C\text{–}C_6H_4\text{–}\dot{S}O_2$.

The study of the thermal and photochemical rearrangement of acetophenone diphenylmercaptal with the aid of TNB showed that the process proceeds via a radical stage:

$$PhC(PhS)_2CH_3 \rightarrow Ph\dot{C}(PhS)CH_3 + PhS\cdot \ .$$



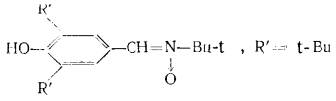
The adducts of TNB with both radicals have been detected. In the presence of O_2, adducts with the $PhC(\dot{O})\text{–}(PhS)CH_3$ and $PhC(PhS)_2\dot{C}H_2$ radicals were also observed [112].

The photolysis of TNB in the presence of diethyl α-halogenophosphonates leads to the formation of phosphorus-containing nitroxy-radicals [113] of the type t-Bu–N(·)–CH(R)–P(=O)$(OC_2H_5)_2$. Phosphorus-containing nitroxy-radicals can also be obtained from the nitroso-compound

$(CH_3)_2C(NO)-P(OEt)_2$, whose synthesis has been described [114].

(c) Other Types of Organic Reactions

It has been shown for the first time with the aid of TNB that, when tropylium tetrafluoroborate is reduced with zinc, the product is a tropyl radical, the EPR spectrum of the adduct of which with TNB is a triplet of doublets (a_N = 14.5 G, a_β^H = 2.2 G).[28] This nitroxy-radical is subsequently oxidised to PBN:



The dark reaction of tetranitromethane with nucleophiles (N_3^-, NO_2^-, OH^-, F^-, Cl^-, I^-, t-BuO^-, etc.) has been investigated with the aid of PBN.[48,115,116] According to the authors, there is electron transfer from the nucleophile to tetranitromethane. The adduct with the NO_2 radical was not detected, the benzoyl-t-butylnitroxy-radical, which is a PBN oxidation product, being formed instead.

The adducts of PBN with radicals derived from nucleophiles [t-BuO^-, $C(NO_2)_3^-$] were detected in the interaction of $FClO_3$ with nucleophiles [116]. In the presence of nucleophiles, the fluorine atom is captured. The formation of nitroxy-radicals was observed also in TNB solutions containing aromatic compounds and nucleophiles (OH^-, CH_3O^-)[48,117,118]. However, the authors' conclusions[48,115,118] are not unambiguous, since nitroso-compounds and nitrones can react with nucleophiles in the absence of oxidants, forming nitroxy-radicals[20,119,120] (Section II, subsection 3). The formation of the t-BuNO$^\cdot$ radical-ion has been noted, for example, in TNB solutions in the presence of t-BuOK [120].

Adducts of PBN with fluorine atoms have been detected in the products of the decomposition of NF_3O in benzene in the presence of PBN.[1] Since NF_3O is used in preparative chemistry as a fluorinating agent, the fluorination reaction may occur with participation of fluorine atoms. Adducts with chlorine atoms have been detected in the thermal decomposition of t-BuOCl in benzene in the presence of PBN [101].

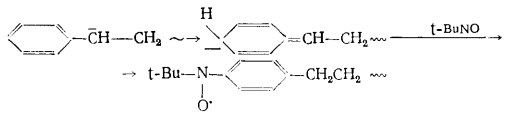
The reaction of *N*-chlorosuccinimide with toluene-*p*-sulphonic acid has been investigated[69,121,122]. In the presence of the bifunctional trapping agent

the phenoxy-radical was detected and in the presence of PBN the product was found to be the radical PhC(O)N(O$^\cdot$)-Bu-t, arising, according to the authors [121], as a result of the oxidation of PBN by chlorine atoms or the succinimyl radical. The adducts of PBN with the succinimyl radical and chlorine atoms were not, however, detected. When t-butylmethylenenitrone and TNB were used as spin-trapping agents, the EPR spectra of the adduct of the succinimyl radical were detected[69,121,122]. The adducts of the succinimyl radical with TNB and MN also appeared in the photolysis of *N*-chloro- and *N*-bromo-succinimides in benzene, but in polar solvents the adducts were not detected [69].

The possibility of the radical rearrangement of $XCH_2\dot{C}HCCl_3$ to $XCH_2CH\dot{C}Cl_2$ (X = t-BuO or CCl_3) has been investigated [123]. In the presence of 2-methyl-2-nitroso-3-butanone the adduct with the radical $XCH_2\dot{C}HCCl_3$ was detected, while in the presence of TNB the product was the adduct with the radical $XCH_2CH\dot{C}Cl_2$. The adducts of both radicals with the same spin-trapping agent were not found, so that secondary reactions of the radical adducts probably take place in the system.

The radical arylation of disulphides has been studied in the presence of TNB. Phenyl radicals attack the disulphide at a sulphur atom and the EPR spectra contain lines due to the adducts of the radicals Ph$\dot{S}$ (triplet with a_N = 16.3 G) [159]:

$$\dot{Ph} + (PhS)_2 \rightarrow PhSPh + Ph\dot{S} \ .$$



Spin-trapping agents have been used in the study of polymerisation processes[20,124-126]. By varying the concentration of the spin-trapping agent, it is possible to detect adducts with radicals having different degrees of polymerisation. At a high concentration of the spin-trapping agent (0.1 M and above) mainly radicals derived from the initiator are captured, while at low concentrations (0.001 M) polymeric radicals are captured. Radicals arising in the photolysis of TNB have been used to initiate the polymerisation of unsaturated phosphonic acid esters [124].

MN and TNB have been used [125] to investigate the polymerisation of styrene initiated by t-BuO$^\cdot$ radicals:

$$t\text{-}BuO^\cdot + PhCH=CH_2 \rightarrow Ph\dot{C}HCH_2O\text{—}Bu\text{-}t \ .$$

At a TNB concentration of 0.05 M the adduct with the radical $Ph\dot{C}HCH_2O$-Bu-t (a_N = 14.3 G, a_β^H = 2.3 G) was detected [125]. At low TNB concentrations, (0.001 M) adducts with the longer radicals Ph-$\dot{C}HCH_2(PhCHCH_2)_nO$-Bu-t ($a_N$ = 14.5 G, a_β^H = 3.3 G) were detected.

The spin-trapping agents TNB and PBN terminate the anionic polymerisation of styrene, methyl methacrylate, vinylpyridines, etc. with formation of stable polymeric nitroxy-radicals by the addition of an anion to a nitroso-compound or nitrone [20]:

This process is the simplest pathway to the formation of "spin-labelled" polymers [20]. Spin-trapping agents make it possible to synthesise nitroxy-radicals, the preparation of which in the usual chemical way involves considerable experimental difficulties. The application of nitrones in the synthesis of nitroxy-radicals was first described by Iwamura and Inamoto [5,6].

The electrochemical oxidation of the nitromethanes $C(NO_2)_3^-$, $CH_3C(NO_2)_2^-$, and $(CH_3)_2C(NO_2)^-$ was investigated with the aid of PBN [115,116]. In the reaction with $C(NO_2)_3^-$ the product was found to be an adduct whose spectrum showed splittings with a_N = 14.1 G and a_β^H = 4.2 G. The authors attributed this spectrum to the adduct of PBN with the $\dot{C}(NO_2)_3$ radical. Nitroxy-radicals of the same type are formed also in the photolysis of the anions of nitroso-compounds [115,116]. In the course of the electrochemical reduction of the benzenediazonium cation in the presence of PBN the product is an adduct with the phenyl radical [127]. One must note that nitrones and nitroso-compounds are effective electron acceptors [20,58,92,128,158] and can oxidise anions with formation of the corresponding radicals.

2. THE DETECTION OF RADICALS FORMED IN THE GAS PHASE

Spin-trapping agents can be used for the identification of radicals formed in the gas phase[51,61,129-131]. Both solid trapping agents and their vapours have been used for this purpose. The solid spin-trapping agent (PBN, NTB, or nitrosobenzene) was placed in the stream of gases emerging from the electric discharge and, after switching off the discharge, was transferred (in the absence of oxygen) to a suitable solvent and the EPR spectra of the nitroxy-radicals were observed. The nitroxy-radicals are highly volatile and can be frozen out in a trap cooled with liquid nitrogen[61,129,130].

When a gas discharge was allowed to act on D_2O vapour, H_2, D_2, CH_4, and NH_3, the adducts of PBN with H and D atoms and with the $\dot{O}H$, $\dot{O}D$, and $\dot{C}H_3$ radicals were detected[61]. In ammonia only the adducts with H atoms were found and the adducts with $\dot{N}H_2$ radicals were not detected. In a discharge in toluene adducts with radicals of the phenyl and benzyl type were found[60]. A study was also made of the pyrolysis of organosilicon compounds in the presence of PBN[130]. As in the thermal decomposition of t-BuOCl in benzene[101], in the gas-phase photolysis of this substance[129] the adducts of PBN with chlorine atoms and in addition the $PhCCl_2$–N(O)–Bu-t radical were detected. The gas-phase photolysis of alkyl iodides, ketones, and aldehydes has been studied[131]. Adducts with alkyl radicals were detected in the presence of solid PBN and in the presence of TNB in the vapour phase adducts with acyl radicals were found in the reactions with aldehydes and ketones. The radicals arising in cigarette smoke have been studied with the aid PBN[132].

The spin-trapping method has many advantages compared with the direct gas-phase EPR method[133]. In particular, not only adducts with monatomic and diatomic radicals (the usual species for which EPR is used in the gas phase) but also those with radicals such as $\dot{C}H_3$, $\dot{C}_2H_5$, t-Bu$\dot{O}$, $\dot{P}h$, $Ph\dot{C}H_2$, and R–$\dot{C}$=O have been detected.

3. THE APPLICATIONS OF SPIN TRAPPING AGENTS IN CHEMICAL KINETICS

The high stability of radical adducts makes it possible to use spin-trapping agents in kinetic studies. The reaction of a spin-trapping agent with a radical cannot as yet be observed directly in view of its high rate and the rate constants for these reactions are therefore determined by the method of steady-state concentrations.

The rate constants for the trapping of PhCO$\dot{O}$ radicals by certain PBN derivatives[134] were determined with the aid of the galvinoxy-radical as a competing acceptor. The rate constant for PBN is 4.0×10^5 litre mole^{-1} s^{-1}. The rate constant for the decomposition of di-t-butyl peroxalate into t-Bu$\dot{O}$ radicals ($k = 6.8 \times 10^{-5}$ s^{-1} at 35°C) and the activation energy, which is 30 kcal mole^{-1}, were obtained by the same method. The above values agree with the results obtained by other procedures.

The absolute rate constants for the trapping of t-Bu$\dot{O}$ radicals by various spin-trapping agents have been obtained taking into account the known rate constants for the abstraction of hydrogen by t-Bu$\dot{O}$ radicals from cyclohexane and toluene[68]. Under these conditions, the EPR spectra of the adducts of t-Bu$\dot{O}$ radicals and alkyl radicals arising in the competing reaction of t-Bu$\dot{O}$ with the hydrocarbon were recorded at the same time. Since the EPR spectra of various PBN radical adducts overlap markedly, DMPO was used as the spin-trapping agent (Section II, subsection 3), since the EPR parameters of the adducts of this trapping agent with R$\dot{O}$ radicals differ markedly from those of the adducts with alkyl radicals. The rate constant for the trapping of t-Bu$\dot{O}$ radicals by DMPO molecules proved to be 5×10^8 litre mole^{-1} s^{-1}.[68] The rate constants for the reactions of t-Bu$\dot{O}$ radicals with various spin-trapping agents (Table 7) were determined with the aid of the competition of two trapping agents (one of which was DMPO) for the t-Bu$\dot{O}$ radical.

The rate constants for the trapping of t-BuO–$\dot{C}$=O radicals by TNB and for the decomposition of the adducts of TNB with the t-Bu$\dot{O}$ radical ($k_1 = 1.1 \times 10^{-3}$ s^{-1}) have been estimated[59]. The ratio of the rate constants for the reactions of the t-Bu$\dot{O}$ radicals with ethylbenzene and toluene[33], determined with the aid of TNB, is 8.6 ± 1.0.

The rate constants for the trapping of $\dot{P}h$ and PhCO$\dot{O}$ radicals by PBN molecules, which are 1.2×10^7 and 4.0×10^7 litre mole^{-1} s^{-1} respectively at 20°C, have been measured[135,136]. Previously, unduly low values of the order of 10^5–10^6 litre mole^{-1} s^{-1} had been obtained for these constants[134], since an approximate rate constant for the decarboxylation of PhCO$\dot{O}$ radicals, equal to 10^3–10^4 s^{-1}, had been used in the calculations. Using PBN, 5.0×10^5 s^{-1} was obtained for this constant[135].

The rate constants for the attachment of phenyl radicals to benzene with formation of phenylcyclohexadienyl radicals[135] as well as the rate constants for the abstraction of H atoms from alcohol molecules by phenyl radicals[136] have been determined with the aid of PBN (Table 8). The rate constants for the fragmentation of acyl radicals in benzene have been found by the spin trapping method[39].

Table 8. Reaction rate constants determined with the aid of spin-trapping agents.

Reaction	Rate constant	Reaction conditions	Refs.
PhCO$\dot{O}$ → $\dot{P}h$ + CO_2	5×10^5 s^{-1}	20°C, benzene	135
$\dot{P}h$ + C_6H_6	7.8×10^4 litre mole^{-1} s^{-1}	20°C, benzene	135
$\dot{P}h$ + CH_3OH	1.4×10^5 litre mole^{-1} s^{-1}	20°C, alcohol	136
$\dot{P}h$ + C_6H_5OH	2.3×10^5 litre mole^{-1} s^{-1}	20°C, alcohol	136
$\dot{P}h$ + 2-propanol	4.1×10^5 litre mole^{-1} s^{-1}	20°C, alcohol	136
R–$\dot{C}$=O → $\dot{R}$ + CO			
R = CH_3, n-C_3H_7	~1 s^{-1}	40°C, benzene	39
R = iso-C_3H_7	3.9×10^3 s^{-1}	40°C, benzene	39
R = t-Bu	5.2×10^4 s^{-1}	40°C, benzene	39
R = $PhCH_2$	7×10^6 s^{-1}	40°C, benzene	39

The study of the radiolysis of alcohols yielded the rate constants for the trapping of $CH_3\dot{O}$ and $C_2H_5\dot{O}$ radicals by PBN molecules at 20°C: $k(CH_3\dot{O} + PBN) = 1.2 \times 10^8$ litre mole^{-1} s^{-1} and $k(C_2H_5\dot{O} + PBN) = 2.0 \times 10^8$ litre mole^{-1} s^{-1}.[58,139] The absolute rate constants for the reactions of R$\dot{O}$ radicals with alcohols, determined by pulse radiolysis, were used in the calculations[137,138]: $k(CH_3\dot{O} + CH_3OH) = 2.62 \times 10^5$ litre mole^{-1} s^{-1} and $k(C_2H_5\dot{O} + C_2H_5OH) = 1 \times 10^6$ litre mole^{-1} s^{-1}. The rate constant for the trapping of $CH_3\dot{O}$ by TNB molecules proved to be 1.3×10^8 litre mole^{-1} s^{-1} at −45°C in methanol [method based on the use of *N*,*N*,*N'*,*N'*-tetramethyl-*p*-phenylenediamine (TMPD) as a competing acceptor[157]].

Thus the spin-trapping method makes it possible to obtain extensive information about the reactivities of radicals.

4. THE USE OF THE SPIN-TRAPPING METHOD IN RADIATION CHEMISTRY

The earlier procedures for the investigation of radicals in radiation-chemical processes suffer from serious disadvantages. The difficulty of analysing the EPR spectra of radicals in the solid phase has already been noted. The EPR spectra in the liquid phase under the influence of an electron beam also have a low signal-to-noise ratio and the shortest-lived radicals are not detected[56]. Radicals of the type RȮ and ȮH are not detected in the liquid phase owing to their short relaxation times.

The possibility of using the spin-trapping method for the investigation of radicals formed in solid-phase radiolysis was first demonstrated by Lagercrantz and Forschult[37]. The solid substances subjected to preliminary γ-irradiation were dissolved in a weakly alkaline TNB solution. It was observed that the $\dot{C}H_2COO^-$ radical-ions are stabilised in sodium acetate and glycine, while radicals of the type R–ĊHCOOH are stabilised in alanines, potassium malonate, and succinic and glutamic acids. When the solid was dissolved, adducts of these radicals with TNB were formed. After dissolution of γ-irradiated Na_2HPO_3 the adduct of TNB with the $\dot{P}O_3^{2-}$ radical-ion was detected and the adduct with the ṖOH(O) radical was found in γ-irradiated NaH_2PO_2.[140,141]

Spin-trapping agents have been used most frequently in the liquid phase. Adducts with $\dot{C}Cl_3$ radicals and chlorine atoms have been found in CCl_4 irradiated in the presence of PBN,[1] which agrees with the presence of C_2Cl_6 and Cl_2 in the radiolysis products.

In order to identify the radicals arising in aqueous solutions or organic compounds on γ-irradiation, TNB was used[66,94,142]. Adducts of the $\dot{C}H_2OH$ radical (a_N = 15.5 G, a_β^H = 6.1 G), which are stable at 20°C, were detected in 0.5 M aqueous solution of methanol in the presence of TNB.[94] Well resolved EPR spectra of the adducts of TNB with radicals of the type –ĊH–N= were obtained in dipeptides and nucleic bases γ-irradiated in aqueous solutions at 20°C.[94,142]

Thiols RSH (R = Me, Et, n-Br, iso-Pr, or n-Bu), γ-irradiated at low temperatures (–73°, –102°C) in the liquid phase have been investigated[36] with the aid of TNB. The adducts of TNB with thiyl radicals were identified. They have well resolved EPR spectra, which distinguishes them favourably from the EPR spectra of these radicals in the solid phase, where the hyperfine structures are not resolved and the identification is not unambiguous[155]. For example, the spectra of the adducts with $\dot{C}H_3S$ radicals consist of a triplet of quartets (a_N = 18.9 G, a_β^H = 1.2 G).

Water subjected to an electron beam has been investigated[66] at 20°C with the aid of DMPO, TNB, and PBN. The adducts of the above spin-trapping agents with ȮH radicals and H atoms were detected (the spectral parameters are presented in Tables 2, 5 and 6). In the case of DMPO and TNB hydrogen atoms and solvated electrons lead to the same adduct, since the radical-anion formed as a result of the trapping of electrons is protonated in water:

$$DMPO + e^- \rightarrow DMPO^- \xrightarrow{H_2O} DMP\dot{O}{-}H + OH^- .$$

The radiolysis of benzyl alcohol by means of an electron beam has been investigated in the presence of TNB.[143] The formation of benzyl radicals $Ph\dot{C}H_2$ and the radicals PhĊHOH was demonstrated. The addition of electron-accepting agents showed that the benzyl radicals are formed in the reaction of electrons with the alcohol and the t-BuN(Ȯ)–H adduct detected arises, according to the authors, as a result of electron transfer from the PhĊHOH radicals:

$$\text{t-BuNO} + Ph\dot{C}HOH \rightarrow \quad \text{t-BuN(Ȯ)H} + PhCHO .$$

The adducts with $PhCH_2\dot{O}$ radicals were not detected. The TNB concentration employed (0.01 M) is apparently too low for the effective competition of TNB for the $PhCH_2\dot{O}$ radical[143].

Ethylene glycol γ-irradiated in the liquid and solid phases has been studied with the aid of TNB[144–146]. A triplet of doublets (a_N = 15.4 G, a_β^H = 1.5 G) of the adduct with the $HOCH_2\dot{C}HOH$ radical as well as a triplet of triplets (a_N = 14.4 G, a_β^H = 5.1 G),[146] referring to the adduct with the $\dot{C}H_2OH$ radical, and the 3 × 3 × 2 multiplet (a_N = 15.5 G, a_β^H = 9.1 G, and a_γ^H = 0.6 G), identified as the spectrum of the adduct with the $\dot{C}H_2CHO$ radical, were observed in the EPR spectra. The identification of the last adduct is confirmed[146] by the splitting by γ-protons and the magnitude of the splitting by β-protons, which is characteristic of adducts with radicals of the type $\dot{C}H_2R$ (Table 2). The EPR spectrum of ethylene glycol irradiated at –196°C without spin-trapping agents shows only a poorly resolved triplet and singlet due to stabilised electrons.

The radiolysis of alkanes[91] and aromatic hydrocarbons[13,147] has been studied with the aid of spin-trapping agents. Using nitrosodurene and PBN, phenyl radicals were identified in benzene γ-irradiated at 20°C and benzyl radicals and radicals of the phenyl type were identified in toluene[147]. $t\text{-}Bu_2N\dot{O}$ radicals are formed in a yield of 1.5 radicals/100 eV in benzene, toluene, and *o*-xylene irradiated at 20°C in the presence of 0.1 M TNB.[13,147] It has been shown that the radicals $t\text{-}Bu_2N\dot{O}$ are formed as a result of the transfer of excitation from the aromatic hydrocarbon to the TNB molecule and yields of the excited molecules of these hydrocarbons were measured and found to be 2.5 ± 0.5 molecules/100 eV. Thus certain spin-trapping agents can trap not only radicals but also excited species and can be used for the quantitative determination of the yield of excited molecules.

The γ-radiolysis of nitriles has been studied in the liquid phase in the presence of PBN.[160] $\dot{C}H_2CN$ radicals in acetonitrile, H atoms and $CH_3\dot{C}HCN$ radicals in propionitrile, $\dot{C}H(CN)_2$ radicals in malononitrile, and H atoms and ĊN and $\dot{C}H_2CH_2CN$ radicals in succinonitrile have been identified. Splitting by γ-protons has been observed in the EPR spectra of the adducts of PBN with the radicals $\dot{C}H_2CN$ and $\dot{C}H(CN)_2$ (Table 5).

The radiolysis of alcohols in the liquid and solid phases has been studied in greatest detail by the spin-trapping method[11,12,27,35,40,45,57,58,90–92,139,148–150]. TNB, PBN, and BNB served as the spin-trapping agents. The formation of alkoxy-radicals and H atoms in methanol, ethanol, propanols, and t-butyl alcohol, irradiated by γ-rays and electrons in the liquid phase, was demonstrated for the first time in radiation chemistry. For comparison, we may state that neither H atoms nor RȮ radicals were detected in the study of frozen alcohols[155] nor were they observed directly under an electron beam in the liquid phase[108]. After γ-irradiation in the liquid phase in the presence of TNB, hydroxy-alkyl radicals were detected in methanol, ethanol, 1-propanol, and 2-propanol, while adducts of NTB and H atoms, arising as a result of the trapping of both H atoms and electrons with subsequent

protonation of the t-BuNO$^{\cdot-}$ radical anions, were found after exposure to an electron beam:

$$\text{t-BuNO}^{\cdot-} + \text{ROH} \rightarrow \quad \text{t-Bu(O)} - \text{H} + \text{RO}^- .$$

An analogous electron capture process takes place in the case of BNB. Irradiation of BNB solutions in methanol and ethanol at −196°C leads to the formation of BNB radical-anions which are converted quantitatively into BNB adducts with H atoms on raising the temperature to −155°C.[45]

Analysis of literature data [11,12,35,45,90,94] has shown that TNB and BNB can be used in the radiolysis of alcohols only for the identification of radicals. Complications arise owing to secondary reactions between radical adducts [12] and the low efficiency of the trapping of certain radicals by BNB. As a result of the reaction between TNB adducts with $\dot{C}H_2OH$ radicals and H atoms, the yield of $\dot{C}H_2OH$ and $CH_2\dot{C}HOH$ adducts is low under continuous generation conditions in an electron beam [27,90] and there is a complete absence of $\dot{C}H_2OH$ adducts in methanol γ-irradiated at −80°C [11,35] in the presence of a high TNB concentration. In the case of BNB the adducts of the latter with $CH_3\dot{C}HOH$ radicals were hardly detected[45].

Quantitative yields of primary radicals in the radiolysis of liquid and solid alcohols have been measured successfully with the aid of PBN [58,92,139]. Solvated electrons are fully captured by this trapping agent for [PBN] ≥ 0.1 M and do not contribute to the overall yield of radicals at 20°C, since the adducts of PBN with an electron decompose at temperatures above −150°C without the formation of any radical adducts [92]. The yields of RȮ radicals were determined using irradiation in the presence of O_2. RȮ radicals do not react with O_2, while R$\dot{C}$HOH radicals and H atoms do react with O_2 with high rate constants, forming peroxy-radicals which do not give rise to stable adducts with PBN and are not detected in EPR spectra [92]. The yields of RȮ and R$\dot{C}$HOH radicals and H atoms in methanol, ethanol, 1-propanol, and 2-propanol, γ-irradiated at temperatures from +20° to −196°C, have been measured by the method of competitive kinetics [58,92,130]. For example, in methanol at 20°C $G(CH_3\dot{O}) = 2.5$, $G(H) = 0.6$, and $G(\dot{C}H_2OH) = 3.1$ radicals/100 eV, while in ethanol $G(C_2H_5\dot{O}) = 1.6$ radicals/100 eV. The yields of RȮ radicals obtained with the aid of the spin-trapping method agree with indirect determinations of the corresponding yields by pulse radiolysis [137,138] and with the calculation based on the final products.

Apart from t-BuȮ radicals adducts with the $\dot{C}H_2(CH_3)_2$. COH, $\dot{C}H_3$, and t-Bu̇ radicals were detected in γ-irradiated t-butyl alcohol [11,40]. It was shown [40] that $\dot{C}H_3$ radicals appear only in the decomposition of t-BuȮ radicals and t-Bu̇ radicals do not arise in the radiolysis of alcohol itself, being formed in the decomposition of the spin adducts of TNB and nitrosodurene with t-BuȮ radicals. It has been stated that the use of t-butylmethylenenitrone for the study of the radiolysis of polar systems is promising [70].

Thus the following problems can be solved with the aid of spin-trapping agents: (1) identification of short-lived radicals; (2) determination of the quantity of unstable radicals; (3) determination of the kinetic characteristics of the trapped radicals. In addition, spin-trapping agents can be used for the synthesis of spin-labelled compounds and for the inhibition of chain processes. Spin-trapping agents are used with a high degree of efficiency in various branches of chemistry, primarily in the study of oxidation and reduction reactions, radical rearrangements, catalytic processes, and polymerisation. Another field where they are used involves the chemistry of high energy processes (radiation and laser chemistry, photochemistry, ultrasonic chemistry, plasma chemistry, and mechanochemistry), in the majority of which there are radical stages. The spin-trapping method can prove to be of significant assistance in biological research, particularly in radiobiology.

The spin-trapping method has significant advantages over other versions of the EPR method, primarily because of the possibility of detecting unstable radicals in processes where the radical concentrations are too low for investigation by other methods. The main advantages is the recording of EPR spectra directly in the liquid phase, which makes it possible to increase appreciably the resolving capacity of EPR and to facilitate the identification of radicals compared with the solid phase. Different spin-trapping agents can be used to identify the same radical (Table 1).

The spin-trapping method also suffers from certain disadvantages associated mainly with the fact that a new compound (the spin-trapping agent) is introduced into the test system. In order to eliminate the uncertainty caused by introducing the spin-trapping agent, it is necessary to investigate independently its behaviour in the given system acted upon by the particular procedure. Naturally, one must carry out an additional study of the stability of the radical adducts and the possibility of their participation as free radicals in the test process itself.

The data presented in the review permit certain recommendations for the selection of spin-trapping agents: 1. It is desirable that the spin adducts should have the simplest EPR spectrum with the smallest possible overlapping of lines due to different radicals. 2. The chosen spin-trapping agents should not interact with the test systems. 3. The spin adducts should be fairly stable. 4. The spin-trapping agent should not itself give rise to radical adducts under the influence of light.

Donor-Acceptor Interactions between Non-silver Information Recording Processes

A.D.Grishina and A.V.Vannikov

The use of non-silver layers based on intermolecular charge-transfer complexes (CTC) for the recording of information, the recording of the influence of light, and for microfilming is examined. The processes are based on the ability of the CTC to dissociate following the absorption of light with formation of products whose absorption spectrum is different from that of the initial films incorporating the CTC. General postulates concerning the mechanism of the photodissociation of the CTC are described and the characteristics of the photochemical reactions of specific systems used as light sensitive materials are considered.
The bibliography includes 142 references.

I. INTRODUCTION

Organic systems whose physicochemical properties change under the influence of light have been widely investigated in recent years. Compounds or compositions whose optical properties change as a result of illumination are used to record images[1-4].

Light-sensitive layers based on organic materials are characterised by a high resolving capacity, the possibility in many instances of carrying out repeated recording-deletion cycles, the absence of chemical development and fixing stages, and the development (intensification) of the image on exposure or by simple physical methods (for example, by heat treatment) and hence the possibility of obtaining an image in real time, the elimination of expensive silver from the recording process, and many other valuable properties. At the same time the sensitivity of organic layers is lower by several orders of magnitude than that of silver bromide photographic materials. At the present time all the above factors make such materials promising in copying and special-purpose photography requiring a high resolution. The existing monographs and reviews deal in detail with the mechanisms of the photochromic transformations in organic compounds[1,2,5], the diazo-coupling reaction for diazonium salts in connection with their use in diazo-printing and in the vesicular process[6-10], as well as the physicochemical principles of the electrophotographic process[11,12].

This review discusses the characteristics of the changes under the influence of light in the chemical and optical properties of systems based on charge-transfer complexes (CTC). Two- or multi-component compositions, in which the primary stage of the complex process involving a change in the positions of the optical absorption bands is electron transfer from the donor component of the CTC to the acceptor component, have been examined. The special interest in intermolecular complexes is due to two factors. The first (the presence of an intermolecular bond) rules out the diffusion-dependent limitation of the rate of the photochemical reaction between two molecules. The second (ionisation of the donor component) corresponds to the absorption of a single light quantum, i.e. does not require high-intensity light sources and, depending on the nature of the selected components as well as the properties of the film-forming medium, can occur under the influence of light at wavelengths from 250 to 1500 mm. Systems based on CTC are beginning to find practical applications in the recording of images as a result of their high rate of colour change and the possibility of optical development[13-16] and thermal fixing[17].

The need to obtain materials whose colour changes under the influence of light requires the compounds to have a system of conjugated bonds. In these compounds the delocalised π electrons, characterised by a close proximity of allowed energy levels, are responsible for absorption in the visible and near ultraviolet and infrared regions. The colour of organic molecules is determined by the size of the conjugation system in combination with the presence of electron-donating and electron-accepting groups and their chemical composition[18-20]. The greatest displacement of the optical absorption bands is due to the change in the size of the continuous conjugation regions[18].

The dependence of the position of the optical absorption band on the size of the conjugated bond system was obtained by Kuhn[21-23] for cyanine dyes. It was established that, in symmetrical molecules with equal lengths of single and double bonds, the energy levels are distributed monotonically and correspond to the following relation between the position of the optical absorption maximum and the number of units N in the conjugated chain:

$$\lambda_{max} = \frac{8mcl^2}{h} \cdot \frac{N^2}{N+1}, \qquad (1)$$

where l is the length of a single chain unit. Owing to the difference between the lengths of single and double bonds, the energy spectrum of asymmetric molecules corresponds to an increased distance between the highest occupied and highest unoccupied levels compared with the distances between both highest occupied and lowest unoccupied orbitals. Such distribution of levels is characteristic of many conjugated molecules, which is the reason for the appearance of a spectrum in the long-wavelength region when the molecule is converted into a radical-cation or a radical-anion.

A shift of the absorption spectrum from the visible to the ultraviolet region accompanies the dissociation of the system of conjugated bonds on conversion of thiazine, triphenylmethane, and other dyes into their leuco-forms[18, 24-26, 13-15] and of xanthene dyes into the lactone form[27-31].

Certain specific properties of the CTC, which must be taken into account in selecting the components of the complex, are analysed below. These are the spin state at the dissociative level for complexes of different types as well as the region of maximum light sensitivity under the conditions corresponding to different ways of exciting the system.

II. CONDITIONS GOVERNING THE PHOTODISSOCIATION OF CHARGE-TRANSFER COMPLEXES

Since 1952, when Mulliken surveyed the accumulated data on the donor–acceptor interaction and described the phenomenon for the first time in quantum-chemical terms (in the gas approximation), numerous original papers, reviews, and monographs have been devoted to this field of study[32-39].

According to the ideas developed by Mulliken and Person[33], an intermolecular bond is formed in a system incorporating an electron donor (D) and acceptor (A) as a result of the mixing of the state in which there is only a van der Waals interaction (DA) between D and A and the dative state ($D^{+}-A^{-}$) in which the electron is fully transferred from the donor to the acceptor. The residence time of the system in each state $\tau \simeq h/W_{01} \simeq 10^{-13}-10^{-14}$ s,[40] since the Planck constant $h = 4.2\times10^{-15}$ eV s and the integral $W_{01} = \int\varphi(DA).H.\varphi(D^{+}-A^{-})d\tau = 0.05-0.5$ eV, where $\varphi(DA)$ and $\varphi(D^{+}-A^{-})$ are the wave functions of the non-bonded and dative states respectively. Thus, as a result of the mixing of the states, a dipole $D^{+\delta}A^{-\delta}$ is formed, where δ is the degree of charge transfer. The experimental methods for the measurement of δ have been examined in detail[33,41]. The idea of charge transfer has been introduced by Hausser and Murrel[42] in a quantum-chemical description of the state of dimers comprising identical radical-ions, because the ionisation potential of a radical-ion is close to the electron affinity. In contrast to the dative state of the CTC, in the dimer, owing to the complete identity of the radical-ions, this state corresponds to a jump of two electrons (in a paired state) between radical-ions at a frequency which, as stated above is close to 10^{14} s^{-1} and not to a directional charge transfer from one radical-ion to another.

Fig. 1 presents a generalised energy diagram for donor–acceptor systems of different types. A characteristic feature of the CTC is that, owing to the mixing of the (DA) and ($D^{+}-A^{-}$) states, the energy level of the ground state W_N lies below the positions of its components W_0 and W_1 (section I, Fig. 1). The energy gain is

$$W_N - W_0 = -(W_{01} - W_0S_{01})^2/(W_1 - W_0); \quad (2)$$

for weak CTC, where $W_1 \gg W_0$ (section I*a*, Fig. 1); in the vicinity of $W_0 \simeq W_1$ (section I*b*, Fig. 1) we have

$$W_N - W_0 = -(W_{01} - W_0S_{01})/(1 + S_{01}) \quad (3)$$

if $W_1 \geqslant W_0$ and

$$W_N - W_1 = -(W_0 - W_1S_{01})/(1 + S_{01}) \quad (4)$$

if $W_0 \geqslant W_1$, for the "reverse" CTC, where $W_0 \gg W_1$ (section I*c*, Fig. 1), the energy gain is

$$W_N - W_1 = -(W_{01} - W_1S_{01})^2/(W_0 - W_1). \quad (5)$$

For CTC, the overlap integral $S_{01} = \int\varphi(DA).\varphi(D^{+}-A^{-})d\tau \simeq 0.01-0.1$.[43] The excited energy level W_V in CTC exceeds the components W_1 and W_0 by an amount

$$W_v - W_1 = (W_{01} - W_1S_{01})^2/(W_1 - W_0) \quad (6)$$

or

$$W_v - W_0 = (W_{01} - W_0S_{01})^2/(W_0 - W_1) \quad (7)$$

along sections I*a* and I*c* respectively. We have

$$W_v - W_1 = (W_{01} - W_1S_{01})/(1 - S_{01}) \quad (8)$$

for $W_1 \geqslant W_0$ (section I*b*) or $W_1 > W_0$ and

$$W_v - W_0 = (W_{01} - W_0S_{01})/(1 - S_{01}) \quad (9)$$

for $W_0 \geqslant W_1$.

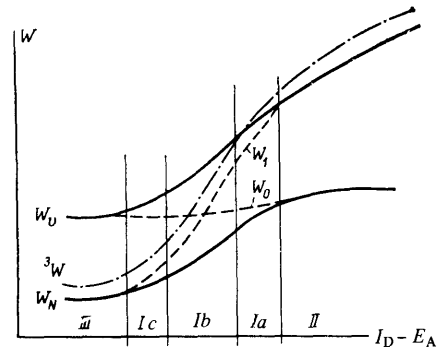

Figure 1. The energy scheme for electronic donor–acceptor complexes. Levels: ground (W_N), excited (W_V), triplet (^3W), non-bonding (W_0)(DA), and dative (W_1)($D^{+}-A^{-}$); I_D is the ionisation potential of the donor and E_A the electron affinity of the acceptor.

In a condensed medium the position of the level W_1 is determined by the relation

$$W_1 = I_D - E_A - Q - P + (C \pm K) \mp V,$$

where Q is the energy of the Coulombic attraction between radical-anions of different signs, P is the polarisation energy of the system, $C + K$ and $C - K$ are the energies of the Coulombic repulsion between unpaired electrons for the singlet and triplet orientations respectively, K is the exchange repulsion energy, and V the contribution of the covalent structure to the dative state. V is large for stable $n\nu$, $\pi\nu$, and $n\sigma$ complexes[35]. Owing to the presence of the contribution of V, the purely ionic triplet level of the dative structure

$$^3W_1 = I_D - E_A - Q - P + C + (V - K) \quad (10)$$

lies above the singlet level

$$^1W_1 = I_D - E_A - Q - P + C - (V - K). \quad (11)$$

for the majority of donor–acceptor systems.

The CTC triplet state (^3W, Fig. 1) arises after the complete electron transfer from the donor to the acceptor and constitutes none other than a purely ionic triplet configuration of the dative structure[33]. The wave function of the triplet state of the complex (φT) is described by a

combination of the wave functions $\varphi(D^{\ddagger})$ and $\varphi(A^{\bar{\cdot}})$ corresponding to the distribution of the unpaired electron densities in the radical-cation ($D^{\ddagger}$) and radical-anion ($A^{\bar{\cdot}}$):[33]

$$\begin{aligned}\varphi_T(m_s = +1) &= A\{\varphi(D^{\ddagger}\uparrow)\varphi(A^{\bar{\cdot}}\uparrow)\},\\ \varphi_T(m_s = -1) &= A\{\varphi(D^{\ddagger}\downarrow)\varphi(A^{\bar{\cdot}}\downarrow)\},\\ \varphi_T(m_s = 0) &= (\psi_I - \psi_{II})/(2 - S_{01}^2)^{1/2},\end{aligned} \tag{12}$$

where

$$\begin{aligned}\psi_I &= A\{\varphi(D^{\ddagger}\uparrow)\cdot\varphi(A^{\bar{\cdot}}\downarrow)\} \text{ and}\\ \psi_{II} &= A\{\varphi(D^{\ddagger}\downarrow)\cdot\varphi(A^{\bar{\cdot}}\uparrow)\}.\end{aligned} \tag{13}$$

The arrows indicate the direction of the spin of the unpaired electron.

In the presence of a contribution by V the ^3W level can lie above W_V for a weak CTC, which in the limit becomes a contact CTC (section II, Fig. 1) with $W_{01} \simeq 0$, $S_{01} \simeq 0$, and $W_V \simeq {}^1W_1$ [Eqn. (6)].[44-46] It shifts to the region $W_N < {}^3W < W_V$ on passing to a stable CTC (section I, Fig. 1) and, as the difference $I_D - E_A$ decreases, it falls to the level $J = {}^3W - {}^1W_1 = 2(V - K)$ on transition to radical-ion salts, for which $W_{01} = 0$, $S_{01} = 0$, and $W_N = {}^1W_1$ [Eqn. (5)].

In $\pi\pi$ complexes the V term is insignificant and the dative structure is largely ionic ($D^{\ddagger}A^{\bar{\cdot}}$). For such complexes, there is a possibility of a shift of the triplet level to a position below the singlet dative level [Eqns. (10) and (11)].[47,48]

As already mentioned, the dissociation of donor–acceptor complexes into radical-ions is the primary step of the complex process leading to a change in the absorption spectra of film materials. Since dissociation takes place with a greater probability after the light-induced population of the level with the most complete charge separation, it follows that the dissociative levels in weak, contact complexes are both the triplet level ^3W and the excited singlet level W_V, in a stable CTC only the ^3W level is dissociative, while in radical-ion salts both the triplet state and the ground singlet state are dissociative.

The dissociative level can be reached in contact complexes and CTC by the action of light corresponding to the absorption band of the complexes:

$$h\nu = W_v - W_N, \tag{14}$$

and in "reverse" CT by thermal excitation. Dissociation occurs when the dissociative level lies above the level of solvent-separated radical-ions ^2W,[49] i.e. under the condition

$$I_D - E_A - Q - \frac{2(\varepsilon - 1)}{2\varepsilon + 1}\cdot\frac{\mu^2}{a^3} \gtrless \gtrless I_D - E_A - Q_i - \frac{2e^2}{r_i}\left(1 - \frac{1}{\varepsilon}\right).$$

Here $[2(\epsilon - 1)/(2\epsilon + 1)](\mu^2/a^3)$ is the polarisation energy of the dipole $\mu = r_{D^{\ddagger},A^{\bar{\cdot}}}e'$,[37,40] $r_{D^{\ddagger},A^{\bar{\cdot}}}$ the distance between the donor and acceptor components of the complex, ϵ the dielectric constant of the medium, a the radius of the cavity polarised by the dipole μ, $(e^2/r_i)(1 - 1/\epsilon)$ the polarisation energy of the radical-ion with radius r_i, and Q_i the energy of the Coulombic attraction between the solvent-separated radical-ions.

The photodissociation process for the dissociative level ^3W is illustrated in Fig. 2. Many non-ordered systems incorporating CTC, liquids and films, are characterised by the presence of radical-ions even under conditions where the difference $^3W - W_N$ [see Eqns. (12), (13), and (2)–(5)] is fairly large and cannot ensure thermal dissociation. According to Stewart and coworkers[50,51], the appearance of radical-ions under dark conditions is associated with the formation of a CTC in an excited triplet state at the instant of formation of the complex on dissolution of an acceptor in a donor liquid. Then $^3W - W_N = \Delta H + \delta$, where $\Delta H = W_0' - W_N$ is the heat of formation of the complex and $\delta = {}^3W - W_0'$ the activation energy for the thermal formation of radical-ions.

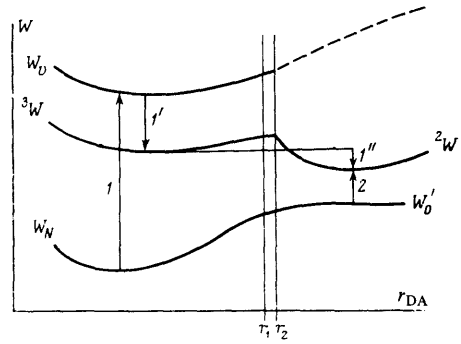

Figure 2. Schematic illustration of the formation of radical-ions in a non-ordered donor–acceptor system: 1),1'), and 1'') photodissociation of the CTC; 2) thermally excited D + A systems; W_0'—the level of separated D and A; ^2W the level of separated $D^{\ddagger}$ and $A^{\bar{\cdot}}$; $r_{DA} < r_1$—the CTC region; $r_1 < r_{DA} < r_2$—exciplexes; $r_{DA} < r_2$—separated D and A or $D^{\ddagger}$ and $A^{\bar{\cdot}}$.

The above explanation is apparently not the only one possible. As shown in Fig. 2, in a liquid and in films where both CTC and solvent-separated D and A exist simultaneously in equilibrium, one may expect the occurrence of reaction via pathway *2* on thermal excitation:

$$D + A \xrightarrow{\Delta E} D^{\ddagger} + A^{\bar{\cdot}}$$

without collision of the species. According to the theory developed by Dogonadze and Kuznetsov[52], reaction via pathway *2* takes place without change of the distance between the components and is due to a tunnel electron transfer. This transfer occurs on thermal excitation of the (D + A) system to the position coinciding with the ^2W level and under conditions where, in consequence of fluctuation-induced changes, the orientation of the solvent relative to the A and D molecules coincides with the orientation about the A^- and D^+ ions.

The photodissociation of CTC into radical-ions was first suggested by McGlynn and coworkers[45,46]. The photochemical decomposition of CTC has been examined in the reviews of Sergeev and coworkers[53,54], Nagakura[55], Davidson[37], and in a study by Irie et al.[58] on the use of this phenomenon in photopolymerisation, photosynthesis, and photochemical oxidation.

The elucidation of the nature of the dissociative level is important for finding the conditions under which light-sensitive systems operate. For dissociation via the triplet level in liquid and film systems, oxygen (the quenching agent for triplet energy) greatly reduces the quantum yield of the photodissociation products, which determines the light sensitivity of the system[13,55,59]; the

lack of an effect by molecular oxygen means that dissociation takes place via a singlet state, a characteristic solely of contact complexes[55,59,60-62].

Photodissociation can also occur via the excitation of both the complex and its individual components. In the latter case the electron transfer from the donor to the acceptor is due to the decrease of the difference $I_D - E_A$ owing to the decrease of I_D by $\sim h\nu_D$ on excitation by light corresponding to the absorption band of the donor or an increase of E_A by $h\nu_A$ when the system is acted upon by light corresponding to the absorption band of the acceptor[18,22,63]. The photoexcitation of an individual component is effective when the component of the complex whose colour changes is light-sensitive and the content of the second component, determined by the equilibrium constant

$$K = [DA]/[D][A], \quad (15)$$

ensures that a dominant proportion of the light-sensitive component exists in the form of the complex. The simultaneous presence of the light-sensitive component both as part of the complex and in the free state is responsible for the decrease of the quantum yield of the photodissociation products of the complexes (as a result of the absorption of part of the light quanta by the free molecules).

III. THE LIMITING LIGHT SENSITIVITY OF THE LAYERS IN THE ABSENCE OF IMAGE INTENSIFICATION

The principal characteristics of photolayers are light sensitivity and resolving capacity. Since in organic materials an individual molecule reacts, the resolving capacity of such materials is extremely high and their light sensitivity is low because it is limited by the quantum yield $\Phi \leq 1$. It is possible to estimate the upper limit to light sensitivity on the basis of the decrease of the concentration c of the component undergoing a colour change (or of the entire CTC):

$$-dc/dt = I_{abs}\,\Phi/l, \quad (16)$$

where I_{abs} is the power of the light flux absorbed by the film and l is the film thickness. After substituting $c = D/\epsilon l$ and $I_{abs} = I_0(1 - 10^{-D_1})$ in Eqn. (16), D being the optical density of the component whose colour changes, D_1 the optical density of the layer in the wavelength range of the incident light, ϵ the extinction coefficient, and I_0 the power of the light flux incident on the film, the relation between the incident energy of the light flux $I_0 dt$ ($J\ cm^2$) and the change in D assumes the following form:

$$I_0\,dt = \frac{dD}{1-10^{-D_1}}\,\frac{1.196\cdot 10^5}{\varepsilon\Phi\lambda}. \quad (17)$$

Here ϵ is expressed in litre^3 mole^{-1} cm^{-1} for a liquid and in dm^3 mole^{-1} cm^{-1} for films, λ being the wavelength of the incident light in nm. According to a USSR Government Standard (GOST), the light sensitivity of silver bromide layers is determined from the energy of the incident light causing a change in optical density by $\Delta D = 0.2$:

$$S_{0.2} = 10^{-4}/I_0\Delta t K,$$

where K is the coefficient of visibility with a maximum value of 680 at 555 nm.[64] Having adopted $\Phi = 1$, $\epsilon = 10^5$ dm^3 mole^{-1} cm^{-1}, $10^{-D_1} \ll 1$, and a wavelength of incident light $\lambda = 555$ nm identical with that corresponding to the absorption maximum of the compound, we find

$$I_0\Delta t_{0.2} \simeq 0.4\cdot 10^{-3}\ J\ cm^{-2},$$

i.e. the limiting attainable light sensitivity corresponds to $S_{0.2} \simeq 4\times 10^{-4}$ GOST units and is lower by several orders of magnitude than for silver bromide films. It is noteworthy that, in order to estimate the light sensitivity of non-silver layers, the value of $I_0\Delta t_1$ corresponding to a change of D by $\Delta D = 1$ was adopted. At the present time $I_0\Delta t_1$ is used mainly when information is recorded by decolorising coloured films, particularly for high optical densities. When a colour was imparted to colourless films, the light sensitivity was estimated in many investigations from $I_0\Delta t_{0.2}$.

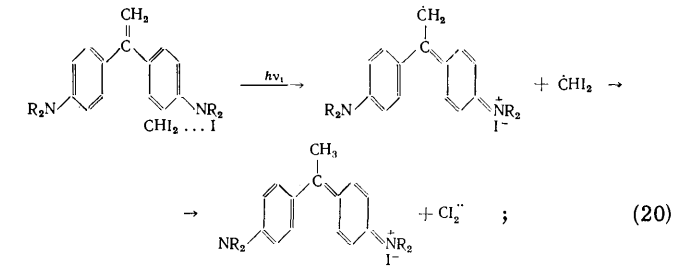
Thus systems with $\Phi \leq 1$ can be used successfully in microfilming, where the resolving capacity of the layer is of decisive importance. The problem of obtaining layers with a high light sensitivity requires image intensification analogous to development in silver bromide photography and leading in its turn to a decrease of the resolving capacity, because a grain and not a molecule is now the light-sensitive element.

IV. LIGHT SENSITIVE CHARGE-TRANSFER COMPLEXES BASED ON ORGANIC SYSTEMS

Light-sensitive compositions, consisting of cyanine dyes[65] and their bases[66,67], leucoxanthenes, leucoanthraquinone, leucodiarylmethanes[66,68], amines[67,69,70], leucotriphenylmethane and styryl dyes[13-16,71,72] (as the donor component which undergoes a colour change), and the A–C–X$_3$ acceptors[13-16,65-72] (where A = H, Cl, Br, or I, and X = Cl, Br, or I) or $Cl_2BrCCBrCl_2$, as well as sulphur-containing acceptors of the type ArSh and ArS_2Ar or sulphophenyl halides[66], are being widely used nowadays and are being introduced into industry. In addition to the above substances, the compositions include also a free radical inhibitor and a polymeric binder. The light sensitive composition is deposited on either a paper or a polymeric support. It is noteworthy that the Horizons Co. Inc. in the USA alone took out more than 250 patents for light-sensitive compositions of this type.

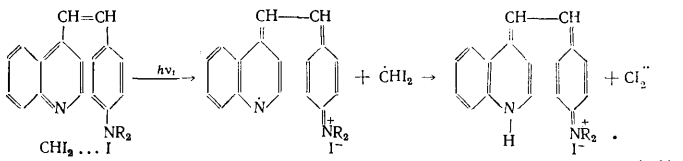
Photochemical reactions in solid layers have been investigated in greatest detail using leucotriphenylmethane dyes[13-16] (DyeH) in combination with CBr_4, for example, leuco-Crystal Violet with added inhibitor of $CBr_2^{\cdot\cdot}$ (triphenylantimony) and a polystyrene binder. It has been shown[13-16] that, in contrast to DyeH and CBr_4, which absorb in the region below 370 nm, compositions with these substances give rise to an additional spectrum up to 450 nm, which imparts a yellow colour to the entire film. The additional absorption indicates the formation of a CTC (we shall designate it by DyeH.CBr$_4$). The photodissociation of the CTC on illumination by light corresponding to its absorption band [Eqns. (14)] takes place only in the absence of O_2 and therefore proceeds via the population of the triplet level ^3W in accordance with reaction

$$\begin{aligned} DyeH\cdot CBr_4 &\xrightarrow{h\nu_1} (DyeH\cdot CBr_4)^* \rightarrow {}^3(DyeH^+ + CBr_4^-), \\ {}^3(DyeH^+ CBr_4^-) &\rightarrow DyeH^+ + CBr_4^-. \end{aligned} \quad (18)$$



The dye responsible for the image (Dye$^+$), which absorbs in the visible region ($\lambda_{2,\max} = 600$ nm, $\epsilon = 1.2\times 10^5$ dm^3 mole^{-1} cm^{-1}), arises via the reaction

$$DyeH^+ + CBr_4^- \rightarrow Dye^+Br^- + HBr + CBr_2^{\cdot\cdot}. \quad (19)$$



The $CBr_2^{\cdot\cdot}$ radicals which fog the film interact with the added inhibitor, restoring the transparency of the film.

The quantum yield at this stage, under the conditions of continuous circulation of gaseous nitrogen, is $\Phi = 0.1$ and corresponds to $I_0\Delta t_{0.2} = 10^{-2}$ J cm^{-2}.

The formation of an image in layers incorporating a CTC based on CHI_3 and vinylidene or substituted styryl components is due to an analogous set of reactions[71]. The absorption spectra of these compounds are displaced under illumination to a lesser extent than in the transition DyeH → Dye$^+$, since it does not entail an increase in the size of the continuous conjugation system [*Nl* in Eqn. (1)] and is due solely to the formation of electron-accepting groups via the following respective reactions:

(20)

(21)

The initial CTC absorb in these systems in the region of 488 nm and the resulting dyes absorb at λ_{max} = 620 and 580 nm respectively.

The problem of the optical development of the exposed film is also discussed in the studies quoted above[13-16,71]. The latent image arising as a result of brief exposure to radiation with $\lambda_1 < 450$ or 488 nm may be developed via reactions (18)–(21) by light corresponding to the absorption band of the dye. The dye molecules are then used as sensitisers. The effect is absent in the presence of O_2, which indicates energy transfer via triplet levels. The formation of a grain consisting of dye molecules during development takes place via the mechanism[13]

$$\mathrm{Dye}^+ \xrightarrow{h\nu_2} {}^1\mathrm{Dye}^{+\bullet},$$

$$^1\mathrm{DyeH}^{+\bullet} \rightarrow {}^3\mathrm{Dye}^+,$$

$$^3\mathrm{Dye}^+ + (\mathrm{DyeH}\cdot\mathrm{CBr}_4) \rightarrow \mathrm{Dye}^{\cdot+} + {}^3(\mathrm{DyeH}^+\cdot\mathrm{CBr}_4^{\cdot-}).$$

and then in accordance with reactions (18) and (19). Owing to the absence of inclusions of dye molecules at the unexposed sites, the film remains yellow after development due to the presence of the CTC. In contrast to the process discussed above, another mechanism, consisting in the thermal dissociation of the complex as a result of the liberation in a microvolume of the energy absorbed by the dye Dye$^+$ inclusions, has been suggested[14-16]. This conclusion is based on the fact that layers containing DyeH become coloured also on heating. The image is fixed by keeping the film at a temperature of ~140°C, which ensures the decomposition of the halogen-containing component and hence the decomposition of the CTC. The yellow colour then disappears and the unexposed sites become clear. It has been shown[13] that the image can be intensified in this way by a factor of ~1400, with an increase of the effective quantum yield to ~140 and of $I_0\Delta t_{0.2}$ to 7×10^{-6} J cm^{-2}. This corresponds to $S_{0.2}$ = 0.03 GOST units. In the best specimens $S_{0.2}$ reaches 0.1 (Fotland and Fichter[72]) and is close to the light sensitivity of silver halide films with a high resolution.

Polymeric films incorporating CTC comprising an amine (Am) (dibenzylaniline)[70,73,74] and CBr_4 are not coloured on heating to 250°C. Analysis of the influence of triplet energy acceptors on photochemical reactions[73] has established that the complex Am.CBr_4 (λ_{max} = 365 nm) does not dissociate on photoexcitation and, after an intercombination conversion, transfers to the triplet levels the energy absorbed by the Am molecules not involved in the CTC. At high concentrations of the added components, the latter form the exciplex ^{3}(Am).CBr_4, which dissociates via the mechanism

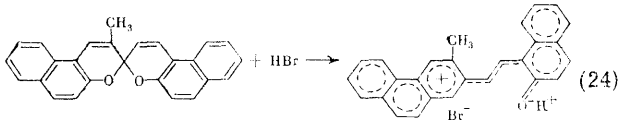
$$^3(\mathrm{Am})\cdot\mathrm{CBr}_4 \rightarrow (\mathrm{Am}^{+\bullet}\cdot\mathrm{Br}^- + \dot{\mathrm{C}}\mathrm{Br}_3) \rightarrow \mathrm{Am}_1^+\cdot\mathrm{Br}^- + \mathrm{HBr} + \ddot{\mathrm{C}}\mathrm{Br}_2 \quad (22)$$

with formation of Am_1^+ (C_6H_5–CH=$\overset{+}{N}$(–C_6H_5)–CH_2–C_6H_5), which absorbs in the visible region with λ_{max} = 665 nm. The optical intensification of the image in this system takes place via a two-quantum mechanism[74] in accordance with the relation (for Am ≫ Am_1^+)

$$\lg\frac{10^D-1}{10^{D_0}-1} = \frac{al_0^2}{bl_0+c[A_1]}\cdot\frac{[Am]}{d[A_2]+f[Am]+g}\cdot\frac{[CBr_4]}{k+h[CBr_4]}\cdot(t-t_0), \quad (23)$$

where D and D_0 are the optical densities at 665 nm at times t and t_0, a, b, c, d, f, g, h, and k are constant coefficients, A_1 and A_2 are oxygen or other acceptors of the triplet energy of singly and doubly excited Am_1^+ species respectively, and I_0 is the intensity of the light acting in the region of λ = 665 nm.

Optical intensification made it possible to increase the effective quantum yield from ~0.14 to ~14 and the light sensitivity at 365 nm from 1.4×10^{-2} to 1.4×10^{-4} J cm^{-2}. In contrast to layers based on leucodyes, amine-containing films are more stable and do not lose their light sensitivity for a long time. In the fixation of films by heating, a stable dye is synthesised simultaneously from Am_1^+ and other components of the layer.



In a photoreproduction process, amines such as *N*,*N*′-diphenylenediamine, *N*,*N*′-diphenyl-*p*-phenylenediamine, and others are used in combination with CBr_4 [75] or CHI_3.[76] These systems are also sensitive to ultraviolet light and the appearance of a colour in them is associated with the formation of stable radical-cations.

The region of spectral sensitivity of the films has been extended to ~540 nm when the bases of cyanine dyes began to be used in conjunction with CBr_4 [66,67] and to 700 nm when cationic cyanine dyes were used[65]. The presence of CTC of CBr_4 and cyanine dyes or their bases has been merely postulated[65,67]. These systems are used without image intensification. Compositions consisting of cationic cyanine dyes and anionic aryl borates $(BR_1R_2R_3R_4)^-$, where R_{1-4} are aryl-substituted groups which are effectively decolorised on photoexcitation of the dye, have also been proposed for use in reproduction using visible light. Lifanov et al.[77] and Chibisov[78] established that, on photoexcitation of cyanine dyes, there is an effective electron transfer to the dye with formation of a radical-anion if the system contains simultaneously a donor (ascorbic acid, diphenylamine, hydroquinone, etc.), but in the presence of acceptors the products are radical-cations.

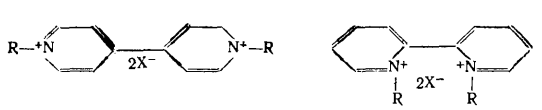
The photographic process involving A–C–X_3 is referred to by convention as a free radical process. It is noteworthy that in all systems free-radical reactions take place under the conditions of the photoexcitation of the halogenomethane (<300 nm) as a result of its dissociation, for example into CBr_3 and Br$^\cdot$, and the occurrence of subsequent reactions with participation of these radicals[69]. When the reactions are initiated by the photoexcitation of

the CTC or the donor under these conditions, the primary stage is electron transfer from the donor to the halogenomethane. This transition has been demonstrated by flash photolysis[18,79] using also the aromatic amine–CCl_4 liquid system. The nature of the subsequent reactions is determined by that of the donor. In contrast to the compositions examined above, these reactions take place with participation of the $\dot{C}Br_3$ radical also in the liquid phase via a chain mechanism when donors such as diphenylamine[69] and polyvinylcarbazole (PVCA) are used[80]. When illuminated films containing PVCA and halogenomethane complexes are placed in a solvent, the effective quantum yield of the PVCA photochemical oxidation product increases from 5×10^{-2} to approximately unity as a result of the decrease of the rigidity of the matrix and the establishment of conditions for the occurrence of free-radical reactions[80].

Smets et al.[81] proposed a complex light-sensitive system incorporating the CTC of polyvinylcarbazole and CBr_4 as well as di-β-naphthospiropyran. The well known[2,5] displacement of the absorption spectra of spiropyrans from the ultraviolet to the visible region under dark conditions when the pH changes as a result of the occurrence of the reaction

(24)

is used in this system. The enhancement of the acid properties of the films is due to the photodissociation of the CTC on exposure to light corresponding to its absorption band [Eqn.(14)] at $\lambda_1 = 405$ nm: $PVCA.CBr_4 \xrightarrow{h\nu_1} (PVCA.CBr_4)^*$ and then



$$(PVCA\cdot CBr_4)^* \rightarrow PVCA^{\ddagger} + HBr + \dot{C}Br_3. \qquad (25)$$

The quantum yield of the products of reaction (25) is close to 0.23 and is independent of the CBr_4 content. The authors demonstrated the possibility of the optical manifestation of the latent image produced on exposure by employing as sensitiser di-β-naphthopyrylium bromide (DNP), formed by reaction (24) and absorbing in the range $\lambda_2 = 600$–700 nm. Since the rate of development increased in proportion to the CBr_4 concentration, the authors postulated the formation of CTC between DNP and CBr_4 and their participation in the development reaction:

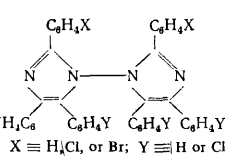
$$DNP\cdot CBr_4 \xrightarrow{h\nu_2} (DNP\cdot CBr_4)^*,$$
$$(DNP\cdot CBr_4)^* + PVCA\,CBr_4 \rightarrow DNP\cdot CBr_4 + (PVCA\cdot CBr_4)^*,$$

this being followed by reaction (25). The HBr formed by reaction (25) ensures the appearance of an additional amount of coloured DNP by reaction (24). It was also established that the $\dot{C}Br_3$ radicals are inserted in the chain and that, together with $PVCA^{\ddagger}$, they ensure the cross-linking of the polymer in the exposed regions. In this system there is a possibility of the appearance of an image as a result of the dissolution of the non-cross-linked PVCA.

Systems based on bipyridylium salts with acceptor properties, such as 2,2′-bipyridylium (2,2′-$BP^{2+}2X^-$) and 4,4′-bipyridylium (4,4′-$BP^{2+}X^-$) also acquire a colour on ultraviolet irradiation:

They exist either in low-molecular-weight[82–85] or polymeric forms[86]. The optical absorption spectra of the above dications lie in the range 200–300 nm. Photoexcitation of the salt in the presence of a donor component such as the film-forming poly(vinyl alcohol)(PVA) [82–85] leads to the formation of the radical-cations $BP^{\ddagger}$ via the mechanism (in relation to the 4,4′-BP^{2+}–PVA system):

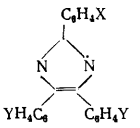
$$BP^{2+} \xrightarrow{h\nu_1} (BP^{2+})^* \xrightarrow{RCH_2OH} BP^{\ddagger} + H^+ + R\dot{C}HOH,$$
$$BP^{2+} + R\dot{C}HOH \rightarrow RCHO + H^+. \qquad (26)$$



It has been established for aqueous solutions of BP^{2+} [87] that the photochemical reduction is irreversible only in the presence of primary and secondary alcohols, owing to the possible elimination of a proton in the α-position relative to the alcoholic group and the formation of the corresponding carbinol. The finding that the alcohols quench the fluorescence of 2,2′-BP^{2+} salts served as a basis for the conclusion that the electron-accepting state is the excited singlet state of the salt. It has been shown for the liquid phase[88–90] that 4,4′-BP^{2+} forms CTC with benzilate and oxalate anions, which absorb in the region of $\lambda_{max} =$ 370 nm and dissociate on photoexcitation with formation of $BP^{\ddagger}$. In a solid-phase system with 4,4′-$BP^{2+}X^-$ and PVA the quantum yield of the formation of the radical-cations depends on the nature of X^-. The values of $I_0\Delta t_{0.2}$, characterising the sensitivity of the films to light with $\lambda_1 =$ 270 nm, and the quantum yields Φ are listed below as a function of the anion in bipyridylium salts:

Anion	Br^-	SO_4^{2-}	NO_3^-	Cl^-
Φ	0.015	0.028	0.045	0.047
$I_0\cdot\Delta t_{0.2}\cdot10^3$, J cm^{-2}	200	130	82	80.6

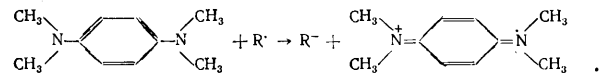
The radical-cations $BP^{\ddagger}$ transfer their charge to oxygen when the latter is introduced. However, the solubility of oxygen in PVA films is so low that the image obtained persisted throughout the period of the observation (1 year). It has been suggested in a patent[85] that cationic dyes be introduced into a chloride–4,4′-bipyridylium–PVA composition. Heat treatment of this system after the photochemical reduction of the salt ensures the transfer of an electron from the radical-cation $BP^{\ddagger}$ to the dye and the decolorisation of the latter as a result of the formation of the leuco-form. Such electron transfer ensures an increase of photosensitivity within the limits of one order of magnitude owing to the increase of the extinction coefficient of the films from $(1.2$–$2.4)\times10^4$ dm^3 mole^{-1} cm^{-1} for $BP^{\ddagger}$ to $(0.8$–$1.2)\times10^5$ dm^3 mole^{-1} cm^{-1} on passing to the dye.



A composition of benzoyl-leuco-Methylene Blue as the donor and an aromatic nitro-compound as a photosensitive acceptor has also been proposed[91] as a system sensitive to ultraviolet light. Illumination of the system in a polymeric polyester binder for 2 s with light from a 20 W lamp and subsequent heat treatment at 120 °C for 5 s ensure the conversion of most of the leuco-form into the dye.

The du Pont de Nemours Co. (USA) developed a "dyelux" process[91–94], where the colour change is associated with the interaction of two basic components. Hexa-arylbisimidazoles having the structure

(27)



are used as the light sensitive component in this process. The component whose colour changes consists of amines[92,93] and leucodyes DyeH (see, for example, Ref. 94).

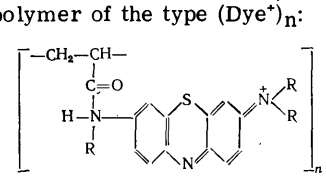
Under the influence of light with $\lambda_1 \simeq 250-360$ nm, the dimers (27) undergo homolytic dissociation with formation of the triarylimidazolyl radicals R$^{\cdot}$:[95]

(28)

These radicals absorb in the visible region (530–620 nm), but are characterised by a lower extinction coefficient [$\epsilon \simeq (1.3 - 8.1) \times 10^3$ litre mole^{-1} cm^{-1} in solution]. A detailed study of the nature of the reactions occurring in solution[1,2,96-100] showed that the radicals (28) oxidise amines in the dark[92,93,96] as well as leuco-dyes[94,96-100]. When amines are used, the appearance of the colour is due to the formation of radical-cations, for example by the following reaction in the case of tetramethyl-*p*-phenylenediamine[93,95]:

The resulting radical-cation has absorption maxima at 575 and 625 nm and the extinction coefficient in the film is $\epsilon \simeq 10^5$ dm^3 mole^{-1} cm^{-1}.

When the leuco-form of the dye is used, the colour is associated with the formation of the dye itself[94] by the reaction[96-100]



$$\mathrm{DyeH} + 2\mathrm{R}^{\cdot} \rightarrow \mathrm{Dye}^{+} + \mathrm{RH} + \mathrm{R}^{-}.$$

In order to rule out the acquisition of a colour by the unexposed regions of the film under the influence of ultraviolet light after the recording of the image, it has been suggested that a third component be used[94]—1,6- or 1,8-pyrenequinone or 9,10-anthraquinone—in combination with a polymeric donor matrix. As a result of the interaction with the matrix in an excited state (under the influence of light with $\lambda_2 = 380-500$ nm), the quinones (O=Ar=O) are converted into hydroquinones (HO–Ar–OH), which react with the dimers under dark conditions:

$$\mathrm{HO—Ar—OH} + \mathrm{R—R} \rightarrow \mathrm{O{=}Ar{=}O} + 2\mathrm{RH}.$$

ensuring the transformation of the dimer R–R (27) into the lophine form (RH), which is insensitive to the action of light with $\lambda > 250$ nm. The "dyelux" process does not provide for image intensification and can be used in the formation of duplicates in microfilming. Its sensitivity is $I_0 \Delta t_{0.2} = 2 \times 10^{-3}$ J cm^{-2}.

In order to obtain non-silver layers sensitive in the red part of the spectrum, Oster and coworkers[101-103] investigated the photochemical reduction of thiazine dyes, which have an optical absorption maximum at 590–665 nm, to the leuco-form, which absorbs in the ultraviolet when present in PVA films and in hydroxylated glasses—fructose, glucose, etc. In order to obtain films whose colour changes under the influence of red light, Kamogawa[104,105] synthesised a polymer of the type $(\mathrm{Dye}^{+})_n$:

(29)

The reduction of Methylene Blue (a thiazine dye) MB^{+} ($\lambda_{max} = 665$ nm) to the leuco-form MBH ($\lambda_{max} \simeq 260$ nm) in layers deposited on a support, under dark conditions on contact with gaseous H_2S as a donor, has been studied by Vartanyan[106,107], who suggested[106] that the photodecolorisation of MB^{+} in gelatine films observed by Lazarev (1912) is associated with the photochemical reduction of the dye to MBH. Oster et al.[101] showed that the rate of decrease of the optical density of the dye in hydroxylated films and glasses is accelerated after the introduction of electron-donating components such as ascorbic acid, phenylhydrazine, allylthiourea, $SnCl_2$, ethylenediaminetetra-acetic acid, etc., increasing linearly with increase of the ratio $(T/\eta)^{1/2}$, where T is the temperature and η the viscosity of the medium. This relation served as a basis for the conclusion that the decolorisation process is controlled by the diffusion of the components. It has been suggested that, in the absence of donors, the unexcited dye molecules serve as a reductant to a greater extent than the medium.

Kamogawa[104,105] investigated the photodecolorisation of polymeric dyes introduced into a PVA or cellulose matrix together with Fe^{2+} as the donor and enzymes. As expected from the consideration of the phenomenon in the liquid phase[108-111], the added Fe^{2+} ions do not ensure the complete decolorisation of the film, since the Fe^{3+} ions formed in the course of the reduction of the dye are a powerful oxidant and induce the reverse reaction in the dark. Enzymes increase the rate of the photochemical reduction of the polymeric dye, but the addition of water constitutes the most effective means of accelerating the photochemical decolorisation process. An estimate based on the experimental data presented in the relevant paper shows that the transmittance at $\lambda = 600$ nm increases from 4 to 94% as a result of the absorption of the light energy $I_0 \Delta t = 1-4$ J cm^{-2}.

The finding that the rate of photochemical reduction is controlled by diffusion and therefore proceeds slowly in the solid phase apparently limited the number of studies whose aim was to employ the photodecolorisation of thiazine dyes in photography. In contrast to solid layers, numerous studies have been devoted to the photochemical reduction of thiazine dyes in the liquid phase. When aqueous and alcoholic solutions are used, the nature of the decrease of the concentration of the dye following its photoexcitation confirms[112-116] the hypothesis but forward for the solid phase that the colourless leuco-form is produced as a result of the interaction of the excited dye molecule with a donor and, in its absence, with an unexcited dye molecule. A slow decomposition of the functional groups as a result of the interaction of the excited dye with the solvent has also been observed in alcoholic solutions. In aqueous and alcoholic solutions Dye^{+} and D do not exist as a complex but interact on collision, as shown by the increase of the quantum yield with increasing donor concentration in accordance with the relation

$$1/\Phi = a + b/[\mathrm{D}]. \qquad (30)$$

Arvan and coworkers[24,117-120] demonstrated the formation of a σ-complex (quasi-leuco-form) between Dye^{+} and the leuco-form of a dye of a different class and also between Dye^{+} and the solvent (pyridine) under the influence of light corresponding to the Dye^{+} absorption band. It was shown[120] that pyridine or an electron-donating additive add to the central nitrogen atom of the dye, which ensures its decolorisation. The increase almost by an order of magnitude of the rate of reduction of MB^{+} by hydrogenated aromatic hydrocarbons under dark conditions after the introduction of amines has been explained[121] by the primary formation of a σ-complex and its subsequent reaction with the hydrocarbons, terminating in the formation of MBH, the initial amine, and an aromatic molecule. In contrast

to PVA films, when poly(vinyl chloride) (PVC) was used as the film-forming material, the independence of the quantum yield of the products of the decolorisation of MB^+, in the presence of tribenzylamine (TBA) as the donor, of the MB^+ and TBA concentrations[122,123] was demonstrated for [TBA] > 0.1 mole dm^{-3}. The yield Φ was calculated from experimental data by the formula

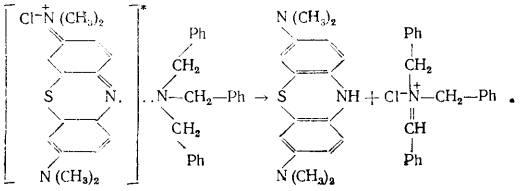
$$\lg(10^{D_0}-1)-\lg(10^{D}-1)=\Phi\frac{\varepsilon\lambda I_0}{1.196\times10^6}\cdot\Delta t, \qquad (31)$$

obtained by integrating Eqn. (17) for $D = D_1$ and amounted to $\Phi = 0.08$. Here D_0 and D are respectively the optical densities (at $\lambda_{max} = 665$ nm) of the initial film and the film illuminated during the period Δt with monochromatic light ($\lambda = 652$ nm) having an intensity I_0.

The independence of Φ of [TBA] and [MB^+] indicates the presence of associated species comprising MB^+ and TBA, for example of the type of weak σ-complexes. The following set of reactions then take place:

$$(MB^+ \ldots TBA) \xrightarrow{h\nu_1} (MB^{+*} \ldots TBA),$$

$$(MB^{+*} \ldots TBA) \xrightarrow{k_1} (MB^+ \ldots TBA),$$



$$(MB^{+*} \ldots TBA) \xrightarrow{k_2} MBH + A_1^+,$$

and Φ is determined by the relation

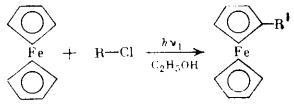
$$\Phi = \frac{[MBH]}{[MB^{+*} \ldots TBA]} = \frac{k_2}{k_2+k_1},$$

which differs from Eqn. (30) for photochemical reduction on collision between the component molecules.

Since the rate of photodecolorisation of coloured PVC films on photoexcitation of MB^+ in the absence of a donor was the same as that measured in the presence of triphenylamine (TPA) but increased by a factor of 130 on passing to TBA and since the radicals MB· arose in the presence of TPA at higher concentration than after the addition of TBA, it was concluded that TBA ensures the reduction of MB^+ to MBH by transferring not only an electron but also a hydrogen atom to the dye via the reaction

At low TBA concentrations, corresponding to an appreciable fraction of MB^+ in a non-associated state according to Eqn. (15), the relation $\lg(10^D - 1) = f(\Delta t)$ gives rise to two sections corresponding to the photochemical reduction of the dye molecules in both associated and free states. The separation of these contributions at different TBA concentrations made it possible to determine $K \simeq 10$ dm^3 $mole^{-1}$ [Eqn. (15)]. In the system considered the light sensitivity in the region of $\lambda \simeq 600$–700 nm corresponds to a decrease of the optical density by $\Delta D = 1$ as a result of the effect of the incident light having an energy $I_0\Delta t_{1.0} = 33\times10^{-3}$ J cm^{-2}.[122,123] This quantity exceeds approximately by two orders of magnitude the light sensitivity of PVA films coloured by MB^+ and is due to the presence of associated species, which rule out diffusion-dependent limitation of the rate of the photochemical reaction.

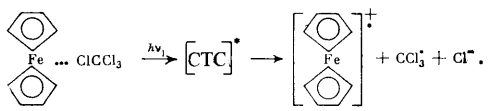
Japanese investigators[1,31] suggested that dye layers vacuum sputtered onto a support at 60–70°C be used in reproduction (they designated these dyes by the abbreviation TED–Thermally Evaporated Dyes). The process is based on the ability of certain dyes to dimerise as a result of photoexcitation[18]. Since the dimers absorb light in the region displaced by several tens of nm towards shorter wavelengths compared with the absorption of the monomer, the image remains coloured and is difficult to distinguish from the unexposed regions. The image is developed by treating the layer with a non-polar solvent and heating. In the former case the dye is removed from the unexposed regions but remains in the exposed regions owing to the decrease of solubility as a result of the formation of dimers. In the case of xanthene dyes such as rhodamine B and its derivatives, the greater thermal stability of the dimers compared with the monomers is used. In order to develop the exposed regions, which have a higher content of dimers, use was made[31] of the ability of these dyes to undergo an irreversible conversion into the lactone form as a result of heating to 70–140°C, which has been thoroughly investigated[24,27,30]. After heating, the coloured layer remains on the exposed regions, but the unexposed regions become colourless, since, in contrast to the cationic dye which absorbs in the region of 550 nm, the absorption spectrum of the lactone form is in the ultraviolet. The light sensitivity of the layers is low (~0.3 J cm^{-2}), but the layers consist of only one component and are distinguished by a high resolving capacity.



V. LIGHT SENSITIVE CHARGE-TRANSFER COMPLEXES BASED ON ORGANOMETALLIC COMPOUNDS

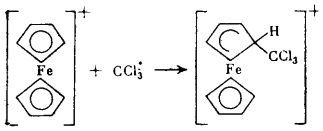
There exists yet another class of compounds which undergo further chemical reactions involving charge-transfer states and are extremely promising for the formation of image recording systems. These are organometallic compounds and in the first place ferrocene and its derivatives.

The fundamental studies carried out during the last ten years showed that the photochemistry of organometallic compounds has its characteristic features and many phenomena have still not been fully explained even for the simplest systems. Photochemical reactions involving the decomposition of many ferrocene derivatives were first observed by Nesmeyanov and coworkers[124–126]. A number of reviews have been devoted to the chemistry of metallocenes and transition metal carbonyls[127–129]. The mechanisms of photochemical reactions have been considered mainly in relation to solutions and it is very difficult to use these results for reactions in solid matrices, particularly since the solvent effects for organometallic compounds are very considerable. The use of organometallic compounds in recording systems is based on photochemical reactions in the solid state and, with a rare exception[130], the chemistry of photochemical processes has not been established at all reliably in most instances.

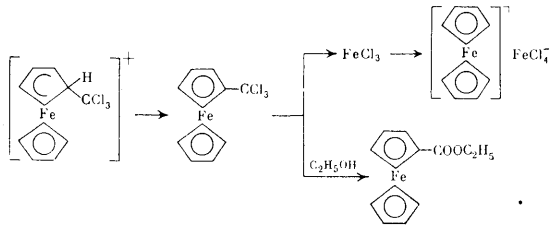


Systems where the photochemical reactions proceed with precipitation of charge-transfer complexes are of interest for the present review. These are the most promising for use in recording systems. Brand and Snedden[131] observed a dissociative charge-transfer band in the absorption spectra of ferrocene solutions in carbon tetrachloride. When these solutions are irradiated with ultraviolet light, ferricenium tetrachloroferrate(III) is formed quantitatively. In the presence of compounds containing mobile hydrogen, the ferricinium salt is transformed into ferrocene[132]. The formation of ferricinium

tetrachloroferrate(III) was also observed[133] in the photolysis of ferrocene in hexachlorocyclopentadiene. In solutions of organic halogeno-derivatives in ethanol photochemical substitution of ferrocene takes place[134]. It is thus possible to introduce ethoxycarbonyl, formyl, ethoxymethyl, benzyl, and allyl groups into the ferrocene molecule under the influence of ultraviolet light[135] via the general mechanism



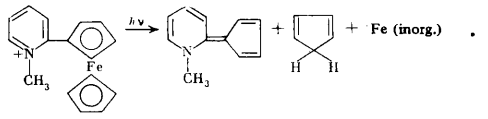
R = CCl_3, $CHCl_2$, or CH_2Cl;
R' = $CO_2C_2H_5$, CHO, or $CH_2OC_2H_5$.



The ultraviolet absorption spectrum of ferrocene in ethanol has a band with λ_{max} = 440 nm, which has been attributed to a $d \rightarrow d^*$ transition and a band with λ_{max} = 325 nm assigned to $3d \rightarrow$ MO*, MO $\rightarrow$ MO*, or symmetry-prohibited $\pi \rightarrow \pi^*$ transitions. The absorption at wavelengths below 300 nm is apparently due to a $\pi \rightarrow \pi^*$ or $n \rightarrow \pi^*$ transition[136]. An absorption with a maximum at 307 nm, associated with charge-transfer, is manifested in ferrocene solutions in carbon tetrachloride. When other halogen-containing organic solvents are used, such as chloroform, dichloromethane, allyl bromide, benzyl chloride, trichloromethylbenzene, and *p*-nitrobenzyl chloride, λ_{max} for the charge-transfer band is located in the region between 300 and 380 nm, while for chlorides such as n-butyl chloride, allyl chloride, and a number of others, a charge-transfer band was not observed in the presence of ferrocene. Accordingly the yield of substitution products in the latter case is much lower than in systems forming CTC. The mechanism of the substitution reaction has been investigated in detail[137]. The dependence of the quantum yield of the photosubstitution reaction (and of the decomposition of ferrocene) on the wavelength shows that it is zero in the region of the $d \rightarrow d^*$ transition, while excited states with charge transfer lead to the effective formation of substitution products. Excitation by light at shorter wavelengths stimulates such reactions as a result of the decomposition of ferrocene molecules by the chlorine atoms generated by the direct photochemical decomposition of the halogenohydrocarbons. Measurements by flash photolysis[137] suggested a mechanism of the formation of coloured products: the first stage of the photochemical reaction is believed[131] to consist of the excitation and decomposition of the CTC:

According to Beckwith and Leydon[138], the ferricinium cation is extremely reactive towards free radicals, in contrast to ferrocene itself:

The subsequent stages were determined less reliably. On pulsed illumination, $FeCl_3$ is formed in an overall process which obeys first-order kinetics and has a rate constant of $\sim(1.6 \pm 0.5) \times 10^5$ s with subsequent formation of ferricinium tetrachloroferrate(III) and, in the presence of ethanol, of ferrocenecarboxylic acid:



In contrast to normal ferricinium ions, ferricinium tetrachloroferrate(III) does not interact with trichloromethyl radicals. It has been suggested that the formation of ferricinium tetrachloroferrate(III) in ferrocene solutions in CCl_4 be used in ^{60}Co γ-radiation dosimeters[139], because the concentration of the ferricinium salt formed is proportional to the absorbed dose.

The formation of CTC between ferrocene and halogenohydrocarbons is used in recording layers. On formation of the CTC in the solid state, the acceptor interacts with the pentadienyl ring and not with the metal[134]. The exact mechanism of the photochemical processes in such solid systems has not been investigated, but there is no doubt that its main stages have much in common with reactions in solution. Compositions containing ferrocene or its derivatives and photolytic halogenohydrocarbons are characterised by a spectral sensitivity which embraces the visible region, in contrast to many other organic systems which are sensitive only in the ultraviolet region. In a system incorporating ferrocene and CBr_4 a complex having the composition Fc.3CBr_4 with λ_{max} = 388 nm is formed[143]. The absorption band of the complex extends into the visible region up to ~600 nm. The bathochromic shift of the CTC absorption band when CCl_4 is replaced by CBr_4 is associated with the increase of the electron affinity (0.15 and 1.17 eV respectively). The formation of the CTC and its absorption spectrum fully determine the light sensitivity of the recording layers and its spectral range[143].

Compositions based on ferrocene or its derivatives and halogenohydrocarbons are used in the manufacture of reproducing materials with an increased sensitivity in the visible light. These layers can be effectively stored in the dark, are fixed on heating, are readily activated, and do not require a chemical treatment[140]. Other ways of employing light-sensitive layers containing CTC have also been proposed. Thus layers based on vinylferrocene copolymers with halogenohydrocarbons become electrically conducting in the exposed regions. The subsequent employment of electrophotographic stages makes it possible to obtain a large number of copies from a single exposed layer. Layers with CTC comprising vinylferrocene copolymers with nitrogen-containing heterocyclic compounds and halogenohydrocarbons have now been obtained; after their exposure and treatment with methanol, a coloured image is produced[141].

The latter process can also be regarded as a photochemical reaction of the ammonium forms of nitrogen-containing ferrocenes[142], which was first observed in relation to α-ferrocenylpyridinium methiodide:

The above discussion shows that definite achievements have been made in the use of charge-transfer states for the formation of light-sensitive layers with a wide variety of photographic characteristics. Interactions with charge transfer are universal—it is difficult to point to a system in which they do not occur and in which they do not contribute to photochemical processes, but their detection involves difficulties in many instances. The formation on photoexcitation of radical-cations and radical-anions changes the spectroscopic characteristics in the visible region under the influence of infrared and ultraviolet radiation, which makes it possible to obtain contrasting layers. One may also note that, among other organic systems, only layers based on the use of charge-transfer states approach the sensitivity of silver bromide layers. This is associated with the possibility of using physical developers and of intensifying the latent image by the action of light corresponding to the absorption band of the coloured photochemical reaction products. These layers also possess special properties—sensitivity within narrow spectral regions of the visible, infrared, and ultraviolet, the possibility of multicoloured recording, as well as the recording of holograms.

The mechanism of the photochemical reactions of CTC has been studied mainly in solution. The application of the results to solid layers is open to serious objections, particularly in systems sensitive to the characteristics of the medium. The study of the photochemistry of charge-transfer states in solid multicomponent systems forming CTC is therefore important for the development of light-sensitive layers.

The Insertion of Diene Hydrocarbons in a Transition Metal - Ligand Bond

M.I.Lobach and V.A.Kormer

Reactions involving the insertion of diene hydrocarbons in transition metal - ligand bonds, leading to the formation of σ- or π-allyl complexes, are examined and their possible mechanisms are discussed.
The bibliography includes 242 references.

I. INTRODUCTION

Progress in polymerisation catalysis achieved in recent years has been largely due to the involvement of organometallic compounds in research. The use of catalytic systems based on aluminium and transition metal compounds made it possible to carry out specific syntheses of many olefin and diene polymers and to organise the industrial production of polyethylene, polypropylene, and stereoregular rubbers, including isoprene rubber.

Among many pathways leading to the reaction of unsaturated hydrocarbons under the influence of organometallic compounds, the addition of the latter to multiple carbon–carbon bonds is of particular interest. Active metal–carbon bonds, capable of involvement in further chemical reactions, persist in the resulting adducts. Numerous repetition of the addition steps, achieved in many instances, leads to the formation of long hydrocarbon chains, i.e. telomer or polymer molecules.

Studies on the addition of organic derivatives of metals to conjugated multiple carbon–carbon bond systems have yielded extremely valuable information for the development of organometallic and organic chemistry. The wide variability of the structures of the adducts formed and their dependence on the nature of the reactants made it possible to outline various approaches to the study of the mechanisms of the reactions of unsaturated compounds.

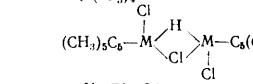
In contrast to the addition of organometallic compounds to mono-olefins, in the case of conjugated diene systems adducts are formed with a metal atom in the β-position relative to the double bond. When there are coordination vacancies in the metal, such σ-compounds can be converted into thermodynamically more favourable π-allyl complexes in which the bond with the metal is formed with participation of three carbon atoms. In the presence of substituents at the terminal carbon atoms of the π-allyl group, the "non-classical" structure of the π-allyl complexes is responsible for the non-equivalence of the bonds of the metal with the first and third carbon atoms and also for the existence of complexes in two isomeric forms (*syn*- and *anti*-). All these facts must be taken into account in determining the mode of addition of transition metal derivatives to diene hydrocarbons.

The synthesis of diene polymers under the influence of metal complex catalysts is carried out by inserting the monomer molecules in metal–carbon bonds. The study of the simplest reactions of this type is therefore of undoubted interest for the development of ideas concerning the mechanisms of the elementary stages in the polymerisation of diene hydrocarbons, which are practically important processes.

An attempt was made in the present review to survey all the available experimental data on the reactions involving the insertion of diene hydrocarbons in active metal–ligand (hydride, alkyl, acyl, allyl, and acido-groups), which can be regarded as model reactions leading to the formation of active centres in various organic synthetic and polymerisation processes with participation of diene hydrocarbons. The insertion of dienes in metal–ligand bonds is also used widely as one of the preparative procedures for the synthesis of allyl complexes of transition metals[1,2].

II. INSERTION IN TRANSITION METAL–HYDROGEN BONDS

1. Buta-1,3-diene



Transition metal hydrides add to butadiene with formation of both σ- and π-crotyl 1 : 1 adducts, the insertion in the latter case being accompanied by the displacement of one monodentate ligand from the coordination sphere of the metal.

At moderate temperatures hydridopentacarbonylmanganese adds to butadiene in the 1,4-positions[3,4]. The reaction products contain 85% of the *cis*-σ-crotyl complex and 15% of the *trans*-isomer. Hydridocyclopentadienyldicarbonyliron reacts similarly under these conditions[5]. At 80–100°C in the former case and under ultraviolet irradiation in the latter, mainly *syn*-π-crotyl complexes are formed. Mild decarbonylation and a mixture of *cis*- and *trans*-σ-crotylmanganese pentacarbonyls with the aid of bis(diphenylphosphinoethane)iridium chloride takes place with retention of the geometrical configuration of the crotyl ligand[6].

The π-crotyl structure has been established for butadiene adducts and all the remaining hydrides listed in Table 1. It is therefore impossible to determine the mode of addition (in the 1,2- and 1,4-positions). Table 2 presents the known examples of reactions involving the

insertion of butadiene in transition metal–hydrogen bonds formed when compounds of these metals are reduced in the presence of butadiene.

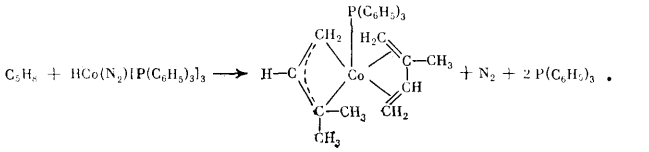
π-Crotyl(cyclo-octa-1,5-diene)rhodium is the product of the addition to butadiene of the intermediate hydride formed from (π-cyclohexenyl)(cyclo-octa-1,5-diene)-rhodium via the reaction [56]

$$(1.5\text{-}C_8H_{12})\,Rh\,(\pi\text{-}C_6H_9) \rightleftharpoons [(1.5\text{-}C_8H_{12})\,Rh\,(\pi\text{-}C_8H_8)]\,(H) \xrightarrow[+C_4H_6]{-C_6H_8} (1.5\text{-}C_8H_{12})\,Rh\,(C_4H_7)\,.$$

The intermediate nickel hydride complexes arising in the reduction of $NiCl_2$ by tri-isobutylaluminium react in succession with several butadiene molecules, giving rise to allyl complexes of nickel with the oligomeric π-allyl ligand [57]. The reactions involving the addition of hydride complexes of transition metals to butadiene with formation of intermediate π- or σ-crotyl complexes take place in the hydrogenation of butadiene under the influence of the pentacyanocobalt ion [58–69] and also in the codimerisation of butadiene with α-olefins in the presence of transition metal compounds capable of forming active metal–hydrogen bonds under the conditions of the synthesis [70–84].



2. Isoprene and Chloroprene

Hydridopentacarbonylmanganese reacts with isoprene and chloroprene to form 1,4-σ-adducts close to room temperature [3]:

$$H_2C{=}\underset{\displaystyle X}{\underset{|}{C}}{-}CH{=}CH_2 + HMn(CO)_5 \rightarrow H_3C{-}\underset{\displaystyle X}{\underset{|}{C}}{=}CH{-}CH_2Mn(CO)_5,\ X = CH_3,\ Cl\ .$$

The iron hydride $HFe(CO)_4SiCl_3$ reacts similarly with isoprene [9].

According to ^1H NMR data, the only product of the interaction of isoprene with the ion $[HCo(CN)_5]^{3-}$ under the conditions of the hydrogenation reaction is the α-3-methylbut-2-enyl complex $[(CH_3)_2C{=}CHCH_2Co(CN)_5]^{3-}$. [88] This structure of the σ-allyl adducts of manganese, iron, and cobalt agrees satisfactorily with the 1,1-dimethyl-π-allyl structure of the complexes formed directly from the diene and the metal hydride under conditions promoting the elimination of one of the ligands. The interaction of isoprene with $HMn(CO)_5$ and $HFe(CO)_4SiCl_3$ at 95 °C yields immediately 1,1-dimethyl-π-allyl complexes [3,9]. The iron and cobalt hydrides $HFe(NO)(CO)_3$ [7,8] and $HCo(CO)_4$ [13] add similarly. It has been shown [85] that $HCo(N_2)[P(C_6H_5)_3]_3$ reacts with two isoprene molecules, one of which is inserted in the Co–H bond and the other is coordinated to cobalt, displacing a nitrogen molecule and two triphenylphosphine molecules:

This complex can also be obtained by the interaction of isoprene with cobalt hydride formed *in situ* (in the reduction of an ethanol solution of $CoCl_2$ by metallic zinc in the presence of triphenylphosphine) [42,86].

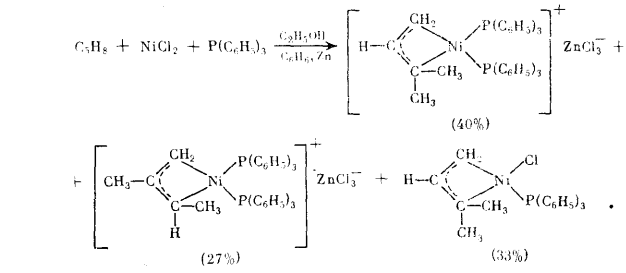
*L_2 = 2,2′-bipyridyl or 1,10-phenanthroline; X = ClO_4 or PF_6.

According to Kruck et al. [87], the hydride $HCo(PF_3)_4$ adds to isoprene with formation of a 1,1-dimethyl-π-allyl adduct. Nixon and coworkers [88] observed that cobalt and rhodium complexes of this type readily undergo a skeletal isomerisation to 1,2-dimethyl-π-allyl complexes [26,89]. It is of interest that *anti*-1,2-dimethyl-π-allyltrifluorophosphine complexes of cobalt and rhodium are isomerisation intermediates. However, the *anti*-isomer of the rhodium complex is rapidly converted into the *syn*-isomer. On the other hand, the hydride $HRh(PF_3)_4$ adds to isoprene

with the immediate formation of the *anti*- and *syn*-1,2-dimethyl-π-allyl adducts[28]; the ratio of the *anti*- and *syn*-isomers depends on the temperature conditions in the reactions.



The iridium compound $HIr(CO)_2[P(C_6H_5)_3]_2$,[23] the titanium compound $[HTi(C_5H_5)_2]_2$,[20] the vanadium compound $HV(CO)_6$,[21,22] the palladium compounds $[HPdL_2]^+PF_6^-$ (L_2 = diphenylphosphinoethane or diphenylarsinoethane),[90,91] and the rhodium and iridium complexes

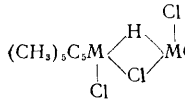
[29] react with isoprene like the rhodium complexes. On the other hand, the vanadium hydride complexes $HV(CO)_4L_2$ (L_2 = bisdiphenylarsinomethane or 1-diphenylarsino-2-diphenylphosphinoethane) add to isoprene with the preferential formation of 1,1-dimethyl-π-allyl complexes[92].

A mixture of adducts of the nickel hydride $\{HNi.[P(OCH_3)_3]_4\}^+HSO_4^-$ and isoprene contains mainly the *anti*-1,2-dimethyl-π-allyl complexes[18]. The fraction of 1,1-dimethyl-π-allyl adducts does not exceed 20%. Under these conditions, chloroprene forms exclusively $\{syn$-1-methyl-2-chloro-π-allyl-$Ni[P(OCH_3)_3]_3\}^+HSO_4^-$.

The mode of reaction of isoprene with nickel hydride complexes, formed in the reduction of nickel chloride by metallic zinc in the presence of bases, differs significantly from that observed by Tolman[18]. The amount of 1,1-dimethyl-π-allyl complexes is in this case much greater[47]:

On the other hand, when this reaction is carried out in acetonitrile, the only product is the 1,1-dimethyl-π-allyl adduct.

The codimerisation of isoprene with ethylene (in the presence of a catalyst comprising a nickel halide complex of trialkylphosphine + dialkylaluminium chloride) leads to the formation of *cis*-4-methylhexa-1,4-diene,[78] which indicates the occurrence of the reaction via an intermediate *anti*-1,2-dimethyl-π-allyl adduct of nickel hydride and isoprene. When a rhodium catalyst is used, the product is the *syn*-1,2-dimethyl-π-allyl complex, responsible for the formation of *trans*-4-methylhexa-1,4-diene from isoprene and ethylene[52]. The reactions involving the insertion of isoprene in the metal–hydride bond with formation of allyl complexes also occur when it [isoprene] is reduced by potassium iron carbonylate[93], in carbonylation under the influence of palladium catalysts[94], and in polymerisation in the presence of rhodium nitrate[95].

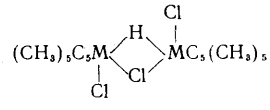


3. Penta-1,3-diene, Its Homologues, and Penta-1,4-diene

Penta-1,3-diene combines with transition metal hydrides, forming preferentially 1,3-dimethyl-π-allyl complexes regardless of the nature of the transition metal.

Among the adducts of hydridotetracarbonylcobalt and penta-1,3-diene, both *syn,anti*-, and *syn,syn*-1,3-dimethyl-π-allylcobalt tricarbonyls (with the latter predominating) were found[13,96-98]. The cobalt hydride, obtained by the reduction of $CoCl_2$ with zinc, reacts with penta-1,3-diene similarly[88].

The relative contents of the *syn,syn*- and *syn,anti*-structures depend primarily on the reaction temperature. The reaction of $HRh(PF_3)_4$ with penta-1,3-diene at 0°C leads to the formation of both isomers in nearly equimolar proportions. An increase of temperature promotes an increase of the yield of the *syn,syn*-1,3-dimethyl-π-allyl adducts. The influence of temperature has been demonstrated particularly clearly by Tolman[18], who showed that the addition of $\{HNi[P(OCH_3)_3]_4\}^+HSO_4^-$ to penta-1,3-diene at 0°C leads to $\{syn,anti$-1,3-dimethyl-π-allyl-Ni$.[P(OCH_3)_3]_3\}^+HSO_4^-$, whereas at 50°C 80% of the total amount of the 1,3-dimethyl-π-allyl complexes are in the *syn,syn*-configuration.



Only the *syn,syn*-1,3-dimethyl-π-allyl ligands were present in the complexes $C_5H_9Ti(C_5H_5)_2$[19,20,99-102] and $[C_5H_9PdL_2]^+PF_6^-$ (L_2 = diphenylphosphinoethane or diphenylarsinoethane)[90,91], synthesised by the reaction of penta-1,3-diene with the corresponding titanium and palladium hydrides. The *syn,syn*-1,3-dimethyl-π-allyl complexes of rhodium and iridium are the main products of the interaction of penta-1,3-diene with the complexes

;[29] but in these instances only 15% of the complexes with the 1-ethyl-π-allyl ligand are formed. Reactions involving the insertion of penta-1,3-diene in metal–hydride bonds also occur when it polymerises under the influence of rhodium chloride[103] and is hydrogenated in the presence of $RuCl_2[P(C_6H_5)_3]_3$.[104]

The influence of the position of the methyl substituents at the double bonds in penta-1,3-diene homologues on the rate and mode of reaction with the nickel hydride $\{HNi[P(OCH_3)_3]_4\}^+HSO_4^-$ was investigated by Tolman[18]. Table 3 shows that dienes with inner double bonds (hexa-2,4-diene and 2,5-dimethylhexa-2,4-diene) exhibit the lowest reactivity. 2-Methylpenta-1,3-diene is five times less reactive than penta-1,3-diene; the presence of substituents at the inner double bond makes the difference between the rates less significant.

The titanium hydride $[HTi(C_5H_5)_2]_2$ reacts with 3-methylpenta-1,3-diene similarly to nickel hydride[20]. On the other hand, the mode of reaction of the iridium hydride $HIr(CO)_2[P(C_6H_5)_3]_2$ with 2,4-dimethylpenta-1,3-diene differs from that indicated in Table 3 for nickel hydride—the product is 1-isopropyl-2-methyl-π-allyldicarbonyltriphenylphosphineiridium[23]. Rhodium and iridium complexes of the type

react with 2-methylpenta-1,3-diene and 2,5-dimethylhexa-2,4-diene to form compounds with 1,1,3-trimethyl- and 3-isopropyl-1,1-dimethyl-π-allyl ligands[29]. However, when the former diene reacts with the rhodium complex, approximately 20% of *syn*-1-ethyl-2-methyl-π-allyl-RhCl$.[C_5(CH_3)_5]$ is also formed.

Only $HCo(CO)_4$ adds to penta-1,4-diene; in this instance a mixture of *syn*- and *anti*-1-ethyl-π-allylcobalt tricarbonyls with an admixture of the 1,3-dimethyl-π-allyl complexes was isolated[96-98]. Under the influence of the

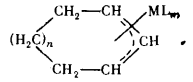
rhodium hydride $HRh(PF_3)_4$,[28] the titanium hydride $[HTi(C_5H_5)_2]_2$,[20], and the nickel hydride $HNi[P(OCH_3)_3]_4 \cdot HSO_4$,[18] penta-1,4-diene initially isomerises to penta-1,3-diene. Subsequently the reaction proceeds via the pathway indicated above.

Table 3. Reactions of $HNi[P(OCH_3)_3]_4HSO_4$ with dienes[18].

Diene	Structure of π-allyl ligand in reaction products	$\tau^*_{1/2}$, h (t, °C)
Penta-1,3-diene (mixture of *cis*- and *trans*-forms)	*syn, anti*-1,3-dimethyl-π-allyl *syn, syn*-1,3-dimethyl-π-allyl	0.3 (0)
trans-3-Methylpenta-1,3-diene	*syn, anti*-1,2,3-trimethyl-π-allyl *syn, syn*-1,2,3-trimethyl-π-allyl	0.5 (0)
trans-2-Methylpenta-1,3-diene	*syn*-1,1,3-trimethyl-π-allyl	1.5 (0) 0.2 (25)
2,4-Dimethylpenta-1,3-diene	1,1,3,3-tetramethyl-π-allyl	0.4 (25)
Hexa-2,4-diene (mixture of *trans, trans*-, *cis, trans*-, and *cis, cis*-forms)	*anti*-1-ethyl-*syn*-3-methyl-π-allyl *syn*-1-ethyl-*syn*-3-methyl-π-allyl	0.5 (25) 0.5 (25)
2,5-Dimethylhexa-2,4-diene	3-isopropyl-1,1-dimethyl-π-allyl	1.5 (25)

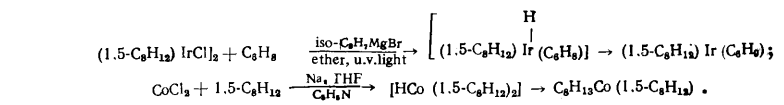
*50% reaction time.

The higher rate of reaction of hydrides with conjugated dienes compared with non-conjugated dienes readily explains the finding that in the codimerisation of 1,3-dienes with α-olefins the hydrides react with 1,3-dienes to form π-allyl complexes.



4. 2,3-Dimethylbutadiene

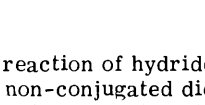
The addition of transition metal hydrides to 2,3-dimethylbutadiene leads to complexes with a 1,1,2-trimethyl-π-allyl ligand. These reactions have been described only for cobalt-group (cobalt[13] as well as rhodium and iridium[29]) hydrides. The iron hydride $HFe(CO)_4SiCl_3$ reacts with 2,3-dimethylbutadiene to form only the σ-adduct[9].

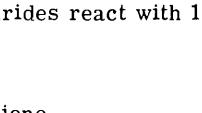


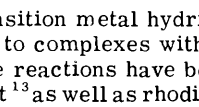
The nickel complexes $\{C_6H_{11}Ni[P(C_6H_5)_3]_2\}^+ZnCl_3^-$ and $C_6H_{11}Ni[P(C_6H_5)_3]Cl$ have been obtained as a result of the addition to 2,3-dimethylbutadiene of the nickel hydride formed in the reduction of $NiCl_2$ by zinc in the presence of triphenylphosphine[47].

5. Cyclic Diene Hydrocarbons

Table 4 presents the structures of the adducts of transition metal hydrides and cyclic dienes, which are complexes with π-allyl cyclic ligands having the general form







π-Cyclohexenyl-π-cyclo-octa-1,5-dieneiridium[108] and π-cyclo-octenyl-π-cyclo-octa-1,5-dienecobalt[86] were obtained as a result of the addition of the intermediate metal hydrides to cyclohexa-1,3-diene and cyclo-octa-1,5-diene respectively:

6. Allene Hydrocarbons

Allene is very readily inserted in a metal–hydrogen bond. The addition of hydrogen leads solely to an *sp*-hybridised carbon atom and π-allyl complexes are formed. The pentacoordinate trigonal-bipyramidal rhodium and iridium complexes $HRh(CO)[P(C_6H_5)_3]_3$ and $HIr(CO)_2[P(C_6H_5)_3]_2$ react with allene to form the complexes $C_3H_5M(CO)[P(C_6H_5)_3]_2$ having the same coordination number[23]. As in the reaction with butadiene, one of the equatorial ligands (triphenylphosphine in the former complex and carbon monoxide in the latter) is displaced. $HRh(PF_3)_4$ and allene give rise to the adduct $C_3H_5Rh(PF_3)_3$;[25,26] $HV(CO)_6$ adds to allene to form π-allylpentacarbonylvanadium[22].

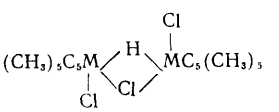


Table 4. Addition of cyclic dienes to transition metal hydrides.

Cyclic diene	Initial hydride complex	Reaction product	Refs.

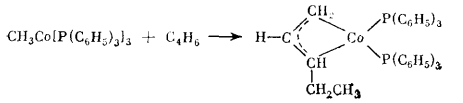
*L_2 = diphenylphosphinoethane or diphenylarsinoethane.

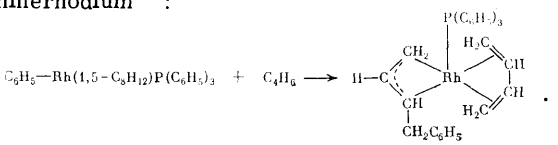
When allene was allowed to react with a solution of *trans*-$HPt(NO_3)[P(C_2H_5)_3]_2$ and $NaB(C_6H_5)_4$ in methanol, the complex $\{C_3H_5Pt[P(C_2H_5)_3]_2\}^+B(C_6H_5)_4^-$ was isolated[31,32]. The reaction of allene with *trans*-$HPt(CH_3OH)[P(C_6H_{11})_3]_2 \cdot PF_6$ led to an analogous π-allyl complex[109].

The hydride complexes of rhodium and iridium



add to 1,1-dimethylallene, forming 1,1-dimethyl-π-allyl complexes[29]. The insertion of the coordinated methylallene in the metal–hydride bond in the intermediate complex, arising in the interaction of π-indenyl-π-dimethylacetylenebis(trimethyl phosphite)molybdenum tetrafluoroborate with $NaBH_4$, leads to an anti-π-crotyl complex of molybdenum[110].

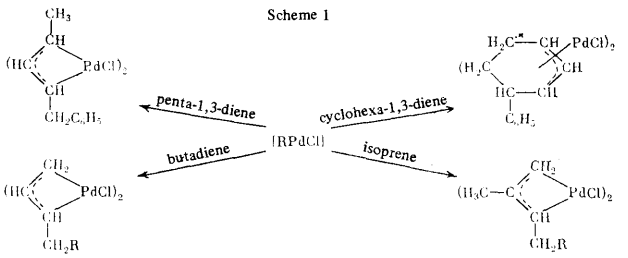
III. INSERTION IN TRANSITION METAL–CARBON σ-BONDS



As a rule, alkyl compounds of transition metals are characterised by a low stability which naturally restricts the range of their reactions with unsaturated hydrocarbons.

1. Conjugated Dienes

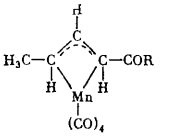
Only one example of a stoichiometric reaction involving the insertion of butadiene in a transition metal–alkyl bond is known at the present time [111]:



The geometrical configuration of the 1-ethyl-π-allyl ligand in this complex was not established by the authors. Butadiene also adds to phenyl(cycloocta-1,5-diene)triphenylphosphinerhodium [112]:

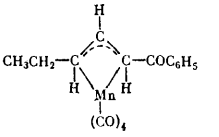
Alkyl- and allyl-palladium chlorides, obtained from $LiPdCl_3$ and the corresponding mercury, magnesium, or tin compounds, react with conjugated dienes to form π-allyl adducts [113]:

Scheme 1



R = CH_3, C_6H_5, *p*-anisyl, or 1-naphthyl

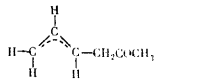
R = C_6H_5 or $C_6H_5CH_2$

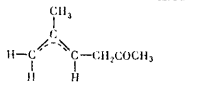


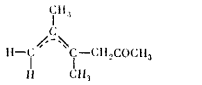
The structure of the adducts in Scheme 1 leads to the conclusion that the mode of insertion of isoprene in Pd–C σ-bonds is the same as in its addition to Pd–H and Pd–acido-ligand bonds (see below).

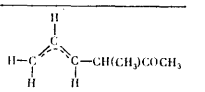
σ-Alkyl and aryl derivatives of manganese, cobalt, and iron carbonyls readily react with 1,3-diene hydrocarbons. The addition reaction is preceded by the conversion of the organometallic compound into an acyl form: the diolefin molecule is inserted in the metal–acyl [M–C(O)–] bond (Tables 5 and 6). The data in Tables 5 and 6 show that the mode of addition of acylmetal carbonyls is determined by the nature of the transition metal in the initial methyl- or acyl-metal carbonyls. Whereas the *cis*-double bond is the most reactive in cobalt complexes and the acyl ligand is attached to the terminal carbon atoms in transoid diolefins, iron complexes react with *cis*-penta-1,3-diene and isoprene to form 1,3- and 1,1-disubstituted π-allyl adducts respectively.

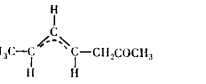
Phenyl- and methyl-manganese pentacarbonyls react with butadiene and *trans*-penta-1,3-diene to form the π-allyl complexes (I) and (II) respectively [118–121]:

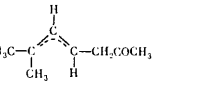


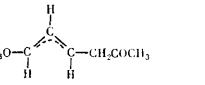


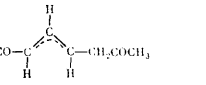


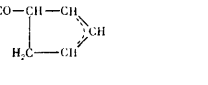






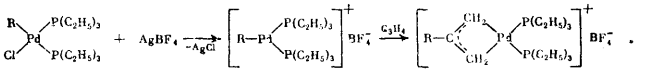






(I)

(II)



R = CH_3 or C_6H_5 .

Table 5. π-Allylcobalt tricarbonyl formed from dienes and $CH_3Co(CO)_4$ or $CH_3COCo(CO)_4$. [114–117]

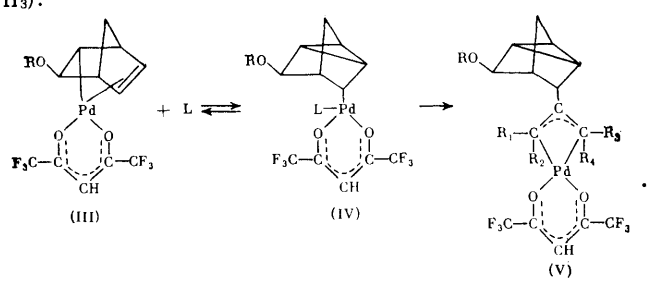
2. Cumulated Dienes

Allene is inserted in the Pt–CH_3 bond with formation of 2-methyl-π-allyl complexes [122–124]. The coordination-unsaturated methyl- or phenyl-bis(triphenylphosphine)-palladium tetrafluoroborates add very readily to allene [125]:



The reactions of cationic vinylplatinum complexes $\{Pt(R^1{=}C{=}CHR^2)[P(OC_2H_5)_3]_2(CH_3COCH_3)\}^+PF_6^-$ (R^1 = CH_3, CF_3, or $COOCH_3$; R^2 = CH_3, CF_3, C_6H_5, $COOCH_3$ or cyclo-C_6H_{11}) react with allene also to form π-allyl products with a 2-alkenyl substituent in the π-allyl ligand [126]. Acyltricarbonylcobalt reacts with allene to form π-allyl complexes containing an acyl group at the central carbon atom of the allyl group [127].

Table 6. The structure of the π-allyl ligands in the iron complexes formed in reactions of $NaFe(NO)(CO)_3$ and CH_3I in the presence of dienes [8].

Diene	Structure of π-allyl ligand

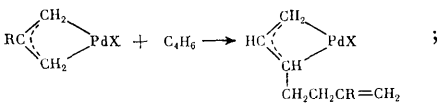
Cyclohexa-1,3-diene	

Allene and 1-methyl-, 1,1-dimethyl-, and 1,3-dimethylallenes are inserted in the palladium–nortricyclenyl ligand σ-bond in complexes (IV) (L = 1,2-diene) arising when allenes react with complexes (III) (R = CH_3CH_2CO or C_6H_5CO). This results in the formation of the corresponding π-allyl complexes (V) (R_1, R_2, R_3, R_4 = H or CH_3): [128]

(III) (IV) (V)

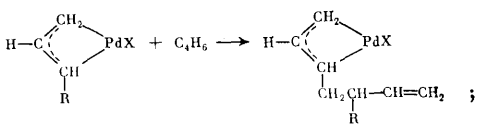
Conjugated dienes (butadiene, isoprene, 2,3-dimethylbutadiene, and *cis*- and *trans*-pentadienes) also readily form complexes of type (IV), in which L is a 1,3-diene coordinated as a monodentate species. However, in contrast to allene, they are not inserted in a Pd–C bond.



IV. ADDITION OF DIENES TO π-ALLYL METAL–CARBON BONDS

The discovery in 1964 of the catalytic activity of the π-allyl complexes of nickel in the polymerisation of 1,3-diolefins [129,130] initiated the systematic investigation of these reactions. However, in the present review we shall not consider in detail the extensive data accumulated at the present time on the polymerisation of dienes under the influence of π-allyl transition metal complexes, attention being concentrated on studies in which the structures of the products of the addition of the 1,3-dienes to the metal–π-allyl ligand bond were rigorously established.

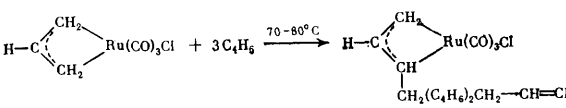
1. Butadiene



Bis-(π-crotylnickel halides) add stereo- and regioselectively to butadiene [131]. Regardless of the nature of the halogen atom, the addition takes place with participation of only the bond between nickel and the unsubstituted carbon atom of the allyl group. Frequent repetition of such steps leads to the formation of polybuta-1,4-diene. The individual stages of this process were investigated in relation to the reactions of bis-(π-crotylnickel iodide) and its deuterated analogues with butadiene, 1,1,4,4-tetradeuterobutadiene, and perdeuterobutadiene [132–141].

The π-allyl complexes of palladium react with butadiene to form 1 : 1 adducts [142–150]:

R = H, CH_3, Cl, $COOCH_3$, or t-C_4H_9; X = acido-ligand.

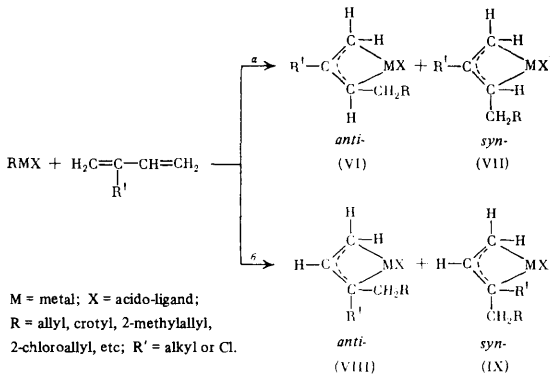


Regardless of the nature of the substituent (R = CH_3, CH_2Cl, Cl, $COOCH_3$, or C_6H_5), in reactions with 1-substituted π-allylpalladium complexes butadiene attacks only the substituted carbon atom of the allyl ligand [143–146,149]:

X = Cl, Br, or hexafluoroacetylacetonate.

When the last two reactions are carried out at a high temperature and a high concentration of the reactants, there is a possibility of the polymerisation of the 1,3-diene [144–146,151–153].

π-Allyltricarbonylruthenium chloride reacts with butadiene to form the product of the insertion of three diene molecules at once [154]:

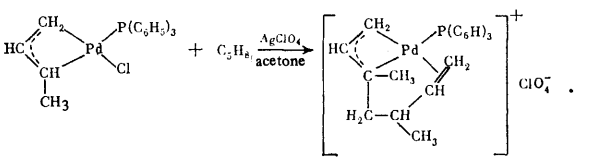


According to infrared spectroscopic data [154], the butadiene units of the complex have the *trans*-1,4-structure.

2. 2-Alkyl-Substituted 1,3-Dienes and Chloroprene

The reactions of these asymmetric dienes with π-allyl complexes of transition metals can lead theoretically to the formation of π-allyl adducts of four types:

Scheme 2

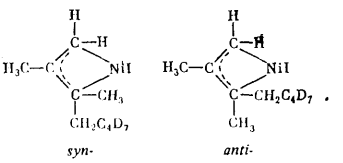


Bis-(π-crotylnickel iodide) reacts with isoprene via both pathways (*a* and *b*). The total fraction of *anti*- and *syn*-1,2-disubstituted complexes (VI) and (VII) is approximately 90%.[155-157] The ratio of these isomers changes during the reaction and tends to a limit, which depends on temperature. During the first period, only the *anti*-complexes (VI) are detected in solution[158,159], but subsequently the latter isomerise to the *syn*-adducts.

The reactions with 2-ethyl-, 2-isopropyl-, and 2-t-butyl-butadienes proceed wholly via pathway *a*.[158-160] The nature of the alkyl substituent has a very significant influence on the ratio of the *anti*- and *syn*-isomers formed. For a long time after the start of the interaction of $(C_4D_7NiI)_2$ with 2-ethyl- and 2-isopropyl-butadienes the concentration of the *anti*-isomers greatly exceeds that of the *syn*-isomers. On the other hand, the adduct of $(C_4D_7NiI)_2$ with 2-t-butylbutadiene exists in the *anti*-configuration (VI) (R′ = t-C_4H_9; R = C_4D_7). The ^{13}C NMR spectra of the 1 : 1 *anti*- and *syn*-adducts of crotylnickel iodide and 2-alkylbutadienes provide an idea about the nature of the distribution of electron density over the π-allyl carbon atoms[161].

In contrast to π-crotylnickel iodide, the π-allyl complexes of palladium react with isoprene only via pathway *b*, yielding 1,1-disubstituted π-allyl complexes (VIII) and (IX) (R′ = CH_3).[143-146,149,162-164] The fraction of the *anti*-isomers (VIII) in the adducts of π-allyl- and π-methylallylpalladium bromides and isoprene is approximately 80%,[146] while bis-(2-chloro-π-allylpalladium chloride)[146,162,163] and 2-chloro-π-allylpalladium hexafluoroacetylacetonate[148] give rise to approximately equal proportions of the *anti*- and *syn*-isomers (VIII) and (IX) (R′ = CH_3, R = CH_2–$CCl=CH_2$). 2-Chloro-π-allylpalladium chloride adds to 2-t-butylbutadiene with formation of a 1,1-disubstituted π-allyl complex in which the chlorobutenyl group is only in the *anti*-position[165].

Structure (X) with a coordinated vinyl group has been proposed for the product of the reaction of π-crotyltriphenylphosphinepalladium chloride with isoprene in the presence of $AgClO_4$, but accurate data for the structure of this compound are not quoted[166]:

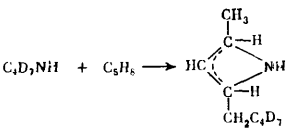


(X)

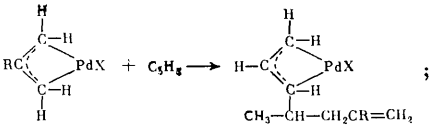
Chloroprene reacts with π-allyl complexes of palladium like isoprene, forming a mixture of the *syn*- and *anti*-isomers of 1,1-disubstituted π-allyl complexes[146,163].

3. 2,3-Dimethylbutadiene

On interaction with 2,3-dimethylbutadiene, π-allyl complexes of nickel and palladium form adducts containing 1,1,2-trisubstituted π-allyl ligands. The ^1H NMR spectrum of the adduct of $(C_4D_7NiI)_2$ and 2,3-dimethylbutadiene showed the presence in solution of complexes having the *syn*- and *anti*-structures[141,160]:



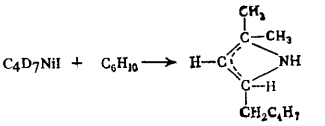
syn- *anti*-



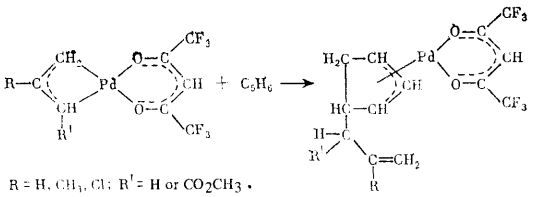
The adducts of the π-allyl complexes of palladium also consisted of a mixture of the *syn*- and *anti*-isomers[149]. In 1-substituted π-allyl complexes of palladium a new carbon–carbon bond is formed between the methylene group of the diene and the substituted carbon atom of the allyl group.

4. Penta-1,3-diene and 4-Methylpenta-1,3-diene

The *cis*- and *trans*-penta-1,3-diene isomers react differently with π-allyl complexes of nickel and palladium. The allyl ligand in the nickel complexes adds to the terminal methylene group of the diene[141,160]:



Palladium compounds react with pentadiene, forming 1-substituted π-allyl adducts[146-149]:

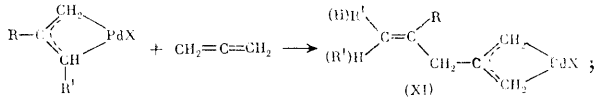


R = H, Cl; X = Cl or hexafluoroacetylacetonate.

[D_7]π-Crotylnickel iodide reacts with 4-methylpenta-1,3-diene to form the 1,3,3-trisubstituted *syn*-π-allyl complex[141,160]:

5. Cyclic 1,3-Dienes

On interaction with π-allyl complexes of palladium, cyclopentadiene forms π-cyclopentenyl compounds[149]:

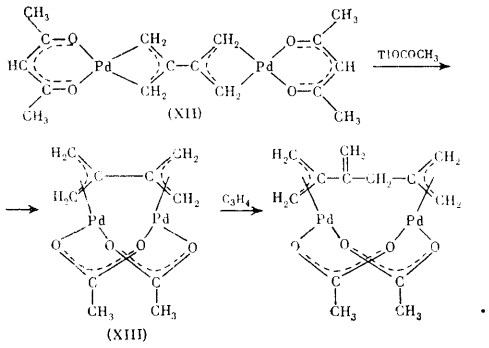


R = H, CH_3, Cl; R' = H or CO_2CH_3.

Palladium 2-chloro-π-allylhexafluoroacetylacetonate adds to cyclohexa-1,3-diene to form the corresponding π-cyclohexenyl complex. Cyclo-octa-1,3-diene is not inserted in the palladium–allyl ligand bond[146,149].

6. Allenes

In contrast to conjugated dienes, allene react with π-allyl complexes of palladium, adding to the less substituted terminal carbon atom of the allyl group[146,148]:



(XI)

R = H, CH_3, or Cl; R' = H, CH_3, Cl, or $COOCH_3$; X = acetylacetonate or Cl.

It is of interest to note that the product of the reaction of bis-(1-chloro-π-allylpalladium chloride) with allene is a mixture of *cis*- (80%) and *trans*-isomers (20%) of compound (XI) (R = H, R' = Cl),[146] which shows that the 1-chloro-π-allyl ligand in the initial complex exists predominantly in the *anti*-configuration.

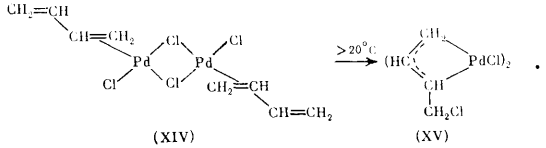
Interaction of π-allylpalladium acetylacetonate with allene results in the formation of compound (XII) in addition to complex (XI) (R = R' = H).[167] If the acetylacetonate ligand in the former compound is replaced by the acetate ligand, the three-bridge complex (XIII) formed under these conditions can combine with yet another allene molecule[168,169]:

(XIII)

The reactions involving the insertion of allene in the bond between the nickel atom and the π-allyl ligand take place in the cyclic oligomerisation of allene by nickel[170–174] and rhodium[175] complexes.

Summarising the available experimental data, it is possible to set up activity series for reactions involving the addition of π-allyl complexes of nickel[141,155–160] and palladium[143,146,149] to 1,3-dienes (Table 7). The data in Table 7 show that the mode of addition of π-allyl complexes of nickel and palladium to diolefins is determined by the nature of the transition metal and the acido-ligand links to it. All the addition reactions examined are characterised by high regio- and stereo-selectivity. Isoprene reacts with nickel derivatives faster than does butadiene; in relation to the palladium analogues, butadiene is more reactive. Among π-allylpalladium halides, the chlorides are more reactive than the iodides; allylnickel iodides react more readily with dienes than do the chlorides.

Table 7. The activity series in the formation of 1 : 1 adducts of the π-allyl complexes of nickel and palladium and 1,3-dienes.



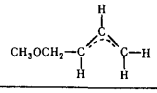
Pd complexes	Ni complexes
Dienes	
Butadiene > isoprene > chloroprene > *trans*-penta-1,3-diene > 2,3-dimethylbutadiene > cyclopentadiene > cyclohexadiene > *cis*-penta-1,3-diene > 2,5-dimethylhexa-2,4-diene	Butadiene < isoprene < 2-ethylbutadiene < 2-isopropylbutadiene < 2-t-butylbutadiene
Substituents in π-allyl ligand	
2-Chloro- > 2-methoxycarbonyl > 1-chloro- > 1-methoxycarbonyl > H > 2-methyl > 1-methyl > 1-phenyl > 2-t-butyl	H > 2-methyl > 2-ethyl > 2-isopropyl ≫ 2-t-butyl
Acido-ligands	
Hexafluoroacetylacetonate > acetylacetonate > Cl > Br > SCN > I	Cl < Br < I

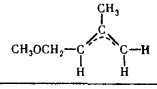
In the palladium complexes a diene molecule attacks the most substituted of the terminal carbon atoms of the π-allyl ligand, while in the reaction of π-crotylnickel halides a new carbon–carbon bond is formed with participation of the unsubstituted carbon atom. Asymmetric 1,3-dienes (isoprene and pentadiene) form adducts with different structures of the π-allyl ligand; palladium forms 1,1-disubstituted and nickel mainly 1,2-disubstituted π-allyl complexes.

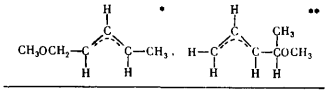
V. INSERTION OF DIENES IN TRANSITION METAL–ACIDO-LIGAND BONDS

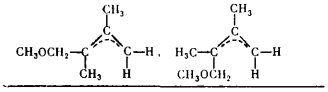
1. Conjugated Dienes

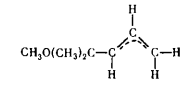
Addition reactions of this type have been described only for palladium compounds. The interaction of butadiene with the palladium salts $(C_6H_5CN)_2PdCl_2$, $PdCl_2$, and $[(olefin)PdCl_2]_2$ at temperatures below −40°C leads to the quantitative formation of the dimeric complex (XIV):[176]

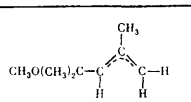


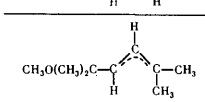


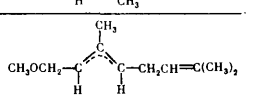


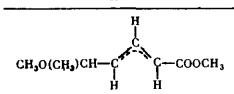








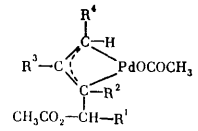




(XIV) (XV)

When the complex (XIV) is heated above 20°C or the interaction of butadiene with the palladium salt is carried out above room temperature, the formation of the π-allyl complex (XV), which is a product of the insertion of the

coordinated butadiene in the Pd–Cl bond, is promoted[176,177]. The addition of palladium chloride to chloroprene takes place with formation of the dimeric 1-chloromethyl-2-chloro-π-allylpalladium chloride[178].



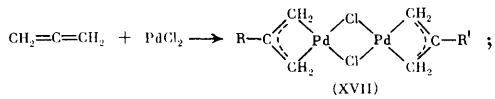
The mechanism of these reactions was studied by Lukas and coworkers[179,180] in relation to the formation of dimeric 1-(1-chloroethyl)-3-methyl-π-allylpalladium chlorides derived from the three isomers of hexa-2,4-diene. If the reaction of the palladium salts with dienes is carried out in an alcoholic medium, then its products are π-allyl complexes with alkoxy-groups. The structures of the π-allyl ligands in the complexes obtained as a result of the interaction of methanol solutions of palladium salts with various dienes are presented in Table 8. Certain cyclic dienes (for example, cyclohexa-1,3-diene) react similarly with palladium salts, giving rise to complexes with cyclic π-allyl ligands containing a methoxy-group in the ring[187]. The stability of these complexes is much lower than that of the corresponding acyclic analogues, which is due to the ease of elimination of the alcohol molecule.

Table 8. The structures of the π-allyl ligands in the complexes formed on interaction of 1,3-dienes with palladium salts in CH_3OH.

Diene	Structure of π-allyl ligand	Refs.
Butadiene		177,181, 182
Isoprene		181–184
Penta-1,3-diene		184
2,3-Dimethyl-butadiene		181
4-Methylpenta-1,3-diene		181
2,4-Dimethylpenta-1,3-diene		181
2,5-Dimethylhexa-2,4-diene		181
cis- or *trans*-Ocimene		185
Methyl sorbate		186

* Principal product at a reaction temperature of 50–60°C.
** Principal product at a reaction temperature of 0–10°C.

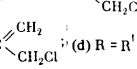
If the interaction of palladium salts with dienes is carried out in acetic acid, complexes with the CH_2OCOCH_3 group at the terminal carbon atom of the allyl group are produced. Butadiene[184,188], isoprene[184,188], and 2,3-dimethylbutadiene[188] react in this way with palladium halides. The π-allyl complexes (XVI) are products of the interaction of palladium acetate with hexa-2,4-dienes ($R^1 = R^4 = CH_3$; $R^2 = R^3 = H$), 2,3-dimethylbutadiene ($R^1 = R^4 = H$; $R^2 = R^3 = CH_3$), and 2-t-butyl-5,5-dimethylhexa-1,3-diene ($R^1 = R^3 = t\text{-}C_4H_9$; $R^2 = R^4 = H$):[189]

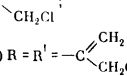


(XVI)

The reactions of diene hydrocarbons with palladium salts in alcoholic media or in acetic acid can be regarded formally as reactions involving the insertion of the diene in the palladium–acido-ligand bond. However, there is good reason to believe at the present time that the nucleophilic methoxide or acetate ions attack directly the diene ligand, resulting in the formation of complexes containing an ether or ester group respectively in the π-allyl ligand[179,183].

The π-allyl complexes with an alkoxy-substituent, generated from butadiene, isoprene, and pentadiene, are intermediates in the carbonylation of these dienes in the presence of palladium chloride[190,191]. The formation of 1-acetoxybutadiene and 1,4-diacetoxybut-2-ene from butadiene and palladium acetate in acetic acid proceeds via the intermediate 1-acetoxy-π-allyl palladium complex[192].





2. Cumulated Dienes

Allene and its homologues (methyl-, dimethyl-, and tetramethyl-allenes) react very readily with palladium chloride, giving rise to π-allyl complexes with various groups at the central carbon atom of the allyl group[182,193–197].

(XVII)

(a) R = R' = Cl; (b) R = R' =  ;

(c) R = Cl, R' =  ; (d) R = R' =  .

The structure of the resulting complex (XVIII) depends on the reaction conditions. If the allene is introduced into a benzene solution of $(C_6H_5CN)_2PdCl_2$, then the product is mainly bis-(2-chloro-π-allylpalladium chloride) (XVIIa). When benzonitrile or methylene chloride is used as the solvent, the complex (XVIIb) is formed; the same compound is produced when allene is passed through a methanol suspension of Na_2PdCl_4. The analogous reaction with $(C_6H_5CN)_2PdCl_2$ leads to approximately equal amounts of complexes (XVIIb) and (XVIId). A dimeric complex with two different π-allyl ligands (XVIIc) is obtained when $(C_6H_5CN)_2PdCl_2$ is introduced into a benzene solution of allene.

The interaction of allene with an acetic acid solution of Na_2PdCl_4 in the presence of sodium acetate leads to bis-(2-acetoxy-π-allylpalladium chloride) (XVII) (R = R′ = CH_3COO).[198] The same complex is a product of the reaction of palladium acetate with allene in benzene in the presence of aqueous NaCl.[199]

The mechanism of reactions of allene with palladium salts, discussed in a number of studies[193,195,197,200], is not altogether clear. Whereas the formation of the complex (XVIIa) apparently involves the simple insertion of allene in the Pd–Cl bond, products containing the dimerised allene can arise via different pathways. At any rate the formation of such complexes does not involve the insertion of a second allene molecule in the Pd–π-allyl bond of complex (XVIIa), because it has been established[197] that this reaction does not occur. Furthermore, such insertion would have resulted in a complex with a different structure of the π-allyl ligand. It has been suggested[197] that the second allene molecule is inserted in the Pd–C bond in the intermediate σ-complex $CH_2=C(CH_2Cl)-Pd-Cl$. There is also a possibility of the dimerisation of two allene molecules in the coordination sphere of palladium with subsequent migration of chlorine from palladium to carbon and the formation of compound (XVIIb).

VI. THE MECHANISM OF STEREOREGULATION IN REACTIONS INVOLVING THE INSERTION OF DIENES IN TRANSITION METAL–LIGAND BONDS

The reactions involving the insertion of dienes in transition metal–ligand bonds are characterised by high regio- and stereo-selectivities. This is due primarily to the fact, despite the significant differences in details, the above processes are based on a coordination mechanism. Preliminary coordination of the diolefin to the transition metal is a necessary condition for the subsequent addition. As a result of coordination, the molecule of the unsaturated compound is not only fixed in a particular configuration, which is responsible for the mode of the subsequent interaction, but, by virtue of its unusual energy state in such a complex, it acquires the ability to be inserted in the metal–ligand bond.

Before being inserted in the metal–ligand bond, the diene forms as a rule a π-complex only in the transition state, which hinders the direct experimental detection of such complexes. However, in a few instances it is possible to isolate intermediates (XIV) of this kind[176].

Preliminary coordination of the diene to the transition metal can be observed indirectly by NMR. For example, the coordination of the diolefin to the palladium atom in π-allylpalladium complexes is responsible for the very rapid merging of the signals due to the *syn*- and *anti*-protons at the terminal carbon atom of the allyl group[148,149,201–203]. The exchange of the *syn*- and *anti*-protons is apparently due to the monodentate coordination of the diene. This is indicated by the satisfactory agreement between the reactivities of many dienes in promoting the *syn*–*anti*-proton exchange[148] and in their reactions with 6-acetoxynorbornenylpalladium(III) hexafluoroacetylacetonate[128]: butadiene $\simeq$ ***cis***-penta-1,3-diene $\simeq$ ***trans***-penta-1,3-diene > isoprene > 2,3-dimethylbutadiene; under these conditions, asymmetric dienes are coordinated via the less substituted double bond.

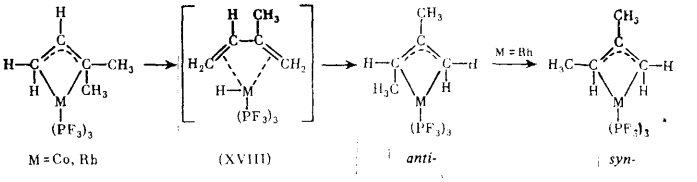
The modern treatment of the nature of the bond in the π-complexes formed by the interaction of the metal with unsaturated compounds, devised by Dewar[204] and Chatt and Duncanson[205] in terms of the molecular orbital theory, has been discussed in many detailed reviews and monographs[206–213]. Here one need only emphasise that dative binding plays a special role in reactions of transition metals. According to the familiar classification of Langford and Gray[214] of ligand substitution reactions involving transition metal complexes, substances capable of dative interaction as a rule react via a bimolecular (associative) mechanism. The interaction between the antibonding orbital of the olefin (diene) and *d* electrons takes place over distances longer than the donor–acceptor bond. This should promote a decrease of the overall activation energy for the formation of the metal–substrate π-complex[212].

It follows from the foregoing that the capacity of the ligand for dative binding can give it an appreciable advantage in coordination to the metal even in comparison with substances having a greater electron-donating capacity and in the case of diolefins can be responsible also for the preferential coordination of the double bond with the lower electron density.

The role of the dative interaction in the formation of the π-complex of a diene and a transition metal can be demonstrated most strikingly in relation to the addition of dienes to bis-(π-allylnickel halides)[131]. The study of the reactions of butadiene with $(C_4H_7NiI)_2$ in a medium containing Lewis bases showed that they can be clearly divided into two groups in terms of their effect on the addition reaction. The first group comprises σ-donors (water, ethers, and tertiary amines), which do not influence the rate and mode of reaction regardless of their σ-donor capacity. The second group includes substances (trialkyl- and triaryl-phosphines or the corresponding phosphites and pyridine), which exhibit a π-acceptor capacity in addition to the σ-donor capacity. Depending on their π-acceptor capacity, the latter substances decrease the yield of adducts or, in the limiting case, fully suppress the addition reaction.

On the basis of these facts, the unique ability of bis-(π-crotylnickel iodide) to initiate the polymerisation of diolefins in an aqueous emulsion[215] can be explained not only by the hydrolytic stability of the nickel–carbon bond, but also by the fact that in the transition state of the reaction the dative binding of the transition metal to tne substrate plays a significant role. In view of the d^8 character of the nickel atom in bis-(π-crotylnickel iodide), the considerable strength of the Ni–I bond, the large *trans*-effect of the iodide anion, and the presence of a diolefin molecule in the coordination sphere of the metal, presumably the insertion process proceeds via an associative mechanism with a pentacoordinate transition state formed with participation of the p_z orbital of nickel[131].

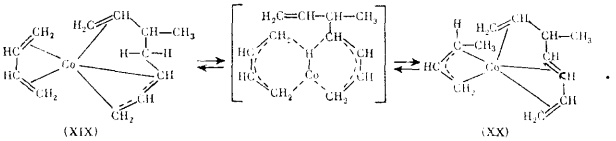
The next stage in the process involving the insertion of the diene in the metal–ligand bond is intramolecular transformation of the π-complex, in the course of which the active ligand (hydrogen, alkyl, allyl, or an acido-group) is bound to one of the carbon atoms of the diene system and a new metal–carbon bond is formed.



It follows from the data presented in Sections II–V that the order in which the diolefin combines with various reagents is determined by the sum of many factors. In contrast to the familiar characteristics, established for the addition of "classical" electrophiles and nucleophiles to diolefins[216–218], which is likely to have an ionic mechanism, the order of addition of transition metal derivatives

is independent of the direction of electron shifts induced in the molecules of these hydrocarbons under the influence of the electron-donating or electron-accepting substituents. The nature of the transition metal, its valence state, the number and nature of the ligands combined with the latter, the polarisation of the substrate molecule in the π-complex, and steric effects play the main role in the reactions which we have been considering. At the present level of our knowledge it is impossible to take into account all these factors in each specific case. However, there is one general very important characteristic of the reactions involving the insertion of diolefins in a transition metal–ligand bond: the addition reaction leads to the formation of only the *anti*-isomers of the π-allyl adducts; the *syn*-complexes are a result of the *anti*-*syn* isomerisation. This situation is illustrated by the examples in Table 9 and also by data obtained in the study of the mechanism of the hydrosilylation of 1,3-dienes under the influence of palladium, nickel, cobalt, and rhodium complexes [219-223].

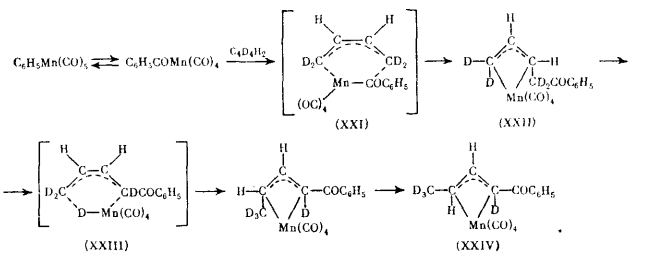
Table 9. The configurations of the π-allyl ligand in the initial and final products of the addition of 1,3-diene to transition metal–ligand bonds.



1,3-Diene	Initial transition metal compound	Configuration of π-allyl ligand		Refs.
		in initial compounds	in final products	
		π-Crotyl		
Butadiene	$HCo(CO)_4$	*anti*- and *syn*-	*syn*-(heating	11-13
Butadiene	$HCo(PF_3)[P(C_6H_5)_3]_3$	*anti*-	*syn*-(heating, addition of electron donors)	16
Butadiene	$CoCl_2 + Zn + P(C_6H_5)_3 + C_2H_5OH$	*anti*-	*syn*-	42,43
Butadiene	$HNi[P(OCH_3)_3]_4HSO_4$	*anti*-(88%) and *syn*-(12%)	*syn*-(95%) and *anti*-(5%) (70°C; 1.4 h)	18
Butadiene	$HFe(CO)_4SiCl_3$	*anti*-	*syn*-(heating)	9
Butadiene	$HPt(ClO_4)[P(C_6H_5)_3]_2$	*anti*-	*syn*-(heating)	34
Butadiene	$HPt(acetone)[P(C_6H_5)_3]_2 \cdot PF_6$	*anti*-	*syn*-(heating)	33,34
		1,3-Dimethyl-π-allyl		
Penta-1,3-diene	$HNi[P(OCH_3)_3]_4HSO_4$	*anti*, *syn*-(100%)	*syn*, *syn*-(80%) and *anti*, *syn*-(20%) (50°C; 0.4 h)	18
Penta-1,3-diene	$HCo(CO)_4$	*anti*, *syn*- and *syn*, *syn*-	*syn*, *syn*-	13
		1,2-Dimethyl-π-allyl		
Isoprene	$HNi[P(OCH_3)_3]_4HSO_4$	*anti*-(62%) and *syn*-(18%)	*syn*-(59%) and *anti*-(24%) (75°C; 0.9 h)	18
		1,2-Disubstituted π-allyl ligands		
Isoprene, 2-ethyl-2-isopropylbutadienes	$(C_4H_7NiI)_2$	*anti*-	*syn*- and *anti*- (heating)	14,16 155-160
2-t-Butylbutadiene	$(C_4H_7NiI)_2$	*anti*-	*anti*-	141,156 158-160

The formation of only the *anti*-isomers of the π-allyl adducts in the first stages of the insertion process suggests that in the transition state of the reaction there is always a *cis*-orientation of the diolefin molecule, which determines the stereoselectivity of the process. The relation between the *cis*-oriented 1,3-diene and the *cnti*-structure of the π-allyl ligand have been established experimentally. Consider, for example, the available data [26,88,89] for the skeletal isomerisation of the 1,1-dimethyl-π-allyl ligand to the 1,2-dimethyl-π-allyl ligand in the tris(trifluorophosphine) complexes of cobalt and rhodium. The proximity of the hydrogen atoms of the *anti*-methyl group in the 1,1-dimethyl-π-allyl complex to the metal permits the transfer of one of them to the metal with formation of the *cis*-dienemetal hydride complex (XVIII):

The migration of this hydrogen atom to the other end of the *cis*-oriented diene determines the ***anti***-structure of the 1,2-dimethyl-π-allyl complex.

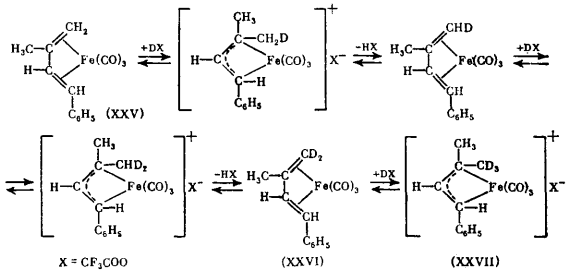


The ease of migration of hydrogen from the *anti*-methyl and *anti*-methylene groups is responsible for the existence of the complex having the general formula $CoC_{12}H_{19}$ in the form of two isomers, (XIX) and (XX), in equilibrium [39,40]. In this equilibrium the transition state is apparently a metallobicyclic complex:

It is easy to account similarly for the structure of the adduct of $C_6H_5Mn(CO)_5$ and butadiene [121] (Scheme 3).

Only the *cis*-orientation of the 1,3-diene in the transition stage (XXI) can lead to the complex (XXII) with deuterium atoms in the *anti*-substituent of the π-allyl ligand. The migration of the deuterium atom nearest to the metal atom via the transition state (XXIII) results in the skeletal isomerisation of the π-allyl ligand. The last reaction stage is the *anti*–*syn* isomerisation with formation of the observed product (XXIV).

Scheme 3

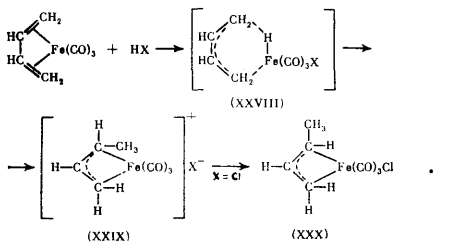


A clear demonstration of the genetic relation between the *cis*-structure of the coordinated diene and the *anti*-configuration of the substituent in the π-allyl complex formed is provided by data for the protonation of the diene complexes of iron [224-235], iridium [236], molybdenum [237,238], and cobalt [239]. For example, the cisoid form of the diene in the butadiene- and pentadiene-iron tricarbonyls is responsible for the selective formation of the *anti*-π-crotyl and *anti*,*syn*-1,3-dimethyl-π-allyl complexes [224,225].

The experimental data for the protonation of butadiene-iron tricarbonyl at low temperatures showed that, regardless of the nature of the protonating agent, the proton adds

exclusively to the *anti*-methyl group of the π-crotyliron complex[226]. Treatment of 3-methyl-1-phenylbutadiene-iron tricarbonyl (XXV) with deuterium chloride yielded a π-allyl complex containing deuterium only in the *anti*-methyl group[227]. In solution in CF_3COOD compound (XXV) undergoes a number of successive transformations leading to the diene complex (XXVI) and the π-allyl complex (XXVII) containing the perdeuteromethylene and *anti*-perdeuteromethyl groups:

Scheme 4

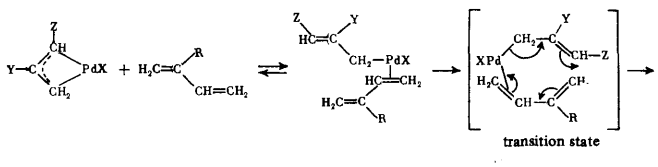


X = CF_3COO (XXVI) (XXVII)

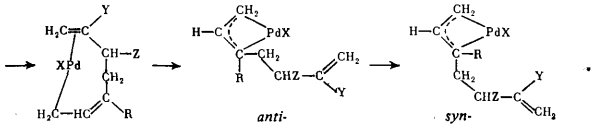
The protonation and deprotonation reactions presented in Scheme 4 proceed via the intermediate hydridodieneiron complexes, whose existence has been demonstrated by a number of data[226,228-231].

The mechanism of the formation of π-allyl adducts, for example, from butadieneiron tricarbonyl and proton-containing acids, can be represented as follows:

Scheme 5



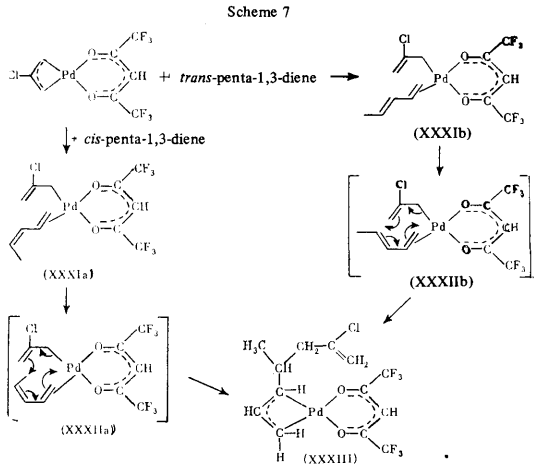
(XXVIII) (XXIX) (XXX)



The first stage of the reaction is the oxidative addition of H–X to the initial zerovalent iron complex ($Fe^0 \rightarrow Fe^{2+}$). The *cis*-structure of the diene in the transition state, which precedes the insertion of the diene in the Fe–H bond in (XXVIII), is responsible for the exclusive formation of the *anti*-π-crotyl complex (XXIX) regardless of the nature of the anion of the Brønsted acid. However, if X = Cl, the latter enters the inner coordination sphere of the iron atom and promotes the rapid *anti*–*syn*-isomerisation of the π-crotyl ligand, giving rise to the observed *syn*-complex (XXX).[232,233] The metallocyclic transition state, analogous to compound (XXVIII), is apparently also responsible for the preferential formation of *cis*-σ-crotylmanganese pentacarbonyl when butadiene reacts with $HMn(CO)_5$.[4]

According to ideas put forward by Hughes and Powell[149], the products of the insertion of dienes in the allyl–palladium bond are formed via a metallocyclic transition state with a *cis*-oriented 1,3-diene. The new carbon–carbon bond then arises outside the coordination sphere of the palladium atom:

Scheme 6



transition state

anti- *syn*-

The proposed mechanism agrees with the order in which π-allyl complexes of palladium add to conjugated dienes and also with the relative reactivity of the latter. For example, the structures of the intermediate π-complexes (XXXIa) and (XXXIb) (Scheme 7), formed on coordination of *cis*- and *trans*-penta-1,3-dienes, explain satisfactorily why the two dienes induce the *syn*–*anti* proton exchange in 2-chloro-π-allylpalladium hexafluoroacetylacetonate at virtually equal rates.

Scheme 7

(XXXIa) (XXXIIa) (XXXIb) (XXXIIb) (XXXIII)

In the transition state generated in the formation of the insertion product (XXXIII) the position of the methyl substituent in the *cis*-pentadiene (XXXIIa) is sterically less favourable than in the *trans*-pentadiene (XXXIIb). This is responsible for the much slower insertion of *cis*-penta-1,3-diene compared with the *trans*-isomer. This stereochemical requirement of a *cis*-planar structure of the diene before the insertion reaction resembles the behaviour of 1,3-dienes in Diels–Alder reactions[240-242].

---o0o---

Thus, summarising the foregoing survey, one must conclude that the formation of *anti*-structures of the π-allyl products of the addition of 1,3-dienes to transition metal compounds is a kinetically controlled process. The subsequent reactions of the *anti*-complexes are determined by thermodynamic and steric factors. The knowledge of the exact chemical compositions of both the initial and final products of the reactions of 1,3-dienes with transition metal compounds is extremely important, since these complexes, involved in the addition reactions of subsequent 1,3-diene molecules, determine the microstructure of the monomeric units of the oligomeric or polymeric molecules formed.

Application of Ion-exchange Resins in Photometry

F.I.Lobanov, G.K.Nurtaeva, and N.V.Makarov

The application of ion-exchange resins in the spectroscopic method of studying complex compounds is discussed. The possible use of ion-exchange resins or poly(vinyl chloride) films impregnated with organic reagents in analytical practice with a photometric detector is examined. 82 references.

I. INTRODUCTION

The new comprehensive programmes of environmental protection have generated new requirements for methods of analytical control of natural waters and waste waters. The foremost needs are for sensitivity, reproducibility, speed, reliability, and demonstrable precision of the relevant measurement, together with the development of analytical methods which can be automated and whose results can be processed on a computer.

One approach to this problem is to develop new analytical procedures (and to improve existing ones) in which a method of detection is combined with an enrichment method. The spectroscopy of ion-exchange resins, in which the wanted element is concentrated in the resin phase before being directly estimated, is a promising example of the newer analytical procedures.

In 1954 Fujimoto[1] studied the colour changes of ion-exchange resins produced by the sorption of various ions: his results have been applied in the development of qualitative and semiquantitative methods of elemental analysis. The first spectrophotometric study of resins was reported by Ryan[2] in 1960. However the full potential of the spectrophotometry of resins as a practical method of quantitative analysis was only demonstrated in 1976 (by a group of Japanese workers[3]).

This review will deal with studies of the spectroscopy of ion-exchange resins in coordination chemistry and in analytical chemistry.

We shall not be concerned with the extensive researches on hydration phenomena which have relied on the spectroscopic characteristics of ion-exchange resins. Molecular interactions during hydration have been studied by i.r. spectroscopy by Zundel over many years, and they are discussed in his monograph[4]. The nature of complex hydrates in ion-exchange resins and the state of the water in these materials, studied by NMR spectroscopy, were recently reviewed by Bystrov and coworkers[5], and further discussion of these phenomena would be superfluous.

II. STUDY OF COMPLEXES BY ION-EXCHANGE RESIN SPECTROSCOPY

Ion-exchange resins are widely used in studies of complex formation to determine the composition and stability of the complexes[6]. Because of the difficulty of determining the composition of complexes sorbed by resins, and of the difference between the forms of the complex in solution and in the resin phase respectively, it is necessary to study the spectral characteristics of the resin phase. Ryan[2,7,8] examined the complex forms of tetravalent and hexavalent actinides sorbed by anion exchange resins. Neptunium, plutonium, and uranium compounds were identified by comparing the absorption spectra of the resins with those of aqueous or non-aqueous solutions of the complexes, and with the spectra of the complexes in the crystalline state. Data on the solubility of the complexes in the various media were required.

In the case of tetravalent actinides sorbed by anion exchange resins from hydrochloric or nitirc acid solutions the anion entering the resin phase is MX_6^{2-}, where M = Pu, Np, Th, U, and X = Cl^-, NO_3^-. We should note that these compounds are sorbed in the presence of both the salts (sodium chloride, calcium nitrate) and the acids of the ligands. On the other hand in an aqueous phase these compounds can exist only at high concentrations of nitric or hydrochloric acid. For example, MCl_6^{2-} (where M = Np, Pu, U) exists in 12 M HCl, $Pu(NO_3)_6^{2-}$ in 13 M HNO_3, $Np(NO_3)_6^{2-}$ in 14 M HNO_3, and $U(NO_3)_6^{2-}$ in 15.7 M HNO_3.

The following mechanism was proposed[2] for the formation and sorption of the complex anions in the resin:

$$M^{+m} + n\,X^{-y} \rightleftarrows MX_n^{-ny+m},$$

$$MX_n^{-ny+m} + \frac{ny-m}{y}\,X^{-y}\,(\text{res}) \rightleftarrows MX_n^{-ny+m}\,(\text{res}) + \frac{ny-m}{y}\,X^{-y},$$

$$MX_n^{-ny+m} + (ny-m)\,H^+ \rightleftarrows H_{ny-m}MX_n.$$

The suggested reactions satisfactorily explain various phenomena observed during the sorption of metal anions by ion-exchange resins: the increased sorption in the presence of acids, the maximum in the curve of distribution coefficient against ligand concentration, and the possible sorption of intermediates formed during the reaction[2].

In the case of the formation of hexavalent actinide complexes in the resin phase the compounds $MO_2(NO_3)_4^{2-}$ and $MO_2(NO_3)_3^-$ are detected, whereas in an aqueous phase the concentration of actinide tetranitrates is very small, and in concentrated nitric acid only $MO_2(NO_3)_3^-$ is formed[7]. The relative concentration of these complex anions in the resin phase is found to be independent of the composition of the aqueous phase, but determined by the properties of the resin (total sorption capacity, extent of saturation by nitrate ions). Before this work it has been generally assumed that the ions entering the resin phase are those already present in solution. Only by using a spectrophotometric method could the difference between the compounds in the two phases be demonstrated. The identification of the actinide tetranitrates in the resin phase relied on the determination of the

charge of the sorbed compounds, on the synthesis of various complexes, and on comparative studies of the optical properties of complexes in the resin phase and in the crystalline state[7].

The sorption of uranyl ions has been studied for fluoride, chloride, bromide, and sulphate systems as well as for nitrate systems[9,10]. Spectrophotometric studies of cation and anion exchange resins after sorption of uranyl compounds gave extensive information on complex formation by the uranyl ion with these ligands, and identified the products of multi-step complex formation reactions (by utilising the selective sorption properties of the resin as a function of resin type and of the nature of the solvent).

The ions UO_2Cl^+ and UO_2Br^+ (identified by their characteristic absorption spectra in the region of stretching vibrations of the U–O bond) are sorbed by the resin from chloride and bromide systems at low concentrations of the halide ion. Fluoride cannot form a positively charged complex with the uranyl ion. Even at very low concentrations of F^- the equilibrium is displaced towards the formation of anionic fluorine complexes. Thus a study of the sorption of halogen complexes of uranyl on a cation exchanger established the following stability sequence of the anionic uranyl complexes with halide ions[9]:

$$F^- > Cl^- > Br^-.$$

The compounds $UO_2F_3^-$, $UO_2Cl_3^-$, $UO_2Cl_4^{2-}$, and $UO_2Br_4^{2-}$ were identified[9] from the visible and i.r. absorption spectra of anion exchange resins after sorption of complex uranyl ions. The coordination numbers and the symmetry of the intermediates were obtained by analysing the spectral characteristics. Thus the $[UO_2X(H_2O)_5]^+$ complexes have a coordination number of 6 and a D_{3h} point-group symmetry. Increasing the number of halogen groups ($UO_2X_3^-$, $UO_2X_4^{2-}$) lowers the coordination number to 4 (D_{4h} point-group symmetry).

Spectroscopic studies of resins used in the sorption of uranyl compounds in the presence of sulphate[10] confirmed the presence of consecutive reactions during the complex formation between uranyl and sulphate. The following compounds were identified: $UO_2HSO_4^+$, $UO_2(SO_4)_2^{2-}$, and $UO_2(SO_4)_3^{4-}$. It was shown that the ion $[UO_2(H_2O)_6]^{2+}$ is sorbed by a cation exchanger from a solution of uranyl sulphate in the absence of an excess of SO_4^{2-} ions. Increasing the concentration of sulphuric acid in the system causes the ion $UO_2HSO_4^+$ to be sorbed by the cation exchanger, whereas in neutral sulphate solutions this ion is not detected. The following compounds were also detected: $UO_2(SO_4)_2^{2-}$ (sorption from solutions containing uranyl sulphate with or without an excess of sulphuric acid) and $UO_2(SO_4)_3^{4-}$ (sorption from solutions containing an excess of lithium sulphate). The force constants f and the radii of UO_2^{2+} were calculated[10] from the U–O stretching vibration frequencies in the i.r. spectra (see Table 1). We note that the replacement of water molecules by SO_4^{2-} groups increases the radius of the UO_2^{2+} ion from 1.719 to 1.740 Å, indicating a change in the nature of the bond during the transition from the hydrated UO_2^{2+} ion to the $UO_2(SO_4)_3^{4-}$ anion.

Choppin and coworkers[11] studied the visible and i.r. absorption spectra of neodymium complexes with various ligands (SCN^-, Cl^-, NO_3^-, NO_2^-, CO_3^{2-}, OCN^-, CH_3COO^-, EDTA) and concluded that the spectra of the ion-exchange resins after sorption of these anionic neodymium complexes are almost indistinguishable from those of the concentrated aqueous solutions.

Most of the reported spectroscopic investigations of complexes sorbed by resins have been concerned with the ions of transition metals such as cobalt, nickel, copper, and iron[12–31]. This work is important not only because it adds to our understanding of the complex formation processes, but also because it highlights possible applications of ion-exchange resins as vehicles for the sample to be analysed by spectroscopic methods, since the formation of complexes by transition-metal ions in aqueous and in non-aqueous media is now well understood. By comparing results for ion-exchange resins containing the sorbed copper cations $[Cu(H_2O)_6]^{2+}$ and $[Cu(H_2O)_5Cl]^+$, and the anions $[CuCl_3(H_2O)]^-$ and $[CuCl_4]^{2-}$, the authors conclude[12,13] that ion-exchange resins are suitable matrices for the measurement of absorption and ESR spectra.

Table 1. Quantitative characteristics of uranyl compounds formed in a sulphate solution.

Compound	Resin	ν_3, cm^{-1}	f	$R_{UO_2^{2+}}$, Å
$UO_2(H_2O)_6^{2+}$	Dowex-50	958	7.625	1.719
$UO_2HSO_4^+$	Dowex-50	950	7.466	1.722
$UO_2(SO_4)_2^{2-}$	Dowex-1	910	6.880	1.738
$UO_2(SO_4)_3^{4-}$	Dowex-1	905	6.805	1.740

Marov and coworkers[14] studied the sorption of the copper cations $[Cu(H_2O)_6]^{2+}$ by a weakly basic anion exchanger containing primary, secondary, and tertiary amino groups, and they explained it in terms of complex formation between Cu(II) and the anion exchanger. This interpretation was confirmed by the ESR spectra. The following mechanism was proposed[14] (in the case of the primary groups) for the interaction between the copper cations and the anion exchanger:

$$4RNH_2 \ldots HOH + [Cu(H_2O)_6]^{2+} \rightarrow [Cu(RNH_2)_4(H_2O)_2]^{2+}.$$

These results are fully consistent with earlier ESR work[15] on the structure of a copper complex sorbed by a weakly basic anion exchanger.

Japanese workers[16] have reported the formation of anionic copper complexes during sorption by anion exchangers, and they have shown that the resins can be used in spectrophotometric studies. They examined the changes in the absorption spectra of the resins (broadening of the absorption peak, extending over the region $\lambda = 400–500$ nm) which occur as the concentration of copper ions in the system is increased. Whereas Heitner-Wirguin and Cohen[12] ascribe this phenomenon to changes in the structure of the sorbed anion (transition from $CuCl_4^{2-}$ to $CuCl_3^-$), these workers[16] assume dimerisation of the copper anions in the resin in contact with a more concentrated solution of copper chloride:

$$2CuCl_3^- + Cl^- \rightleftarrows \left[\begin{array}{cccc} & Cl & Cl & \\ & | & | & \\ Cl-Cu & -Cl- & Cu & -Cl \\ & | & | & \\ & Cl & Cl & \end{array}\right]^{3-}.$$

The formation of $Cu_2Cl_7^{3-}$ was confirmed[16] by applying the previously reported method[17–19] of determining the composition of the complex sorbed by a resin from the distribution coefficient. The quantity $\bar{n}_R$ (the mean

number of ligands in the metal complex within the resin phase) is determined from a plot of $\{\lg D + (\bar{n} - m/l)\lg[L]\}$ against $\lg[L]_R$, where D is the distribution coefficient of the metal M, $\bar{n}$ is the mean number of ligands in the complex, l is the charge on the anion of the ligand, and the subscript R refers to the resin phase. The basic equation for calculating $\bar{n}_R$ can be written

$$\frac{d\{\lg D + (\bar{n} - m/l)\lg[L]\}}{d\lg[L]_R} = \bar{n}_R - \frac{m}{l}.$$

The validity of this method of determining the number of ligands in the complex was tested with the well characterised iron(III)–chloride and cobalt(II)–chloride systems. The final conclusion was that the ion $CuCl_3^-$ is present in an anion exchange resin phase, but an increase in the concentration of copper ions in hydrochloric acid solution leads to the formation of $Cu_2Cl_7^{3-}$ ions.

Waki and coworkers[20] used this method to calculate the stability constants of polyphosphate copper complexes formed in an ammoniacal solution (pH > 10.5) by the reaction

$$Cu(NH_3)_4^{2+} + P_nO_{3n+1}^{(n+2)-} \rightleftarrows Cu(NH_3)_3P_nO_{3n+1}^{n-} + NH_3$$

The following stability sequence of the copper complexes with polyphosphates was established:

$$P_2 > P_3 > P_1 .$$

The difference in the absorption spectra of the resin phase was consistent with the assumed differences in structure.

Rutner[21] has analysed the reflectance spectra of anion exchange resins containing Co(II) and Fe(III) complexes sorbed from chloride solutions. The reflectance spectra of the cobalt complexes have minima at 695, 665, and 635 nm, corresponding to the absorption bands of the $CoCl_4^{2-}$ complex which is formed in the aqueous phase in the presence of 7.25 M HCl. The spectrum of the Fe(III) complex shows a single peak at 362 nm, corresponding to the absorption maximum of the $FeCl_4^-$ complex anion in aqueous solution.

The halogen complexes of cobalt and nickel were studied by Nortia[22], who also concluded that the compounds sorbed by the anion exchanger have the composition MX_4^{2-} (where $M^{2+} = Co^{2+}$, Ni^{2+}, and $X^- = Cl^-$, Br^-, and I^-). He examined[22] the reflectance spectra of the halogen complexes of cobalt and nickel in the resin phase, and he showed that ion-exchange resins can be used as solid solvents for measuring the magnetic moments of these complexes.

Coleman's study[23] of the chloride complexes of cobalt on ion exchangers was conducted at constant concentration of the metal in the resin, which was treated after sorption with gaseous HCl–H_2O mixtures of different component ratio. He showed that the configuration of the complex changes from octahedral to tetrahedral as the concentration of Cl^- increases. The identification of the $CoCl_4^{2-}$ ion in the anion exchanger from spectrophotometric measurements confirms earlier results[21,22].

The coordinational configuration of the cation of an element in the resin phase has attracted a great deal of interest[24-26]. Thus it was shown that Co, Ni, and Cu exist as hydrated ions in a sulphonated cation exchanger saturated with water. On drying the resin (by heating it to 100°C) the i. r. spectra show a decrease in the number of hydrated metal complexes and a corresponding increase in the intensity of the spectral bands arising from the interaction of the metal ions with the sulphonic acid groups of the resin. In contrast to the sulphonated resins, in the case of carboxylic acid resins the metal ions interact with the carboxylic acid groups even in the moist resin[25]. This is consistent with the known relative complexing powers of malonic acid (the monomer of the carboxylic acid resin used in the investigation) and of water.

A series of papers by Heitner-Wirguin and Ben-Zwi[27-31] discusses the Co(II)–X^- system, where $X^- = Cl^-$, NO_3^-, and SCN^-, and identifies the successive steps of the complex formation reaction ($Co(H_2O)_6^{2+}$, $Co(H_2O)_5X^+$, $Co(H_2O)X_3^-$, and CoX_4^{2-}). The cobalt–chloride system was studied in both aqueous and non-aqueous solutions: acetone and ethanol were used as solvents because they form a solvation shell similar to that formed by H_2O in aqueous solutions of the cobalt complex.

III. APPLICATION OF ION-EXCHANGE RESIN PHOTOMETRY IN ANALYTICAL PRACTICE

The changes in optical properties of resins during the sorption of ions were first exploited by a group of Japanese workers[32-34] in the 1950's. The colour changes during the reaction are an indication of the presence of various ions, and they can be used very successfully in qualitative spot tests. Furthermore the depth of colour, estimated visually against a reference scale of standard colours, offers a semiquantitative method of analysis of various ions. Therefore the work on spot tests with resins deserves to be mentioned as the earliest example of the application of resin photometry in analytical chemistry. Qualitative drop tests for various elements, leading to the formation of coloured complexes, chelate compounds, and dyes, are listed in Table 2.

A change in colour may be due also to the formation of a precipitate at the phase boundary[66-68], or to catalytic reactions[69]. Fujimoto[70] proposed the addition of an organic solvent (immiscible with water) after complex formation and sorption. In this case the colour change can be obseved without separating the phases.

Drop reactions on resins can be carried out by two fundamentally different methods[71]: 1) the formation of a coloured compound which is subsequently taken up by the resin phase, and 2) prior impregnation of the resin with the reagent, so that the reaction between the ion to be determined and the reagent occurs within the resin phase. Detailed information on experimental procedure and on the advantages of qualitative drop reactions on resins can be found in a review by Fujimoto[72] and in textbooks[73,74].

A sensitive new photometric method of determining various elements in natural waters, based on the direct measurement of light absorption in an ion-exchange resin containing sorbed ions, was proposed in 1976 by Yoshimura and coworkers[3]. The determination relies on the colour reactions of Cr(VI) with diphenylcarbazide, of Fe(II) with 1,10-phenanthroline, of Cu(II) with Zincon, and of Cd(II) with thiocyanate. These workers[3] only used standard analytical reactions, which they combined with measurements of light absorption by an ion-exchange resin. The sensitivity of this method is more than 10 times greater than that of the direct spectrophotometric method. Table 3 lists some comparative data on the sensitivity of photometric analysis in ion-exchange resins and in aqueous solutions[3]. The measurement error is 5–10%

An improved method of determination of Cr(VI) by the reaction with diphenylcarbazide, using ion-exchange resin photometry, has been described[75]: up to 1 mg litre^{-1} of Cr can be determined in natural waters by using the recommended procedure.

Fujimoto's method of impregnating the resin with the reagent[71] consists in replacing the mobile counter-ions of the polymer network (containing chemically bound ions) by ions of the organic reagent. When the resin is placed in contact with the ions to be determined the latter penetrate into the resin phase where they form the corresponding coloured complexes.

Table 2. Drop reactions on resins.

Tanaka and coworkers[76,77] suggested the use of transparent polymer films based on poly(vinyl chloride) (PVC) to determine various metal ions. They examined[76] the possibility of determining copper, zinc, cadmium, nickel, mercury, and manganese by using PVC membranes impregnated with 1-(2-pyridylazo)-2-naphthol (PAN). Some analytical characteristics of PVC membranes[76] after contact with solutions of these ions are given in Table 4. The optical density was shown to be proportional to the concentration of the metal being determined in the range 10^{-5}–10^{-4} M. Because the absorption by the membrane itself is negligible in the region of absorption by the complexes (550–570 nm) it is legitimate to measure the absorption of the membrane with respect to that of air.

Table 3. Relative sensitivity of the photometric analysis of ion-exchange resins (c_1) and of solutions (c_2). (The quoted figures are the metal concentrations giving an optical density $A = 0.50$.)

Zn^{2+}	558
Cd^{2+}	558
Ni^{2+}	574
Hg^{2+}*	565
Mn^{2+}*	565

*Glycine + NaOH buffer solution; in the other cases NH_4Cl + NH_4OH (pH ~ 10).

A PVC membrane impregnated with bathophenanthroline has been used[77] for the rapid semiquantitative determination of iron in water. Because the reaction between Fe(II) and bathophenanthroline (Bphen) gives the charged complex $Fe(Bphen)_3^{2+}$, the PVC membrane was additionally impregnated with tributyl phosphate. It was shown that the colour developed by the membrane has an absorption peak at $\lambda = 540$ nm. The optimum concentration of hydrogen ions is in the range pH 3–6 (0.1 M acetate buffer). The optical density of the membrane depends on the time of contact between the phases: as Fig.1 shows, the optical density for a contact time of 20 min is significantly higher than for a contact time of 5 min. It is important to note that the optical density remains constant for a long period. The light absorption of the membrane is affected also by the nature of the anion present in solution. For a total anion concentration of 2×10^{-2} M the effect of the anion on the colour of a membrane in contact with a solution of Fe(II) increases in the sequence

$$Cl^- < Br^- < I^- < ClO_4^- < \text{alkylbenzoylsulphonate}.$$

Metal ions which form coloured complexes with Bphen (copper, cobalt, nickel, manganese) interfere with the determination of iron in solutions by a PVC membrane

impregnated with Bphen and tributyl phosphate. Alkali and alkaline earth metals, aluminium, and also the anions sulphate, phosphate, chloride, and nitrate have practically no effect on the determination of Fe(II).

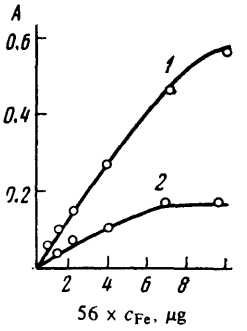

Figure 1. Calibration curves for the determination of iron: contact time 20 min (*1*) and 5 min (*2*).

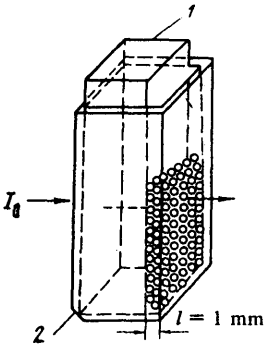

Figure 2. Conventional form of the cell for photometric analysis of the resin: *1*) quartz insert, *2*) drainage hole.

IV. METHODS OF PREPARATION OF SAMPLES FOR ANALYSIS

There are several methods of preparing the sample for photometric analysis (i.e. of preparing a light-absorbing layer uniformly packed with the ion-exchange resin). As in the photometric method of analysis of solutions, one uses quartz cells with parallel walls filled with resin grains[2,3,7,8,11,16,27]. Light absorption is measured 15–20 min after addition of the resin (the time needed to form a uniformly packed layer). In order to obtain the maximum packing density (and thus ensure reproducible results) it may be desirable to use a centrifuge[11,27].

Trace amounts of chromium in natural waters have been determined[75] in a cell with an outlet at the bottom: this allows the solution between the resin grains to be drained away, and helps the formation of a densely packed layer. A common form of the cell is shown in Fig.2. A quartz insert is used to decrease the thickness of the measured layer[8,16,75].

In the quantitative determination of elements[3] corrections must be applied for the light absorbed by the resin, the reagent, and the solution between the grains:

$$A' = A_{meas} - A_{sol} - A_{res} - A_{reag}.$$

Spectral measurements can be made with a mixture of the resin and colourless petroleum jelly, which is either added to the cell[24] or uniformly smeared on a glass plate[20]. Coleman[23] described a method of pressing the resin granules into disks, which are then used for sorption experiments and for light-absorption measurements. These disks are 0.2–0.6 mm thick.

A method of grinding the resin and pressing a mixture of the powdered resin with potassium bromide (or with petroleum jelly) has been used for i.r. spectral measurements[78-82]. Poly(vinyl chloride) membranes impregnated with an organic reagent were prepared [76,77] by dissolving PVC powder, a known weight of the reagent, and the required amount of plasticiser in tetrahydrofuran. After removing the solvent by evaporation the layer was placed between steel plates and pressed in a vacuum at 90°C. There is no information on the effect of lengthy storage on the analytical properties of the membrane.

V. POSSIBLE FUTURE DEVELOPMENTS OF ION-EXCHANGE RESINS IN PHOTOMETRY

The work discussed in this review suggests possible future developments of this area of analytical chemistry. First of all it should be possible to vary several parameters in order to achieve selectivity while increasing still further the sensitivity of the method, taking advantage of the concentration of the coloured complex which the resin offers. Furthermore the fund of knowledge available in the literature on the selectivity and sensitivity of reactions between metal ions and organic reagents still remains to be exploited.

Thus we envisage two main directions for further development, differing in the method used to produce the coloured complex in the resin.

1. The coloured resin is produced by allowing the metal ion to react with the anion of an organic reagent already present in the resin as an impregnant:

$$\text{R—X}^-\text{(res)} + \text{A}^- \rightleftarrows \text{R—A}^-\text{(res)} + \text{X}^-,$$
$$n\text{-R—A}^-\text{(res)} + \text{M}^{n+} \rightleftarrows \text{M(A—R)}_n\text{(res)}.$$

2. The coloured resin is produced by sorption of the complex formed by an organic reagent with the metal ion in the aqueous phase:

$$M^{n+} + m\,HA \rightleftarrows MA_m^{-(m-n)} + m\,H^+,$$
$$R\text{—}X^-\text{(res)} + MA_m^{-(m-n)} \rightleftarrows R_{(m-n)}\text{(res)}\,(MA_m) + (m-n)\,X^-.$$

Each approach has its own specific features and limitations. When further improvements in spectrophotometric apparatus and techniques are introduced, and the existing measurement problems are resolved, we can expect this combined method to be widely adopted in analytical practice for the determination of metal ions in natural waters and in waste waters.

Diffusion of Electrolytes in Polymers

A.L.Iordanskii, A.L.Shterenzon, Yu.V.Moiseev, and G.E.Zaikov

The quantitative aspects of the diffusion of electrolytes in polymers are discussed. Methods of studying diffusion are reviewed. The transport of electrolytes in hydrophilic and in hydrophobic non-ion-exchange polymers is analysed. 179 references.

I. INTRODUCTION

The diffusion of electrolytes in polymers has attracted a great deal of attention in recent years because of the theoretical and practical importance of this phenomenon. The prediction of the protective properties of polymer coatings, the permeability of biological membranes and tissues, dialysis in medicine, the desalination of sea water, the purification of sewer waters: all this is only a partial list of the processes in which diffusion plays a crucial role. Furthermore we can establish the mechanism of the degradation of polymers in aggressive media (solutions of electrolytes) only if we know the diffusion parameters and the state of the aggressive medium, i.e. the degree of dissociation and of interaction of the components of the electrolyte solution with the macromolecules and with the water molecules.

The theory used to discuss the diffusional transport of electrolytes treats diffusion systems as quasi-binary. However we must make allowance for a number of factors which are characteristic of the diffusion of electrolytes though they are irrelevant to other diffusants: dissociation into ions, hydration, interaction of flows, etc. A proper understanding of these factors is the main objective of current research on the quantitative description of the diffusion of acids, bases, and salts in polymers.

II. CHARACTERISTICS OF THE DIFFUSION OF ELECTROLYTES IN POLYMERS

1. The Presence of Ions

Electrolytes in a polymeric matrix can dissociate into ions which (unlike neutral particles) can move under the influence of a gradient in electrochemical potential. There are three main approaches to the description of the diffusional transport of electrolytes in polymers: the Nernst–Planck electro-diffusion equations[1,2], the thermodynamics of irreversible processes[3], and the theory of absolute reaction rates[4,5]. In spite of some differences in the description of the transport process (mainly, the treatment of the membrane as a heterogeneous matrix in the theory of absolute rates and the allowance for the interaction of the diffusion flows in the irreversible theory) all these approaches give mutually consistent results.

By definition, a flow of ions of a given kind (J_i) can be expressed as

$$J_i = u_i c_i A_i, \tag{1}$$

where u_i is the mobility of the ion (referred to unit force), c_i is its concentration in the polymer, and A_i is the generalised driving force of the transport process. Combining Eqn. (1) with the Nernst–Einstein expression for the electrochemical potential

$$D_i = u_i RT \tag{2}$$

and equating concentrations to activities we arrive at the basic Nernst–Planck equation for the diffusion of ions

$$J_i = -D_i c_i \left[\frac{1}{c_i}\frac{dc_i}{dx} + \frac{\bar{V}_i}{RT}\frac{dp}{dx} + \frac{z_i F}{RT}\frac{d\psi}{dx} \right]; \tag{3}$$

where $\bar{V}_i$ is the partial molar volume of the ion i, z_i is its charge, dp/dx and $d\psi/dx$ are the pressure gradient and the gradient of diffusion potential in the membrane respectively, T is temperature, R and F are the gas constant and the Faraday respectively.

In the absence of mobile or fixed charges, and of pressure gradients, Eqn. (3) is equivalent to the formulation of Fick's first law for a binary system of non-electrolytes. In the case of multicomponent diffusion a system of equations of type (3) can be solved by introducing the electroneutrality condition in the absence of electric current and of pressure gradients. In the simplest case (diffusion of a 1–1 fully dissociated electrolyte) the diffusion coefficient (D_{AC}) and the gradient of diffusion potential are given by

$$D_{AC} = \frac{D_A D_C}{D_A + D_C}; \quad \frac{d\psi}{dx} = -\frac{RT}{F}\left(\frac{u_C - u_A}{u_C + u_A}\right), \tag{4}$$

where D_i and u_i are the diffusion coefficient and the mobility of the cation (C) and of the anion (A) in the polymer. The diffusion coefficient of a partially dissociated electrolyte can be expressed as

$$D = [\alpha D_{AC} + 2(1-\alpha) D_n]\left(1 + \frac{d\ln y_\pm}{d\ln c}\right), \tag{5}$$

where α is the degree of dissociation of the electrolyte in the polymer, D_n is the diffusion coefficient of the neutral molecule, $y_\pm$ is the activity coefficient of the electrolyte, and c is the concentration of electrolyte in the polymer[6].

2. Allowance for Several Components

Experimental data for n-component diffusion systems show that each of the independent diffusion flows is a linear function of all the independent concentration gradients. According to the Gibbs–Duhem equation we can have $n - 1$ independent concentration gradients in such a system, giving rise to an equal number of diffusion flows. A full treatment of diffusion by irreversible thermodynamics involves the determination of $(n - 1)^2$ diffusion coefficients, which is a difficult experimental problem.

However in the diffusion of electrolytes the number of freely moving particles (N_0) is not necessarily equal to the number of components: it is given by the expression

$$N_0 = H + n_i - R_0 - 1, \quad (6)$$

where H is the number of types of independently mobile neutral molecules (including water, polymer, etc.), equal to the difference between the total number of types of uncharged molecules and the number of possible reactions between them, n_i is the number of electrolyte ions, and R_0 is the number of ionic reactions[3].

In order to satisfy the Onsager relation[7], which postulates equality of the cross diffusion coefficients, the number of independent D_i coefficients describing the diffusion of N_0 independently moving components must be decreased to

$$D_i = \frac{1}{2} N_0 (N_0 - 1). \quad (7)$$

The determination of a large number of diffusion coefficients in a multicomponent system requires a great deal of diffusion and thermodynamic information, which is seldom available. We usually have to rely on various simplifying assumptions on the relationship between the various diffusion coefficients and on the distribution of component concentrations in the system (see, for example, Refs. 7–9). Multicomponent diffusion is described most exactly by the Stefan–Maxwell equations, which are applied to transport phenomena in gases[10]. In biological systems and in reverse osmosis experiments diffusion is usually described by the Kedem–Katchalsky equations[10,11].

3. Choice of a Characteristic Diffusion System

The overall flow of any diffusing component with respect to an arbitrary system of coordinates (J_{0i}) can be expressed as the sum of a convective flow, due to the motion of the system as a whole with velocity w_s, and a true diffusion flow, measured relatively to the convective flow:

$$J_{0i} = w_s c_i + J_i. \quad (8)$$

The choice of a characteristic velocity depends on the properties of the system and on the method of investigation. The following characteristic systems are most commonly used: the Fick characteristic system, based on measurements of the mean volume velocity, 2) the Hittorf characteristic system, based on measuring the velocity of any one component (for example, the solvent) in the membrane, 3) the centre of mass characteristic system, based on measuring the velocity of the centre of mass, and 4) the lattice characteristic system, based on measuring the rate of displacement of the lattice sites in the crystal. The relationship between the flows and the diffusion coefficients in the various systems is discussed in detail in Ref. 3 (p. 239) and in Ref. 12.

4. Effect of an Unstirred Layer of Electrolyte Solution

When an electrolyte is diffusing in a polymer we often have to consider the effect of a liquid film of solution in contact with the polymer surface and adhering to that surface even when the system is stirred. This immobile layer, called the Nernst layer (see Ref. 2, p. 129), is found in all multicomponent systems. Allowance for the retardation of diffusion near the polymer surface is essential in the case of hydrophilic polymers with a high water content.

The criteria which determine whether the fixed layer can be ignored are discussed by Helfferich[13]. The transport of solute through a polymer membrane in the presence of a Nernst layer is described by the equation

$$J = -Dc\left[l\left(1 + \frac{2cl_N D}{D_N c_N l}\right)\right]^{-1}, \quad (9)$$

where l_N is the thickness of the Nernst layer, l is the thickness of the polymer, and the parameters with the subscript N refer to the solution in which the polymer is immersed. It follows from Eqn. (9) that for $D_N c_N l \gg Dcl_N$ the diffusion process is controlled by the polymer membrane, and for $Dcl_N \gg D_N c_N l$ the Nernst layer is rate-limiting.

The measurement of the thickness of the fixed layer is a difficult experimental problem. Peterson and Gregor[14] have calculated l_N as a function of the stirring rate by combining Eqn. (9) with indirect kinetic measurements. They found that l_N decreases by more than an order of magnitude as the stirring rate is increased. Other methods of measuring the thickness of the liquid layer include a new procedure[15] based on the current–voltage characteristics of the membrane. Measurements of l_N for spherical samples are described in Ref. 16.

5. Interaction Between the Electrolyte and the Polymer

If the polymer contains inorganic groups, strong interactions can occur between these groups and the diffusing electrolytes. A typical example of this behaviour is found in the aqueous electrolyte–polyamide system, discussed below. In polymers which are practically free from polar groups (polyethylene, polypropylene) the interactions between the diffusing components are predominant.

At present there is no general quantitative theory relating the structural parameters of the polymer to the diffusion coefficients of electrolytes within that polymer. An analysis of the diffusion of various electrolytes suggests that polymers can conveniently be classified into three groups according to their water content: polymers which easily dissolve water (> 10 wt.%), polymers in which the solubility of water is limited, and polymers which dissolve very little water (< 1 wt.%). The polymers of the first group are hydrophilic, the others are hydrophobic.

III. METHODS OF INVESTIGATION

1. Methods Based on Measuring the Permeability of the Polymer

The determination of diffusion parameters by measuring permeability consists in measuring the amount of electrolyte transported in unit time through unit area of the polymer film. The diffusion coefficients can be calculated

from data on the rate of transport under steady-state conditions and on the solubility of the electrolyte in the polymer by integrating Fick's equation

$$\bar{D} = q(c_0)\, l/(c_0 - c_p), \qquad (10)$$

where $\bar{D}$ is the integral diffusion coefficient[17], $q(c_0)$ is the rate of transport, and c_0 and c_p are the concentrations of electrolyte in the surface layer of the polymer on the side of the diffusion source (usually assumed to be equal to the solubility in the polymer) and on the side of the detector cell respectively. Under most experimental conditions $c_0 \gg c_p$, which simplifies Eqn. (10). We should note that the calculation of diffusion coefficients by this equation can lead to low values because the quantity c_0 as determined from solubility measurements includes both mobile and immobile (strongly sorbed) forms of the electrolyte[17].

Another method of calculating diffusion coefficients is based on the Frisch equation[18], which in the case of concentration-independent diffusion coefficients reduces to the well known Dienes–Barrer equation

$$D_\theta = l^2/6\theta, \qquad (11)$$

where θ is the time-lag for the electrolyte–polymer system. In general, when D is a function of concentration, it can be expressed in terms of the directly measurable parameters θ and $\bar{P}$ (the permeability)[19]:

$$D_\theta = l^2\left[6\theta + 6\frac{d\theta}{d\bar{P}}\bar{P} + \frac{d^2\theta}{d\bar{P}^2}\bar{P}^2\right]^{-1}. \qquad (12)$$

At temperatures above the glass transition point of the polymer, and in the absence of interactions between the diffusing components, the diffusion parameters determined from the stationary and the non-stationary region of the kinetic curve are usually in good agreement over a wide range of concentration[20]. A variety of measuring cells can be used for the measurement of diffusion coefficients; the apparatus usually consists of two cells separated by the experimental polymer. The measuring cell contains a sensor which detects the arrival of electrolyte by diffusion through the polymer. Various methods of detection have been used: electrical conductivity[21,22], pH measurements[23–25], radioactive isotopes[26–29], chemical analysis[30–33], and optical methods[34]. Some of these methods give a direct measurement of the stationary concentration gradient of electrolyte in the polymer during diffusion. These include the layer removal method[35–37] and the multifilm method[38,39]. Knowing the concentration gradient and the flow of electrolyte we can calculate the diffusion coefficient, but in all these methods some uncertainty arises from the possibility of abnormal effects at the boundaries of the various layers.

Methods based on the measurement of permeability are fairly precise and convenient, but they suffer from the following complications. 1) Interactions between the flows of diffusing species. For example, it has been reported[40] that both the permeability and θ can vary during the counter-diffusion of water and electrolyte, and furthermore a new phase appears within the polymer. 2) Discrepancies between stationary and non-stationary diffusion coefficients. Usually $\bar{D} > D\theta$,[20] which may be due either to relaxation processes in the polymer occurring at a rate comparable to the rate of diffusion or to specific interactions such as water–oxygen interactions in hydrophobic polymers (see below). 3) The samples must be free from interconnected micropores and cracks, which would lead to erroneous results by allowing phase flow.

2. Methods Based on Measurements of the Properties of the Polymer–Electrolyte System

The measurement of diffusion parameters by these methods relies on directly or indirectly monitoring the amount of electrolyte in the polymer as a function of time. The equations describing the sorption kinetics for different initial and boundary conditions are discussed in Ref. 41, which also describes the effect of sample geometry on sorption.

To keep the boundary conditions constant during sorption the amount of diffusant in the solution should be much greater than the maximum sorption in the polymer[41]. The following methods can be used to determine the diffusion coefficients of electrolytes in polymers.

Gravimetric method. This method can be used when the sorption of the different components occurs at widely different rates. Concentration is monitored by the methods listed in the previous section. Complications may arise from interactions between solvent and electrolyte flows. The best results are obtained in studies of volatile electrolytes, whose concentration is determined by desorption into the gas phase in a stream of inert carrier gas[42].

Radioactive isotope methods. These methods are very convenient not only for measuring diffusion coefficients but also for measuring the self-diffusion of individual ions and of associated molecules of the electrolyte.

An interesting application is the measurement of diffusion parameters by isotope exchange reactions in the diffusion-limited regime. The course of the reaction (for example, H–D exchange) can also be monitored by i.r. spectroscopy[43].

Spectral methods. The concentration of diffusant in the polymer can be determined by modern spectral methods: optical[44], NMR[45,46], ESR (if the diffusant is paramagnetic[47,48]), and spin-echo[49].

Electrical conductivity method. Four types of conduction are possible in a polymer under the influence of an electric field: ionic, protonic, electronic, and induced. The first two types are the most important during the diffusion of electrolyte solutions.

A full analysis of the conduction processes requires a knowledge of the extent of dissociation of the electrolyte, its hydration, and its interaction with the polymer. The difficulty of obtaining this information is obvious, and therefore the relationship between diffusion coefficients and electrical conductivity is seldom unambiguous over a wide range of experimental conditions[50]. For example, a transition from the ionic to the electronic mechanism of charge transfer occurs as the water content of the polymer decreases[51]. Temperature has a marked effect on electrical conductivity[52].

In many polymers (especially in hydrogels) we can expect Kohlrausch's law of independent migration of ions to apply:

$$\chi = \sum_i z_i c_i u_i \qquad (13)$$

where χ is the specific conductance and μ_i is the mobility of the ions in an electric field. If Eqn. (13) applies the integral diffusion coefficient of the ion in the polymer ($\bar{D}_i$) can be calculated by the expression

$$R_e^{-1} = \frac{z_i^2 F^2}{RT} c_{pi}\left[\left(\frac{2l_N}{D_N} + \frac{l}{K_i D_i}\right)\right]^{-1}, \qquad (14)$$

where R_e is the electrical resistance of a sample of unit cross-sectional area and length l, c_{pi} is the concentration of the ion in solution, l_N is the thickness of the unstirred layer, and K_i is the distribution coefficient of the ion between the polymer and the solution[1]. If we can ignore the resistance of the Nernst layer Eqn. (14) simplifies to

$$R_e^{-1} = \frac{(z_i F)^2}{RT} \frac{c_{pi} D_i k_i}{l} . \qquad (15)$$

The electrical conductivity is a sensitive function of both the strength and the frequency of the applied electric field. As we increase the voltage the ionic transport process is increasingly limited by the unstirred layers at the surface (rather than by the bulk of the membrane), because the conductivity of the membrane increases sharply with field. At low a.c. frequencies the conductivity is determined by the diffusion-induced polarisation of the unstirred layers. At high frequencies the relationship between the diffusion parameters and the electrical conductivity becomes more complex, because under these conditions the ions do not move across the membrane but merely oscillate within a small region.

The methods of determining mobility from electrical conductivity data have recently been reviewed[1,53]. Correct results are obtained with dilute solutions of electrolytes in porous[54] and in charged polymers[55]. As the concentration of the electrolyte increases the concentration dependence of the conductivity becomes non-linear because of the following effects: the increased potential step at the polymer–solution interface, the increased electro-osmotic flow of the solvent, and the increased relaxation effect[56].

The electrical conductivity of polymer membranes is measured by applying electrodes, which can be classified[57] into three groups: electrodes not in contact with the membrane, platinum electrodes, and mercury electrodes. Mercury electrodes appear to be the best, whereas electrodes of the second group give low results and those of the first group give high results. The methods and circuits used in measuring electrical conductivity are described in Refs. 58 and 59.

Other methods used to measure diffusion parameters include micro-hardness methods[60] and the ion-selective electrode method[61], which has been applied to biological systems.

3. Methods Based on Monitoring the Moving Boundary of Electrolyte in the Polymer

A characteristic form of micro-motion has been observed during studies of diffusion in systems including a polymer and a low-molecular substance: the motion of a diffusion front into the bulk of the polymer. The mean diffusion velocity of the particles is related to the observed macroscopic motion of these particles by Eqn. (8). In practice the rate of displacement of the electrolyte is measured with respect to the surface of the polymer, and therefore Fick's equation is conveniently expressed in terms of the characteristic Hittorf system (see Chapter II) with $w_S = 0$. For a relatively low concentration of diffusant in the polymer the solution of the continuity equation for this system

$$c_i = c_0 \left(1 - \operatorname{erf}\left[\frac{x}{2(Dt)^{1/2}}\right]\right) \qquad (16)$$

applies to a semi-infinite solid bounded by a plane at $x = 0$ and having initial ($c = 0$ for $x > 0, t = 0$) and boundary conditions ($c = c_0$ for $x = 0$, $t > 0$). Assuming that $c/c_0 = \text{const}$, i.e. monitoring the motion of a fixed concentration $c = c_X$, we obtain

$$x = \lambda t^{1/2}; \qquad (17)$$

where x is the depth of permeation of a boundary of diffusant of constant concentration c_X in time t, and λ is the permeation coefficient. The depth of permeation of the diffusant in the polymer can be determined by a variety of methods: autoradiographic[62], optical[63], interferometric[64], or by acid–base indicators[65].

The latter method is the most widely used, but it is difficult to apply to the polymer–electrolyte system. Two types of result have been reported in the literature: 1) different indicators change colour at almost the same value of x (suggesting an anomalous distribution of diffusant in the polymer (steep front), or that the chosen indicators have similar pK values), and 2) the colour change of different indicators occurs at different values of x. From these results we can determine the true distribution of diffusant in the polymer only if the relationship of the pK values of the indicators in the polymer matrix to those in water has been established by independent experiments. The concentration gradient of the electrolyte is assumed to be not very steep, so that the colour changes of indicators with different pK in the polymer will occur in different regions of the c–x curve. Thus the observed depth of permeation should be a function of the type of indicator used.

In organic solvents the mechanism of the colour change of the indicator is seldom known, and the pK values have not been determined. Furthermore the transition from aqueous to non-aqueous or mixed solvents often causes inversion of the pK values. For example, the colour change of Methyl Red in water occurs at a higher pH than that of Bromophenol Blue, but in alcoholic solutions the opposite is true. Since acids and bases in polymers can be treated (to a first approximation) as mixed solutions, all the uncertainties associated with the use of indicators in non-aqueous and mixed solvents apply to our system. Therefore, with rare exceptions (e.g. gels) the method of acid–base indicators cannot be used to measure the concentration of an acid or a base in a polymer matrix. We can only conclude that the concentration of acid in the coloured part of the resin is greater than in the colourless part.

Because of the difficulty of measuring concentration in a polymer many workers confine themselves to determining the "depth of permeation" at some time τ, or they use the poorly substantiated expression

$$D = x^2/a\tau, \qquad (18)$$

where a is an arbitrary number.

We should stress that the use of this formula can lead to an incorrect treatment of the often reported concentration dependence of the diffusion coefficient. It is better to use Eqn. (17), and to express the variation of λ with concentration by Eqn. (16).

Mention must be made of a method of correctly determining diffusion coefficients from the velocity of a diffusant front of constant concentration without a knowledge of c_X and c_0 (see Ref. 50, p. 209).

The description of the diffusion process becomes even more complicated in the presence of interactions between the electrolyte and the solvent, or of relaxation processes leading to a rearrangement of the polymer structure. These effects will be considered below.

IV. HYDROPHILIC POLYMERS

Hydrophilic polymers include those in which water is easily soluble [poly(vinyl alcohol) PVA, cellulose, etc.) and those in which water has a moderate solubility (polyamides, some polyesters, etc.). The diffusion of electrolyte in ion-exchange polymers has been studied in great detail, and several monographs on this topic have recently been published[2,13,66]. It is not the purpose of this review to discuss specifically the processes which occur in ion-exchange polymers, but we shall nevertheless examine some of their basic features when the conclusions are equally applicable to non-ion-exchange polymers.

1. State of the Electrolyte in Polymers

Some attempts to measure pH in a resin phase have been based on doubtful assumptions. One estimate[67] was made from the colour change of an indicator sorbed by the resin, another[68] by measuring the degree of dissociation of amino-acids in an adsorbed state. The results show a large difference between the pH values in solution and in the polymer, but they cannot be used to evaluate the dissociation constants of the ionogenic groups.

Three methods of determining the dissociation constants of electrolytes in polymers by applying the law of mass action are known: the spectrophotometric method[69,70], the sorption method[71], and the conductimetric method[69].

Table 1. Dissociation constants of electrolytes in polymers containing 60–70 wt.% of water (pK_1 is quoted for ampholytes).

System	pK_{diss}	References
PVA – H_3PO_4	3.1	69
PVA – *m*-nitroaniline	2.6	69
Dowex-50 – *m*-nitroaniline	2.5	70
Sulphonated polystyrene – glycine	2.5	71
KU-2 × 4 – glycine	2.3	71
KU-2 – glutamic acid	2.2	71

Dissociation constants measured in various polymer–electrolyte systems are listed in Table 1. The pK values are close to the corresponding values for aqueous solutions. The small difference between the pK values in the resin and in solution is explained by selective absorption of one of the forms of the sorbed electrolyte. For example, in the case of aliphatic amino-acids the selectivity of the resin towards the univalent cation is small, and not very different from the selectivity towards the zwitter-ion: hence the pK of the acid in the polymer is practically the same as in water. The selectivity for bivalent cations is higher as a result of the electrostatic interaction with the charged groups of the resin, and the dissociation of the amino-acid is displaced towards the formation of the bivalent cation[71]. The equality of the pK_1 values of phosphoric acid in poly(vinyl alcohol) and in water can be explained either by the presence of micropores in the polymer, allowing access to the aqueous solution[72], or by the formation in the polymeric alcohol of structures having the same affinity towards the ions as the aqueous solution.

We note that in the PVA–H_2O–KCl system (in the same concentration range) the dielectric constant (which influences the dissociation of the electrolyte) is lower than in water by a factor of two, whereas the kinetic parameter (electrical conductivity) is an order of magnitude lower[73].

The dissociation of sulphuric acid in polycaproamide has been studied by an electrical conductivity method[74]. By making a number of assumptions the authors concluded that sulphuric acid can dissociate in the polymer containing as little as 6% of water. Only the first ionisation is significant, with $pK_1 = 2.5$.

The behaviour of ions is largely determined by their hydration. It has been shown[75] that the self-diffusion coefficients of the alkali metal cations in sulphonated polystyrenes increase in the sequence $Li < Na < K < Rb < Cs$, in qualitative agreement with the radii of the hydrated cations. The influence of hydration on the self-diffusion of ions in these polymers is confirmed by the relative values of the self-diffusion coefficients of multivalent ions ($Th^{4+} < In^{3+} < Ca^{2+} < Na^{+}$), since it is well known that the number of water molecules in the hydration shell of an ion increases with the valency of the ion.

On increasing the parameter which characterises the stability of the hydration shell of anions $(z_i/(r_i - 0.25)$, where r_i is the crystallographic radius of the ion) a proportionate decrease was observed in the ability of salts to diffuse into cellulose acetates ($NaNO_3 > NaCl > NaF > Na_2SO_4$), accompanied by a change in selectivity in the opposite sense[77].

2. Main Theories of the Diffusion of Electrolytes in Polymers

The following theories have been proposed to explain the diffusion of electrolytes in polymers.

The Mackie and Mears theory[78] ascribes the lower diffusion coefficients of electrolytes in hydrophilic polymers (as compared with aqueous solutions) to the increased diffusion path produced by the presence of the macromolecules. In the absence of interaction between the functional groups of the polymer and the ions this effect can be allowed for by introducing the factor $[(1 + \varphi_2)/(1 - \varphi_2)]^2$, where φ_2 is the volume fraction of the polymer.

The discrepancy between experimental and calculated diffusion coefficients necessitated the introduction of a correction for the difference in viscosity (as compared with aqueous electrolytes)[79]. However the validity of this correction is doubtful because of the ambiguity of the concept of viscosity in polymers[80].

The Yasuda theory[81–83] is a development of the free volume theory specifically aimed at hydrophilic polymers. It is assumed that the free volume of a swelled membrane is determined by the mole fraction of solvent (φ_1). The diffusion coefficient of the electrolyte in the membrane becomes

$$\lg D = \lg D_w - k\varphi_1^{-1}, \qquad (19)$$

where D_W is the diffusion coefficient of the electrolyte in water and k is a proportionality constant related to the volume taken up by the migrating electrolyte and to the free volume of the whole system. Fig. 1 shows a plot of the logarithm of the diffusion coefficient of sodium chloride in copolymers based on polyacrylamide with different amounts of hydroxyl groups against the mole fraction of water in the polymer. Eqn. (19) is not obeyed at low mole

fractions of water. Two important conclusions stem from this theory: 1) in the case of ions we expect a linear plot of $\lg D$ against $\lg D_w - q_i$, where q_i is equivalent to the cross-sectional area of the ion, and 2) the higher the water content of the membrane, the less marked is this relationship.

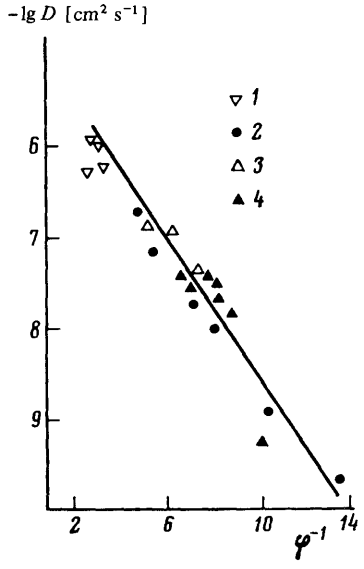

Figure 1. Diffusion coefficients in copolymers with different hydroxyl group contents against volume fraction of water in the polymer[81]: 1) hydroxyethyl methacrylate, 2) copolymers of methyl methacrylate with glyceryl methacrylate, 3) ditto with hydroxyethyl methacrylate, 4) ditto with hydroxypropyl methacrylate.

Boyd's approach[84] is a further development of previous theories. The decrease in mobility of ions upon being transferred from water into ion exchange polymers can be explained by three effects: a) the decrease in diffusion cross-section due to steric hindrance by the polymer network, b) the increase in the length of the diffusion path due to the need to avoid the polymer network, and c) interactions with pore walls. The relative importance of these three factors depends on the nature of the polymer and of the diffusant.

The model of Medley[85] and Marshall[86] is used to explain the dependence of the diffusion coefficients on the structure of polymers in which the solubility of water is limited. For example, in contrast to the case of high water solubility, the water dissolved in polyamides cannot form a continuous aqueous environment for the motion of the electrolyte in the polymer matrix. The water exists mainly near the polar end-groups, and to a lesser extent near the amide bonds. The ions diffuse by activated jumps from one polar group to another, passing through regions of low dielectric constant. For example, in polyhexamethylenediamine the distance between two nearest groups having the same charge is 30–40 Å, which probably determines the jump length.

If we assume that polyamides exist in a zwitter-ion form, the active centres for the diffusion of ions are the positively charged amino-groups, and those for the diffusion of protons the carboxyl groups.

Measurements of spin–spin and spin–lattice relaxation times for the polyamide–water system as a function of composition have shown that up to 0.5 wt.% of water can be present as water molecules strongly bound to the amide bonds. When the water content is increased from 0.5 to 8.0 wt.% the mobility of the water molecules in the polymer gradually increases to a level approaching the mobility of free water molecules. Addition of sodium chloride also increases the mobility of the water molecules: this effect is explained[87] by the ability of electrolytes to break down the clusters of H_2O molecules formed in the polymer.

3. Concentration Dependence of the Diffusion Coefficient

The most characteristic feature of the diffusion of electrolytes in hydrophilic polymers is the concentration dependence of the diffusion coefficients, which can arise in general from the following factors: a) a change in the degree of dissociation of the electrolyte, b) non-ideality of the thermodynamic behaviour of the polymer–electrolyte system, c) swelling of the polymer, causing increased mobility of the polymer segments, d) binding of the electrolyte by the ionogenic groups of the polymer.

We shall examine each of these factors separately. In practice factors b) and c) can be excluded by studying the diffusion of dilute solutions of electrolytes in polymers free from ionogenic groups and previously saturated with solvent.

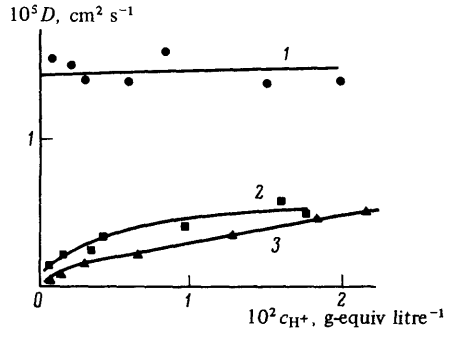

Figure 2. Concentration dependence of the diffusion coefficients of acids in PVA[25]: 1) HCl, 2) H_2SO_4, 3) H_3PO_4.

a) Concentration dependence of the diffusion coefficient due to changes in the degree of dissociation of the electrolyte

The effect of factors a) and b) stems directly from Eqn. (5). Fig. 2 shows the concentration dependence of the diffusion coefficients of acids in poly(vinyl alcohol) at 25°C. The diffusion coefficients were measured under steady-state conditions from the change in concentration of hydrogen ions in the measuring cell[25].

For a fully dissociated electrolyte (e.g. a dilute solution of HCl) Eqn. (5) can be simplified to

$$\bar{D}=D_{AC}\equiv D_{H^+(Cl^-)}, \qquad (20)$$

Solutions of H_2SO_4 of similar concentration show substantial dissociation up to the second ionisation, and hydrogen ions diffuse through the polymer matrix with the counterions HSO_4^- and SO_4^{2-}. Allowance for dissociation leads to the equation

$$\bar{D}=D_{H^+(HSO_4^-)}\left[1+2\left(\frac{f-2}{[c_{H^+}/K_2+2]^2}\right)\right], \qquad (21)$$

where c_{H^+} is the concentration of hydrogen ions, K_2 is the second dissociation constant of sulphuric acid, and $f=D_{H^+}(SO_4^{2-})/D_{H^+}(HSO_4^-)$. In the case of the weaker acid H_3PO_4 only the first ionisation is important in this range of concentrations:

$$\bar{D}=D_{H^+(H_2PO_4^-)}\left[1+\frac{2\beta}{K_1}c_{H^+}\right], \qquad (22)$$

where $\beta=D_{H_3PO_4}/D_{H^+}(H_2PO_4^-)$, and K_1 is the first ionisation constant of phosphoric acid.

During the diffusion of phosphoric acid in poly(vinyl alcohol) some of the diffusant molecules are bound in the polymer matrix and do not contribute to the mass transfer. In Eqn. (22) all the parameters relate to the free molecules of phosphoric acid.

The concentration of acid bound to the polymer is calculated by the Langmuir equation.

Table 2. Diffusion coefficients (10^6D, $cm^2\,s^{-1}$) of the ionised forms of acids in PVA and in water[25].

Ionised form of the acid	PVA	Aqueous solution
$H^+(Cl^-)$	14.4	30.0
$H^+(HSO_4^-)$	5.9	12.0
$H^+(SO_4^{2-})$	1.8	3.6
$H^+(H_2PO_4^-)$	1.2	16.1

The diffusion coefficients in PVA of HCl, H_2SO_4, and H_3PO_4 (a strong monobasic acid, a dibasic acid, and a partially dissociated acid) calculated by Eqns. (20) and (22) are given in Table 2. These values are quite close to the diffusion coefficients of the same acids in water. We may conclude that in a polymeric matrix containing 78 vol.% of water the presence of the polymer has little effect on diffusion, because the molecules and the tons of the acid are effectively screened by the water from interactions with the polymer. Hence the only obstacle to diffusion is the need to avoid the PVA macromolecules (except in the region of low concentrations). The theory of Mackie and Mears, which allows for this type of obstacle[78], yields diffusion coefficients close to the experimental values.

The self-diffusion coefficient of the hydrogen ion is approximately an order of magnitude greater than the self-diffusion coefficients of the anions and of the undissociated molecules in PVA.[69] This very high mobility of the proton is difficult to explain in terms of size only, particularly since the protons in the polymer matrix are in a hydrated state. The anomalously high value of $D^0_{H^+}$ is probably due to the specific mechanism of migration of the proton in a hydrophilic matrix, similar to the "relay" mechanism[88].

b) Concentration dependence of the diffusion coefficient due to thermodynamic non-ideality of the polymer–electrolyte system

In the previous section the diffusion of an acid was treated as the diffusion of an electrolyte showing practically ideal thermodynamic behaviour. However as the volume fraction of water decreases we must expect the polymeric molecules to influence the diffusion of the electrolyte, and the system to deviate from thermodynamic ideality. Thus, in the case of a polymer containing 38 vol.% of water the experimental diffusion coefficients of phosphoric acid are different from the values calculated by Eqn. (22). It is reasonable to assume that the difference is due to non-ideality of the diffusion system: in this case we obtain from Eqn. (5) the expression for the mean molar activity coefficient of the ions ($y_\pm$)

$$\lg y_\pm = 0.869\int_0^{c^{1/2}}\frac{D/D^0-1}{v}\,dv, \qquad (23)$$

where $v=c^{1/2}$. Graphical solution of this equation gives $y_\pm$. The results are discussed in Ref. 69.

c) Diffusion complicated by relaxation processes

In polymers close to and below the glass transition temperature the diffusion processes cannot be described in terms of Fick's equations with constant boundary conditions and with a diffusion coefficient depending only on concentration. Diffusion under these conditions is usually termed anomalous.

Anomalous diffusion is characterised by the following criteria[89]: a) the sorption plots of M_t/M_∞ against $t^{1/2}/l$ (where M_t and M_∞ are the amounts of electrolyte sorbed at time t and at equilibrium respectively) are not monotonic, but show characteristic points of inflection or are S-shaped; b) the kinetic sorption curves depend on the thickness of the sample; c) the plots of permeability against time can have maxima or minima in the non-stationary portion, and the time-lag does not obey the modified Frisch equation (12); d) the displacement of the moving boundary of the electrolyte solution is proportional to t^n (where $\frac{1}{2}<n\leqslant 1$) rather than to $t^{1/2}$ [as required by Eqn. (17)].

Several theories have been proposed to describe anomalous diffusion in polymers, but they can all be reduced to two: the molecular relaxation model and the diffusion–convection model[90].

The molecular relaxation model allows for the structural rearrangement of the macromolecules accompanying the penetration of the diffusing species into the polymer matrix[91,92]. At temperatures close to and below the glass transition temperature of the polymer the relaxation times of the molecular segments are similar to (or greater than) the characteristic times of the diffusion process. The case in which the rate of transport is limited only by the relaxation of the macromolecules is often called type II diffusion to distinguish it from diffusion according to Fick's law, which is termed type I diffusion. The criterion for type I diffusion is the applicability of Eqn. (17) to the motion of the diffusant boundary[93].

The effect of molecular relaxation is a time-change (by the first-order equation) in the concentration of diffusant in the surface layer [90,92] or in the diffusion coefficient [91]. For example, the change in surface concentration (c_t) with time is described by the equation

$$c_t = c_0 + (c_\infty - c_0)(1 - \exp[-t/\bar{\tau}]), \quad (24)$$

where c_0 is the surface concentration of diffusant at $t \to 0$, c_∞ is the equilibrium concentration of the diffusing species in the polymer, and $\bar{\tau}$ is a proportionality coefficient which characterises the mean relaxation time of the macromolecules [94,95].

Solution of Fick's equation with asymmetric boundary conditions [a surface concentration varying according to Eqn. (24)] for steady-state transport leads to the expression [96]

$$\frac{\theta}{l^2} = \frac{1}{6\bar{D}} + \bar{\tau}\left(1 - \frac{c_0}{c_\infty}\right) l^{-2}. \quad (25)$$

Eqn. (25) has the following properties: a) it explains the dependence of the diffusion coefficient $D\theta$ obtained from the non-stationary portion of the permeation curve upon the thickness of the sample; b) it explains the difference between diffusion coefficients determined under stationary and non-stationary conditions respectively; c) it shows that the time-lag experimentally observed in relaxing systems is equal to the sum of the time-lag associated with diffusion by Fick's law and of the time to reach the equilibrium concentration in the surface layer (characterised by the parameter $\bar{\tau}$).

Though the molecular relaxation model can explain a wide range of experimental results it relies on a number of empirical parameters whose physical significance is not always sufficiently clear. Therefore a full understanding of the effects involved in anomalous diffusion is impossible without additional information, obtained independently.

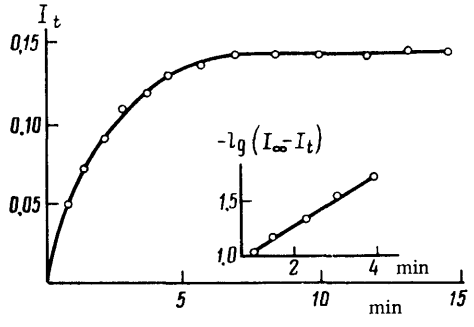

Figure 3. Time dependence of the intensity of absorption of an aqueous solution in PVA at 1675 cm^{-1}. Insert: graphical solution of Eqn. (24) [99].

The diffusion–convection model applies to strongly swelled glassy polymers. In the limit we observe the motion at constant speed of a sharp front separating the swelled outer layer from the unswelled inner layer [93,97]. In this case the motion of the liquid as a whole, under the influence of various forces, causes transport of the electrolyte dissolved in the liquid at a rate equal to that of the liquid. In some cases the motion of the front of diffusant can occur by an intermediate law,

$$x = \lambda t + \lambda t^{1/2}, \quad (26)$$

which is the sum of Fick's law diffusion and type II diffusion. The diffusion–convection model satisfactorily accounts for the experimental results except when the sorption curves are concave to the time axis [90].

The relaxation and the convection model described above can explain practically any anomalous diffusion phenomenon (except those associated with micro-cracking of the polymer [98]) and, in spite of some lack of physical clarity, they are the only means of describing and interpreting diffusion processes in glassy polymers.

In PVA below T_g we expect the relaxation processes to be slow, and to influence the surface concentration of diffusant. A change in the concentration of the aqueous solution in the surface layer of a PVA film (equivalent to 1% of the total thickness of the film) has been observed experimentally [99] by total internal reflection in the i.r. region. The choice of this thickness of surface layer was arbitrary, and determined primarily by the sensitivity of the measurement. Since a concentration gradient is produced in this layer, the calculation was based on an average concentration $\bar{c}_t$,

$$\bar{c}_t = \int_0^{l_m} c(x)\,dx/l_m,$$

where l_m is the effective depth of penetration of the light beam. The change of $\bar{c}_t$ with time was described by Eqn. (24). Fig. 3 shows the absorption intensity at 1675 cm^{-1} as a function of time for the surface layer of PVA, and a graphical solution of Eqn. (24). The $\bar{\tau}$ values are found to depend on the structure of the polymer.

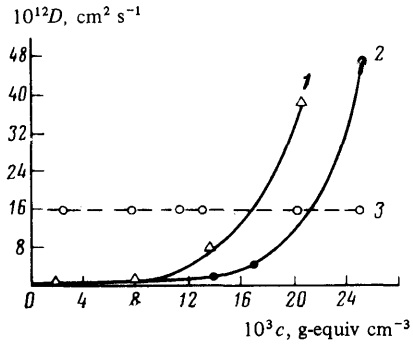

Figure 4. Concentration dependence of the diffusion coefficients in a polyamide [86] of: 1) HBr, 2) H^+, 3) Br^-.

d) Concentration dependence of the diffusion coefficient due to the presence of ionogenic groups in the polymer

The most detailed studies of the concentration dependence of diffusion coefficients relate to the sorption of acids by polyamides. Most workers report a large increase in diffusion coefficient with the concentration of electrolyte in solution [100–108] (see Fig. 4). These results

are explained by assuming that the electrolyte (acid) is sorbed successively by the amino groups and the amido groups of the polyamide, which exists in a zwitter-ion form. The causes of the observed increase in diffusion coefficient are the following.

1. The relative number of mobile ions in the polymer increases (as compared to the ions sorbed on the ionogenic groups).

2. The dielectric constant of the polymer increases with the concentration of the polar diffusant, leading to enhanced dissociation of the acid electrolyte and to generation of the more mobile ionic forms (protons).

3. The transfer of the acid from the amino to the amido sorption region shortens the distance between the positively charged groups of the polymer. This increases the probability of the "jump" of an anion from one positively charged group to the next through the non-polar medium provided by the weakly swelled polymer[86]. For example, keratin contains approximately 30 times more charged groups than Nylon-66, and as a result the self-diffusion coefficients in keratin are ~ 300 times greater than in Nylon. On the other hand uncharged molecules diffuse at comparable rates in these polymers, confirming the important role of electrostatic interactions in the polymer.

In the case of sulphuric acid the increase of the diffusion coefficient with concentration is due to the greater mobility of the hydrogen sulphate as compared with the sulphate ion[85]. It is assumed that the ratio of the first and the second dissociation constant of sulphuric acid is the same in the polymer as in the solution.

Table 3. Self-diffusion coefficients (D, $cm^2\ s^{-1}$) of ions and of alcohols in polyamides[85].

Diffusant	Polycaproamide	Poly(hexamethylene diamine)	Keratin
H^+ (free)	—	$3\cdot10^{-8}$	$8\cdot10^{-6}$
H^+ (bound)	—	$6\cdot10^{-13}$	$1.2\cdot10^{-10}$
Br^-	—	$6\cdot10^{-11}$	$2\cdot10^{-8}$
HSO_4^-	$1.1\cdot10^{-6}$	$6.8\cdot10^{-10}$	$2.2\cdot10^{-8}$
SO_4^{2-}	$1.9\cdot10^{-7}$	$2.0\cdot10^{-13}$	10^{-11}
CH_3OH	—	$1.0\cdot10^{-7}$	$1.0\cdot10^{-7}$
C_2H_5OH	—	$6\cdot10^{-8}$	$6\cdot10^{-8}$

The diffusion coefficients of the proton were calculated independently by the Nernst–Hartley equation[6], assuming that the mobility of the proton is determined by the concentration of free ions. The anomalously high mobility of the proton in the polymer (as compared with other ions, see Table 3) suggests a special transport mechanism, similar to the "relay" model[6].

4. Effect of Water on the Diffusion of Electrolytes

When considering the diffusion of aqueous solutions of electrolytes in polymers with a high affinity for water we must inquire into the extent to which the transport of the electrolyte is affected by the competing (or independent) transport of water, and also into any structural changes in the polymer under the influence of a solvent as specific as water.

Studies of the diffusion of pure water in polymers are discussed in a number of reviews[109–111], and the kinetics and mechanisms of the sorption and diffusion of water in polymers are examined in detail. We shall only be concerned with those features of the transport of water which influence the mechanism of diffusion of electrolytes in polymers.

In the absence of capillary flow we have to consider two types of water transport: a) the diffusion mechanism, in which the driving force is a concentration gradient, and b) the viscous flow of water, in which the driving force is a difference in hydrostatic pressure between the two sides of the membrane. The relationship between the hydraulic (G) and the diffusional ($\bar{P}$) permeability is given by the dimensionless coefficient w according to the equation[112]

$$w = GRT/\bar{P}\bar{V}_{H_2O}, \qquad (27)$$

where $\bar{V}_{H_2O}$ is the molar volume of water. The parameter w is unity for the diffusion mechanism, and increases as we move towards a viscous flow regime.[113]

We must identify the type of transport if we wish to interpret the kinetic results correctly and to arrive at valid conclusions on the interactions between the flows of water and of electrolyte in the polymer. In the diffusion mechanism this interaction is unlikely, but in the case of viscous flow of the solvent through a membrane we can expect interaction between the flows of the components of an aqueous solution of electrolyte[113]. Since most diffusion measurements are made without an excess hydrostatic pressure of solvent we can assume that diffusional transport is predominant (at least, in the case of moderately swelled polymers).

The absence of interaction between opposing flows of electrolyte and of water in a hydrophilic system (acetyl cellulose) has been demonstrated[114] by comparing the forward and the reverse osmosis of sodium chloride solutions.

When discussing the ingress of an aqueous solution of electrolyte into a polymer we must consider the water content of the polymer matrix, since the specific state of the electrolyte (i.e. its dissociation and its hydration) are determined by it. Furthermore active absorption of water weakens the intermolecular interactions, increasing the mobility of the polymer segments and hence increasing the diffusion coefficients.

Another factor which must be considered when discussing the diffusion behaviour of electrolytes is the state of the water in the polymer. Three types of system can be formed by the interaction of the polymer with water: a) the water dissolves in the polymer with formation of a uniform, quasi-homogeneous medium, b) local groupings (clusters) are formed[109,115–117]), and c) the interaction results in filling of the macro-structural holes, pores, and capillaries (which may be either interconnected or isolated)[118,119].

Recent work by electrical conductivity and NMR methods (among others) has shown that macromolecular gels contain both free and quasicrystalline water[120]. The transition temperature of the latter form is below 0°C. In addition to these two forms we must also consider an intermediate form with its own distinct electrophysical and thermal properties[121,122].

The great variety of possible structural forms of the solvent in polymers makes it difficult to identify the mechanism of ion transport.

5. The Moving Electrolyte Boundary

The diffusion of electrolytes in hydrophilic polymers may involve, as was stated above, on the one hand specific interactions between the components of the diffusing

medium and the polymer and on the other hand interactions between the components themselves in the polymer matrix. Depending on which of these effects is predominant the motion of the electrolyte solution can occur as a single front or as a macroscopic distribution of flows. Experiment shows that the former situation is more typical of polymers in which the solubility of water is limited.

Fig. 5 shows the change in concentration of water and HCl in a film of ethyl cellulose during the diffusion of hydrochloric acid vapour. The concentration of water was determined gravimetrically, and that of HCl by a chemical desorption method and by a combustion method [123].

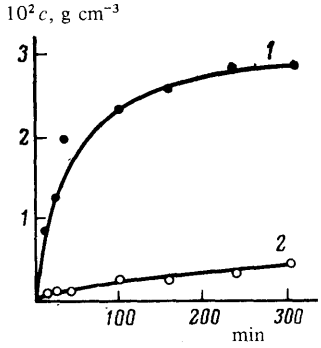

Figure 5. Kinetic curves for the sorption of H_2O (*1*) and HCl (*2*) in ethyl cellulose [123].

The diffusion of electrolyte solutions in polymers very often gives rise to a sharp boundary between a region containing the electrolyte and a region in which no electrolyte is detected by the analytical method employed. The reasons for the formation of this sharp boundary have been discussed [124-126], and the following explanations have been suggested: a) a chemical reaction between the components of the diffusion system, and b) a sharp change in the structure of the polymer at the boundary between the swelled and the free zone.

The interaction between an acid and water has been shown [19] to produce a boundary of constant concentration of electrolyte whose motion is described by Eqn. (17) with

$$\lambda = [2D(c_0/c_x - 1)]^{1/2},$$

if the electrolyte and the solvent are diffusing as a single front, and

$$\lambda = (\pi D)^{1/2}(1 - c_x/c_0),$$

if the electrolyte and the solvent are diffusing at different rates as separate flows. For example, the diffusion of an aqueous solution of sulphuric acid in polycaproamide is typical of case a). The calculated value $D = (1.5 \pm 0.2) \times 10^{-9}$ cm^2 s^{-1} is close to D_{H_2O} in polycaproamide. The time for contact between the two oppositely moving fronts in diffusion from both sides has been used [127] to calculate diffusion coefficients. The motion of the boundary in the polymer in its most general formulation is discussed in Ref. 128.

V. HYDROPHOBIC POLYMERS

One of the main characteristics of the transport of an electrolyte in hydrophobic polymers is the large difference in the rates of diffusion of different electrolytes. For example, the penetration of nitric acid through a Fluorlon-42 film 0.1 mm thick can be detected in 20–30 min, whereas over a year is needed with sulphuric acid [129]. In many cases the diffusion of electrolytes in these polymers is immeasurably slow.

We should note that permeability (as opposed to non-permeability) of a polymer by a particular electrolyte can usually be established with greater confidence. This is because the failure to observe permeation may be due to inadequate sensitivity of the method of detection or to insufficient time for diffusion. Evidently in this case it is better to characterise the permeability by the quantity $\bar{P}_{arb}$, calculated by the equation

$$\bar{P}_{arb} = c_{min} Vl/s\tau_0,$$

where c_{min} is the minimum concentration of electrolyte which can be detected by the chosen analytical method, and V is the extent of the medium in which transport is taking place through a film of thickness l and working surface s in time τ_0. If no penetration is detected we can only state that the true permeability of the system is less than $\bar{P}_{arb}$.

Table 4. Diffusion coefficients of electrolytes in hydrophobic polymers (c is the concentration of electrolyte in the aqueous solution).

Polymer	Electrolyte	c, wt.%	Temp., °C	D, cm^2 s^{-1}	Method of detection	References
Polyethylene	HNO_3	98	50	$2.9 \cdot 10^{-7}$	sorption	134
Polyethylene (NP)	HCl	28—36	50	$8 \cdot 10^{-7}$	sorption	135
Polyethylene (NP)	NaCl	1—10	20	$(6-8) \cdot 10^{-11}$	radio-isotope	136
Polyethylene (NP)	NaI	—	24	$2.2 \cdot 10^{-8}$	radio-isotope	137
Teflon-4	HNO_3	98	50	$2 \cdot 10^{-9}$	sorption	134
Teflon-4	NaI	—	24	$9.6 \cdot 10^{-9}$	radio-isotope	137
Teflon-4	NaCl	1—10	20	$2-3 \cdot 10^{-11}$	radio-isotope	136
Teflon-3	HNO_3	98	50	$7.7 \cdot 10^{-9}$	sorption	134
Teflon-3	NaI	—	24	$9.6 \cdot 10^{-9}$	radio-isotope	137
Polystyrene	NaI	—	24	$25 \cdot 10^{-8}$	radio-isotope	137

The permeability of polymers to electrolytes has been compared with the volatility of the electrolytes [130-132], with the conclusion that the permeability of hydrophobic polymers to involatile electrolytes is at least three orders of magnitude lower than their permeability to volatile electrolytes. The low diffusivity of involatile electrolytes is ascribed to negligible sorption of these electrolytes in polymers. This classification into volatile and involatile electrolytes is useful in qualitative predictions of the permeability of polymers towards specified electrolytes by using only generally available tabulations. After studying the transport of electrolytes in polyester resins Alt [133] classifies electrolytes as "strongly diffusing" (HCl, HF, HNO_3, H_2SO_4), "weakly diffusing", and "involatile". We must stress the arbitrariness of the distinction between "volatile" and "involatile" electrolytes. For example, the permeation of sulphuric acid through Fluorlon is easily detected at high temperatures and concentrations, when the vapour pressure of sulphuric acid is only a few thousandths of a mmHg.

Many measurements of the diffusion coefficient D in polymers have been reported, but in most cases the method used was inadequate[50]. Some results obtained by acceptable methods (see Chapter III) are listed in Table 4. We note the following facts. The diffusion coefficients of NaI in all the polymers examined are similar ($\sim 10^{-8}$ cm^2 s^{-1}), and almost three orders of magnitude higher than the diffusion coefficient of NaCl, although the molecular weight of NaI is almost twice that of NaCl. Obviously, the D value for sodium iodide is anomalously large: this may be due to reduction of the iodide ion to I_2.[138] The diffusion coefficients of HCl and HNO_3 in polyethylene are similar, and their relative values are consistent with expectations from the molecular weights of the two acids. They are of the same order of magnitude as the diffusion coefficient of benzene in polyethylene (at "zero" concentration) 1.32×10^{-7} cm^2 s^{-1}.[17] The diffusion coefficient of NaCl is several orders lower than the diffusion coefficients of HCl and HNO_3. No explanation of this fact has so far been offered.

1. Effect of the Concentration of Electrolyte in the External Solution on the Transport Parameters

The effect of the concentration of electrolyte in the external solution on the diffusion coefficients in the polymers presents a difficult problem. For example, in the polyethylene–HNO_3 system the D value decreases by a factor of 1.5 when the concentration of the acid is increased from 45 to 60%.[134] However these results are not very reliable, because they were obtained from kinetic data on the change in weight of samples immersed in aqueous solutions and they do not describe the diffusion of the acid itself. An analysis[139] of kinetic sorption curves gave very complex results. Evidently, the Johnston equation (which can be used to calculate D for a one-component diffusant) is not directly applicable to these systems.

The D value for nitric acid in polyethylene was found[140,141] to increase from 3.2×10^{-10} to 9×10^{-10} cm^{2}s^{-1} as the concentration of the acid in the external solution changed from 7 to 80%. It was determined by measuring (as a function of time) the electrical conductivity of a membrane in contact with the acid solution. These results are three orders of magnitude lower than the more reliable results reported in Refs. 134 and 142. The discrepancy probably arises from the failure to detect the diffusion of neutral particles in the electrical conductivity method.

The diffusion coefficients of HCl and H_2SO_4 in films of the KhSL lacquer (based on a perchlorovinyl resin) have been measured[27] as a function of concentration of the acid solution. At 60°C the coefficient D_{HCl} increases from 3×10^{-9} to 7.5×10^{-9} cm^2 s^{-1} as the acid concentration increases from 25 to 30%, and $D_{H_2SO_4}$ increases from 4×10^{-10} to 19×10^{-10} cm^2 s^{-1} as the concentration increases from 50 to 90%. The authors ascribe the concentration dependence of D to the transport of particles of different kind and different size from solutions of different concentration.

We have studied[135] the concentration dependence of D_{HCl} in polyethylene. The diffusion coefficients were determined by the method of Dienes and Barrer, and they were also calculated by the formulae

$$\bar{D} = \bar{P}[c\rho]^{-1}, \tag{28}$$

$$D = \frac{1}{\rho}\frac{d\bar{P}}{dc}, \tag{29}$$

where ρ is the density of the polymer and c is the concentration of HCl in the polymer. For comparison we also measured D for dry HCl at different partial pressures. We found that $\bar{D}$ increases with the concentration of the acid, approaching the value for dry HCl. The latter is independent of the partial pressure of HCl. The differential diffusion coefficient was found to be independent of the concentration of hydrochloric acid and equal to D for dry HCl. These observations were explained and quantitatively described by postulating the presence of "free" HCl and "hydrated" HCl in the polymer[135].

It was also assumed that the hydrated molecules are practically immobile and do not contribute to the transport process. The conclusion was that under steady-state conditions D_{HCl} does not depend on the concentration of hydrochloric acid. On the other hand under non-stationary conditions the effective diffusion coefficient varies because some of the diffusing molecules of acid are bound in hydrates, and therefore the integral diffusion coefficient $\bar{D}$ depends on the concentration of water in the polymer. The following equations for the concentration dependence were obtained:

$$\begin{gathered}\bar{D} = D_0\gamma, \\ \bar{D} = D_0(1 + MK\sigma^n_{H_2O}h^n_{H_2O})^{-1},\end{gathered} \tag{30}$$

$$D = D_0\left[1 + \frac{6n\,(Kc_{H_2O})^{n-1}}{[(n-1)+2][(n-1)+3]} + \frac{6\,(Kc_{H_2O})^n}{(n+2)(n+3)}\right]^{-1}, \tag{31}$$

where γ is the activity coefficient of HCl in the polymer, defined as the ratio of the concentration of "free" molecules to the total concentration of HCl in the polymer, D_0 is the diffusion coefficient of the free HCl molecules, c_{H_2O} is the concentration of "free" water molecules in the polymer, and the other symbols are defined above. From the $\bar{D}$ values determined by the method of Dienes and Barrer, together with Eqn. (31), we found the value of n (the number of H_2O molecules associated with one hydrated HCl molecule) to be 4.13 ± 1.69, which can be compared with the value obtained from sorption measurements[129–131] ($n = 5.01 \pm 1.28$). Thus consistent values of n were obtained in independent series of experiments, giving indirect confirmation of the validity of our postulate of hydrate formation. We should stress that these results were obtained for a single "polymer–acid" system, over a restricted range of HCl concentrations (28–34%), and at a single temperature (50°C), and therefore the problem of the dependence of the number of molecules in the hydrate upon the nature of the polymer and of the acid, the concentration of the acid, and temperature is still unsolved.

A rapid increase in the permeability of polymers with concentration of the electrolyte solution has been reported[130,143]. It is pointed out[131] that this rapid growth can be explained by assuming proportionality between the permeability and the vapour pressure of the electrolyte above its aqueous solution (which increases very rapidly with concentration). The concentration dependence of the permeability of films towards volatile electrolytes is accurately described by the expression

$$\bar{P} = \bar{P}_0 h, \tag{32}$$

where $\bar{P}_0$ is the permeability constant, independent of the concentration of electrolyte in the external solution, and h is the vapour pressure of the electrolyte over the aqueous solution[132,144]. Eqn. (32) was tested by studying the permeability of films to HCl, HF, and HNO_3.

2. Effect of the Nature of the Polymer on the Transport Parameters

Experimental data on the effect of the nature of the polymer on the diffusion coefficients of electrolytes are very few. We see from Table 4 that D_{HNO_3} in polyethylene is much greater than the diffusion coefficients in Fluorlons. This is consistent with the conclusion that gases have relatively low diffusion coefficients and relatively high solubilities in fluorine-containing polymers [145]. However in the case of the involatile electrolyte NaCl the diffusion coefficients in polyethylene and in Teflon are very similar. This may be due to differences in the diffusion mechanisms of HNO_3 and NaCl. Indirect information on the effect of the nature of the polymer on the diffusion coefficients of electrolytes in the polymer can be obtained from data on the permeation constants [Eqn. (17)].

The permeation coefficient is a function not only of the diffusion coefficient but also of the concentration of electrolyte solution in the surrounding medium. Sometimes it is also a function of the chosen method of detection [146]. Therefore it is important to ensure that when permeation coefficients are compared they are obtained under identical external conditions. The functional relationship between the permeation coefficient and the diffusion coefficient (and other factors) is not known in general. The following empirical relation applies to some systems [147]

$$\lambda_0 = A_0 h_a^b, \qquad (33)$$

where λ is the permeation coefficient, A_0 and b are empirical constants, and h_a is the vapour pressure of acid over the solution. For many polymer–electrolyte systems D can be evaluated from data on the concentration dependence of permeation coefficients [65].

The diffusion coefficients of NaOH, HCl, and H_2SO_4 in Pentaplast (3,3-bis(chloromethyl)oxacyclobutane polymer) have been measured [148]. At 40°C they are 1.4×10^{-5}, 0.4×10^{-5}, and 1.7×10^{-5} $cm^2\ s^{-1}$ respectively (radiometric method). These values are surprisingly high: thus, D_{HCl} in NP polyethylene, a material in which diffusion coefficients are relatively high, is only 8×10^{-7} $cm^2\ s^{-1}$. These high values of D are all the more remarkable in view of the low values of the permeability constant and of the permeation constant of HCl in Pentaplast in comparison with other polymers [149]. Equally surprising are the unusual dependences of the diffusion coefficients for volatile and for involatile electrolytes for water and nitric acid upon the logarithm of the permeation constants of these polymers for HCl. It follows that polymers can be classified according to their permeability towards electrolytes, as had been done previously for their permeability towards gases [150]. Fluorlon-3M has the lowest permeability of all the polymers examined. Within the Fluorlon series we note a clear correlation between the permeability for HCl and the permeabilities for HNO_3 and H_2O. The permeability for the latter diffusants is always much greater than that for HCl.

The introduction into hydrophobic polymers of polar substances or polar groups (carboxyl, carbonyl, or amino) invariably increases the permeability towards electrolytes, possibly as a result of increased sorption of the diffusant [142,151–153].

3. Effect of Temperature on Transport

The linearity of the plots of $\lg D$ against reciprocal temperature has been noted by many workers. The activation energies for diffusion E_D were calculated from these plots: some of the reported E_D values are listed in Table 5. Comparing these values with the activation energies for the diffusion of gases and vapours of similar molar volumes [17,50] we note that the former are somewhat lower. The cause of this phenomenon has not yet been analysed.

Table 5. Activation energy for the diffusion of electrolytes in polymers.

Polymer	Electrolyte	E_D, kcal mole^{-1}	Refs.
Poly(ethylene terephthalate)	H_2SO_4 (53%)	12	177
Poly(vinyl chloride) (plasticised)	HNO_3 (60%)	14	176
Poly(vinyl chloride)	HCl	3.3	176
Teflon-4	HNO_3 (98%)	4.5 (>323 K) 12.1 (<323 K)	134
Polycarbonate	HNO_3	10	178
Polyethylene	HNO_3 (98%)	4.3	179

Linear relationships are found also between the logarithm of the permeability constant λ and reciprocal temperature [147,154], but the physical significance of the "activation energies" calculated from these results has not been discussed.

The activation energy of the permeability has been determined [144] for HCl diffusing through polyethylene (PE), polystyrene, and poly(ethylene terephthalate): 8.5, 4.3, and 10 kcal mole^{-1} respectively. These values are typical of activated diffusion processes.

4. Views on the Transport Mechanism of Electrolytes in Hydrophobic Polymers

In the earlier work the permeation of electrolytes was treated as diffusion through interconnected pores (see, for example, Refs. 129, 155, and 156). However this model could not explain factors such as the high selectivity of the films, the concentration dependence of the permeability, and the high activation energies involved. A full analysis of the experimental information on the permeation of gases through polymer films has shown that in sufficiently thick films and at temperatures above T_g the mechanism of transport is diffusion rather than motion through a system of pores [157]. Therefore most workers now believe that the transport of electrolytes through hydrophobic polymers also occurs by diffusion.

These views on the mechanism of transport in hydrophobic polymers do not take account of the defects which may be present in a particular sample (for example, thin films may contain pores extending across the whole thickness of the sample, which are absent in thicker films of the same material). Transport associated with the presence of micro-defects has been discussed in some recent papers [158,159]. In particular, defects can be produced in polyethylene films by irradiation with a mercury lamp [160].

Various views have been expressed on the nature of the diffusing particles. According to some, the diffusing species are individual ions (hydrated, or not hydrated). According to others the diffusing species are undissociated molecules freed from their hydration shell. The resolution of this problem is complicated by the failure of some workers to distinguish between particles present in the polymer and particles responsible for matter transport.

The polymer must contain some particles able to transport matter, but there is no justification for the assumption that all particles present in the polymer can contribute to the transport process.

Let us consider the validity of the assumption that electrolytes are transported as ions in hydrophobic polymers. The concentration of ions in these polymers is probably low: this follows both from general considerations of the dissociation of electrolytes in media of low dielectric constant [161] and from experimental data. Films in contact with solutions of electrolytes keep a high electrical resistance [132,162]. In contrast, the electrical resistance of a hydrophilic film of PK-4 polyamide decreases by 7 orders of magnitude in 20–40 min after immersion in a solution of ammonium hydroxide [132]. Calculation shows [132] that if the whole of the HCl sorbed by polyethylene from hydrochloric acid solution were in an ionic form the electrical conductivity of the film would be 10 orders of magnitude higher than the experimental value. (See also Refs. 163 and 164 on the formation of ion pairs in polymers.) The fact that polyethylene films in contact with electrolyte solutions have a higher conductivity than films with metallic contacts has been ascribed to the adsorption of ions on the film surface [165,166].

The active conductance of plasticised poly(vinyl chloride) (PVC) is found [167] to be increased by diffusion of HCl: even involatile acids such as phosphoric acid diffuse readily in plasticised PVC [168,169], possibly as a result of the "hydrophilisation" of PVC by the plasticiser. The increase in electrical conductivity of hydrophobic polymers resulting from the addition of polar plasticisers has been discussed [170] in terms of the increased mobility and concentration of the ions in the polymer. Another possible explanation of the change in conductivity and dielectric constant of the films is chemical interaction between the diffusing species and the film, analogous to that observed in the "polyethylene–nitric acid" system [167].

It has been pointed out [170,171] that the activation energy for conduction is much higher than the activation energy for the migration of small molecules in polymers, the values for polypropylene and polystyrene being 34.6 and 30 kcal mole^{-1} respectively. These high activation energies for conduction are observed because they include contributions from the energy of the ionic "jump" (corresponding to the activation energy for molecular diffusion) and from the energy of formation of the ion (which is inversely proportional to the dielectric constant of the medium [172]). It has been suggested [170] that the ionic conductivity is determined mainly by ionisation under the influence of the electric field. In the presence of a sufficiently strong field the energy barrier is lowered and the conductivity increases as a result of the increased concentration of ions [173]. Thus the transport of electrolyte as ions in a hydrophobic polymer seems unlikely in the absence of an external electric field.

The hypothesis that transport occurs by undissociated molecules is supported by the following facts. The rate of transport of HCl through films of polyethylene, polystyrene, and poly(ethylene terephthalate), and of ammonia through polyethylene, does not depend on whether the electrolytes are diffusing from an aqueous solution or from the dry gas phase: in other words, the rate of transport under steady state is unaffected by the presence of water in the external phase [131,144]. Hence we conclude that the transport involves the same particles in both cases, and that these particles must be undissociated molecules free from their hydration shell since no other particles can be conceived in the case of diffusion from the dry gas. The lack of hydration shells around the diffusing molecules can be inferred also from the observed lack of dependence of the rate of transport of water from acid solution upon the nature of the acid. If the electrolyte were transported by hydrated particles we would expect the transport to be accompanied by varying amounts of water as a result of differences in the degree of hydration of different ions and of differences in the various flows. However it is found that for a given polymer the rate of transport of water is uniquely determined by the partial pressure of water vapour above the solution of acid [132,174].

In general [132,144] the transport of volatile electrolytes through films of hydrophobic polymers involves three steps: extraction of the electrolyte by the surface layer of the polymer, diffusion through the thickness of the polymer, and re-extraction on the far side of the film. Under steady-state conditions this process is analogous to the transport of gases, and is described by the equation

$$J = D(a_{1n} - a_{2n})/l \simeq Da_{1n}/l, \tag{34}$$

where J is the flow through a film of thickness l, D is the differential diffusion coefficient, and a_{1n} and a_{2n} are the activities of the electrolyte in the polymer on the near and the far side of the film respectively. The quantity a_{1n} is related to the activity of the electrolyte in the external solution (a_B) by the expression

$$a_{1n} = Ka_B, \tag{35}$$

where K is the thermodynamic distribution constant of the electrolyte between the polymer phase and the aqueous solution. Combining Eqns. (34) and (35) we obtain an equation for the permeability of the film as a function of the composition of the external solution, and of the properties of the diffusant and of the polymer:

$$J = DKa_B/l. \tag{36}$$

The product DK is, effectively, the permeability constant P_0, which depends on the properties of the polymer and of the diffusant, and the effect of the composition of the external medium on the permeability is uniquely determined by the quantity a_B. The parameter K is related to the standard change in free energy of extraction (ΔG°_e) by the equation

$$\Delta G^\circ_e = -RT \ln K. \tag{37}$$

The transfer of the electrolyte from the aqueous solution into the polymer can be described as the removal of the electrolyte from the aqueous solution (i.e. the reverse of dissolution) followed by the mixing of the electrolyte with the polymer:

$$\Delta G^\circ_e = -\Delta G^\circ_{sol} + \Delta G^\circ_m, \tag{38}$$

where ΔG°_{sol} is the standard change in free energy accompanying the formation of an aqueous solution at infinite dilution, and ΔG°_m is the standard free energy change on mixing the electrolyte and the polymer. Tentative calculations for acids have shown [132] that the main contribution to ΔG_e comes from the term $(-\Delta G^\circ_{sol})$, i.e. the energy needed to remove the electrolyte from the aqueous solution is determined mainly by the distribution constant. However differences in extractability are themselves related to differences in the ΔG°_m value, which is directly related to the amount of sorption by the expression

$$\Delta G^\circ_m = -RT \ln \varphi_1. \tag{39}$$

The quantity φ_1, i.e. the volume fraction of solute, can be calculated to a first approximation by using the Flory equation [175] in the simplified form

$$-\ln\varphi_1 = 1 + \bar{V}_1(\delta_1 - \delta_2)^2/RT, \qquad (40)$$

where $\bar{V}_1$ and δ_1 are the molar volume of the solute and its solubility parameter respectively, and δ_2 is the solubility parameter of the polymer. There is indirect evidence (weak concentration dependence of the permeability, similarity of the diffusion coefficients in different polymers) that Eqn. (36) does not apply in real systems.

The nature of the polymer, its affinity towards water molecules, and the concentration of water (which affects the physicochemical properties of the polymer) have a strong influence on the type and on the mechanism of the transport of electrolytes in polymer systems.

The diffusion of electrolyte solutions in hydrophilic polymers, in which the solubility of water is high, is characterised by equilibrium parameters (such as the dissociation constant and the diffusion parameters D, λ_0, and u_i) close to the values of the same parameters for solutions. The decrease in mobility of molecules and ions in a polymer (as compared to their mobility in solution) is due to the increased length of the diffusion path and to interactions between the diffusing particles and the polymer. In hydrophilic polymers with a limited water solubility the dissolved water cannot form a continuous aqueous environment within the polymer matrix, and the diffusion of ions occurs by activated jumps between polar groups, resulting in a D value much lower than in the solution.

The diffusion of electrolytes in hydrophobic polymers is similar (in general) to the diffusion of gases and vapours which are inert towards the polymer, but the interaction of water with the polymer has a substantial effect on the diffusion process during the initial non-stationary period.

Non-isothermal Processes and Methods of Investigation in the Chemistry and Mechanics of Polymers

A.M.Stolin, A.Ya.Malkin, and A.G.Merzhanov

We shall discuss kinetic processes relevant to the chemistry and the mechanics of polymers in which the internal evolution of heat (due to exothermic reactions or to dissipative deformation) exceeds the ability of the system to transfer heat to its surroundings, so that the chemical reaction or the mechanical process occurs under non-isothermal conditions at a rate which is dependent on temperature. Processes of this type include: non-isothermal polymerisation (in a batch or a flow reactor), thermal phenomena during the cyclic deformation, extension, and external friction of polymers, and flow under conditions of dissipative heating. We shall describe the common features of all these phenomena, their characteristics, and their most important consequences from the standpoint of research and technology. 164 references.

I. INTRODUCTION

Many processes in the chemistry and mechanics of polymers are accompanied by evolution of heat. The resulting increase in temperature can affect the process very substantially if the relevant rate constants are strongly temperature dependent. Non-isothermal effects have many interesting and important consequences, and their study is an unusual and very revealing (though indirect) method of highlighting the basic features of the phenomenon under study.

The aim of this review is to discuss the non-isothermal processes of relevance to the chemistry and mechanics of polymers. The direct analogy which exists between these two topics justifies a common approach. Thus the analogue of the evolution of heat during polymerisation is the dissipative nature of deformation processes in all polymers. The analogue of the increased rate of a chemical reaction at elevated temperatures is the increased rate of the relaxation processes. In both cases the temperature rise is opposed by the transfer of heat to the surroundings, but the finite thermal conductivity of the reaction medium or of the polymer undergoing deformation gives rise to non-isothermal conditions. These analogies are by no means trivial, because the phenomena being compared are different in nature, and each phenomenon has its own specific features (such as the gradual disappearance of the monomer during chemical reaction and the formation of a new phase during polymerisation, or the relaxation into different physical states during deformation). Heat evolution during deformation is a well-known phenomenon for polymers in any physical (relaxation) state, and is due to internal friction or to the visco-elastic properties of most polymeric materials[1-4].

Thus the basic feature common to the whole of our discussion will be the dissipative nature of the polymerisation and mechanical deformation processes, which gives rise to an increase in the temperature of the reacting mass (deformation) and hence to an increase in the rate of the chemical reaction (relaxation).

II. GENERAL THEORY OF NON-ISOTHERMAL PROCESSES

The development of the theory of non-isothermal processes is closely associated with the theory of combustion. The work on combustion by Semenov, Zel'dovich, Frank-Kamenetskii, and others[5-7] laid the foundations of our understanding of chemical reactions under non-isothermal conditions. More recently the theory of non-isothermal processes has been further developed in connection with various problems in chemical technology[8,9] and in thermal analysis[10-12].

Non-isothermal processes can be classified in different ways, but the most rational classification relies on the origin of the non-isothermal behaviour. From this point of view we can distinguish two important classes of non-isothermal phenomena: internally non-isothermal and externally non-isothermal. Processes of the first class are characterised by constant external conditions, for example an invariant temperature at the surface of the reacting system. Non-isothermicity is produced by an internal source of heat, such as an exothermic or endothermic reaction, energy dissipation by viscous flow, etc. The power output of the source is usually strongly temperature-dependent, and therefore we can expect positive or negative feedback loops. Processes of this type are considered in detail in the theory of combustion.

The second class of phenomena includes processes with weak heat evolution. In this case the non-isothermicity arises mainly from changes in external conditions. Non-isothermal processes preceding the establishment of thermal equilibrium under constant external conditions are sometimes of interest. In both cases the thermal field in the system is not substantially affected by the internal source of heat, and the feedback is not marked. This situation often arises in the thermal analysis of reacting systems, and occasionally in chemical technology[9].

Exothermic processes of the first class are the most interesting. Their strong positive feedback produces specific non-isothermal phenomena which can only be

explained by combined heat evolution and heat transfer effects. These processes include thermal explosions, ignition phenomena, and the propagation of a thermal wave.

1. Thermal Explosion[13-16]

Consider a system including a source of heat with a high and strongly temperature dependent energy output (for example, an exothermic reaction with a large exoergicity and a high activation energy). The heat evolved by the reaction is partly transferred to the surroundings and partly retained in the system, leading to self-heating. The resulting temperature rise accelerates the evolution of heat by a positive feedback mechanism. Under suitable conditions the process can become self-accelerating and produce a thermal explosion if some well-defined critical (or limiting) conditions are met. Below the thermal explosion limit the exothermic reaction proceeds "quietly", with a small amount of self-heating in a stationary (or quasi-stationary) regime. Feedback effects are not very marked in this case.

The simplest form of the thermal explosion equations for condensed systems is

$$C\rho\frac{\partial T}{\partial t}=\lambda\left(\frac{\partial^2 T}{\partial x^2}+\frac{n}{x}\frac{\partial T}{\partial x}\right)+Q\rho k_0 e^{-E/RT}\varphi(\eta), \quad (1)$$

$$\frac{\partial\eta}{\partial t}=k_0 e^{-E/RT}\varphi(\eta), \quad (2)$$

$$\left.\begin{array}{ll} t=0 & T=T_0,\ \eta=0; \\ x=0 & \partial T/\partial x=0;\ \ x=r:\ -\lambda\partial T/\partial x=\alpha(T-T_0)\end{array}\right\}, \quad (3)$$

In these equations T is the temperature of the system, T_0 is the temperature of the surroundings, x is the spatial coordinate, r is the characteristic dimension of the reactor, η is the extent of conversion of the reactant, t is time, C, ρ, and λ are the specific heat, density, and thermal conductivity of the system, Q is the thermal effect (exoergicity) of the reaction (per unit volume), k_0 is the pre-exponential factor, E is the activation energy, α is the thermal emission coefficient, n is a geometric coefficient ($n = 0$ for a plane-parallel plate, $n = 1$ for an infinite cylinder, $n = 2$ for a sphere), and $\varphi(\eta)$ is the kinetic function. The problem consists in defining the critical phenomena: the critical condition (i.e. the relationship between the parameters which distinguish the two regimes, $F(T_0, r, \alpha\ldots) = 0$), and the induction period (the duration of the period of gradual temperature rise preceding the explosion, $t_{ind} = t_{ind}(T_0, r, \alpha\ldots)$).

The structure of the thermal field plays a very important role in the theory of non-isothermal processes. Both the amount of self-heating and the temperature gradients are usually small in the non-explosive regimes. Often Eqn. (1) is replaced by the simpler heat balance equation, ignoring spatial non-isothermality:

$$C\rho\frac{dT}{dt}=Q\rho k_0 e^{-E/RT}\varphi(\eta)-\alpha\frac{S}{V}(T-T_0), \quad (4)$$

where S is the heat transfer surface and V is the reaction volume. Eqn. (4) is physically justified when the Biot number is small ($Bi = \alpha r/\lambda \ll 1$),[17-19] and also under conditions of forced or free convective mixing[20,21]. A more general treatment of Eqn. (4) can be developed by introducing two new parameters: the average temperature and the effective heat transfer coefficient. The error introduced by using Eqn. (4) in general is small, because the temperature rise preceding the explosion is usually small.

2. Ignition[22,23]

During a thermal explosion the self-accelerating reaction occurs throughout the volume of the system, whereas during ignition it is localised (usually on the surface layer, under the influence of a powerful flow of heat from an external source). The mechanism and the rate of supply of heat are always important in ignition processes, and also the non-stationary thermal field in the system. The kinetic features of the source of heat are less important, because ignition occurs in the initial stages of the process. Ignition is often described by a single equation based on the model of a zero-order reaction:

$$C\rho\partial T/\partial t=Q\rho k_0 e^{-E/RT}+\lambda\partial^2 T/\partial x^2,$$

$t=0$ $\quad T=T_{init}$;

$x=0$ 1) $T=T_0$ (heated plate),

2) $-\lambda\partial T/\partial x=q_0$ (radiant flux of intensity q_0),

3) $-\lambda\partial T/\partial x=\alpha(T-T_0)$ (convective flow),

where T_{init} is the initial temperature.

We are sometimes interested in pulsed regimes, when the external source of heat acts for a limited time only. The commonest problems in ignition theory are to calculate the delay time of the ignition and the critical conditions (as in the case of the thermal explosion).

3. Propagation of a Thermal Wave[24-28]

This is the most interesting of the phenomena considered in the theory of non-isothermal processes. It is well known that a thermal wave cannot exist in an inert system: any injected heat pulse immediately decays. However, in systems including a non-linear source of heat which is strongly temperature dependent non-isothermal processes can become self-propagating, giving rise to a wave of temperature rise moving at constant speed through the "cold" substrate.

Thermal waves are described by the system of equations

$$C\rho\partial T/\partial t=Q\rho k_0 e^{-E/RT}\varphi(\eta)+\lambda\partial^2 T/\partial x^2, \quad (5)$$

$$\partial\eta/\partial t=k_0 e^{-E/RT}\varphi(\eta), \quad (6)$$

$$\left.\begin{array}{ll} t=0 & T=T_{init},\ \ \eta=0; \\ x=0 & T=T_{ign}>T_{init}, x=\infty,\ \partial T/\partial x=0\end{array}\right\} \quad (7)$$

and the solution is expressed in the form

$$T=T(x-ut),\ \eta=\eta(x-ut); \quad (8)$$

where u is the velocity of propagation of the wave and T_{ign} is the ignition temperature.

The sytem (5)–(7) also describes the ignition process which precedes the stationary propagation of the wave. The velocity of the wave is often determined from steady-state equations in a coordinate system for which the wave front is stationary and the reactants are moving towards the front:

$$\lambda\frac{d^2T}{dx^2}-C\rho u\frac{dT}{dx}+Q\rho k_0 e^{-E/RT}\varphi(\eta)=0, \quad (9)$$

$$u\frac{d\eta}{dx}=k_0 e^{-E/RT}\varphi(\eta), \quad (10)$$

$$\left.\begin{array}{ll} x=-\infty & T=T_0, \quad\ \eta=0, \ dT/dx=0, \\ x=+\infty & T=T_0+Q/C\rho, \ \eta=1, \ dT/dx=0.\end{array}\right\}. \quad (11)$$

The existence of thermal waves and their velocity usually depend on the total emission of energy from the heat source: in other words regimes with $\varphi(1) = 0$ are usually considered.

All these phenomena are critical, and they occur only if

$$\beta = \frac{RT_*}{E} \ll 1, \quad \gamma = \frac{C\rho}{Q} \cdot \frac{RT_*^2}{E} \ll 1, \tag{12}$$

where T_* is a scaling temperature which characterises the process. They are studied in the theory of combustion—the most important topic in the theory of non-isothermal processes. If the inequalities (12) are not extreme the phenomena tend to degenerate, and their boundaries become more diffuse.

In the case of endothermic processes the feedback loop is negative, and this simplifies the problem and leads to stable stationary regimes with varying degrees of non-isothermality.

Externally non-isothermal processes are very interesting in chemical kinetics because they offer the possibility of non-isothermal methods of investigation[10-12]. The course of a chemical reaction in these systems is almost entirely determined by the external conditions and by heat transfer, and the reciprocal effect of the reaction on the heat transfer process is unimportant. Under heat exchange conditions such that the temperature gradients in the reacting volume are small, and the system is able to "absorb" the small temperature changes produced by the heat of reaction, we can calculate the reaction rates and their dependence on temperature and on the extent of reaction, i.e. we can study the chemical kinetics of the system. This is usually done by imposing a linear temperature rise on the surrounding medium.

Non-isothermal processes are widespread in chemistry, physics, energetics, chemical industry, and other branches of science and technology. They are typical of oxidation reactions, thermal decomposition, synthesis from the elements, polymerisation, etc. Many physical processes such as nuclear reactions, phase transitions, viscous flow, the interaction of matter with high-frequency electromagnetic fields, etc. also occur in a non-isothermal regime[29]. The theory of non-isothermal processes and the ideas which have been developed from it are independent of the specific nature of the processes considered, and are based on the general phenomenological laws of heat evolution and heat transfer. Not surprisingly, therefore, we can legitimately rely on analogies and transfer results from one system to another when discussing specific non-isothermal processes.

III. NON-ISOTHERMAL POLYMERISATION

1. General Description

Polymerisation usually occurs under conditions of self-heating, produced by the exothermicity of the chain growth reaction. If the thermal effect of this reaction is small, the reaction rate is only weakly temperature dependent, and the viscosity of the reacting mass in the initial stages of polymerisation is low, then we can maintain approximately isothermal conditions and keep the temperature constant by vigorous stirring and by thermostatting the walls of the apparatus. On the other hand the temperature of the system will tend to increase continuously during polymerisation if the viscosity is high, the thermal conductivity of the mixture is low, and the thermal acceleration resulting from the temperature dependence of the reaction rate is large. Under the latter set of conditions polymerisation processes must be classified as non-isothermal.

Heat evolution effects have recently been recognised as a favourable feature in polymerisation reactions, often responsible for the practical success of a proposed reaction. Typical examples are adiabatic and frontal[30,31] polymerisation reactions, thermal initiation[32], etc. These methods allow us to impose "extreme" conditions on the reaction and thus to accelerate the polymerisation process.

The study of non-isothermal polymerisation is concerned with two basic problems. The first (or direct) problem consists in obtaining information on the process itself from data on the properties of the mass undergoing polymerisation (physical, rheological, and chemical). A macro-kinetic approach is used, and a model of the process is developed from the transport equations, the equations of chemical kinetics, and the equations of state. By solving this problem we arrive at the temperature distribution, the extent of reaction, and the structural characteristics (molecular weight distribution) of the product in space and in time.

The second (or inverse) problem consists in obtaining the characteristics of the chemical reaction (rate constants and activation energies) from information on the process itself, for example from the experimentally determined time dependence of the heat evolution or of the temperature at one point or at a small number of points. The solution of this problem usually involves the use of macro-kinetic relationships previously obtained by solving the direct problem.

Polymerisation processes can also be classified in terms of the complexity of the chemical reaction involved. The kinetically simplest polymerisation processes are those strongly dominated by a single reaction. A number of polycondensation and vulcanisation reactions[33,34] are of this type. Radical polymerisation reactions involve a more complex kinetic scheme which must, in general, allow for the initiation, growth, and breaking of chains[35].

We shall discuss the results of studies of the thermal regimes of polycondensation and radical polymerisation processes in chemical reactors of simple design. Some results on the macro-kinetics of ionic polymerisation are examined in Refs. 36 and 37, and will not be considered here. There are no published data on the macro-kinetics of emulsion, suspension, and other types of polymerisation under non-isothermal conditions.

2. Simple Kinetic Scheme

The thermal regimes of reactions of this type are generally similar to those of true or degenerate thermal explosion reactions. We can therefore describe the macro-kinetics of these polymerisation processes by applying the methods of the classical theory of thermal explosions (see above) in a static reactor. However due allowance must be made for some specific features of polymerisation processes, such as the lower values and the greater range of the heats of reaction (Q) and of the activation energies (E) of polymerisation processes as compared with explosive systems.

Temperature and concentration gradients cannot exist in an ideally stirred reactor. This model is described by the heat balance equation (4) and the kinetic equation (2). The system of equations (2)–(4) has been analysed[38,39] with special reference to polymerisation processes involving a wide range of the parameters Q and E. It was

found that three characteristic regions of thermal regimes are possible.

1) A region of non-degenerate thermal self-acceleration. Depending on the relative magnitude of the heat evolution and of the heat extraction, described by the Semenov criterion $\kappa = QE\rho k_0 \exp(-E/RT_0)/[\alpha(S/V)\cdot RT_0^2]$, the self-heating during polymerisation can be small (if $\kappa < \kappa_{cr}$) or large and rapidly increasing (if $\kappa > \kappa_{cr}$). The critical value κ_{cr} is very sharply defined. The extent of reaction during the development of the maximum heating rate is negligible, and therefore regimes corresponding to $\kappa > \kappa_{cr}$ are undesirable in polymer technology.

2) A region of degenerate thermal self-acceleration. In this case we have a sub-critical regime in which the rate of growth of the temperature is decreasing continuously, and a super-critical regime corresponding to thermal self-acceleration. However the transition between these two regimes is gradual (degeneracy of the critical conditions). The degree to which the polymerisation can be accelerated is limited by the availability of the monomer, and the extent of reaction during the development of the maximum temperature is considerable.

3) A region of thermal regimes without self-acceleration. In this region the rate of self-heating decreases with time, and the monomer has almost completely disappeared when the maximum temperature is reached.

The boundaries between these three regions are not sharp: they are determined by the values of the two dimensionless parameters $\gamma = C\rho RT_*^2/(QE)$ and $\beta = RT_*/E$, which describe the thermal effect and the activation energy of the reaction. The last two regions are technologically important.

Three thermal regimes exist also in the case of polymerisation in a batch reactor without stirring[40-42], to which the heat balance equation for conductive heat transfer (1) applies. Different boundary conditions for the temperature are possible. The heat dissipation conditions are usually defined in terms of the Biot criterion. Since the thermal field is not uniform over the cross-section of the reactor the extent of reaction is also, in general, not uniform. The degree of non-uniformity increases with the Frank-Kamenetskii criterion $\delta = Qk_0Er^2/(\lambda RT_0^2 e^{E/RT_0})$, which characterises the ratio of the rates of heat evolution and heat relaxation by conductive heat transfer. At low values of δ the polymerisation occurs fairly uniformly over the volume of the reactor (volume polymerisation). At large values of δ the reaction goes to completion first in the outer layers of the reaction volume, after which the polymerisation front moves towards the centre of the reactor (frontal polymerisation)[40,41].

The quantity η is the only kinetic characteristic in the initial equations (1), (2), and (4) on which the present discussion is based. This characteristic could be, for example, the concentration of monomer in the reaction mixture. However the structure and the properties of the product depend on a whole range of reactions of the growing chain, which yield polymers with different molecular weight distributions (MWD) and, in general, different amounts of chain branching. In non-isothermal polymerisation (which includes the vast majority of technological processes) the rate constants of the various steps of the polymerisation reaction have different temperature coefficients, and as a result the MWD can be very different from the distribution expected for isothermal polymerisation. This is a serious problem, which can radically alter the properties of the product (see, for example, Refs. 43 and 44).

A quantitative estimate of the effect of non-isothermicity on the MWD of the resulting polymer cannot be made in general, because the solution of the problem is sensitively dependent on the special kinetic features of the process. However we can develop a general approach to this problem by introducing the "generalised" time τ, defined by the pattern of the previous temperature changes. Thus in the case of anionic polymerisation with very fast initiation, when only the rate constant for chain growth (K) is relevant to the overall kinetics, the generalised time τ is given by[45]

$$\tau = \int_0^t K[T(t)]\, M(t)\, \mathrm{d}t, \qquad (13)$$

where M is the concentration of monomer in the reaction mixture (depending on time t), and K depends on temperature (which also varies with time). This approach allows us to calculate the MWD of the resulting polymer by postulating quasi-isothermal conditions with respect to the variable τ. Some technological aspects of the effect of non-isothermal polymerisation on the MWD of the resulting polymer are discussed in Refs. 46 and 47.

We must stress that a very similar approach, relying on the use of a "generalised" time, had been developed previously[48] to describe non-stationary processes during visco-elastic relaxation. The approach can be applied to any non-isothermal deformation or relaxation phenomenon, making the system quasi-isothermal. The most detailed studies in this area have been on problems of polymer creep[49,50].

3. Radical Polymerisation

The macro-kinetics of radical polymerisation under non-isothermal conditions were first investigated by Maksimov[31,51-53], who combined the kinetic equations for chain growth and initiator decomposition with the heat balance equation (1) on the assumption of constant concentration of free radicals during the polymerisation (quasi-stationary hypothesis).

Because of the kinetic peculiarities of radical polymerisation, new and interesting types of behaviour are possible. The basic kinetic feature, associated with the consumption of the initiator, is that high levels of self-heating are not reached in the "explosion" regime (because of the rapid "burning up" of the initiator). Another characteristic feature of radical polymerisation is the gel effect, which consists in an increased rate of polymerisation as a result of the increase in viscosity (and decrease in the rate of chain breaking) as the extent of reaction increases. Corrections for the gel effect in macroscopic treatments are usually applied by various empirical formulae[53-55]. Under non-isothermal conditions the increase in temperature assists the motion of macrochains, and the gel effect is displaced towards higher extents of reaction (or is eliminated).

The gel effect during radical polymerisation produces a new thermal regime, called the intermediate regime[53]. In this regime the self-heating is small during the initial stages of polymerisation, but in the later stages the reaction rate increases rapidly and the mixture reaches high temperatures.

4. Propagation of the Polymerisation Front

The polymerisation reaction can occur in layers, with a propagating polymerisation front, the heat evolved in the reaction zone being taken away by the colder layers in which the reaction had started. This "frontal" polymerisation regime has considerable practical importance because it offers lower working temperature and lower polymerisation (shrinkage) stresses.

Enikolopyan and coworkers[56-59] describe the macrokinetics of this regime by starting from steady-state equations of type (8)–(10). The problem consists in determining the linear velocity of polymerisation, the width and structure of the front, the temperature distribution, and the extent of reaction: this can be done by using the concepts and methods of the theory of thermal waves[25-29]. The basic assumption needed to arrive at an analytic solution of the system (9)–(11) is that the reaction is confined to a narrow region where the temperature T_m is a maximum. Allowance should also be made for the difference in thermal and physical properties between the initial mixture and the polymerised product, i.e. for the dependence of the thermo-physical properties of the system on the extent of reaction. This is not possible with existing methods of calculation.

In radical polymerisation under frontal conditions it is important to consider the presence of the gel effect. An attempt to allow for the gel effect by using empirical formulae is described in Ref. 60.

5. Optimisation of Technological Processes

Optimisation problems can be formulated from a macrokinetic description of the polymerisation process. Various optimisation criteria are possible: the only requirement is that the criterion should be consistent with well validated methods of calculating and predicting the behaviour of polymerisation reactors. To solve the optimisation problem we must allow for the changes in structural parameters and in physical and mechanical characteristics resulting from the polymerisation, because these characteristics determine the properties of the finished item of interest to the consumer. Work on these problems has only just begun. Thus some recently reported investigations[61-63] of the optimisation problem aimed to minimise the reaction time while maintaining externally controllable temperature gradients, extents of reaction, and radical temperature differences at all extents of reaction.

6. Determination of the Kinetic Characteristics

Failure to allow for the exothermic effects of the reaction, which give rise to variations in temperature, reaction rate, and extent of reaction over the reacting volume, can lead to serious errors in the kinetic description of the non-isothermal polymerisation process. The problem of the kinetics of setting of a phenol–formaldehyde resin, which has been discussed in the literature for many years, is a particularly good example: different workers arrive at contradictory conclusions on the main kinetic features of this reaction. Most of them assume the presence of a significant induction period, because the time dependence of the measured kinetic factor is S-shaped. However Basov and coworkers[64] studied the dependence of the observed induction period t_{ind} on the size of the reaction vessel in a series of experiments with flat vessels of variable thickness d. They observed a square-law dependence of t_{ind} on d, and the induction period vanished on extrapolation to $d = 0$. This means that the induction period is an apparent "non-isothermal" effect. When the experimental results are extrapolated to isothermal conditions the rate of poly-condensation becomes constant, and the induction period disappears.

One consequence of the development of the theory of non-isothermal polymerisation was the appearance of new methods of determining the kinetic model of the process and of calculating the kinetic parameters. The most rigorous solution of this (inverse) problem relies on continuous measurement of self-heating against time. This is often done under conditions of uniform heating, when temperature distributions within the reaction volume can be ignored.

For polymerisation under adiabatic conditions we can write[65,66]

$$C\rho \mathrm{d}T/\mathrm{d}t = -Q\mathrm{d}M/\mathrm{d}t, \tag{14}$$

where M is the concentration of monomer. If the ratio $Q/C\rho$ is constant this simplifies to

$$M_0 - M = (T - T_0)C\rho/Q, \tag{15}$$

where M_0 and T_0 are the initial concentration and temperature respectively. When the reaction is complete we have

$$\Delta T = T_\infty - T_0 = M_0 Q/C\rho. \tag{16}$$

Thus the fact that the self-heating $\Delta T = T_\infty - T_0$ is independent of T_0 and is proportional to the initial monomer concentration M_0 confirms on the one hand that polymerisation is proceeding under truly adiabatic conditions and on the other hand that the ratio $Q/(C\rho)$ is constant.

The extent of reaction can be expressed in terms of the dimensionless parameter $\eta = (M_0 - M)/M_0$, or

$$\eta = (T - T_0)/(T_\infty - T_0). \tag{17}$$

For a reaction of the n-th kinetic order we have

$$-\mathrm{d}M/\mathrm{d}t = k_0 M^n \exp(-E/RT). \tag{18}$$

In this case Eqns. (14)–(18) allow us to express the rate of change of temperature as

$$(T_\infty - T)^{-n}\frac{\mathrm{d}T}{\mathrm{d}t} = k_0 (T_\infty - T_0)^{1-n}\exp(-E/RT). \tag{19}$$

Thus a plot of $\lg[(T_\infty - T)^{-n}dT/dt]$ against $1/T$ should be a straight line from which the kinetic constants k_0, E, and n can be evaluated (in the case of n, by trial and error). This method has been used by several workers[63-73].

This simple procedure has been extended to more complex kinetic schemes[74-76]. We shall consider its application to radical polymerisation with full allowance for the three basic steps (initiation, chain growth, and chain breaking). The reaction is usually assumed to be quasi-stationary (rate of change of the concentration of macroradicals much smaller than their rate of formation and of disappearance, and rate of initiation equal to the rate of chain breaking). With this assumption the kinetics of radical polymerisation can be described by the expressions

$$-\mathrm{d}M/\mathrm{d}t = k_{\mathrm{eff}} I^{1/2} M \exp(-E_{\mathrm{eff}}/RT), \tag{20}$$

$$-\mathrm{d}I/\mathrm{d}t = k_{i0} I \exp(-E_i/RT), \tag{21}$$

where M and I are the time-dependent concentrations of monomer and of initiator, k_{eff} and E_{eff} are the effective kinetic constants of the polymerisation reaction ($k_{\mathrm{eff}} = k_{p0}(k_{i0}/k_{t0})^{1/2}$; $E_{\mathrm{eff}} = E_p + \frac{1}{2}(E_i - E_t)$; k_{i0}, k_{t0}, k_{p0}, E_i,

E_t, and E_p are the pre-exponential factors and the activation energies for the initiation, chain breaking, and chain growth reactions respectively).

If the reaction occurs under adiabatic conditions we can write

$$-Qm\mathrm{d}M=(C_1m_1+C_2m_2+C_3m_3)\,\mathrm{d}T \tag{22}$$

or

$$\mathrm{d}M/\mathrm{d}T=-C/Q, \tag{23}$$

where $C = C_1 + C_2m_2/m_1 + C_3m_3/m_1$, Q is the heat of the chain growth reaction, C_1, C_2, C_3 and m_1, m_2, m_3 are the specific heats and the masses of the reaction medium, the solvent, and the bulb respectively. In Eqn. (22) the thermal contributions of the initiation and chain breaking reactions are ignored because these reactions are weakly exothermic in comparison with the chain growth reaction.

Replacing M by the dimensionless parameter $\eta = (M_0 - M)/M_0$ we can re-write Eqn. (20) in the form

$$\mathrm{d}\eta/\mathrm{d}t = k_{\mathrm{eff}}\,(1-\eta)\,I^{1/2}\exp(-E_{\mathrm{eff}}/RT). \tag{24}$$

By introducing the simplifying assumption that the concentration of initiator remains constant ($I = I_0 = \mathrm{const}$) we can write $k' = k_{\mathrm{eff}}I_0^{1/2}$, and the problem reduces to the vase of adiabatic polymerisation with a simple kinetic scheme. Tonoyan and coworkers[74] proposed a formula for the concentration of initiator which allows for its variation with temperature and time:

$$I=I_0\exp\{-k_{i0}t\exp(-E_i/RT)\}. \tag{25}$$

In this case Eqn. (24) becomes

$$\lg\left(\frac{\varepsilon_1}{T_\infty-T}\frac{\mathrm{d}T}{\mathrm{d}t}\right)+\frac{k_it}{4.6}\exp\left(-\frac{E_i}{RT}\right)=\lg k_0+\frac{1}{2}\lg I_0-\frac{E}{RT}. \tag{26}$$

Truly adiabatic conditions are not usually possible, and the solution of the inverse problem should take account of the transfer of heat to the surroundings. A thermographic method[77,78] has been proposed to evaluate the function $\varphi(\eta)$ in the case of simple kinetics. The same method is used in Ref. 37.

If temperature distribution over the volume of the reactor can be ignored the thermal regime of the reaction is given by the heat balance equation

$$C\rho\frac{\mathrm{d}T}{\mathrm{d}t}=Q\rho\frac{\mathrm{d}\eta}{\mathrm{d}t}-\alpha\frac{S}{V}(T-T_0) \tag{27}$$

with the initial conditions

$$t=0\quad T=T_{\mathrm{init}},\ T_0=T_{0\,\mathrm{init}},\ \eta=0. \tag{28}$$

From Eqn. (27) the rate of the non-isothermal reaction and the extent of reaction are found to be

$$\frac{\mathrm{d}\eta}{\mathrm{d}t}=\frac{C}{Q}\frac{\mathrm{d}T}{\mathrm{d}t}+\frac{\alpha(S/V)}{Q\rho}(T-T_0),\quad \eta=\frac{C}{Q}(T-T_{\mathrm{H}})+\frac{\alpha(S/V)}{Q\rho}\int_0^t(T-T_0)\,\mathrm{d}t. \tag{29}$$

Eliminating time as a parameter in Eqn. (29) we can evaluate the kinetic function $d\eta/dt = \varphi(\eta)$. If the semi-logarithmic plot of reaction rate against reciprocal temperature for a fixed η is linear we can determine the pre-exponential term and the activation energy. It is sometimes found that the activation energy varies with the extent of reaction. This effect may be associated with the increase in viscosity of the reaction medium. By carrying out non-isothermal polymerisation without temperature gradients we can convert the non-isothermal kinetic curves into isothermal curves, and thus simplify the treatment of the experimental results. Hence the kinetics of non-isothermal polymerisation are most conveniently investigated with special experimental arrangements to ensure this condition. The solution of the inverse problem outlined above in the presence of temperature distributions requires experimental measurement of the distribution and calculations on a computer.

IV. NON-ISOTHERMAL DEFORMATION OF SOLID POLYMERS

1. Cyclic Deformation

During the cyclic deformation of solid polymers heat is evolved as a result of the non-ideality of the elastic deformations, which causes some of the mechanical work done in the cycle to be irreversibly dissipated and converted into heat. If the properties of the material do not change within the cycle this work is given by the formula

$$A_\tau=\pi\varepsilon_0\sigma_0\sin\delta, \tag{30}$$

where ϵ_0 and σ_0 are the amplitude of the deformation and the stress respectively for a frequency ω, and δ is a characteristic of the material called the mechanical loss angle. It is important to note that δ is a function of temperature and frequency, and it can vary quite sharply within some ranges of these parameters. From the point of view of the present discussion we should also note the steep fall in elasticity and the increase in mechanical losses of polymers in the region of relaxation transitions (the most important of which is the glass transition). Sharp changes in mechanical properties and in δ are observed also as a result of phase transitions if the temperature rise produced by the deformation is sufficient to exceed the phase transition temperature.

Since the number of vibrations per unit time is $\omega/(2\pi)$, the energy A evolved per unit time during the cyclic deformation of polymeric materials is

$$A=\frac{\omega}{2\pi}A_\tau=\frac{\varepsilon_0\sigma_0}{2}\omega\sin\delta=\frac{\varepsilon_0^2\omega}{2}G'', \tag{31}$$

where G'' is a characteristic of the mechanical properties of visco-elastic materials called the loss modulus.

The values of δ and G'' for various polymeric materials in different physical states are listed in standard tabulations (see, for example, Refs. 2 and 79). We should stress that in every case $G'' > 0$, i.e. the deformation process is invariably dissipative. Formulae (30) and (31) apply both to solid and to rubbery substances. As in the cases considered above the rise in temperature is controlled by the transfer of heat to the surroundings, and the material constants which characterise the level of heat evolution are strongly temperature dependent, at least in some critical regions of temperature. Therefore, as has already been pointed out[80-83], this mechanical phenomenon is analogous to non-isothermal chemical reactions. The similarity extends to the critical effects: thermal explosion in the case of a chemical reaction and a similarly sharp and uncontrollable increase in temperature during cyclic deformation (leading to the destruction of the item or to the loss of its ability to withstand changes in shape.

Different regimes of temperature change are possible during cyclic deformation[80,84]. In the case of efficient heat exchange and moderate stresses we observe self-heating up to some equilibrium temperature which depends on the amplitude of the stresses[85] (since this amplitude

determines the intensity of the heat evolution). This is the "stationary" case, the most favourable mode of operation of plastics components, and is the mechanical analogue of a non-isothermal reaction proceeding under conditions far removed from the "thermal explosion" regime (for example, a polymerisation with a relatively small heat of reaction). The analogy can be extended to the manner in which the process comes to an end: the reaction stops by the depletion of reactants (in the absence of "topping up"), and the component is destroyed by the exhaustion of its mechanical durability.

The analogy between the thermal effects associated with cyclic deformation and those produced by a chemical reaction applies also under non-stationary self-heating conditions, resulting in an avalanche-like temperature rise followed by destruction of the sample (or component). The increase in temperature causes an increase not only in the heat transferred to the surroundings (as a result of the increased temperature difference) but also in the heat evolution within the sample, since the mechanical losses are greatest at softening (or relaxation transition) temperatures. If the temperature dependence of the heat evolution (dQ_+/dT) is more marked than that of the heat losses (dQ_-/dT) the temperature continues to rise up to the critical region where the material softens and resistance to deformation is lost.

These general cosiderations define the conditions of the transition from the non-stationary regime of temperature growth during cyclic loading to the stationary regime of isothermal deformation (though at a temperature higher than the initial temperature). The conditions are given[80-83] by the simultaneous solution of the two equations

$$Q_+ = Q_-; \quad dQ_+/dT = dQ_-/dT. \tag{32}$$

The solution of this system depends on the temperature (and frequency) dependence of the mechanical losses accompanying the cyclic loading of the particular polymeric material, on the size and shape of the sample, on the way in which the load is applied (since this determines the non-uniformity of the stress distribution, and therefore the rate of heat evolution), and on the heat exchange conditions. Some typical calculations of the critical parameters (i.e. some solutions of Eqns. (32) for various assumed types of loading) are given in the literature[84,86].

Thus studies of the non-isothermal cyclic loading of solid polymers indicate the existence of two basic non-isothermal deformation regimes: a "stationary" regime, leading to a "new" isothermal state in which the stable temperature level depends on the amplitude of the applied stresses, and non-stationary regime characterised by the onset of a critical self-heating ΔT_K at a well-defined amplitude of the applied stresses. It is important to note that the value of ΔT_K is almost independent of the external conditions (loading regime and heat exchange conditions), and in this sense it is a characteristic constant of the material. Critical values of the self-heating (ΔT_K) and of the stresses for many constructional polymers have been tabulated[84].

The stationary and the non-stationary heating regimes described above for samples undergoing cyclic deformation can be interpreted as "pure" manifestations of the heating effects arising from specific combinations of a dissipative factor and a heat transfer factor. At very high levels of applied stress the self-heating can be small if the sample is destroyed before reaching very high temperatures. Another important non-extreme case is a continuous slow rise in temperature—or even a rise followed by a fall in temperature—without reaching a stationary regime. This behaviour is usually associated with changes in the mechanical (visco-elastic) properties of the material during deformation as a result of concomitant physical or chemical structural processes[87-91].

2. Uniaxial Strain

The evolution of heat during the non-cyclic deformation of solid polymers in the uniaxial strain regime reflects the specific features of the molecular mechanism responsible for the structural changes accompanying the deformation. These changes are invariably accompanied by heating effects[92-99] which are a measure of the deviation of the material under study (under the particular deformation conditions) from the "ideal elastic body" or "ideal rubber" models which describe the purely energetic or entropic mechanisms of reversible deformation. In extreme cases the structural changes can lead to oriented crystallisation, with its accompanying thermal effect[100].

Heat evolution of this type has relatively little effect on the way in which the polymer deforms, because the temperature dependence of the mechanical properties of the material in a single physical (or relaxation) state is relatively weak: in other words, the "feedback" effect which plays a crucial role in most non-isothermal processes is absent in this case. Large effects can be expected if the rise in temperature produced by the heat evolved during deformation is sufficient to bring the sample to a transition region where the properties of the polymer are changing rapidly, thus affecting the subsequent deformation. This behaviour is most clearly seen when the temperature of the glassy sample rises to the glass transition temperature T_g. The mechanism of the stretching process changes radially above T_g. The most important aspect of this "devitrification" effect is the necking down of the sample, i.e. the sudden transition from a non-oriented to an oriented state[102], which occurs whether the devitrification takes place under isothermal conditions by an increase in the free volume[101] or whether it is due to a rise in temperature above T_g. The rapid increase in molecular mobility above T_g contributes to the relaxation processes and produces a sudden decrease in the rate of heat evolution.

The way in which this process develops depends on a number of factors: the ratio of the intensity of heat evolution by the mechanical deformation of the rigid polymer to the rate of heat transfer to the surroundings, the compliance (ability to store elastic energy) of the neck or of the yielding sections of the test piece, and also the strength of the polymer. In the simplest and most obvious case the local heating in the necking region, which can be as high as several tens of degrees, leads to a stationary necking down regime[98,103,104].

We shall not attempt to compare alternative mechanisms of the necking down effect, or to discuss the possibility of neck formation under strictly isothermal conditions (which is well established, and suggests that the mechanism of this phenomenon is not necessarily thermal[102,105]). For our present purpose we only need to mention the relevance to the set of phenomena considered here of a non-isothermal mechanism of neck formation (more strictly, the quasi-isothermal mechanism, analogous to the stationary cyclic loading process discussed in the previous section). This mechanism depends on intense, local heat evolution, temperature rise, and a sudden increase in molecular mobility before reaching devitrification conditions (and therefore before reaching the possibility of changes in

physical state, which tend to suppress the mobility by assisting molecular orientation of the polymer). This thermal mechanism of neck formation causes stationary propagation of the neck over the sample at a rate equal to the rate of deformation until the whole of the sample is included in the neck.

These are not the only non-isothermal phenomena during uniaxial stretching. Under certain conditions[106,107] the stationary neck propagation mechanism (which can be likened to a stationary chemical reaction) is replaced by an oscillatory stretching mechanism which has no analogues among the polymerisation processes but is similar to the oscillatory regimes observed in chemical reactions[108].

The critical condition for the appearance of self-oscillations during stretching under non-isothermal conditions is a particular combination of mechanical properties (which determine the elastic and the dissipative properties of the specimen being deformed) and heat-transfer properties (which determine whether the temperature of the polymer can rise above T_g). In these circumstances the stored elastic energy is suddenly released, leading (after a period of elastic deformation up to the critical strain) to an explosive growth in the rate of deformation when the local temperature in the necking region reaches T_g, and to a very sharp increase in the compliance of the polymer in this region. The increase in temperature causes a decrease in stress and an equally sharp decrease in the rate of heat evolution. The length of the high-temperature region of the sample is limited by the low thermal conductivity. Therefore, after the stress has collapsed and the cold zone has been reached we expect a new stage of slow stretch in the elastic region with accumulation of elastic energy in the easily deformed parts of the kinematic circuit and with a slow increase in stress until a new "collapse" is produced by the strong non-isothermal effect. The repetition of these phenomena produces a periodic (oscillatory) mechanism of non-isothermal stretching, and the resulting neck develops a clearly defined "banded" structure.

The direct link between the peaks in the local rate of deformation, the changes in stress during elongation, and the surges in heat evolution (with corresponding sharp changes in temperature) has been confirmed by direct observations[98,99,109]. This is a convincing illustration of the non-isothermal nature of the effect, involving all the aspects of the phenomena with which the present review is concerned: the role of heat evolution as an internal property of the system, the strong temperature dependence of the parameters which determine the rate of heat evolution (feedback effect), and the crucial importance of heat transfer to the surroundings.

These experimental facts on the oscillatory regime of neck formation during the stretching of polymers, and their physical treatment in terms of the general model of non-isothermal deformation processes, have been discussed in the literature[106,107] and formulated mathematically[110].

3. External Friction

External friction is a typical dissipative effect, limited by the transfer of heat to a solid support or to the surrounding atmosphere, and originating from heat evolution by surface friction. The system usually reaches an equilibrium temperature (corresponding to equality of heat evolution and heat extraction) which can be much higher than the initial temperature. This phenomenon is well understood, including the extreme temperature increases (similar to the "thermal explosion" in chemical reactions) which lead to the melting of metal bearings under excessive load. Equally catastrophic results can be produced in bearings made of polymeric materials by heat evolution and uncontrolled temperature rise, especially since the poor thermal conductivity of polymers allows the temperature of the friction surface to increase by a large amount. This can lead to true melting of the surface layer or to substantial softening (loss of hardness and strength) if the polymer cannot melt.

The critical self-heating is analogous to the uncontrolled temperature rise during cyclic deformation, and it involves essentially the same mechanism, since the frictional resistance to slip is due in part to periodic visco-elastic deformations of the polymeric material. The combined measure of the resistance to deformation and of heat evolution by friction is the coefficient of friction, which depends on the slip velocity, to some extent on the load, and on the temperature, and which is found to increase very rapidly near the melting (or softening) temperature of the polymer, leading in extreme cases to a transition from external slip to viscous flow in a layer of very high viscosity[111-115]. A mathematical theory of this phenomenon has been developed[116].

Melting effects as a result of heat evolution by external friction in polymers are not always unfavourable in polymer technology. In the initial stages of polymer treatment processes, when the material must be converted into a state capable of flowing, heat evolution by strong external friction can contribute very significantly to the temperature rise of the charge. This effect is especially marked in extrusion, because the conversion of the solid polymer into a flowing state in the first few turns of the worm conveyor occurs mainly by the heat of external friction.

The reverse transition—from a flowing to a rigid state—occurs in parallel with the flow of the polymer, and it plays an important role in the feed channels of moulding machines and during the filling of the mould. In this case the flowing material is cooled at the walls of the channel, forming a solid layer of increasing thickness. However the continuing flow causes dissipation in the layer, maintaining the flow properties and hindering the growth of the solid layer. Thus we have a complicated interaction between the increase in viscosity due to heat transfer to the cold walls of the channel and the resulting increase in dissipation, which limits the increase in viscosity. This technologically important and complex problem—the growth of solid layers under non-isothermal conditions—has been discussed by many workers[117-121]. The most convincing results were obtained in a recent study[122] of a material with well characterised thermo-physical properties (polyethylene), which clearly established the basic features of the phenomenon. In particular it was shown that under certain conditions the boundaries of the solid layers in a plane-parallel channel remain almost parallel as a result of the interplay of these effects. On the whole, the thickness of the solid layer increases with t^m (where t is time). The exponent is $m \simeq 0.4$, but its exact value depends on the properties of the material. The method of calculation used in Ref. 122 can be applied to other materials of technological interest.

The transition of the melt from a flowing to a rigid state occurs under non-isothermal conditions, and is due to crystallisation of the polymer. Therefore it should not be confused with the basically different transition from a flowing to a rigid state discussed in Refs. 123–126, which

occurs primarily under isothermal conditions and is due to relaxation phenomena. We note that crystallisation during flow can occur under isothermal conditions under the influence of orientation effects, which cause a shift in the temperature of the phase transition[127-131]. This mechanism can also produce a transition from a flowing to a rigid state, but in contrast to the non-isothermal mechanism discussed above it does not involve the two features common to the whole groups of mechanical phenomena discussed in this review: heat transfer and heat evolution by deformation.

V. NON-ISOTHERMAL FLOW

1. Dissipative Flow and Non-isothermal Viscometry

One of the most important aspects of the deformation of flowing systems is the evolution of heat. The deformation is non-isothermal for a number of reasons. The most important is the viscous or dissipative evolution of heat at high rates of deformation in highly viscous systems. In rheologically complex systems the thermal effects are accompanied by structural changes at various levels. In the deformation of reactive media additional heat can be evolved by chemical reaction (for example, polymerisation).

In the non-isothermal flow of liquids the resistance to deformation does not vary monotonically with flow rate. This is easily explained, for example, in the simple case of the shear flow of a Newtonian liquid, for which

$$\tau = \mu(T)\dot{\gamma}, \tag{33}$$

where τ is the stress, $\dot{\gamma}$ is the shear rate, and $\mu(T)$ is the temperature-dependent viscosity. The viscosity coefficients of many polymer systems (both solutions and melts) are accurately known and have been tabulated systematically[2,79,132-135].

In the isothermal case τ increases with $\dot{\gamma}$ according to formula (33). However in the non-isothermal case the resistance to deformation increases only as long as the self-heating is small. At higher strain rates the intensity of the dissipative evolution of heat increases, the self-heating becomes more pronounced, and the viscosity decreases. When the temperature dependence of the viscosity is non-linear this factor becomes even more important, and τ begins to decrease. The variation of the dissipative heat evolution $q(T)$ with temperature depends on the flow conditions[136]. Since

$$q(T) = \tau\dot{\gamma}, \tag{34}$$

it follows that for a constant kinematic parameter $\dot{\gamma}$ (flow rate under forced flow conditions, or velocity of the moving boundary under Couette flow) we can write

$$q(T) = \dot{\gamma}^2\mu(T). \tag{35}$$

In this case $q(T)$ decreases with increase of temperature.

On the other hand if we keep constant the dynamic parameter τ (the drop in pressure, or the driving force at the moving boundary) we have

$$q(T) = \tau^2/\mu(T). \tag{36}$$

In this case the evolution of heat increases with temperature, and the temperature of the liquid rises continuously as a result of thermal feedback[136]. This is the essential analogy between the progress of a chemical reaction in a viscous liquid and the non-isothermal flow of that liquid.

These features are observed in a number of dissipative phenomena[136-139]. The most fully investigated is the hydrodynamic thermal explosion[136], which can be realised experimentally in a rotating viscometer[140]. This is essentially a thermally unstable flow situation, in which the heat generated by internal friction cannot be extracted through the walls of the vessel. This produces a gradual increase in temperature and in the angular velocity of the rotor (for a constant applied torque).

Specific dissipative phenomena are possible during the forced flow of polymers in a tube of finite length. The convective flow of heat through the outlet cross-section and the limited residence time of the liquid in the tube are analogous to the consumption of reactant in a chemical reaction. However the non-linearity of the dissipative (heat evolution) function does not lead to a hydrodynamic thermal explosion in this case: it produces a sharp, discontinuous transition from a low-temperature and low-flow stationary regime to a high-temperature regime, and *vice-versa*, as the pressure drop is gradually changed. The critical conditions for the forward and the reverse transition are not identical (hysteresis effect). This phenomenon has been called hydrodynamic thermal ignition and extinction[138].

Interesting effects are observed from the interaction of dissipative heat evolution and elastic deformation. Self-oscillating flow regimes are possible for some combinations of the characteristic times of heat evolution, heat transfer, and elastic deformation, leading to relaxation fluctuations in stress, temperature, and heat evolution function. A wide variety of different flow regimes can be induced by different ratios of the characteristic times[139].

An important practical application of the theory of non-isothermal flow in viscous liquids has been the development of the non-isothermal method of studying rheological properties[141-143], which relies on the self-heating of the liquid in order to measure viscosity at different temperatures. The non-isothermal method consists in analysing the experimentally measured time-dependent changes in the temperature of the liquid $T(t)$ and in the speed of the rotor of a rotating viscometer $n(t)$ for a constant applied torque M = const, or by measuring $M(t)$ for n = const. This procedure ensures uniform heating of the liquid over the entire volume and minimises heat transfer to the surroundings. Under quasi-stationary hydrodynamic conditions, which exist for relatively high values of the Prandtl criterion $\mathrm{Pr} = \mu/(\rho a) \gg 1$ (where μ is the viscosity, ρ is the density, and a is the thermal diffusivity coefficient) we can determine the variation of the effective viscosity with temperature and with shear stress from experimental plots of $T = T(t, M)$ and $n = n(t, M)$.

This approach is specially useful for determining the variation of viscosity with temperature T and with the extent of reaction of the polymerising mass η, whose value (together with the rate of polymerisation $d\eta/dt$) can be obtained from the heat balance equation[77,78].

2. Non-isothermal Polymerisation in Flow Reactors

Macro-kinetic studies of flow reactors have progressed slowly in recent years. The special features of these reactors (outflow of the reaction products and limited residence time in the reactor) do not allow direct application of the theory of thermal explosions, as was done for batch reactors. Nevertheless the methods of this theory can be applied successfully to an analysis of the thermal

regimes. Typical of this approach are a number of studies[8,144,145] of the course of exothermic reactions in reactors assumed to have ideal mixing, ideal displacement, or displacement with longitudinal transport. The system of equations which describes the thermal regime in these reactors differs from the equations for batch reactors only in having additional terms for the rate of removal of heat and of the reaction products of the flow. In the simplest case of a single exothermic reaction in an ideally mixed flow reactor the equations can be expressed in the dimensionless form[145]

$$\gamma\, d\theta/dt = \exp[\theta/(1+\beta\theta)]\varphi(\eta) - \theta/\varkappa, \qquad (37)$$

$$d\eta/dt = \exp[\theta/(1+\beta\theta)]\varphi(\eta) - \eta/Da,$$

$$\theta = \frac{E}{RT_*^2}(T-T_*), \quad \tau = k_0 e^{-E/RT_*}t, \quad \eta = \frac{M_0 - M}{M_0}, \quad \beta = \frac{RT_*}{E},$$

$$\gamma = \frac{C}{Q}\frac{RT_*^2}{E}, \quad \varkappa = \frac{Q\rho}{\alpha_*(S/V)}\frac{E}{RT_*^2}M_0 e^{-E/RT_*},$$

$$Da = \frac{V}{\omega}k_0 e^{-E/RT_*}, \quad \alpha_* = \alpha + \frac{C\rho}{S}\omega. \qquad (38)$$

In these equations T_* is a scaled temperature defined as

$$T_* = (\alpha S T_0 + C\rho\omega T_{in})/(\alpha S + C\rho\omega), \qquad (39)$$

where T, T_0, and T_{in} are the temperatures of the material, of the surroundings, and of the incoming flow respectively, α_* is the effective heat transfer coefficient (allowing for all the heat losses), ω is the volume flow rate, $\varkappa$ is the Semenov criterion, and Da is the Damkeler criterion.

The most important parameters are the Semenov criterion (which expresses the ratio of the characteristic times for the removal and the production of heat) and the Damkeler criterion (which expresses the ratio of the residence time to the reaction time).

In the case of ideal displacement reactors the convective flows of heat and of matter in the longitudinal direction are important, and they give rise to a boundary condition at the inlet of the reactor. In displacement reactors with longitudinal transport we must introduce additional second-order terms for the effect of the diffusional flows of heat and of matter in the flow direction, and these give rise to a boundary condition at the outlet of the reactor.

A unique feature of polymerisation in flow reactors is the possibility of several stationary states. Zel'dovich[146,147], and, later, van Heerden[148], showed that the stable low-temperature and high-temperature regimes of an ideally mixed reactor depend on the ratio of the Semenov and the Damkeler parameter. The transition from the low-temperature to the high-temperature regime (ignition and extinction), and *vice-versa*, shows hysteresis: the critical conditions for the forward and the reverse transition are not usually identical. Similar features are observed in an adiabatic displacement reactor of finite length[149-151]. In the presence of lateral heat exchange the number of possible stationary states increases to five[152,153].

The existence of a low-temperature (quasi-isothermal) and a high-temperature (quasi-adiabatic) regime is demonstrated in Ref. 154 for an ideally mixed reactor and in Ref. 149 for a displacement reactor. In both these papers the sharp change from one regime to the other is ascribed to changes in the criteria describing the external conditions of the process. Beskov and coworkers[155] also point out the possibility of two regimes in a displacement reactor, but they ascribe it to changes in the internal criterion γ, i.e. to degeneracy of the critical conditions[38,39].

The general formulation of the non-stationary problem with allowance for longitudinal transport is discussed in Refs. 156 and 144. The results obtained are highly relevant to our understanding of the validity of our current models of flow reactors (ideally mixed, or displacement).

The thermal regimes of flow reactor operation have so far been treated as the displacement of an elementary volume in space. Maksimov and coworkers[156] attempted to allow for a radical velocity distribution in the liquid in the form of a Poiseuille profile, which causes a marked spread of residence times. The result is a "saddle-shaped" temperature and extent of reaction profile, and also the extension of the high-temperature (quasi-adiabatic) regime to include conditions in which the mean residence time is smaller than the induction period of the adiabatic thermal explosion.

Numerical solutions[157,158] of the equations describing polymerisation in a tube reactor have shown that the initial parabolic velocity profile becomes "stretched" in the axial direction if allowance is made for the variation of viscosity with temperature and concentration.

The residence time of the charge in the reactor depends on the viscosity. As the viscosity increases (due to the formation of products) the dissipative self-heating of the charge becomes increasingly important. This factor determines the conditions for changes in regime, and it can produce novel hydrodynamic effects. Even in the absence of chemical heat evolution we can find critical hysteresis effects due to the non-linearity of the variation of viscosity with temperature[138] or with extent of reaction[159]. These phenomena are reflected by discontinuous changes in flow rate with applied pressure. The increase of viscosity under forced flow can also result in blocking of the channel[159].

The interaction of dissipative and chemical heat evolutions is discussed in Refs. 160–164. Various "hydrodynamic", "chemical", and "intermediate" regimes have been demonstrated, and the number of possible stationary states of the system has continued to increase.

A full mathematical analysis of polymerisation in a flowing medium is given in Ref. 164, where the problem is treated as a one-dimensional case of the viscometric flow between two rotating cylinders separated by a narrow gap. Of course, this simple model can only reveal the principal effects produced by non-isothermal flow during the polymerisation of a liquid. In this model formulation it is assumed that the variation of the viscosity μ with reciprocal temperature and with extent of reaction is experimentally known:

$$\mu = \mu_0 \exp(U/RT + B\eta), \qquad (40)$$

where U is the activation energy for viscous flow, R is the gas constant, and B is a constant which allows for the effect of the reaction on the viscosity of the charge, and hence on the intensity of the dissipative processes. It is assumed that U is independent of η.

A full formulation of the problem includes the kinematic equation for the distribution of velocity in the gap, the equation for the temperature distribution with allowance for the dissipative factors and for the heat transfer conditions at the walls of both cylinders, and the kinetic equation for η, allowing for the strong temperature dependence of the reaction rate. We note that η occurs in formula (40) as well as in formula (4), i.e. there is a complex interaction between the basic factors (temperature, flow rate, and rate of reaction), which is typical of the class of non-isothermal problems considered in this review.

A study[164] of several variants of the solution of this model problem has shown that the presence of dissipative heat sources (associated with the flow of the charge) assists the transition to a flow regime similar to the

hydraulic thermal explosion, i.e. to a sudden, uncontrolled decrease in viscosity and increase in the speed of rotation (if the torque applied to the rotating cylinder is kept constant) or decrease in torque (if the speed of rotation is kept constant). However it is important to note that if we fix the angular velocity of the rotating cylinder and we ignore the heat of the chemical reaction we always arrive at a stationary flow regime[160]. The role of the parameter B in formula (40), which allows for the effect of the reaction on the dissipation by viscous flow, is most important in flow regimes which fall short of the thermal explosion conditions. In this case the parameter B (i.e. the effect of the extent of reaction on the viscosity of the system) determines the maximum self-heating and the change in extent of reaction with time.

In spite of the great practical importance of a combined study of non-isothermal flow and chemical reaction the number of publications in this area is relatively small. Studies of this type are only just beginning, and existing results are limited to a few special model systems. These results show that the effects are far from trivial, but they cannot be applied directly to real technological situations or even to laboratory experiments.

---o0o---

The number of non-isothermal effects in the chemistry and mechanics of polymers is vast. Their basic qualitative features in various regimes of polymerisation and deformation are now well recognised, and the most important effects produced by non-isothermal regimes have been described. However the work so far has been confined to observations in the laboratory. Yet, most industrial processes in polymer technology occur under essentially non-isothermal conditions. The need is quite obvious, but so far it has had very little effect on the general approach to non-isothermal processes because of the great complexity of an adequate quantitative treatment of the interplay of dissipation, deformation, and heat transfer phenomena. Only recently, with the development of appropriate theoretical models and computational techniques, have solutions of the model problems been obtained. Further developments in this direction must remain the main objective of quantitative studies of non-isothermal industrial processes for the production and application of polymeric materials.

Progress in the Theory of Acids and Bases†

M.I.Kabachnik

Published data on the acid-base properties of organic substances in the gaseous phase have been reviewed. The proton affinity (PA) of bases is taken as the enthalpy of the gaseous reaction $M + H^+ \rightarrow MH^+$, with the opposite sign, and the basic strength of the bases (GB) is taken as the change in the standard free energy of this reaction (again with opposite sign). Correspondingly, the acidity in the gaseous phase is taken to be the enthalpy of the reaction $AH \rightarrow A^- + H^+$ or the change in the standard free energy of this reaction.
The dependence of the acid strength and base strength in the gaseous phase on the structures of the molecules of the acids and bases has been examined, and the lack of agreement between the observed facts and the classical electronic interpretation based on the inductive and mesomeric effects of the groups has been discussed. Attention has been drawn to the change in the acid-base properties of organic molecules on going from the gaseous to the liquid phase, and the energetic effects of the solvation of the molecules and ions have been examined.
The bibliography contains 78 references.

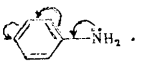
I. INTRODUCTION



The modern electronic theory of organic chemistry, developed in the early nineteen-thirties on the basis of the classical theory of chemical structure, uses an electronic description of the structure of molecules and their reactivity[1].

The description of the structure has two sources and, correspondingly, two languages. The first is the theory of electronic effects (inductive and mesomeric), developed mainly by the efforts of the English school of chemists, and the second is quantum chemistry. The establishment of a satisfactory correspondence between these two descriptive systems was the greatest achievement of theoretical organic chemistry.

The electronic theory of *reactivity* has not reached this high level. The situation is better in the theory of radical reactions. The free valency indices and the energy of homolytic bond rupture can be calculated theoretically and made the basis of an examination. In the theory of ionic reactions, an important role is played by a fundamental principle: "nucleophilic reacts with electrophilic". Although there are exceptions to this principle, it works well in the great majority of cases. The determination of the degree of nucleophilic or electrophilic character of molecules and their fragments and complexes has therefore become an important task of theory. This degree of nucleophilic or electrophilic character is not equivalent to the distribution of the effective charges on the atoms, which can be calculated theoretically. Here, therefore, it is necessary to resort to the use of hypotheses and ideas constructed on the basis of so-called common sense. They appear to be reasonable, although in fact they are often somewhat doubtful. These hypotheses and ideas have in fact been accepted without proof as the only possible translation of the familiar regular features of the classical theory of chemical structure into the language of electronic theory. Since there has been no doubt that the classical theory adequately describes objective reality, these hypotheses have acquired the appearance of principles.

This applies particularly to the acid–base properties of substances, that is to proton transfer reactions. These reactions represent the simplest illustration of the principle "nucleophilic combines with electrophilic". This will therefore be the subject of the subsequent discussion, which begins with several examples of well known facts and their explanations to which we have become accustomed and whose possible revision we have not considered.

First example. The long familiar fact that the base strength of ammonia decreases on the successive attachment of phenyl groups, that is the series $NH_3 > C_6H_5NH_2 > (C_6H_5)_2NH > (C_6H_5)_3N$, has always been explained by stating that in aniline, the unshared pair of electrons is partly transferred to the ring (+*M*-effect):

The mesomeric stabilisation of the base and the partial positive charge on the nitrogen are the factors responsible for the decrease in the base strength of aniline compared with ammonia, where these effects are not found. In diphenylamine, which has two phenyl rings, this effect is stronger, and triphenylamine is not basic at all. All appears sufficiently convincing and clear!? It is not quite so clear, however, why the resonance effect in the aniline molecule should produce such a marked decrease in the proton affinity of the molecule that aniline becomes a much weaker base than ammonia.

Second example. It is well known that pyridine is a much weaker base than ammonia and aliphatic amines. The lower base strength of pyridine has been attributed to the nature of the hybridisation of the unshared pair of electrons of the nitrogen atom. Its hybrid orbital has more *s*-character than in the case of ammonia and amines. In

† Paper presented to the Research Council of the Institute of Hetero-organic Compounds of the Academy of Sciences of the U. S. S. R., 8th September 1978.

pyridine the hybridisation is sp^2, and in ammonia and amines sp^3. Since s-electrons are more firmly bound to the nucleus of the atom, the basic strength decreases with increase in the s-component[1]. Again, all appears logical. Not altogether, however! Why can it be assumed that the greater strength of attachment of the unshared pair to the nucleus alone can produce a much smaller proton affinity of the molecule? The attachment of a proton to two comparable molecules leads to extensive and different changes in their entire energetics, which primarily determine the magnitude of the relative proton affinity! Until recently, this has not been taken into account.

Third example. The introduction of methyl (and in general alkyl) groups in the series $NH_3 < CH_3NH_2 < (CH_3)_2NH$ leads to an increase in base strength, which we readily attribute to the $+I$-effect, that is the positive inductive effect of the methyl groups. On going from dimethylamine to trimethylamine, however, the basic strength decreases: $(CH_3)_2NH > (CH_3)_3N$ ($pk_{a(H_2O)}$ 10.77 and 9.80 respectively). To explain this anomaly, Brown[2] proposed his B-strain hypothesis. Later, under the influence of modern ideas, Condon[3] attributed it to be a change in solvation. In either case, special additional hypotheses were introduced, the aim of which was to save the *a priori* view of the decisive role of the $+I$-effect of the methyl groups.

Fourth example. The acidity of alcohols. We are accustomed to the fact that trimethylcarbinol is an incomparably weaker acid than ethanol. Alcohols can be arranged in the following order of acid strength[4]: $H_2O > CH_3OH > C_2H_5OH > (CH_3)_2CHOH > (CH_3)_3COH$; $H_2O > CH_3OH > C_2H_5OH > C_3H_7OH > C_4H_9OH$..... These series we explain without strain in terms of the inductive $+I$-effect of the alkyl groups. Clear and obvious! Really!? In exactly the same way we used the $+I$-effect to explain the course of the change in the acid strength of the carboxylic acids ($pK_{a(H_2O)}$ values in parenthesis): HCOOH (3.75) $>$ CH_3COOH (4.76) $>$ C_2H_5COOH (4.87) $>$ C_3H_7COOH (4.82) $\geqslant$ C_4H_9COOH (4.86) $\geqslant$ $C_5H_{11}COOH$ (4.86), and the $-I$-effect to explain the change in the strength of the halogenoacetic acids: FCH_2COOH (2.57) $>$ $ClCH_2COOH$ (2.86) $>$ $BrCH_2COOH$ (2.90), recalling that the electronegativities of the halogens decrease in the familiar order: F (4.0) $>$ Cl (3.0) $>$ Br (2.8).

These facts, which can easily be multiplied, are apparently fairly well interpreted by theory. If we were not convinced of this, we would not tell the students. The trouble is not that our arguments are not sufficiently logical. The trouble is that many of the facts which we can explain so successfully in fact are incorrect (in the context in which they are interpreted). This means that our explanations are also incorrect.

To anticipate, it may be said that this error has arisen because absolutely correct results on the measurement of acid or base strengths in the liquid phase have always been assigned only to the actual molecules of the substance being studied. In fact, however, these data should be related to the system consisting of the molecules of the substance being studied and the surrounding molecules of the medium. The acid–base properties of the actual molecules of the substance — outside the medium —are often quite different.

The lack of correspondence between our explanations and the data being explained and the actual state of affairs became clear with the development of high-pressure mass spectroscopy and, somewhat later, ion-cyclotron resonance spectroscopy. These methods made it possible to study the properties of molecules in the gaseous phase, that is when they are not distorted by the influence of surrounding molecules. It is the properties of the molecules in the gaseous and not the liquid phase that must be related to their electronic structure, various electronic effects, etc; in the liquid phase the distortions produced by the environment may be very great.

Here it should be specially stated that the subsequent treatment will deal not with any one or even several studies but with a large number of studies by various workers. Thus the data presented below are now firmly established. Reviews of the new results have been published, for example by Agami[5], Taft[6], and Kebarle[7].

II. PRINCIPLES OF THE EXPERIMENTAL METHODS

In high-pressure mass spectrometry[8–11], a pressure of $\sim 10-10^{-4}$ mmHg is used. Since ions in the gaseous phase are unstable (they disappear rapidly as a result of recombination or discharge on the walls), they must be continually created by the action of radiation. The apparatus must be constructed in such a way that it is possible, within the limited lifetime of the ions, to observe the interaction of the ions with molecules, leading to ion–molecular equilibrium.

The direct mass-spectrometric method of measuring the proton affinity of a molecule M involves the measurement of the appearance potential of the ion MH^+ as a fragment of the degradation of another molecule. From the appearance potential of the ion it is possible to calculate its enthalpy of formation, that is $\Delta H^\circ(MH^+)$, and hence the proton affinity (PA).

$$PA = \Delta H^0(H^+) + \Delta H^0(M) - \Delta H^0(MH^+)$$

The enthalpy of formation of hydrogen ions is calculated from the ionisation potential of atomic hydrogen, and the enthalpy of formation of the molecules M from thermochemical data. It is thus possible to calculate the proton affinity of the molecules M.

The method is one of the few giving absolute results. Its disadvantage is the frequently encountered difficulty of assigning the peaks to a specific ion and the occasional impossibility of obtaining a known given protonated species MH^+ of definite structure[12,13].

Soon after the first publications in this field[14,15], various methods were developed for determining the relative basic strength of molecules in the gaseous phase by high-pressure mass spectrometry. In all cases, a mixture of gases M_1 and M_2 is placed in the reaction cell. Positive ions are generated by electron collision, and the ratio of the concentrations of the ions M_1H^+ and M_2H^+ is measured by a suitable method. The results are used to calculate the equilibrium constant and standard free energy:

$$M_1H^+ + M_2 \rightleftarrows M_1 + M_2H^+$$
$$K = [M_2H^+] \cdot [M_1]/[M_1H^+] \cdot [M_2]$$
$$-\Delta G^0 = RT \ln K$$

To determine the relative acid strength of organic acids A_1H and A_2H in the gaseous phase by high-pressure mass spectrometry, various special methods for generating negative ions are used. An example is provided by the determination of the relative acid strength of two benzoic acids, developed in the University of Alberta in Canada[7]. A gas mixture consisting of the carrier gas methane

(5 mmHg), a weaker acid A_2H (0.050 mmHg), and a smaller quantity of a stronger acid A_1H is irradiated in a compartment by a beam of electrons (e); SO_2F_2 (0.1 mmHg) is added to the mixture for the formation of negative ions. The following principal reactions take place:

$$e + SO_2F_2 = SO_2F + F^-,$$
$$F^- + A_2H = HF + A_2^-,$$
$$A_1H + A_2^- \rightleftarrows A_2^- + A_2H.$$

The capture of an electron by sulphuryl fluoride is exothermic, since the electron affinity of fluorine is greater than the dissociation energy of the F–SO_2F bond. The reaction of the fluoride anion with A_2H is practically irreversible, since benzoic acids in the gaseous phase are much stronger than HF.

The resulting gaseous mixture is "withdrawn" continuously by a fast-acting vacuum pump into the compartment of the mass spectrometer, in which a high vacuum is maintained, and the usual separation according to mass is then carried out. This gives the ratio of the equilibrium concentrations of the ions A_2^- and A_1^- and hence the equilibrium constant:

$$K = [A_1^-] \cdot [A_2H]/[A_2^-] \cdot [A_1H].$$

K can be used to calculate the free energy of proton transfer ΔG°.

The generation of negative ions in the gaseous phase is often carried out using the radiolysis of methyl nitrite or NF_3 [24];

$$e + CH_3ONO = CH_3O^- + NO$$
$$e + NF_3 = F^- + NF_2.$$

The principles of ion-cyclotron resonance spectroscopy are as follows[16,17]. The ion MH^+ with charge q_1 and mass m_1, entering the uniform magnetic field H of the cyclotron, begins to move around a circular orbit of radius r^1, with velocity v_1 and angular frequency ω_1:

$$\omega_1 = v_1/r_1 = q_1H/m_1c.$$

On the applications of a variable electric field E_1 having a frequency ω, resonance occurs when $\omega = \omega_1$. The energy of the electric field is then absorbed, and the ions MH^+ obtain additional kinetic energy. The absorption of the energy of the electric field is reflected on the oscilloscope screen (scanning along the frequency scale ω) by an absorption peak.

To determine the relative proton affinity by the double resonance method, the ions M_1H^+ are generated by a suitable method in the cell of the ion-cyclotron spectrometer; these ions then react with the molecules M_2:

$$M_1H^+ + M_2 \rightleftarrows M_1 + M_2H^+.$$

On the application of two variable electric fields E_1 and E_2 having frequencies corresponding to the angular velocities ω_1 and ω_2 ($\omega_2 = q_2H/m_2c$), two signals are produced on the oscilloscope screen. From these two signals, using appropriate procedures, it is possible to calculate the proton affinity of the molecules M_2 relative to the molecules M_1.

A number of versions of the ion-cyclotron resonance method have been developed and are being used successfully, including the highly effective pulsed method[18–23]. In all cases the experiments are carried out at a low pressure ($p \leq 10^{-4}$ mmHg) and only at room temperature. The method makes it possible, however, to determine the relative concentrations of ions in situ, and has a high accuracy[21].

Basic strength in the gaseous phase is often expressed by the proton affinity of the molecule M, that is by the enthalpy of the reaction $M + H^+ \rightarrow MH^+$, taken with opposite sign: $PA = \Delta H^\circ(MH^+)$ kcal mole^{-1}. The acid strength in the gaseous phase is given by the enthalpy of the reaction $AH \rightarrow A^- + H^+$, again in kcal mole^{-1}. The higher the numerical value of the proton affinity, the stronger the base, and hence the weaker the acid. Strictly speaking, the negative enthalpy of the reaction $M + H^+ \rightarrow MH^+$ gives not the basic strength but the proton affinity. The basic strength GB (Gas-phase Basicity) is given by the change in the standard free energy of this reaction (again taken with negative sign). In practice, however, these quantities are equal or almost equal, since the entropy contribution here is very small. In fact, most published data have been obtained by relative measurements. Since proton transfer reactions are practically isentropic (free energies independent of temperature), the enthalpies for the equilibria measured are equal (or almost equal) to the free energies. Here the entropy term usually does not exceed 2 e.u., which at 298 K is 0.6 kcal mole^{-1}, and hence often lies within the limits of error of the measurement.

In most relative measurements, the standard used is ammonia, that is the equilibrium constant of the proton transfer: $NH_4^+ + M \rightleftharpoons NH_3 + MH^+$, is measured experimentally and used to calculate the free energy of proton transfer ($-\delta\Delta G^\circ$, kcal mole^{-1}) or the enthalpy of proton transfer ($-\delta\Delta H^\circ$, kcal mole^{-1}), which is equal to the latter.

In order to use these data to calculate quantities characterising the equilibrium $M + H^+ \rightleftharpoons MH^+$, namely the basic strength of the molecules $GB(M) = -\Delta G^\circ$ or their proton affinity $PA(M) = -\Delta H^\circ$, it is necessary to know the values of the basic strength and proton affinity of ammonia, that is the values of $-\Delta G^\circ$ and $-\Delta H^\circ$ for the equilibrium $NH_3 + H^+ \rightleftharpoons NH_4^+$. These values have been verified repeatedly, and it has been established that at 298 K they are: $GB(NH_3) = -\Delta G^\circ = 198 \pm 3$ kcal mole^{-1} and $PA(NH_3) = -\Delta H^\circ = 207 \pm 3$ kcal mole^{-1}.[8,9] The entropy term $T\Delta S^\circ$ includes a correction for the change in the symmetry on protonation (for ammonia, $\Delta S^\circ_{symm} = 0.82$ e.u.) and for the translational entropy of the ion H^+[$\Delta S^\circ(H^+) = 26.1$ e.u.].[25] ‡

Thus the published values of the basic strength of the molecules M are $GB(M) = -\Delta G^\circ = -\delta\Delta G^\circ + 198$ kcal mole^{-1}, and the values of the proton affinity of the molecules M are $PA(M) = -\Delta H^\circ = -\delta\Delta H^\circ + 207$ kcal mole^{-1}. These quantities naturally differ by approximately 9 kcal mole^{-1}.

Finally, it should be noted that both methods — high-pressure mass spectrometry and ion-cyclotron resonance spectroscopy — are based on the determination of the ions MH^+ or A^- from their masses. The question of the structure of the ion (protonation position) must be resolved independently by other methods, for example by isotopic substitution.

This entire field has developed comparatively recently. The first pioneer work of the late nineteen-fifties and early nineteen-sixties was carried out by Tal'roze[14]. Since 1965, after the work of Munson[15], the field began to develop rapidly. There are now five main centres in which proton transfer reactions in the gaseous phase are being studied.

---

‡ A new and more accurate value, $-\Delta H^\circ(NH_3) = 202$ kcal mole^{-1}, has been reported[26]. If these data are confirmed, all the numerical values of the relative thermodynamic parameters, related to ammonia as standard substance, are altered by 5 kcal mole^{-1}.

1. Kebarle's group[7,10,24,27-31] in the University of Alberta, Edmonton, Canada. Here, high-pressure (~1 mmHg) mass spectrometry is used; the experiments are carried out at 600 K (at this temperature it is possible to avoid the formation of higher aggregates, which is unavoidable at the given pressure and room temperature). The group is studying the basic and acid strength of organic compounds in the gaseous phase and also the products of the attachment of neutral molecules to gaseous ions, which are regarded as a model of "supermolecules" — solvated molecules in the liquid phase.

2. Bowers, Aue, and coworkers[21,23,32] in the University of California at Santa Barbara. They use ion-cyclotron resonance at varying pressure. The experiment is carried out at room temperature and medium pressure ($\sim 10^{-4}$ mmHg). The group is studying the relative basic strength of organic compounds in the gaseous phase and the relationship between gas-phase and liquid-phase basic strengths.

3. McIver and coworkers[18,20,22,33-37] in the University of California at Irvine; this group is using pulsed ion-cyclotron resonance, suitable for accurate measurements at room temperature and low pressure ($\sim 10^{-6}$ mmHg). Both the basic and acidic properties of molecules in the gaseous phase are being studied. In the discussion of the results obtained in relation to the structure of the molecules and in comparison with the acid-base properties in the liquid phase, the group is cooperating with Taft, a well-known specialist in the correlation analysis of organic reactions, and Arnett, a specialist in the theory of solutions.

4. Beauchamp and coworkers[19,38] in the California Institute of Technology at Pasadena are studying the basic strength of organic compounds by ion-cyclotron resonance at low pressure ($\sim 10^{-6}$ mmHg) and room temperature.

5. Bohme and coworkers[11,39] at York University, Ontario, Canada are using a flow method to measure the rate constants and equilibria for proton transfer at room temperature.

The groups of McIver, Beauchamp, Bowers, and Aue have achieved a high accuracy in their measurements (±2 kcal mole^{-1}).

III. BASIC STRENGTH IN THE GASEOUS PHASE

1. Basic Strength of Various Simple Molecules in the Gaseous Phase[9,11]

Of the hydrides of the elements, ammonia has the highest proton affinity: $PA = 207 \pm 3$ kcal mole^{-1}.[9] In the first period of the periodic system, the lowest basic strength is naturally shown by methane §, so that it is possible to write the series (proton affinities in parentheses):

$$CH_4\ (126) < NH_3\ (207) > H_2O\ (165) > HF\ (137)\ .$$

In the second period, phosphine has the highest proton affinity: SiH_4 (146) < PH_3 (186) > H_2S (170) > HCl (141).

In the halogen series the basic strength of the hydrides increases from HF to HI:

$$HF\ (137) < HCl\ (141 \pm 3) \approx HBr\ (140 \pm 3) < HI\ (145)\ .$$

§ The proton affinity of methane was first measured by Tal'roze in 1958. The value obtained, $PA = 122$ kcal mole^{-1}, is close to the presently accepted value.

2. Basic Strength of Amines in the Gaseous Phase¶

a) Aromatic and heterocyclic amines

In contrast to all measurements in the liquid phase, in the gaseous phase aniline has been found to be a stronger base than ammonia, and only a slightly weaker base than methylamine. Diphenylamine has been found to be an even stronger base, of approximately the same strength as methylamine, and triphenylamine is the strongest of these bases, its strength being greater than that of methylamine[41]. Everything is reversed! Table 1 shows that the proton affinity of aniline in the gaseous phase is 8.9 kcal mole^{-1} greater than that of ammonia. According to other authors[42], the relative basic strength of aniline in the gaseous phase, that is the free energy of the proton transfer: $NH_4^+ + C_6H_5NH_2 \rightleftharpoons NH_3 + C_6H_5NH_3^+$, is slightly less than that, $-\delta\Delta G^\circ = 6.70$ kcal mole^{-1}.[6] According to these data also, however, aniline is a much stronger base than ammonia.

Table 1. Basic strength of various aromatic amines and ammonia in the gaseous phase and in water[41].

Basic strength	NH_3	$C_6H_5NH_2$	$(C_6H_5)_2NH$	$(C_6H_5)_3N$
PA, kcal mole^{-1}	207	215.9[29]	~218	225>PA>218*
pK_a (H_2O)	9.27	4.58	0.9	<0

* Estimated by us from the data in Ref. 41.

Table 2. Basic strength of methylanilines in the gaseous phase and in water[29,30].

Basic strength	$C_6H_5NH_2$	$C_6H_5NHCH_3$	$C_6H_5N(CH_3)_2$
PA, kcal mole^{-1}	215.9	222.1	228.7
pK_a (H_2O)	4.58	4.85	5.06

Dzidic[41], who was the first to observe this phenomenon, wrote that the results which he obtained made it necessary to re-examine our ideas on the mesomeric effect. In fact, it is apparently necessary to re-examine not the idea of the mesomeric effect but the view that it plays a role in determining the basic strength of molecules.

An interesting feature is that the basic strength of N-alkyl derivatives of aniline in the gaseous phase increases with increasing replacement of the hydrogen atoms attached to nitrogen, in the same way as the basic strength increases in a liquid medium. Table 2 gives as an example the data for methylanilines[29,30]. In contrast to the previous case, the ratios of these quantities here have their usual values.

¶ The numerical values of the proton affinity given below are related to ammonia as standard [$PA(NH_3) = 207 \pm 3$ kcal mole^{-1}].

The usual change is also observed in the basic strength of aniline on hydrogenation. Table 3 shows that the basic strength of cyclohexylamine is greater than that of aniline both in the gaseous phase and in water[6,30]. According to Taft and coworkers[6,42], the free energy of proton transfer from the anilinium to the cyclohexylammonium ion

$$(C_6H_5NH_3^+ + \text{cyclo-}C_6H_{11}NH_2 \rightleftarrows C_6H_5NH_2 + \text{cyclo-}C_6H_{11}NH_3^+,$$

measured by ion-cyclotron resonance, is $-\delta\Delta G^\circ = 9.6$ kcal mole^{-1}. The order of the basic strength of heterocyclic bases was completely unexpected (Table 4). In water and in any other liquid medium, pyridine is incomparably weaker than ammonia, not to mention methylamine. In the gaseous phase, however, and hence by itself, its "intrinsic basic strength" is much greater than that of ammonia (by 18.9 kcal mole^{-1}) and is similar to that of dimethylamine. Thus the explanation of the lower basic strength of pyridine compared with ammonia, based on the type of hybridisation of the unshared pair of electrons of the nitrogen in pyridine, hangs in mid-air: pyridine is intrinsically a stronger base than ammonia.

Table 3. Basic strength of aniline and cyclohexylamine in the gaseous phase and in water[8,30].

Basic strength	$C_6H_5NH_2$	cyclo-$C_6H_{11}NH_2$
PA, kcal mole^{-1}	215.9	226.7
$pK_{a\ (H_2O)}$	4.58	10.64

Table 4. Basic strength of various heterocyclic bases in the gaseous phase and in water.

Basic strength	NH_3				
PA, kcal mole^{-1} (Ref.30)	207	214.15	225.6	228.7	231.5[21] 230.1
$-\delta\Delta H^\circ$ ($-\Delta H^\circ_{NH_3} = 0$) (Ref.30)	0	7,1	18,0	21.7	24.5
GB, kcal mole^{-1} (Ref.26)	198	205	216,9	220.4	221.5
$pK_{a(H_2O)}$	9.27	−0.27	5,23	11.27	11.22

At the same time, the influence of γ-substituents in the pyridine ring on the basic strength in the gaseous phase was studied. A good linear correlation is observed between the data for the gaseous phase and for water, with constants σ_I and σ_{R^+}[43]:

$$[\Delta H^0/\Delta H^0_0]^\dagger = 16{,}7\sigma_I + 10{,}3\sigma_R^+ \text{ (in the gaseous phase);}$$
$$\lg(K/K_0) = 5{,}15\sigma_I + 2.69\sigma_R^+ \text{ (in water).}$$

The basic strength in the gaseous phase is much more sensitive to change in the parameters σ, that is to the influence of substituents, than the basic strength in water. Water, as a medium for acid–base equilibria, shows a clearly defined levelling action compared with the gaseous phase.

† In log K units.

Thus the influence of substituents in the pyridine ring on the basic strength in both the gaseous phase and a liquid obeys the Hammett equation, and it seems that here there is no anomaly. It should be noted that quantum-chemical calculation by the CNDO/2 method also gives a similar result. Recently, Aue and coworkers[44] extended this correlation (with slight exceptions) to pyridine derivatives having substituents in the three positions, α, β, and γ.

b) Aliphatic amines[15,23,30,32,33,45]

A large number of studies have been devoted to amines. As alkyl groups are introduced into the ammonia molecule there is a monotonic increase in the basic strength in the gaseous phase, without any deviation for tertiary amines (Table 5). The basic strength in the gaseous phase also increases with increased length of the normal chain in the amine (Table 6). Moreover, it can be seen that, beginning from C_3–C_4, the increase in the basic strength in the gaseous phase becomes less marked. In water, all primary amines have the same basic strength, within the limits of experimental error.

Table 5. Basic strength of primary, secondary, and tertiary aliphatic amines in the gaseous phase and in water.

Basic strength	NH_3	CH_3NH_2	$(CH_3)_2NH$	$(CH_3)_3N$	$C_2H_5NH_2$	$(C_2H_5)_2NH$	$(C_2H_5)_3N$
PA, kcal mole^{-1}	207	218.4	224.9	229.1	221.1	230.1	235.8
GB, kcal mole^{-1} (Ref.26)	198	210.0	216.6	220.8	213.0	221.2	227.7
$pK_{a(H_2O)}$	9.27	10.62	10.77	9.80	10.63	10.93	10.87

Table 6. Dependence of the basic strength of aliphatic amines on the length of the normal chain in the gaseous phase and in water.

Basic strength	CH_3NH_2	$C_2H_5NH_2$	$C_3H_7NH_2$	$C_4H_9NH_2$	$C_5H_{11}NH_2$	$C_6H_{13}NH_2$
PA, kcal mole^{-1}	218.4	221.1	222.3	222.8	223.1	223.2
ΔPA, kcal mole^{-1}	11.0	3.1	1.2	0.5	0.3	0.1
GB, kcal mole^{-1} (Ref.26)	210.0	213.0	214.4	214.9	—	—
$pK_{a(H_2O)}$	10.62	10.63	10.53	10.60	10.63	10.64

The basic strength of amines in the gaseous phase also increases with branching in the substituent (Table 7). An interesting feature is that in aqueous solution the basic strength decreases in this case; this was attributed to *B*-strain. In general, however, the order of the change in the basic strength of amines agrees with the inductive $+I$-effect of the alkyl groups. It appears that here it is possible to retain the explanation based on this effect. This would be the case if there were no data on the acid strength of amines in the gaseous phase. To anticipate, it may be noted that the relative acid strength of alcohols and amines in the gaseous phase, which Brauman and Blair studied by semi-quantitative ion-cyclotron resonance[46,47] also

increases with increased number of alkyl groups on the nitrogen, the number of carbon atoms in them, and the degree of branching of their hydrocarbon skeleton, that is under the influence of the factors which led to an increase in the basic strength of amines:

$$(C_2H_5)_2NH > H_2O > NH_3;$$
$$(C_2H_5)_2NH > (CH_3)_2NH > NH_3;$$
$$C_3H_7NH_2 > C_2H_5NH_2 > CH_3NH_2 > NH_3;$$
$$(CH_3)_3CCH_2NH_2 > (CH_3)_3C{-}NH_2 > (CH_3)_2CH{-}NH_2 > C_2H_5{-}NH_2 > CH_3{-}NH_2 .$$

At the same time, naturally, the $+I$-effect also increases. According to all our ideas, however, the $+I$-effect cannot increase the acid strength; it can only decrease it. This means that the concept of the $+I$-effect cannot be used to explain the acid–base properties of amines. It is necessary to look for other ways of interpreting the experimental data.

Table 7. Dependence of the basic strength of aliphatic amines on the degree of branching of the carbon chain in the gaseous phase and in water.

Basic strength	n-$C_4H_9NH_2$	iso-$C_4H_9NH_2$	s-$C_4H_9NH_2$	t-$C_4H_9NH_2$
PA, kcal mole^{-1}	222.8	223.2	224.4	225.4
GB, kcal mole^{-1} (Ref.26)	214.9	215.4	216 4	217.3
$pK_{a(H_2O)}$	10.60	10.49	10.56	10.45

c) Aliphatic cyclic amines

The basic strengths of several cyclic amines have been measured in the gaseous phase. Here, the basic strength increases with increase in the size of the ring, whereas in water it is practically constant[21] (Table 8).

Table 8. Basic strength of various saturated heterocyclic bases in the gaseous phase and in water[20,30].

Base			
PA, kcal mole^{-1}	231.5 230.1[21]	228.7	227
$pK_{a(H_2O)}$	11.22	11.27	11.29

d) Aliphatic diamines

Unexpected results were obtained in the study of the basic strength of alkylenediamines[30,32]. These substances were found to be very strong bases in the gaseous phase; they show a greater (by 10–20 kcal mole^{-1}) proton affinity than the corresponding monoamines. This is not observed in the liquid phase (Table 9). Proton transfer to the monoamine molecule in the gaseous phase is almost isentropic, that is $\Delta G^\circ = \Delta H^\circ$, whereas in the case of diamines there is a considerable decrease in entropy. This is related to the formation of an intramolecular hydrogen bond[32], which is assumed to be linear:

Studies of aqueous solutions of diamines have not detected hydrogen bonds of this type in monoprotonated diamines.

Table 9. Basic strength of mono- and diamines in the gaseous phase and in water[30,32].

Basic strength	*n* = 2	3	4	5	6	7
Monoamines $CH_3(CH_2)_nNH_2$						
PA, kcal mole^{-1}	222.3	222.8	223.1	223.2	—	—
$pK_{a(H_2O)}$	10.53	10.60	10.63	10.64	10.66	10.65
Diamines $NH_2(CH_2)_nNH_2$

$pK_{a(H_2O)}$	10.09	10.62	10.80	10.86	—	—

3. Basic Strength of Oxygen Bases in the Gaseous Phase

This question will not be dealt with in detail. The regular features here are in principle the same as in the case of amines. The basic strength of all oxygen compounds in the gaseous phase is greater than that of water; with increase in the number of carbon groups, their size, and their degree of branching, the basic strength increases in all cases[15,48,49].

1. Alcohols				
a) the effect of homology	H_2O	CH_3OH	C_2H_5OH	C_3H_7OH
PA, kcal mole^{-1}	165	182, 180[51]	187, 186[51]	189
b) the effect of branching	CH_3OH	CH_3CH_2OH	$(CH_3)_2CHOH$	$(CH_3)_3COH$
PA, kcal mole^{-1}	182	187	193, 195[51]	198, 206[51]
2. Esters of carboxylic acids	$HCOOCH_3$	CH_3COOCH_3	$C_2H_5COOCH_3$	$CH_3COOC_2H_5$
PA, kcal mole^{-1}	188	202	205	205
3. Carboxylic acids	HCOOH	CH_3COOH	C_2H_5COOH	
PA, kcal mole^{-1}	175	188	190	
4. Oxo compounds	CH_2O	CH_3CHO	CH_3COCH_3	
PA, kcal mole^{-1}	168[51, 52]	183[49, 53]	202[48], 190[51]	

Table 10. Basic strength of various alkyl halides in the gaseous phase[50].

Basic strength	CH_3F	CH_3Cl	CH_3Br	CH_3I	C_2H_5F	C_2H_5Cl	C_2H_5Br	C_2H_5I
PA, kcal mole^{-1}	151	160	163	170	163	167	170	175

4. Basic Strength of Alkyl Halides and Alkenes in the Gaseous Phase

Alkyl halides are protonated according to the equation:

$$RX + H^+ \rightleftarrows (R{-}X{-}H)^+ .$$

In general, the readily understood order given in Table 10 [50]

is observed. An interesting feature is that the basic strength of alkyl halides in the gaseous phase is comparable with that of alkenes, benzene, and acetylene (Table 11).[51] This should be borne in mind for the study of the mechanism of gaseous reactions.

Table 11. Basic strength of various alkenes, benzene, and acetylene in the gaseous phase[51].

Basic strength	$CH_2=CH_2$	$CH_3CH=CH_2$	$C_2H_5CH=CH_2$	$(CH_3)_2C=CH_2$	C_6H_6	$CH\equiv CH$
PA, kcal mole^{-1}	160	179	183	195	183[a]	151

IV. RATIO OF THE BASIC STRENGTHS IN THE GASEOUS AND LIQUID PHASES

The study of the basic strength of organic substances in the gaseous phase and comparison with the basic strength in solutions lead to contradictory results. On the one hand, there is a marked lack of correspondence. between the values of the basic strength (ammonia–aniline, ammonia–pyrrole, ammonia–pyridine, trimethylamine–dimethylamine, etc.), and this undoubtedly requires a change in existing ideas regarding the factors determining basic strength in the liquid phase. On the other hand, there are cases where the structure of molecules influences the basic strength in the liquid and in the gaseous phases in qualitatively the same way (and sometimes quantitatively, with linearity of the free energies). Thus in some cases the liquid medium changes only the scale of the differences in the basic strength for a series of substances, leaving the order of the changes unaltered; in other cases, however, the actual order of the basic strength is altered. In these latter cases, the change from the gaseous phase, in which the basic strength of *isolated* molecules is measured, to the liquid phase, where the basic strength of molecules in a liquid environment, that is *solvated* molecules, is measured, has such a marked effect that the ratio of the basic strengths of the substances being compared is reversed. This question has been examined in detail by Taft and Arnett and coworkers[6,54,55], Aue and coworkers[23,26,56], and others; good reviews have been published by Arnett[55,57].

The basic strength in the liquid phase is determined by two factors: the "intrinsic" or "internal" basic strength, measured in the gaseous phase as the proton affinity (more accurately as $-\Delta G$ for the attachment of a proton), which is a property of the molecules themselves; and an external factor, the solvation factor, which is a property of the "molecule of the base + molecule of the medium" system[58]. The effect of the external factor may be stronger than the influence, to which we are accustomed, of the structure of the molecules of the base with their characteristic inductive and mesomeric effects; the effect of this factor often masks everything completely. Thus our explanations of the acid–base properties of substances in the liquid phase only by means of inductive effects (aliphatic amines, alcohols, esters), mesomerism (aniline and its derivatives, naphthylamines, etc.), and hybridisation (pyridine, quinoline, pyrimidine) are primitive and often simply incorrect.

It should be said that the theory of the gas-phase and liquid-phase basic strength of organic substances is still in the development stage. Many questions, not at all of secondary importance, are still disputed. These include the understanding of the essential features and role of the inductive effect of alkyl groups, polarisability in the stabilisation of ions, resonance and hyperconjugation effects, the effect of hybridisation, etc. The research groups of Aue and Kebarle on the one hand, and of Taft and Arnett on the other, have different views. The application of electrostatic concepts, widely used by Aue, is not favoured by other workers. Taft's efforts to break down all thermodynamic functions according to the additive contributions of the effects is not supported either, however. Some selections from the literature on this topic, which seem more correct to the present author, are discussed below.

The basic strength of organic substances is determined by the difference between the free energies of the neutral molecules and the corresponding protonated forms, in most cases onium ions. The main contribution is made by the stability of the ion MH^+. Ions are unstable in the gaseous phase. Once formed, they rapidly disappear by recombination with oppositely charged ions or on the walls. In the liquid phase, ions are stabilised by solvation, the energy of which may exceed the energy of formation of the ion from the molecule. The least stable in the gaseous phase are the simplest ions: H_3O^+, NH_4^+, NH_2^-, OH^- . . . . The replacement of a hydrogen atom in these ions by organic groups stabilises the ions by delocalisation of the ionic charge. Kebarle calls this "internal solvation" [7]. The greater the "capacity" of the organic group for delocalisation of the charge (in this sense, the higher its polarisability ‡), the greater the delocalisation, the more stable the ion, and, other conditions being equal, the higher the base strength.

Aniline in the gaseous phase is a stronger base than ammonia, so that the ammonium ion is unstable, and the anilinium ion is stabilised by delocalisation of the onium charge, possibly by an inductive–mesomeric mechanism. For an analogous reason, pyridine is a stronger base than ammonia, trimethylamine is a stronger base than dimethylamine, and the base strength (and acid strength) of aliphatic amines increases with increase in the number, size, and degree of branching of the hydrocarbon groups present[59–61]. This is confirmed by theoretical quantum-chemical calculations[62–65], although, as pointed out by Huheey[61], it would have been better if these calculations had not been carried out a posteriori.

Nevertheless, in the examination of the questions of base strength it is also necessary to take account of factors stabilising the neutral molecules of the base. Taft and coworkers[42] drew attention to the fact that comparison of the base strength of amines is justified only if they have equal numbers of carbon atoms and a similar skeleton. In this case aniline should be compared not with ammonia but with cyclohexylamine. The base strength of the latter is greater than that of aniline in the gaseous phase by

‡ Here and subsequently the concept of the polarisability of a group will be used only in the sense of the ability of this group, when attached to an ionic centre, to delocalise its charge.

9.6 kcal mole^{-1}. Taft[6] considers that the main contribution to this difference is made by the mesomeric stabilisation of the neutral aniline molecules (~ 5.5 kcal mole^{-1} according to Taft) §.

Similarly, according to Taft, pyridine should be compared not with ammonia but with, for example, N-methylpyrrolidine ($-\delta\Delta G^\circ$ in the gaseous phase 7.5 kcal mole^{-1}). In this case the role of the hybridisation effect is distinguished (the weighting of the *s*-orbital of the unshared pair of electrons of the nitrogen is greater for pyridine). Arnett points out that Aue[66] attributes too much importance to the hybridisation effect in the examination of the base strength of ethyleneimine (compared with dimethylamine). The question of the role of hybridisation has also been dealt with by Brauman and Blair[67].

Taft and, following him, Arnett probably overestimate the role of electronic effects in neutral molecules and underestimate their role in protonated ions (the polarisation effect according to Taft). In any case, our view that the mesomeric effect and the effect of hybridisation play a definite role in determining the base strength of organic substances is not refuted by the results of measurements in the gaseous phase. Those comparisons and conclusions unjustifiably based on incorrectly understood facts have been refuted.

The relationships change most significantly on going to the liquid phase. Appropriate thermodynamic studies were carried out by Arnett[55] by applying the Born cycle[68]:

$$\begin{array}{ccc} MH^+_{(gas)} & \xrightarrow{\Delta G^\circ_{ion(gas)}} & (M + H^+)_{(gas)} \\ \uparrow -\Delta G^\circ_{solv\ (MH^+)} & & \downarrow \Delta G^\circ_{solv\ (M+H^+)} \\ MH^+_{(liquid)} & \xrightarrow{\Delta G^\circ_{ion(liquid)}} & (M + H^+)_{(liquid)} \end{array} .$$

In this cycle, the ionisation of the cation MH^+ in the liquid phase takes place in two ways: the first is the ionic dissociation in the liquid phase, for which $\Delta G^\circ_{ion(liquid)} = -RT \ln K_{a(liquid)}$. The second is the desolvation of the cation (transfer to the gaseous phase, free energy of solvation $-\Delta G^\circ_{solv\,(MH^+)}$), dissociation in the gaseous phase ($\Delta G^\circ_{ion(gas)}$), followed by reverse transfer to the liquid phase ($\Delta G^\circ_{solv(M + H^+)}$).

The two routes naturally lead to the same free energy change, so that:

$$\Delta G^\circ_{ion(liquid)} = \Delta G^\circ_{ion(gas)} - \Delta G^\circ_{solv\,(MH^+)} + \Delta G^\circ_{solv\,(M+H^+)} .$$

If $\Delta G^\circ_{ion(liquid)}$ is known from the ionisation constant in the liquid phase, $\Delta G^\circ_{ion(gas)}$ from measurements in the gaseous phase, and $\Delta G^\circ_{solv(M + H^+)}$ from thermochemical measurements, it is possible to calculate $\Delta G^\circ_{solv(MH^+)}$. Similar cycles can be constructed for ΔH° and $T\Delta S^\circ$.

In fact, these calculations are carried out as relative calculations (usually relative to ammonia as reference standard). In this case the difficulties associated with the choice of standard states disappear, and, in addition, the terms relating to the proton are eliminated. In fact, this relative calculation is related not to the simple equilibrium $MH^+ \rightleftharpoons M + H^+$ but to the double equilibrium $MH^+ + NH_3 \rightleftharpoons M + NH_4^+$. Thus from the Born cycle:

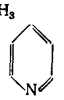
$$\delta\Delta G^\circ_{ion(liquid)} = \delta\Delta G^\circ_{ion(gas)} - \delta\Delta G^\circ_{solv\,(MH^+)} + \delta\Delta G^\circ_{solv(M)} ,$$

where the latter δ denotes the relative change in the free energy (relative to the ionisation of NH_4^+).

The free energy of solvation of ions is very high. Its relative value may be only slightly less than the relative free energy of ionisation in the gaseous phase, but may be equal to it and even exceed it. If the difference in the free energies of solvation of the ions M_1H^+ and M_2H^+ being compared is less than the difference in the energies of ionisation in the gaseous phase, no anomalies are observed in the qualitative order of the change in base strength in the gaseous phase and in solution. If however the difference in the free energies of the solvation of the ions is greater than the difference in the free energies of ionisation in the gaseous phase, the above-mentioned lack of agreement will be observed between the base strength in the gaseous phase and the base strength in solution.

This is the case, for example, for aniline and ammonia. The protonation of aniline in the gaseous phase is energetically more favourable than the protonation of ammonia, by 7–8 kcal mole^{-1}. This means that the protonation constant of aniline is greater than that of ammonia by 5–6 orders of magnitude. When the ammonium ion is transferred to the aqueous phase, however, the large energy of solvation $-\Delta G_{solv(NH_4^+)} = 77.1$ kcal mole^{-1} is gained, and this is much greater than that for the transfer of the anilinium ion. As a result, the ammonium ion becomes energetically much more favourable than the anilinium ion in the aqueous phase. As a consequence, in the aqueous phase the protonation of aniline is less favourable by 6.5 kcal mole^{-1} than the protonation of ammonia (pK_a 9.27 and 4.58 respectively). Thus the fact that in the liquid phase aniline is weaker than ammonia is due to the less extensive solvation of the anilinium ion compared with the ammonium ion, and not to the basic properties of the unshared pair of electrons of the nitrogen atom in the aniline molecule.

A complete thermodynamic calculation has been carried out for many primary, secondary, and tertiary amines[26,54]. It has been found, for example, that in the case of trimethylamine, the protonation in the gaseous phase ($\delta\Delta G^\circ_{ion(gas)}$) is more favourable by 20.4 kcal mole^{-1} than in the case of ammonia, and the free energy of solvation of the trimethylammonium ion ($\delta\Delta G_{solv(MH^+)}$) is lower by 20.7 kcal mole^{-1}. In the gaseous phase, trimethylamine is a stronger base than ammonia, as a result of the inductive effect of the three methyl groups, but in the liquid phase this advantage is almost completely quenched by the less extensive solvation of the ion. Thus the basic strength of trimethylamine in the aqueous phase is only slightly greater than that of ammonia (by 0.8 kcal mole^{-1}).



This quenching does not take place in the case of dimethylamine, which in water is a stronger base than trimethylamine. Here, the following results have been obtained for the MH^+ ion: $\delta\Delta G^\circ_{ion(gas)} = 15.8$ kcal mole^{-1}, $\delta\Delta G^\circ_{ion(liquid)} = 2.1$ kcal mole^{-1}, $\delta\Delta G^\circ_{solv(M)} = 0$, and

§ Here there may be one objection. Quantum-chemical calculation of the effective charges on the atoms in alkylammonium molecules[56] shows that the positive charge of the ion is distributed to the extent of more than 90% on the hydrogen atoms. It may therefore be doubted if it is justifiable to assign the observed differences to the resonance effect when comparing amines which satisfy only the requirement that the numbers of carbon atoms be equal and the skeleton similar, but for which the numbers of hydrogen atoms differ to such a great extent.

$\delta\Delta G^\circ_{solv(MH^+)}$ = 13.7 kcal mole^{-1}. In the gaseous phase, dimethylamine is weaker than trimethylamine $\delta\Delta G^\circ_{ion(gas)}$= 15.8 kcal mole^{-1} for $(CH_3)_2NH_2^+$ and 20.4 kcal mole^{-1} for $(CH_3)_3NH^+$, the difference in favour of trimethylamine being 4.6 kcal mole^{-1}). In aqueous solution, however, $\delta\Delta G^\circ_{ion(liquid)}$ = 0.8 kcal mole^{-1} for $(CH_3)_3NH^+$ and 2.1 kcal mole^{-1} for $(CH_3)_2NH_2^+$. The difference in favour of dimethylamine is 1.3 kcal mole^{-1}, in spite of the increased $+I$-effect in the case of trimethylamine from the introduction of the third methyl group. The difference in the hydration energies is greater.

Extensive data have been published[26] on the terms of the Born cycles for a number of bases. Of particular interest, for example, are the ratios[26] of the free energies of dissociation and solvation of the molecules and ions of pyridine, N-methylpyrrolidine, and piperidine, given in Table 12 (as before, the protonation of ammonia is taken as standard). Here, $-\Delta H^\circ_{solv(NH_4^+)}$ = 83.8 kcal mole^{-1}, $-\Delta G^\circ_{solv(NH_4^+)}$ = 77.1 kcal mole^{-1}¶.

Table 12. Born cycle data for pyridine, N-methylpyrrolidine, and piperidine[26] ($\delta\Delta G^\circ$, kcal mole^{-1}).

Compound	$\delta\Delta G^\circ_{ion(liq.)}$	$\delta\Delta G^\circ_{solv.(MH^+)}$	$\delta\Delta G^\circ_{ion(gas)}$	$\delta\Delta G^\circ_{solv.(M)}$
NH_3	0	0	0	0
	—5.49	26.9	18.9	1.99
	2.69	22.9	23.5	1.58
	1.65	27.9	26.4	2.71

In the gaseous phase, the protonation of pyridine is more favourable by 18.9 kcal mole^{-1} than the protonation of ammonia, but in aqueous solution, as a consequence of the loss of 26.9 kcal mole^{-1} for solvation, the protonation of pyridine is less favourable by 5.5 kcal mole^{-1} than that of ammonia. The relationships between pyridine and N-methylpyrrolidine are different. The protonation of the latter is more favourable both in the gaseous phase and in solution, by 7.5 kcal mole^{-1} in the gaseous phase and by 7.14 kcal mole^{-1} in solution. The effect of solvation is approximately the same in both cases (the difference is ~1.0 kcal mole^{-1}), and does not alter anything. This equality of the solvation effects apparently lies at the basis of Taft's rule[42], mentioned above.

¶ The change in the standard free energy for the transfer of 1 mole of NH_4^+ at a pressure of 1 atm from the gaseous phase to a hypothetical molal aqueous solution[69].

The free energy of solvation of an ion can be calculated approximately from the Born equation[68]:

$$-\Delta G^\circ_{solv}\ \frac{z^2e^2}{2r}\left(1-\frac{1}{D}\right).$$

According to this equation, the standard free energy of the transfer of a spherical ion of radius r, having a charge ze, from a vacuum to a medium with a dielectric constant D is proportional to the square of the charge and inversely proportional to the radius of the ion. The solvation energy decreases with increase in the radius of the ion. Moreover, on delocalisation of the charge, when $ze = \Sigma q_i$, the solvation energy decreases, since $\Sigma q_i^2 < z^2e^2$ (the sum of the squares is always less than the square of the sum). The purely electrostatic picture of solvation is naturally insufficient for an adequate description, but the relationships given are nevertheless useful for a qualitative examination of the part played by solvation. The greater the size of the ion and the more extensively delocalised the charge, the less extensive the solvation. It should be noted that the effect of decrease in solvation on delocalisation of the charge was first noted by Mason[70].

Thus the part played by the hydrocarbon groups attached to the atom which acts as protonation centre is appreciably different in the gaseous phase and in solution. In the gaseous phase, increase in the polarisability (in the sense of delocalisation capacity) of the groups — their number, size, degree of branching, etc. — stabilises the ions and hence makes the base stronger. In the liquid phase, increase in the volume and polarisability of the groups decreases solvation, destabilises the ion, and hence decreases the strength of the base.

In the liquid phase, it is also necessary to take account of the volume effect: increase in the volume of the ion in all cases requires the expenditure of work to create a cavity in the solvent; this work decreases the energy of solvation, particularly in highly associated solvents; the steric hindrance of solvation also decreases the solvation energy. On the other hand, it is also necessary to take account of the possible formation of hydrogen bonds or other complexes with the solvent, since this leads to a significant increase in the solvation energy. The effect of this factor is effectively illustrated by the decrease in the exothermic character of the hydration of primary, secondary, and tertiary substituted ammonium ions compared with the unsubstituted NH_4^+ ion.[55] For primary ammonium ions, $\delta\Delta H^\circ_{solv(MH^+)}$ has an average value of ~6.8 kcal mole^{-1}, for the secondary ions ~13 kcal mole^{-1}, and for the tertiary ions ~19 kcal mole^{-1}, that is there is a decrease of ~6 kcal mole^{-1} for each hydrogen bond lost. Within each type, however, the decrease in the solvation energy increases with the volume of the ion (±20% of the average value). Thus the effect of hydrogen bonds predominates in this case.

Aue and coworkers[26] consider that the number of hydrogen bonds formed by the alkylammonium ions with water does not play such an important role in determining the solvation energy. They attribute more importance to the strength of the hydrogen bonds, which decreases with decreased charge on the NH_X^+ group. Since the charge decreases with increased number of alkyl groups attached to nitrogen, the illusion is created that a part is played by the number of hydrogen bonds, which also decreases with increased number of alkyl groups. In Aue's opinion, hydrogen bonds produce only a slight change in the solvation energy; the main contribution to the solvation energy of ammonium ions is made by the hydrophobic solvation of the alkyl groups and the electrostatic effects in the spirit of the Born theory.

It can be seen that the question of the dependence of the solvation energy on the structure of a molecule is fairly complex. No rational approach has yet been developed for its complete interpretation or more particularly its theoretical calculation.

V. ACID STRENGTH IN THE GASEOUS PHASE

1. Acid Strength of Alcohols in the Gaseous Phase

The first qualitative results of the study of the acid strength of alcohols in the gaseous phase were obtained by Brauman and Blair in 1968.[46] They immediately attracted the attention of chemists, since they contradicted the accepted conclusions and ideas of theoretical organic chemistry. This was followed by the publication of a number of papers by different authors, confirming the results of Brauman and Blair. Qualitatively, they reduce to the following: the acid strengths of alcohols having a normal chain increase in the order[46,59]: $H_2O < CH_3OH < CH_3.CH_2OH < CH_3CH_2CH_2OH < CH_3CH_2CH_2CH_2OH < CH_3CH_2.CH_2CH_2CH_2OH$, that is the acid strength in the gaseous phase increases with increase in the chain length. Branching of the group also leads to an increase in the acid strength, the effect being greater than the effect of the increase in its size: $CH_3OH < CH_3CH_2OH < (CH_3)_2.CHOH < (CH_3)_3COH < (CH_3)_3CCH_2OH$; $(CH_3)_3COH \geqslant n\text{-}C_5H_{11}OH$ †.

Increase in the formal $+I$-effect of the alkyl groups is accompanied by an increase in their electron-acceptor effect, that is the $-I$-effect. Similar relationships were observed for the acid strength of amines, as noted above.

Within the framework of the concept of the $+I$-effect, which is fixed for the alkyl groups, this sounds paradoxical. It can be shown, however, that we ourselves have created this paradox. The fact is that a constant $+I$-effect, characteristic of alkyl groups, is one of the dogmas characteristic of present-day work in organic chemistry. A dogma which has appeared from nowhere! Ingold, one of the founders of the electronic theory of organic chemistry, wrote in the early nineteen-thirties[71]: "It can be deduced from the premises stated above that the inductive effect of all alkyl groups *is zero* ... (They) will merely exert those polar effects which are impressed on them by the other polar groups ... The important property of alkyl groups is that they are more polarizable than hydrogen ... Since the majority of substituents commonly encountered are attractors of electrons, alkyl groups generally function as feebly electron-repelling groups: the possibility of the other type of behaviour can, however, be foreseen..."

Thus the direction of the inductive effect of alkyl groups depends on whether they are attached to an atom (or group) with a greater or lesser electronegativity than the alkyl groups. The first case leads to the relationships called the $+I$-effect, and the second to the relationships called the $-I$-effect.

This very perspicacious warning of Ingold was forgotten, and we teach students that alkyl groups exhibit a $+I$-effect. In fact, this is not the case. In proton attachment reactions, the principal role is played by the stabilisation of the cation formed, for example R_3N^+H or RO^+H_2. Here, the alkyl groups "deliver" electrons, since they are attached to an atom carrying a positive charge, that is an atom which is much more electronegative than the alkyl groups. Here, the larger the alkyl group, the greater its polarisability in the sense of "delocalisation capacity", the greater the $+I$-donor power and the greater the basic strength.

In the acidic dissociation of amines and alcohols, the principal role is played by the stabilisation of the resulting anion RNH^- or RO^-. Here, the alkyl groups "withdraw" electrons, since they are attached to an atom carrying a negative charge, that is an atom which is less electronegative than the alkyl groups. In this case, the larger the alkyl, the stronger its $-I$-effect, leading to greater acidity. Thus the t-butyl and neopentyl groups are both the strongest donors and the strongest acceptors among the alkyl groups, since they have the greatest ability, among alkyl groups, to delocalise any charge (Brauman and Blair[59-61]). Later, Arnett and coworkers[37] supported this view. The acid strength of alcohols in the vapour phase was also examined theoretically by MINDO and CNDO/2 methods and calculated *ab initio*. The results confirmed these suggestions. Reversal of the order of acid strength of the alcohols is observed on going to the liquid phase. The factors responsible are the same as in the case of the basic strength of amines. The smaller the anion, the stronger the effect of solvation. The order is reversed, not because of the $+I$-effect, which is not present in this case, but because of the solvation effect.

2. Acid Strength of Carboxylic Acids in the Gaseous Phase

The acid strength of carboxylic acids in the gaseous phase is expressed as the free energy change in the dissociation:

$$RCOOH \rightleftarrows RCOO^- + H^+ ,$$

When a standard acid AH is used, relative measurements are made for the reaction:

$$RCOOH + A^- \rightleftarrows RCOO^- + AH ,$$

In these reactions, the entropy change is small and does not exceed 1–2 e.u., so that it is usually assumed that $\Delta G^\circ = \Delta H^\circ$, and the acid strength is measured by the proton affinity of the anion, that is the enthalpy of the reaction

$$A^- + H^+ \rightarrow AH,$$

taken with the opposite sign ($-\Delta H^\circ$).

It is possible to write:

$$\Delta H^0 = D\,(A{-}H) + IP\,(H) - EA\,(A),$$

where $D(A-H)$ is the energy of rupture of the bond, O–H, $IP(H)$ the ionisation potential of atomic hydrogen, and $EA(A)$ the electron affinity of the radical $RCO\dot{O}$. Since $IP(H)$ is a constant equal to 313.6 kcal mole^{-1}, a measure of the acid strength is usually obtained by calculating the quantity

$$\delta\Delta H^0 = D\,(A{-}H) - EA\,(A), \text{ that is } \delta\Delta H^0 = \Delta H^0 - IP\,(H) = \Delta H^0 - 313{,}6$$

(kcal mole^{-1}). For water, $D(A-H) - EA(A) = D(HO-H) - EA(OH^\cdot) = 77$ kcal mole^{-1}. In the gaseous phase, water is a very weak acid. All other oxygen acids are stronger,

† McIver's group[37] carried out quantitative measurements of the acid strength of various alcohols in the gaseous phase relative to methanol The following values were obtained for $-\delta\Delta G_{ion(ROH)}$ in kcal mole^{-1} (at 298 K; an increase in the numerical value indicates an increase in the acid strength): CH_3OH 0, C_2H_5OH 2.9, iso-C_3H_7OH 4.8, t-C_4H_9OH 5.6, neo-$C_5H_{11}OH$ 6.9. These data confirm the qualitative conclusions of Brauman and Blair.

that is their $\delta\Delta H^\circ$ values are less than 77 kcal mole^{-1}, and the smaller the numerical value of $\delta\Delta H^\circ$, the stronger the acid.

In the homologous series of carboxylic acids, the value of $\delta\Delta H^\circ$ for ionisation decreases with increase in the number of carbon atoms (Table 13 [24]). Thus butyric acid is stronger than propionic acid, and propionic acid is stronger than acetic acid; the order is reversed compared with the acid strength in water or other liquid media. Formic acid is the strongest acid in this series, however. To enable the reader to estimate the numerical values of the strength of acids in the gaseous phase ($\delta\Delta F^\circ$), the gaseous acid strength of the hydrogen halides is given (Table 14).

Table 13. Acid strength of various carboxylic acids in the gaseous phase and in water[24].

Acid strength	CH_3COOH	C_2H_5COOH	C_3H_7COOH	HCOOH
$\delta\Delta H^0$, kcal mole^{-1}	31.8	30.6	29.7	28.6
pK_a (H_2O)	4.76	4.87	4.82	3.75

Table 14. Acid strength of hydrogen halides in the gaseous phase and in water[24,74].

Acid strength	HF	HCl	HBr	HI
$\delta\Delta H^0$, kcal mole^{-1}	56.3	20.0	10.0	0.7
pK_a (H_2O)	+3.2	−7	−9	−11

The study of the gas-phase acid strength of halogen-substituted carboxylic acids gave unexpected results. They are of course stronger than the unsubstituted acids (Table 15).

Table 15. Acid strength of chloroacetic acids in the gaseous phase and in water[24].

Acid strength	CH_3COOH	$ClCH_2COOH$	$Cl_2CHCOOH$
$\delta\Delta H^0$, kcal mole^{-1}	31.8	19.0	12.0
pK_a (H_2O)	4.76	2.86	1.25

The order of the halogens is here reversed, however, compared with the liquid phase (Table 16). Bromoacetic acid in the gaseous phase (that is in itself) is stronger than chloroacetic acid, and the latter in turn is stronger than fluoroacetic acid; the concept of the *-I*-effect does not apply. The electronegativities of the halogens decrease in the order F > Cl > Br. This means that there are other factors in addition to the *-I*-effect (which is observed in the comparison with the unsubstituted acid). In fact, in the XCH_2COO^- anion, bromine is apparently more readily polarised, and its polarisation by the anionic charge stabilises the anion (the negative charge is delocalised). In an aqueous or in general liquid medium, on the other hand, in least polarisable fluorine-containing anion, in which the negative charge is concentrated in a small volume, is most effectively stabilised by the liquid medium; in the liquid phase, fluoroacetic acid is stronger than the others.

Table 16. Acid strength of various halogenoacetic acids in the gaseous phase and in water[75].

Acid strength	FCH_2COOH	$ClCH_2COOH$	$BrCH_2COOH$
$\delta\Delta H^0$, kcal mole^{-1}	21.0	19.0	17.9
pK_a (H_2O)	2.57	2.86	2.90

If however the carboxylic acid molecule contains substituents which each exhibit inductive and mesomeric effects, but which produce only slight changes in the total "delocalisation capacity" of the acid residue, the usual influence of electronic effects on the acid strength are observed satisfactorily in this series of derivatives. This is the case for the benzoic acid derivatives XC_6H_4COOH (X = NH_2, CH_3O, HO, CH_3, Cl, F, CN, NO_2). In this series, satisfactory correlations were obtained between ΔG° for dissociation in the gaseous phase (and pK_a in liquid phases) and the constants σ of Brown and Taft[31].

3. Acid Strength of Phenols in the Gaseous Phase

Here, reference may be made to the literature[35,75].

Table 17. Acid strength of thiols in the gaseous phase and in water[76].

Acidity	H_2S	t-C_4H_9SH	iso-C_3H_7SH	n-C_3H_7SH	C_2H_5SH	CH_3SH
$\delta\Delta H^0$, kcal mole^{-1}	37.5	39.4	40.3	41.1	41.7	43.2
pK_a (H_2O)	7.02	11.05	10 89	10.78	10.61	10.33

4. Acid Strength of Thiols in the Gaseous Phase[76]

Here, very interesting relationships are observed (Table 17). Hydrogen sulphide is a stronger acid than thiols both in the gaseous phase and in aqueous solution. In the gaseous phase, however, the strongest acid among the thiols is t-butyl mercaptan, which is the weakest acid in water. On the other hand, methanethiol, which is the

weakest acid in the gaseous phase, is a stronger acid than the other thiols in water. These relationships show a greater resemblance to those for the carboxylic acids than to those for the alochols (where water is weaker than all alcohols). The explanation for these phenomena is apparently similar to the explanation of the influence of alkyl groups on the strength of carboxylic acids (see below).

5. CH Acid Strength of Hydrocarbons and Their Derivatives

Carbon atoms in the hybridisation states sp^2 or sp have a greater electronegativity than in the state sp^3. Thus the bond $C_{(sp^3)} - C_{(sp^2)}$ should have a dipole moment directed from the sp^3- to the sp^2-hybridised carbon atom:

$$C_{(sp^3)} \longrightarrow C_{(sp^2)} .$$

Thus alkyl groups should exhibit the familiar donor $+I$-effect. In this connection, the acid strengths of various unsaturated and aromatic hydrocarbons were studied in the gaseous phase[67]. The following series were obtained (some of the quantitative data are given in Ref. 36):

$$C_6H_5OH > C_6H_5CH_3 > CH_3OH > n\text{-}(CH_3C_6H_4CH_3 > H_2O;$$
$$CH \equiv CH > n\text{-}C_4H_9C \equiv CH > CH_3C \equiv CH > H_2O.$$

Here everything is remarkable!

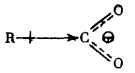
1. Toluene is found to be a stronger acid than water. This indicates that the benzyl anion $C_6H_5CH_2^-$ is intrinsically more stable than OH^-. This is understandable, since the OH^- anion in the gaseous phase, that is when there is no solvation, is very unstable.

2. The fact that *p*-xylene is less acidic than toluene indicates that the methyl group has a destabilising action in the anion, since here the methyl "delivers" electrons ($+I$-effect):

3. Similarly, aklylacetylenes are less acidic than acetylene itself. A destabilising effect is present:

$$R \longrightarrow C \equiv O^- .$$

4. It is much more difficult to explain why t-butylacetylene is nevertheless a stronger acid than methylacetylene (by 3.4 kcal mole^{-1}). For this case, an apparently justified explanation has been put forward. In the general case, the stability of an anion is influenced by the dipole



$$C_{(sp^3)} \longrightarrow C_{(sp)}$$

but in the butyl derivative the charge on the positive end of the dipole is assigned to the butyl group, which has a greater volume and polarisability. This decreases slightly the destabilising action of the alkyl group compared with the methyl group.

The question of the strength of carboxylic acids can now be considered:

$$HCOOH > C_3H_7COOH > C_2H_5COOH > CH_3COOH .$$

Here it is necessary to consider the system

containing the bond

$$C_{(sp^3)} \longrightarrow C_{(sp^2)} .$$

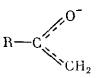
The action of an alkyl group produces a dipole, which is directed from the carbon atom of the alkyl group to the carbon atom of the carboxylate anion and destabilises the anion‡. This destabilisation, which is greatest for the methyl group, decreases slightly with increase in the size of the alkyl group, as a consequence of the delocalisation of the charge at the positive end of the dipole.

In an aqueous medium, however, the stability of the anion decreases with increase in its volume: $HCOOH^- > CH_3COO^- > C_2H_5COO^- > C_3H_7COO^-$, since there is a decrease in solvation, and the familar order of acid strengths is obtained:

$$HCOOH^- > CH_3COOH^- > C_2H_5COOH^- > C_3H_7COOH^- \ldots$$

This explanation naturally requires verification, but in any case this order cannot be attributed to the $+I$-effect of the alkyl groups (as is done in the most recent and best textbooks of organic chemistry).

6. Acid Strength of Ketones in the Gaseous Phase



Recently, Brauman and coworkers[77] determined the acid strength of various ketones in the gaseous phase. The following order of acid strength was obtained:

$$C_6H_5COCH_3 > (CH_3)_3CCOCH_3 > CH_3COCH_3.$$

This differs from the order of acid strength in the liquid phase[78]:

$$C_6H_5COCH_3 > CH_3COOH_3 > (CH_3)_3CCOCH_3.$$

Here, the factors operating are apparently the same as in the case of carboxylic acids. In the anion

compared with the anion of acetaldehyde (R =H), the alkyl groups have a destabilising action (the dipole is directed to the anionic centre).

$$R \longrightarrow C_{(sp^2)}$$

This destabilising action is least for R = t-Bu, and greatest for R = CH_3. In the liquid phase, for reasons which are readily understood, acetone and methyl t-butyl ketone change places.

VI. SUMMARY

The intrinsic acid–base properties of molecules are observed only in the gaseous phase. In a liquid medium, these properties are distorted; they are deformed by the very strong interaction with the medium. In the examination of acid–base properties (and chemical properties in general) in the liquid phase, that is properties which necessarily belong to the system "molecule of the reactant plus surrounding molecules of the medium", these properties have been assigned only to the molecule of the

---

‡ It should be noted that the effect of the dipole $C_{sp^3} - C_{sp^2}$ or $C_{sp^3} - C_{sp}$ is also observed in other cases. Thus prōp-2-ynylamine in the gaseous phase is a weaker base than propylamine by 6.3 kcal mole^{-1}; diprop-2-ynylamine is weaker than dipropylamine by 10.5 kcal mole^{-1}, and triprop-2-ynylamine is weaker than tripropylamine by 13.7 kcal mole^{-1} [6]. This results from the fact that in the corresponding cations $(CH \equiv C\text{-}CH_2)_nNH_{4-n}^+$ the dipole $C_{sp^3} \rightarrow C_{sp}$ destabilises the cation. Taft calls these hybridisation–inductive effects.

reactant, and very beautiful but incorrect explanations have been constructed from the non-existent consequences of the action of inductive and mesomeric effects. These ideas have been re-examined in recent years.

The present review has dealt with only proton transfer reactions. The same situation is observed in reactions of other types. Extremely interesting results have been obtained by Kebarle's group[7] in the study of ionic clusters in the gaseous phase. These products of the attachment of neutral molecules to ions provide models of short-range order on solvation ("supermolecule" formation). Reactions involving addition to multiple bonds, nucleophilic substitution at a saturated carbon atom, and other reactions have also been studied in the gaseous phase. In these fields it has been found that the role of intramolecular effects in neutral molecules has been exaggerated and frequently distorted, and the problems of the stability of ions in relation to the influence of solvation have been insufficiently analysed. It is now time for a painstaking re-examination and correction of all the errors made in theoretical organic chemistry in the last 40 years. We are standing on the threshold of great events in the theory of heterolytic reactions in organic chemistry, which will be realised in the near future.

The Isomerisation of Unstable Organoelemental Radicals in Liquid-phase Reactions

R.Kh.Freidlina and A.B.Terent'ev

The studies carried out in recent years on the rearrangement of radicals involving the migration of Cl and Br atoms as well as the R_3Si, R_3Ge, RC = O, $RC\overset{O}{\underset{O}{<}}$, and RS groups in liquid-phase reactions are examined. Chemical and physicochemical data (obtained by EPR, stereochemical, tracer atom, etc. methods), supporting the idea of the intermediate formation of bridging radicals in 1,2- and 1,3-migrations of atoms and groups, are presented. The unusual rearrangements of aromatic perfluoro-radicals are discussed.
The bibliography includes 113 references.

I. INTRODUCTION

Studies on the rearrangements of organic radicals in the liquid phase constitute a rapidly developing field of modern radical chemistry[1-8]. The wide variety of the known types of rearrangements of radicals is due to the differences in the nature of the migrating groups, the variable nature of the atoms from which the migrating group is split off, the nature of the radical centre, and the length of the chain separating the radical centre from the migrating atom or group.

This review deals with true intramolecular rearrangements associated with the migration of atoms or groups via the mechanisms

It includes the rearrangements of radicals involving the migration of Cl, Br, and F atoms and of the R_3Si, R_3Ge, $RC\overset{O}{\underset{O}{<}}$, RCO, and RS groups; the literature on these rearrangements up to 1978 inclusive is considered. Despite all the differences between them, the above types of rearrangements have the following common features: the structure of the hydrocarbon skeleton of the radical remains unchanged in the rearrangement; heteroatoms (halogens) or groups incorporating heteroatoms (R_3Si, R_3Ge, RCO, RCOO, or RS) migrate; the migrating atoms or groups contain lone electron pairs, π-bonds, or unoccupied *d* orbitals.

All the known rearrangements of short-lived radicals can apparently be divided into two types: (1) rearrangements of radicals involving the migration of a hydrogen atom; (2) rearrangements involving the migration of atoms and groups containing lone electron pairs, π-bonds, and vacant *d* orbitals. These two types of rearrangements differ in their characteristics. For example, the 1,2-migration of hydrogen in radicals is virtually unknown; on the other hand, 1,2-migration and to a lesser extent 1,3-migration of atoms and groups are characteristic of all the rearrangements considered in the present review. An important problem for the understanding of 1,2-rearrangements involves criteria which make it possible to distinguish an intramolecular rearrangement from the formation of rearranged radicals via an elimination–addition mechanism, which can be formally represented schematically as follows:

In certain cases it is possible to distinguish these two types of reaction. The detection of the eliminated migrating group with the aid of a suitable trapping agent is sometimes used as proof that the reaction proceeds via an elimination–addition mechanism. It is noteworthy that this method does not provide an unambiguous answer, since the migrating group can be split off simultaneously with an intramolecular rearrangement.

The formation of intermediate three-membered bridged intermediate radicals or a bridged transition state is postulated for all the rearrangements involving 1,2-migration of atoms enumerated above. Indeed, it has been shown by EPR in instances where it was possible to obtain a resolved spectrum that the presence of chlorine and silyl, germyl, and certain other groups in the β-position with respect to the radical centre has a marked influence on the conformation of the radical. Thus a detailed study of the spectroscopic parameters of β-chloroalkyl radicals and their temperature variation showed[8] that in the most stable conformation of this radical the chlorine atom is located in the "eclipsed" position relative to the *p* orbital of the radical centre, which is favourable for the interaction between them.

The formation of bridged radicals can be to some extent detected by chemical methods. Thus anchimeric cooperation with the selective elimination of hydrogen from the β-position with respect to the atom or group which is capable of forming a bridged radical is observed in some reactions. A characteristic feature of the intermediate formation of a bridged radical is also the retention of optical activity in reactions involving a rearrangement of radicals.

Most of the known rearrangements of radicals have been investigated by methods of preparative organic chemistry. It can now be assumed that the information obtained by these methods about the radical-chain mechanisms of the rearrangements, the structures of the rearranged and non-rearranged radicals, and the intramolecular nature of the reaction has been confirmed in

many instances by various physicochemical methods (EPR, stereochemistry, tracer atoms, etc.).

II. REARRANGEMENTS OF RADICALS WITH MIGRATION OF CHLORINE, BROMINE, AND FLUORINE ATOMS

1. 1,2-Migration of Chlorine

Nesmeyanov et al.[9] first demonstrated reliably, in the case of the rearrangement of polychloroalkyl radicals I to radicals II with 1,2-migration of chlorine (1,2-Cl), the possibility of the liquid-phase isomerisation of unstable aliphatic radicals:

$$\underset{\text{(I)}}{XCCl_2\dot{C}YCH_2Z} \rightarrow \underset{\text{(II)}}{X\dot{C}ClCYClCH_2Z} \ ;$$

X=H, F, Cl, or CH_3; Y=H, Cl, Br, or CH_3; Z=Br, CCl_3, or SR.

The possibility of such a rearrangement in the above investigation has been questioned[10]. Radicals of type (I) have been generated by the addition of the radicals Ż to polychloropropenes $CH_2 = CYCCl_2X$. For the reaction of 3,3,3-trichloropropene with HBr initiated by benzoyl peroxide, the following scheme has been put forward:

$$HBr + C_6\dot{H}_5 \rightarrow C_6H_6 + \dot{B}r \ :$$
$$\dot{B}r + CH_2{=}CHCCl_3 \rightarrow BrCH_2\dot{C}HCCl_3 \ :$$
$$BrCH_2\dot{C}HCCl_3 \xrightarrow{\text{rearrangement}} BrCH_2CHCl\dot{C}Cl_2 \ :$$
$$BrCH_2CHCl\dot{C}Cl_2 + HBr \rightarrow BrCH_2CHClCCl_2H + \dot{B}r \text{ etc.} \qquad (1)$$

Data on this rearrangement (literature up to 1964) have already been surveyed[4] (see also Wilt[2] and Walling[5]). In recent years rearrangements of this type have been investigated vigorously, but comparatively few new examples have been described. In particular, a study has been made of the rearrangement of primary radicals (III) to radicals (IV):

$$\underset{\text{(III)}}{CCl_3\dot{C}H_2} \rightarrow \underset{\text{IV}}{\dot{C}Cl_2CH_2Cl} \ .$$

This rearrangement was investigated by methods of preparative chemistry[11], EPR,[12,13] and the spin trapping technique[14,15]. Other examples of rearrangements of this type have been found[16-18] in the decomposition of acetyl peroxide in polychloroethanes and polychloropropanes containing the CCl_3, $CHCl_2$, or CCl_2 groups; among other products, there are compounds whose formation is treated as a 1,2-Cl rearrangement via mechanisms analogous to mechanism (1).

The rearrangement of β-monochloroalkyl radicals with 1,2-migration of chlorine has been described in recent years for radicals obtained by the abstraction of hydrogen from $(CH_3)_3CCl$ by t-butoxy-radicals[19]:

$$(CH_3)_3CCl \xrightarrow{RO\cdot} (CH_3)_2CCl\dot{C}H_2 \rightarrow (CH_3)_2\dot{C}CH_2Cl \xrightarrow{ROBr} (CH_3)_2CBrCH_2Cl \ .$$

Analogous rearrangements have been observed with the aid of EPR at low temperatures. The rearranged radicals have been identified by this method in reactions involving the abstraction of bromine from $(CH_3)_2CClCH_2Br$ and $CH_3CBrHC(CH_3)_2Cl$ by $(C_2H_5)_3Si$ radicals[12] and the abstraction of hydrogen from $(CH_3)_3CCl$.[12] The rearranged radicals, obtained by γ-irradiation from $(CD_3)_3CCl$, have been identified by EPR.[20]

The rearrangement of radicals with 1,2-migration of chlorine from C to Si in the gas phase[21] and from S to C in the liquid phase[22] has been described.

The study of the 1,2-Cl rearrangement on interaction of polyhalogenohydrocarbons with diazomethane has been developed to some extent[23]. The reactions of polyhalogeno-derivatives with diazomethane had been described earlier[24]:

$$CCl_4 + CH_2N_2 \xrightarrow{h\nu} (ClCH_2)_4C \ ;$$
$$XCCl_3 + CH_2N_2 \xrightarrow{h\nu} XCH_2C(CH_2Cl)_3 \ ;$$
X=H, Br, or CH_3CO_2 .

It has been suggested[24] that the reaction involves a series of consecutive stages in which methylene adds to the radical centre with subsequent 1,2-Cl migration. New examples of reactions of this type have been studied in recent years[23] and it has been shown that, depending on the reactant ratio and temperature, it is possible to isolate from the reaction mixture products obtained by the stabilisation of intermediate rearranged radicals formed by an exchange reaction with the initial polyhalogeno-derivative. For example, the reaction of diazomethane with $BrCCl_3$ led to the isolation of $BrCCl_2CH_2Cl$, $BrCCl.(CH_2Cl)_2$, $BrC(CH_2Cl)_3$, and $BrCH_2C(CH_2Cl)_3$. Analogous compounds were obtained in the reaction of diazomethane with $BrCCl_2CH_2Cl$, $BrCCl_2CH_3$, or $BrCCl_2H$.[23] A possible mechanism of this reaction has been discussed in detail in a review[2].

There are no data on the kinetics of the elementary stage of the 1,2-Cl rearrangement. The overall kinetics of reactions of this type, initiated by ultraviolet irradiation or benzoyl peroxide at 60°C, have been investigated in relation to the homolytic isomerisation of polyhalogenopropenes via the mechanism[25]

$$XCCl_2CBr{=}CH_2 \xrightarrow{h\nu} XCCl{=}CClCH_2Br \ (X{=}Cl, CH_3, \text{or F}) \ . \qquad (2)$$

It was established that the reaction is fastest in the case of 2-bromo-3,3,3-trichloropropene ($k = 2.2 \times 10^{-4}$ s^{-1}), which is followed by 2-bromo-3,3-dichlorobutene ($k = 1.5 \times 10^{-5}$ s^{-1}), the isomerisation of 2-bromo-3,3-dichloro-3-fluoropropene being slowest ($k = 5 \times 10^{-6}$ s^{-1}), It has been shown that the chain propagating species is the bromine atom. The quantum yield in the photochemical initiation of the isomerisation of 2-bromo-3,3,3-trichloropropene has been determined as 980 ± 30. The data obtained confirmed the mechanism of this rearrangement proposed by Nesmeyanov et al.[26] and made it possible to specify the chain initiation and termination stages. Presumably, the above series, in terms of decreasing rates of isomerisation of polyhalogenopropenes, corresponds to the series based on decreasing stabilities of the rearranged radicals:

$$Cl_2\dot{C}CBrClCH_2Br > CH_3\dot{C}ClCBrClCH_2Br > F\dot{C}ClCBrClCH_2Br \ .$$

It has been noted in the literature that most of the known rearrangements lead to the formation of more stable radicals from less stable ones. However, a number of instances are known in which the non-rearranged and rearranged radicals do not differ in stability; rearrangements have also been encountered in which more stable and relatively unreactive radicals rearranged to more reactive radicals with a lower stability. Certain examples of 1,2-Cl rearrangements of secondary chloroalkyl radicals to yield less stable primary radicals have been published[4]. However, comparatively few examples of such rearrangements are known and they give a low yield of the rearranged products. The calculation of the total electronic energies of two pairs of radicals is therefore of interest: $ClCH_2\dot{C}HCCl_3$ (V) and $ClCH_2CHCl\dot{C}Cl_2$ (VI); $ClCH_2\dot{C}ClCHCl_2$ (VII) and $ClCH_2CCl_2\dot{C}HCl$ (VIII). Radicals (VI) and (VIII) should be formed in the 1,2-Cl

rearrangement of radicals (V) and (VII) respectively. It had been shown earlier that radicals of type (V) do indeed rearrange to radicals (VI); under the same conditions, radical (VII) does not rearrange[4]. Calculation[27] showed that the relative stabilities of the radicals depend on their conformations and that, among the radicals enumerated above, radical (VI) is the most stable; the rearrangement of (V) to (VI) should be accompanied by an energy gain. The energies of radicals (VII) and (VIII) in the ground state differ little, but the rearrangement of radical (VII) to (VIII) nevertheless requires an expenditure of energy:

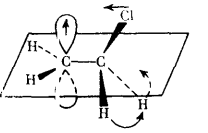
$$E\,(ClCH_2\dot{C}HCl_2) - 0.85\ eV = E\,(ClCH_2CHCl\dot{C}Cl_2)\ ;$$
$$E\,(ClCH_2\dot{C}ClCHCl_2) + 0.06\ eV = E\,(ClCH_2CCl_2\dot{C}HCl)\ .$$

The absence of the rearrangement of radical (VII) to radical (VIII) with 1,2-migration of chlorine is thus apparently really associated with the unfavourable ratio of the stabilities of the above radicals, as had been suggested previously[4].

The rearrangement of radicals with 1,2-migration of chlorine has been observed also in the polymerisation of polyhalogenopropenes. It has been established[28,29] that the radical polymerisation of 3,3,3-trichloropropene and 3,3-dichloro-3-fluoropropene leads to polymers which contain mainly the rearranged $CH_2CClHCCl_2$ and $CH_2CH.ClCClF$ units respectively according to ^1H and ^{19}F NMR and ^{35}Cl NQR data.

Rearrangements with 1,5- and 1,6-migration of chlorine in chloroalkyl radicals proceed with difficulty if they are possible at all. Indirect data supporting the possibility of 1,5-Cl and 1,6-Cl rearrangements have been published[30-32].

The application of the EPR method and the spin trapping technique in the study of rearrangements with 1,2-migration of chlorine. Significant progress in identifying rearranged and non-rearranged radicals, formed in many reactions and in demonstrating the intramolecular nature of the rearrangements has been achieved in recent years with the aid of the EPR method, including the use of spin-trapping agents.



β-Chloroalkyl radicals. A number of workers have shown that the chlorine atom in the β-position with respect to the radical centre has a strong influence on the conformation of the radical[3,12,13,20,33,34], as had been observed earlier for certain other β-substituted alkyl radicals[35]. The EPR spectrum of the radicals obtained from t-butyl chloride under the influence of ^{60}Co γ-rays at 77 K exhibits a very large splitting between the components due to the hyperfine interaction (HFI) with the halogen atom[20].

The following HFI constants have been found for the EPR spectrum of $\dot{C}H_2CH_2Cl$: $a_\alpha(H) = 21.5$ G, $a_\beta(H) = 11.5$ G, and $a_\beta(Cl) = 17.4$ G at $-60°C$;[12] $a_\alpha(H) = 21.75$ G, $a_\beta(H) = 10.20$ G, $a_\beta(^{35}Cl) = 18.78$ G, and $a_\beta(^{37}Cl) = 15.65$ G at $-125°C$;[3] $g = 2.60199$. These data correspond to an asymmetric bridged structure (A) in which the chlorine atom eclipses the orbital of the odd electron, which requires a definite deviation from the regular tetrahedral geometry at the β-carbon atom[36]:

(A)

The EPR spectra have been investigated in greatest detail for a series of β-chloroalkyl radicals[3,13,33,37]. A detailed study of the spectral parameters—the g-factor, the hyperfine interaction constants for the β-protons and β-chlorine atoms, their temperature dependence, and the width of the lines in the spectrum—led to the conclusion[3] that the most stable conformation of the β-chloroethyl radical is of the type illustrated below†:

In this "eclipsed" conformation the chlorine atom is located at the optimum position for interaction with the radical centre. In conformity with Kochi's cautious formulation[3], the EPR data suggest that the structure of the β-chloroalkyl radicals can be regarded as the bridged type in a broad sense of the term. Radicals with chlorine in a more remote position relative to the radical centre cannot exist in the analogous conformation and do not isomerise with 1,3-, 1,4-, or 1,5-migration of chlorine. Bearing this fact in mind as well as the observed conformation of the β-chloroalkyl radicals, one can regard it as established that the 1,2-migration of chlorine in monochloroalkyl radicals has an intramolecular mechanism.

Table 1. EPR study of the rearrangement of radicals with 1,2-migration of chlorine.

Initial compound	Attacking radical	t, °C	Non-rearranged radicals (unidentified)	Rearranged radicals (identified)	Refs.
CH_3CCl_3	$CF_3O^\cdot$	−140	$\dot{C}H_2CCl_3$	$ClCH_2\dot{C}Cl_2$	13
$BrCH_2CCl_3$	$Et_3\dot{S}i$	−140	$\dot{C}H_2CCl_3$	$ClCH_2\dot{C}Cl_2$	13
ICH_2CCl_3	$n\text{-}Bu_3\dot{S}i$	−120	$\dot{C}H_2CCl_3$	$ClCH_2\dot{C}Cl_2$	12
$(CH_3)_2CClCH_2Br$	$Et_3\dot{S}i$	−110 −130	$(CH_3)_2CCl\dot{C}H_2$	$(CH_3)_2\dot{C}CH_2Cl$	12, 33
$(CH_3)_2CClCHBrCH_3$	$Et_3\dot{S}i$	−60	$(CH_3)_2CCl\dot{C}HCH_3$	$(CH_3)_2\dot{C}CHClCH_3$	12, 33
$(CH_3)_3CCl$	t-BuO·	−200	$(CH_3)_2CCl\dot{C}H_2$	$(CH_3)_2\dot{C}CH_2Cl$	12, 33
$(CD_3)_3CCl$	($\gamma^{60}Co$)	−196	$(CD_3)_2CCl\dot{C}D_2$	$(CD_3)_2\dot{C}CD_2Cl$	20

Rearranged radicals were identified by EPR in the liquid phase at low temperatures in the reactions presented in Table 1; non-rearranged radicals were not detected. Despite the incompleteness of the information obtained, these data are extremely important. They confirm the radical mechanism of the rearrangements, the high rate of 1,2-migration of chlorine in the radicals, and the greater stability of the rearranged radicals compared with the non-rearranged radicals.

gem-Polychloroalkyl radicals. For the purpose of the identification of both rearranged and non-rearranged radicals, the EPR method combined with the spin-trapping technique proved to be fruitful (Table 2).[34] The method has definite advantages for the solution of this problem. The spin-adducts (nitroxy-radicals) formed

† The arrows indicate the direction of the shifts of atoms in the transition state.

Table 2. EPR study of the rearrangements with 1,2-migration of chlorine using spin trapping agents.

are sufficiently stable for their study by EPR in the liquid phase at the usual temperatures [38-40]. The large selection of spin-trapping agents available makes the method virtually universal for the detection of a wide variety of radicals. The method is experimentally simple. It has been shown [14,41,42] that various radicals formed in the reaction system can be identified by employing the selectivity of the spin-trapping agents [34,43]. Thus in a series of reactions (Table 2, Nos. 3–6) rearranged radicals of the type $R\dot{C}Cl_2$, $R\dot{C}ClF$, and $R\dot{C}HCl$ were identified in experiments carried out in the presence of methylnitrosopropane $(CH_3)_3CNO$(MNP) as the spin-trapping agent. Non-rearranged radicals of the type $R\dot{C}HR$ could be identified by carrying out the same reactions in the presence of another spin-trapping agent, namely 2-methyl-2-nitrosobutan-3-one $CH_3COC(CH_3)_2NO$ (MNB); Table 2 shows that other applications of the selectivity of spin-trapping agents have also been made.

Particularly important results have been obtained by employing the EPR method in the study of the detailed mechanism of the rearrangement of $XCCl_2\dot{C}H_2$ radicals with 1,2-migration of chlorine. Hoag and Heiba [44] suggested (without carrying out their own experiments on this subject) that the rearrangement proceeds via an elimination–addition mechanism. Significant evidence in support of an intramolecular mechanism of this rearrangement has been adduced in a number of papers and reviews [4,5,13]; it can now be assumed that this has been rigorously demonstrated by EPR. [14,41] It has been shown in a number of instances [14] that the EPR spectra of the spin adducts of the radicals $RCCl_2\dot{C}Cl^1Cl^2$ with $(CH_3)_3CNO$ and other trapping agents contain signals which show that the Cl^1 and Cl^2 atoms are equivalent in relation to the p_z orbital, when their environments in the nitroxy-radical are the same, but are non-equivalent when the environments are not the same. This observation has been used in the study of the rearrangements of radicals (IX) to (X) and of (XI) to (XII):

$$\underset{\text{(IX)}}{CCl_3\dot{C}HCl} \rightarrow \underset{\text{(X)}}{\dot{C}Cl_2CCl_2H} \quad \underset{\text{(XI)}}{CCl_3\dot{C}ClCH_2Cl} \rightarrow \underset{\text{(XII)}}{\dot{C}Cl_2CCl_2CH_2Cl} \ .$$

Radicals (IX) and (XI) were generated by the abstraction of hydrogen from CCl_3CH_2Cl or $CCl_3CHClCH_2Cl$ by phenyl radicals (Table 2, Nos. 2 and 7). The radicals C_6H_5 were obtained by the method of Razuaev et al. [45] The parameters of the EPR spectra of the spin-adducts of these radicals with MNP are presented in Table 3. In both cases the EPR spectra consist of a superposition of signals due to the spin-adducts of both non-rearranged and rearranged radicals with $(CH_3)_3CNO$. It was found that the β-chlorine atoms in the spin-adducts of the rearranged radicals are non-equivalent with respect to the $2p_z$ orbital of the nitrogen atom; this establishes unambiguously that the migrating chlorine atom in the radical is located in the plane of the $2p_z$ orbital of the carbon atoms to which the chlorine migrates and hence the intramolecular nature of the rearrangement is demonstrated [14,41].

Table 3. Parameters of the EPR spectra [14] of the nitroxy-radicals $RN(\dot{O})C(CH_3)_3$.

Non-rearranged radical	a_N, G	a_{Cl}, G	Rearranged radical	a_N, G	a_{Cl}, G
$CCl_3\dot{C}HCl$	17.9	4.8	$\dot{C}Cl^1Cl^2CCl_2H$	12.7	Cl^1 4,5; Cl^2 1,0
$CCl_3\dot{C}ClCH_2Cl$	12.1	4.0	$\dot{C}Cl^1Cl^2CCl_2CH_2Cl$	12.2	Cl^1 4,0; Cl^2 1,0

2. The 1,2-Migration of Bromine

The rearrangement of radicals with 1,2-migration of bromine was described for the first time by Skell et al. [46] in 1961 in relation to the photochemical chlorination of t-butyl bromide and isopropyl bromide by t-butyl hypochlorite with formation of 1-bromo-2-chloro-methylpropane and 1-bromo-2-chloropropane respectively. Rearrangements of this type have been investigated vigorously in recent years in the photochemical halogenation of bromohydrocarbons [20,44,46-52]. The primary radical rearranges to a tertiary radical with a higher yield than in the rearrangement to a secondary radical, which is consistent with the general behaviour [4]. Thus the rearrangement in the photochemical chlorination of t-butyl bromide, resulting in 1-bromo-2-chloro-2-methylpropane, proceeds with a nearly quantitative yield [46], while the rearrangement of isopropyl bromide under the same conditions gives rise to 1-bromo-2-chloropropane with a yield which is only 15% of theoretical [46]. It is noteworthy that in the series of examples investigated a formally unusual rearrangement of more stable radicals to less stable radicals takes place, which undoubtedly reflects the characteristics of the mechanism of this rearrangement. For example, the photochemical bromination of labelled butyl bromide,

$$CH_3CH_2CH_2CH_2^{82}Br \xrightarrow{Br^\cdot} CH_3CH_2CH^{82}BrCH_2Br \ ,$$

results in the conversion of a secondary radical into a primary radical [48].

There are no reliably established examples of rearrangements with migration of bromine to a more remote radical centre [53]. It has been suggested [31] that the

formation of $[(CH_3)_2CBrCH_2CBr_2]_2SO_2$ in the reaction of bis(tribromomethyl)sulphone with isobutene includes a stage where the radicals rearrange with 1,5-migration of bromine:

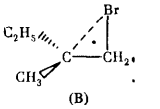
$$CBr_3SO_2CBr_2CH_2\dot{C}(CH_3)_2 \rightarrow \dot{C}Br_2SO_2CBr_2CH_2CBr(CH_3)_2 \ .$$

The mechanism of the rearrangement of radicals with 1,2-migration of bromine. The problem of the mechanism of the rearrangement of radicals with 1,2-migration of bromine proved to be closely related to the problem of the anchimeric cooperation in the elimination of the β-carbon atom in bromoalkanes and the formation of a bromine bridge in the radical. In this case the rearrangement involves the mechanism

$$R_2CBr-CHR'_2 \xrightarrow[-HX]{+X^\cdot} R_2C(\overset{\cdot}{Br})-CR'_2 \xrightarrow{+X^\cdot} R_2CX-CR'_2Br \ .$$
X = Cl, or Br

The anchimeric cooperation in the abstraction of a β-hydrogen atom and the formation of a bridged radical is also indicated by data published in a number of reports [46, 48,50,54,55].

The high selectivity of the radical hydrogenation of bromohydrocarbons with formation of vicinal dihalogeno-derivatives, noted by many workers [46-52], confirms the bridged structure of bromoalkyl radicals. However, in another series of studies data have been adduced in support of an elimination–addition mechanism for reactions of this kind [40,56,57]. It has also been stated [48] that there are no data whereby one could distinguish the situation where the intermediate bromoalkyl radicals are static symmetrical bridged structures from one where there is an equilibrium conversion of a pair of asymmetric intermediate bridged species ($\tau_{1/2} \simeq 10^{-11}$ s).



Data have also been presented in support of the intermediate formation of the classical radicals $\dot{C}-C-Br$ [44,52] (see also Cristol et al.[58]). It is noteworthy that none of the above series of studies can explain without contradictions all the observed facts in terms of a single reaction mechanism [47,58].

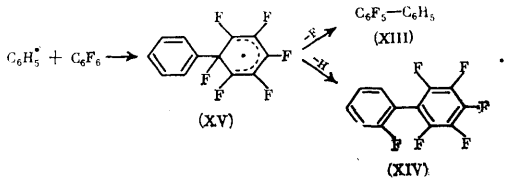
The attempts to obtain the EPR spectra of β-bromoalkyl radicals in the liquid phase were unsuccessful even at $-120°C$ owing to the instability of these radicals [59]. The reaction of HBr with *cis*- and *trans*-but-2-ene as well as certain other unsaturated compounds has been investigated [60] by EPR at 70 K; the authors have attributed the observed spectra to the radical-adducts of bromine and but-2-ene. These spectra are compatible with the idea that bridged radicals of the type

$$CH_3CH(\overset{\cdot}{Br})-CHCH_3$$

are formed. However, the possibility of another assignment of the spectral signals and of a different interpretation of the results of Abel and Peitte [60] has been pointed out [61].

Chemical data, in particular the results of the study of the stereochemistry of the photochemical halogenation of bromoalkanes, support the bridged structure of the β-bromoalkyl radicals. Thus the liquid-phase photobromination of the optically active 1-bromo-2-methylbutane with bromine [62] yielded 1,2-dibromo-2-methylbutane with a high optical purity. The rearrangement in the photochlorination of (+)(2*S*)-bromobutane by t-butyl hypochlorite leads to the formation of optically active 1-bromo-2-chlorobutane [48]. Analogous results were obtained in a study [63] where the authors were able to trap an asymmetric intermediate radical (B) in the form of a product $C_2H_5CD.(CH_3)CH_2Br$ of the addition of deuterium (from DBr) to the bridged radical with retention of the initial configuration to an extent greater than 96%:[63]

(B)



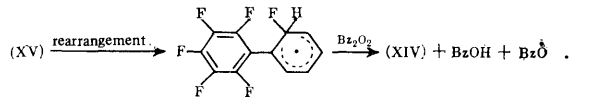
These facts cannot be accounted for either by an elimination-addition mechanism or by the hypothesis of the classical structure of β-bromoalkyl radicals, since in these cases racemic compounds should have been obtained [48,64,65]. From a study of the tritium isotope effect in the reaction

$$R\dot{C}HCH_2Br + TBr \rightarrow RCHTCH_2Br + \dot{B}r \ , \qquad (3)$$

it was concluded [66] that the presence of Br in the β-position relative to the radical centre lowers the energy of the bromoalkyl radical, possibly by the formation of a radical analogue of the cyclic bromonium ion.

3. The Migration of Fluorine

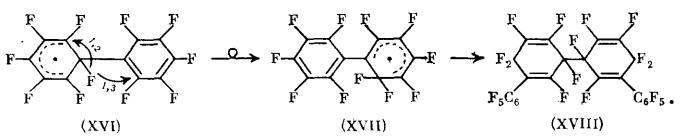
Very little is known about the possibility of the rearrangement of radicals with migration of fluorine. It has been shown [67,68] that the interaction of phenyl radicals, generated by the decomposition of nitrobenzene, with perfluorobenzene in the gas phase at 600°C leads to a mixture of products, the principal of which are pentafluorobiphenyl(XIII) and hexafluorobiphenyl (XIV):



Compound (XIII) is formed via the usual aromatic substitution mechanism involving the addition of a phenyl radical to perfluorobenzene with formation of the radical-adduct (XV) containing the cyclohexadienyl group, this being followed by the elimination of fluorine. The formation of compound (XIV) has been explained [67,68] by the intramolecular substitution of hydrogen in the benzene ring by fluorine. Thus in this instance an unusual rearrangement of radical (XV) takes place with migration of fluorine to the neighbouring aromatic ring and not to the radical centre. The homolytic abstraction of fluorine from radical (XV) in this process is unusual. In the liquid phase hexafluorobiphenyl is not formed in the reaction of perfluorobenzene with benzoyl peroxide.

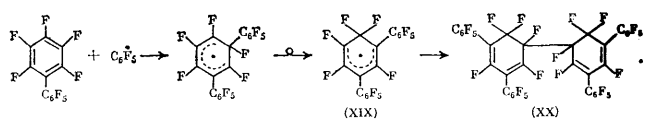
The reaction of hexafluorobenzene with phenyl radicals generated from other sources (phenylazotriphenylmethane [69], benzoyl peroxide [69,70]) has been investigated [69,70] at much lower temperatures. A detailed study has been made of the decomposition of benzoyl peroxide in hexafluorobenzene at 78.2°C [the kinetics of the decomposition process, the influence of the addition of benzoic or *p*-fluorobenzoic acid and the ratio of the yields of (XIII) and (XIV)]. This study established that the elimination of

fluorine from the σ-complex (XV) takes place in the reaction with an arenecarboxylic acid with formation of compound (XIII), HF, and ArCOO. This reaction of carboxylic acids is of independent interest.



A study[70] of the kinetics of the decomposition of Bz_2O_2 in hexafluorobenzene showed that, together with the dissociation of the O–O bond (a first-order reaction), sensitised decomposition of the peroxide takes place (a reaction order of 1.5). The formation of the rearranged product (XIV) and benzoic acid is coupled with the last reaction:

It has been stated[70] that the high-boiling fraction apparently contains isomeric dodecafluorotetrahydroquaterphenyls. Thus a deeper understanding of the individual stages of this interesting process has been achieved. The mechanism of the stage involving a rearrangement with migration of fluorine to the neighbouring ring is at present least clear.



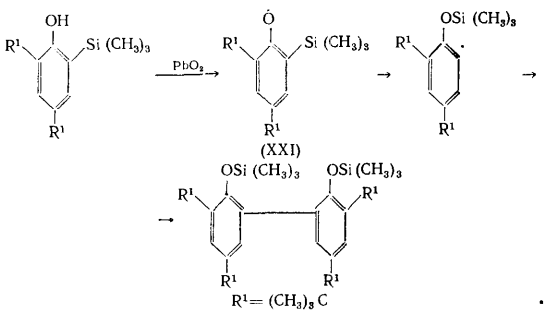
The interaction of hexafluorobenzene with nitromethane at 550°C gives a low yield of hexafluorotoluene $C_6F_5CH_2F$; this process also involves a rearrangement stage[71]. It is of interest to note that at 150°C hexafluorobenzene interacts with acetyl peroxide without a rearrangement; the main reaction products are 4,4′-dimethylperfluoro-1,1′,4,4′-tetrahydrobiphenyl and its isomers[72].

Interesting results were obtained in a study of the reaction of perfluorobenzene with perfluorobenzoyl peroxide[73] (in sealed tubes at 200°C). The pure substance (XVIII) was isolated from the mixture of products on repeated recrystallisation; according to ^1H and ^{19}F NMR, the substance is 3,3′-bis(pentafluorophenyl)perfluoro-1,1′,4,4′-tetrahydro-1,1′-biphenyl. The authors suggest that the radical-adduct (XVI), formed as a result of the addition of the pentafluorophenyl radical to perfluorobenzene, rearranges to the perfluorophenylcyclohexadienyl radical (XVII), whose dimerisation leads to compound (XVIII):

The authors[73] state that this example does not permit a choice between 1,2- and 1,3-migration of fluorine in the radical-adduct (XVI), since the rearranged radical-adduct (XVII) is formed in both cases.

The study of the reaction of pentafluorobenzoyl peroxide with decafluorobiphenyl[74] and with octafluorotoluene[75] suggested the migration of fluorine to a neighbouring carbon atom. For decafluorobiphenyl, the reaction involves the mechanism[74]

Perfluoro-3,3′,5,5′-tetraphenyl-1,1′,2,2′-tetrahydro-1,1′-biphenyl (XX), which is formed by the recombination of radicals (XIX), was isolated from the mixture of isomers.

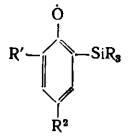


III. REARRANGEMENTS OF RADICALS WITH MIGRATION OF ORGANOELEMENTAL GROUPS

One of the new fields of study involving the rearrangement of radicals comprises the detection and investigation of rearrangements where the migrating group incorporates a heteroatom, which participates in the formation of a transition state via free *d* orbitals or π-bonds. Instances of the migration of the R_3Si, R_3Ge, RC(O)O, RCO, and RS groups are examined below.

1. The Migration of Silicon-, Germanium-, and Tin-Containing Groups

An interesting series of studies have been devoted to the investigation of the radical 1,3-migration of the R_3Si group from carbon to oxygen. This rearrangement was apparently first discovered in the thermolysis of 2,4,6-bis(trimethylsilyl)phenol,[76,77] but a detailed and systematic investigation of this type of migration of the trialkylsilyl group was undertaken by Razuvaev and coworkers[78–83], who demonstrated, in particular, the radical mechanism of this process.

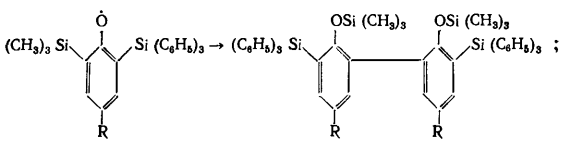


The oxidation of 4,6-di-(t-butyl)-2-trimethylsilylphenol by PbO_2 or $K_3Fe(CN)_6$ in a neutral solvent in the absence of oxygen leads to the formation of the relatively stable phenoxy-radical (XXI), whose rearrangement and subsequent recombination give a quantitative yield of the corresponding dimers[78,79]:

The formation of the phenoxy-radical was observed by EPR (1 : 2 : 1 triplet spectrum due to splitting by the *meta*-protons of the aromatic ring). It was shown that the R_3Si group migrates exclusively from the *ortho*-position[80] regardless of the number and positions of other such groups in the ring.

There is no rearrangement (1,5-, from C to O) in 2,6-di-t-butyl-4-trimethylsilylphenol. On the other hand, the degree of rearrangement involving the migration of the R_3Si group from the *ortho*-position depends significantly on the nature of the substituents in the *para*-position[81]. The yields of the rearranged dimers of 2,6-bis(trimethylsilyl)-4-R-phenols are presented in Table 4. The absence of a rearrangement for R = CH_3 (Table 4) is attributed to the lower stability of the corresponding rearranged phenoxy-radical[81]. When the capacities of the $(C_6H_5)_3Si$ and $(CH_3)_3Si$ groups for migration were compared, an unusual dependence of the rate on the nature of the substituent R′ in the phenoxy-radical (XXII) was

noted[82].

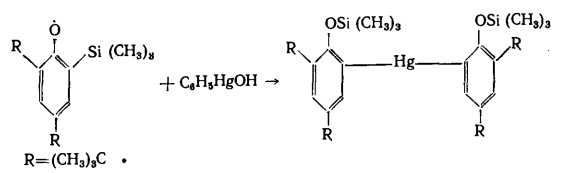


(XXII)
$R^2 = (CH_3)_3C$

Thus, when $R' = CH_3$, the trimethylsilyl group (where $R = CH_3$) migrates to the oxygen atom and the triphenylsilyl group ($R = C_6H_5$) does not migrate; for $R' = Br$, the opposite behaviour is observed.

Table 4. The 1,3-migration of the $(CH_3)_3Si$ group in 4-R-2,6-$[(CH_3)_3Si]_2C_6H_2\dot{O}$.

R	CH_3	$CH(CH_3)_2$	$C(CH_3)_3$	$Si(CH_3)_3$
Yield of rearranged dimer, %	0	77	95	81



A phenoxy-radical in which there is a possibility of a competitive migration of these groups has also been investigated:

(XXIII)
$R = (CH_3)_3C$.

The dimer (XXIII) is the only reaction product, i.e. under these conditions only the $(CH_3)_3Si$ group migrates.

Only silylphenoxy-radicals capable of rearrangement yield mercurated derivatives on interaction with C_6H_5HgOH:[83]

$R = (CH_3)_3C$.

Less sterically hindered phenols react without rearrangement.

The radical mechanism of the migration of organosilicon radicals and the significant role of bulky *ortho*-substituents, ensuring the stability of the phenoxy-radical, was undoubtedly demonstrated in this series of studies; an intramolecular process mechanism appears to be extremely probable. On the other hand, the nature of the transition state and the special role of the silicon atom are still obscure, in view of the fact that the carbon analogues of silicon-containing phenoxy-radicals do not rearrange under these conditions with migration of $C(CH_3)_3$ groups[81].

The study of the decomposition of silicon-containing peracid esters made it possible to observe, together with other processes, the 1,4-migration of the trimethylsilyl group from carbon to oxygen[84]:

$$(CH_3)_3SiCH_2CH(CH_3)C(O)OOC(CH_3)_3 \xrightarrow[CCl_4]{120-130^\circ} \rightarrow (CH_3)_3SiCH_2CH(CH_3)COO\cdot \xrightarrow{\text{rearrangement}} \cdot CH_2CH(CH_3)COOSi(CH_3)_3 \rightarrow \rightarrow CH_2{=}C(CH_3)COOSi(CH_3)_3 .$$

An analogous rearrangement was noted also for organogermanium compounds[85]:

$$(C_2H_5)_3GeCH_2CH_2C(O)OOC(CH_3)_3 \xrightarrow[CCl_4]{100-105^\circ} \rightarrow (C_2H_5)_3GeCH_2CH_2COO\cdot \xrightarrow{\text{rearrangement}} \cdot CH_2CH_2COOGe(C_2H_5)_3 \rightarrow \rightarrow CH_2{=}CHCOOGe(C_2H_5)_3 .$$

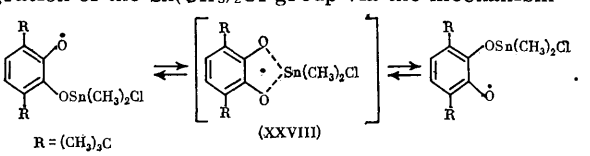
The acrylate formed as a result of the rearrangement has been obtained in a yield of ~10%.

Such parallelism in the ability of organosilicon and organogermanium radicals to migrate has been discovered also in the rearrangement of *N,O*-bisorganosilyl(germyl)-hydroxylamines with 1,2-migration from oxygen to nitrogen[86]. When $RSi(CH_3)_2NHOSi(CH_3)_2R$ [$R = CH_3$, C_2H_5, $C(CH_3)_3$, or C_6H_5] was irradiated in the presence of t-butyl peroxide, only the signal due to the nitroxy-radical (XXV) (triplet with $a_N = 6.5$ G) was observed:

$$\underset{\text{(XXIV)}}{RSi(CH_3)_2\dot{N}OSi(CH_3)_2R} \rightarrow \underset{\text{(XXV)}}{[RSi(CH_3)_2]_2N\dot{O}} . \quad (4)$$

The signal of the non-rearranged radical (XXIV) could not be detected even at −80°C. For the analogous germyl radical $[RGe(CH_3)_2]_2N\dot{O}$, the EPR signal consisted of a triplet with $a_N = 8.8$ G.

The migration of the $(CH_3)_3Si$ and $(CH_3)_3SiSi(CH_3)_2$ groups from silicon to the sulphur atom in the thiyl radicals (XXVI) and (XXVII) proceeds under mild conditions in the presence of radical initiators[87]:



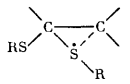
$$[(CH_3)_3Si]_2Si(CH_3)SH \xrightarrow{Bz_2O_2} \underset{\text{(XXVI)}}{[(CH_3)_3Si]_2Si(CH_3)\dot{S}} \rightarrow$$

$$\rightarrow (CH_3)_3Si\dot{S}i(CH_3)SSi(CH_3)_3 \rightarrow (CH_3)_3SiSiH(CH_3)SSi(CH_3)_3 . \quad (5)$$

$$\underset{\text{(XXVII)}}{(CH_3)_3SiSi(CH_3)_2Si(CH_3)_2\dot{S}} \rightarrow \dot{S}i(CH_3)_2SSi(CH_3)_2Si(CH_3)_3 . \quad (6)$$

Both reactions are inhibited by hydroquinone. It has been suggested that the transfer of the radicals $(CH_3)_3Si\dot{S}i(CH_3)_2$ proceeds via a three-membered transition state.

In stable phenoxy-radicals there is reversible 1,4-migration of the $Sn(CH_3)_2Cl$ group via the mechanism[88]



$R = (CH_3)_3C$ (XXVIII)

The rearrangement was inferred from the EPR spectra.

2. The Migration of Oxygen- and Sulphur-Containing Groups

When the behaviour of O- and S-containing radicals is compared in rearrangements, one often has to emphasise differences rather than similarities in the capacity of O- and S-containing groups for migration in the radical. The

differences are apparently due to the ability of the sulphur atom to interact with the neighbouring carbon atom carrying the unpaired electron (possibly with participation of the *d* orbitals of sulphur). Hence arose the hypothesis of the three-membered transition state (XXIX) in the 1,2-migration of the RS group:

(XXIX)

1,2-Migration is in fact characteristic of radicals containing two geminal alkylthio- or arylthio-groups in the β-positions relative to the radical centre.

On the other hand, a rearrangement of radicals with migration of alkoxy- or aryloxy-groups has not been described. The 1,2-migration of the acyloxy-group has been most thoroughly investigated for oxygen-containing radicals; it is suggested that the rearrangement proceeds via a five-membered transition state with unpairing of the electrons in the π-bond of the C=O group.

On the other hand, the preferential migration to the vicinal carbon atom is a common characteristic of these rearrangements.

(a) Migration of Oxygen-Containing Groups

Migration of the acyloxy-group. The Unusual behaviour of the acyloxy-group in the radical rearrangement consists in the fact that the oxygen atom of the carbonyl group can participate in the formation of an intermediate transition state.

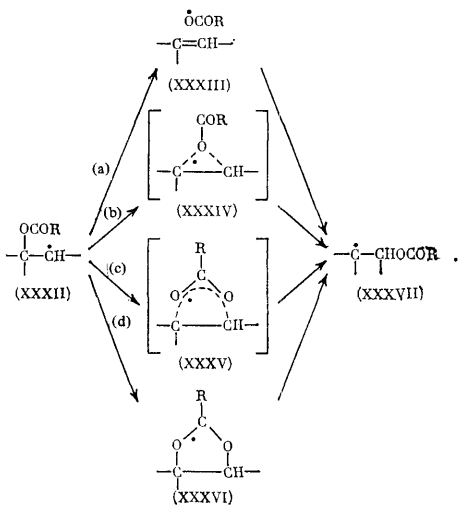
The rearrangement of radicals with 1,2-transfer of the AcO group was first demonstrated in 1967 for the addition of radical species to α,α-dimethylallyl acetate[89,90]:

$$(CH_3)_2C(OAc)CH{=}CH_2 + \dot{R} \rightarrow \underset{(XXX)}{} \rightarrow (CH_3)_2C(OAc)\dot{C}HCH_2R \begin{cases} \rightarrow (CH_3)_2C(OAc)CH_2CH_2R \\ \rightarrow (CH_3)_2\dot{C}CH(OAc)CH_2R \xrightarrow{RH} \underset{(XXXI)}{(CH_3)_2CHCH(OAc)CH_2R} \end{cases} \quad (7)$$

The degree of rearrangement then depends significantly on the nature of the addend RH and the structure of the non-rearranged radical. A rearrangement involving migration to a more remote radical centre does not occur, nor does it take place when one of the methyl groups has been replaced by hydrogen. If a malonate ester [R = $CH(CO_2.C_2H_5)_2$] is used as an addend, then the yield of the rearranged acetate (XXXI) is 95%, while with R = $CH(CN).CO_2C_2H_5$ it is only 25–30%, which the authors attribute to the different efficiencies of these compounds as hydrogen donors. For the relatively ineffective cyclohexane (R = C_6H_{11}), it was possible to detect the acetate (XXXI) (yield 4%) even when one of the CH_3 groups in the initial acetate (XXX) has been replaced by hydrogen[90].

It is of interest to note that the analogous reaction with the thioloacetate $(CH_3)_2C(SAc)CH = CH_2$ takes place without a rearrangement even for cyclohexane[90].

The migration of the acetoxy-group was observed by studying the radical decarbonylation of 3-acetoxy-3-methylbutanal in the presence of benzoyl peroxide[91]:

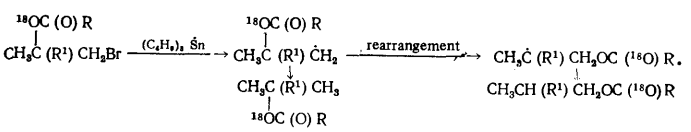


$$(CH_3)_2C(OAc)\dot{C}H_2 \rightarrow (CH_3)_2\dot{C}CH_2OAc \quad .$$

Further studies of rearrangements of this type were devoted mainly to the investigation of the mechanism of the migration of the AcO group[92,93]. In principle, several mechanisms can be put forward for the 1,2-transfer of the acyloxy-group[92].

One of these (*a*) involves elimination-addition and two others (*b* and *c*), involve the transfer of the AcO group via a three-membered (XXXIV) or five-membered (XXXV) unstable transition state; the last mechanism (*d*) involves 1,2-transfer with formation of the 1,3-dioxolanyl radical (XXXVI) as an intermediate.

The elimination–addition mechanism has been rejected[94] because it had been established previously[95] that the free acetoxy-radical ȮC(O)R rapidly decomposes to CO_2 and $\dot{C}H_3$ even in the presence of effective radical trapping agents. In addition it has been shown[91] that a decrease of the concentration of the initial aldehyde (in the decarbonylation reaction) promotes a relative increase in the yield of the rearranged product, which is also inconsistent with an elimination–addition mechanism.



The spectrum of the dioxolanyl radical (XXXVI), known to have been obtained (Scheme 8) was detected by EPR;[92] it did not contain signals which could be attributed to the rearranged radical (XXXVII).

(8)

On the other hand, by studying the abstraction of hydrogen by OH radicals from $(CH_3)_3COAc$, Beckwith and Tivdal[96] obtained a set of signals characterising the radicals $\dot{C}H_2C(CH_3)_2OAc$ and $(CH_3)_2\dot{C}CH_2OAc$, but did not observe any signs of the formation of the cyclic radical (XXXVI).

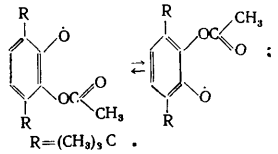
The choice between pathways *b* and *c* was made in favour of *c* in the study of radicals labelled with ^{18}O. It was shown[92] that the rearrangement involves the inversion of the label in the molecule of the labelled specimen:

An analogous result was obtained with a specimen labelled at the oxygen atom of the carbonyl group. Naturally, in the three-membered transition state (XXXIV) (Scheme 8) there should be no inversion.

The only example of the 1,3-migration of the acetoxy-group has been found[97] in the oxidation of γ-acetoxy-carboxylic acid (XXXVII):

$$\begin{array}{l} \mathrm{AcOCRR^1CH_2CHR^2COOH} \xrightarrow[60^\circ]{S_2O_8^{2-}} \\ \quad (\mathrm{XXXVIII}) \\ \rightarrow \mathrm{AcOCRR^1CH_2\dot{C}HR^2} \left\{ \begin{array}{l} \longrightarrow \mathrm{AcOCRR^1CH_2CH_2R^2} \\ \longrightarrow \mathrm{\dot{C}RR^1CH_2CHR^2OAc} \rightarrow \mathrm{CHRR^1CH_2CHR^2OAc} \end{array} \right. \\ \quad (\mathrm{XL}) \qquad\qquad\qquad\quad (\mathrm{XLI}) \qquad\quad (\mathrm{XXXIX}) \end{array} \quad (9)$$

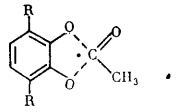
The yield of the isomerised ester (XXXIX) ranges from 3 to 10%, depending on the nature of the substituent: 3% for $R = R^1 = H$, $R^2 = CH_3$; 6% for $R = R^2 = H$, $R^1 = CH_3$; 10% for $R = R^1 = CH_3$, $R^2 = H$; i.e. the greater the difference between the stabilities of the initial radical (XL) and the rearranged radical (XLI), the greater the degree of rearrangement.



The migration of the acyl group. In the decomposition of the peracid ester (XLII) [Scheme (10)] both the non-rearranged ketone (XLIII) and the ketone (XLIV), corresponding to the radical (XLV) formed as a result of the 1,2-migration of the acyl group[98] in the radical (XLVI), were identified among the reaction products:

$$\begin{array}{l} \mathrm{CH_3C(O)CR^1R^2CH_2C(O)OOC(CH_3)_3} \xrightarrow{130^\circ} \\ \quad (\mathrm{XLII}) \\ \rightarrow \mathrm{CH_3C(O)CR^1R^2\dot{C}H_2} \left\{ \begin{array}{l} \longrightarrow \mathrm{CH_3C(O)CR^1R^2CH_3} \\ \qquad (\mathrm{XLIII}) \\ \longrightarrow \mathrm{\dot{C}R^1R^2CH_2C(O)CH_3} \xrightarrow{DH} \mathrm{CHR^1R^2CH_2C(O)CH_3} \end{array} \right. \\ \quad (\mathrm{XLVI}) \qquad\qquad\qquad\quad (\mathrm{XLV}) \qquad\quad (\mathrm{XLIV}) \end{array} \quad (10)$$

For $R^1 = R^2 = H$, there is no rearrangement; for $R^1 = R^2 = CH_3$, the ratio of the yields (XLIV)/(XLIII) is approximately unity; for $R^1 = CH_3$ and $R^2 = C_6H_5$, the ratio (XLIV)/(XLIII) $\simeq$ 1.3. In the generation of the radicals (XLVI) in the $CH_3C(O)C(CH_3)_2CH_2X + R_3SnH + R^1\dot{O}$ system this ratio is 0.4 for X = Br and $R = C_6H_5$, 0.15 for X = Cl and $R = C_6H_5$, and 0.18 for X = Cl and $R = C_4H_9$ respectively.



The most probable mechanism of the rearrangement involves the formation of the unstable cyclopropoxy-radical in the transition state. However, it has been suggested[99] that the isomerisation can proceed, at least partially, via an elimination–addition mechanism. In the case of the radical $CH_3C(O)CH_2\dot{C}H_2$ the authors were able to detect the formation of $CH_3\dot{C}O$ and ethylene. The radical $CH_3\dot{C}O$ reacted with cyanopyridine to give a substitution product. The radicals (XLVI, $R^1 = H$, $R^2 = CH_3$) and (XLV, $R^1 = H$, $R^2 = CH_3$) were also detected as substitution products. Thus the occurrence of the reaction via two mechanisms simultaneously can be postulated.

For stable radicals, the reversible 1,4-migration of the acetyl group was observed by EPR:[100]

$R = (CH_3)_3C$.

It was suggested[100] that the migration proceeds via the cyclic transition state

(b) Migration of Sulphur-Containing Groups

The rearrangement of radicals with 1,2-migration of the thiyl group was discovered for the first time in 1963 in relation to the isomerisation of acetone diphenyl mercaptole under the influence of t-butyl peroxide[101]:

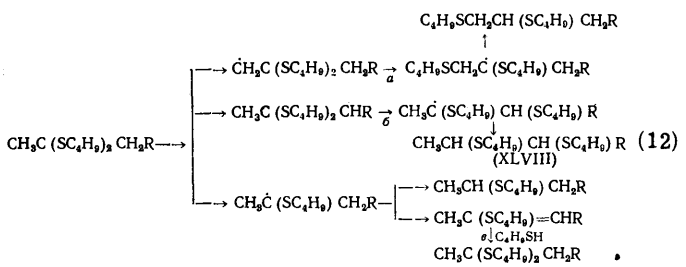
$$\begin{array}{l} \mathrm{CH_3C(SC_6H_5)_2CH_3} \xrightarrow[140^\circ]{(CH_3)_3C\dot{O}} \mathrm{CH_3C(SC_6H_5)_2\dot{C}H_2} \longrightarrow \left[\begin{array}{c} \mathrm{CH_3C(SC_6H_5)CH_2} \\ \mathrm{SC_6H_5} \end{array} \right] \longrightarrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (\mathrm{ILVII}) \\ \longrightarrow \mathrm{CH_3\dot{C}(SC_6H_5)CH_2SC_6H_5} \xrightarrow{H^\bullet} \mathrm{CH_3CH(SC_6H_5)CH_2SC_6H_5} \end{array} \quad (11)$$

A radical chain mechanism of the process was demonstrated and evidence was adduced in support of an intramolecular mechanism of the transfer of the RS radical[101]. On heating in the absence of an initiator, acetone mercaptoles do not isomerise. It has been suggested[4] that the migration of the RS group proceeds via a cyclic three-membered transition state (XLVII) as a result of the ability of sulphur to delocalise the unpaired electron at the neighbouring carbon atom.

Soon examples of the thermal isomerisation of mercaptoles in the absence of radical initiators were described[102,103]. Thus, on heating without the peroxide, acetophenone diphenyl mercaptole gives rise to 1,2-diphenylthioethylbenzene (~10%), but the main products are α-phenylthiostyrene and diphenyl disulphide:

$$\mathrm{C_6H_5C(SC_6H_5)_2CH_3} \xrightarrow{135^\circ} \mathrm{C_6H_5C(SC_6H_5)=CH_2} + \mathrm{C_6H_5CH(SC_6H_5)CH_2SC_6H_5} + (\mathrm{C_6H_5S})_2 .$$

A similar behaviour was observed also for pinacolone diphenyl mercaptole; the formation of appreciable amounts of an unsaturated compound, diphenyl disulphide, and traces of thiophenol justified the hypothesis[103] that thermal rearrangements proceed via an elimination–addition mechanism. Depending on the reaction conditions and the structure of the initial mercaptoles, both mechanisms can apparently operate. The pathway leading to the initiation of thermal rearrangement and the problem of the possible chain transfer by the extremely stable benzyl radicals $C_6H_5\dot{C}(SC_6H_5)CH_2SC_6H_5$, formed as a result of the rearrangement, remains obscure.



The use of the EPR method with spin trapping agents in the study of the rearrangement of mercaptoles capable of thermal isomerisation (in the absence of an initiator) confirmed the radical nature of the process and led to the determination of the nature of the initiating radicals[104]. Together with signals due to the known radicals, the spectrum obtained on irradiation of acetophenone diphenyl mercaptole in the presence of 2-methyl-2-nitrosopropane (as the spin trapping agent), showed the presence of a triplet (a = 25.7 G), which was assigned to the spin-adduct of the oxy-radical $C_6H_5C(\dot{O})(SC_6H_5)CH_3$, formed as a result of the oxidation of the $C_6H_5\dot{C}(SC_6H_5)CH_3$ radicals formed initially in the thermolysis. The oxy-radicals abstract hydrogen from the methyl group of the mercaptole regenerating the initial radical $C_6H_5C(SC_6H_5)_2\dot{C}H_2$. It has been shown[102] that acetophenone diphenyl mercaptole is capable

of initiating the rearrangement of acetone diphenyl mercaptole in the absence of a peroxide. Presumably the rearrangement is in this case initiated by the oxy-radicals formed in the thermolysis of the acetophenone mercaptole.

The mechanism of the 1,2-migration of thiyl radicals as well as the influence of various factors on the course of the rearrangement of mercaptoles became the subject of further discussion and investigations carried out in recent years in relation to the mercaptoles of higher symmetrical and asymmetric ketones[105,106], cyclic ketones[107], and ketones containing functional groups[108]. In a few studies it has been suggested[94,109] that the radical migration of the RS groups takes place in all cases via an elimination–addition mechanism. The authors based their conclusion on the absence of a rearrangement, which they demonstrated in the reaction of α,α-dimethylallyl phenyl sulphide with free radicals, where the intermediate radical fragments with elimination of the RS group:

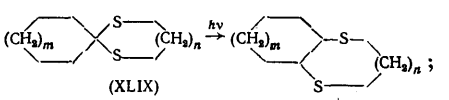
$$(CH_3)_2C(SC_6H_5)-CH=CH_2 + R^{\cdot} \rightarrow (CH_3)_2\dot{C}CHCH_2R(SC_6H_5) \rightarrow (CH_3)_2C=CHCH_2R.$$

However, subsequent studies showed that such analogy between monosulphides and *gem*-bis-sulphides is insufficiently well-founded. The intramolecular mechanism of the 1,2-migration of the thiyl group was clearly demonstrated in a study of the isomerisation of the dibutyl mercaptole of acetoacetic ester (R = $CO_2C_2H_5$) in the presence of t-butyl peroxide [Scheme (12)], where the authors obtained for the first time a complete material balance and were able to trace the fate of all the radicals formed[108]:

(12)

Here there is a possibility of two competitive pathways involving the migration of RS groups (*a* and *b*); it was shown that the migration proceeds preferentially to the carbon of the methyl group (*a*). Presumably this pathway in the transition of the RS group is related to the more favourable conditions for the formation of a transition state of type (XLVII) with participation of the terminal CH_2 group. Special experiments have shown that the addition of butanethiol to ethyl 3-butylthiocrotonate [Scheme (12), pathway *c*] results in a low yield of only the initial ketone mercaptal and not the rearranged product (XLVIII). Thus, by virtue of the mode of addition, the elimination–addition mechanism cannot account for the formation of the products of the rearrangement in this instance.

Acetone mercaptoles isomerise also on irradiation with ultraviolet light[110]. When the reaction was carried out at different temperatures (70° and 140°C), it was found that an increase of temperature leads to a sharp increase of the yield of the rearrangement product (almost by a factor of 20 for acetone diphenyl mercaptole). Instead of the expected formation of $CH_3CH(SC_4H_9)CH_2SC_6H_5$ (via an elimination–addition mechanism), in the isomerisation of $CH_3C(SC_6H_5)_2CH_3$ in the presence of 20 mole% $CH_3C(SC_4H_9) = CH_2$ the process was found to be inhibited and the unsaturated sulphide was fully consumed in side reactions. The study of the rearrangement of mixed ketone mercaptoles (acetone butyl phenyl and butyl *p*-tolyl mercaptole) initiated by t-butyl peroxide showed[111] that, together with symmetrisation, there is a rearrangement of both symmetrical and mixed mercaptoles; in the latter case the rearrangement proceeds mainly as a result of the migration of the arylthio-group.



In the isomerisation of 2-butanone and 2-hexanone dibutyl mercaptoles under the influence of t-butyl peroxide at 140°C the butylthio-group migrates in two directions—to the neighbouring methyl and methylene carbon atoms[105]. In both examples [Scheme (12), R = CH_3 or C_3H_7] the 1,2-bis-sulphides $C_4H_9SCH_2CH(SC_4H_9)CH_2R$ are formed preferentially, i.e. the migration proceeds to a large extent towards the carbon of the methyl group.

The study of the isomerisation of butanone diphenyl mercaptole by EPR in the presence of 2-methyl-2-nitrosopropane as the spin trapping agent made it possible to detect the spin-adducts of the initial radical $CH_3C(SC_6H_5)_2.\dot{C}HCH_3$ and the rearranged radical $CH_3\dot{C}(SC_6H_5)CHCH_3$.[112]
SC_6H_5

It is noteworthy that the migration of the RS group to a radical centre more remote than a neighbouring centre has not so far been observed.

For the mercaptoles of cyclic ketones, the yield of the rearrangement products is influenced significantly by the ring size[107]. Thus the yield of 1,2-bis(butylthio)cycloalkane is twice as high for a six-membered ring as for a five-membered ring. This rearrangement proceeds solely on heating with t-butyl peroxide. On the other hand, thermolysis yields mainly 1-butylthiocyclohex-1-ene and butanethiol. The absence of rearrangement products on thermolysis and ultraviolet irradiation shows that the reverse addition of butanethiol to the unsaturated compound does not occur under the given conditions, which rules out an elimination–addition mechanism.

The study of the photochemical isomerisation of cyclic ketone mercaptoles (XLIX, *a* = *d*) showed that the possibility of isomerisation depends significantly on the ring size[113]:

(a) $m = 1$, $n = 0$; (b) $m = n = 0$, (c) $m = n = 1$, (d) $m = 0$, $n = 1$. (13)

In the reaction involving ethylene mercaptoles (XLIX, *a* and *b*) the main process is the splitting off of ethylene sulphide with formation of cyclic thiones. The propylene mercaptoles (XLIX, *c* and *d*) undergo a kind of isomerisation under these conditions with transfer of one of the geminal sulphur atoms to a neighbouring carbon atom [Scheme (13)]. It has been suggested that the reaction proceeds in this case via an elimination–addition mechanism. However, the usual intermolecular transfer is naturally ruled out.

The study of the rearrangement of radicals has come to be a permanent and very important topic in the modern chemistry of free radicals. The possibility of rearrangements must be reckoned with in studies on new reactions and also in industrial radical processes such as chlorination, oxidation, reduction, polymerisation, telomerisation, and many other processes.

NMR Study of Equilibrium Intermolecular Exchange Processes Involving Univalent Organometallic Groups of the Type R_nM, Containing an Atom of a Heavy Non-transition Metal from Periods V and VI

L.A.Fedorov, A.S.Peregudov, and D.N.Kravtsov

The results of NMR studies of intermolecular exchange reactions accompanied by the rupture of a metal - carbon or metal - heteroatom bond for the case where the role of the metal is played by a univalent organometallic group containing a heavy non-transition metal as central atom have been systematised. The bibliography contains 146 references.

I. INTRODUCTION

Exchange reactions of type (1) represent one of the most widely encountered types of chemical transformation, characteristic of inorganic, organic, and organometallic compounds:

$$AX + BY \rightleftarrows BX + AY \ . \qquad (1)$$

In the field of organic compounds, the exchange reactions include replacement at a carbon atom, and hydrogen exchange[1-5]. In the field of inorganic compounds, exchange reactions include ligand exchange at a metal or non-metal atom, where the ligands may be anions or neutral molecules[3]. A specific feature of exchange reactions in inorganic compounds is that, since many metal compounds are insoluble in aprotic organic solvents, ligand exchange is studied in an aqueous medium, and the materials studied have been mainly complex compounds[6-9]. Finally, for organometallic compounds of non-transition and transition metals, exchange reactions (1) involve chiefly intermolecular transfer of the organometallic groups from one ligand to another with the rupture of metal–carbon or metal–heteroatom σ- or (π-) bonds.

The present review deals chiefly with exchange reactions of the type:

$$R_nMX + R_nM^*Y \rightleftarrows R_nM^*X + R_nMY \ , \qquad (2)$$

where R_nM and R_n^*M are univalent organometallic groups.

The choice of this process is determined by the following considerations. Exchange reactions of type (2) in organometallic derivatives of EH-acids (where the anionic residue E contains as connecting atom the elements C, N, O, S, etc.) formally resemble hydrogen exchange in the EH-acids themselves:

$$HX + H^*Y \rightleftarrows H^*X + HY \ . \qquad (3)$$

In both cases there is intermolecular exchange of species of cationic type. The specific feature of this exchange is that both R_nM and H are able to act as unshared electron pair acceptors, exhibiting a greater or lesser coordinating power, depending on the nature of the partner. The lability of M–X bonds usually decreases with decrease in their polarity. It is therefore appropriate to determine the specific features of the migrating power of organometallic groups compared with the hydrogen atom with the minimum difference in the polarity of the corresponding bonds. This condition is satisfied to the greatest extent by the heavy non-transition metals of periods V and VI. Unlike the metals of periods II–IV, the heavy non-transition metals form bonds of low polarity, and the electronegativity differences between them and the hydrogen atom are appreciably smaller than those between the hydrogen atom and the metals of the higher periods.

In this connection, the present review deals with the intermolecular exchange of univalent particles of cationic type, containing heavy non-transition metals of periods V and VI.

In the analysis of reactions of type (2) it is possible to concentrate attention on the dynamics of either the anionic or the cationic groups. In the first case, the exchange reactions (2) and (3) can be divided into three types[10]:

metal–metal (M–M*) exchange;
metal–proton (M–H) exchange;
proton–proton (H–H*) exchange.

In the second case, reactions (2) can be classified as follows:

exchange of the carbon–carbon type (C,C-exchange of organometallic groups);
heteroatom–heteroatom exchange (N,N-, O,O-, S,S-, etc. exchange);
carbon–heteroatom exchange (C,N-, C,O-, C,S-, etc. exchange).

The chief method of studying exchange processes in many cases is by NMR[11-15], which makes it possible to obtain the quantitative characteristics of exchange reactions and to analyse the mechanism by which they take place. The "popularity" of NMR is related to the fact that exchange reactions of the type being considered often take place at rates commensurate with the time scale of this method. Even in those cases where the rate of exchange is low on the NMR time scale, the method makes it possible to determine the composition of the reaction mixture without resorting to preparative isolation of the components.

In recent years, NMR has been widely used to study the migrating power of organometallic groups in exchange reactions of type (2), and in particular to study exchange in which $R_nM = R_n^*M$. In this case the NMR method makes it possible to study exchange reactions both for non-degenerate exchange ($X \neq Y$) and for degenerate exchange ($X = Y$). In the case of non-degenerate exchange (2), evidence of the process may be provided by the changes in the shielding of the groups R of R_nM, which should in principle be different. In the study of degenerate exchange, the shielding of the groups of the group R will not change in the course of the exchange. If however the metal contains isotopes having half-integral spin, and the substituent contains indicator atoms or groups of atoms, it is possible to reach conclusions regarding the characteristic features of the exchange (2) from the presence or absence of spin–spin coupling between them and the nucleus of the metal atom.

Most discussion in the literature has dealt with the spin–spin coupling of the nuclei of the metal with a proton in the fragment M–E–C–H (where E = O, S, N) in organometallic derivatives in which the M–E bond is the most labile part of this fragment. However, although the existence of spin–spin coupling in this fragment makes it possible to conclude that intermolecular exchange is slow (on the NMR time scale), the absence of this type of interaction in the NMR spectrum (without special search for it under conditions of slow exchange) is not a strict indication of a fast reaction.

II. INTERMOLECULAR EXCHANGE OF THE METAL–METAL TYPE TAKING PLACE WITH THE RUPTURE OF METAL–CARBON BONDS (C,C-EXCHANGE OF ORGANOMETALLIC GROUPS)

Intermolecular exchange processes accompanied by the rupture of an R_nM-C bond and the formation of a new bond of this type have been most widely studied for M = Cd[16–25] and Tl[26–31] and to a lesser extent for M = Hg[32–35]. For other metals, only fragmentary data are available.

1. Exchange in Derivatives of Metals of Group IIb

In a series of organic compounds of the group IIb metals, the exchange reactions being considered can be represented in general form as follows:

$$RM_1{-}R' + RM_2{-}R'' \rightleftarrows RM_1{-}R'' + RM_2{-}R' \quad . \qquad (4)$$

Degenerate intermolecular exchange ($M_1 \neq M_2$, $R' = R''$), accompanied by the rupture of M–C bonds, has been most widely studied for the methyl derivatives of cadmium (reaction (4), $M_1 = M_2 = Cd$ and $R = R' = R'' = CH_3$)[18,19,21,24,36–39]. It has been shown that under certain conditions (medium, temperature, concentration) the exchange reaction (4) in $(CH_3)_2Cd$ takes place at rates comparable with the NMR time scale, that this reaction shows second-order kinetics (in ether), and that its activation energy is 15.6–17.0 kcal mole^{-1} (in toluene) or 5.6–7.0 kcal mole^{-1} (in THF, triethylamine, ether). The reaction rate increases considerably when basic compounds are added to solutions of $(CH_3)_2Cd$ in inert media.

A study of the ^1H NMR spectra of diethyl- and di-isobutylcadmium in toluene and pyridine[14] revealed $^{111/113}Cd$ satellites, which became slightly broader with increase in temperature, again possibly indicating that the exchange reaction (4) takes place in these compounds.

In contrast to the case of the dialkyl compounds of cadmium, the ^1H NMR spectrum of $(H_2C{=}CH)_2Cd$, because of rapid exchange, does not show $^{111/113}Cd{-}C{-}^1H$ spin–spin coupling in ether and hydrocarbon media[32]. At the same time, $^{111/113}Cd{-}C{-}^{19}F$ satellites are observed for solutions of $(CF_3)_2Cd$ in THF, indicating fairly slow exchange (4) in this compound[23].

In contrast to the cadmium compounds, the complete organometallic mercury compounds R_2Hg and $RHgR'$ show $^{199}Hg{-}C{-}^1H$ (R = CH_3, C_2H_5, $C_6H_5CH_2$, $H_2C{=}CH$, etc.)[40–44], $^{199}Hg{-}^{13}C$,[45–47] and $^{199}Hg{-}C{-}^{19}F$ (R = CF_3, C_2F_5, $F_2C{=}CF$, etc.)[48–51] spin–spin coupling over a wide range of conditions. This feature is evidently related to the high stability of the Hg–C bonds with respect to exchange in these compounds.

The Hg–C bond is activated by including, in symmetrical organo-mercury compounds, multiple bonds in the β-position relative to the Hg–C bond[52]. A ^1H NMR study of $(C_5H_5)_2Hg$ at room temperature and lower temperatures in weakly solvating solvents revealed rapid intermolecular exchange of C_5H_5Hg groups from one C_5H_5 group to another[35]. The rate of the process increases sharply with increase in temperature and (or) increase in the solvating power of the solvent:

$$C_6H_6 < R_2O < C_5H_5N < DMF < DMSO \ .$$

The earliest studies of non-degenerate exchange reactions in organic derivatives of group IIb metals by NMR were carried out by Allred and McCoy[16,17] for various mixtures of the type (4) (M_1 = Cd, M_2 = Zn or Hg, R = R′ = R″ = CH_3). These and subsequent studies[18,20,22,24,25] revealed the main characteristics of these non-degenerate C,C-exchanges of organometallic groups. It was suggested[16,17] that the averaging of the shielding of the methyl groups, observed in mixtures of dimethylcadmium and dimethylzinc, is due to the rapid exchange of CH_3M groups from one methyl group to another. The order of this reaction in all solvents except ethyl ether is 1.7 ± 0.3, and its rate is independent of the dielectric constant of the solvent, but depends on its donor power. This indicated that ionisation is not the rate-determining stage of the exchange reaction (4). When one of the components of the system is dimethylmercury, the exchange is slow on the NMR time scale[17,18].

Thus in alkyl derivatives of the group IIb metals, the reactivity of the M–C bonds in intermolecular exchange increases in the order: Hg–C ≪ Cd–C < Zn–C.

Another illustration supporting this conclusion is provided by data for $R_2'M + R_2''M$ mixtures (M = Cd and Hg). Thus a ^{113}Cd NMR study of an equimolar $(CH_3)_2Cd + (CH_3CH_2)_2Cd$ mixture showed[25] that the spectrum contains three $^{113}Cd\{^1H\}$ signals with intensity ratio 1 : 2 : 1; the central signal corresponds to the mixed derivative $CH_3CdC_2H_5$. This indicates that the rupture of the Cd–C bond is slow on the NMR time scale.

The NMR data for $R_2'Hg + R_2''Hg$ mixtures (R′ = $C_6H_5CH_2$, R″ = CH_3 or C_6H_5; R′ = CH_3, R″ = C_6H_5 or CF_3, etc.) indicate that the exchange leading to the formation of the compounds R′HgR″ can take place only when the corresponding mixtures are heated for a long time at a high temperature[43].

The dependence of the reactivity of the Cd–C bond in non-degenerate exchange (4) on the nature of R has been studied[20]. Thus for M_1 = Cd, M_2 = Zn, and R = R′ = R″ = $CH_2{=}CH$, the $M{-}CH{=}CH_2$ σ-bond is more labile than the $M{-}CH_3$ bond. A similar conclusion follows from the study of this reaction for $M_1 = M_2$ = Cd and R = R′ = CH_3;

$R'' = CH_2{=}CH$; or $R = R' = H_2C{=}CH$; $R'' = CH_3$.

2. Exchange in Derivatives of Group III Metals

Exchange reactions in organic derivatives of group III metals can be represented in general form as follows

$$R_2M{-}R + R_2M^*{-}R^* \rightleftarrows R_2M{-}R^* + R_2M^*{-}R \quad . \qquad (5)$$

Degenerate exchange in compounds of this type has been studied in most detail for trimethylthallium [26,27]. At low temperatures the ^1H NMR spectra of solutions of $(CH_3)_3Tl$ in CH_2Cl_2 or $C_6D_5CD_3$ show two signals of equal intensity, due to the splitting of the methyl protons on the thallium isotopes. With increase in temperature these signals become broader and merge, indicating that Tl–C bond rupture is fairly frequent on the time scale of the method. The reaction is of approximately second order, and its activation energy is 6 ± 1 kcal mole^{-1} in CH_2Cl_2 and 6.3 ± 0.5 kcal mole^{-1} in $C_6D_5CD_3$. When $C_6D_5CD_3$ is replaced by the solvating solvents $(CH_3)_2O$ and $(CH_3)_3N$, the rate of exchange decreases slightly [27]. It is suggested [27] that the mechanism of this intermolecular exchange involves the formation of a dimeric transition state.

Reaction (5) was also studied by ^1H NMR for $(C_2H_5)_3Tl$ and $(C_6H_5)_3Tl$. [26,27] For $(C_6H_5)_3Tl$, the following order of decrease in the exchange rate with increase in the solvating power of the medium was established:

$$CH_2Cl_2 > C_6D_6,\ (CH_3)_2O > (CH_3)_3N \quad .$$

Non-degenerate C,C-exchange involving groups containing indium or thallium has been comparatively little studied. Thus the formation of compounds of the type R_2TlR' and $RTlR'_2$ in R_3Tl and R'_3Tl mixtures has been detected by ^1H NMR for $R = CH_3$ and $R' = C_2H_5$. At room temperature, the exchange is rapid on the NMR time scale, whereas at low temperatures in CH_2Cl_2 the individual spectra of all possible compounds are observed [26]. NMR data have also been obtained for the exchange of groups in the system $(CH_3)_3Tl + (CH_3)_2Tl(HC{=}CH_2) + CH_3Tl(HC{=}CH_2)_2$. [27] The study of the last process established that the exchange of vinyl groups is more rapid than that of methyl groups.

NMR data [54–61] make it possible to reach conclusions regarding the limits of stability of Tl–C bonds in exchange reactions. Thus the ^1H NMR spectra of R_2TlX, where X represents electronegative substituents, at room temperature in different media show $^{203/205}Tl{-}C{-}^1H$, $^{203/205}Tl{-}C{-}C^1H$, and $^{203/205}Tl{-}^{13}C$ splitting, indicating that the Tl–C bond is stable under these conditions. This was confirmed [28] by a study of $(CH_3)_2TlX + (C_2H_5)TlX$ mixtures, which showed that the system does not contain mixed derivatives $(CH_3)(C_2H_5)TlX$.

Exchange with rupture of Tl–C bonds is not observed in various compounds of the type $(CH_3)_2Tl{-}R$, where $R = C{\equiv}CC_6H_5$ or C_5H_5. [30,31] There are few data on exchange reactions in derivatives of other group III metals. The intermolecular exchange (5) for $M_1 = In$ and $M_2 = Ga$ ($R = R' = R'' = CH_3$) is rapid on the NMR time scale even at $-65°$ in toluene [62]. A study of exchange in a $(CH_3)_3In + (CH_3)_6Al_2$ mixture in toluene [62] showed that the rate of this process depends on the reagent ratio but is independent of the concentration. This indicates that the reaction is not bimolecular, and that the exchange is preceded by the conversion of the $(CH_3)_6Al$ dimers into monomers, which limits the overall process.

3. Exchange in Mixtures of Derivatives of the Metals of Groups II and III

C,C-exchange of organometallic groups in mixtures of the alkyl derivatives of metals of groups IIb and III by NMR was first studied by McCoy and Allred [17]. In mixtures of $(CH_3)_2Cd$ and $(CH_3)_3Al$ in benzene at room temperature, methyl groups are exchanged (reaction (6), $M_1 = Cd$, $M_2 = Al$, $R = R' = R'' = CH_3$):

$$RM_1{-}R' + R_2M_2{-}R'' \rightleftarrows RM_1{-}R'' + RM_2{-}R' \quad . \qquad (6)$$

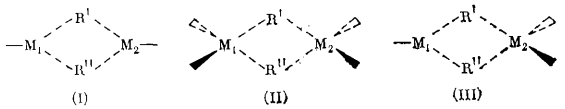
Important kinetic and thermodynamic data were obtained [20,24] for the case where $R = R' = R'' = CH_3$, $M_1 = Cd$, and $M_2 = In$ or Ga. In most cases the reaction is bimolecular, and $(CH_3)_2Cd$ exchanges with $(CH_3)_3In$ more slowly than with $(CH_3)_3Ga$. For $R = R' = R'' = CH_3$ and $M_1 = Cd$, $M_2 = Ga$ or $M_1 = Zn$, $M_2 = In$, [24] the rate of exchange decreases with increase in the coordinating power of the solvent.

4. Exchange in Derivatives of Group IVb Metals

M–C bonds, where M = Sn and Pb, are much more stable than the bonds formed by these metals with heteroatoms. Intermolecular C,C-exchange of organometallic groups in a series of organotin and organolead compounds has been detected by NMR only under catalytic conditions [63].

Under ordinary conditions, the NMR spectra of organotin and organolead compounds show $^*M{-}C{-}^1H$ ($^*M = {}^{119}Sn$ [64–67] and ^{207}Pb, [68,69]) $^*M{-}^{13}C$ (^{119}Sn, [70–72] ^{207}Pb [70,73,74]), $^*M{-}C{-}^{19}F$ (^{119}Sn, [65] ^{207}Pb [75]), etc. spin–spin coupling, indicating that the M–C bonds are stable on the NMR time scale.

One example of exchange accompanied by the rupture of an Sn–C bond is known, however: broadening of the signals of the $^{117/119}Sn$ satellites is observed [76] when $(CH_3)_3SnC{\equiv}CCF_3$ is dissolved in hexamethylphosphortriamide.



5. Mechanism of Intermolecular C,C-Exchange

The available data on exchange reactions accompanied by the rupture of metal–carbon bonds and subsequent intermolecular C,C-exchange of organometallic groups from one group to another can be summarised briefly as follows (Table 1).

1. All C,C-exchange reactions studied are bimolecular for derivatives of metals in groups IIb and III and for mixtures of group IIb and III derivatives [15,16,18,20,22,25,33]. The only exception is exchange in the $(CH_3)_3In + (CH_3)_6Al_2$ system, in which one of the reagents is a dimer [62].

2. C,C-exchange takes place in derivatives of metals of groups IIb (Cd) and III (In, Tl) and is practically unknown for metals of group IVb (Sn, Pb). For isostructural compounds in non-solvating solvents, the reaction rate is greatest for group III derivatives and lowest for derivatives of group IIb metals, and is intermediate in mixtures of compounds of metals of groups IIb and III. [20]

3. The rate of C,C-exchange is increased by solvating solvents of basic character in the case of group IIb metals (Cd) and decreased for group III metals (In, Tl) or mixtures containing a group III metal [18,21,24,20,27].

(I) (II) (III)

4. For organometallic derivatives of metals of groups IIb and III with identical groups but different metals, the rate of C,C-exchange decreases on going from compounds of metals of period V (Cd or In) to compounds of metals of period VI (Hg or Tl) [17,18,24,27,20]. For derivatives with identical metals but different groups, the rate of C,C-exchange increases on going to groups with more nucleophilic carbon atoms [27,22].

Table 1. Data on the intermolecular C,C-exchange of organometallic groups in a series of methyl derivatives of non-transition metals of periods V and VI: $(CH_3)_{n-1}M_1^*CH_3 + (CH_3)_{m-1}M_2CH_3 \rightleftharpoons (CH_3)_{n-1}M_1CH_3 + (CH_3)_{m-1}M_2^*CH_3$.

The basic hypothesis regarding the mechanism of intermolecular C,C-exchange in the reactions being considered usually assumes that the transition state has a four-unit structure [17,18,20,22,24,27,35].

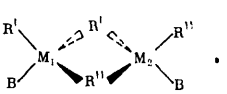
Evidence in support of this suggestion is provided by the bimolecular character of all reactions for which the concentration dependence has been studied, and also by the negative entropy of activation of most exchange reactions (Table 1) [20,24].

The ease of formation of a cyclic transition state with delocalised bonds should be influenced significantly by the coordinating power of the metal atom and in particular by its ability to form cyclic associates. This is due to the fact that the organic groups R′ and R″ and the non-transition metals M_1 and M_2, following Henold and coworkers [20], can be regarded as Lewis bases and acids. On the other hand, a cyclic transition state is a structure intermediate between real or hypothetical cyclic associates:

Exchange between them must involve the overcoming of an energy barrier, the height of which determines the ease of formation of a cyclic transition state with delocalised bonds. For hydrogen-bonded associates, increase in the energy of the hydrogen bonds is accompanied by a decrease in the height of the barrier, and the state of the system approaches a state with delocalised bonds [77,78]. An analogous phenomenon should be observed for organometallic associates with increase in the intensity of coordination interactions. Thus the stable dimer of trimethylaluminium corresponds structurally to a cyclic transition state with delocalised bonds for exchange between two trimethylaluminium molecules [79].

It may therefore be expected that the ease of formation of the transition states (I)–(III) and the rate of exchange reactions will increase with increase in the coordinating power of the metal atom and the donor power of the groups R, including the case where associates are not formed in the solution of the compound R_mM. [17,80] Thus for example the order of change in the rate of exchange:

$$Zn + Cd > Cd + Cd \gg Zn + Hg,\ Cd + Hg,\ Hg + Hg;$$
$$In + Zn > In + Cd;$$
$$Ga + In > Tl + Tl$$



in methyl derivatives $(CH_3)_mM$ (m = 2 or 3) corresponds to the decrease in the acidity of the non-transition metals in isostructural compounds with increase in the period number [81,82] and also to the decrease in the ability of the structure to change from the normal configuration to that realised in the transition state [83]. The increase in the rate of exchange on going from methyl to vinyl compounds (M = Cd [22] or Tl [27]) is due to the greater ease of formation of transition states in the case of vinyl compounds due to the participation of the π-electrons of the vinyl group.

The available data on the influence of the medium on the rate of exchange reactions can also be explained if account is taken of the fact that in solvating media the compounds R_2M (M = Cd, Hg) and R_3M (M = In, Tl) are in the solvated state. The fundamental differences found in the analysis of C,C-exchange between compounds of the metals of groups IIb and III are evidently related to the following feature.

As a result of solvation (B is a unidentate solvent of basic character)

$$R_2M + 2B \rightleftarrows R_2M \cdot B + B \rightleftarrows R_2M \cdot 2B$$
$$R_3M + B \rightleftarrows R_3M \cdot B$$

derivatives of group IIb metals, which have two vacant orbitals, form solvates of two types, whereas compounds of group III metals with one vacant orbital form only one. The solvates $R_2M.2B$ and $R_2M.B$ with completely blocked vacant metal orbitals evidently cannot undergo exchange reactions because of the negligibly low acid strength of the metals†. At the same time the solvate $R_2M.B$ [84] may be more reactive than R_2M, since solvation leads to an increase in the basic strength of the group R, [85] and in addition the vacant metal orbital required for the formation of the transition state (IV) is preserved:

(IV)

Thus in solvating media the rate of exchange is limited by the formation of the transition state (IV) in the case of R_2M, and by the decomposition of the solvated species $R_3M.B$ in the case of R_3M. This last feature also applies to exchange in mixtures of derivatives of the metals of groups IIb and III, where the rate decreases in solvating solvents [24].

---

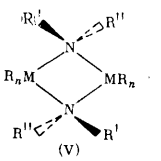
† An example is provided by the complex $(CH_3)_2Cd.[(C_2H_5)_2NCH_2CH_2N(C_2H_5)_2]$, in which both vacant orbitals of cadmium are blocked, and which, because of its stability, can be isolated in the crystalline state [81]. These features explain why the ^1H NMR spectrum of a solution of $(CH_3)_2Cd$ in tetramethylethylenediamine clearly shows satellites due to $^{117/119}Cd$–C–H spin–spin coupling, indicating slow exchange of the methyl groups [37].

III. INTERMOLECULAR EXCHANGE OF ORGANOMETALLIC GROUPS TAKING PLACE WITH METAL–HETEROATOM BOND RUPTURE

1. N,N-Exchange of Organometallic Groups

For most metals except mercury [10,87,88] and tin [89-94], there are comparatively few published data on the NMR spectra of compounds containing the fragment $R_nM-N<$ which might give an indication of the range of lability of these bonds in exchange reactions of the type

$$R_nM—NR'R'' + R_nM^*—N^*R'R'' \rightleftarrows R_nM—N^*R'R'' + R_nM^*—NR'R'' \quad (7)$$



For mercury derivatives, there were until recently only fragmentary data on N,N-exchange of organomercury groups. Thus for $CH_3HgN(CF_3)_2$, $^{199}Hg-N-C-^{19}F$ spin–spin coupling was not detected, and this can be attributed to exchange of methylmercury groups between different $N(CF_3)_2$ groups [87].

Exchange reactions have been studied [10] in organomercury derivatives of substituted N-methylbenzenesulphonamides. In these compounds there is relatively rapid N,N-exchange of arylmercury groups (7) (R_nM = ArHg, $NR'R'' = N(CH_3)SO_2Ar'$). The reaction rate increases considerably with increase in the concentration of the organomercury derivative and decreases slightly when the solvent chloroform or chlorobenzene is replaced by the solvating pyridine.

Electron-accepting substituents in the arylmercury group increase the rate of the N,N-exchange of the arylmercury groups, and electron-donating substituents decrease it:

$$4\text{-}(CH_3)_2NC_6H_4 < 2,4,6\text{-}(CH_3)_3C_6H_2 < 4\text{-}CH_3OC_6H_4 < C_6H_5 < 4\text{-}ClC_6H_4 < 3,4,5\text{-}Cl_3C_6H_2.$$

These results indicate [10] that in sufficiently inert media, the mechanism of the N,N-exchange of arylmercury groups (7) is associative in character and is accompanied by the formation of a cyclic transition state (structure (V), R_nM = ArHg, $R' = CH_3$, $R'' = SO_2Ar'$).

(V)

In the ^1H NMR spectra of various compounds of the type $R_2TlN(CH_3)_2$, the $N(CH_3)_2$ group corresponds to a triplet signal, indicating splitting of the methyl protons not on one but simultaneously on two equivalent thallium nuclei [95,96]. This proves that this compound is dimeric in solution (structure (V), $R_nM = R_2Tl$, $R' = CH_3$) and that the Tl–N bonds are stable on the ^1H NMR time scale.

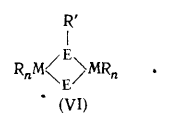
The N,N-exchange of organometallic groups has been studied to a slightly greater extent in organotin derivatives. A study of the ^1H NMR spectra of 20% solutions of organotin derivatives of diethylamine $R_3SnN(C_2H_5)_2$ in CCl_4 at room temperature revealed spin–spin coupling of the $^{117/119}Sn$ nuclei with the CH_2 protons in the diethylamino-group, indicating that the Sn–N bond has a fairly long lifetime [89,90]. It was later found, however, that the ^1H NMR spectrum of $(CH_3)_3SnN(CH_3)_2$, studied in the absence of solvent, does not show $^{117/119}Sn-N-C-^1H$ spin-spin coupling either at room temperature or at −50° [91] (or even at −68° [92]). The most acceptable explanation of these results is that there is rapid exchange of the organotin groups between the dimethylamino-groups (reaction (7), $R_nM = (CH_3)_3Sn$, $NR'R'' = N(CH_3)_2$). $^{117/119}Sn-N-C-^1H$ spin–spin coupling was subsequently observed [93] in the ^1H NMR spectra of 20% solutions of $R_3SnN(CH_3)_2$ in benzene.

The temperature dependence of the form of the signals due to $^{117/119}Sn-N-C-^1H$ coupling has been studied [92]. Comparison of the temperatures at which the signals of the tin satellites merge for different compounds revealed the influence of the nature of the organic group, attached to the tin atom, on the rate of exchange:

$$(C_4H_9)_3SnN(CH_3)_2 < (C_2H_5)_3SnN(CH_3)_2 < (CH_3)_3SnN(CH_3)_2 .$$

In the compounds $(CH_3)_3SnN(CH_2)_n$ with heterocyclic $N(CH_2)_n$ groups, $^{119}Sn-N-^{13}C$ spin–spin coupling was observed [94] only for $n = 5$ or 6, but not for $n = 2-4$, indicating that the Sn–N bonds have a comparatively short lifetime.

In a discussion of the mechanism of exchange accompanied by the rupture of Sn–N bonds [94], it was suggested that this exchange is a bimolecular process, involving the formation of intermediates of type (V) ($R_nM = R_3Sn$). Evidence in support of this is provided, for example, by the dimeric structure of the compound $(CH_3)_3SnN(CH_2)_2$ in solution [94].



2. O,O-, S,S-, and O,S-Exchange of Organometallic Groups

Reactions of this type in the series of compounds being considered can be expressed as follows (E = O or S):

$$R_nM—ER' + R_nM^*—E^*R' \rightleftarrows R_nM—E^*R' + R_nM^*—ER' \quad (8)$$

They have been studied in most detail for organotin compounds [90,97-102] and less fully for derivatives of mercury [102-105], thallium [28,96,106-108], and lead [102,109,110].

Thus a study of solutions of the compounds C_6H_5HgOR' did not detect $^{199}Hg-O-C-^1H$ spin–spin coupling in any case [103], indicating that in CH_2Cl_2 at 33.5°, O,O-exchange of phenylmercury groups from one OR′ group to another is fairly rapid on the ^1H NMR time scale (reaction (8), $R_nM = C_6H_5Hg$, E = O). It was suggested that the reaction mechanism involves an associative scheme with the intermediate formation of dimers of type (VI), where E = O and $R_nM = C_6H_5Hg$.

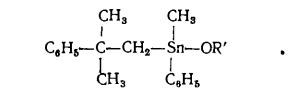
(VI)

A ^1H NMR study of the phenylmercury derivative of toluene-ω-thiol [102] showed that the spectrum of solutions of this compound does not show $^{199}Hg-S-C-^1H$ spin–spin coupling at −40° (in chlorobenzene or pyridine) or even at −110° (in a $CH_2Cl_2 + CHCl_3$ mixture), indicating fairly rapid S,S-exchange of the phenylmercury groups (reaction (8), $R_nM = C_6H_5Hg$, $ER' = SCH_2C_6H_5$). Similar results were obtained in a study of the S,S-exchange of organomercury groups in mixtures of the compounds $t\text{-}C_4H_9HgSCH_3 + t\text{-}C_4H_9HgSCH(CH_3)C_6H_5$. [104] In this case the rate of the S,S-exchange of the organomercury groups in relatively inert media is so great that the rate of this bimolecular process can be decreased only at ~ −140°.

Data on the O,O- and S,S-exchange of organothallium groups R_2Tl have been published [28,96,106-108]. At room temperature the ^1H NMR spectra of many compounds of the type $(R_2TlX)_2$ (structure (VI), $R_nM = R_2Tl$), the signals due

to the spin–spin coupling of the protons of the R groups with ^{203}Tl and ^{205}Tl nuclei are broadened considerably and often are not resolved.

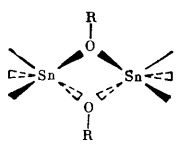
With decrease in the temperature of a solution of $[(CH_3)_2TlOC_2H_5]$ in $C_6D_5CD_3$,[108] the ^1H NMR spectrum shows broadening of the signals of the CH_3Tl groups. With further cooling of the solution below −10°, however, the signals of the methyl protons again become narrow and at −60° acquire the same form and width as at room temperature. A characteristic feature is that the $^{203/205}Tl-C-^1H$ spin–spin coupling constant is the same at +39° and at −60°. In the discussion of this phenomenon, the authors of Refs. 96 and 103 examined several possible associative exchange mechanisms, which reduce to the same form of exchange between the dimeric and monomeric state of the derivative being analysed.



For the compounds R_3MER' (M = Pb, Sn; E = O, S) the exchange reactions with the rupture of M–O bonds have been least studied for the lead derivatives. Thus the ^1H NMR spectra of solutions of R_3PbOR' in CCl_4[109] do not show $^{207}Pb-O-C-^1H$ spin–spin coupling. Similar results were obtained in Ref. 110. Davies and Puddephat[109] suggested that this phenomenon is related to rapid exchange of organometallic groups from one OR′ group to another.

A study of the ^1H NMR spectra of organotin alkoxides of the type R_3SnOR' in CCl_4 at room temperature[90] did not detect $^{117/119}Sn-O-C-^1H$ spin–spin coupling. It was suggested that this result is due not to exchange but to the ionic character of the Sn–O bonds. Subsequent temperature studies of the ^1H NMR spectra of a number of organotin compounds containing an Sn–O bond[99–101] made it possible to observe this spin–spin coupling and hence to establish that the absence of $^{117/119}Sn$ satellites from the NMR spectra of R_3SnOR' derivatives in a number of cases is due not to the ionic character of the Sn–O bond but to the rapid exchange of the organotin groups from one oxygen atom to another (reaction (8), $R_nM = R_3Sn$, E = O). The rate of exchange increases in the order[99]:

$$CH_2C(CH_3)_3,\ CH(C_6H_5)_2,\ CH(CH_3)_2 < CH_2C_6H_5 < C_2H_5 < CH_3.$$

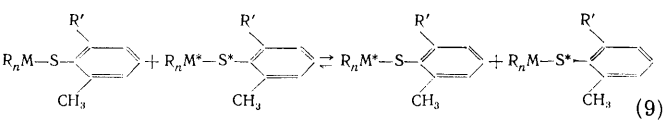


It was suggested that the exchange involves a bridged dimer (VI) ($R_nM = R_3Sn$, E = O).

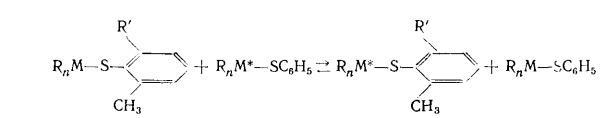
The influence of a number of factors on the mechanism of exchange accompanied by the rupture of Sn–O bonds has been studied[100]. A study was made of the exchange reactions in compounds (VII); in solutions of these compounds in benzene, exchange of OR′ groups may be accompanied by inversion of the configuration of the tin atom[101].

R=CH₃, i-C₃H₇, t-C₄H₉, C₆H₅ (VII)

The rate of exchange of OR′ groups is not equal to the rate of inversion, that is not every exchange act is accompanied by inversion of the configuration of the metal atom. The nature of the group R′ has a greater influence on the rate of exchange than on the rate of inversion. A probable transition state for both processes may be the dimeric cyclic intermediate (VIII), the formation and decomposition of which take place with preservation of the configuration of the metal atom.



(VIII)



A study of the ^1H NMR spectra of the compound $(CH_3)_3SnSCH_3$ in chloroform[111] showed that the signals due to $^{117}Sn-S-C-^1H$ and $^{119}Sn-S-C-^1H$ spin–spin coupling are not resolved. Abel and Brady[112], in a study of this compound in a 30% solution in CCl_4, on the contrary, observed these signals separately; when even very small quantities of impurity (such as, for example, acids and thiols) are present in the solutions, however, the ^{117}Sn and ^{119}Sn satellites are not resolved; this is due to the catalysis of reaction (8) ($R_nM = (CH_3)_3Sn$, E = S, R′ = CH_3) by the impurities.

A number of subsequent papers give data on the values of $^3J(^{119}Sn-S-C-^1H)$[113] and $^2J(^{119}Sn-S-^{13}C)$[94] in R_3SnSR' compounds; the very fact that these data were obtained indicates that the Sn–N bonds in them have a fairly long lifetime. In particular, the study of the ^1H NMR spectra of the individual compounds $R_nMSCH_2C_6H_5$ or their mixtures in chlorobenzene and pyridine at different temperatures ($R_nM = (C_6H_5)_3Pb$ or $(C_6H_5)_3Sn$) did not detect any signs of exchange reactions of type (8).[102] Available data on the lability of the bonds M–O and M–S are too fragmentary to permit a comparison of the mobility of univalent organometallic groups with different metals for a fixed element E or to estimate the influence of the nature of the element E on the mobility of the organometallic groups of each type. A systematic examination of this problem was begun only recently[10,102,114–117].

Thus the dependence of the lability of the M–S bonds in thiophenol derivatives on the nature of the organometallic group has been studied[102,114,115] for the reactions

(9)

R′ = H or CH_3; $R_nM \neq R_nM^*R_nM$ and $R_nM^* = C_6H_5Hg$, $(C_6H_5)_3Pb$, $(C_6H_5)_3Sn$, $(C_6H_5)_2Sb$, $(C_6H_5)_4Sb$. (10)

The data[102,114,115] on the S,S-exchange of organometallic groups in these mixtures established the following regular features: a) the rate of the S,S-exchange increases when chlorobenzene is replaced by pyridine; b) the increase in the steric hindrance when a proton as R′ is replaced by a methyl group is accompanied by a decrease in the rate of exchange; c) the ability of organometallic groups to undergo intermolecular exchange in chlorobenzene increases in the order:

$$(C_6H_5)_3Sn < (C_6H_5)_2Sb \sim (C_6H_5)_3Pb < C_6H_5Hg < (C_6H_5)_4Sb\ .$$

These regular features are for the most part preserved[117] for O,O-exchange of organometallic groups in substituted phenols:

$$R_nM-OAr + R_nM^*-O^*Ar \rightleftarrows R_nM-O^*Ar + R_nM^*-OAr$$
$$R_nM \neq R_nM';\ R_nM \text{ and } R_nM^* = C_6H_5Hg,\ (C_6H_5)_3Pb,\ (C_6H_5)_3Sn,\ (C_2H_5)_3Sn\ . \quad (11)$$

As in the case of thiophenols, the C_6H_5Hg group has the highest mobility, and the $(C_6H_5)_3Sn$ group the lowest mobility in the exchange reaction (11). The rate of the process increases both with increase in the electron-acceptor

properties of the group Ar and when chloroform as solvent is replaced by pyridine. Steric hindrance, and also the presence, in the ortho-positions, of substances capable of intramolecular coordination interaction with the metal, on the other hand, decrease the rate of the O,O-exchange.

Data obtained by Kravtsov and coworkers [102] were interpreted on the basis of an associative exchange mechanism with the intermediate formation of cyclic four-unit transition states with delocalised bonds:

3. Exchange of Organometallic Groups Between Halogen Atoms

In the study of dynamic processes accompanied by the rupture of metal–halogen bonds, it is only in the case of Hal = F that it is possible to use NMR, which can be used successfully for derivatives of the type M–ER where E = O or S, and M–NR′R″, where E = N or P (analysis of the form of the signals corresponding to the spin–spin coupling *M–*E, *M–E–C–^{1}H, *M–E–^{13}C, *M–E–^{1}H, etc.). Thus in a study of the ^{1}H NMR of the compounds R_3SnF (R = CH_3, C_2H_5) in methanol solution [108], ^{1}H–C–Sn–^{19}F spin–spin coupling was not reported, although its value in $[C_6H_5CH(CH_3)_2CH]_3SnF$, measured later [119], was fairly high (~ 5 Hz). The absence of splitting can be attributed to F,F-exchange of organotin groups:

$$R_nM{-}X + R_nM^*{-}Y \rightleftarrows R_nM^*{-}X - R_nM{-}Y$$

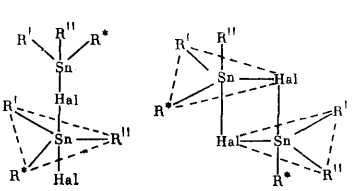
$$R_nM = [C_6H_5CH(CH_3)_2CH_2]_3Sn,\ X = Y = F \quad , \qquad (12)$$

In this connection, in the study of halogen exchange in series of organometallic compounds, extensive use is made of the examination of the non-degenerate exchange of organometallic groups in mixtures of compounds with different halogen atoms (reaction (12), X ≠ Y = Hal, R_nM = RHg [42,43,120–122] or R_3Sn [123–128]). Another method makes it possible to study degenerate exchange in the case where the compound being studied contains a chiral (or prochiral) atom, inversion at which, detected by NMR, can in principle be related to reaction (12) (X = Y = Hal, R_nM = R_3Sn, etc. [125,129–134]).

In the ^{1}H NMR spectra of solutions of individual compounds of the type RHgI and RHgBr (R = CH_3,[42,43] $C_6H_5CH_2$,[43] $H_2C{=}CH$,[120] etc.), the satellites due to ^{199}Hg–C–^{1}H spin–spin coupling are either broadened or completely absent [42,43,120]. To explain this phenomenon it was first suggested [42,43,120] that in solutions of these compounds, fast exchange with rupture of C–Hg bonds takes place. Subsequent studies showed, however, that there is insufficient evidence for these suggestions. In particular, it has been found [53] that the C–Hg bond in alkyl derivatives of mercury is fairly stable and that exchange accompanied by its rupture cannot take place in fractions of a second.

The study of compounds RHgI [32,121,135] shows that the broadening in the NMR spectra of mercury satellites is due not to exchange but to relaxation effects‡. Thus in later studies [121,122] of exchange in organomercury layers, the results were interpreted in terms of halogen exchange.

Thus Hatton and coworkers [42], in a study of the ^{1}H NMR spectra of an equimolar mixture of methylmercury halides (X = Cl, Y = I) in pyridine at room temperature observed an averaged picture. Similar results were obtained in a study of the NMR spectra of ternary mixtures (RHgCl + RHgBr + RHgI; R = CH_3 or $C_6H_5CH_2$).[43] In mixtures of type (12) for R_nM = CH_3Hg, X = Cl or Br, and Y = I in DMF, exchange is rapid even at −71°.[122]



The reactivity of organotin compounds R_3SnX in halogen exchange reactions has been studied fairly frequently in recent years. In discussion relating to the interpretation of NMR data on halogen exchange in a series of organotin derivatives, many aspects of the problem became evident—the complexity of this reaction, and also a number of characteristic features of the compounds R_3SnX, which distinguish them from other derivatives R_nMX. Up to the present, however, there is still lack of agreement regarding the mechanism of this process.

A number of studies of the degenerate exchange of organotin groups between halogen atoms have been carried out for compounds of the type R′R″R*SnHal, in which the tin atom is chiral (R′ ≠ R″ ≠ R*) and the carbon group R* has a prochiral centre containing groups suitable for NMR study [$(CH_3)_2CH$, $C_6H_5(CH_3)_3CCH_2$, $C_6H_5CH_2$, $(CH_3)_2CHCH_2$, etc.] [129–131,192]. For these compounds in solution there is ready rapid inversion of the geometric configuration of the tin atom. There may be several reasons for this inversion: intermolecular exchange of organotin groups between halogen atoms is the most probable, but not the only explanation (reaction (12), R_nM = R′R″R*Sn, X = Y = Hal).

The conclusion that the observed phenomenon is of intermolecular origin is confirmed by the fact that in all cases, increase in concentration is accompanied by an increase in the rate of the process. The exchange involves the tin–halogen bond, since when the halogen atom in R′R″R*SnHal is replaced by a carbon group the dynamics are no longer recorded by NMR [130,131,137–139].

Direct proof has been obtained [131] for the relationship between the inversion of the tin atom and the exchange of the halogen atom in the compounds R′R″R*SnHal. The NMR study of the compounds (Hal = Cl and I, R* = C_6H_5·$(CH_3)_2CCH_2$, R′ = CH_3 and R″ = $C_6H_5CH_2$) showed that the rates of intermolecular exchange are exactly equal to the rates of inversion at the tin atom, and these two processes possibly take place by the same mechanism.

In a more detailed discussion of the associative mechanism of the exchange of halogens in the compound R′R″R*SnHal, accompanied by racemisation of the asymmetric tin atom, two versions were considered [131], with one or two bridging halogen atoms:

which agree with the bimolecular character of the process.

The non-degenerate exchange of anionic residues in the compounds R_3SnX (reaction (12), X ≠ Y, R_nM = R_3Sn) including the case where at least one of the substituents X or Y is a halogen atom, has been studied by NMR chiefly for systems with R = CH_3. [123–128,140] A NMR study of mixtures of these compounds (Y = Cl, Br, I) [123] showed that the rate of reaction (12) for the organotin halides

‡ The broadening of the mercury satellites in CH_3HgSCN has been shown [136] to be due to the presence of traces of CH_3HgI, used [42] to prepare methylmercury thiocyanate. The ^{1}H NMR spectrum of the compound CH_3HgSCN, obtained from methylmercury chloride, did not contain any sign of broadening of the mercury satellites [136].

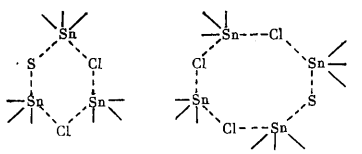
changes in the order:

$$Cl + I < Br + I < Cl + Br \ .$$

Subsequently, several groups of workers made more detailed studies of the exchange reaction (12) in trimethyltin derivatives [124-126]. Thus Redl and Winokur [124], in a study of this reaction in cyclohexane (X = Cl, Y = I) found that with increase in temperature from 33° to 95°, the apparent rate constant of the reaction does not increase, but decreases§. Moreover, the order of the reaction with respect to each of the components is different, is not integral, and changes considerably with change in temperature. These results [124] indicate that in mixtures of organotin compounds, the kinetics of reaction (12) are complex. The authors cited believe that different types of associative equilibria, preceding the actual exchange, may be established in the solution:

$$2\,(CH_3)_3SnBr \overset{K}{\rightleftarrows} [(CH_3)_3SnBr]_2$$
$$(CH_3)_3Sn^*I + [(CH_3)_3SnBr]_2 \rightleftarrows (CH_3)_3Sn^*Br + (CH_3)_3SnBr + (CH_3)_3SnI \ . \quad (13)$$

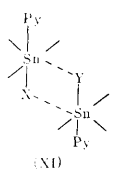
The rate of exchange is given by the expression:



$$v = k_{app}[(CH_3)_3SnI]\,[(CH_3)_3SnBr]^2 = kK\,[(CH_3)_3SnI] \cdot [(CH_3)_3SnBr]^2 \quad (14)$$

Since the experimentally determined order of the reaction with respect to $(CH_3)_2SnBr$ is 2.6, it is possible that the exchange act is preceded by the formation of not only dimers but also associates with a larger number of units. Increase in temperature on the one hand should increase the rate of exchange by increasing k, but on the other hand will lead to a decrease in the concentration of associates (decrease in K in Eqn. [14]). If the absolute magnitude of the last effect is greater than that of the first, the overall rate of the reaction should decrease with increase in temperature.

Later, a ^1H NMR study for $R_nM = (CH_3)_3Sn$, X = Cl, and Y = I in toluene [125] showed that the overall order of reaction (12) at 27° is approximately three, again indicating a possible associative mechanism, although the rate of this reaction in the range from −70° to 30° does not decrease with increase in temperature, as shown in Ref. 124, but increases. At higher temperatures, however, the ^1H NMR spectrum did not show temperature reproducibility. The rate of exchange increases considerably on going from toluene to pyridine, whereas when Y = I is replaced by $Y = SC_6H_5$ or $C{\equiv}CC_6H_5$, the rate of exchange decreases. Reaction (12) was subsequently studied for the case where one of the anionic groups contains a sulphur atom ($Y = SCH_3$ [127] and SC_6H_5 [140,141]).



When X = Cl and $Y = SCH_3$, [127] the exchange reaction (12) in methylene chloride is rapid not only on the ^1H NMR time scale but also on the ^{119}Sn NMR time scale, and with decrease in the temperature of the solution there is only a slight broadening of the ^1H NMR signal. Unfortunately, the concentrations of the compounds studied were not reported [127], so that the results cannot be compared with earlier [123] and later (X = Cl, $Y = SC_6H_5$) [140,141] data.

A study of the regular features of the exchange reaction (12) for $R_nM = (CH_3)_3Sn$, X = Cl, and $Y = SC_6H_5$ [141] gave additional information on the mechanism of exchange reactions involving organotin halides. When the reaction was carried out in toluene, the "inverse" temperature dependence of the rate of exchange was observed, and the activation energy had a negative value (−2.3 kcal mole^{-1}). The calculated orders of the reaction (2.8 with respect to $(CH_3)_3SnCl$ and 1.0 with respect to $(CH_3)_3SnSC_6H_5$) do not depend significantly on temperature; the entropy of activation of the process has a high negative value (−62.0 kcal mole^{-1} K^{-1}). These results indicated that in relatively inert media the reaction takes place by an associative mechanism with the intermediate formation of cyclic transition states:

(IX) (X)

Since the decisive factor determining the characteristic features of the associative mechanism of exchange is the ability of the compounds R_3SnX to undergo association in inert media, a cardinal change might be expected when the reaction is studied in solvating solvents. In this case the elementary act of the reaction may involve solvated organotin molecules:

(XI)

These considerations explain the sharp increase in the rate of the exchange reaction (12) ($R_nM = (CH_3)_3Sn$, X = Cl, and Y = I) in pyridine [125], for which the transition state (XX) was proposed.

The mechanism of the exchange (12) may be even more complex in solvents of medium solvating power. In this case the equilibrium $R_3SnX + B \rightleftharpoons R_3SnX.B$ may not be displaced very far to the right, and the elementary act may involve both solvated and non-solvated molecules. This apparently explains the two-stage character of the changes observed on going from toluene to tetrahydrofuran for the exchange reaction (12) with X = Cl and $Y = SC_6H_5$ ($R_nM = (CH_3)_3Sn$); in THF the rate of the reaction decreases below −30° and increases at higher temperatures [140].

The associative mechanism has been assumed to be the most probable mechanism of the exchange reaction (12) for organotin compounds [124,125]. Two recent papers [126,128] dealing with exchange reactions (12) ($R_nM = (CH_3)_3Sn$; X, Y = Hal, X ≠ Y) explain the results by assuming a dissociative mechanism, including preliminary dissociation of the organotin halide and subsequent attack by the halide anion on an undissociated molecule:

$$(CH_3)_3SnX \rightleftarrows (CH_3)_3Sn^+ + X^-$$
$$(CH_3)_3SnY + X^- \rightleftarrows (CH_3)_3SnX + Y^- \ . \quad (15)$$

Reaction (12) has been studied in toluene [126]. Unfortunately, a detailed kinetic analysis was not carried out, and the conclusion that mechanism (15) is preferred is based only on the fact that when small quantities (~ 2×10^{-4} M) of molecular iodine are added to the solutions being studied a decrease in the rate of exchange is observed, and the pseudo-first-order rate constant is linearly dependent on $[I_2]^{-1/2}$. It is assumed [126] that molecular iodine binds the halide ions formed on dissociation (15), thus decreasing

§As already noted, a similar phenomenon was observed [108] in a study of exchange reactions in the compounds $(R_2TlOR')_2$.

their effective concentration in the solution and hence lowering the rate of the exchange reaction (the greater inhibiting action of I_2 on the exchanging systems containing $(CH_3)_3SnI$, in the authors' opinion [126], agrees with the increase in the stability constants of the ionic complexes $[I_2X]^-$ in the order $I_3^- > I_2Br^- > I_2Cl^-$).

Ladd and Glasberg [128], who studied reaction (12) in chloroform and methylene chloride, favour the ionic mechanism on the basis of the fact that with increase in the polarity of the medium there is an increase in the pseudo-first-order rate constant. In their opinion, within the framework of the associative mechanism of exchange, change in the polarity of the medium should not have such a marked influence. Various thermodynamic characteristics of this reaction have also been determined [128]. In particular, it has been shown that the exchange has a large negative entropy of activation and fairly low activation energies. Moreover, the quantity τ_A^{-1} is linearly dependent on the square of the concentration of the components of the reaction. This last fact was interpreted as indicating that the exchange is of second order not only in the cases which they studied but also for system (12) for X = Cl and Y = I; the overall order of this reaction was found to be three [125].

It may be suggested, however, that the discrepancy in the conclusions in Refs. 124, 125 and Refs. 126, 128 is due to misunderstanding and is related to the fact that the authors of Refs. 126 and 128 used pseudo-first-order rate constants in the kinetic calculations. Simple analysis¶ shows that detection of a linear relationship between τ_A^{-1} and $[A]^2$ by NMR spectroscopy unavoidably leads to the conclusion that the reaction being studied is of third order, as confirmed experimentally [125].

Proceeding to the discussion of the observations [136,138] used as arguments in support of the ionic mechanism of the exchange reactions (12), it should be noted that these observations also agree with an associative mechanism for these reactions. Thus for example the reason for the inhibiting action of small quantities of molecular iodine may be that the I_2 molecules, by coordinating to the organotin halides, prevent the formation of associates of type (IX) and (X). As far as the influence of large quantities of molecular iodine are concerned, they will act as ordinary basic additives.

The observed [128] effect of increase in the exchange rate in the study of the reaction in more polar media, within the framework of the associative mechanism, can be attributed to an increase in the polarity of the Sn–X bond. In this case there is an increase in the electrophilic character of the metal atom and the nucleophilic character of the anionic residue and hence an increase in the ability of the molecules of the organometallic halide to form associates (IX) and (X). Thus the apparent rate of exchange should increase in polar media. It should be emphasised that the suggested [126] ionisation of organotin halides is unlikely in inert media. Finally, the ionic mechanism does not explain either the high and non-integral orders observed in a number of cases for the reaction being considered or the inverse temperature dependence of the apparent reaction rate [124,141].

Thus the available facts indicate that an associative mechanism is more probable for reaction (12) for organotin compounds. It is clear, however, that more rigorous confirmation of this suggestion requires additional studies, in particular for the case where the anionic residues X and Y are halogens.

IV. C,E-EXCHANGE OF ORGANOMETALLIC GROUPS

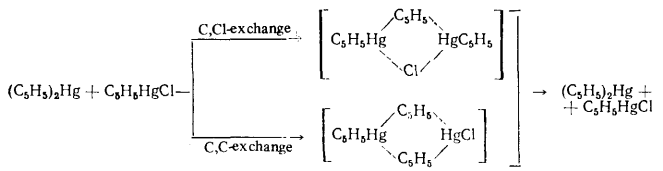
A number of papers describe the study of the exchange of organometallic groups between anionic residues, including both carbon (R) and heteroatom groups [19,37,143,144]:

$$R_nM^*-R' + R_nM-X \rightleftarrows R_nM^*-X + R_nM-R' \quad (16)$$

Thus the ^1H NMR spectrum of an equimolar mixture of diphenylmercury and phenylmercury bromide (R = R′ = C_6H_5, M = Hg, X = Br) in dimethyl sulphoxide [143] even at 34° shows broadening of the signals of the *ortho*- and *meta*-protons corresponding to both compounds, and also of the signals due to vicinal $^{199}Hg-C-C-^1H$ spin–spin coupling. Since this effect is not observed in the study of either of these compounds individually, it was concluded that it is due to fairly intensive C,Br-exchange of phenylmercury groups in the solution.

In a number of organocadmium compounds, reactions of type (16) can be assumed on the basis of familiar results of the study of two types of compound—aryl and methyl. In particular, data on reaction (16) were obtained [144] by ^{19}F NMR for perfluoroaryl derivatives of Cd (R = R′ = C_6F_5, X = I). The study of this reaction in various solvating solvents (DMSO, DMF, etc.) showed that its rate depends on the nature of the medium.

In connection with the discovery that the rate of exchange of methyl groups in dimethylcadmium is increased catalytic quantities of CH_3CdOCH_3 and in general CH_3CdOR'',[19] reaction (16) for R = R′ = CH_3 and X = OR″ was studied by ^1H NMR [19,37]. It was found, however, that the mechanism is extremely complex and that the tetrameric molecules CH_3CdOR'' [145] exert practically no catalytic influence†. It was suggested [19,37] that this exchange process is catalysed not by tetrameric CH_3CdOR'' molecules but by small quantities of dimeric or monomeric molecules. The rate of the process in the presence of added CH_3CdOR'' increases in the order [37]: C_6H_5O, C_2H_5O > CH_3O > iso-C_3H_7O.



The problem of the dual character of the possible reaction mechanism also arises in the analysis of the NMR spectroscopic data obtained [35] for cyclopentadienyl derivatives of mercury. The data [35] indicated that in a mixture of the compounds $(C_5H_5)_2Hg$ and C_5H_5HgCl there is intensive intermolecular exchange. In view of the familiar lability

---

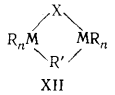
¶ The rate of an exchange reaction involving both molecules of reagent A and molecules of reagent B is given by the equation: $d[A]/dt = k[A]^n[B]^m$. The lifetime of the exchanging particle in position A (τ_A) in turn is related to the reaction rate by the expression [142]: $d[A]/dt = \tau_A^{-1}[A]$. Thus $\tau_A^{-1} = k[A]^{n-1}[B]^m$. Similarly, for τ_B: $\tau_B^{-1} = k[A]^n[B]^{m-1}$. Thus the experimental determination of the values of τ_A and τ_B for different values of [A] and [B] makes it possible to find the values of m and n. For the case where [A] = [B], it is possible to determine only the overall order of the reaction $m + n$: $\tau_A^{-1} = k[A]^{m+n-1}$.

† Evidence in support of this is provided, in particular, by the detection, in the ^1H NMR spectrum of a $(CH_3)_2Cd + CH_3CdOCH_3$ mixture, of satellites of the signal of the OCH_3 group, due to $^{111/113}Cd-O-C-^1H$ vicinal spin–spin coupling [37].

of the C_5H_5Hg bond, however, there are at least two fundamentally different processes which satisfactorily explain the observed results:

In the system studied, C,Cl-exchange evidently takes place. The specific features of C_5H_5–Hg σ-bonds suggest, however, that the corresponding C,C-exchange takes place simultaneously in the system [35].

For R = CN, the exchange in mixtures (16) is of the C,E-type only from formal indications. However, since in the organic derivatives of the transition metals being considered the R_nM–CN bond is appreciably covalent, it is also appropriate to examine C,E-exchange for R = CN in this section also.



The C,E-exchange of the groups $R_nM = CH_3Hg$ [see Eqn. (16)] has been studied [104,122] for R′ = CN and X = Hal or SR″. In the case where X = Hal, the systems studied can be arranged in the following order of increasing rate of exchange with change in the halogen atom: I < Cl < Br. A study of the concentration dependence of the rate of this exchange for X = Cl [122] or SR″ [116,104] in DMF showed that the reaction is bimolecular and of first order with respect to each of the components. The reaction rate also increases sharply when DMF as solvent is replaced by pyridine [122].

Reaction (16) for $R_nM = CH_3Hg$ was also studied in aqueous solutions for R′ = CN and anionic residues X with different properties [121]. Kinetic NMR measurements showed that for X = OH (at pH > 9), Cl, SO_3^{2-}, and $S_2O_3^{2-}$, a mechanism of anion attack is possible

$$CH_3HgCN + X^{\ominus} \rightleftarrows CH_3HgX + CN^- \qquad (17)$$

whereas for exchange in the systems with X = OH (at pH < 9) and CH_3COO^-, the direct exchange reaction (16) apparently takes place.

From the data obtained, two fundamentally different routes for the exchange reaction (16) for $R_nM = CH_3Hg$ were examined [104]. The first assumes the formation of a cyclic transition state (XII) ($R_nM = CH_3Hg$, R′ = CN):

XII

whereas the second assumes that the reaction involves pre-exchange equilibria, in which ions or ion pairs separated by solvent are formed. The question of the mechanism was examined in a quantitative study [104] of exchange in system (16) ($R_nM = CH_3Hg$, R′ = CN) in DMF for a wide range of substituents X. The observed order of change in the rate of exchange:

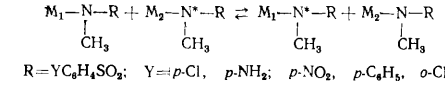
$$Cl < OCOOH_3 < Br < SCN < SCH_3 < SC_6H_5 < SC_6H_4Cl\text{-}p < SC(CH_3)_3$$

does not coincide with the familiar order of increase in the ionic character of the bonds Hg–X (RS < CN < Br < SCN < Cl < $OCOCH_3$). Moreover, it was found that the rate constants of the exchange reactions, calculated from the ionisation constants of the compounds RHgX, are appreciably smaller than the experimental values, particularly for the case of compounds in which the Hg–S bond is highly covalent.

Thus the most probable mechanism of exchange in the compounds CH_3HgX in aprotic solvents is an associative mechanism, accompanied by the intermediate formation of cyclic transition states (XII). When both X and R′ in (XII) are substituents containing unshared pairs of electrons (Hal, SCN, SR″), the rate of exchange is too high to be observed on the NMR time scale. The replacement of one anionic group R′ by the SCN group, which is sufficiently polar but which has less tendency to coordinate to the metal atom, is accompanied by a decrease in the reaction rate constant by at least four orders of magnitude, so that the study of exchange in these systems becomes possible on the ^1H NMR time scale. When the second anionic group is replaced by the SCN group, however, the exchange reaction becomes slow on the same scale.

V. EXCHANGE BETWEEN ORGANOMETALLIC GROUPS AND A PROTON, TAKING PLACE WITH RUPTURE OF A CATIONIC PARTICLE–HETEROATOM BOND (E,E-EXCHANGE WITHIN THE FRAMEWORK OF EXCHANGE OF THE METAL–PROTON TYPE)

Among the different types of intermolecular dynamics, the least extensively studied is non-degenerate E,E-exchange, in which there is equilibrium exchange of a proton and an organometallic group:



$$R_nM{-}ER'_m + H{-}E^*R'_m \rightleftarrows R_nM{-}E^*R'_m + H{-}ER'_m \ . \qquad (18)$$

Dynamics of this kind were apparently first observed by Alcock and Timms [146], when the existence of reaction (18), rapid on the PMR time scale, was assumed on the basis of an NMR study of mixtures of acetic acid and organotin or organolead acetates. It was also pointed out [146] that the replacement of phenyl groups in $R_nM = R_3Sn$ by cyclohexyl and isopropyl groups is accompanied by a decrease in the rate of exchange.

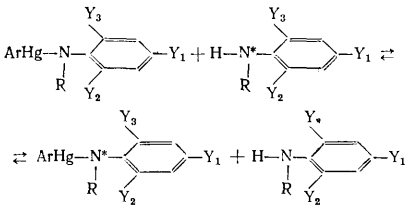
Analysis of published data shows few examples of the observation of reaction (18) by NMR. For example, the ^1H NMR spectrum of a $CH_3CdOCH_3 + HOCH_3$ mixture did not show two separate OCH_3 group signals corresponding to the individual compounds, and this result was interpreted as indicating that there is intermolecular exchange of the OCH_3 groups [37].

It should be noted that special NMR study of exchange processes of the metal–proton type in mixtures of EH-acids and their organometallic derivatives began relatively recently, and these reactions have been studied chiefly in a comparison with proton–proton reactions in EH-acids and metal–metal reactions in their organometallic derivatives.

In particular, a comparison of this kind, which made it possible to estimate the relative mobility of the hydrogen atom and organometallic groups for the case where E = N and M = Hg was carried out [10] for the case of N-methylbenzenesulphonamides and their N-phenylmercury derivatives:

$R = YC_6H_4SO_2$; Y = *p*-Cl, *p*-NH_2, *p*-NO_2, *p*-C_6H_5, *o*-Cl; (19)

a) $M_1 = M_2 = H$, proton–proton exchange;
b) $M_1 = M_2 = C_6H_5Hg$, metal–metal exchange;
c) $M_1 = H$, $M_2 = C_6H_5Hg$, metal–proton exchange.



Analysis of the results showed that in a mixture of pyridine solutions of these NH-acids and their N-phenylmercury derivatives, the degenerate exchange (19a) and (19b) characteristic of the individual compounds is accompanied by another type of exchange involving the mutual

exchange of hydrogen atoms and phenylmercury groups between the same sulphonamide residues (reaction 19c). The rate of this exchange is extremely sensitive to the nature of the substituent in the benzenesulphonamide group; the rate of exchange (19c) increases in the order:

$$o\text{-Cl} < p\text{-}C_6H_5 < p\text{-}NH_2 < p\text{-}NO_2 < p\text{-Cl}\ .$$

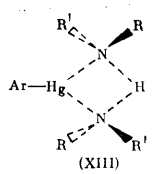
For the system with Y = *p*-Cl it was found that this exchange is slightly slower in nitromethane than in pyridine, and much slower in chloroform than in pyridine and nitromethane. It was established[10] that under certain conditions the HgC_6H_5 group is more mobile in intermolecular exchange than the hydrogen atom.

A quantitative study of metal–proton exchange accompanied by the exchange of an arylmercury group by a hydrogen atom was carried out[116] for benzenesulphonanilides and their N-arylmercury derivatives in a pyridine–chlorobenzene (2 : 3) mixture:

(20)

R = $C_6H_5SO_2$;

a) $Y_2 = CH_3$; Ar = C_6H_5; Y_3 = H; Y_1 = H, Br, NO_2, $N(CH_3)_2$;

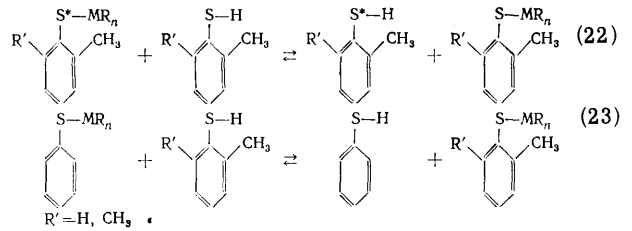


b) $Y_2 = Y_3 = CH_3$; Ar = C_6H_5; Y_1 = Br;

c) $Y_3 = CH_3$; Ar = C_6H_5; $Y_1 = Y_2$ = Br;

d) $Y_2 = CH_3$; Y_3 = H; Y_1 = Br; Ar = *p*-XC_6H_4, X = OCH_3 Cl, $N(CH_3)_2$.

The results show that the rate of reaction (20a) is increased by electron-acceptor substituents in the aryl group Y_1 on the nitrogen atom and is decreased by electron-donor substituents. At the same time, both electron-acceptor and electron-donor substituents in the arylmercury group increase the rate of this exchange process. It was shown for system (20b)[116] that reaction (20) is of first order with respect to each reagent, and its activation energy is 11.3 ± 1.3 kcal mole^{-1}. It was also demonstrated that steric hindrance, which increases on going from reaction (20a) to reaction (20b), and to a greater extent intramolecular coordination [possible on going from reaction (20b) to reaction (20c)], increase the rate of metal–metal exchange.



All the results indicated that the exchange reaction (19) is bimolecular and involves the intermediate formation of the cyclic transition state (**XIII**):

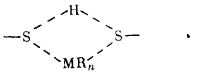
(XIII)

In a study of exchange between organometallic groups and a proton, accompanied by the rupture and redistribution of the bonds M–S and H–S, toluene-ω-thiol[102] or substituted thiophenols and the corresponding organometallic derivatives[102,114,115] were used as model systems:

$$C_6H_5CH_2S^*MR_n + C_6H_5CH_2SH \rightleftarrows C_6H_5CH_2S^*H + C_6H_5CH_2SMR_n \qquad (21)$$

(22)

(23)



R′ = H, CH_3.

It was found that exchange (21) is slow on the NMR time scale. This feature, and also the fact that the degenerate exchange of PhHg groups in solutions of $C_6H_5CH_2SHgPh$ in chlorobenzene (8) is rapid, indicate that, as in the case of compounds containing N–H and N–Hg bonds, the PhHg group has a greater ability to undergo intermolecular exchange than the hydrogen atom.

The PMR spectra of the mixtures (22) in chlorobenzene showed[114] that metal–proton exchange is rapid only for $R_nM = SbPh_4$. In all other systems, reaction (22) is slow on the classical NMR time scale even at high temperatures. The PMR spectra of the mixtures (23) in chlorobenzene showed that the organometallic groups and the proton can be arranged in the following order of increasing ability of these cationic groups to undergo intermolecular exchange:

$$Ph_3Sn < H < Ph_3Pb \approx Ph_2Sb < PhHg < Ph_4Sb.$$

The concentration dependence of the rate of reaction (23) ($R_nM = SnPh_3$, R′ = H) showed that it is of first order with respect to each component. In addition, the steric hindrance arising on going from 2-methylthiophenol and its derivatives to 2,6-dimethylthiophenol and its derivatives decreases the rate of exchange. A study of the effect on the rate of reaction (23) of various factors which influence radical reactions (ultraviolet radiation, atmospheric oxygen, the addition of phenothiazine as inhibitor) showed fairly conclusively that this reaction does not take place by a radical mechanism. It was suggested that metal–proton exchange takes place by an associative mechanism including the formation of a cyclic transition state with delocalised bonds.

The change from solutions of systems (22) and (23) in the relatively inert chlorobenzene to solutions of the same systems in pyridine leads to an increase in the rate of metal–proton exchange (22) only in one case, namely for R′ = H, R_nM = PhHg. In all other systems, the reaction remains slow on the PMR time scale. Thus in pyridine also, the PhHg group is more mobile than the Ph_3Sn, Ph_3Pb, and Ph_2Sb groups. The effect of an increase in the rate of metal–proton exchange under the influence of pyridine in the case of other R_nM groups was shown for the case of reaction (23) (R_nM = Ph_3Sn or Ph_3Pb).

Metal–proton exchange taking place with the rupture of M–O and H–O bonds was studied for mixtures of substituted phenols and their organometallic derivatives[117]:

$$ArO^*{-}H + ArO{-}MR_n \rightleftarrows ArO^*{-}MR_n + ArO{-}H$$

Ar = 2,6-$(CH_3)_2$-4-BrC_6H_2, 2-CH_3-4-BrC_6H_3, 2-CH_3-4,6-$Br_2C_6H_2$, 2,6-$(CH_3)_2$-4-$NO_2C_6H_2$. (24)

Reaction (24) showed the following principal characteristic features at 33°: a) the PhHg group is the most mobile, and the Ph_3Sn group the least mobile in intermolecular exchange both in chloroform and in pyridine; b) increase in the

electron-acceptor properties of Ar leads to an increase in the rate of exchange; and c) the change from solutions of the corresponding systems in chloroform to solutions in pyridine also increases the rate of reaction (24).

The common features in these relationships and those previously obtained for M–N and H–N bonds on the one hand and M–S and H–S bonds on the other suggested that in the case of M–O and H–O bonds also, metal–proton exchange takes place by an associative mechanism with the formation of cyclic transition states with delocalised bonds, although additional quantitative data are required for a more detailed study of the mechanism of this reaction.

Hydrogen Bonds and the Reactivity of Organic Compounds in Proton Transfer and Nucleophilic Substitution Reactions

L.M.Epshtein

Recent data on various relations between the characteristics (spectroscopic and thermodynamic) of hydrogen bonds in different classes of organic compounds and the acid-base properties of the latter are examined. The principal approaches to the study of the influence of hydrogen bonds on acid-base equilibria in various solvents are demonstrated. Fundamentally new results, obtained in combined studies of proton transfer reactions in the gas phase and in solution, are analysed and approaches to allowance for the influence of hydrogen bonds on the reactants and the transition state in nucleophilic substitution reactions as well as the role of hydrogen bonds in the alteration of the rates and modes of chemical reactions are discussed.
The bibliography includes 152 references.

IV. Hydrogen bonds in nucleophilic substitution reactions 864

I. INTRODUCTION

Increasing attention has been devoted in recent years to problems of the dependence of the reactivity of organic compounds on the medium. Among various types of interactions contributing to the solvation energy, weak specific interactions—hydrogen bonding between the solvent and the reactants—are frequently the most important.

"During the last five years there has been a revolution in the understanding of the thermodynamics of the solvation of organic ions" [1] as a result of studies on proton transfer reactions in the gas phase in combination with quantum-chemical calculations on such reactions, whose development has been strikingly rapid. The importance of this revolution is enormous, since it leads to a change in many important postulates of theoretical organic chemistry. A comparative analysis of data on acid–base equilibria in the gas phase and in solution established that solvation factors play a much more important role than had been realised previously. For many classes of organic compounds, the influence of these factors proved to exceed in magnitude the electronic effects of substituents. The nature of the influence of substituents is in many instances different from that assumed in the study of reactions in solution. In the course of investigations the role of hydrogen bonds, which in the view of many workers determine the solvation effects, was rediscovered in a new light. In the immediate future one may expect that even more valuable information will become available and that such approaches will be extended to other types of reactions, since the growing number of studies on gas-phase reactions has an avalanche-like character.

The aim of the present review is analysis of the methodology of studies designed to discover the influence of hydrogen bonds on the equilibrium position in proton transfer reactions and on the rates, mechanisms, and modes of nucleophilic substitution reactions. From the large number of studies in which hydrogen bonds are mentioned, we therefore selected only those which provide approaches to the assessment of their role in these reactions. Acid–base equilibria are analysed in greatest detail.

II. HYDROGEN BONDS AND ACID–BASE PROPERTIES OF ORGANIC COMPOUNDS

Despite many warning signals, such concepts as acidity (basicity) and proton-donating (proton-accepting) capacity in the formation of hydrogen bonds are still treated as synonymous in the literature. The roots of this kind of confusion can be understood by comparing the following equilibria:

$$AH + B \rightleftarrows AH \ldots B \quad \text{(formation of hydrogen bonds);} \qquad (1)$$

$$AH + B \rightleftarrows A^- + HB^+ \quad \text{(acid-base equilibrium).} \qquad (2)$$

The formation of hydrogen bonds is necessary for proton transfer; it can be either an intermediate stage or it can occur in a transition state, which is assumed to consist of a hydrogen-bonded complex.

There have already been many studies (see Section III) in which possible pathways of reaction (2) have been demonstrated in relation to many examples. The overall mechanism of the interaction can be represented as follows:

$$\underset{I}{AH} + B \rightleftarrows \underset{II}{AH \ldots B} \rightleftarrows \underset{III}{A^- \ldots HB^+} \rightleftarrows \underset{IV}{A^- \ldots (S) \ldots HB^+} \rightleftarrows \underset{V}{A^- + HB^+}. \qquad (2a)$$

Here stage II involves the formation of a molecular hydrogen-bonded complex, stage III the formation of an ionic hydrogen-bonded complex or an ion pair†, stage IV the formation of a solvate-separated ion pair (S is the solvent), and stage V the dissociation into ions. Fig. 1*a* illustrated schematically the potential surface of the AH + B system, which has two minima[3]. Fig. 1*b* illustrates the dependence of the potential energy on the reaction coordinate. Curves *1* and *2* correspond to cases where either a molecular complex (the equilibrium I ⇌ II), for example,

† One should note that the term "ion pair" is a consequence of traditional usage in the literature, since complexes of a conjugate acid with an anion differ from the ion pairs formed on ion association via electrostatic forces. According to Odinokov et al.[2], such "ion pairs" resemble molecular hydrogen-bonded complexes as regards their infrared spectroscopic properties.

in a phenol–amine system, or only an ion pair (I–III), for example, in a pentachlorophenol–amine system, is formed. Curve *3* represents the situation in which both molecular and ionic complexes are in equilibrium (I⇌II⇌III), for example, in a 2,6-dichlorophenol–amine system.

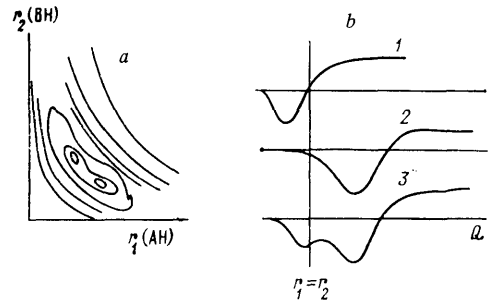

Figure 1. The potential surface of the AH + B system [3].

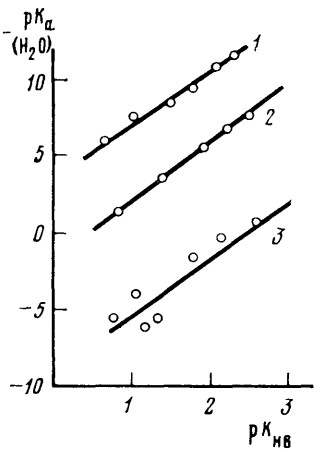

Figure 2. Relation between the free energies of protonation (pK_a) and hydrogen bond formation (pK_{HB}) reactions[10]: 1) amines; 2) pyridines; 3) carbonyl compounds.

By altering the proton-donating properties of AH, the proton-accepting properties of B, and the solvating capacity of the solvent, it is possible to drive reaction (2a) via one or other pathway. The fact that reaction (2) includes reaction (1) in some form gives rise to the idea that there is a general relation between their energetic characteristics. A relation between the linear dependence of the shifts of the stretching vibration frequencies of the AH bond [$\Delta\nu$(OH)] on formation of the hydrogen bond and the pK_a was given in an early investigation[4]. Many linear relations between frequency shifts or the hydrogen bond formation energies and the pK_a have been published in original papers[5,6] and in monographs (for example, in Ferjenson's monograph[7]). The frequency shifts $\Delta\nu$(OH) are adopted as a measure of the basicity of all solvents[8].

Convincing evidence for the absence of a single relation can be found, for example, in studies[9,10] where a thorough analysis of the relations between the free energies of reactions (1) and (2) was carried out. By analogy with pK_a, the concept of $pK_{HB} = -\lg K_{HB}$, where K_{HB} is the equilibrium constant for the formation of a hydrogen bond via reaction (1), was introduced. For all classes of compounds (aliphatic amines, pyridines, and carbonyl compounds), for which sufficient experimental data were available, three significantly linear relations, displaced along the ordinate axis (Fig. 2), were obtained. For the same capacity for the formation of hydrogen bonds (i.e. for the same pK_{HB} values), the basicity of aliphatic amines is greater by five orders of magnitude than that of substituted pyridines and by thirteen orders of magnitude that that of carbonyl compounds.

The most thorough comparative study of the hydrogen bond formation reaction (1) and the proton transfer reaction (2) was carried out by Arnett et al.[11], who analysed the ratios of the enthalpies of these reactions. The comparative analysis was based on the calorimetric method for the determination of the enthalpies of protonation (ΔH_i) in a superacid (fluorosulphonic acid) proposed previously[12]. The values of ΔH_i were compared with the calorimetric enthalpies of formation of hydrogen-bonded complexes with *p*-fluorophenol (ΔH_f). Separate linear relations are observed between ΔH_i and ΔH_f for different classes of organic compounds, similarly to data for pK_a and pK_{HB}.[10] Fig. 3 shows that the slopes of the straight lines are approximately the same.

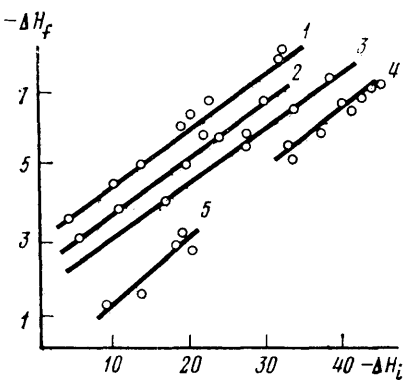

Figure 3. Relations between the enthalpies of protonation (ΔH_i) and hydrogen bond formation (ΔH_f) reactions[11]: 1) P=O; 2) S=O; 3) amides; 4) pyridines; 5) sulphides.

Studies involving such careful analyses of the relations between acid and proton donating properties of compounds of different classes have not so far been described in the literature and the amount of data permitting a comparison of the energies of different hydrogen-bonded complexes with the same base is insufficient. We therefore suggested the hydrogen-bond acidity factor (P_i), introduced[13] on the basis of the principle of the constancy of the acid and basic properties on formation of hydrogen bonds, as a characteristic of proton-donating properties.

We calculated the hydrogen-bond acidity factors from the formula

$$P_i = \Delta H_{ij}/\Delta H_{11} \cdot E_j,$$

where ΔHij is the energy of the hydrogen bond between the ith H-acid and the jth base and Ej is the basicity hydrogen-bond factor of the given base. The hydrogen-bonded complex of diethyl ether ($E_1 = 1$) and phenol ($P_1 = 1$) was chosen as the standard: $\Delta H_{11} = -5.3$ kcal mole^{-1}, i.e. the proton-donating capacity of the given acid is estimated relative to the proton-donating properties of phenol[13]. Fig. 4 clearly demonstrates the existence of different relations for different classes of compounds between the factor Pi, which we calculated from literature data[14-17], and the acidity of the compounds (alcohols, phenols, carboxylic acids, thiols). When the heteroatom in the acid AH is changed, the acid strengths of the compounds (thiols > alcohols) and their hydrogen bond proton-donating properties (thiols < alcohols) vary in opposition. The relations which obtain with retention of the heteroatom, for example, in alcohols, phenols, and carboxylic acids, can also be different (Fig. 4). Even for structurally similar "alcohols" Ph_3COH and Ph_3SiOH,[18] different relations between $\Delta\nu/\nu$ and the pK_a of the bases are observed (Fig. 5).

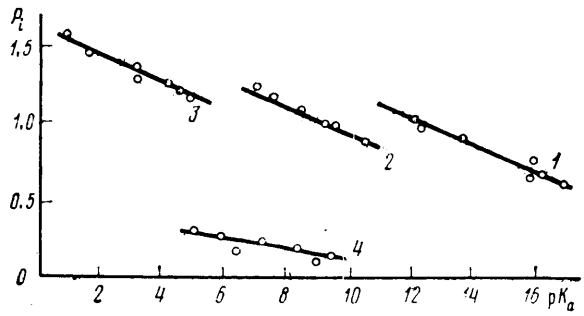

Figure 4. Relations between the acidity (pKa) and the hydrogen bond acidity factor Pi for different groups of compounds: 1) alcohols; 2) phenols; 3) carboxylic acids; 4) thiols.

Thus, as stated correctly in the review of Gur'yanova et al.[19], linear relations between thermodynamic (spectroscopic) characteristics of hydrogen bonds and acid–base properties exist only within the limits of a single class of organic compounds. The "general" relation between ΔpK_a and ΔH_{HB}, quoted by Gordi and Stanford[5], is undoubtedly erroneous and the basicity scale for solvents based on $\Delta\nu$(OH) for phenol[18] is in fact the scale of their capacity for the formation of hydrogen bonds.

The differences between the changes in the energetics of hydrogen bond formation and protonation processes for different classes of compounds are determined by many factors. In the first place, as will be shown below, the solvation energy depends significantly on the type of compound. It plays a very important role in acid–base equilibria, which had been studied previously as a rule in strongly solvating media. On the other hand, in the study of hydrogen bonds, there is a possibility of a wide-scale employment of inert solvents and in addition the influence of solvating solvents on hydrogen-bonded complexes is much smaller than on ions. Furthermore, the energetics of acid–base reactions depends on the energy of the homolytic dissociation of AH and BH^+ bonds, on the electron affinity of the A atom, and on the ionisation potential of the B atom. Proton transfer is accompanied by a significant rearrangement of the reacting molecules. The formation of hydrogen bonds does not require the dissociation of covalent bonds and a radical rearrangement of the molecule. Quantum-chemical calculations in recent years showed (see, for example, Refs. 20–23) that the changes in electron density on formation of hydrogen bonds, which are determined by charge-transfer and polarisation effects, are not restricted to a three-atom fragment including the AH bond and a heteroatom (:)B with a lone electron pair. However, these changes are much smaller than in proton transfer. At the same time, electrostatic interactions, which make the greatest contribution to the energy of hydrogen-bonded complexes according to non-empirical calculations, depend mainly on the local polarity in the region of the hydrogen bond[22], i.e. on the charges of the B and H atoms and not on the overall polarity of the reacting molecules.

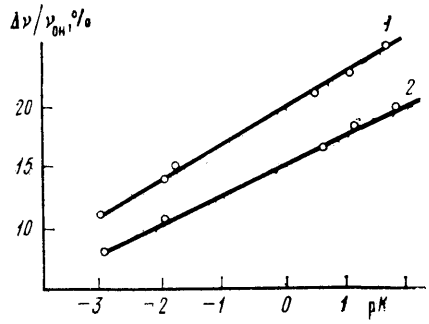

Figure 5. Relations between $\Delta\nu/\nu$ and the pK_a for Ph_3COH (line *1*) and Ph_3SiOH (line *2*).[19]

Thus, one can assume that the hydrogen bond behaves as a probe which hardly alters the given molecule during the measurement. The energy of the hydrogen bond characterises the distribution of electron density in the molecule in the ground state more adequately than does basicity or acidity.

In many instances the study of hydrogen bonds constitutes the only possibility of estimating the electron-donating properties of heteroatoms. For example, the basicity of compounds contains X–X or X–Y bonds, which are unstable when acted upon by acids (X = S, Se, or P and Y = N), cannot be determined. The study of the spectroscopic and thermodynamic characteristics of hydrogen bonds between such compounds and H-acids makes it possible to estimate their donor properties and to characterise the mutual influence of the heteroatoms[24,25]. The study of hydrogen-bonded complexes with aromatic compounds containing as a substituent a heteroatom with a lone electron pair provides a unique possibility of investigating the problem of p–π conjugation[26]. In contrast to protonation and complex formation reactions with Lewis acids, in which the n electrons of the heteroatom

constitute the reaction centre, hydrogen bonds are also formed with the aid of the π electrons of the aromatic system; infrared spectra reveal the existence of two types of hydrogen-bonded complexes [26-28]. Comparison of the spectroscopic and thermodynamic parameters of n-complexes (with a heteroatom) with the corresponding characteristics of aliphatic compounds and comparison of the parameters of π-complexes (with a π-electron system) with the characteristics of carbon analogues makes it possible to determine the redistribution of electron density on $p-\pi$ conjugation and to estimate quantitatively the degree of $p-\pi$ conjugation for different heteroatoms [25,26].

III. THE ROLE OF HYDROGEN BONDS IN PROTON TRANSFER REACTIONS

The interaction of acids and bases leading to the dissociation of acids and the protonation of bases proceeds via the formation of hydrogen bonds and ion pairs [reaction (2a)], as stated above. However, apart from this main reaction, there are a number of side reactions associated with the formation of hydrogen bonds and ion pairs with solvent molecules and the formation of hydrogen-bonded complexes between the acid (or base) and the ionic component of the anion (or conjugate acid) formed. As a result, a change in the nature of the solvent leads to a change in the thermodynamic parameters and sometimes in the relative sequence of the acidities (basicities) of various organic compounds. For this reason, investigators have endeavoured to represent thermodynamic functions as the sum of two contributions: "internal", which is independent of the influence of the medium, and "external", which is associated with the solvation of molecules [29,30]. However, the problem of the separation of these contributions and of a quantitative estimation of the role of hydrogen bonds or other types of interaction with the medium requires the development of experimental methods for the determination of the "internal" acidity (basicity), i.e. for the measurement of acid–base equilibria in the gas phase. Such data have been obtained for a wide range of organic compounds only in the last few years as a result of the development of mass-spectrometric methods.

The principal approaches to the elucidation of the influence of hydrogen bonds, obtained in the study of acid–base equilibria in solvents of different types and also when the latter were compared with the corresponding equilibria in the gas phase, are discussed below.

1. Acid–Base Equilibria in Various Solvents

Many reviews and monographs present data for the acidity and basicity constants in various solvents and the medium effects are discussed in one way or another (see, for example, Refs. 31–36). We shall consider the approaches to the isolation of the role of hydrogen bonds in proton transfer reactions.

Studies on acid–base equilibria in various media require that side reactions associated with the formation of hydrogen bonds, which are therefore different for protic and aprotic solvents, be taken into account. In view of the amphoteric nature of protic solvents, the latter exhibit two functions—those of a proton donor and acceptor. As a donor, the solvent interacts with

(a) the base:

$$SH + B \rightleftarrows SH \ldots B \rightleftarrows S^- \ldots BH^+ \rightleftarrows S^- + BH^+; \quad (3)$$

(b) with the anion formed:

$$SH + A^- \rightleftarrows SH \ldots A^- \rightleftarrows S^- \ldots HA \rightleftarrows S^- + HA. \quad (4)$$

As a proton acceptor the solvent interacts with

(a) the acid:

$$AH + SH \rightleftarrows AH \ldots SH \rightleftarrows A^- \ldots HSH^+ \rightleftarrows A^- + SH_2^+; \quad (5)$$

(b) with the conjugate acid formed:

$$BH^+ + SH \rightleftarrows BH^+ \ldots SH \rightleftarrows B + SH_2^+. \quad (6)$$

In media with a dielectric constant $\epsilon < 24$ there is a large number of ion pairs and hydrogen-bonded complexes; if $\epsilon > 24$, dissociated ions are also present [32].

Aprotic solvents can be divided into two groups: "inert", which hardly interact or only weakly interact with the reacting species (hydrocarbons and their halogeno-derivatives), and dipolar aprotic solvents, which can behave as proton acceptors [reactions (5a) and (6a) analogous to reactions (5) and (6)]:

$$AH + S \rightleftarrows AH \ldots S \rightleftarrows A^- \ldots HS^+ \rightleftarrows A^- + SH^+, \quad (5a)$$

$$BH^+ + S \rightleftarrows BH^+ \ldots S \rightleftarrows B \ldots HS^+ \rightleftarrows B + HS^+. \quad (6a)$$

In aprotic solvents of these two types reactions involving the formation of hydrogen bonds between the reactants assume a major role:

(a) between the acid and its anion:

$$AH + A^- \rightleftarrows AH \ldots A^-; \quad (7)$$

(b) between the conjugate acid and the base:

$$BH^+ + B \rightleftarrows BH^+ \ldots B. \quad (8)$$

Table 1. The equilibrium constants and the pK_a for substituted phenols–substituted pyridines and substituted phenols–triethylamine series [48].

Substituent in Ar	X	K	ΔpK_a
	$ArOH + XPy \rightleftarrows ArO^- \ldots HXPy^+$*

* The relation between K and $\Delta pK_a = 0.7\Delta pK_a - 3.4$.
** The relation between K and pK_a is $K = -0.5pK_a + 3.5$.

In "inert" aprotic solvents acid dimers and hydrogen-bonded complexes of the acid and the base may be present together with associated species formed by reactions (7) and (8). The interaction of acids and bases in such media does not lead to dissociation into ions; it stops at the

stage involving the formation of ion pairs, which can associate into larger aggregates [36,37]. Thus the treatment of acid–base equilibria in solvents virtually lacking the capacity for specific interactions with the reactants proved to be fairly complex [31,36].

Studies devoted to the conversion of molecular hydrogen-bonded complexes into ion pairs have therefore acquired particular importance. Reliable spectroscopic criteria have been established for the identification of molecular (II) and ionic (III) hydrogen-bonded complexes in ultraviolet [38–40], infrared [2,41,42], and ^{1}H NMR spectra at low temperatures [43]. The study of the first stages of equilibrium (2a) in "inert" media made it possible to follow the changes in the nature of the interaction as a function of the proton-donating (for example, in series of halogeno- and nitro-phenols [3,38,39] and carboxylic acids [41–47]) and proton-accepting properties of the reactants (aliphatic and aromatic amines).

It has been shown [48] that there are linear relations between the equilibrium constants for the formation of ion pairs and the quantities $\Delta pK_a = pK_a(AH) - pK_a(BH^+)$ for certain series (see, for example, Table 1). In a number of studies the problem of the values of ΔpK_a for which ion pairs are formed (the II $\rightleftharpoons$ III equilibrium) [45,46,49,50] and of the differences between the enthalpies of formation of complexes II and III [2,38,44,51] has been discussed.

Much attention has been devoted to the investigation of the influence of the medium on the position of equilibrium (2). [38,48,52,53] It has been shown that the role of the solvent in the formation of ion pairs does not reduce the influence of the dielectric constant ϵ; the formation of hydrogen bonds with the solvent is of great importance, i.e. an enhancement of the proton-accepting properties of the medium shifts the equilibrium towards form III. [45,46,53]

In dipolar aprotic solvents the ion pairs $A^-...HB^+$ can be solvated specifically by the solvent with formation of solvate-separated ion pairs $A^-...(S)...HB^+$. Thus the solvation of a nitrophenol–amine complex has been investigated [54]; according to the authors, dimethyl sulphoxide is incorporated in the ion pair, forming a π-complex with the anion and hydrogen bonds with the cation: $A^-...(DMSO)...HB^+$. The molecular complex $\rightleftharpoons$ ion pair equilibrium has not been observed for oxygen-containing proton acceptors. It has been suggested that, with increase of the strength of hydrogen bonds, the evolution of complex formation proceeds from a molecular complex to an ion pair via a system in which the proton has a symmetrical position [55].

Reactions (7) and (8), occurring in dipolar aprotic solvents, have been studied by potentiometric titration and conductimetry in a series of investigations [56–60]. The formation of hydrogen bonds between the acid and the anion [reaction (7)] and between the conjugate acid and the base [reaction (8)] is referred to by the authors of the above investigations as homoconjugation processes. They showed that homoconjugation of type (7) plays a very important role; the formation constants of the complexes $(AHA)^-$ are much larger than K_{BHB^+}. [56,57,59] Enhancement of the proton-accepting properties of the solvent diminishes the homoconjugation constants. Thus the homoconjugation constants of benzoic acids in dimethylformamide (DMF) and in DMSO are smaller by a factor of 10 and 100 respectively than in acetonitrile [59].

In order to estimate the influence of homoconjugation on the proton transfer reaction, studies were made [56,57,59,60] of hydrogen bond formation reactions between the test acids AH and a model anion, for which the Cl^- anion was chosen [reaction (9)], and also between the test anion A^- and a model acid—*p*-bromophenol [reaction (10)] (the authors call these processes heteroconjugation):

$$AH + Cl^- \rightleftarrows AH \ldots Cl^-, \quad (9)$$

$$Br{-}C_6H_4OH + A^- \rightleftarrows BrC_6H_4OH \ldots A^-. \quad (10)$$

In this approach use is actually made of the principle of the constancy of acid-base functions in hydrogen bonds, already mentioned in Section II. [12,61] It has been shown in relation to benzoic acids and phenols that the sensitivity of the heteroconjugation reaction (the parameter ρ) to the electronic influence of substituents is smaller by a factor of approximately 4 than for the full proton transfer. The ratio ρ(phenol)/ρ(benzoic acid) $\simeq$ 1.8–2.0 remains constant for all the dipolar aprotic solvents employed [60].

The influence of solvents on acid–base reactions is determined overall by the operation of a large number of factors, namely (1) the formation of hydrogen bonds, (2) electrostatic interactions, (3) the basicity of (or acidity) the solvent, (4) van der Waals interactions, among which dispersion interactions are the most important, and (5) the structural organisation of the solvent. Allowance for the contributions of different factors is a complex problem, but certain approaches to its solution are available. Thus, in order to eliminate the role of electrostatic interactions, it has been suggested [62,63] that a pair of solvents of different types but with similar dielectric constants ϵ be used, namely methanol and DMF. The thermodynamic characteristics of acid–base equilibria in these two media differ greatly, demonstrating an important role of specific interactions.

Dispersion forces depend significantly on the shape and size of the interacting species, so that they must be taken into account in those cases where the equilibrium involves large highly delocalised and therefore readily polarisable anions. Such anions have a low capacity for the formation of hydrogen bonds and the role of dispersion interactions increases and may become decisive. For example, a whole class of CH acids such as derivatives of fluorene, diphenylmethane, and triphenylmethane exhibit a greater acidity in DMSO than in water, in contrast to OH acids [34,64]. In their analysis of the influence of the above factors the authors [64] note that, in solvents such as water and DMSO, factors (2) and (3) cancel out. Namely, as a result of the greater basicity of the solvent, the acidity of a given acid in DMSO should increase by 1.5 ± 0.5 pK_a units, while as a result of the lower dielectric constant ϵ it decreases by 1 pK_a unit compared with water. In the case of CH acids dispersion interactions are of greatest importance, while for OH acids the formation of hydrogen bonds is the decisive factor. The differences between the relative strengths of OH and CH acids in protic and dipolar aprotic solvents are determined by the operation of these factors. DMSO molecules, which have a larger dipole moment and polarisability than H_2O molecules, stabilise carbanions as a result of the operation of dispersion forces, which increases the acidity of CH acids in this solvent. The anions of OH acids are stabilised as a result of the formation of hydrogen bonds with water, so that their acidity in water is greater by 4–6 orders of magnitude than in DMSO.

It is noteworthy that in CH acids, whose negative charge is localised at the heteroatom (for example, benzoylacetone, nitromethane, and hydrogen cyanide), the decisive factor is the formation of hydrogen bonds with the solvent. As a result, the acidity in water is greater by 2–3 orders of magnitude than in DMSO, [34,64–66] as for OH acids. At the same time, an increase in the size of the anions of OH

acids combined with an increase of the degree of delocalisation of the charge leads to a decrease of the strength of hydrogen bonds with water and to an enhancement of dispersion forces. Thus, on passing from phenol to 4-nitro- and 2,6-dinitrophenols, the difference between the acidities in DMSO and water diminishes: the ΔpK_a values are 6.4, 3.8, and 1.3 respectively. In picric acid the sign of this quantity changes ($\Delta pK_a = -1.3$); this shows that the above acid is stronger in DMSO as a result of the stabilisation of the anion by dispersion forces [64]. A change of the sign of ΔpK_a (where ΔpK_a is the difference between the acidities in DMSO and MeOH) also takes place for 4-nitrophenol: $\Delta pK_a = 2.2$ for phenol and -0.8 for 4-nitrophenol [66].

Thus, apart from the acids giving rise to large anions with a highly delocalised charge, hydrogen bonding effects predominate over the dispersion forces and lead to a greater acidity in protic solvents.

The problems of the differentiating action of solvents, associated with their solvating capacity, have been examined in detail in a review [32] in relation to phenols and benzoic acids. It was shown that the differentiating effects of solvents can be estimated with the aid of three parameters:

(1) the autoprotolysis constant of the solvent (pK_S);

(2) the coefficient α in the equation

$$pK_{HA}(S) = \alpha pK_{HA}(H_2O) + \beta;$$

(3) the coefficient ρ in the Hammett equation:

$$pK_{HA}(S) = pK_0 - \rho\sigma.$$

Table 2. Parameters characterising the differentiating influence of solvents for monosubstituted benzoic acids [67] and phenols [32], and the solvent acidity factors in hydrogen bonds*.

Solvent	$\varepsilon_{25}°$	pK_S	α	ρ(b.a.)	ρ(ph.)	P_i

*The parameters pK_S, α, and ρ(b.a.) for benzoic acids and ρ(ph.) for phenols are presented.

Table 2 shows that the values of pK_S, α, and ρ vary in parallel, demonstrating thereby the role of factor (3). At the same time the data in Table 2 indicate the absence of any parallelism in the variation of these parameters and the dielectric constant ϵ. Since the solvents belong to different classes of organic compounds, there need be no direct relation between their acid–base properties and their capacity for the formation of hydrogen bonds, as stated above. The role of hydrogen bonds is manifested by the fact that all the solvents which behave as proton donors exhibit smaller differentiating effects than aprotic solvents. However, Table 2 shows [32,67] that there is no direct relation between the hydrogen bond acidity factors P_i and the values of ρ. It may be that the absence of such a relation is due to the fact that the enthalpies of hydrogen-bonded complexes, from which the values of P_i were determined, had been obtained under the conditions leading to the formation of 1 : 1 complexes.

The relative activity coefficients have been used in some studies [58,68] in order to take into account the ability of solvents to form hydrogen bonds‡. The ability of a given solvent (S) to function as a proton acceptor in relation to a standard (S_0), for which acetonitrile (AN) was selected, was defined as $\lg {}^{AN}_{\gamma}{}^{S}(H_\alpha)$ with the aid of the expression

$$\lg {}^{AN}\gamma^{S}(H_\alpha) = \lg {}^{AN}\gamma^{S}(HA) - \lg {}^{AN}\gamma^{S}(MeA),$$

where HA is the acid and MeA is its methyl ester. It was assumed that the activity coefficient of the methyl ester takes into account all types of interaction other than hydrogen bonding. The activity coefficients of the acids and their esters were determined from measurements of the solubilities s:

$$\lg {}^{AN}\gamma^{S} = \lg s^{AN} - \lg s^{S}.$$

The same activity coefficients were obtained independently from differences between the heteroconjugation constants. Thus it was concluded that the quantities $\lg {}^{AN}_{\gamma}{}^{S}(H_\alpha)$ characterise the ability of the solvents to function as proton acceptors, which decreases in the following sequence:

$$DMSO\,(-1.9) > MeOH\,(-1.5) > DMF\,(-1.4).$$

The relative abilities of solvents to function as proton donors in hydrogen bonds with the anion was estimated from the values of $\lg {}^{M}_{\gamma}{}^{S}_{A^-}$, methanol (M) being selected as the standard solvent. The large negative activity coefficients obtained for dipolar aprotic solvents indicate a much higher degree of solvation of anions by methanol. The quantity $\lg {}^{M}_{\gamma}{}^{S}_{A^-}$ increases linearly with increasing basicity of the anion [68].

The activity coefficients obtained from studies on S_N2 reactions have been used [69] to estimate the influence of hydrogen bonds with the anion on the acid dissociation constant in protic solvents (H_2O, MeOH). However, one must bear in mind that this method is fairly approximate. The coefficients $\lg {}^{S_0}_{\gamma}{}^{S}_{A^-}$ for individual ions can be determined only with the aid of non-thermodynamic postulates.

Information obtained in the study of the thermodynamic characteristics of hydrogen bonds with ions by infrared spectroscopic, ^{1}H NMR, conductimetric, and calorimetric methods proved to be much more accurate and reliable (see, for example, Refs. 51 and 70–72). We believe that, in analysing the influence of solvents on acid–base equilibria, one can employ widely the enormous amount of experimental data on the thermodynamic properties of hydrogen bonds of the type AH...B (see, for example, Refs. 14 and 73). The most valuable data concerning the role of hydrogen bonds have been obtained in recent years by combining the results of studies on proton transfer reactions in the gas phase and in solutions.

‡ The relative activity coefficients $-\lg {}^{S_0}_{\gamma}{}^{S}$ reflect the change in the standard chemical potential of the solute on passing from an arbitrary standard solvent (S_0) to another solvent (S).

2. Comparison of the Parameters of the Acid–Base Equilibria in the Gas Phase and in Solution

The development of methods of ionic cyclotron resonance [74,75] and high-pressure mass spectrometry [76,77] permitted fairly accurate determinations of thermodynamic equilibria in the gas phase. The most important results in this field have been reviewed [78,79].

Proton transfer reactions of the following types were studied in the gas phase:

$$AH + B^- \rightleftarrows A^- + BH, \quad (11)$$

$$AH^+ + B \rightleftarrows A + BH^+. \quad (12)$$

If the acidity is defined as the free energy ΔG^0 of reaction (13), then the free energy of reaction (11) is a measure of the relative acidities of two acids AH and BH:

$$AH \rightleftarrows A^- + H^+. \quad (13)$$

The basicity in the gas phase is the term given to the corresponding free energy ΔG^0 of reaction (14) and ΔG^0 of reaction (12) is a measure of the relative basicities of the bases A and B:

$$BH^+ \rightleftarrows B + H^+ . \quad (14)$$

The enthalpies ΔH^0 of reactions (11)–(14) are believed to be approximately equal to the ΔG^0 in view of the smallness of the entropy effects. Special measurements of ΔS^0 of reaction (12) showed that these quantities are indeed very small [80]. The small contribution of entropy factors to reaction (11) is indicated by the insignificant changes in ΔG^0 when the temperature is altered by 300 K for a series of benzoic acids and phenols ($\Delta S^0 < 2-3$ e.u.). [81] The relative acidity or basicity [reactions (11) and (12)] are frequently designated by $\delta\Delta G^0$; the relative enthalpies are designated by $\delta\Delta H^0$.

In order to construct an absolute acidity scale [reaction (13)] or basicity scale [reaction (14)], it is necessary to calculate a thermodynamic cycle. The enthalpy change in reaction (13) caused by the proton affinity of the anion $PA(A^-)$ corresponds to the heterolytic dissociation energy and is defined as follows:

$$PA(A^-) = \Delta H^0 = DH^0(AH) - EA(A) + IP(H), \quad (15)$$

where DH^0(AH) is the homolytic dissociation energy, EA(A) electron affinity of the atom A, and IP(H) the ionisation potential of the hydrogen atom. The values of $PA(A^-)$ for a series of carboxylic acids have been determined with the aid of data for HCl and H_2S [82] and were then used as reference values in the study of benzoic acids and phenols [51].

The proton affinity of the base PA(B), corresponding to enthalpy of reaction (14), is defined in terms of the homolytic dissociation energy $DH^0(BH^+)$ and the ionisation potentials of the atoms B and H:

(16)

The internal correspondences in measurements of repeatedly overlapping thermodynamic cycles ensured an accuracy of the measurements to within 0.5 kcal mole^{-1}; the errors in the absolute values of $PA(A^-)$ and PA(B) are ±2 kcal mole^{-1}.

The existence of a linear relation between the acidities (or basicities) in the gas phase and the σ constants of the substituents has been demonstrated for certain classes of acids and bases. In all cases the sensitivity to the electronic effects of the substituents is much greater in the gas phase than in solution. Thus ρ in the gas phase is greater by a factor of 6.8 for phenols and by a factor of 10.6 for benzoic acids than in water [79,81]. According to other data [83–84], the values of ρ in the gas phase amount to 5.5–5.7 for carboxylic acids and 7.0–8.4 for alcohols; in protic solvents these quantities decrease to 1.7–1.8 and 2.7 respectively. The electronic influence of substituents on the basicity of pyridine in the gas phase is greater by a factor of 3.5 (Taagepera et al. [85]) (by a factor of 2.5, according to Arnett et al. [1]) than in water.

Table 3. The free energies and enthalpies of the reactions $XC_6H_4OH + C_6H_5O^- \rightleftharpoons XC_6H_4O^- + C_6H_5OH$ in the gas phase, water, and DMSO. [81]

X	$\Delta G^\circ_{gas} \approx \Delta H^\circ_{gas}$, kcal mole^{-1}	$\Delta G^\circ_{H_2O}$, kcal mole^{-1}	$\Delta H^\circ_{H_2O}$, kcal mole^{-1}	$\Delta G^\circ_{DMSO} \approx \Delta H^\circ_{DMSO}$, kcal mole^{-1}	$\delta\Delta H_{hydr}(A^-)$*, kcal mole^{-1}
p-OCH_3	−0.7	0.5	0.22	−0.6	−0.4
m-CH_3	0.4	0.18	0.02	0.1	−0.7
p-CH_3	1.3	0.42	0.02	1.7	−2.2
o-Cl	−6.3	−1.9	−1.1	−4.5	—
m-Cl	−7.9	−1.2	−0.3	−2.8	9.3
p-Cl	−6.6	−0.7	0.2	−1.5	10.9
p-NO_2	−25.8	−3.8	−0.8	−8.6	17.9

*$\delta\Delta H_{hydr}(A^-)$ corresponds to the difference between the heats of hydration of the anions $XC_6H_4O^-$ and $C_6H_5O^-$ on passing from the gas phase to an aqueous medium: $\delta\Delta H_{hydr}(A^-) = \Delta H_{hydr}(XC_6H_4O^-) - \Delta H_{hydr}(C_6H_5O^-)$.

Arnett et al. [1] and Mahon and Kebarle [81] claim that the main factor responsible for the weakening of the influence of substituents in protic solvents is the formation of hydrogen bonds with the anion for acids [81] and with the conjugate acid for bases [1]. Analysis of the hydration energies of the anion A^- in Table 3 on passing from the gas phase to an aqueous medium and the internal acidities of substituted phenols permits a semiquantitative characterisation of the contribution of hydrogen bonds to the change in the effect of substituents in water. Comparison of the acidities ($\Delta G^0_{gas} \simeq \Delta H^0_{gas}$) and heats of hydration of the anions [$\delta\Delta H_{hydr}(A^-)$] shows that the enhancement of the electron-accepting properties of substituents, leading to an increase of internal acidity, is almost fully compensated by the decrease of the hydration of the anion as a result of its lower basicity and ability to form hydrogen bonds§. Thus the acidity of *p*-nitrophenol increases relative to phenol by 25.8 kcal mole^{-1} in the gas phase and solvation, which stabilises the p-$NO_2C_6H_4O^-$ anion with its lower capacity for the formation of hydrogen bonds, is weakened by 17.9 kcal mole^{-1}; as a result $\Delta G^0_{H_2O}$ increases by only 3.8 kcal mole^{-1}. The decrease of the strength of $A^-\ldots(HOH)_n$ hydrogen bonds leads to an increase of the degree of disorder among solvent molecules in the vicinity of the anion, which is reflected in a greater entropy change and hence in a higher value of $\Delta G^0_{H_2O}$ compared with $\Delta H^0_{H_2O}$. Dipolar aprotic solvents, which only weakly solvate anions, have

§ As will be made clear below, the differences between the electrostatic and dispersion interactions for anions of similar size are negligible and the hydrogen bonds with the base should play a smaller role than those with the anion.

higher values of ρ (this was indicated in Section II for benzoic acids). Table 3 shows that the values of ΔG DMSO are much closer to those of ΔG gas for phenols; the attenuation factor is ~2. In contrast to the values in water, the influence of substituents is manifested in DMSO mainly by a change in enthalpy (ΔG DMSO $\simeq \Delta H$ DMSO), i.e. as in the gas phase.

The smaller the ability of the anion to form hydrogen bonds, the greater the decrease of the acidity of the corresponding acid on passing from the gas phase to water (and any other protic solvent). Thus the acidities of acetic acid and phenol are similar in the gas phase, while in water they differ by six orders of magnitude[81]. The delocalisation of the negative charge owing to the resonance effect in the phenoxide anion lowers its ability to form hydrogen bonds, which makes phenol a much weaker acid in solution. In certain classes of compounds it is necessary to take into account the stabilisation of the acids themselves in addition to the hydrogen bond with the anion. Thus benzoic acid is much stronger in the gas phase than phenol, while in water its pK_a is almost the same. This has been explained[81] by the greater ability of benzoic acid, compared with phenol, to function as a proton donor in a hydrogen bond.

The role of hydrogen bonds in the attenuation of the observed electronic influence of substituents and the change in the relative sequence of acidities in solution is manifested also by the fact that these effects are absent for acids whose anions do not possess a sufficient capacity for the formation of hydrogen-bonded complexes. Indeed, it has been shown in a series of studies[85-89] that the influence of substituents in CH acids giving rise to large ions with a delocalised charge is the same in the gas phase as in solutions; the relative acidity sequence does not change. The negligible influence of water as a solvent on the energy of proton transfer has been demonstrated for a large number of CH acids[86-88]. The differences between the basicities in the gas phase and water for aryl carbonium ions with appreciable differences in structure are constant. There is a linear relation between $\delta\Delta G_i$(gas) and $\delta\Delta G_i(H_2O)$ with a slope of unity and an intercept on the ordinate axis at ~35 kcal mole^{-1}, i.e. the enthalpy of solvation does not involve a specific interaction[87]. A satisfactory linear relation (with a slope of unity and $\rho = 1$) has been obtained [86] between the acidities of a large set of CH acids in the gas phase and in DMSO.

The most detailed study of solvation effects has been made recently[1]. The authors analysed the influence of hydrogen bonds on the acid–base equilibria of substituted pyridines and showed that the apparent weakening of the effect of substituents (by a factor of 2.5) in water can be accounted for wholly on the basis of a solvation model in which hydrogen bonds play the main role. They state that the acid–base equilibria of substituted pyridines involve an optimum reaction for this solvation model, because the ions and acid molecules have similar dimensions and shapes, so that the effects of their electrostatic and dispersion interactions are similar.

Arnett et al.[1] analysed a thermodynamic cycle and isolated the contribution of the hydrogen bonds (ΔH_{HB}) to the enthalpy of solvation (ΔH_S) calculated from heats of solution and vaporisation:

$$\begin{array}{ccc} XPyH^+_{gas} + Py_{gas} & \overset{\delta\Delta H_{i\,gas}}{\rightleftharpoons} & XPy_{gas} + PyH^+_{gas} \\ \downarrow \Delta H_S(BH^+) \quad \downarrow \Delta H_S(Py) & & \downarrow \Delta H_S(B) \quad \downarrow \Delta H_S(PyH^+) \\ XPyH^+_{H_2O} + Py_{H_2O} & \overset{\delta\Delta H_{i\,H_2O}}{\rightleftharpoons} & XPy_{H_2O} + PyH^+_{H_2O} \end{array}$$

The authors follow Krishnan and Friedman[90,91] in separating the solvation energy into (1) the enthalpy of formation of hydrogen bonds, (2) the energy of van der Waals interactions, (3) the energy of formation of a "cavity", and (4) the energy of the change in solvent structure. The last three "physical" factors were determined as an overall factor[1].

Three procedures have been used to isolate the contribution of hydrogen bonds.

1. On the basis of the principle of the constancy of the acid and basic functions in hydrogen bonds[13,61], the coefficients for the transition from *p*-fluorophenol to water as a proton donor were determined and the data of Taft et al.[10] for the p-$FC_6H_4OH\ldots XPy$ system were used.

2. The difference between the heats of solvation of substituted benzenes and pyridines was attributed to hydrogen bonds.

3. A quantum-chemical calculation was carried out on the hydrogen bond formation and proton transfer reactions.

It was shown that the experimental coefficient α ($\alpha = 0.1$) in the linear relation between the energy of formation of hydrogen bonds and the energy of proton transfer in the gas phase ΔH_{HB} ($XPy\ldots H_2O$) $= \alpha\Delta H_i$ is twice as great as the calculated value ($\alpha = 0.05$), which can be accounted for by the lower strength of the 1 : 1 hydrogen-bonded complexes, assumed in the quantum-chemical calculation, compared with the real complexes $XPy\ldots(H_2O)_n$.

The hydrogen bonds formed by charged ions play the most important role; their energy exceeds approximately by a factor of five the enthalpy of formation of hydrogen-bonded complexes of substituted pyridines¶. The influence of substituents in the $XPyH^+\ldots OH_2$ hydrogen bonds leads to the opposite relation compared with the proton transfer reaction, $\Delta H_{HB}(XPyH^+\ldots OH_2) = 0.5\Delta H_i$(gas), as for the hydrogen bonds between benzoic acids and the anions. The attenuation factor for the influence of substituents in water (2.5) can be explained satisfactorily by such variations in the strength of the hydrogen bond.

The study of Arnett et al.[1] demonstrated brilliantly the fruitfulness of this approach to the analysis of the thermodynamic cycle using the following set of data: the experimental enthalpies of proton transfer in the gas phase and in solution and the enthalpies of solvation and hydrogen bond formation in combination with the results of quantum-chemical calculations. A test of the applicability of this solvation model for hydrogen bonds to other classes of acids and bases is presumably a task for the immediate future.

The possibility of using the model for the analysis of solvation effects involving aliphatic amines is of particular interest, because the problem of the preferential contribution of electrostatic interactions or of the formation of hydrogen bonds continues to remain controversial [93-97]. Measurements of the basicities of alkylamines in the gas phase established that the anomalous basicity series in water ($NH_3 < MeNH_2 < Me_2NH > Me_3N$) is related to the solvation effects[93,96]. In the gas phase the basicity varies in accordance with expectation ($NH_3 < MeNH_2 < Me_2NH < Me_3N$). There are different linear relations between the enthalpies in the gas phase and

¶ It is of interest that comparison of the influence of hydrogen bonds formed by the pyridinium ion ($C_6H_5N^+H\ldots Cl^-$) with $MeOH\ldots Py$ showed[92] that the effect of substituents in the first case is greater by a factor of approximately 5.

aqueous solution for primary, secondary, and tertiary amines, whose slopes decrease in this sequence (Fig. 6).[93] The basicity of amines in the gas phase is 5–6 times higher than in water.

However, the interpretations of the results by Aue et al.[94] and by Arnett and coworkers[96,97] are contradictory. Aue et al.[94] believe that the irregular basicity sequence cannot be accounted for solely by the formation of hydrogen bonds of the type $BH^+ \ldots OH_2$. They claim that hydrogen bonds of this type are responsible only for the difference between the slopes of the linear plots of proton affinity against ΔH_S for primary, secondary, and tertiary amines.

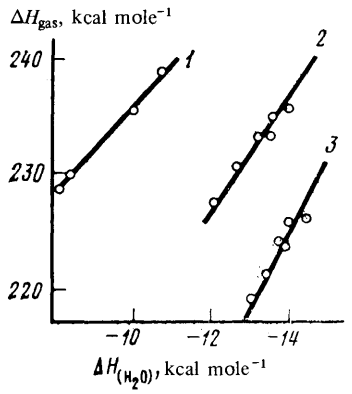

Figure 6. Relation between the enthalpies of protonation of aliphatic amines in the gas phase and water[94]: 1) tertiary amines; 2) secondary amines; 3) primary amines.

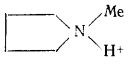

The claim by Arnett and coworkers[96,97] that hydrogen bonds are the principal differentiating factor in the solvation of ammonium ions is based on the following facts. Firstly, the solvation energy depends to a greater extent on the number of hydrogen bonds than on the size and shape of the ion. The dependences of the heat of hydration of ammonium ions on the reciprocal of the radius are different for primary, secondary, and tertiary ions, the differences increasing for large ions where the contribution of electrostatic interaction is reduced. Secondly, the average solvation energies for the three types of amines differ by 6–7 kcal mole^{-1}, which corresponds to the energies of strong $N^+H \ldots OH_2$ bonds.

Additional confirmation of the rule of hydrogen bonds was obtained on comparing the influences of substituents on the acidity of ammonium, oxonium, sulphonium, and phosphonium ions[98]. Ions of the last two types exhibit a much weaker capacity for the formation of hydrogen bonds, which means that the weakening influence of the solvent should be significantly smaller for such ions than for ammonium and oxonium ions. Indeed the influences of substituents in all four classes of compounds in the gas phase, characterised by the quantities $\Delta PA = PA(MeXH_{n-1}) - PA(XH_n)$, differ little. On the other hand, the differences between the enthalpies of protonation of methylated derivatives and hydrides in fluorosulphonic acid $[\Delta(-\Delta H)_{HSO_3F}]$ are much greater for phosphorus and sulphur derivatives than for nitrogen and oxygen derivatives. The maximum weakening of the influence of substituents in solution $[\Delta PA = 16.9$ kcal mole^{-1}; $\Delta(-\Delta H)_{HSO_3F} = 2.2$ kcal mole$^{-1}]$ is observed for oxonium ions, which corresponds to their capacity for the formation of hydrogen bonds and cannot be accounted for by electrostatic interactions. The values of ΔPA from later studies are indicated below in brackets[80,99]:

	ΔPA, kcal mole^{-1}	$\Delta(-\Delta H)_{HSO_3F}$, kcal mole^{-1}		ΔPA, kcal mole^{-1}	$\Delta(-\Delta H)_{HSO_3F}$ kcal mole^{-1}
$H_2O \rightarrow MeOH$	16,9(11,9)	2.2	$NH_3 \rightarrow MeNH_2$	11.0(9,0)	4.0
$H_2S \rightarrow MeSH$	15,0(12,0)	8.8	$PH_3 \rightarrow RPH_2$	14,4(14.4)	13.0

Comparative data on the basicities of aromatic and aliphatic amines in the gas phase and in water have been analysed in several studies[85,100–102] and several instances of the inversion of the basic strengths in solution compared with the "internal" basicity in the gas phase were noted. Thus, pyridine, which is four times less basic than ammonia in water, is eleven times more basic in the gas phase. The basicity sequence of anilines and amines in water ($Ph_3N < PhNH_2 < NH_3$) is also inverted in the gas phase: $NH_3 < PhNH_2 < Ph_3N$.[100] However, it was found that these changes are not related to the small role of resonance effects in the gas phase, but can be accounted for by the fact that the differences between the heats of solvation exceed the resonance effect in unsaturated compounds. In has been shown[85] that ΔH_S for the NH_4^+ cation is greater by 20 kcal mole^{-1} than for PyH^+, which leads to a much greater stabilisation of the ammonium ion in water. The higher heat of solvation was attributed to the greater strength of $NH_4^+ \ldots OH_2$ hydrogen bonds. However, the extent of the electrostatic interactions involving the small ion should also be greater, so that each contribution requires a special assessment.

Table 4. The heats of solution and relative acidities in the gas phase and in water of three pairs of conjugate acids differing in the degree of unsaturation[101]. The proton affinities and percentages of *s* character of the lone pair of the nitrogen atom in the corresponding amines[102].

Conjugate acid	$\Delta H_S(BH^+)$, kcal mole^{-1}	$\delta\Delta G_i$(gas), kcal mole^{-1}	$\delta\Delta G_i$(H$_2$O), kcal mole^{-1}	PA, kcal mole^{-1}	Amount of *s* character, %
	73.0	−4.3	−3.88	220.9	30
$Me_2NH_2^+$	73.0	0	0	224.6	25
	64.0	−8.3	−7.16	224.8	83
	62.0	0	0	230	25
	76.0	−9.6	−8.2	—	—
	76.0	0	0	—	—

As stated by Taft et al.[101], in order to establish the role of resonance effects one must compare the basicities of compounds with similar values of $\Delta H_S^0(BH^+)$. Such compounds are bases with the same number of acid hydrogen atoms and carbon atoms and also with a similar skeleton, differing only in the degree of unsaturation.

Under these conditions, the basicity of unsaturated compounds in the gas phase is lower than that of saturated compounds. Consequently, the resonance effect is manifested quite explicitly (Table 4) and there is no inversion in the relative basic strengths on passing from the gas phase to the solution. The changes in the basicities of unsaturated compounds are greater by 10–20% compared with saturated compounds in the gas phase relative to water, which has been explained[101] by the presence of hydrogen bonds between the bases or conjugate acids and water. The existence of a linear relation between the proton affinity and the percentage of *s* character of the lone pair orbitals of the nitrogen atom for compounds with similar values of ΔH_S has been demonstrated[102]. A greater percentage of *s* character corresponds to a lower value of *PA*, as for basicity in solution.

Marked changes on passing from the solution of the gas phase have been observed in studies devoted to the acid properties of aliphatic amines, alcohols, and thiols[103,107] (Table 5). The acidities in water decrease when the substituents are varied in the sequence Me > Et > iso-Pr > t-Bu, and there is a linear relation with the σ^* constant of the substituent. The same series, with an effective correlation between the heats of deprotonation and the σ^* constants, has been obtained in a study in DMSO.[15] However, the data in Table 5 show that in the gas phase the acidity sequence is inverted (Me < Et < iso-Pr < t-Bu), which demonstrates the lack of validity of the generally accepted relation between acidity and the inductive effect.

Table 5. The relative acidities of alcohols and thiols in the gas phase and in water ($RX^- + BuXH \rightleftharpoons BuX^- + RXH$; X = O or S).[107]

RXH	$\delta\Delta G_{gas}$, kcal mole^{-1}	$\delta\Delta G_{H_2O}$, kcal mole^{-1}	RXH	$\delta\Delta G_{gas}$, kcal mole^{-1}	$\delta\Delta G_{H_2O}$, kcal mole^{-1}
H_2O	−17.8	1.1	H_2S	1.7	5.75
MeOH	−5.6	1.7	MeSH	−4.1	1.22
EtOH	−2.7	1.0	EtSH	−1.7	0.78
iso-PrOH	−0.8	0.3	iso-PrSH	−0.8	0.49
t-BuOH	0	0	t-BuSH	0	0

The role of solvation effects has been analysed[108,109]. The enthalpies of solvation ΔH_S obtained for the anions RO^- can be arranged in the sequence $MeO^- > EtO^- >$ iso-$PrO^- >$ t-BuO^-. The values of ΔH_S then exceed the stabilisation energy of the ions in the gas phase which varies in the opposite sequence. Thus the usual ideas concerning the sign of the inductive effect, based on measurements of equilibria in solutions, are incorrect. Quantum-chemical calculations by the CNDO/2 [110] and non-empirical[111,112] methods established that, owing to its high polarisability, the alkyl group can exhibit both positive and negative inductive effects, depending on the charge on the atom to which it is linked. The calculated proton transfer energies agree with the acidities and basicities in the gas phase.

Thus measurements of the acid–base properties in the gas phase showed that solvation interactions, among which the formation of hydrogen bonds is the most important, can influence not only the magnitude but also the sequence of the properties of a series of compounds having similar structures.

We shall now consider the problem whether or not there is a general relation between acid or basic properties of organic componnds in the gas phase and the characteristics of hydrogen bonds. Strictly speaking, the comparison should be made using the characteristics of hydrogen bonds formed in the gas phase. However, the amount of data for hydrogen-bonded complexes in the gas phase is at present very small. Nevertheless, it can be shown that a general relation of this type does not exist. The lack of correspondence between the energetics of hydrogen bonds and acidity in the gas phase has been observed, for example, when the O atom in the H-acid XH was replaced by an S atom. The acidity of thiols in the gas phase is greater, as in solution, than the acidity of alcohols, while their ability to form hydrogen bonds is much weaker. This difference can be readily understood if account is taken of the fact that the energy of the acid–base equilibrium in the gas phase is an overall characteristic including the dissociation energy and the electron affinity. The lower strength of the SH bond compared with OH is the principal cause responsible for the greater acidity of thiols in the gas phase. Consequently, as one moves downwards along the Group [in the Periodic Table?] the acidity in the gas phase increases, as in solution, while the strength of hydrogen bonds with bases diminishes.

It is noteworthy that, for certain classes of compounds (aliphatic amines and pyridines), a greater similarity of the properties of hydrogen bonds and the basicities in the gas phase compared with the basicity in the solution was observed. Thus a linear relation has been obtained[113] between the energy of formation of hydrogen bonds by phenol and *p*-fluorophenol with substituted amines or pyridines and the proton affinities of these bases in the gas phase. A correlation between the basicity in the gas phase and the pK_a in water is not observed in this case, as stated previously. Studies on the frequency shifts $\Delta\nu$(OH...N) [114] and $\Delta\nu(Cl_3CH...N)$ [115] in the gas phase and the thermodynamic parameters of the $CH_3OH...N$ systems[116] in the gas phase also showed that they vary in parallel with the proton affinities in the gas phase ($Et_3N > Me_3N > Me_2NH > MeNH_2$). It is of interest to note that studies on the OH...N hydrogen bonds in solution yield other results, namely, the energies of hydrogen bonds with tertiary amines are lower than those of the bonds with secondary amines[117], i.e. there is a correlation with the basicities in solution and not in the gas phase.

Measurements on ionic equilibria of the type $(BHR^-)_{gas} \rightleftharpoons B^-_{gas} + HR_{gas}$ yielded a series corresponding to changes in the enthalpies of hydrogen bonds in parallel with the acidities of HR in the gas phase: HOH < MeOH < t-BuOH < $CHCl_3$ < PhOH < H_3CCOOH < HCOOH,[118] but it does not correspond to the energies of hydrogen bonds in solution in all respects.

We believe that there is no doubt about the importance of more extensive studies on hydrogen bonds in the gas phase and of their comparison with data for solutions and gas-phase acidities and basicities. Studies on the electron-donating and electron-accepting properties of acids and bases, extending as far as the significant rearrangement of the latter associated with the proton transfer

process, are necessary for a deeper understanding of the reactivities of compounds in acid–base reactions.

IV. HYDROGEN BONDS IN NUCLEOPHILIC SUBSTITUTION REACTIONS

The two main classes of nucleophilic substitution reactions are known to differ as regards the influence of solvents on the rate of the process:

$$Y^- + RX \begin{cases} \xrightarrow{S_{N1}} Y^- + R^+ + X^- \rightarrow YR + X^- & \text{(protic solvents accelerate the reaction),} \\ \xrightarrow{S_{N2}} [Y \ldots R \ldots X]^{\neq} \rightleftarrows YR + X^- & \text{(protic solvents retard the reaction, while aprotic dipolar solvents accelerate it).} \end{cases}$$

Unimolecular reactions are accelerated by protic solvents, since the formation of hydrogen bonds promotes the formation of the anion X^-.

The role of hydrogen bonds, which retard reactions of the S_N2 type, has been elucidated by Parker and coworkers (see, for example, Refs. 119–121). For the analysis of the influence of the solvent, use is made of the relative activity coefficients ${}^{M}_{\gamma}{}^{DMF}$, which make it possible to eliminate the influence of electrostatic interactions, since methanol (M) and DMF have similar dielectric constants, as stated previously. Examination of the results led Parker [120] to the conclusion that the main factor which determines the solvation properties of the medium is the hydrogen bonds between the protic solvent and the anion. The values of $\lg {}^{M}_{\gamma}{}^{DMF}_{Y^-}$ increase in a sequence which is the same as that corresponding to the ability of the anions to form hydrogen bonds: ClO_4^- (−0.4); 2,4,6-$NO_2C_6H_2O^-$ (−0.4) < SCN^- (2.7) < 4-$NO_2C_6H_4S^-$ (2.9) < $4NO_2C_6H_4O^-$ (4.1) < $C_6H_5S^-$ (4.9) < $C_6H_5O^-$ (7.7) < $CH_3CO_2^-$ (9.2). The delocalisation of the charge in the picrate and perchlorate anions leads to a higher degree of solvation by DMF, which is assumed to be due to the enhancement of dispersion interactions.

Analysis of the influence of the solvent made it possible to determine more effectively than by other methods the nature of the transition state. The "looser" the transition state, the greater the localisation of the negative charge, and the greater the capacity of the given substance to behave as a proton acceptor in the hydrogen bond. The quantity $\lg {}^{M}_{\gamma}{}^{DMF}_{[YR.X]^{\neq}}$ increases and the ratio of the logarithms of the rate constant $\lg k^{DMF}/\lg k^{M}$ decreases.

The change in the nucleophilicity sequence when the nature of the solvent is altered can be accounted for qualitatively from the standpoint of the ability of the solvents to form hydrogen bonds: we have $I^- > SCN^- \simeq CN^- > N_3^- \simeq Br^- > Cl^- > OAc^-$ in protic solvents [122] and $CN^- > OAc^- > Cl^- \simeq Br^- \simeq N_3^- > I^- > SCN^-$ in dipolar aprotic solvents [119]. Thus the ratio of the nucleophilicities of OAc^- and SCN^- decreases by a factor of 10^5 on passing from DMF to methanol, since the acetate ion is a much more effective proton acceptor [120].

Thus analysis of the influence of hydrogen bonds on the reaction rates assists in the study of the nature of the transition state and the prediction of the changes in the rate on replacement of the solvent. The influence of the formation of hydrogen-bonded complexes can be detected qualitatively by employing mixed solvents (see, for example, Refs. 123–126) or by analysing the changes in the rate constants which do not parallel the dielectric constants ϵ of different solvents (see, for example, Refs. 127 and 128).

For a quantitative estimate, one resorts to many-parameter equations relating the rate constant to different characteristics of the solvents (n and ϵ), including those which determine their ability to function as proton donors and acceptors (see, for example, Refs. 129–131). Thus the two-parameter expression for dipolar solvents includes the quantity $\Delta\nu_D$, which represents the shift of the stretching vibration frequency of deuteromethanol $\Delta\nu(CH_3OD \ldots B)$: [129,130]

$$\lg K_0 = -A + Bf(\varepsilon) - C(\Delta\nu_D).$$

Thus the above expression estimates the ability of the solvent to behave as a proton acceptor in the hydrogen bond [129].

Unfortunately it was found that, for a quantitative description of the effects of the medium, an equation with an even greater number of parameters is needed. Furthermore, in the case of strong specific solvation effects, the equations are inapplicable owing to the significant non-additivity of the contributions of interactions of different types [129,130].

The change from protic to dipolar aprotic solvents can also alter the mode of reaction. It has been shown in a review [132] devoted to ambident anions that, depending on the type of solvent, alkylation reactions lead to different products. The change from protic to dipolar aprotic solvents, which do not form hydrogen bonds with oxygen atoms, induces attack on the oxygen centre with formation of O-alkylation products.

Table 6. Synthesis of different products by a standard method and in the presence of KF. [135]

Product of synthesis	Reactants	t, °C	Yield, %	Time, h
$CH_3CH(O_2CPh)CO_2H$	$PhCO_2H/KF/CH_3CH(Cl)CO_2H$	130	90	0.5
ditto	$PhCO_2K/CH_3CH(Cl)CO_2H$	130	20	6
$PhO(CH_2)_4OPh$	$PhOH/KF/Br(CH_2)_4Br$	120	93	0.5
ditto	$PhOH/NaOH/Cl(CH_2)_4Cl$	150	49	1
$CH_4\langle O \rangle CH_2$	$Ph(OH_2)/KF/CH_2Br_2$	120	85	1
ditto	$Ph(OH)_2/CH_2Cl_2/NaOH(H_2O)$	110	23	15–18
$PhN(Me)CH_2N(Me)Ph$	$PhN(Me)H/KF/Cl(CH_2)_2Cl$	110	92	6
ditto	$PhN(Me)H/Na_2CO_3/Br(CH_2)_2Br$	105	83	24
$MeCH(SPh)CH_2Me$	$PhSH/KF/MeCH(I)CH_2Me$	130	92	8
ditto	$PhSNa/MeCH(Br)CH_2Me$	120	45	24

During the last two years, a series of studies by Clark and coworkers [133–136] has been published under the title "Hydrogen Bonds and Organic Synthesis". The authors showed that the formation of hydrogen bonds with KF added to the solvent greatly increases the reactivity of compounds containing the OH, NH, and SH groups in alkylation reactions. All the reactions are much faster than in the absence of KF and the yields are 80–95% (instead of 23–45%). Several examples from Clark and Miller [135] are presented in Table 6. The authors showed convincingly that KF does not participate in the reaction as a catalyst. The reactions do not rule out an initial proton transfer mechanism, because neither HF nor HF_2^- appear in solution, but hydrogen bonds are formed. Clark and Emsley [137–139] investigated the strength of the hydrogen

bonds formed by infrared spectroscopy and NMR and showed that the OH...F^- bonds are very strong (with an energy of 20–30 kcal $mole^{-1}$). It is of interest that even the much weaker NH...F^- and SH...F^- bonds also accelerate the reactions extremely effectively (by a factor of 3–4) and increase the yield by a factor of 1.5–3. In the presence of protic solvents the rate of reaction naturally decreases and the yields fall. Consequently strong hydrogen bonds can "assist" in organic synthesis, permitting the elimination of competing reactions and leading to higher yields and higher rates.

It may be hoped that the development of recently initiated studies on nucleophilic substitution reactions in the gas phase[140] will permit a quantitative assessment of the role of specific solvation, particularly the role of the formation of hydrogen bonds with the solvent.

---o0o---

Thus all the facts described above show that the influence of hydrogen bonds is very great not only in proton transfer reactions but also in reactions of other types. Investigators working in the field of physical organic chemistry have sought various ways of estimating the role of hydrogen bonds, but we believe that the accumulated data on the properties and energetics of hydrogen bonds have so far been inadequately used. At the same time, within the framework of studies on hydrogen bonds, there are trends which are very important for the solution of problems associated with the reactivity of organic compounds. This concerns studies on molecular hydrogen-bonded complex–ion pair transitions, the determination of spectroscopic and energetic characteristics of ionic hydrogen bonds (between conjugate acids BH^+ and bases and between acids AH and anions), the study of the structure of the complexes $[BHB]^+$ and $[AHA]^-$, the study of hydrogen bonds in the gas phase, and the study of the influence of polar solvents on the properties of hydrogen-bonded complexes. The combination of these data is undoubtedly necessary for a deeper understanding of problems of the reactivity and structure of organic compounds.

Mention should be made of a number of studies which were published during the preparation of the manuscript for the press: on problems associated with the spectroscopic and thermodynamic characteristics of molecular hydrogen-bonded complexes and the structure of ion pairs in various solvents[141–145]; on problems concerning the elucidation of the role of hydrogen bonds by comparing the acidities and basicities in the gas phase and in solutions in different solvents[146–149]; on the problem of the influence of strong hydrogen bonds on nucleophilic substitution reactions[150–152].

Reactions of Copper and Silver Organoacetylides

A.M.Sladkov and I.R.Gol'ding

The methods of synthesis of Group IB metal organoacetylides in weakly alkaline and neutral electron-donating media are examined and a systematic account is given of extensive experimental data concerning the reactions of copper and silver organoacetylides. Their chemical properties are compared with those of other classes of organic and organoelemental derivatives of the same metals. Much attention is devoted to the mechanisms of the reactions of copper and silver acetylides and their practical use in organic synthesis.
The bibliography includes 270 references.

I. INTRODUCTION

Since the publication of the first review[1] devoted to the chemistry of copper (COA) and silver (SOA) organoacetylides, this field of organometallic chemistry has greatly expanded and has been investigated in much greater depth. Copper and silver organoacetylides have been used successfully for the introduction of ethynyl groups into a wide variety of organic compounds. The heterocyclisation reaction via COA has developed greatly and heterocyclic compounds of new types have been synthesised. The ethynylation of organoelemental compounds by copper and silver organoacetylides is being used to an increasing extent. A new field of the chemistry of COA and SOA has arisen—the synthesis on their basis of ethynyl polynuclear clusters and complexes containing copper or silver together with transition metals. The synthetic scope of COA has greatly expanded with the latter used as homo- and hetero-cuprates—complexes with salts and organic derivatives of lithium, sodium, and magnesium. The COA and ethynyl cuprates have come to be used particularly frequently in the syntheses of natural products, their analogues and fragments, and physiologically active substances.

During the last ten years approximately 200 papers containing data on the structures and chemical properties of COA and SOA have been published, some of these studies having been reviewed[2-7], but the majority of the reviews are purely factual without due attention being devoted to COA and SOA from the standpoint of the characteristics of their structure and the mechanisms of their reactions.

The aim of the present review is a systematic examination and survey of extensive experimental data on COA and SOA and a discussion of the mechanisms of their reactions.

II. REACTIONS INVOLVING THE FORMATION OF GROUP IB METAL ORGANOACETYLIDES

The traditional methods for the synthesis of copper[8], silver[9], and gold[10] organoacetylides in strongly alkaline media have now been supplemented by a number of milder methods involving the use of new metallating agents, organoelemental derivatives of the acetylene series, and aprotic electron-donating solvents to which weak bases are added. These methods proved to be particularly suitable for sterically hindered or hydrolytically unstable acetylenes and acetylides as well as diacetylene compounds.

The transmetallation reaction can also be of preparative importance; copper(I) and silver(I) t-butoxides[11-13], copper(I) phenylmercaptide[14], copper(I) [15] and gold(I) [16] ketenides, as well as dry silver(I) acetate[17] have been used as metallating agents:

$$RC\equiv CH + m_i\text{-t-BuOM} \rightarrow RC\equiv CM \quad ,$$

$$M=Cu,\ R=Ph,\ SiMe_3;\ M=Ag,\ R=Ph \quad ,$$

$$PhC\equiv CH + Ph\,SCu\cdot(PPh_3)_3 \rightarrow PhC\equiv CCu\cdot PPh_3 \quad ,$$

$$PhC\equiv CH + \begin{matrix} M \\ M \end{matrix}\!\!>\!C=C=O + PhNH_2 \xrightarrow{L} PhC\equiv CM + PhNHCOMe \quad ,$$

where M = Cu and L = acetone or M = Au and L = pyridine.

The silver derivative of diazomethane also exhibits a metallating activity[18]:

$$PhC\equiv CH + \begin{matrix} Ag \\ Ag \end{matrix}\!\!>\!C=N=N \xrightarrow{\text{pyridine}} PhC\equiv CAg \quad .$$

The phosphine complexes of gold(I) organoacetylides are formed when the phosphine complexes of methylgold are acted upon by acetylenes[19,20]:

$$[AuMe(PPhR_2)] + R'C\equiv CH \xrightarrow{L} [(AuC\equiv CR')(PPhR_2)] + CH_4$$

$$R=Ph,\ R'=Ph,\ L=\text{benzene};\ R=Me,\ R'=CF_3,\ L=\text{ether}.$$

The principle of the synthesis of organocopper(I) and organosilver(I) compounds of the alkyl, vinyl, and aryl series, by treating the corresponding organoelemental derivatives with copper(I) and silver(I) salts[6], has been successfully transferred to acetylenes. Thus COA are formed almost quantitatively when tetra(arylethynyl)-borammonium is decomposed by copper(I) chloride[21,22]:

$$NH_4B(C\equiv CAr)_4 + CuCl \xrightarrow{\text{alcohol } NH_4OH} ArC\equiv CCu \quad ;$$

$$Ar=Ph;\ 2,4\text{-}Me_2C_6H_3 \quad .$$

The sterically hindered copper 2,4,6-tri-(t-butyl)-phenylacetylide was obtained in a mixture of hexane, ether,

and benzene via the mechanism[23]

$$2,4,6\text{-(t-Bu)}_3C_6H_2C\equiv CH \xrightarrow[2.\ CuI]{1.\ BuLi} 2,4,6\text{-(t-Bu)}_3C_6H_2C\equiv CCu \ .$$

This procedure is widely used nowadays for the synthesis of ethynyl organocuprates.

The synthesis of a new type of ethynyl derivatives of hexanuclear copper(I) clusters (I) is a novel application of this method[24-26]:

$$Ar_4Cu_6Cl_2 + 2LiC\equiv CR \xrightarrow[70-90\%]{\text{ether/benzene}} \underset{(I)}{Ar_4Cu_6(C\equiv CR)_2} \ ;$$

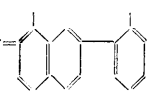
Ar=2-$Me_2NC_6H_4$; R=Ph; 4-MeC_6H_4, 2,4-$Me_2C_6H_3$, 2, 4, 6-$Me_3C_6H_2$, or $SiMe_3$.

The clusters (I) are also the products of a more complex reaction involving a transmetallation stage[25]:

$$6ArCu + 2RC\equiv CCu \xrightarrow[60\%]{\text{benzene}} (I) \ .$$

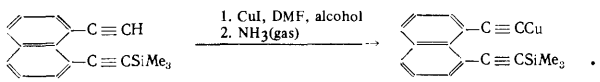
SOA can be obtained by treating Iotsich reagents with silver halides[27]:

$$BuC\equiv CMgBr + AgBr \xrightarrow[60\%]{\text{ether}} BuC\equiv CAg \ .$$



Certain representatives of organoelemental copper acetylides [compounds (II)] have been synthesised by the decomposition of ethynyl complexes of copper(I) halides in dimethyl sulphoxide (DMSO) using weak alkaline agents[28], together with dicopper(I) derivatives of diacetylene [compounds (III)][29,30], which cannot be obtained by other methods:

$$RC\equiv CH \xrightarrow[2.\ NH_4OH\ (dil.)]{1.\ CuCl,\ DMSO} \underset{(II)}{RC\equiv CCu} \ :$$

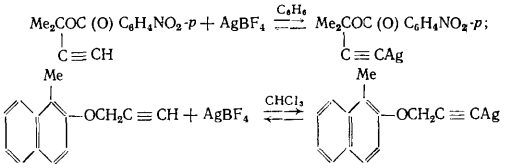


R=Bu_3P or Ph_2As

$$HC\equiv CArC\equiv CH \xrightarrow[2.\ NaHCO_3]{1.\ CuI,\ DMSO} \underset{(III)}{CuC\equiv CArC\equiv CCu} \ :$$

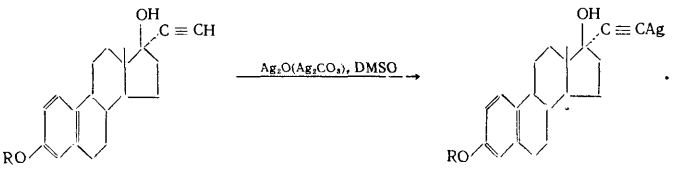
(a) Ar=2,2'-$C_6H_4ZC_6H_4$ (where Z=CH_2CH_2, *trans*-CH=CH, or C≡C), ;

(b) Ar=  .



Mitchell and Sondheimer[31] obtained copper(I) arylacetylides by passing dry NH_3 for a short time through a suspension of arylacetylene and CuI in an ethanol–dimethylformamide (DMF) mixture; under these conditions, the trimethylsilyl protecting group attached to the second ethynyl group was preserved:

It has been shown[32] that copper arylacetylides are formed on heating terminal arylacetylenes and CuI in pyridine in the presence of K_2CO_3. Silver perchloroarylacetylides have been obtained by treating the corresponding acetylenes [$C_6Cl_5C\equiv CH$ and 4,4'-$(HC\equiv CC_6Cl_4)_2$] with $AgNO_3$ in a water–tetrahydrofuran (THF) mixture[33]. The oxidative disproportionation of acetylenes under the influence of copper(II) leads to COA:[11]



$$4PhC\equiv CH + 2Cu(OBu\text{-}t)_2 \rightarrow 2PhC\equiv CCu + (PhC\equiv C)_2 + 4\text{-t-BuOH}.$$

It has been established[34,35] that equilibrium in the system

is displaced significantly towards SOA when Ag_2CO_3 is introduced.

SOA unstable under the conditions of the synthesis are formed when 17α-ethynyl-17β-hydroxysteroids are acted upon by Ag_2O or Ag_2CO_3 in DMSO:[36]

SOA derived from disubstituted acetylenes (IV) have been obtained by the reaction of the latter with $AgNO_3$ in an aqueous or alcoholic medium[37-39]:

$$\underset{(IV)}{R_3M(C\equiv C)_nMR_3} + 2AgNO_3 \rightarrow Ag(C\equiv C)_nAg + 2R_3MNO_3 \ ;$$

n=1; M=Sn or Pb; R=Et or Ph; M=Si, R=Me or OMe; n=2 or 3; M=Pb; R=Et, C_6H_{13} or Ph .

The complex AgC≡CAg.AgCl was isolated in the decomposition of stereochemically pure *cis*- and *trans*-β-chlorovinylboronic acid with an aqueous solution of $AgNO_3$.[40]

It has been shown[41] that the complex PhC≡CH.CuCl is converted into copper phenylacetylide on treatment with solvents containing traces of water.

III. REACTIONS OF COPPER AND SILVER ORGANOACETYLIDES WITH HALOGENO-DERIVATIVES

1. Aryl and Heteroaryl Halides

A general reaction of all types of organic and heteroorganic copper(I) compounds is their condensation with aryl and heteroaryl halides in an inert atmosphere:

$$RCu + HalAr \rightarrow R\text{—}Ar + CuHal \ .$$

The compounds RCu of the first group, in which R is a powerful nucleophile [RCu = AlkCu.PR'_3, (π-C_5H_5) Cu.PR'_3, Ar_fCu, or ArC(O)OCu] [3] react in a non-ionising aprotic medium with a moderate electron-donating capacity (ether, THF, diglyme; Table 1). COA belong to the second group of the compounds RCu [where R = Alk,[43] Ar,[3] $SAlk_f$,[44,45] RS,[46] $(Me_3Si)_2N$, $(Me_3Si)_2NN(SiMe_3)$,[47] halogen[48], or CN [49]], in which the nucleophilicity of the residue R (and the amount of ionic character of the R–Cu bond) is reduced owing to coordination and possibly dative interactions of R with the copper atom. In this case the reaction medium consists of powerful electron-donating solvents (for example, DMSO, DMF, quinoline, or pyridine; see Table). 2-Methylpropenylcopper,[50] which occupies an intermediate position, approaches compounds of the first group as regards reactivity, while AlkOCu and ArOCu [51] approach compounds of the second group in this respect. The only example of the above reaction for silver(I) compounds is the condensation of perfluorophenylsilver with iodobenzene in DMF.[52]

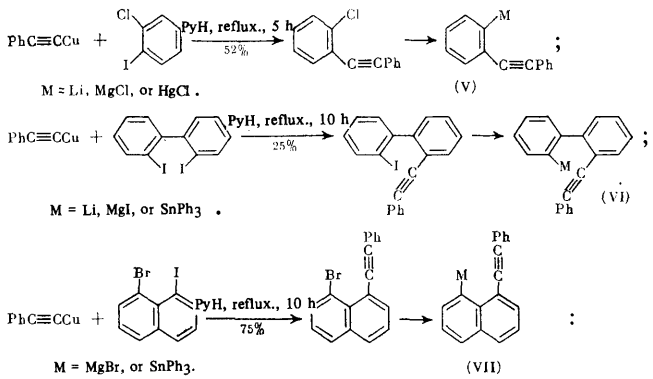
The ethynylation of aromatic and heteroaromatic compounds with the aid of COA, first described in 1963, [53,54] is at present one of the most frequently used preparative methods in organic synthesis.

A procedure has been recently proposed for the introduction of the ethynyl group into an aromatic ring via COA, in accordance with a mechanism which does not involve their preliminary isolation[32]:

$$RC\equiv CH + IAr \xrightarrow{PyH,\ CuI,\ K_2CO_3} ArC\equiv CR \quad .$$

Table 1. The electron-donating properties and dielectric constants (ϵ) of certain aprotic solvents[42].

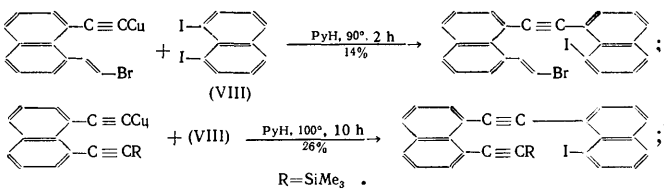
Solvent (D)	*Donor number* ($-\Delta H_{D,SbCl_5}$), kcal mole^{-1}	ϵ
Ether	19.2	4.3
Tetrahydrofuran	20.0	7.6
Acetone	17.0	20.7
Acetonitrile	14.1	38.0
Dimethylformamide	26.6	36.1
Dimethylacetamide	27.8	38.9
Pyridine	33.1	12.3
Hexamethylphosphoramide	38.8	30.0
Dimethyl sulphoxide	29.8	45.0
Benzonitrile	11.9	25.2
Nitrobenzene	4.4	34.8
Acetyl chloride	0.7	15.8
Benzoyl chloride	2.3	23.0



Apart from some simplification of the process, this method makes it possible to employ the complex, COA-forming terminal acetylenes which are unstable and difficult to isolate. However, one should note that successful condensation as a rule requires a large excess of CuI and of the corresponding acetylene.

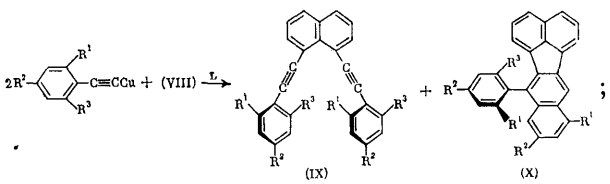
In another modification of this method, used only in the synthesis of terminal arylacetylenes, a double molar excess of the acetylene compound relative to a ArI is necessary[55]:

$$(EtO)_2CHC\equiv CH \xrightarrow[2.\ CuI]{1.\ BuLi;\ hexane} \xrightarrow{PyH,\ ArI,\ 48\ h} ArC\equiv CCH(OEt)_2 \rightarrow ArC\equiv CH.$$



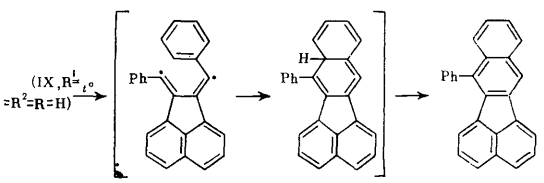
The reaction does not occur for Ar = 4-$O_2NC_6A_4$ and is facilitated in the presence of electron-donating substituents in the Ar group.

A wide variety of ethynyl derivatives of benzene, biphenyl, and naphthalene, which are the starting materials in the study of specific intramolecular electronic interactions of C≡C bonds, have been obtained by treating aryl iodides with COA. Kandil and Dessy[56] synthesised compounds (V)–(VII) with different geometrical dispositions of M and the C≡C bond:

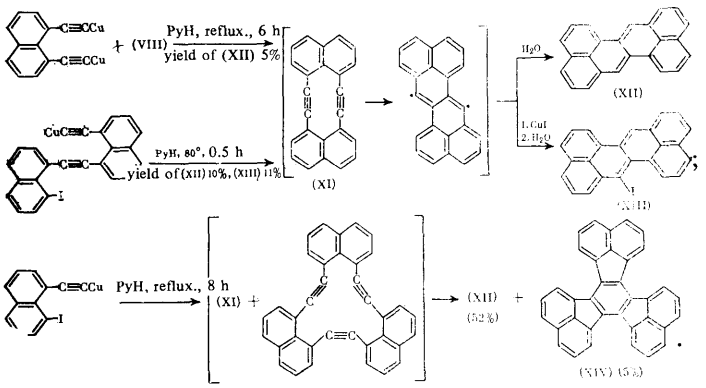


According to spectroscopic data, the metal M is not coordinated to the C≡C bond in these systems.

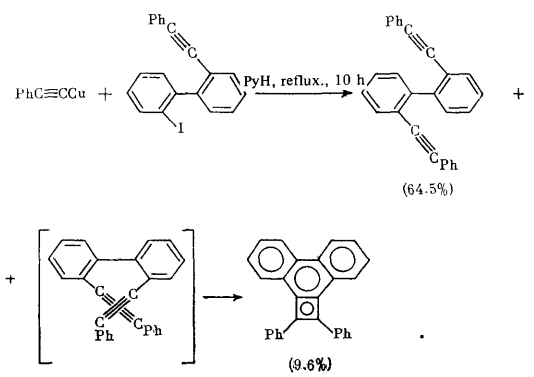
Interesting possibilities arise when 1,5- and particularly 1,8-di-iodonaphthalenes are used[57]. The products of the monosubstitution of 1,8-di-iodonaphthalene (VIII) have been obtained[31]:



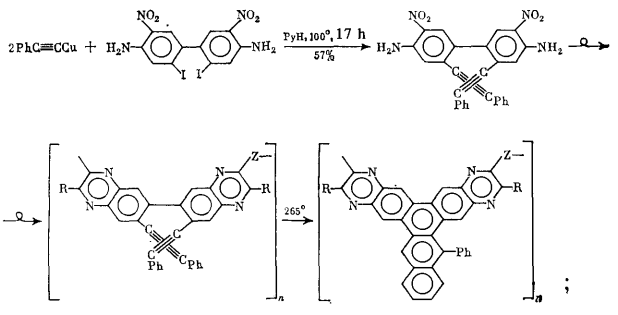
The interaction of COA with 1,8-di-iodonaphthalene has been studied in detail[58,59] and it has been shown that an increase of reaction time does not affect the overall yield of compounds (IX) and (X) (~80%), but alters sharply the (IX) : (X) ratio in favour of the latter compound if Ar = Ph and does not affect the composition of the products if Ar = mesityl [yield of (X) up to 10%] or *p*-anisyl [compound (IX) is not formed]:



L = boiling pyridine, R^1, R^3 = H or Me; R^2 = H, Me, or OMe.

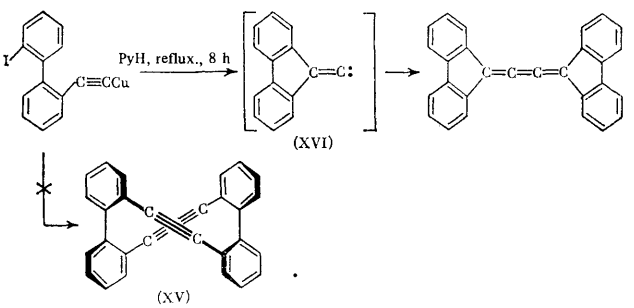


Although the system of C≡C bonds in 1,8-diethynyl derivatives of naphthalene has the non-linear *trans*-conformation[60], it is extremely reactive in intramolecular cyclisation processes, which apparently proceed via a radical mechanism. Thus it has been suggested[57] that 1,8-di(phenylethynyl)naphthalene undergoes thermal cyclisation to 7-phenylbenzo[*k*]fluoranthene via the mechanism

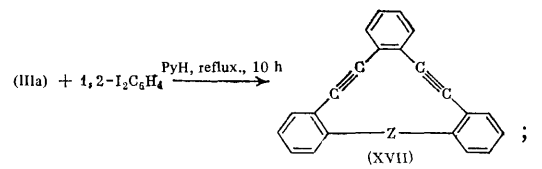


The formation of zethrene (XII), 7-iodozethrene (XIII), and decacyclene (XIV) instead to the expected dinaphthyl-1,6-bisdehydro[10]annulene (XI) [31,61] can also be readily accounted for by a radical mechanism:

It has been suggested that, when copper phenylacetylide reacts with 2-iodo-2′-phenylethynylbiphenyl, a system of crossing C≡C bonds can arise owing to rotational isomerism, in which intramolecular cyclisation takes place readily[56]

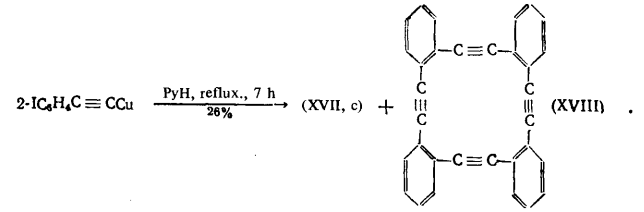


However, later it was shown[62] that the product of the cyclisation of 2,2′-di(phenylethynyl)biphenyl is 9-phenyldibenzo[*a*,*c*]anthracene, which is apparently formed by a radical mechanism analogous to that described by Bossambrock and Strechter[57]. The inclusion of such units in the polymer chain made it possible to increase significantly the thermal stability and to improve the workability of thermostable polymers. Thus the interaction of copper phenylacetylide with polyketoesters and polyesterketosulphones[63] based on 2,2′-di-iodobiphenyl-4,4′-di-carboxylic acid yielded thermally reactive binders for glass plastics [fibre glass?]. A method has been developed for the synthesis of heat-resistant polyphenylquinoxalines using 5,5′-diamino-2,2′-di(phenylethynyl)-benzidine as the tetra-amino-component[64]:

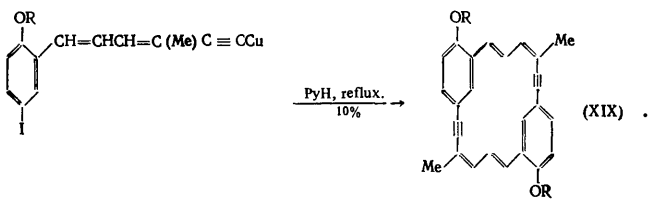


(a) R = Ph, Z = 4,4′-$C_6H_4OC_6H_4$; (b) R = 4-C_6H_4OPh, Z = 1,3-C_6H_4

At high dilutions (in pyridine) copper 2-iodo-2′-biphenylylacetylide does not form the expected homocondensation product (XV), but is converted, according to the authors[65], into di[fluorenylidene(9)]ethylene via a carbene (XVI) stage [intramolecular elimination of copper(I)]. When anaerobic conditions are not sufficiently carefully maintained, part of the initial acetylide undergoes oxidative dimerisation:

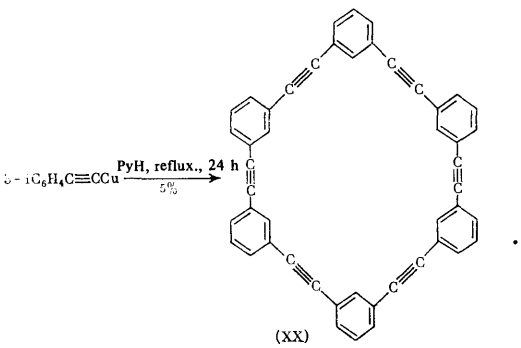


Staab and Rader[29] synthesised stable benzo[12]annulenes (XVII) by the interaction of copper(I) derivatives of diacetylenes (XIIa) with *o*-di-iodobenzene:

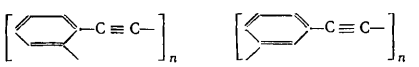


(a) Z = CH_2CH_2 (22%); (b) Z = *trans*-HC=CH (21%); (c) Z = C≡C (8%)

Previously compound (XVIIc) and the tetramer (XVIII) had been obtained by the homocondensation of copper *o*-iodophenylacetylide in pyridine[66]; structure (XVIIc) has been revised[67]:



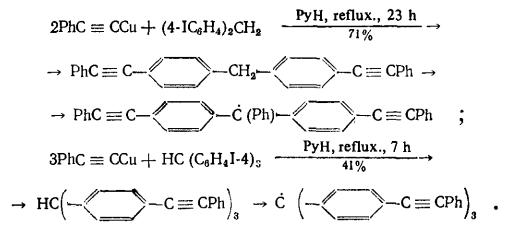
The same principle was used in the synthesis of the dehydro[18]annulenes (XIX, R = H, Me, or CH_2OMe) condensed with benzene[68]:



(XIX) .

We may note that, according to ultraviolet spectroscopic[67] and X-ray diffraction[69] data, there is no extended π-conjugation system in compounds (XVII, b and c). The same conclusion was also reached in relation to a 30-unit macrocyclic compound (XX) produced by the condensation of copper *m*-iodophenylacetylide[70]:

(XX)

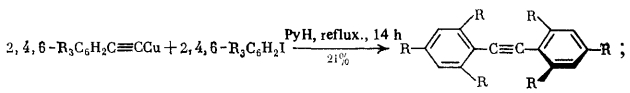


However, the main pathway in the homocondensation of copper *o*- and *m*-iodophenylacetylides in pyridine or DMF involves the formation of the open-chain polymeric systems (XXI) and (XXII) [poly(phenylene carbides)], the elementary unit of which retains the structure of the initial acetylene[71]:

(XXI) (XXII)

The polymers (XXI) and (XXII) (M_n = 2000–10000) are distinguished by a high content of carbon (approximately 95%), are readily soluble (up to 50 wt.%) in chloroform and benzene, soften at 170°C, and are readily worked into pressed articles, fibres, and films, which, after brief heat treatment at 500°C, withstand prolonged heating without loss of weight or shape (in an inert atmosphere and even in air) at 900–1000°C. Poly(phenylene carbides) can be actively combined with many transition metal compounds via π-complex formation. Heat treatment of such compositions yields carbon-containing materials with homogeneously distributed metal particles (approximately 100 Å), which ensure protection from radiation. It has been reported[71] that the interaction of copper acetylide with di-iodobenzene isomers in pyridine or DMF also leads to poly(phenylene carbides)[71].

Diarylacetylenes have proved to be convenient for the investigation of the ability of the C≡C bond to transmit electrons. Kotlyarevskii and coworkers[72,73] used copper phenylacetylide in the synthesis of triphenylmethyl free radicals containing phenylethynyl groups:



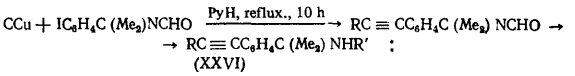
The transfer of electron density via a C≡C bond in the radical-anions (XXIII) [74] and (XXIV) [23] has also been investigated by EPR:

(XXIII)

a) R = cyclopropyl (33%); b) R = Me (<1%); c) R = iso-Pr(4%).

R = t-Bu. (XXIV)

In contrast to tolanes, which do not contain bulky substituents and in which there is unhindered internal rotation of the benzene rings about the C≡C bond which leads to their preferential mutual coplanar disposition[75], di-(2,4,6-tri-t-butylphenyl)-acetylene (XXIV) constitutes a combination of two orthogonal π-systems[23].



Monosubstituted tolanes (XXVa) have been synthesised for the investigation of polar and stereochemical effects in the introduction of organoaluminium groups into C≡C bonds[76]; compounds (XXVb) served as models of the products of the reaction of the phenylethynyl radical with benzene derivatives[77]:

(XXV)

(a) R = 4-Me_2N, 4-SMe, or 4-SO_2Me;
(b) R = *o*-, *m*-, or *p*-Me, Et, $CHMe_2$, CMe_3, F, Cl, or Br.

Ethynyl-substituted *N*-benzylamines, which can be readily obtained from the corresponding *N*-formyl derivatives (XXVI), proved to be effective agents for the prevention of cardiac arrhythmia[78]:

(XXVI)

a) 1,4-derivatives: R=Ph, 4'-YC_6H_4 (Y=F, Me, or OMe), 3-Py, or Bu;
b) 1,3-derivatives: R=Ph, or 3-Py .

Examples of the use of COA in the synthesis of diarylacetylenes, including derivatives with functional groups, are presented in Table 2.

Functional groups can be introduced into tolanes, which are readily available via a reaction involving COA, also in the course of subsequent treatment (see, for example, Table 3).

Table 2. The applications of COA in the synthesis of diarylacetylenes by the reaction $ArC{\equiv}CCu + IAr' \rightleftharpoons ArC{\equiv}CAr'$.

The condensation of copper phenylacetylide with aromatic di-iodo-derivatives, previously described[8,53] in relation to di-iodobenzenes, yielded the diacetylene derivatives (XXVII), which are intermediates in the synthesis of heat-resistant and thermostable polyarylquinoxalines[64,83,88]:

$$3PhC{\equiv}CCu + IArI \xrightarrow[65-95\%]{PyH\ (DMF),\ reflux.} PhC{\equiv}CArC{\equiv}CPh\ ;$$

(XXVII)

Ar=  ;

Ethynylation in the *trans*-stilbene[29,89] and tolane[90] series has been carried out similarly:

$$2RC{\equiv}CCu + (2\text{-}IC_6H_4)_2Z \xrightarrow[60-70\%]{PyH,\ reflux.,\ 10\ h} (2\text{-}RC{\equiv}CC_6H_4)_2Z\ ;^{\dagger}$$

(a) R = *o*-tolyl, Z = *trans*-CH = CH;
(b) R = THP* $-OCH_2$, Z = *trans*-(Me)C = CH;
(c) R = Ph, Z = C≡C.

The initial configuration is largely retained in the reactions of copper vinylacetylides with aryl iodides[91-93]:

$$\underset{cis}{ROCH{=}CHC{\equiv}CCu} + IAr \xrightarrow{PyH,\ reflux.} \underset{cis}{ROCH{=}CHC{\equiv}CAr}$$

a) R=Me, Ar=$2,4\text{-}Y^1Y^2C_6H_3$ (60—90%), (Y^1=H, Y^2=H, Me, Cl, or NO_2; Y^1=NO_2, Y^2=H, or OMe); b) R=Et, or Bu, Ar=Ph (15%)

$$\underset{trans}{THPOCH_2CH{=}CHC{\equiv}CCu} + I\text{—}\langle S \rangle \xrightarrow[58\%]{PyH,\ reflux.,\ 6\ h} \underset{trans}{THPOCH_2CH{=}CHC{\equiv}C\text{—}}\langle S \rangle .$$

The formation of a mixture of *cis*- and *trans*-products by condensation in these systems[94,95]

$$\underset{trans}{MeCH{=}CH\ (C{\equiv}C)_nCu} + IAr \xrightarrow{PyH,reflux} \underset{cis,\ trans}{MeCH{=}CH\ (C{\equiv}C)_nAr}$$

(XXVIII)

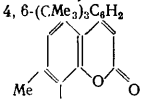
a) n=1, Ar=  —$C{\equiv}CCH_2OTHP$;

(b) n=2, Ar=Ph, or 1-[^{3}H] Ph

is apparently associated merely with the instability of the *trans*-forms of compounds (XXVIII) under the reaction conditions.

The ethynylation of aromatic compounds with the aid of COA of the propargyl series is of great preparative value. Derivatives of aryl (heteroaryl) propargyl alcohols, aldehydes, and acids, which are intermediates in the synthesis of terminal aryl(heteroaryl)acetylenes, have been obtained by this method[23,96-102] (Table 4).

Arylpropargyl alcohols have been used for the chemical modification of penicillins[93] and in the synthesis of natural products of the coumarin series[102].



† Here and henceforth THP denotes 2-tetrahydropyranyl.

In contrast to the usual aryl iodides, the condensation of polyhalogenophenyl iodides (C_6Cl_5I, C_6Br_5I,[103] C_6F_5I,[103-104] and 4-XC_6F_4I, where X = H, F, Me, OMe, CF_3,[99] or 1,2-$I_2C_6F_4$[106,205]) with COA is complicated by transmetallation and reductive deiodination processes leading to a complex mixture of products, for example[106]:

$$2PhC\equiv CCu + 1,2\text{-}I_2C_6F_4 \xrightarrow{PyH,\ 120^\circ,\ 10\ h} 2\text{=}PhC\equiv CC_6HF_4\ (40\%) + 1,2\text{-}(PhC\equiv C)_2C_6F_4\ (25\%) + (PhC\equiv C)_2\ (20\%) + (2\text{-}C_6HF_4)_2\ (2\%)$$

Table 4.

$$RC\equiv CCu + IAr \xrightarrow{PyH} ArC\equiv CR$$

R	Ar	Refs.	R	Ar	Refs.

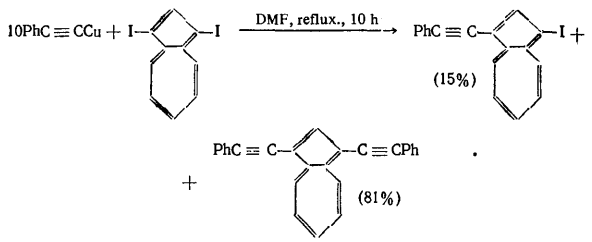
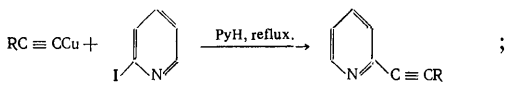
CH_2OTHP	3-$CF_3C_6H_4$	100	$C(Me)_2OTHP$		102



The yield of the corresponding biphenyls and 1,4-disubstituted butadiynes increases with increasing ionising capacity of the solvents (pyridine < DMF, hexamethylphosphoramide (HMP), DMSO),[99] with increase of temperature[99], and with increase of the O_2 content in the reaction mixture[103]. These factors apparently promote the exchange $RC\equiv CCu + IAr \rightleftharpoons RC\equiv CI + ArCu$, which leads to the appearance of new agents capable of condensation with the initial $RC\equiv CCu$ and ArI. In addition biphenyls and butadiynes can be formed as a result of the thermal or oxidative dimerisation of $RC\equiv CCu$ and CuAr.

Exchange processes play a major role also in the following reaction[99]:

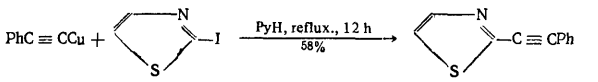


$$THPOCH_2C\equiv CCu + 4\text{-}IC_6HF_4 \xrightarrow[2.\ H^+]{1.\ PyH,\ reflux.} 4\text{-}HC_6F_4C\equiv CCH_2OH + 1,4\text{-}(OHCH_2C\equiv C)_2C_6F_4 + (4,4'\text{-}C_6HF_4)_2 + (HOCH_2C\equiv C)_2$$

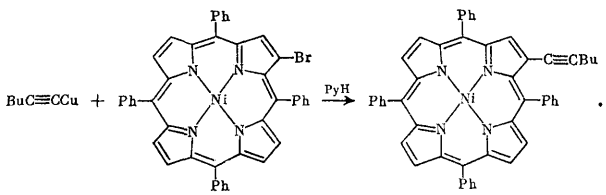
COA are of great interest as agents for the ethynylation of heteroaromatic and non-benzenoid aromatic compounds. The iodo-derivatives of both electron-enriched (azulene, thiophen, and furan) and electron-deficient (compared with benzene) systems (pyridine) interact with COA much more vigorously than aryl iodides. The causes of this will be discussed when the mechanisms of the reactions of COA are considered.

Even in the presence of a large excess of copper phenylacetylide, 1,3-di-iodoazulene forms an appreciable amount of the monosubstituted product together with the disubstituted product[107]:

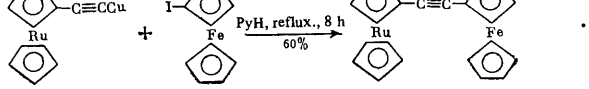
The condensation of COA with 2- and 3-iodopyridines is 5–10 times faster than the condensation with iodobenzene[8,108] and leads to high yields of pyridylacetylenes for the optimum reaction time (2 h):[108]



R=Ph (86%), 4-$MeOC_6H_4$ (68%), 4-$O_2NC_6H_4$ (52%), 4-PhC_6H_4 (54%), or Bu (95%)



2-Iodo-derivatives of furan[96,109,110] and thiazole[110] as well as derivatives of 4-iodopyrazole[139] readily enter into a similar reaction:



(a) R^1=H, R^2=CH_2OH, CH_2Ph, or Ph; (b) R^1=Me, R^2=CH_2OH; (c) R^1=C(O)OEt, R^2=Me; (d) R^1=CHO, or C(O)Me, R^2=Ph, or $C\equiv CPh$;

The condensation of COA with iodo-derivatives of the thiophen series has been frequently used by Bohlmann and by Atkinson, Curtis, and Taylor in the syntheses of the analogues of natural acetylenic products and their fragments (Table 5). This method provides unique possibilities for the introduction of asymmetric ethynyl groups in the 2,5-positions of the thiophen ring and the synthesis of disubstituted acetylenes containing 2-bithienyl groups. Examples of the interaction of COA with iodothiophens (the bromo-derivatives do not react) are presented below. The bromo-derivative of the Ni-tetraphenylporphyrin system is fairly reactive in relation to COA:[118]

Iodoferrocenes condense smoothly with COA, forming substituted ferrocenylacetylenes[111,119,120]:

As in the case of the mono iodo-derivative, copper ferrocenylacetylide reacts much more vigorously with 1,1-diiodoferrocene than does copper phenylacetylide[120]. The homocondensation of copper 1-ferrocenyl-1-iodoacetylide

yielded 2,2-ferrocenophane-1,3-diyne[121]:

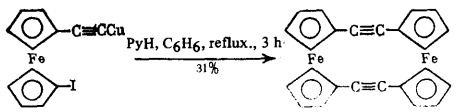


Table 5. The applications of COA in the synthesis of thienylacetylenes.

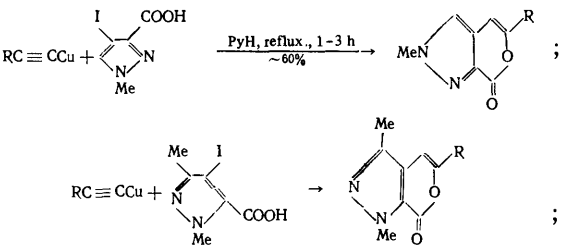
COA containing heteroaromatic substituents have been little investigated. Apart from the reactions discussed above, the condensation of copper 1-ferrocenylacetylide with 2-iodothiophen[111], 1-iodonaphthalene, and 2-iodophenol[119], of copper 2,5-dideutero-1-ferrocenylacetylide with iodobenzene[122], of copper 2-thienylacetylide with 2-iodothiophen[110], 5-formyl-2-iodothiophen, and 5-acetyl-2-iodothiophen[101], and of copper 2-pyridylacetylide with 2-iodoaniline[8] have been described.

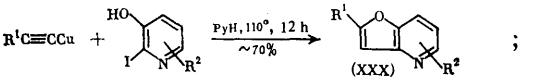
Castro and coworkers established in early investigations[8,123] that the interaction of COA in DMF or pyridine with aryl halides containing nucleophiles Y = NH_2, SH, OH, or COOH in the *o*-position leads to heterocyclic products of the intramolecular nucleophilic addition of Y to the newly formed disubstituted C≡C bond π-linked to CuHal. In subsequent studies the range of *o*-substituted aryl halides and COA used was greatly extended, which made it possible to synthesise many heterocyclic systems which had been difficult to obtain hitherto or were completely new.

COA readily condense with *o*-iodobenzyl alcohol and *o*-iodophenylacetic acid, while the alkyl homologues of the latter form only homocyclisation products under these conditions[124]:



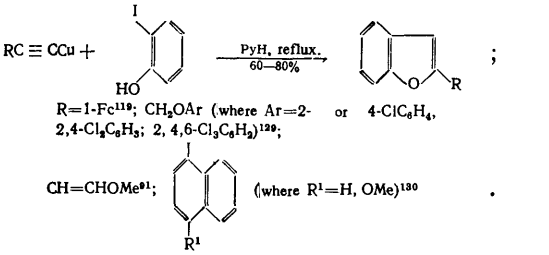
The first examples of a new class of heterocyclic compounds—substituted 1*H*-thieno[3,4-*b*]-2-alkyl(aryl)-1-pyranones (XXIX)—have been described[125]:

(XXIX)



R=Pr, Bu, C_6H_{13} or Ph.

Similarly 4-iodo-*N*-methylpyrazolecarboxylic acids react with COA to form exclusively δ-lactones derived from 6-methyl-1-oxopyrano[3,4-*c*]pyrazole and 5,7-dimethyl-1-oxopyrano[3,4-d]pyrazole[126]:



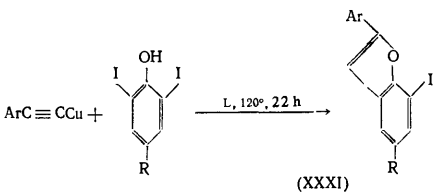
R=Ph, Pr, CH_3, or OMe.

The syntheses of condensed furan systems from *o*-iodoxyarene derivatives and COA have acquired considerable practical importance. Furo[3,2-*b*]pyridines (XXX a and b) have been obtained by this procedure for the first time[125, 127, 129]:

(a) R^1 = Pr, Bu, C_6H_{13}, CH_2CH_2OH, or Ph; R^2 = H;
(b) R^1 = Pr or Bu; R^2 = 2- or 4-Me.

Complex substituents have also been introduced into the 2-position of benzofuran with the aid of COA:

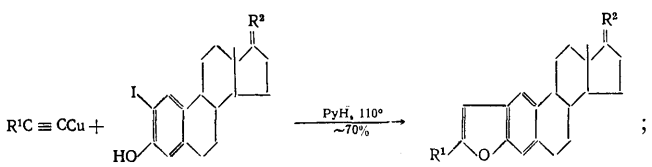
R=1-Fc[119]; CH_2OAr (where Ar=2- or 4-ClC_6H_4, 2,4-$Cl_2C_6H_3$; 2, 4,6-$Cl_3C_6H_2$)[129];



(where R^1=H, OMe)[130]

A wide variety of derivatives of this series—natural products and their analogues—have been synthesised similarly.

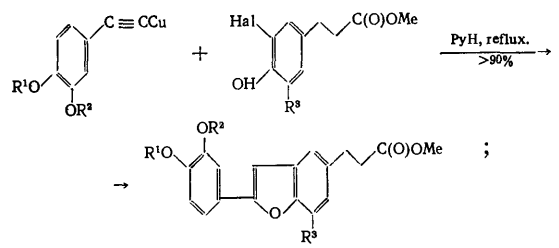
Table 6.



L	Ar	R	Yield of (XXXI), %
PyH	Ph	CHO	26
		$CH_2C(O)OMe$	44
		$CH_2CH(NHAc)C(O)OMe$	32
DMF	$4\text{-}MeOC_6H_4$	$CH_2C(O)OMe$	16
		$CH_2CH(NHAc)C(O)Me$	18
DMF	$4\text{-}MeO\text{-}3\text{-}iso\text{-}PrC_6H_3$	$CH_2C(O)OMe$	63
		$CH_2CH(NHAc)C(O)OMe$	40

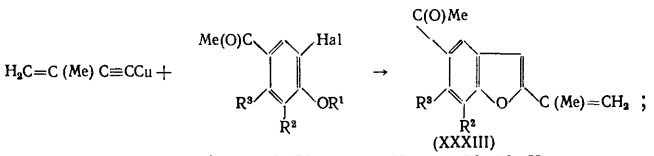
4-Substituted 2,6-di-iodophenols react with copper phenylacetylide in pyridine and with COA whose benzene ring contains electron-donating substituents in DMF to form iodobenzofurans (XXXI), which are potential analogues of thyroxine (Table 6)[131]:

(XXXI)



The use of COA opens a new pathway to the synthesis of heterocyclic steroids[132]:

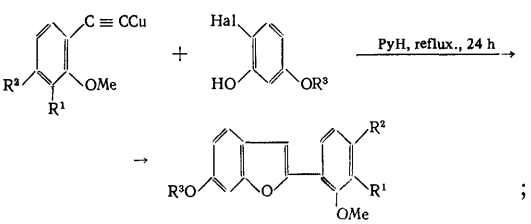
(a) R^1=Pr, Bu, C_6H_{13}, or CH_2OH, Ph; R^2=O;
(b) R^1=Pr; R^2=



The natural "lignanes" (XXXII) are the only products of the reaction when the halogen is iodine; with bromine as the halogen, appreciable amounts of diarylbutadiynes were isolated[133]:

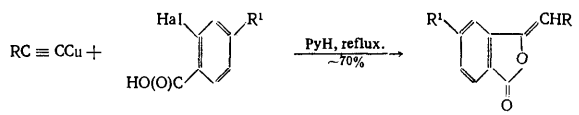
(XXXII)

(a) R^1 R^2=$-CH_2-$; R^3=H or OMe;
(b) R^1=R^2=Me; R^3=H or OMe.



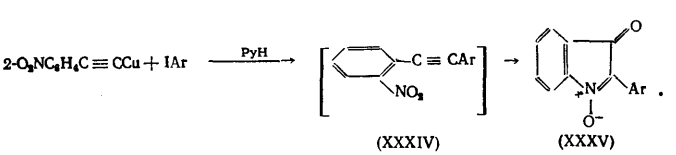
Natural products of the 5-acetyl-2-isopropenylbenzofuran series ("norlignanes") have been obtained by the condensation of copper isopropenylacetylide with 3-halogeno-4-hydroxyacetophenones in quinoline (XXXIIIa)[134] and pyridine (XXXIII, b–g).[135] Compound (XXXIIIa) is not formed if the initial phenol reacts in the free rather than acylated form[134]:

(XXXIII)



(a) Hal=Br, R^1=Ac, R^2=R^3=OAc; (b) Hal=Br, R^1=R^3=H, R^2=OH; (c) Hal=I, R^1=R^2=R^3=H;
(d) Hal=I, R^1=H, R^2=OMe, R^3=OH.

The synthesis of two natural products of the 2-arylbenzofuran series was described recently[136]:

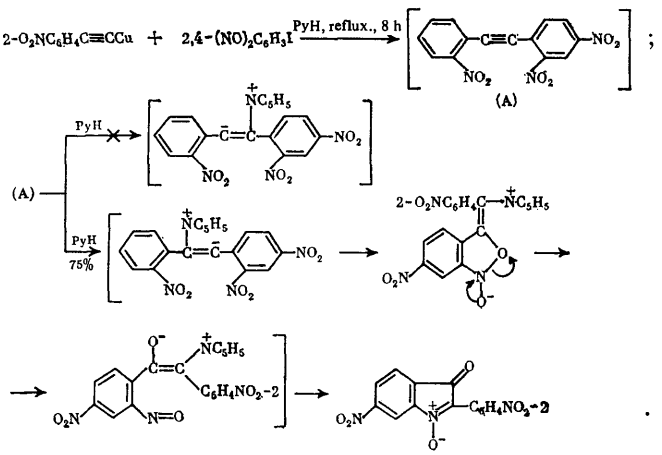


(a) R^1=OAc, R^2=OMe, R^3=CH_2Ph, Hal=I (78%);
(b) R^1=H, R^2=OCH_2Ph, R^3=Me, Hal=Br (34%)

The cyclisation reactions examined above take place unambiguously at the β-carbon atom (relative to copper), whereupon a hydrogen atom migrates from the functional group in the ring to the α-carbon atom of the ethynyl fragment of the COA. The mode of cyclisation of *o*-halogenobenzoic acids is reversed[8]: with R = n-Pr, R′ = H, and Hal = I, a mixture of 3-n-propylisocoumarin and 3-n-butylidenephthalide is formed, i.e. both cyclisation pathways operate[8]:

R=Ph; R^1=H, Cl; Hal=Cl

The key factor in the cyclocondensation of COA involving NO_2 and $C(O)NH_2$ groups is the migration of the O atom to the α-carbon atom. Thus heating of copper *o*-nitrophenylacetylide with aryl iodides in pyridine leads to 2-aryl-substituted isatogens[84] (Table 7):



(XXXIV) (XXXV)

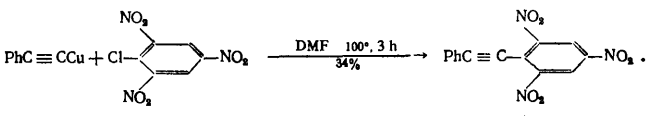


Table 7.

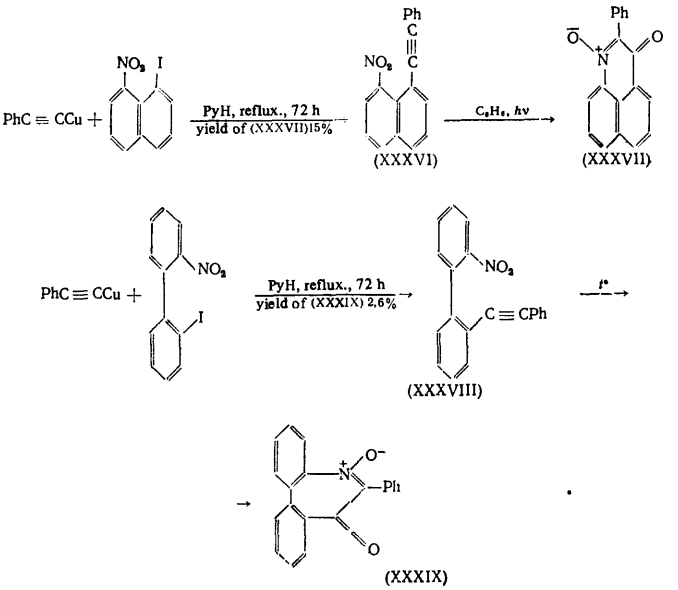
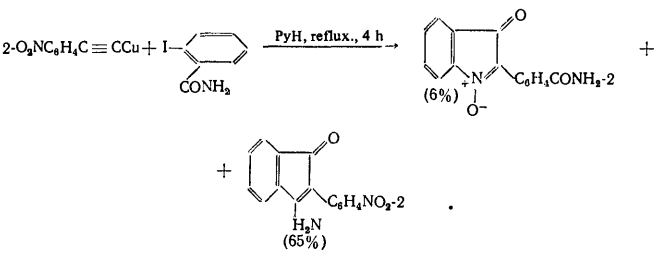
Ar	Yield of (XXXV), %	Ar	Yield of (XXXV), %
4-$MeOC_6H_4$	37	2-O_2N-4-$MeOC_6H_3$	66
4-$O_2NC_6H_4$	71	2-$C_6H_4C_6H_5$	73
2-O_2N-3-$MeOC_6H_3$	70	3-Py	22
		2-Thienyl	69

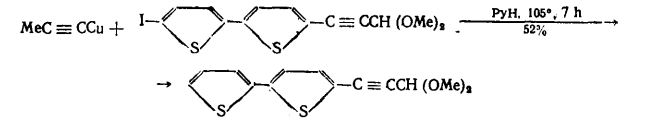


In conformity with the proposed mechanism, the cyclisation proceeds in the direction of the aromatic ring with the most pronounced electron-accepting properties:



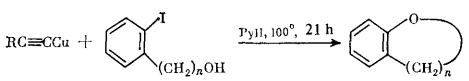
Steric factors (for example, *o*-substituents in the aryl group have a strong influence on the cyclisation. Thus the yield of (XXXIV) with Ar = 2-MeC_6H_4, 2-$MeOC_6H_4$, 2-$NO_2C_6H_4$, 2-alkOCOC_6H_4, or 1-naphthyl amounted to 70–90%; after prolonged heating in pyridine, the yields remained unchanged. Isatogen is apparently not formed in DMF:[8]

In the reactions of copper phenylacetylide with 1-iodo-8-nitronaphthalene and 2-iodo-2′-nitrobiphenyl only the products of the intramolecular cyclisation of the tolanes (XXXVI) and (XXXVIII) were isolated in a pure form—3-oxo-2-phenylbenzo[*d*,*e*]quinoline *N*-oxide (XXXVII) and 7-oxo-6-phenyldibenzo[*b*,*d*]azepine *N*-oxide (XXXIX):[137]

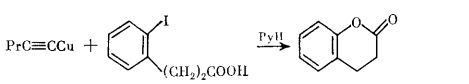


When copper phenylacetylide reacts with *o*-iodocarbamoylbenzene in pyridine, the product is 3-amino-2-phenylindenone; this reaction pathway predominates also in the case of copper *o*-nitrophenylacetylide[84]:

Electron-donating and bulky substituents Ar hinder the cyclisation of the tolanes (XL):[84]



The reaction of COA with aryl halides also suffers from certain limitations. Thus COA having a discrete structure with bulky substituents at the C≡C bond, possessing a strong +*I* effect, do not condense with aryl halides (for example, copper t-butylacetylide does not react with C_6F_5I in pyridine[138]). On the other hand, electron-accepting substituents at the C≡C bond promote the reaction [for example, in the case of ($EtO_2CHC{\equiv}CCu$) [55]]. In the reaction



copper methylacetylide apparently behaves as a *C*-metallating agent. It can be assumed that COA exhibit an *O*-metallating activity in the intramolecular cyclisation

reactions[124]

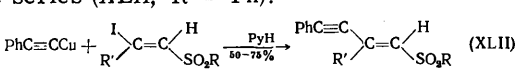
$n = 2$, R = Pr (90%), Ph (100%); $n = 3$, R = Pr (54%), or Ph (85%) ;

We may note that HMP, which is a powerful electron-donating and ionising solvent (Table 1), has not found extensive applications in the synthesis of disubstituted arylacetylenes from COA and aryl halides[140]. It has been shown[141] that the Hal^- and CN^- ions inhibit the main reaction in this instance.

2. 1-Halogeno-olefins and 1-Halogenoacetylenes

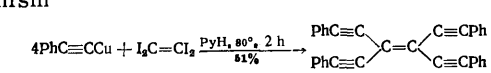
The condensation of COA with 1-halogeno-olefins in pyridine or DMF has many features in common with the condensation of the series of compounds RCu, where R = Hal, CN, aryl, alkyl, R'C(O)O (see Refs. 142–144 and the literature quoted therein), Alk_f,[143,145] or SR'.[145] This type of reaction has not been described for silver(I) derivatives.

The interaction of copper(I) derivatives with 1-halogeno-olefins takes place stereospecifically with retention of the initial configuration of both the olefin[142–146] and the COA.[91] As for aryl halides, the reactivity of the halogen then decreased in the sequence I > Br ≫ Cl (F does not react), which is the reverse of that for the direct nucleophilic substitution at an sp^2-hybridised carbon atom[1].



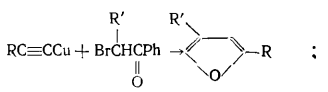
The use of *trans*-chloro(iodo)vinylacetylenes (XLI), which are readily formed when the corresponding vinyl iodides interact with COA in pyridine[145,146], can greatly simplify the synthesis of monosubstituted diacetylenes:

(a) X=Cl, R=Ph, or $PhOCH_2$; (b) X=I, R=Bu, Ph, 4-ClC_6H_4, or 4-IC_6H_4.



2-*C*-Ethynyl-1-*C*-phenyl-*o*-carbaborane(12) was obtained for the first time from 4-iodo-1-phenyl-*trans*-buten-1-yne.[147]

Electron-accepting substituents at the carbon atoms of the C≡C bond lower the reactivity of 1-iodo-olefins in reactions with COA. Thus the duration of the reaction involving *trans*-1-iodoalk-2-enyl sulphones (XLII) is greater by a factor of 5–10 compared with ICH=CHX (X = Cl or I),[144,148] and sulphones of the propene series (XLII, R' = Me) are more reactive than those of the styrene series (XLII, R' = Ph):[144]

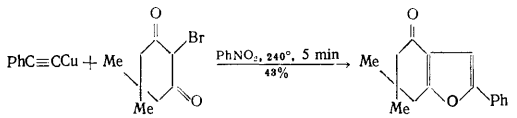


(a) R=4-MeC_6H_4, R'=H, Me, n-Bu, n-C_6H_{13}, or Ph; (b) R=Ph, R'=H, Me, or Ph; (c) R=Me; R'=Me, or Ph; (d) R=Et, R'=Me, or Ph .

Tetra(phenylethynyl)ethylene has been obtained via the mechanism[145]

It has been shown[150] that α-bromoketones react with COA under the same conditions (brief heating to a high temperature without a solvent or in nitrobenzene) as S_N1 halides(benzyl and allyl bromides). Since it has been suggested that the reaction proceeds via a stage involving an α-bromoenol coordinated to copper(I), it is useful to quote examples of such reactions in the present section of the review:

(XLIV)



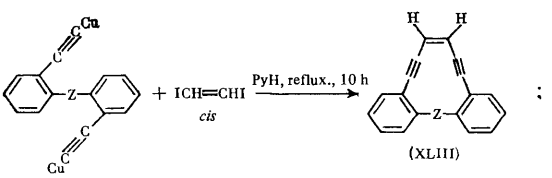


Table 8.

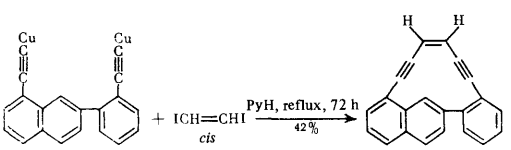
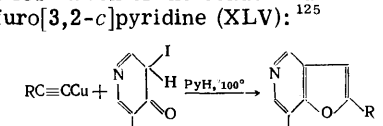


Reaction conditions	R	R'	Yield of (XLIV), %
Without solvent, 140°, 5 min	n-Pr	H	29
Nitrobenzene, 240°, 5 min	Ph	H	54
Nitrobenzene, 240°, 5 min	Ph	C (O) Ph	24

Staab and coworkers used *cis*-di-iodoethylene successfully in the synthesis of benzo[12]annulenes (XLIII)[29,30] and benzonaphtho[12]annulenes[149]:

(XLIII)



(a) Z = *trans*-HC=CH (17.5%); (b) Z = C≡C (10%); (c) Z = CH_2CH_2 (23%)

In a protic medium copper phenylacetylide promotes the reduction of ω-bromoacetophenone[150]:

The interaction of 3,5-di-iodo-4-pyridone with COA leads to the formation of the condensed heteroaromatic system of furo[3,2-*c*]pyridine (XLV):[125]

(XLV)

R=Ph, α-Py, n-Pr, n-C_6H_{13}, or CH_2CH_2OH

C-Derivatives of copper(I) (the compounds RCu) can be divided into definite groups in relation to 1-halogeno-acetylenes, as in the case of aryl halides. Thus, for

R = Ar, Ar_f,[151-153] and *o*-, *m*-, or *p*-*C*-carboranyl(12),[154] the ethynylation reaction takes place in ether and THF, for R = Alk_f it takes place in DMSO,[155] and for R = CN, it takes place in pyridine[156] and DMF.[157] COA belong to the last group[158].

The interaction of the cuprates $RCu.MgBr_2$ (R = Ar[159] or vinyl[160]) with 1-iodo(bromo)acetylenes is facilitated in the presence of DMF or $(Me_2N)_2C_2H_4$.

Curtis and Taylor[161] used bromopropargyl alcohol to obtain monosubstituted di- and tri-acetylene derivatives:

$$RC{\equiv}CCu + BrC{\equiv}CCH_2OH \xrightarrow{PyH,\ 35-50^\circ} R(C{\equiv}C)_2CH_2OH \rightarrow RC{\equiv}CC{\equiv}CH\ ;$$

R = Me, Ph, Me(OH)CH, $THPOCH_2$, $(EtO)_2CH$, MeC≡C, or 2-(2'-bithienyl).

A new direct ethynylating agent has been described—monobromoacetylene in DMF:[162]

$$Ar(C{\equiv}C)_nCu + BrC{\equiv}CH \xrightarrow{DMF,\ 0^\circ,\ 24\ h} Ar(C{\equiv}C)_nC{\equiv}CH\ :$$

a) n=1, Ar=Ph, 1- or 2-naphthyl

b) n=2, Ar = 1-naphthyl .

3. The Mechanisms of Reactions of COA with Aryl Halides, 1-Halogeno-olefins, and 1-Halogenoacetylenes

In the first studies Castro and coworkers[89,54] already considered the condensation of COA with aryl halides in pyridine within the framework of a general reaction involving nucleophilic substitution in an aromatic ring under the influence of copper(I) compounds, which had been investigated in detail previously[49] in relation to the CuX + ArAl → ArX + CuHal (X = Br, Cl, or CN) exchange. The findings obtained in this study were subsequently confirmed in an investigation of the exchange reactions of CuX with C_6F_5Hal (X = Cl, CN, or OAc),[163] FcHal (X = Cl, Br, or CN),[164,165] and IAr (X = C≡CPh,[124] Ph,[166] 2-furyl, or 2-thienyl[167]) in DMF, pyridine, and quinoline. It was established in all cases that the reactivity of Hal in ArHal decreases in the sequence I > Br ≫ Cl (F does not react), which is the reverse of that for direct nucleophilic substitutions; substituents in Ar have a consistent but weak influence on the rate of reaction, which is of second order overall and of first order with respect to each reactant.

Kinetic and thermodynamic parameters (Table 9) determined for the reaction

$$PhC{\equiv}CCu + IC_6H_4Y \xrightarrow{PyH,\ 100^\circ} PhC{\equiv}CC_6H_4Y + CuI$$

led to certain qualitative conclusions concerning the mechanism[124]: (a) copper phenylacetylide reacts in the dissociated, "monomeric" form (the rate of reaction is described by a second order equation):

$$-\frac{d[IC_6H_4Y]}{dt} = \frac{d[CuI]}{dt} = k_2[PhC{\equiv}CCu][IC_6H_4Y];$$

(b) the ring substitution under the influence of COA is indirectly nucleophilic (although the reactivity of IC_6H_4Y does decrease on passing from Y = NO_2 to Y = OMe or NH_2, the dependence of k_2 on the nature of Y is quantitatively weak); (c) the transition state is distinguished by a high degree of order (high negative activation entropy). According to the authors[124], these data confirm the four-centre concerted mechanism of the reaction of aryl halides with COA, proposed previously[8] (by analogy with the mechanism of Bacon and Hill[49]), which can be represented schematically in the following way in the presence of nucleophilic *o*-substituents in the ring (Y = QR'):[124]

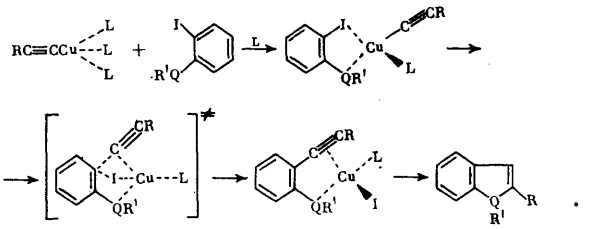


Table 9. Kinetic and thermodynamic parameters (calculated for 25°C) of the reaction

$$PhC{\equiv}CCu + IC_6H_4Y \xrightarrow{PyH,\ 100^\circ} PhC{\equiv}CC_6H_4Y + CuI$$

Y	k_2, litre mole^{-1} s^{-1}			Y	$\Delta F^{\neq}$, kcal	$\Delta H^{\neq}$, kcal	$\Delta S^{\neq}$, e.u.
	o-	*m*-	*p*-				
COOH	$7.0\cdot10^{-2}$	$2.9\cdot10^{-5}$	$4.6\cdot10^{-5}$	H	26	7,2	−63
OH	$8.6\cdot10^{-3}$	$1.3\cdot10^{-5}$	$2.0\cdot10^{-5}$	*o*-NO_2	26	16	−29
NO_2	$2.0\cdot10^{-3}$	$9.1\cdot10^{-5}$	$1.4\cdot10^{-4}$	*m*-NO_2	27	15	−36
OMe	$1.7\cdot10^{-5}$	$1.4\cdot10^{-5}$	$0.85\cdot10^{-5}$	*p*-NO_2	26	13	−41
NH_2	$3.4\cdot10^{-5}$	$1.0\cdot10^{-5}$	$1.4\cdot10^{-5}$				
H	$0.8\cdot10^{-5}$						

A significant factor in this mechanism is the initial I... Cu coordination, the copper atom retaining the tetrahedral configuration.

A similar mechanism has also been postulated by Burdon et al.[105], where the reactive form of COA is regarded as an ion pair, which can be involved in the equilibrium

$$[CuL_AX] \rightleftarrows [CuL_B]^+X^-$$

contact ion pair — separated ion pair

(A = 1 − 3; B = 1 − 4; X=SBu, SPh, C≡CPh) ,

depending on the nature of the solvent ligand L.

The reaction is regarded as a competitive process involving the substitution of ligands at the central copper(I) atom:

It is assumed that only the contact ion pair, in which X is bound strongly to Cu(I) and cannot react independently of the latter, is reactive in the condensation. In the first stage ligands (solvent molecules) are displaced by the substrate ArHal (neutral process); this is followed by the nucleophilic substitution of Hal by X (via a four-centre mechanism), Hal being coordinated to copper(I), which leads to an indirect exchange of Hal for X in the second stage.

The weak dependence of the rate of condensation of COA with Y−ArHal on the nature of Y can be accounted for, within the framework of the four-centre mechanism (by analogy with the mechanism of Sato et al.[168]), by the opposite influence of Y on the rate of attack Hal → Cu and X → C (in Ar), the relative contributions of which determine the overall rate of reaction.

The formation of biaryls, disubstituted butadiynes, and reductive deiodination products from poly(halogenophenyl iodides)[90,106] can be accounted for by the electrophilic

exchange occurring in the intermediate four-centre complex in competition with the nucleophilic exchange and leading to the appearance of the additional condensation agents $ArHalCu$ and $IC{\equiv}CR$.

In order to describe the mechanism of this reaction, one may resort to the radical scheme considered by Atkinson et al.[96] [oxidative addition of a halogen to copper(I) and transfer of the ethynyl ligand from copper(II) to the aryl radical]. In the general case the interaction

$$ArC{\equiv}CCu + Ar_1Hal \rightarrow Ar_1^{\cdot} + Hal{-}Cu{-}C{\equiv}CAr \rightarrow ArC{\equiv}CAr_1 + CuHal$$

should occur in a "cage", although a free-radical reaction pathway can be postulated also for poly(halogenophenyl iodides).

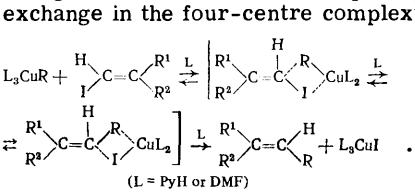
The observation[96] that the reaction is accelerated when the reaction mixture is irradiated by infrared light, unconfirmed by experimental data, has been quoted in support of a radical mechanism. The concept of a radical mechanism has been developed by van Koten and Noltes, who proposed a mechanism with one-electron transfer in an oligomeric copper(I) complex for processes of this kind[169]:

$$(CuX)_n\,(DMF)_m + ArHaI \rightarrow ArHal\,(CuX)_n\,(DMF)_m \rightarrow$$
$$\rightarrow Ar^{\cdot}\,(Cu^{II}XHal)\,(CuX)_{n-1}\,(DMF)_m \rightarrow ArX + CuHal\,(CuX)_{n-1}\,(DMF)_m \quad .$$

In a study of stable arylcopper compounds the same workers isolated and characterised hexanuclear copper clusters having the formula $Ar_4Cu_6X_2$.[25,26,170] The thermolysis of these clusters in DMF leads to biaryls[170] for X = Br or I and to tolanes[26] $ArC{\equiv}CAr_1$ for $X = C{\equiv}CAr$. In principle, such clusters can be formed and can play a definite role in those instances of the condensation of COA with aryl halides where the structure of the initial compounds (for example, for $Ar = C_6X_5$, where X = Cl, Br,[103] or F [99,104,106]) favours the exchange $RC{\equiv}CCu + HalAr = RC{\equiv}CHal + CuAr$. The subsequent course of the reaction (in addition to the condensation steps with liberation of CuHal) is then described by the scheme[26]

$$2RC{\equiv}CCu + 4CuAr \rightarrow Ar_4Cu_6(C{\equiv}CR)_2 \xrightarrow{t^\circ} ArC{\equiv}CR \quad ;$$
$$6ArCu + 2HalAr \rightarrow 2ArAr + Ar_4Cu_6Hal_2 \rightarrow ArAr + 2ArH + 2CuHal + 4Cu^\circ \quad ;$$
$$ArCu \xrightarrow{t^\circ} ArAr + ArH + Cu^\circ \quad .$$

On the other hand, in the general case the "cluster" mechanism is inconsistent with the kinetic data of Castro et al.[124], involves the formation of appreciable amounts of zero-valent copper together with CuHal, and cannot be regarded as a secondary mechanism accompaning the main mechanism of the condensation of COA with aryl halides.



The condensation of COA with ArHal via an intermediate copper(III) compound, in accordance with the mechanism whose prototype is that of the exchange interaction of CuCl with aryl and vinyl iodides (R = Ar or vinyl)

$$CuCl + RI \rightarrow RCu(I)Cl \xrightarrow[-CuI]{+CuCl} RCu + 2CuCl_2 \rightarrow 2CuCl + RCuCl_2 \rightarrow RCl + CuCl \quad ,$$

put forward by Cohen et al.[171], is unlikely if only because the "soft" ligand ArHal cannot stabilise the "hard" Lewis acid copper(III).[172] However, this possibility cannot be ruled out for poly(halogenophenyl iodides).

It has been mentioned, incidentally[173], that copper(II) has a catalytic effect (in the form of a complex of $CuCl_2$ with NH_4Cl) in the reaction of COA with heteroaryl iodides, but the mechanism of the action of copper(II) is obscure.

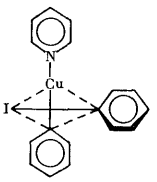
The condensation of COA with 1-halogeno-olefins is regarded, by an analogy with aryl halides, as a competitive process involving the displacement of the ligand-solvent from the copper(I) coordination sphere by the substrate (1-halogeno-olefin) and the subsequent indirect nucleophilic exchange in the four-centre complex[142,145]:

(L = PyH or DMF)

Since such condensation takes place unambiguously with retention of the initial configuration of the olefin and does not lead to dimerisation and reductive deiodination side products, the free-radical reaction mechanism is ruled out, as well as the intermediate formation of the copper(II) compound[142]. The addition of COA to the double bond of the olefin with subsequent elimination of CuHal should also lead to a more complex mixture of reaction products[145].

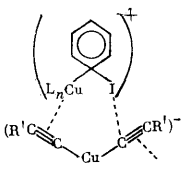
No information is available in the literature about the mechanism of the condensation of COA with 1-halogeno-acetylenes.

Thus, despite the unambiguous nature of the approach to the mechanism of the direct transfer of the ethynyl residue from copper(I) to the organic substrate (aryl, vinyl), the initial coordination of the halogen atom of the substrate to the copper(I) atom of the "depolymerised" (under the influence of the nitrogen-containing ligand-solvent) form of COA is generally assumed in all the schemes.



We believe that a common disadvantage of all the schemes discussed above is that they do not reflect the specific features of the COA both as coordination polymers[174] and as copper(I) compounds.

It is known that the polymeric (3c–2e) structure of the σ-aryl derivatives of copper(I) [and apparently silver(I)] is disturbed (as a result of complex formation) by nitrogen-containing electron-donating ligands (pyridine, DMF)[166,167,170]. Subsequent interaction of such complexes, for example, with ArI, can proceed in accordance with a four-centre mechanism via a tetrahedral transition state of type (XLVI).[166] On the other hand, the COA are inert in relation to the action of DMF, pyridine[124], and 2,2- and 4,4-bipyridyls[175] and form discrete (in most instances polynuclear) complexes with strong n-donor ligands—tertiary phosphines[174–176], arsines, stibines[174], cyclic amines[177], *o*-phenanthroline[175], and NH_3,[178] in which the π-interaction of copper(I) atoms with the C≡C bond persists. Evidently the "depolymerisation" of the COA in the L–RHal system (L is an electron-donating nitrogen-containing ligand-solvent, in most cases pyridine or DMF, R = Ar, vinyl, or ethynyl, and the halogen is usually iodine) should occur under the joint influence of both components and should lead immediately to the reaction complex. In view of the wide occurrence and stability of the $Cu^IX_2^-$ bridging anions in the form of discrete species[179] as well as part of the complexes $Y^+CuX_2^-$, where $Y = R_4N$ or Ph_4As for X = Cl, $Y = R_4N$ or Ph_4P for X = Br,[180] and $Y = Cu(PMe_3)_2$ for $X = C{\equiv}CPh$,[181] and the ylids



where E = P or As,[182] we suggest that this complex should have the zwitter-ionic structure (XLVII, R = Ar, Hal = I) incorporating the principal features of the structure of the

complex $[PMe_3.CuC{=}CPh]_4$ [181]

(XLVI)

(XLVII)

Since the reactivity of RI in condensation reactions with COA decreases in the series of substituents R ethynyl > vinyl ≫ aryl (alkyl substituents do not react)[1], in which the electronegativity of R and its capacity for the formation of bridge bonds (see below[215]) also diminish, we assume that there is no simple Cu–I coordination in the complex (XLVII). The cationoid component of (XLVII) is a system with a C_{Ar} bridge atom involved in a 3c–2e bond with copper and iodine atoms. The ease of formation of compound (XLVII) and the stability of its cationoid component should evidently increase when n-donor heteroatoms in the aromatic ring are in geometrical proximity to the copper atom (by analogy with stable Cu- and Ag-aryl compounds[170]). Indeed aryl iodides with the NH_2, OH, or COOH substituents in the *ortho*-position as well as 2-iododerivatives of furan, thiophen, and pyridine are much more reactive in reactions with COA than iodobenzene.

The ease of electron transfer from the anionoid component of (XLVII) to the cationoid component is determined by the electron-accepting properties of the ring; this results in the formation (on homolytic dissociation of the ≡C–Cu bond) of the ethynyl radical R′C≡C′. In the cationoid component the 3c–2e bond (Cu–C_{Ar}–I) is converted into a 2c–2e bond (Cu–I) with formation of an aryl radical when the aryl is a weak acceptor, or into a Cu–C_{Ar} bond with formation of the I′ radical species when the aryl is a strong acceptor. Recombination of the radicals in the "cage" should lead to the final products.

Within the framework of the proposed mechanism, the influence of the substituents in Ar on the rate of reaction of ArI with COA is to a large extent cancelled out by their opposed influence on the ease of formation of a complex of type (XLVII) and subsequent one-electron transfer as well as the radical mechanism of the last reaction stage. In this interpretation the condensation of COA with RI (R = Ar, vinyl, or ethynyl) is related to the nucleophilic substitution in diaryliodonium salts catalysed by copper(I) salts, for which the following mechanism has been proposed[183]:

$$Ar_2I^+Cl^- + CuCl \rightleftharpoons Ar_2I^+ + CuCl_2^- \xrightarrow{e} \underset{\text{(ion pair)}}{Ar_2I^+CuCl_2^-} \longrightarrow$$
$$\longrightarrow ArI + ArCl + CuCl \quad .$$

The electron-donating ligand-solvent, which stabilises the cationoid component of the complex (XLVII), should not exhibit a high ionising capacity which would hinder significantly the interaction within the ion pair (XLVII); otherwise (HMP, $\epsilon = 30$, Table 1) the yield of the ethynylation products is sharply reduced[140,141].

Furthermore, the formation of a complex by the ligand-solvent with the copper atom in the cationoid component should influence the oxidation-reduction potential and the strength of the C–Hal bond.

Finally, copper t-butylacetylide[138] as well as silver and gold organoacetylides[174], in which the coordination of the metal atom to the C≡C bond is weak, apparently form under the conditions of reactions of the given type complexes with a nitrogen-containing ligand-solvent, inert with respect to RI (R = Ar, vinyl, or ethynyl), and not structures of type (XLVII); furthermore, one must assume that oxidation of the anionoid component of silver(I) and gold(I) complexes proceeds with greater difficulty than in the case of COA.

4. Compounds with an Element–Halogen Bond

Many inorganic and organoelemental compounds, containing readily polarisable E–Hal bonds, where E is as a rule a nucleophilic heteroatom, react vigorously with COA and SOA in solvents with moderate electron-donating capacities, forming MHal and σ-E-ethynyl derivatives. The simplest examples of reactions of this kind are provided by those of COA with Cl_2, Br_2, I_2, and IBr,[1] for example[147,184]:

$$HCB_{10}H_{10}CC{\equiv}CCu + I_2 \xrightarrow[68\%]{\text{heptane}} HCB_{10}H_{10}CC{\equiv}CI + CuI \quad ;$$
$$Cl_2C{=}CClC{\equiv}CCu + Br_2 \xrightarrow{CCl_4} Cl_2C{=}CClC{\equiv}CBr \quad .$$

Halogens react analogously with SOA:[33,185,186]

$$Me_2CHC{\equiv}CAg + I_2 \rightarrow Me_2CHC{\equiv}CI + AgI \quad :$$
$$C_6Cl_5C{\equiv}CAg + Cl_2 \xrightarrow[90\%]{CCl_4} C_6Cl_5CC{\equiv}CCl \quad :$$
$$4,4'\text{-}(AgC{\equiv}CC_6Cl_4)_2 + Cl_2 \xrightarrow[85\%]{CCl_4} 4,4'\text{-}(ClC{\equiv}CC_6Cl_4)_2 \quad .$$

A method has been developed recently for the synthesis of 1-bromo- and 1-iodoacetylenes via SOA without the preliminary isolation of the latter[187]:

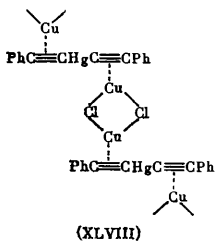
$$RC{\equiv}CSiAlk_3 \xrightarrow[2.\ Hal_2]{1.\ AgNO_3} RC{\equiv}CHal \quad ;$$
(a) Hal=I, R=C(Me)=CHCO(O)Me;
(b) Hal=Br, R=C(Me)=CHCO(O)Me,
CH=CHCO(O)Me, Ph(Et)C(OH), or $Ph_2C(OH)$.

In contrast to the synthesis via COA, the synthesis of 1-chloro- and 1-bromo-acetylenes via SOA is not complicated by the formation of oxidative dimerisation products.

Trisphenylethynyl derivatives of phosphorus, arsenic, and antimony have been obtained by the reaction of silver(I) phenylacetylide with ECl_3 (E = P, As, or Sb) in a benzene–THF mixture[188]:

$$3PhC{\equiv}CAg + ECl_3 \xrightarrow[50\rightarrow70\%]{} E(C{\equiv}CPh)_3 \quad .$$

Copper(I) phenylacetylide reacts only with PCl_3, forming (even in the presence of a large excess of PCl_3) tris-(phenylethynyl)phosphine[1].



The interaction of silver(I) arylacetylides with $HgHal_2$ leads to bisarylethynyl derivatives of mercury[188]:

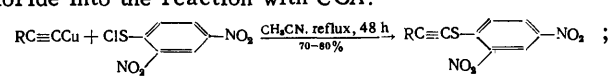
$$2RC{\equiv}CAg + HgHal_2 \xrightarrow[\sim 90\%]{THF} Hg(C{\equiv}CR)_2 + 2AgHal \quad :$$
Hal=Cl, Br, or I; R=Ph, C≡CPh .

An analogous reaction has also been described for C_6F_5Ag [52] and for ethoxy-(*p*-tolylimino)methylsilver, i.e. $[p\text{-}MeC_6H_4N{=}C(OEt)Ag]_3$, which is unusually stable in air[189].

In solvents with a moderate electron-donating capacity (THF, alcohol, ether, and acetone) COA react with $HgHal_2$ (Hal = Cl or Br), regardless of the ionising capacity of the solvents, to form complexes having the formal composition $(RC{\equiv}C)_2HgCu_2Cl_2$, to which the structure of

the coordination polymers (XLVIII) was attributed on the basis of Raman spectroscopic data and chemical properties[190]:

(XLVIII)



The polymeric complex (XLVIII) has also been obtained by the interaction of copper(I) phenylacetylide with *trans*-β-chlorovinylmercury in CH_3CN and THF and as a result of the oxidative disproportionation of bis(phenylethynyl)-mercury under the influence of copper(II) chloride in the same solvents[190]. On treatment with pyridine, the complex (XLVIII) is converted into bis(phenylethynyl)mercury, while treatment with aqueous ammonia yields copper phenylacetylide (apparently as a result of the selective interaction of the nitrogen-containing ligands with the metal atoms)[191].

Organoelemental halides are beginning to play an increasingly notable role in the chemistry of organic derivatives of copper(I) and silver(I). So far only a few examples of such reactions have been described, for example, the reaction of RM with Me_3SiCl (M = Cu, R = Me_3SiCH_2;[192] M = Ag, R = C_6F_5 [52]), the reaction of ArCu with R_2SnBr_2 [R = Me, Ar = YC_6H_4, where Y = 2-Me_2NCH_2, 2-Me_2N, 4-Me_2N, 2-MeO, 2,6-$(MeO)_2$, or 2,4,6-$(MeO)_3$; R = Ph, Ar = 2-Me_2NCH_2],[193] which take place in weakly polar solvents with a moderate electron-donating capacity. Similar reactions involving COA and SOA take place in more polar media.

In the search for systems with optical manifestations of conjugation via a phosphorus(III) atom, arylbis-(4-nitrophenylethynyl)phosphines were synthesised (with a low yield owing to side reactions)[194]:

$$4\text{-}O_2NC_6H_4C{\equiv}CCu + Cl_2PAr \xrightarrow{THF} (4\text{-}O_2NC_6H_4C{\equiv}C)_2PAr \ ;$$
$$Ar = 4\text{-}YC_6H_4, \text{ where } Y = H, Cl, OMe, \text{ or } NMe_2 \ .$$

Castro et al. introduced 2,4-dinitrophenylsulphenyl chloride into the reaction with COA:[124]

R = n-Pr or Ph.

Organotin compounds are readily ethynylated with the aid of silver alkylacetylides having functional groups[195]:

$$(EtO)_2CHC{\equiv}CAg + BrSnPh_3 \xrightarrow[80\%]{\text{acetone, } 80^\circ} Ph_3SnC{\equiv}CCH(OEt)_2 \ .$$

It has been noted that copper(I) arylacetylides are extremely inert in relation to organotin halides[193]:

$$4\text{-}MeC_6H_4C{\equiv}CCu + Br_2SnMe_2 \xrightarrow[88\%]{17 \text{ days}} 4\text{-}MeC_6H_4C{\equiv}CSn(Br)Me_2 \ .$$

When copper acetylide and 1-*C*-ethynyl-*o*-carbaborane were heated with MeHgBr in a heptane–THF mixture, (*o*-carbaboranyl-1-*C*-ethynyl)methylmercury was obtained[147].

The reactions of covalent transition metal halide complexes with organic derivatives RM, where M = Cu(I) or Ag(I) and R is a powerful inductive acceptor, are of great interest. Thus the halogen atom in the complexes $ClIr(CO)(PPh_3)_2$, $ClRh(CO)(PPh_3)_2$, $ClRh(C_8H_{12})(PPh_3)$, and $Fe(CO)_4I_2$ is substituted by the C_6F_5 group on treatment with C_6F_5Ag in ether[196]; *cis*-$(PPh_3)_2PtCl_2$ reacts with [*p*-$MeC_6H_4N{=}C(OEt)Ag]_3$ in $CHCl_3$, forming a monosubstituted product[189]. In the synthesis of σ-aryl- and σ-carbaboranyl-π-cyclopentadienyldicarbonyliron via the reaction

$$RCu + BrFe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{\text{ether, THF}} R{-}Fe(CO)_2(\pi\text{-}C_5H_5) \ ;$$
$$R = Ph, 3\text{- and } 4\text{-}FC_6H_4; \ o\text{- and } m\text{-}HCB_{10}H_{10}C{-}; \text{ or}$$
$$o\text{- and } m\text{-}{-}CB_{10}H_{10}C{-} \ ,$$

use was made of aryl and carbaboranyl derivatives of copper(I), apparently in the form of cuprates[197].

Table 10.

$$CuI \xrightarrow{HNEt_2} (HNEt_2)_nCuI \xrightarrow[HNEt_2]{HC{\equiv}CR} (HNEt_2)_nCuC{\equiv}CR + HI{\cdot}HNEt_2 \xrightarrow{MCl} MC{\equiv}CR + (HNEt_2)_nCuCl \ .$$

The catalytic effect of copper(I) salts in condensation reactions of nickel, palladium, and platinum halide complexes with acetylenes in Et_2NH is attributed to the possibility of the formation under these conditions of amine complexes of COA [198,199] (Table 10). The catalytic reaction proceeds with retention of the initial configuration of the metal atom, which made it possible, in particular, to simplify significantly the synthesis of the *cis*-isomers of platinum(II) complexes which are difficult to obtain:

Under the same conditions, high-molecular-weight polyconjugated polymers, which are stable in air and contain both homogeneous and alternating metal atoms in the chain, were obtained[200,201] via the reaction

$$trans\text{-}(HC{\equiv}CC{\equiv}C)_2M(PBu_3)_2 + trans\text{-}Cl_2M'(PBu_3)_2 \xrightarrow[55\text{–}95\%]{CuI/Et_2NH,\ 20^\circ,\ 20\text{–}50\ h} \rightarrow trans\text{-}[-(PBu_3)_2M(C{\equiv}C)_2(M'(PBu_3)_2(C{\equiv}C)_2-]_n \ ;$$
(a) M=M'=Pt (M_w 20 000); (b) M=M'=Pd; (c) M=Pt, M'=Pd;
(d) M=Pd, M'=Pt (M_w 26 000)

In the reaction involving the bisdiacetyleneplatinum(II) complex products resulting from the monosubstitution of the Cl atoms in *trans*-$(PBu_3)_2M'Cl_2$ (M' = Pt or Pd) were isolated[201].

The mechanism proposed[202] for the catalytic action of the Q = $PdCl_2(PPh_3)_2/CuI/NEt_2X$ system, where X = H or Et, which is highly effective in single-stage syntheses of aryl- and vinyl-acetylenes[202] as well as α-ethynyl ketones[203],

$$RHal + HC{\equiv}CR' \xrightarrow[70\text{–}90\%]{Q} RC{\equiv}CR'$$
$$R = Ar, \text{ Vin or } C(O)R''$$

always includes stages involving the formation of σ-ethynyl derivatives of palladium(II) in accordance with the scheme discussed above:

$$(PPh_3)_2PdCl_2 \xrightarrow{R'C{\equiv}CH,\ CuI,\ NHEt_2} (PPh_3)_2Pd(C{\equiv}CR')_2 \rightarrow$$
$$\rightarrow (R'C{\equiv}C)_2 + (PPh_3)_2Pd(0) \xrightarrow{RHal} (PPh_3)_2Pd\begin{matrix}R\\Hal\end{matrix} \rightarrow$$
$$\xrightarrow{R'C{\equiv}CH,\ CuI,\ HNEt_2} (Ph_3P)_2Pd\begin{matrix}R\\C{\equiv}CR'\end{matrix} \rightarrow RC{\equiv}CR' + (Ph_3P)_2Pd(0) \ .$$

The ethynyl derivatives of benzene, pyridine[202], pyrimidene[204], and pyridazine[205] were obtained by this method; in contrast to COA, the $(PPh_3)_2PdCl_2/CuI$ catalytic system makes it possible to introduce aryl bromides into reactions with terminal acetylenes[202].

The reaction of COA, isolated beforehand, with the complexes $Cl_2Pt(PR'_3)_2$ proceeds similarly to the catalytic process[199,206] (Table 11).

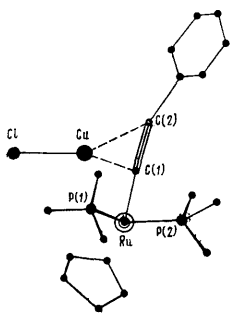

Figure 1. The molecular structure of $(\pi\text{-}C_5H_5)Ru(PPh_3)_2.(C\equiv CPh)CuCl$ (XLIXb); the benzene rings at the phosphorus atoms are not shown.

New types of discrete heteronuclear copper(I) and silver(I) compounds, in which the C≡C groups play an important structure-forming role, have been synthesised by the interaction of COA and SOA with iron, ruthenium, rhenium, iridium, and rhodium halide complexes. These compounds have been partly considered in two reviews[7,207].

The 1 : 1 COA adducts, which have the simplest structures, can be formed as a result of direct exchange and subsequent π-binding of CuHal to the C≡C group[208-211]:

$$RC\equiv CCu + [HalML_n] \rightarrow [L_nM(C\equiv CR)CuHal] .$$

Monomeric ethynyl complexes of ruthenium (XLIX), containing linearly coordinated copper(I) atoms according to X-ray diffraction data (R = Ph) (Fig. 1)[208], have been obtained by the reaction[209]

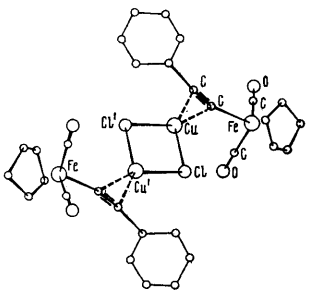
$$RC\equiv CCu + ClRu(\pi\text{-}C_5H_5)(PPh_3)_2 \xrightarrow{C_6H_6\ \text{reflux.,}\ 20\ h} \underset{(XLIX)}{(\pi\text{-}C_5H_5)Ru(PPh_3)_2(C\equiv CR)CuCl} ;$$

(a) R=Me (55%); (b) R=Ph; (c) R=4-MeC_6H_4 (7%) .

In complexes (XLIX) the π-bond between the copper atom and the C≡C group is resistant to the action of PPh_3 in benzene and is decomposed only by a powerful agent such as the tridentate chelating ligand $MeC(CH_2PPh_2)_3$.[209]

In contrast to (XLIX), in complexes (L)—the dimeric products of the interaction of copper(I) arylacetylides with $(\pi\text{-}C_5H_5)Fe(CO)_2Hal$ (Hal = Cl or Br), a Cu–Cl–Cu bridge bond is formed and the copper atoms have a trigonal coordination environment (Fig. 2)[210-212]:

$$ArC\equiv CCu + HalFe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{Q,\ \text{relufx.}} [(\pi\text{-}C_5H_5)Fe(CO)_2(C\equiv CAr)CuHal]_2 .$$



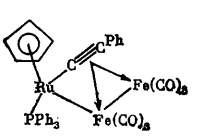


Figure 2. The molecular structure of $[(\pi\text{-}C_5H_5)Fe(CO)_2.(C\equiv CPh)CuCl]_2$ (L, Ar = Ph, Hal = Cl).

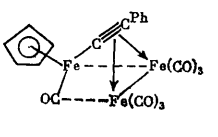
Table 12.

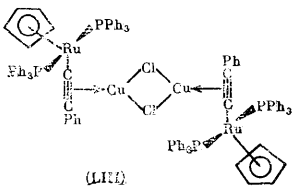


Hal	Q	Ar	Yield of (L), %	Hal	Q	Ar	Yield of (L), %
Cl	Acetone	Ph	42	Cl	THF	C_6F_5	20
Cl	THF	4-MeC_6H_4	27	Br	THF	Ph	10
Cl	THF	4-FC_6H_4	16				

The complexes (L) have been obtained also by specific synthesis from $(\pi\text{-}C_5H_5)Fe(CO)_2(C\equiv CPh)$ and CuHal (the yield is 55% for Hal = Cl and 20% for Hal = Br) in acetone[211]. The use of bromo-derivatives in the direct and specific syntheses lowers the yield of (L) significantly (Table 12).

The thermal decomposition of (L) *in vacuo* results in the formation of ferrocene and diarylbutadiyne[210]. Treatment of (XLIX) and (L) with the carbonyl $Fe_2(CO)_9$ in benzene led to trinuclear clusters with the tentative structures (LI) [210] and (LII):[211]

(LI)



(LII)

In compounds (L) there is no direct interaction between the metal atoms; X-ray diffraction data indicate the presence of a strongly delocalised electron system incorporating the acetylenic fragment, Fe and Cu atoms, and possibly the benzene ring[212].

The structure (LIII), which is analogous to (L), has been attributed to the 1 : 1 dimeric adduct, isolated together with (XLIXb) in the reaction of PhC≡CCu with

$ClRu(PPh_3)_2(\pi\text{-}C_5H_5)$:[209]

(LIII)

The discrete ethynylrhenium complex (LIV) apparently also belongs to the above type of compounds[209]:

$$PhC{\equiv}CCu + cis\text{-}ClRe(CO)_3(PPh_3)_2 \xrightarrow[65\%]{C_6H_6,\ reflux.,\ 6\ h} [(PPh_3)_2Re(CO)_3(C{\equiv}CPh)CuCl]_n \quad (LIV)$$

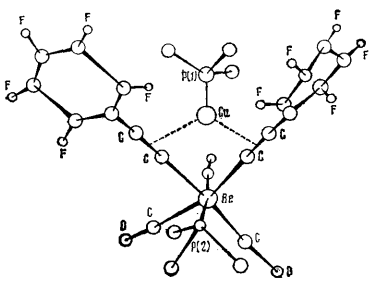
One may expect that, when $n = 1$, (LIV) will have a structure similar to that of (XLIX) and, when $n = 2$, its structure will resemble that of (L).

Thus it has been established for both (XLIX) [208] and (L) [212] and it has been postulated for (XLVIII), (LIII), and (LIV) that each copper atom is linked centrosymmetrically to one C≡C fragment. It is postulated that the complexes (L) are stabilised as a result of the large contribution of the dative component ($d \rightarrow \pi^*$) to the π-bond between the copper atom and the C≡C group[212].

The 1 : 1 adduct of copper(I) 4-tolylacetylide with $ClRu(\pi\text{-}C_5H_5)(PPh_3)_2$ (XLIXc) as well as the monoethynyl products of the condensation of copper(I) fluorophenylacetylides with $ClRu(\pi\text{-}C_5H_5)(PPh_3)_2$ (LV) and $ClRe(CO_3).(PPh_3)_2$ (LVI), which contain no π-linked copper(I) atoms, react with an excess of the corresponding COA, the process being accompanied by a redistribution of the PPh_3 ligand and the formation of diacetylenecopper(I) complexes of a new type[204], for the prototype of the structure of which the zwitter-ionic structure of tertiary phosphine complexes of COA was chosen[181]:

According to X-ray diffraction data[213] (Fig. 3), the complex (LVII) includes a cationoid group, comprising a copper(I) atom asymmetrically π-linked to two C≡C fragments and located in a planar trigonal configuration, and an anionoid group with a central octahedral Re(I) atom; interaction between the metal atoms in (LVII) is unlikely. It is of interest that, among all known phosphine complexes of copper(I), the Cu–P bond length is smallest in (LVII):

$$C_6F_5C{\equiv}CCu + cis\text{-}[ClRe(CO)_3(PPh_3)_2] \xrightarrow{THF,\ reflux.,\ 24\ h} [Cu(PPh_3)]^+[Re(C{\equiv}CC_6F_5)_2(CO)_3(PPh_3)]^- + Re(C{\equiv}CC_6F_5)(CO)_3(PPh_3)_2$$
(LVII), 21% (LVI), 6%



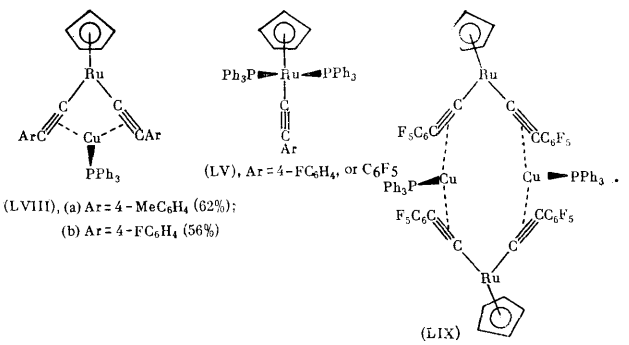


Figure 3. The molecular structure of $[Cu(PPh_3)]^+[Re(C{\equiv}CC_6F_5)_2(CO)_3(PPh_3)]^-$ (LVII); the benzene rings at the phosphorus atoms are not shown.

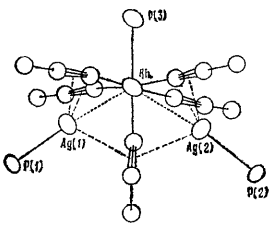
By analogy with (LVII), a zwitter-ionic structure has been attributed to the main products of reaction of $ArC{\equiv}CCu$ with $ClRu(\pi\text{-}C_5H_5)(PPh_3)_2$—the monomeric (in benzene) complexes (LVIII) and the dimeric complex (LIX):[209]

(LVIII), (a) Ar = 4-MeC_6H_4 (62%); (b) Ar = 4-FC_6H_4 (56%)

(LV), Ar = 4-FC_6H_4, or C_6F_5

(LIX)



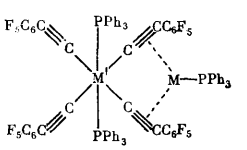


Figure 4. The molecular structure of $PhAg_2(C{\equiv}CC_6F_5)_5.(PPh_3)_3$ (LXI); the pentafluorobenzene rings as well as benzene rings at the phosphorus atoms are not shown.

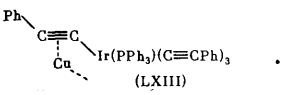
Together with compound (LVIIIb), the complex (LVa) was isolated from the reaction mixture (yield 5%). The complex (LIX) was obtained after refluxing for 7 h a mixture of $C_6F_5C{\equiv}CCu$ with $ClRu(\pi\text{-}C_5H_5)(PPh_3)_2$ in benzene; an increase of reaction time (to 13 h) results in the formation of (LVb) only. It is suggested that the copper and ruthenium in compounds (LVIII) and (LIX) are univalent and bivalent and that there is no bond between them[209]. The zwitter-ionic complexes $[M'(C{\equiv}CC_6F_5)_4(PPh_3)_2]^-.[M(PPh_3)]^+$ (LX), which are isostructural with (LVIII), have been obtained in a low yield by the reaction of $C_6F_5C{\equiv}CM$ (M = Cu [214] or Ag [215]) with $ClIr(CO)(PPh_3)_2$ in toluene and of $C_6F_5C{\equiv}CAg$ with $ClRh(PPh_3)_3$ in THF and dimethoxyethane (DME).[215]

(LX), (a) M^I = Ir (III), M = Cu (I) or Ag (I); (b) M^I = Rh (III), M = Ag (I)

In the latter case the main product (yield 10%) is an unusual trinuclear complex $RhAg_2(C{\equiv}CC_6F_5)_5(PPh_3)_3$ (LXI),[215,216] which has been investigated in detail[215,217].

It contains (Fig. 4) a central Rh atom in a regular octahedral coordination with a PPh_3 molecule and five σ-ethynyl ligands. Each silver atom has a tetrahedral coordination environment, which includes a PPh_3 molecule and three asymmetric π-ethynyl fragments, the *trans*-C≡C group being π-linked to both silver atoms. Data for the coordination environment of the silver and rhodium atoms as well as the absence of interaction between them make it possible to represent structure (LXI) as zwitter-ionic: $[Ag(PPh_3)]_2^{2+}[(PPh_3)Rh^{III}(C{\equiv}CC_6F_5)]^{2-}$. The shortened [compared with other phosphine complexes of copper(I) and silver(I) compounds] P → M bond [M = Cu(I) or Ag(I)] in (LVII) and (LXI) shows that there is a strong M–P d_π–d_π interaction, according to Churchill and DeBoer[217].

The mechanism of the interaction of SOA with $ClRh(PPh_3)_3$ is apparently of fundamentally the same type for all the reactions of COA and SOA with complex transition metal halides examined and is based on a key role of the intermediate $Rh(C{\equiv}CAr)_3(PPh_3)_3$, which is a product of the oxidative addition of two SOA molecules to the complex $Rh(C{\equiv}CAr)(PPh_3)_3$ formed in the first (exchange) stage. Subsequent substitution of the PPh_3 ligands by the ethynyl anion with simultaneous transfer of PPh_3 to the Ag atom should lead to the zwitter-ionic complexes (LXb) and (LXI) according to the mechanism of Abu Salah and Bruce[215].



Bruce and coworkers obtained for the first time the ethynyl hexanuclear clusters (LXII) having the general formula $M_4M'_2(C{\equiv}CAr)_8(PPh_2R)_2$ (Table 13) by the reaction of COA [214,218] and SOA [215] with *trans*-$ClIr(CO)(PPh_2R)_2$ and *trans*-$ClRh(PPh_3)_3$ and of COA with *trans*-$ClRh(CO).(PPh_2R)_2$.[214]

Table 13.

M	M′	Ar	R	M	M′	As	R
Cu	Ir	Ph, C_6F_5	Ph, Me	Cu	Rh	Ph, C_6F_5, 4-MeC_6H_4, 4-FC_6H_5	Ph, Me
Cu	Ir	4-MeC_6H_4, 4-FC_6H_4	Ph				
Ag	Ir	Ph, C_6F_5	Ph	Ag	Rh	Ph, C_6F_5	Ph

COA react with *trans*-$ClM'(CO)(PPh_3)_2$ (M′ = Ir or Rh) and *trans*-$ClRh(PPh_3)_3$ on refluxing in benzene or toluene. Reactions of the complexes *trans*-$ClM'(CO)(PPh_2Me)_2$ are better differentiated—in benzene [M′ = Ir(PhC≡CCu) or $Rh(C_6F_5C{\equiv}CCu)$] or DME [M′ = Ir($C_6F_5C{\equiv}CCu$) or Rh(RhC≡CCu)].[214] The reactions of SOA with *trans*-$ClIr(CO)(PPh_3)_2$ take place in toluene and those with *trans*-$ClPh(PPh_3)_3$ proceed in a more polar medium (THF, DME).[215] We may note that the yields of (LXII) decrease on passing from Ir to Rh and from Cu to Ag. The rhodium clusters (LXII) are apparently less stable than the iridium clusters and the extensive formation of diarylbutadiynes in reactions of rhodium halide complexes with COA and SOA is specifically attributed to this fact[214,215]. The enhancement of the electron-accepting properties of the ring in ArC≡CCu and the replacement of PPh_3 by the stronger electron-donating ligand PPh_3Me stabilise the clusters (LXII, M = Cu).[214]

The reaction of the complex PhC≡CCu.PPh_2Me with *trans*-$ClIr(CO)(PPh_3)_2$ proceeds with exchange of the phosphine ligand at the Ir atom and leads to $Ir_2Cu_4(C{\equiv}CPh)_8(PPh_2Me)_2$ with a low yield[214]. According to X-ray diffraction data[218,219], the "skeleton" of the cluster $Ir_2Cu_4(C{\equiv}CPh)_8(PPh_3)_2$ consists of a slightly distorted octahedron in which the equatorial positions are occupied by the Cu atoms and the apical positions are occupied by Ir atoms (Fig. 5). Each $(Ph_3P)Ir$ fragment is σ-linked to four ethynyl ligands and the Ir–C≡CPh system has the transoid configuration (LXIII), unusual for acetylene complexes, which ensures the possibility of the formation of a Cu–Ir bond and the π-interaction of the copper atom with two acetylene groups belonging to different iridium atoms:

(LXIII)

A distinctive feature of the structure of the cluster is a pronounced asymmetry of such interaction.

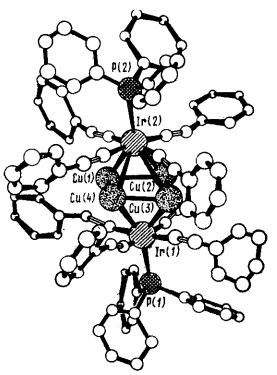


Figure 5. The molecular structure of $Cu_4Ir_2(PPh_3)_2.(C{\equiv}CPh)_8$ (LXII, M = Cu, M′ = Ir, Ar = R = Ph).

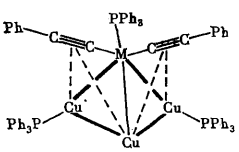

Figure 6. The proposed molecular structure of the cluster $IrCu_3(C{\equiv}CPh)_2(PPh_3)_2$.

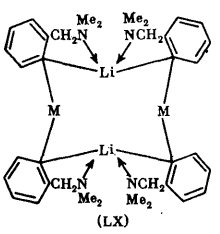
It has been suggested[215,244] that all the clusters (LXII) have structures of the same type; the formal valence states of the metal atoms in them are identical: Ir(IV), Rh(IV), Cu(0), and Ag(0). The clusters (LXII) are electron-enriched systems; for M = Cu, it is assumed that the excess electrons are located in the antibonding M′–Cu and Cu–Cu orbitals and are responsible for a bond order of 3/4.[214] A structure (Fig. 6) intermediate between (LXa) and (LXII, M = Cu, M′ = Ir) has been attributed for the electron-deficient cluster $IrCu_3(C{\equiv}CPh)_2(PPh_3)_2$, which has been isolated together with $Ir_2Cu_4(C{\equiv}CPh)_8(PPh_3)_2$ in the reaction of PhC≡CCu with *trans*-$ClIr(CO)(PPh_3)_2$ in benzene[214].

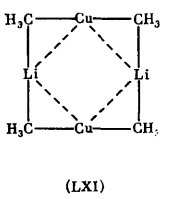
The clusters (LXII, M = Cu, M′ = Ir, Ar = Ph or 4-MeC_6H_4, and R = Ph) react with $Fe_2(CO)_9$ in benzene, forming the octanuclear clusters $Ir_2CuFe_2(C{\equiv}CAr)_8(CO)_8 \cdot (PPh_3)_2$, which retain the Ir_2Cu_4 "skeleton" and do not contain CO bridge groups[214].



IV. COPPER AND SILVER ORGANOACETYLIDES IN ADDITION REACTIONS

Although the mechanisms of the numerous reactions of COA and SOA with nucleophilic, electrophilic, and 1,3-dipolar compounds considered in this section have not been investigated at all, it is possible to isolate in a purely formal manner the common stage in reactions of this kind where the reactant adds directly to the monomeric R≡C–M (M = Cu or Ag) fragment. In terms of topological features, these reactions can be subdivided into three groups: (1) addition of nucleophiles to copper and silver atoms in COA and SOA; (2) addition of electrophiles and nucleophiles to the ≡C–M (M = Cu or Ag) bond; (3) addition of 1,3-dipolar compounds to the C≡C bond in COA.

1. Addition of Nucleophiles to the Copper and Silver Atoms in COA and SOA



Like organocopper compounds RCu (R = alkyl, vinyl, or aryl), COA react with alkali metal salts in ether and THF to form reactive heterocuprates having the empirical formula $M^+[RC{\equiv}CCuX]^-$ (M = Na, X = CN; M = Li, X = Hal).[3] The reaction of alkali metal organoacetylides RC≡CM with COA (M = Li, Na, or K) and SOA (M = Na or K) in liquid ammonia yielded homoethynyl cuprates and argentates $M[M'(C{\equiv}CR)]_{n+1}$ (M = alkali metal; M′ = Cu(I) or Ag(I); n = 1 or 2), and the available information about them has been surveyed[1]. Mixed ethynyl homocuprates based on COA and various types of organolithium or organomagnesium compounds $M^+[RC{\equiv}CCuR']^-$ (M = Li or MgHal) [3,5] have no analogues in the SOA series.

It has been suggested[170,172] that all organocuprates are structurally similar and have the cluster structure with metal bridge atoms and an electron-deficient 2e–3c M–C–M bond characteristic of Group IB metal compounds. On the basis of experimental data, this type of structure has been proposed for the homocuprates (LX) [170,220] (and the corresponding homoargentates[221]) and the homocuprate (LXI) [172] {cf. with the structure $[CuCH_2SiMe_3]_4$ of a discrete centrosymmetric tetramer consisting of a planar square of Cu atoms, involved in the linear coordination C–Cu–C and the 3c–2e Cu–C–Cu bonds[207]}.

(LX)

M = Cu (I) or Ag (I)

(LXI)

It has been noted that the reactivity of organocuprates is determined by the strength of the M–C–M bridge bond and increases when the latter is weakened in the series N≡C– < C≡CR < aryl < alkyl.[220]

Van Koten and Noltes discovered a fundamentally new structural-chemical type of reactions of COA—the formation of mixed organocopper compounds with ArCu.[24-26] They had shown earlier[222] that, depending on the nature and position of the complex-forming substituent in the ring, arylcopper compounds ArCu react with the halides CuHal to form either 1 : 1 polymers (Ar = 2-$Me_2NCH_2C_6H_4$ or 4-$Me_2NC_6H_4$; Hal = Br) or discrete hexanuclear clusters $Ar_4Cu_6Hal_2$ (Ar = 2-$Me_2NC_6H_4$, Hal = Cl or Br), whose structure has been investigated in detail in relation to $(5\text{-Me-2-}Me_2NC_6H_3)_4Cu_6Br_3$.[170,223] Ethynyl clusters of the type $Ar_4Cu_6(C{\equiv}CR)_2$ (I), where Ar = 2-$Me_2NC_6H_4$, the methods of synthesis of which (including syntheses from COA and ArCu) were examined above, contain an octahedral skeleton of copper atoms, by analogy with the study of Guss et al.[223] (and on the basis of spectroscopic data), the equatorial copper atoms being involved in trigonal coordination with Ar (2e–3c Cu–C bond), the Me_2N group (2e–2c Cu–N bond), and the C≡CR fragment (4e–3c Cu–C bridge bond), while the apical copper atoms are involved in diagonal coordination with Ar (2e–3c Cu–C bridge bond) (Fig. 7)[25].

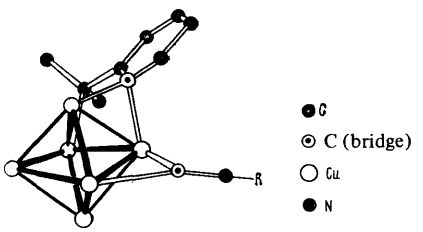


Figure 7. The proposed molecular structure (fragment) of $Ar_4Cu_6(C{\equiv}CR)_2$ clusters (I, Ar = 2-$Me_2NC_6H_4$, R = Ph or 4-MeC_5H_4).

Thermal decomposition of such clusters leads consistently to tolanes[24,26]:

$$Ar_4Cu_6(C{\equiv}CR)_2 \xrightarrow{t^\circ} ArC{\equiv}CR + Ar_3Cu^I_4Cu^0_2(C{\equiv}CR) \rightarrow$$
$$\rightarrow [ArCu^I_2Cu^0_3(C{\equiv}CR)] + 2\,ArCu \rightarrow ArC{\equiv}CR + 4Cu^0 \quad .$$

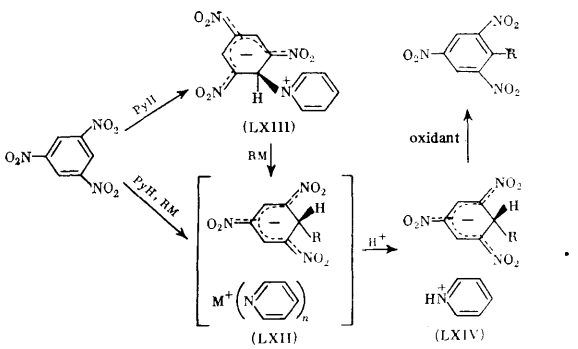
It has been shown[26] that clusters of type (I) (see Section II) play a key role in 1 : 1 reactions of COA with ArCu of the type

$$RC{\equiv}CCu + ArCu \xrightarrow{DMF,\ 135^\circ} RC{\equiv}CAr + Cu^0 \ ;$$
(a) Ar = 2-$Me_2NC_6H_4$, R = Ph, 2-MeC_6H_4, 2, 4-$Me_2C_6H_3$, 2, 4, 6-$Me_3C_6H_2$, 4-$MeOC_6H_4$, 4-ClC_6H_4, or 4-$O_2NC_6H_4$;
(b) Ar = 4-$Me_2NC_6H_4$, R = 4-YC_6H_4 (where Y = Me, OMe, Cl, or NO_2)

with Ar = 2-$Me_2NC_6H_4$; when Ar = 4-$Me_2NC_6H_4$, the reaction proceeds in all probability via mixed polymeric compounds in which copper atoms form regular bridge bonds with alternating Ar and C≡CR groups. Thus the reaction under consideration reduces to the thermal decomposition of intermediate mixed organocopper compounds, asymmetric dimerisation of the organic residues in the 2e–3c bond with the copper atom occurring more specifically in clusters[26]. It is noteworthy that the symmetrical dimerisation of the arylacetylene residue takes place similarly in the thermal decomposition of copper and silver arylacetylides[224].

The formation of mixed intermediates (of either polymeric or cluster type) can be postulated also in the reaction[225]

$$YC_6H_4C{\equiv}COOH + CH_3Cu \xrightarrow{\text{ether, } 20^\circ,\ 55\text{–}70\%} \left[YC_6H_4C{\equiv}CCOOCu \xrightarrow[-CO_2]{} YC_6H_4C{\equiv}CCu\right] \xrightarrow{2CH_3Cu} \rightarrow YC_6H_4C{\equiv}CCH_3 + Cu^0 \quad ;$$



Y=H, 3-Cl, 3-F, 4-Me, or 4-Cl

In this case butylcopper is less reactive than methylcopper; the alkylcopper compounds do not contain lithium salts and were used in proportions of 3 : 1 in relation to arylpropiolic acids. The intermediate formation of COA was demonstrated by a model reaction of the COA obtained beforehand with CH_3Cu:

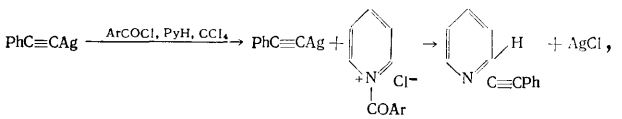
$$RC{\equiv}CLi \xrightarrow{CuI} RC{\equiv}CCu \xrightarrow[R=Ph\ (75\%),\ \text{or}\ C_{12}H_{25}\ (35\%)]{3CH_3Cu,\ \text{ether, } 20^\circ} RC{\equiv}CCH_3 \quad ;$$

2. The Addition of Electrophiles and Nucleophiles to the ≡C–M (M = Cu or Ag) Bond

Nilsson, Wennerstrom, and coworkers investigated nucleophilic substitution in aromatic compounds by treatment with arylcopper compounds and showed that the compounds RM [M = Cu, R = 2,6-$(MeO)_2C_6H_3$,[226] 2-furyl, 2-thienyl[227], PhC≡C, n-BuC≡C;[228] M = Ag, R = 2,6-$(MeO)_2$.C_6H_3 [229] or PhC≡C [228,229]] react with 1,3,5-trinitrobenzene (TNB) in pyridine to form σ-anionic Meisenheimer complexes (LXII), which coexist with the pyridinium complex (LXIII).

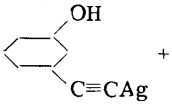
For aryl derivatives of copper and silver, the formation of (LXII) was demonstrated by spectroscopic methods and by the isolation of the pyridinium salts (LXIV) in a pure form (with a yield of 20–40% for M = Cu and 80% for M = Ag). The evidence for the formation of the ethynyl complexes (LXII) is not so rigorous, because it is assumed that their absorption in the visible region is masked by the absorption due to the complexes (LXIII). Treatment of the reaction mixture with dilute H_2SO_4 does not lead in this case to (LXIV) and yield TNB for PhC≡CAg (80% relative to the initial amount), while a more complex set of products is obtained for PhC≡CCu (67% of TNB, 6% of diphenylbutadiyne, 5% of 2,4,6-trinitrotolane, and 6% of its intramolecular cyclisation product 4,6-dinitro-2-phenylisatogen).

The difference between the chemical behaviour of organoderivatives of copper(I) and silver(I) can be clearly traced in relation to the σ-anionic complexes (LXII): thus the complexes (LXII) with M = Ag are more stable and are formed in higher yields than those with M = Cu. The explanation is that the copper(I) complexes (LXII) can be oxidised by atmospheric oxygen or NO_2 groups to R-2,4,6-trinitrobenzenes and RR, while the silver(I) complexes (LXII) require a more powerful oxidant (CrO_3).[226–229]



We believe that the acylation of COA and SOA by carboxylic acid halides is the commonest instance of the addition of electrophiles to the ≡C–M bond. This reaction has broad analogies in the chemistry of organocopper(I) and organosilver(I) compounds. Thus (π-C_5H_5)Cu.$P(n\text{-}Bu)_3$, ArCu, C_6F_5Cu,[3] ArOCu,[230] and C_6F_5Ag [52] react smoothly with RCOCl in ether or in the presence of an excess of the acid chloride.

In order to account for the characteristics of the interaction of SOA and COA with acid chlorides (XA), it is convenient to employ the reaction mechanism proposed by Nef for silver phenylacetylide as early as 1899,[231] which is apparently valid for both COA and SOA:



$$RC{\equiv}CM + ClCR' \rightarrow \left[R'{-}\overset{O^+M^+}{\overset{|}{C}}{-}Cl \quad C{\equiv}CR\right] \xrightarrow{-MCl} R'CC{\equiv}CR \quad .$$

Within the framework of this mechanism, the factors promoting an increase of the effective charge on the oxygen atom of XA will favour the reaction. Indeed, the data in Table 14 show that electron-donating substituents R′ and the formation of complexes of XA with $AlCl_3$ and Et_3N constitute in many instances the necessary conditions for the acylation of COA and SOA. It has been noted[232] that 3,5-dinitrobenzoyl chlorides does not react to silver alkylacetylides even in the presence of $AlCl_3$. The acylation of the isomeric *cis*- and *trans*-$C_6H_{13}CH{=}CHC{=}CAg$ proceeds with retention of configuration[233].

In a carbon tetrachloride–pyridine mixture the interaction of silver phenylacetylide with an acylpyridinium salt, and not with XA, becomes the dominant pathway for Ar = Ph and is apparently the only pathway for Ar = 4-$NO_2C_6H_4$ and 3-$NO_2C_6H_4$:[234]

It is of interest to note that this type of reaction does not occur in the systems PhC≡CAg + MeCOCl, n-BuC≡CAg + RCOCl (R = Me or 4-$O_2NC_6H_4$), and

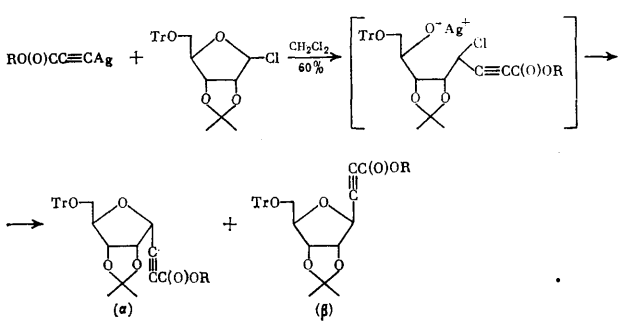
+ RCOCl

(R = Me, Ph, or 4-$O_2NC_6H_4$).

The ethynyl derivative of 1,2-dihydroquinoline was obtained in the reaction of PhC≡CAg with PhCOCl in a carbon tetrachloride–quinoline mixture[234].

The reaction of the copper derivatives of aryl propargyl ethers with PhC(O)Cl under the conditions proposed by the authors of the review[235,236] (benzene, Et_3N, PyH) is accompanied by a prototropic rearrangement with the

resulting α-acetylenic ketones and leads to allenic ketoethers (Ar = Ph or 4-MeC_6H_4):[237]



$$ArOCH_2C{\equiv}CCu + PhCOCl \xrightarrow[\sim 30\ \%]{C_6H_6,\ Et_3N,\ PyH} [ArOCH_2C{\equiv}CC(O)Ph] \rightarrow$$
$$\rightarrow ArOCH{=}C{=}CHC(O)Ph$$

The reaction of SOA with 2,3-*O*-isopropylidene-5-*O*-trityl-β-D-ribofuranosyl chloride, leading to a 1 : 3 mixture of the α- and β-anomers[238] as in the case of XA, can be represented in terms of the following mechanism (R = Me or Et):

The analogous reaction of copper phenylacetylide with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide is complicated by a secondary process[239]:

Within the framework of the above mechanism of the acylation of COA and SOA by carboxylic acid halides, it is possible to describe the interaction of the complex Et_2PhP. PhC≡CCu with terephthaloyl chloride in THF [236] as well as the interaction of the complexes PhC≡CM (M = Cu or Ag) with CO_2:[12]

$$PhC{\equiv}CM \xrightarrow[2.\ CO_2,\ 80°,\ 50\ atm]{1.\ L,\ THF} [PhC{\equiv}CC(OM) \xrightarrow{3.\ CH_3I} PhC{\equiv}CC(O)OCH_3$$

a) L=PBu_3, M=Cu (50%), or Ag (70%); (b) L = t-BuNC, M = Cu (71%) or Ag (65%).

The reversible insertion of CO_2 in the ≡C–Cu bond has been observed in the system[240]

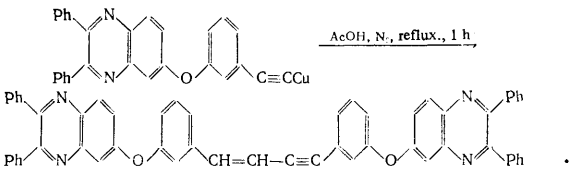
$$PhC{=}CC(O)OCu \cdot (PBu_3)_3 \underset{}{\overset{DMF}{\rightleftharpoons}} PhC{=}CCu \cdot (PBu_3)_3 + CO_2$$

at atmospheric pressure and a low temperature. The nature of the ligand determines the state of equilibrium: a ligand with a high σ-donor capacity accelerates the decarboxylation [$PBu_3 < PPh_3 < P(OMe)_3$]. Treatment of the reaction mixture with methyl iodide leads to two products: PhC≡CC(O)OMe and PhC≡CMe.

Table 15.

$$ArC{\equiv}CCu + Pt(C_2H_4)(PPh_3)_2 \xrightarrow{L} \left[Ph_3P\!-\!Pt(C{\equiv}CAr)\!-\!PPh_3\ (Cu)\right] \xrightarrow{ArC{\equiv}CCu} \rightarrow Pt(C{\equiv}CAr)_2(PPh_3)_2 + 2Cu^0$$

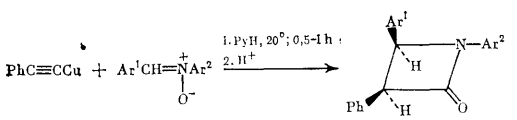
Ar	L	Yield, %	As	L	Yield, %
Ph	benzene	15	4-FC_6H_4	benzene	12
4-MeC_6H_4	THF	11	C_6F_5	benzene	25



In terms of their formal features, certain reactions of COA, which have no analogy in the chemistry of SOA, can be included in the present section. It is assumed that the reaction of ArC≡CCu with $Pt(C_2H_4)(PPh_3)_2$ proceeds via the intermediate product of the oxidative addition of ArC≡CCu to a zerovalent platinum compound[206] (Table 15). The ethynyl derivative of platinum formed has the *cis*-configuration for Ar = C_6F_5 and the *trans*-configuration in all remaining cases.

The Straus condensation[241,242] or COA can be regarded as addition of the COA complex to a terminal acetylene:

$$2RC{\equiv}CCu \xrightarrow{AcOH,\ N^+} RC{\equiv}CCu \cdot CuOAc + HC{\equiv}CR \xrightarrow{AcOH,\ O_2} \underset{trans}{RC{\equiv}CCH{=}CHR};$$



R=Ph, $PhCH{=}CH_2$, or $MeO(O)C(CH_2)_n$, where $n = 0, 1, 8$.

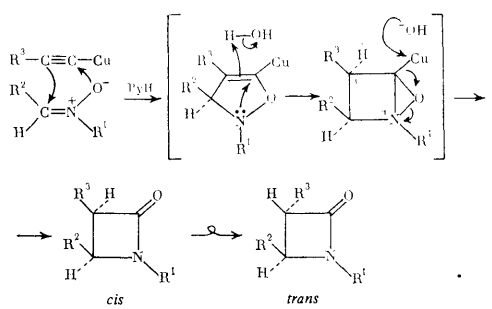
It has been shown recently that this reaction proceeds smoothly also in an oxygen-free medium[243]:

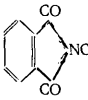
3. Addition of 1,3-Dipolar Compounds to the C≡C′ Bond in COA

It was shown in 1972 that *C,N*-diarylnitrones undergo a cycloaddition reaction with copper phenylacetylide, leading to *cis*-β-lactams, which are difficult to obtain by other methods[244]:

(a) Ar^2 = Ph, Ar^1 = Ph, or 2-YC_6H_4 (where Y = Me or Cl); (b) Ar^1 = Ph, Ar^2 = 4-ClC_6H_4.

A detailed study of this reaction established that it is accompanied by the base-catalysed isomerisation of the initial *cis*-form of the β-lactam into the *trans*-form[245] (Table 16):





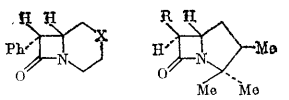


Table 16. β-Lactams derived from COA and nitrones.

R^1	R^2	R^3	Yield of lactam, %	*cis* : *trans*
Ph	Ph	Ph	32	5:3
Ph	Ph	4-MeC_6H_4	50	7:3
Ph	4-MeC_6H_4	Ph	40	4:1

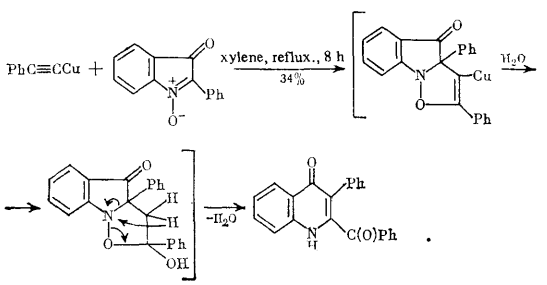
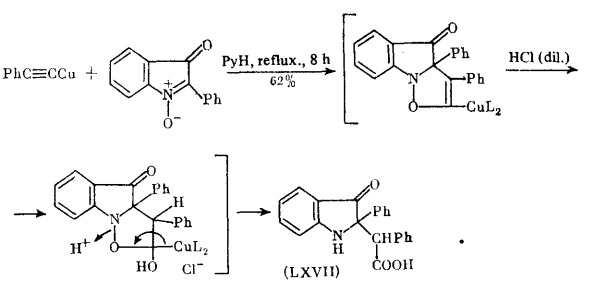
4-MeC_6H_4	Ph	Ph	25	3:4
4-MeC_6H_4	4-ClC_6H_4	Ph	14	5:4
Ph	Ph	Bu	66	12:1
Ph	4-$MeOC_6H_4$	Bu	55	*cis*-isomer
4-MeC_6H_4	4-ClC_6H_4	Bu	9	*trans*-isomer
Ph	4-MeC_6H_4	EtO(O)C	42	*trans*-isomer
Ph	4-MeC_6H_4		31	9:1
Ph	4-ClC_6H_4	ditto	12	*cis*-isomer
Ph	4-ClC_6H_4	$PhN(Me)CH_2$	52	1:1
Ph	4-$MeOC_6H_4$	$PhN(Et)CH_2$	39	*trans*-isomer
Ph	4-ClC_6H_4	4-$EtO(O)CC_6H_4NHCH_2$	75	*cis*-isomer



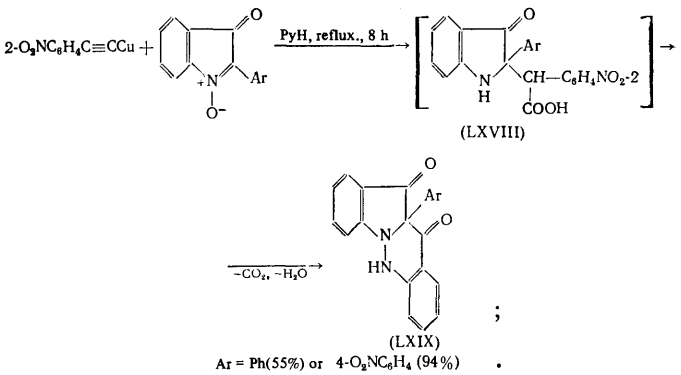
When D_2O was added to the reaction medium, lactams containing the D label in the 3-position were obtained, which demonstrated the incorporation of an H atom from the solvent in this position. The addition of $H_2{}^{18}O$ did not lead to the incorporation of ^{18}O atoms into the final product. Copper n-butylacetylide is less reactive than PhC≡CCu; the *cis*-isomer then predominates in the product. On the other hand, EtO(O)CC≡CCu is more reactive than PhC≡CCu and only the *trans*-isomer is formed in pyridine in this case. The replacement of pyridine by EtOH makes it possible to obtain a 3 : 1 mixture of the *cis*- and *trans*-isomers (R^1 = Ph, R^2 = 4-MeC_6H_4, R^3 = EtO(O)C).

COA based on aminoacetylenes were not isolated beforehand and were used *in situ*. Unstable cyclic nitrones were also introduced into the reaction, which made it possible to synthesise the bicyclic compounds (LXV) and (LXVI):



(LXV), X = O or CH_2 (LXVI), R = Ph, Bu, or EtO(O)C.

Aromatic bicyclic nitrones react with COA via two pathways, depending on the solvating (in relation to the C atom) capacity of the medium[74]. In xylene the reaction of copper phenylacetylide with 2-phenylisatogen leads to 2-benzoyl-3-phenyl-4-quinolone:

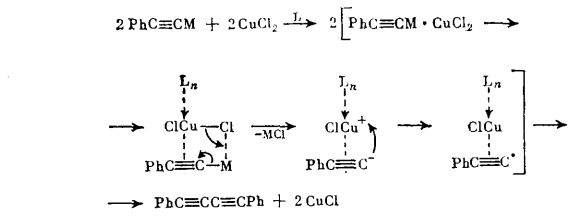


The copper atom is solvated in pyridine, so that the mode of its addition to isatogen is inverted for steric reasons:

The formation of cinnolines (LXIX) from copper 2-nitrophenylacetylide and 2-arylisatogens apparently proceeds via the indolinone (LXVIII), which is analogous

to compound (LXVII):[74]

(LXVIII)



(LXIX)

Ar = Ph(55%) or 4-$O_2NC_6H_4$ (94%) .

V. OXIDATIVE CONDENSATION OF GROUP IB METAL ORGANOACETYLIDES

The oxidative condensation of COA under the influence of O_2 in the presence of coordinating agents of the amine type (strong donors), which stabilise the copper(II) valence state, has been examined in a review[1]. The formation of dicyanogen from CuCN is analogous to this reaction[246].

Extensive experimental data have now accumulated on the use of coordinating agents of moderate electron-donating capacity (Table 1), which destabilise the copper(II) state and stabilise the copper(I) state. Under these conditions, the oxidative condensation of aromatic organolithium and organomagnesium compounds, which lead to either open-chain or cyclic polyarylenes, takes place particularly effectively under the influence of $CuCl_2$.[246,247] The present authors were able to introduce for the first time silver(I) and gold(I) phenylacetylides into the oxidative condensation reaction in THF, acetone, and dioxan[248]:

L = coordinating agent (THF, acetone, and dioxan);
M = Cu(I), Ag(I), or Au(I).

According to this mechanism, the valence state of the metal in the organoacetylide does not change during the reaction and the specific role of copper reduces to a decrease of the oxidation potential of the ethynyl anion and the stabilisation of the ethynyl radical by the π-coordination of Cu...$\overset{C}{\underset{C}{|||}}$, which ensures a convenient geometrical disposition of these radicals for recombination in the "cage". It may be that the dative component Cu $\rightarrow \overset{C}{\underset{C}{|||}}$ predominates in this coordination, which imparts nucleophilic properties to the ethynyl radicals and facilitates their recombination. We may note that, according to Fedenck[249], the free-radical recombination of RC≡C· is thermodynamically unfavourable; it has also been shown that the free radicals PhC≡C· have electrophilic properties and form only tolanes in aromatic hydrocarbons[77]:

$$PhC{\equiv}Cl \xrightarrow{h\nu,\ ArH} PhC{\equiv}CAr \quad .$$

The oxidative dimerisation of COA under the influence of certain transition metal chlorides ($TlCl_3$, $FeCl_3$, $NiCl_2$, $CoCl_2$, $CrCl_3$ [248]) in a fairly wide variety of media (alcohols, nitriles, ether, ethyl acetate, and nitromethane) can also take place in the framework of the above mechanism. The copper(I) chloride formed in the initial stage then remains in the reaction complex as a result of the π-interaction with the C≡C bond.

In solvents with a moderate electron-donating capacity certain oxidants enter into additional interactions with COA. Thus the formation of phenylchloroacetylene in the reactions of copper phenylacetylide with transition metal chlorides[250] can be represented by the following mechanism by analogy[251] with the reaction $R^{\cdot} + CuX_2 \rightleftharpoons [RCuX_2 \rightarrow R^{+}CuX_2^{-}] \rightarrow RX + CuX$:

$$PhC{\equiv}\underset{\underset{Cu^{I}}{|}}{C}{\cdot} + MCl_n \rightarrow PhC{\equiv}CCl + MCl_{n-1} \quad .$$

Thus the composition of the products of the oxidative condensation of COA is determined by the contribution of both reaction pathways of the ethynyl radical. For example, when copper phenylacetylide is treated with bromine (in ether) and chlorine (in CCl_4), a large amount of diphenylbutadiyne is formed together with the corresponding phenylhalogenoacetylenes. On the other hand, the bromination of copper 4-nitrophenylacetylide takes place unambiguously—without the formation of a dimerisation product[1]. In the reaction of tetracyanoethylene (in THF) with 4-$YC_6H_4C{\equiv}CCu$ the main product is phenylethynyltricyanoethylene for Y = H and (4-$YC_6H_4C{\equiv}C)_2$ for Y = I. Tetracyanoquinodimethane oxidises PhC≡CCu smoothly (in CH_3CN) to diphenylbutadiyne[252].

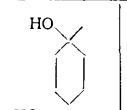
We may point to the syntheses of dicyanodiacetylene by the reaction of NCC≡CCu with $K_3[Fe(CN)_6]$ in a water–benzene mixture[253] and of diphenyltetra-acetylene from PhC≡CC≡CCu under the influence of $CuCl_2$ in water[254] as practical examples of the oxidative condensation of COA in an amine-free medium. The oxidation of the acetylides $Cu(C{\equiv}C)_nR$ (R = H or Cu) (which are in their turn the products of the oxidative dehydropolycondensation of acetylene in an aqueous ammonia solution of $CuCl_2$) by an aqueous solution of $FeCl_3$ or $K_3[Fe(CN)_6]$ yielded a linear polymer (carbine)—a new allotropic form of carbon[255].

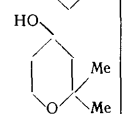
It has been shown[249] that the catalytic reaction

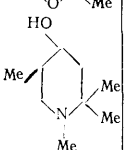
$$PhC{\equiv}CH \xrightarrow{PyH,\ CuCl,\ O_2} (PhC{\equiv}C)_2$$

can proceed via the intermediate copper phenylacetylide. Possibly the COA occur in the pathways of catalytic oxidative dimerisation reactions also in many other instances[1].

VI. REACTIONS OF SILVER ORGANOACETYLIDES WITH ARENEDIAZONIUM HALIDES



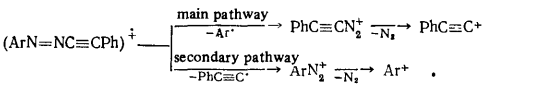




It was shown in 1964 [256] that in an aqueous medium (at pH ~3) arenediazonium chlorides react with SOA of the phenylacetylene series to form azoethynyl compounds (LXX), which are difficult to obtain by other methods:

$$RC{\equiv}CAg + ArN_2^{+}Cl^{-} \rightarrow \underset{(LXX)}{RC{\equiv}CN{=}NAr} \quad .$$

The study of this reaction began with benzenediazonium chlorides containing electron-accepting substituents in the 2- or 4-position in the ring[257,258]. Subsequently the arenediazonium chlorides $YC_6H_4N_2^+Cl^-$, where Y = H,[259] 2-Me, or 4-Me,[260] were introduced into the reaction under the same conditions but using this time SOA of the propargyl type. Thus benzene- and toluene-diazonium chlorides form compounds (LXX) in yields of 8–35% for R = 2-$YC_6H_4C(O)OCH_2$ (Y = H [259] or Cl [260]). Reactions of 4-$YC_6H_4N_2^+Cl^-$ (Y = H or Cl) with silver acetylides derived from 1-ethynyl-1-cyclohexanol, 2,2-dimethyl-4-ethynyltetrahydro-4-pyranol, and 4-ethynyl-1,2,5-trimethyl-4-piperidinol lead to (LXX) in yields of 70–90%.[261] When purified benzenediazonium chlorides and bromides were used and the reaction was carried out in an alcohol–chloroform mixture, the yields of (LXX) with R and Ar belonging to the benzene series were increased greatly and it was possible to isolate the unstable azoethynyl compounds with R = Ph and Ar = Ph and even 4-$MeOC_6H_4$.[262]



Compounds (LXX) known at the present time and obtained via SOA are listed in Table 17.

Table 17. The azoethynyl compounds $RC{\equiv}CN{=}NC_6H_4Y$ (LXX).

$PhC(O)OCH_2$	H, 2-Me, 4-Me	259		H, 4-Cl	261
2-$ClC_6H_4C(O)OCH_2$	H	260			

The possible mechanisms of the interaction of SOA with arenediazonium chlorides have been discussed[1]; we may note that this reaction has no analogies in the chemistry of organic compounds of copper(I) and silver(I) and is apparently related to the reactions of diazonium salts with powerful nucleophiles—organomagnesium and organozinc compounds[1] and R_fCs [R_f = $C(CR_3)_3$, $(CR_3)_2CF$, or $CF_2CF_2CF_2CF_2$ [263]].

The structure of compounds (LXX) has been investigated by infrared and ultraviolet spectroscopy, NMR, and mass-spectrometry[258,262]. It has been shown that the inclusion of the C=C group in the azobenzene structure leads to a strong bathochromic shift in the ultraviolet spectrum[258]. According to mass-spectrometric data, the fragmentation of (LXX) of the benzene series takes place preferentially with elimination of aryl and not phenylethynyl groups[262]:

The thermal cyclodimerisation of (LXX), leading to derivatives of a new heteroaromatic mezoionic system—2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalenes (LXXI)—leads to great synthetic possibilities for SOA:[262,264]

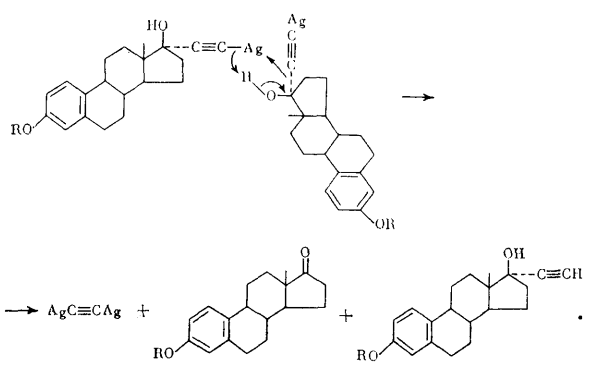
(LXXI)

Ar^1=4-XC_6H_4, Ar^2=4-YC_6H_4; (a) X=H, Y=Cl, Br, or NO_2; (b) X=NO_2, Y=Cl; (c) X=Br, Y=Cl, NO_2; (d) X=Me, Y=Cl, or NO_2 .

Compounds (LXXI) fuse at temperatures in excess of 320°C and are distinguished by high thermal and hydrolytic stabilities: they do not decompose *in vacuo* on heating to 500°C and withstand prolonged boiling in 65% H_2SO_4.[264] A dimer of type (LXXI) is not formed for Ar^1 = Ph and sterically hindered Ar^2 = 2-$PhC(O)C_6H_4$.[262]

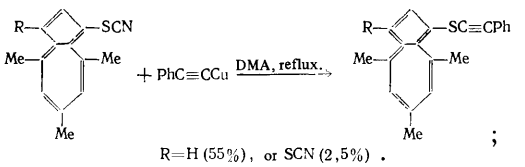
VII. OTHER REACTIONS OF COPPER AND SILVER ORGANOACETYLIDES

In contrast to COA, SOA react with alkyl iodides (on heating in a sealed tube) via the mechanism[265]



R=Me, CD_3, or Et.

When the reaction is carried out in ether or benzene, a terminal acetylene, corresponding to the initial SOA, is formed together with an alkylacetylene. Since RH and RR are absent from the reaction products, it is assumed that the alkylation of SOA proceeds via a "push-pull" mechanism rather than a free radical mechanism:

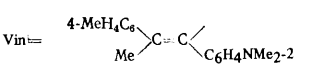


It has been observed that the silver derivative of 17α-ethynyl-17β-hydroxyoestratriene is stable in methanol but disproportionates in aprotic solvents (DMSO, benzene, THF) via the mechanism (R = cyclo-C_5H_9):[36]

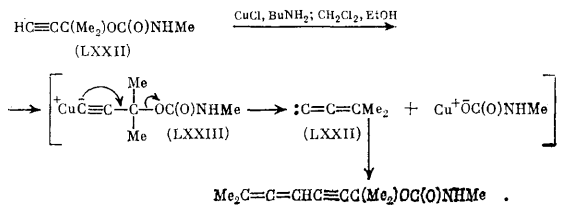
Coppy phenylacetylide reacts with bromocyanogen in an ether–acetonitrile mixture to form PhC≡CCN (yield 60%) and $(PhC{\equiv}C)_2$ (yield 28%); under these conditions, copper methylacetylide is converted into dimethyldiacetylene (yield 65%).[266]

Thiocyanoazulenes react with copper phenylacetylide in dimethylacetamide (DMA) to form thioethynyl derivatives[267]:

R=H (55%), or SCN (2,5%) .



It has been suggested[193] that the catalytic reaction



takes place with participation of the intermediate RC≡CCu.

The formation and decomposition of the COA (LXXIII) are adduced to account for the mechanism of another catalytic reaction[268].

By analogy with stable arylcopper compounds[170], the vinyl complex $Vin_2Cu_4Br_2$ has been recently obtained; by treatment with ArC≡CLi, it was converted into a copper(I) vinylethynyl complex $(VinCu_2C{\equiv}CAr)_n$,[269] where

The structure of this complex should differ from that of the arylethynyl clusters $Ar_4Cu_6(C{\equiv}CR)_2$, which has been proposed by ten Hoedt et al.[25] (Fig. 7) and confirmed by X-ray diffraction data[270].

---o0o---

The data presented in the review show that Group IB metal organoacetylides (in the first place COA) have been firmly incorporated in practical organic syntheses. At the same time the review does not consider numerous instances of the use of COA as homo- and hetero-cuprates, which are widely employed in the synthesis of physiologically active substances (for example, prostaglandins). The reactions of terminal acetylenes and their organoelemental and organometallic derivatives, which take place under the influence of catalytic amounts of copper(I) salts, apparently with participation of COA in a pure form or as cuprates, are of great interest.

It is to be expected that further development of this field of organometallic chemistry will involve a deeper investigation of the mechanisms of the reactions of Group IB metal organoacetylides and the discovery of their new synthetic possibilities.

Plasteins. Their Preparation, Properties, and Use in Nutrition

V.M.Belikov and M.Yu.Gololobov

The theoretical and practical aspects of the plastein reaction, which consists in the formation of a gel following the addition of an endopeptidase to a concentrated solution of a partial protein hydrolysate, are examined and the properties and possibilities of using plasteins in nutrition are discussed in detail. It is shown that valuable protein food products can be obtained with the aid of the plastein reaction from proteins with an unbalanced aminoacid composition and from chemically synthesised amino-acids. Other applications of plasteins in nutrition are discussed and the studies carried out hitherto on the mechanism and driving forces of plastein formation are considered.
The bibliography includes 143 references.

I. INTRODUCTION

One of the most important taks of the food industry at the present time is to provide the rapidly growing world population with balanced food products, in the first place protein food products. The proteins used by man as food must be non-toxic, must be free from toxic or other undesirable impurities, and must have a balanced amino-acid composition, i.e. must contain in the first place the essential aminoacids† in the required amounts and proportions[1,2]. Animal proteins fully meet the above requirements, but the sharp increase in their production necessary to satisfy man's needs encounters many economic and technical difficulties. The task of wide-scale employment of proteins derived from non-traditional sources, for example, from sources of plant or microbiological origin, is becoming increasingly urgent.

However, such proteins usually contain toxic and other undesirable impurities and have an unbalanced aminoacid composition. For a wide-scale employment in man's food of proteins from non-traditional sources, it is necessary, in the first place, to free these proteins from impurities and, in the second place, to balance their aminoacid composition. In order to improve the aminoacid composition, it is as a rule necessary to increase their content of essential aminoacids. From the economic point of view, the use of synthetic aminoacids, which can be obtained in large amounts from cheap raw materials, is of greatest promise[3]. Since the presence of free aminoacids in protein food products has a negative influence on their food value, it is necessary for the added essential aminoacids to be present in the final product in the form of polypeptides consisting of one or different aminoacids. One of the ways of obtaining pure protein products with a high food value from contaminated proteins with an unbalanced aminoacid composition and from chemically synthesised aminoacids involves the use of the so-called plastein reaction.

† The aminoacids which are not synthesised in the human organism and must be supplied as food products are referred to as essential. They include isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Histidine is an essential amino-acid only for children[2].

Almost 100 years ago Denilevskii found that, when gastric juice is added to a concentrated solution of the enzymatic hydrolysate of any protein, an opaque solution is formed after a time and is gradually converted into a gel[4]. Later Zav'yalov suggested that the reaction be referred to as the plastein reaction and that the gel be called plastein[5]. Up to the end of the 1950's, the plastein reaction was regarded as a possible way of synthesising proteins in the human organism, but, after the discovery of the true mechanism of protein biosynthesis[6-9], studies on plastein formation temporarily ceased. Interest in the plastein reaction grew again at the beginning of the 1970's, because in many instances it proved to be convenient for the preparation of food products.

The plastein reaction is most likely to be used for the following practical purposes: (1) purification of proteins and the formation of protein products with the necessary aminoacid composition; (2) the elimination of the bitter taste from enzymatic protein hydrolysates; (3) the preparation of protein pastes and gels with a high food value for use as fillers in various food products and capable of being used independently as food; (4) the preparation of mixtures of peptides with a definite smell, taste, and other characteristics for use as food additives and odorants.

Various aspects of the plastein reaction have been examined in a number of reviews[10-17]. They show that, although the ways for the practical employment of plasteins have already been defined on the whole, much remains obscure, particularly from the theoretical standpoint. The present review has been written to summarise the studies carried out in this field hitherto and to examine the further prospects of the plastein reaction.

II. CONDITIONS AND REAGENTS NECESSARY FOR THE PLASTEIN REACTION

The plastein reaction takes place in solutions of peptides with a molecular weight between 500 and 1500[5,22-30] at a concentration exceeding 10%[18-21] and a pH of the reaction mixture between 4 and 7.[22,23,31-33]

It can probably be now regarded as established that plasteins are obtained when any endopeptidase acts on hydrolysates of virtually any proteins. The hydrolysates can be obtained both by treatment with any endopeptidase and by partial non-enzymatic hydrolysis of protein. The influence of the properties of the enzyme and protein employed on plastein formation will be examined below in the Section devoted to the influence of various factors on the plastein reaction. One should note that the problem of which properties of a particular plastein can be regarded as common to all plasteins and which depend on the method of synthesis of the plastein has not been studied experimentally hitherto.

III. PHYSICAL PROPERTIES AND STRUCTURE OF PLASTEINS

1. The Structure of Plasteins

The structure of plasteins resembles that of denatured proteins. X-Ray diffraction studies on plasteins revealed the presence of linear polypeptides with close-packed chains extended to the maximum extent[23,34]; structures resembling the secondary and tertiary structures of the protein from the hydrolysates of which they have been obtained have not been detected in the plasteins investigated. The fact that the structure of the initial protein is not restored on plastein formation is confirmed by the absence of enzymatic activity in plasteins obtained from pepsin and trypsin hydrolysates[35] and also by the absence of hormonal activity in plasteins obtained from insulin[36]. The immunological activity of certain plasteins can be explained by the entrainment of a certain amount of the active enzyme and of impurities from the initial protein[11,37-40]. Denaturing agents do not affect the solubility of plasteins, which shows that they do not have an ordered structure[41]. A tertiary structure of the type of an α-helix can probably exist only in plasteins enriched in glutamic acid where the content of the latter is 42% against 24% in the initial protein. The circular dichroism spectra of solutions of such plasteins indicate the possibility of the formation of oligomers with an α-helix structure from glutamic acid residues[42]; the circular dichroism spectra of the usual plasteins do not indicate the presence of such structures. It has been suggested at one time that cyclic polypeptides play a major role in the structure of plasteins[43,44]. Such hypotheses have not been put forward in studies devoted to the plastein reaction in recent years.

Thus the data enumerated above suggest that plasteins consist of a conglomerate of intertwined polypeptide chains with different lengths and structures.

2. The Properties of Plasteins

Despite the fact that plasteins differ from the initial proteins in their secondary and tertiary structures, they resemble proteins in many chemical and physical properties. They are cleaved by various proteolytic enzymes such as endopeptidases and exopeptidases[20,25,42,45-47]. Plasteins have the lowest solubility in the region of the isoelectric point and the dependence of their solubility on the pH of the solution is similar to that for the initial protein[48]. The isoelectric point has been determined for plasteins obtained by treating with α-chymotrypsin the pepsin hydrolysate of soya-bean protein. It has been shown by the method of isoelectric focussing that it is located in the pH range between 3.7 and 4.8.[42,48] Isoelectric focussing of plastein enriched in glutamic acid showed that it has several isoelectric zones in the pH range from 1.5 to 4.0. Plasteins obtained from human serum albumin and casein proved to be electrophoretically homogeneous, in contrats to the initial proteins, and their electrophoretic mobility is somewhat lower than that of the initial proteins. Plasteins synthesised from various proteins differ somewhat in their electrophoretic mobilities[43,49-51]. Like proteins, plasteins react with ninhydrin to form coloured compounds, form complexes with Cu^{2+} ions, and are precipitated by typical protein precipitants such as trichloroacetic acid or various dyes[20,44,52-55].

3. The Molecular Weights of Plasteins

The molecular weights of plasteins have been frequently determined by various methods, but the problem of the molecular weight which plasteins can acquire and the factors on which it depends has not been finally solved. The molecular weights and the methods used for their determination are listed in Table 1.

Table 1. Molecular weights of plasteins and methods of their determination.

Molecular weight	Method	Refs.
Hydrolysate 685-1045, plastein 25000	Polyacrylamide gel electrophoresis (PAGE)	22
Plastein < 21000	PAGE	32
Plastein > 1200	PAGE; precipitation with trichloroacetic acid and dyes	41
Hydrolysate 1280, plastein without additives 12050, plastein enriched in glutamic acid 6240	Amino-nitrogen determined by Van Slyke method	42
Plastein < 1000	Ultracentrifugation	44
Plastein 250000-500000	Ultracentrifugation	57
Plastein ~ 5000	Ultracentrifugation	58
Hydrolysate 1550, plastein 5490	Amino-nitrogen determined by the Van Slyke method	59
Plastein without additives 12000, plastein enriched in glutamic acid 6500	PAGE	60
Plastein enriched in methionine 12000	Amino-nitrogen determined by the Van Slyke method	61
Molecular weight remains unchanged on plastein formation	Chromatography on Sephadex	62
Hydrolysate 1089, plastein without additives 2748, plastein enriched in tryptophan 3019, plastein enriched in threonine 2832, plastein enriched in lysine 2791	Amino-nitrogen determined by Van Slyke method	63
Plastein 5000-6000	Amino-nitrogen determined by the copper complex and cryoscopic methods	64 65
Plastein ~ 1000	Ultracentrifugation	66
Plastein 3000	Cryoscopy	67
It has been shown that plasteins do not contain low-molecular-weight peptides in the absence of substrate	Chromatography on Sephadex	68

One should note that the extremely high molecular weights found by Tauber[57] are probably due to the pronounced ability of plasteins to aggregate; as a result of this, one determines the molecular weight of aggregates linked via hydrophobic interactions and not of the polymeric molecules themselves, from which the plasteins are made up[48]. As regards other molecular weights obtained it is difficult to say what factors are responsible for the observed differences. The only regularity is that plasteins enriched in glumatic acid have the lowest molecular weights. Plasteins are polydisperse[58] and it is most

likely that in the majority of cases their molecular weights are in the range from 5000 to 15 000.[41,42,58-61] However, there exist fairly reliable data showing that the molecular weight does not change on plastein formation[42,52,62]. It appears that, under various process conditions, either the polycondensation reaction, which increases the molecular weight, or transpeptidation, in which the molecular weight remains unchanged, predominates.

It is not possible to state exactly at the present time which particular conditions are responsible for the alteration of the plastein formation mechanism, which leads to the formation of plastein specimens with different molecular weights. The factors suggested in various studies as responsible for the change in the mechanism of the plastein reaction will be examined further in the text below.

4. The Aminoacid Compositions and Solubilities of Various Plastein Fractions‡

Plasteins are on the whole sparingly soluble in all the solvents and mixtures investigated. Unfortunately in the majority of the studies the solubility of plasteins was studied only qualitatively. It can be assumed that at approximately pH 4.0 the solubility of plasteins in water is less than 1%.[42] The higher the concentration of the hydrolysate from which the plastein is formed, the greater the weights of the water-soluble fraction[47].

Table 2. Dependence of the solubility of plastein synthesised with pepsin from the pepsin hydrolysate of soya-bean protein on the pH of the solution[48].

pH	A^*_{600}	pH	A_{600}	pH	A^*_{600}	pH	A_{600}
2.0	0.155	4.5	0.307	6.0	0.253	10.0	0.009
4.0	0.294	5.0	0.267	8.0	0.206	—	—

* Turbidimetric determination; A_{600} is the optical density of the plastein suspension at 600 nm.

The solubility of plasteins has been studied as a function of the pH of the solution, its ionic strength, and the concentrations of urea, guanidinium chloride, and sodium dodecyl sulphate[47,48,53,62]. The dependence of the solubility of plasteins synthesised with pepsin from the pepsin hydrolysate of soya-bean protein on pH is illustrated in Table 2. Evidently the plastein investigated has a solubility minimum at pH ~4, i.e. in the region of the isoelectric point[42]. Presumably all plasteins therefore have a solubility minimum at pH 3–4, because the isoelectric points of the majority of peptides are located in this precise region. Data for the solubilities of plasteins in concentrated acids and alkalies are contradictory. It has been shown[20,53] that certain plasteins dissolve in concentrated nitric and hydrochloric acids. On the other hand, there are data indicating the opposite behaviour[24]. Plasteins apparently dissolve more effectively in concentrated alkalies[20,24,50].

It has been noted that the solubility of plasteins depends little on the ionic strength in neutral solutions, increasing only by 40% with increase of ionic strength from 0.1 to 1.[48] However, it is most likely that the dependences of the solubilities of different plasteins on ionic strength are different. The salting out of plasteins from their solutions in 0.025 M aqueous sodium hydroxide following the addition of NaCl has been noted[53]. In certain cases it has been observed that the dependence of the solubility of plasteins on ionic strength is represented by a curve with a minimum corresponding to an ionic strength of 0.5.[78]

Table 3. Aminoacid composition of various plastein fractions obtained with the aid of pepsin from the pepsin hydrolysate of soya-bean protein[41].

Aminoacid	Aminoacid content in given fraction, wt.%*			
	№ 1	№ 2	№ 3	№ 4
Asp	17.92	11.21	5.42	11.83
Glu	37.22	7.21	5.89	14.90
Lys	5.73	6 03	6.65	3.54
Arg	3.25	3 20	1.12	1.76
His	1.10	1.50	0.62	0.87
Met	0.74	1.70	0.95	0.38
Cys	0.73	2.26	1.21	1.34
Trp	0.63	2 47	0.79	1.72
Gly	5.79	5.26	5.10	3.52
Ser	6.93	5.95	4.75	7.24
Thr	2.05	3.72	2.55	2.53
Ala	2.67	4.95	6.02	3.34
Val	2.00	5.39	8.41	4.60
Leu	4.51	16.91	31.00	22.34
Pro	4.84	10.83	7.70	5.39
Tyr	0.63	1.23	1.32	1.84
Ile	1.76	4.40	7.61	5.96

* Fraction No. 1 dissolves in neutral buffer solutions; fraction No. 2 does not dissolve in neutral buffer solutions but dissolves in sodium dodecyl sulphate solution; fraction No. 3 does not dissolve in either neutral buffer solutions or in sodium dodecyl sulphate solution; fraction No. 4 dissolves in 50% aqueous ethanol but does not dissolve in water.

The solubility of plasteins increases markedly in aqueous solutions of urea, guanidinium chloride, and sodium dodecyl sulphate, the effect of a 6 M aqueous solution of urea or guanidinium chloride being equilvalent to that of a 0.002 M aqueous solution of sodium dodecyl sulphate[37,48]. Certain plasteins[62] readily dissolve also in 50% aqueous acetic acid and in 2 M aqueous sodium perchlorate at pH 6–7. The exact mechanism of the action of these solvents on plasteins and proteins is unknown, but it is extremely likely that they decrease the hydrophobic interactions, which promotes the transfer of non-polar aminoacid residues to the aqueous phase[79,81].

‡ The aminoacid compositions of the initial proteins and various plastein fractions, isolated mainly on the basis of their solubilities in water, have been published[19,41,42,48,52,57,63,69-77]. One should note that the term "aminoacid composition of plasteins" is usually understood as the aminoacid composition of the fraction of the plastein formation product isolated in a particular way. The aminoacid composition of plasteins as a whole should not change. When the aminoacid compositions of various plastein fractions are compared, the influence of the method of fractionation on the aminoacid composition of the fraction is as a rule disregarded, which can lead to incorrect conclusions concerning the nature and mechanism of the formation of plasteins.

The increase of the solubility of plasteins under the influence of substances which reduce hydrophobic interactions suggests that plasteins are sparingly soluble in water precisely owing to the hydrophobic properties of their polypeptide chains. Consequently an increase of the content of hydrophobic aminoacids in the water-insoluble fractions should be observed. The data in Tables 3 and 4 show that there is more of hydrophobic aminoacids in the fraction insoluble in sodium dodecyl sulphate solution than in the fraction insoluble in the buffer solution. The content of hydrophobic aminoacids also increases in the fraction soluble in 50% aqueous ethanol but insoluble in water. In other words, the lower the solubility of the plastein fraction in water, the higher its content of hydrophobic aminoacids regardless of the enzyme and the particular hydrolysate used to obtain the plastein. All these findings suggest that a low solubility of plasteins is due to the accumulation of hydrophobic aminoacids in the sparingly soluble fraction[48].

Table 4. Aminoacid composition of the plastein fraction* soluble in 50% aqueous ethanol but insoluble in water (p), relative to the aminoacid composition of the initial hydrolysate (S)[74].

Amino-acid	S	P	P/S
Asp	1.25	0.85	0.69
Glu	1.35	0.84	0.62
Lys	0.87	0.68	0.78
Arg	0.40	0.39	0.98
Gly	1.00	1.00	1.00
Ser	0.76	0.79	1.04
Thr	0.62	0.57	0.92
Ala	1.31	1.32	1.01
Val	0.76	1.18	1.55
Leu	0.91	2.98	3.27
Pro	0.23	0.68	2.44
Phe	0.45	1.39	3.09
Tyr	0.50	0.60	1.20
Ile	0.62	1.15	1.85

*The plasteins were synthesised with the aid of bioprase from the pepsin hydrolysate of baker's yeast protein. The weight content of glycine was assumed to be unity.

A difference in the aminoacid composition is also observed in the fractions separated from the reaction mixture by ultrafiltration or dialysis, i.e. fractions consisting of peptides having a molecular weight higher than a certain definite value. The data in Table 5 show that in this case the test fraction also exhibits an increase of the content of hydrophobic aminoacids and a decrease of that of hydrophilic aminoacids relative to the initial hydrolysate, although the effect is not so marked.

Thus the solubility of any fraction of plasteins is presumably determined primarily by its aminoacid composition, the plastein formation process involving a rearrangement of the aminoacid residues with formation of a sparingly soluble fraction having an increased content of hydrophobic aminoacids. The possibility of a change in the aminoacid composition of the high-molecular-weight fraction of plasteins on addition of ethyl esters of aminoacids to the initial reaction mixtures has been demonstrated. Typical changes in the aminoacid composition in this instance are presented in Table 6. Evidently the aminoacid composition of the high-molecular-weight fraction can change fairly considerably relative to the aminoacid composition of the same fraction of the given plastein obtained in the usual way - without the addition of the ethyl esters of aminoacids to the reaction mixture. The mechanism of this process and the possible ways of employing such plasteins will be discussed in the following Sections. For the moment, we shall merely point out that the specimens of high-molecular-weight fractions of plasteins obtained, which are enriched in glutamic acid, are much more soluble than either the plasteins with the unchanged composition or the initial protein[42].

Table 5. Aminoacid composition of the high-molecular-weight fraction of plastein obtained by treating the papain hydrolysate of zein with papain, relative to the aminoacid composition of the initial protein[63].

Amino-acid	Aminoacid content, wt.%		γ*	Amino-acid	Aminoacid content, wt.%		γ*
	protein	plastein			protein	plastein	
Asp	4.61	3.91	0.85	Ser	4.42	4.28	0.97

*γ is the ratio of the content of aminoacids in the plastein specimen to their content in the protein.

Table 6. The increase in the content by weight (γ) of certain aminoacids in the high-molecular-weight fractions (molecular weight > 500) of plasteins derived from various proteins* when the ethyl esters of the aminoacids are introduced into the reaction mixture[19].

Amino-acid	Number of protein				
	№ 1	№ 2	№ 3	№ 4	№ 5
Lys	—	1.36	1.69	1.37	9.29
Glu	2.80	—	—	—	—
Met	6.76	8.40	6.0	2.79	—
Try	—	1.81	1.94	1.25	—

*Glutamic acid was used in the form of the α, γ-diethyl ester. When the plastein reaction is carried out in the usual way, the content of these aminoacids in the plastein fraction investigated decreases. Proteins from soya (protein No. 1), clover *Trifolium repens* L. (protein No. 2), seaweed *Spirulina maxima* (protein No. 3), bacterial protein from *Phodopseudomonas capsulatis* (protein No. 4), and gluten (protein No. 5) were used.

The data in Table 7 show that the introduction of glutamic acid makes it possible to increase significantly the solubility of plasteins. The solubility of plasteins enriched in glutamic acid is not influenced by heating the solution at 60°C for 30 min, while the solubility of the usual plasteins changes by a factor of three under the same conditions[42]. This indicates a major contribution of hydrophobic interactions to the formation of plasteins[82-84]. The increased solubility and thermal stability of plasteins enriched in

glutamic acid are probably due to their comparatively low molecular weight and the increased content of glutamic acid as a result of which the hydrophobic interactions in such plasteins are greatly weakened.

Table 7. Dependence on the pH of the solution of the solubilites at room temperature of soya-bean protein (A), plastein synthesised with the aid of papain from the pepsin hydrolysate of soya-bean protein (B), and plastein enriched in glutamic acid and obtained from the same hydrolysate with the aid of papain (C). The glutamic acid contents were 24% in (A) and (B) and 42% in (C)[42].

Specimen	Percentage content of nitrogen in solution relative to the total nitrogen of the sample in a 1% mixture at the pH values indicated							
	1	2	3	4	5	6	7	9
A	75.1	80.2	70.3	12.5	18.3	44.4	83.7	97.5
B	90.2	88.5	81.0	75.0	77.2	80.3	83.5	87.4
C	98.1	98.0	97.6	97.5	97.7	98.0	98.3	98.3

5. The Rheological Properties of Plasteins

The rheological properties of plasteins have been studied systematically in relation to the plastein obtained with the aid of bioprase from the pepsin hydrolysate of soya-bean protein[18]. It was shown that the plastein gels obtained are thixotropic and that the rheological properties change in the direction of greater plasticity and elasticity with increase of the initial concentration of the substrate. This supports the view that plasteins are typical coagulation structures[85], i.e. structures obtained as a result of aggregation via van der Waals forces. The main condition for the formation of coagulation structures is an inhomogeneous mosaic structure–the presence of relatively hydrophobic sections of the chain on the surface of the particles coated by solvation shells. Point contacts–primary units of the structure–arise on these hydrophobic sections. Indeed studies have shown that hydrophobic forces are in fact the cause of gel formation when plasteins are synthesised[41,48].

Thus the gel formation reaction in the preparation of plasteins belongs to the third class of solution–gel transitions[86]. This class of transitions includes processes in which a gel is formed as a result of the loss of solubility by the dissolved substance on altering the temperature or the solvent or when a chemical reaction takes place. In the initial substrate solution all the species are hydrated. A chemical reaction results in the formation of species which exhibit a smaller tendency towards hydration, which makes their aggregation a thermodynamically favourable process as a result of the increase of the entropy of the system[82,83,87].

It follows from the rheological properties of the plastein specimens obtained at different initial substrate concentrations that the most cross-linked structure is observed for specimens obtained from a 35% solution of the hydrolysate[18]. On further increase of substrate concentration, the plastein reaction product solidifies and begins to exhibit the properties of condensation-crystallisation structures[85]. The great strength of the structures obtained from substrate solutions at an initial concentration in excess of 35% is confirmed by the finding that such specimens do not separate into layers with liberation of water even on centrifugation for 30 min at 6500 g at room temperature[18,88]. It is of interest that the plastein gels obtained hardly manifest the phenomenon of syneresis.

The relative viscosities of various plastein specimens have been investigated as a function of their concentration in solution or suspension[18]. The results of the study of the relative viscosities of 5% suspensions of specimens are presented in Table 8. The viscosity of the P-10 specimen is lower than that of the hydrolysate, which suggests that, at a substrate concentration of 10%, the substrate undergoes appreciable hydrolysis and this entails a decrease of viscosity. The sharp fall of the viscosity from the P-35 to the P-45 specimen is apparently a consequence of a qualitative rearrangement of the plastein structure from the coagulation type to the condensation-crystallisation type at an initial substrate concentration in excess of 35%.

Table 8. Relative viscosities η of a 5% solution or suspension of soya-bean protein, the pepsin hydrolysate of soya-bean protein, and various specimens of plasteins obtained from the pepsin hydrolysate of soya-bean protein with the aid of bioprase[18]*.

Specimen	Hydrolysate	Soya-bean protein	P-10	P-20	P-25	P-30	P-35	P-45
η	13	33	9.3	12.5	15	15.8	19	14

*Specimens of plasteins obtained from hydrolysates with initial substrate concentrations of 10, 20, 25, 30, 35, and 45% were investigated. The specimens were designated by P-10, P-20, P-25, P-30, P-35, and P-45 respectively.

In order to understand the driving forces of the plastein reaction, we shall consider how important is the formation of a precipitate and a gel on plastein formation from the thermodynamic standpoint. The thermodynamics of the plastein reaction is influenced solely by the properties of the peptides constituting the substrate, because the enzyme is added in an amount such that it cannot influence significantly the equilibrium position in the system. Comparatively few studies have been made on the thermodynamics of the peptide bond[89-96]. Unfortunately, owing to experimental difficulties, only the thermodynamic parameters of protected dipeptides and certain aminoacid derivatives have been investigated. It can be shown that the hydrolysis of a protected dipeptide is a satisfactory model, from the thermodynamic point of view, of the hydrolysis of a long peptide, which does not alter the ionisation constants of the terminal ionogenic groups. As will be shown in the Section devoted to the influence of the length of the substrate peptide on plastein formation, the synthesis and hydrolysis of peptides of precisely this length occur in the plastein reaction. It has been found that the change in the standard free energy in the hydrolysis of a long polypeptide to shorter peptides is negative and amounts to between -0.5 and 1.5 kcal mole^{-1}. If it is assumed that a mixture of peptides with an average molecular weight of 1000 is used as the substrate and that the concentration of the substrate in the reaction mixture is 50%, then the molar concentration of the substrate is 0.5 M. Taking into account the above standard free energies of hydrolysis, it

is easy to show by calculation that the reaction mixture will contain between 2 and 12% of the dimers of the initial peptides. Clearly the content of peptides with a high degree of polymerisation will be altogether negligible.

Thus the decrease of the free energy of the system on plastein formation cannot be due to the formation of new peptide linkages in concentrated solutions of protein hydrolysates. Consequently the main driving force of plastein formation is the increase of the entropy of the system, which occurs when the hydrophobic aminoacid chains, formed by a rearrangement of the aminoacid residues of the initial peptides, aggregate. Unfortunately a comparison of the aminoacid sequences of the peptides constituting the substrate and the plastein has not so far been made in any instance of plastein formation.

Thus, despite the fact that the rheological properties of plasteins have been investigated for a very limited number of specimens, the studies which have been carried out not only permit the determination of the possible ways of the practical employment of plasteins (see Section VI) but also definite conclusions concerning the driving forces in plastein formation and the structure of plastein molecules.

IV. THE INFLUENCE OF VARIOUS FACTORS ON PLASTEIN FORMATION

For a correct assessment of the influence of various factors on plastein formation, it is necessary to know precisely whether the system is or is not in a state of thermodynamic equilibrium at the instant of measurement. It is still not clear whether the yields of the plastein reactions refer to equilibrium conditions. It has been shown in some studies that the process parameters cease to change with time after 6–8 h,[48] whilst the others it is stated that this requires 2–3 days[73]. No regularities have so far been observed as regards this problem. Nor is it known whether all the system parameters cease to change simultaneously, for example, parameters such as turbidity, molecular weight, amount of the given fraction precipitated from a 10% solution of trichloroacetic acid, etc. However, even if it were known that all the parameters cease to vary at a certain instant, there is still a possibility that the system is then at a local free energy minimum and that the activation barrier to further transformation is very high, i.e. the system is not in a state of equilibrium but is kinetically inhibited. For these reasons, the concept of the yield of the plastein reaction is better replaced by the concept of the efficiency of the plastein reaction, implying by this term the degree of plastein formation under certain specified conditions with respect to the given parameter.

1. Dependence of the Efficiency of Plastein Formation on the Characteristics of the Protein Employed

The efficiency of plastein formation has been investigated[97] as a function of the protein used to prepare the pepsin hydrolysate as the substrate. The efficiency of plastein formation was estimated from the amount of plastein precipitated in a 10% solution of trichloroacetic acid. The experiments were performed at a substrate concentration of 20% and a concentration of α- chymotrypsin, used to synthesise the plastein, of 0.1%. The mixture was incubated for 24 h at 37° C and then a solution of trichloroacetic acid was added at a concentration such that the final concentration was 10%. Under these conditions, the degree of plastein formation from the hydrolysates of different proteins is as follows: 94% for soya-bean protein, 58% for cod protein, 61% for a 9 : 1 mixture of cod and soya-bean proteins, 54% for chlorella protein, 80% for gluten, 35% for casein, 65% for baker's yeast protein, and 93% for petroleum yeast protein.

As stated above, the formation of the water-insoluble fraction is one of the main driving forces in the plastein reaction. Hydrophilic substrates do not form plasteins in high yields, because the products of the plastein reaction are then soluble and are difficult to remove from the system[97,98]. Thus attempts to synthesise plasteins from a highly hydrophilic protein (gelatin) were unsuccessful[53,98]. On the other hand, if the hydrolysate is too hydrophobic, the product is readily precipitated before the plastein formation reaction reaches an advanced stage[63].

Table 9. Dependence of the efficiency of plastein formation on the molecular weight of the substrate[22].

Molecular weight	Percentage content of fraction precipitated with 10% trichloroacetic acid after incubation		Molecular weight	Percentage content of fraction precipitated with 10% trichloroacetic acid after incubation	
	with enzyme	without enzyme		with enzyme	without enzyme
>1043	6.6	3.3	685	33.2	0.0
1043	23.0	0.0	<685	0.0	0.0

It has been shown[99] that, knowing the yield of the plastein reaction with respect to the high-molecular-weight fraction of the hydrolysates of individual proteins, it is possible to predict the component ratio for which the yield of the plastein reaction with respect to the high-molecular-weight fraction will be a maximum. For this purpose the parameter β/α was introduced, β being the degree of insolubility of the plastein, defined as the ratio of the nitrogen insoluble in 20% aqueous acetone solution to the overall nitrogen content in the plastein and α the yield of the plastein reaction, defined as the ratio of the amount of nitrogen precipitated in 10% trichloroacetic acid solution to the overall nitrogen content in the plastein.

It has been shown in relation to extensive experimental data that, whatever the substrates or their mixture, the plot of the yield of the plastein reaction with respect to its high-molecular-weight fraction against the parameter β/α is bell shaped with a mixmum at $\beta/\alpha \simeq 0.5$. The dependence of the parameter β/α on the ratio of the contents (by weight) of the two substrates is then linear. Thus the ratio of the substrates in the mixture for which the plastein reaction has a maximum yield with respect to the high-molecular-weight fraction can be calculated from the formula

$$x/y = \frac{0.5 - \beta/\alpha\,(x)}{\Delta\beta/\alpha},$$

where x/y is the ratio of the weight fractions of the two substrates, $\beta/\alpha(x)$ the value of the parameter β/α for the substrate x, and $\Delta\beta/\alpha$ the difference between the values of the parameter β/α for the substrates x and y.

Thus, when the parameter β/α is used, it is possible to select a mixture of substrates giving the maximum yield of the plastein reaction with respect to the high-molecular-weight fraction.

2. The Influence of the Structure of the Substrate on the Efficiency of Plastein Formation

We shall now consider the requirements which must be met by the peptides in the substrate in order that plastein formation should be successful to the maximum extent.

The efficiencies of the fractions of soya-bean hydrolysate of different molecular weight in the plastein reaction have been compared[22]. The initial concentration of the substrate was 35% and the ratio of the weight concentrations of subtilisin BPN' and the substrate was 0.01. The reaction mixture was incubated for 24 h at 37° C. The intensity of plastein formation was estimated from the amount of precipitated fraction in 10% trichloroacetic acid solution. The results of the study are presented in Table 9, which leads the conclusion that plastein formation takes place most effectively in the system containing peptides consisting of 5–8 aminoacid residues[5,22–24]. In addition, it was found that the plastein reaction proceeds most effectively when the degree of hydrolysis of the initial protein is such that 20% of the hydrolysate (by weight) is precipitated in 10% trichloroacetic acid solution[10,15,25]. The synthesis of plasteins and peptides from pure aminoacids was unsuccessful[26,27]. The fact that free aminoacids do not participate in the plastein reaction has been confirmed by numerous experiments, which have demonstrated the impossibility of enriching the plastein in aminoacids when the latter are introduced into the reaction mixture in a free state[52,94] and also by the fact that the plastein is formed more successfully from the non-dialysable fraction of the protein hydrolysate[52].

There exists a view that, with increase of the molecular weight of the substrate, the mechanism of plastein formation changes from polycondensation to transpeptidation[23]. One of the incomprehensible features of the plastein reaction is the nature of the change of the content of amino-nitrogen in the reaction mixture when plasteins are formed. It was noted that, in the process investigated, the amount of primary amino-groups can decrease[47,64], increase[25,62], remain unchanged[52,101], and pass through a minimum[23,32,68]. It is very likely that, when 5–8-membered peptides are used, a polycondensation reaction, accompanied by a decrease of the content of primary amino-groups in the reaction mixture, takes place.

Subsequently, after the attainment of a critical length of the peptides, mainly a rearrangement of the aminoacid residues occurs with formation of sparingly soluble peptides and the liberation of freeamino acids and low-molecular-weight peptides[23,73]. As a result of this, the content of primary amino-groups in the reaction mixture increases. It may be that the contradictory data concerning the changes in the content of amino-nitrogen on plastein formation can be accounted for by using substrates of different molecular weight.

The problem of which aminoacids should make up the peptides in order that plasteins can be formed from the latter is very interesting. In the previous section it was stated that proteins should be moderately hydrophobic in order to produce hydrolysates capable of giving rise to plasteins in a high yield. Plastein-active peptides were first identified by Determann and coworkers[102–104], who showed that the peptides forming the plastein under the influence of pepsin and α-chymotrypsin have the following structure:

H—Met—Thr—Leu—Leu—(Leu, Thr, Val)—Thr—Ser—Met—Leu—OH
H—Tyr—Ile—(Glu, Gly, Phe)—(Glu, Ile)—Phe—OH
H—Tyr—(Asp, Val)—Glu—Glu—Ile—OH
H—Ile—Asp—Val—Glu—Glu—Ile—OH

The structure of these peptides shows that the efficiency of plastein formation is determined primarily by the terminal aminoacid. This hypothesis was first put forward by Virtanen et al.[51].

In order to establish a relation between the structure of peptides and their ability to form plasteins, studies were performed using as substrates various peptides having a definite structure[24,28–30,105,106]. The plastein reaction was carried out with the aid of pepsin at pH 4.0 and chymotrypsin at pH 8.6. A 25–50% solution of the substrate, incubated with the enzyme at 37° for 24 h, was used. The high-molecular-weight fractions of the plasteins were separated by centrifugation or were precipitated with trichloroacetic acid. The plasteins obtained under the influence of pepsin have a molecular weight of ~2250 with an average degree of polymerisation of 2.5, which was established by the photometric determination of the amount of terminal aminoacid residues in the form of dinitrophenyl derivatives[30]. The authors explain the low degree of polymerisation by the poor solubility of the resulting plasteins. It was found that, under the above conditions, plasteins are formed by peptides having the following structure[29]:

H—L—Tyr—L—Leu—Gly—L—Glu—L—Phe—OH
H—L—Tyr—L—Leu—Gly—D—Glu—L—Phe—OH
H—L—Tyr—L—Leu—Gly—L—Val—L—Phe—OH
H—L—Tyr—L—Leu—Gly—L—Lys—L—Phe—OH
H—L—Tyr—L—Ile—Gly—L—Lys—L—Phe—OH
H—L—Tyr—L—Lys—Gly—L—Glu—L—Phe—OH
H—L—Tyr—L—Lys—Gly—L—Lys—L—Phe—OH
H—L—Tyr—L—Leu—Gly—L—Glu—L—Tyr—OH
H—L—Tyr—L—Leu—Gly—L—Glu(NH_2)—L—Tyr—OH

On this basis, it was concluded that aminoacid residues located in the centre of the peptide chain have no influence on the plastein reaction catalysed by pepsin and chymotrypsin. It is also unimportaint whether the peptide is basic, neutral, or acid.

The influence of chain length and of the nature of *N*- and *C*-terminal aminoacid residues on the plastein reaction has been investigated[24]. For this purpose, the following peptides were synthesised:

H—Ala—Leu—Gly—Glu—Phe—OH
H—Tyr—Leu—Gly—Glu—Ala—OH
H—Ala—Leu—Gly—Glu—Ala—OH
H—Tyr—Leu—Ala—Glu—Glu—Phe—OH
H—Tyr—Leu—Glu—Phe—OH
H—Tyr—Glu—Phe—OH

It was found that, for a peptide to be capable of involvement in the plastein reaction catalysed by pepsin or chymotrypsin, it is necessary that it should have hydrophobic *C*-terminal aminoacids and should consist of at least four aminoacid residues.

Thus two main requirements must be met by the substrate of the plastein reaction when the plastein is synthesised with the aid of pepsin or chymotripsin: it must consist of peptides formed from 5–8 aminoacid residues and in addition the aminoacid residues at the ends of these peptides should be hydrophobic. The possible reason why the plastein reaction takes place most successfully with peptides of a definite length is as follows. According to the thermodynamics of the peptide linkage, the polycondensation of peptides is thermodynamically more favourable than the polycondensation of aminoacids[89–96]. However, in solutions of peptides at identical weight concentrations the concentration of amino- and carboxy-groups is lower the higher the molecular weight of the substrate. In solutions

of peptides consisting of 5–8 aminoacid residues there is probably, on the one hand, still a fairly high concentration of amino- and carboxy-groups and, on the other, the formation of a peptide linkage between such peptides is already more favourable than between aminoacids. The fact that plastein formation requires the presence of hydrophobic aminoacids at the ends of polypeptides can be accounted for by two causes. Firstly, the thermodynamics of the peptide linkage can be such that the bond formed by hydrophobic aminoacids is thermodynamically most favourable. One can hardly expect a large difference between the thermodynamic parameters of the bonds formed by different aminoacids[89-96]; at the same time, it is known that the majority of proteolytic enzymes exhibit a greater or smaller specificity with respect to hydrophobic aminoacids[107,112]. It is therefore most likely that the limitations imposed on the structure of plastein-active peptides are due to the specificity of the enzymes employed. This hypothesis is supported by the fact that trypsin, the enzyme which hydrolyses and synthesises solely bonds formed by the carboxy-groups of lysine and arginine[113], does not exhibit a plastein-forming activity[114]. Nor is it possible to obtain plasteins from hydrolysates produced under the influence of trypsin[115].

3. The Influence of Substrate Concentration on Plastein Formation

The dependence of the efficiency of plastein formation on substrate concentration has been studied[18] using different enzymes. Plasteins were synthesised from the pepsin hydrolysate of soya-bean protein at substrate concentrations of 5, 10, 20, 30, 40, and 50% and for enzyme and substrate concentration ratios (by weight) in the range 0.01–0.03. The reaction mixture was incubated for 24 h at 37°C. The following enzymes were used: chymotrypsin, pepsin, coronase, bioprase, and molsin. The pH of the reaction mixture was maintained at values indicated by Yamashita et al.[114]. The efficiency of plastein formation was estimated from the weight of the fraction precipitated with a 10% solution of trichloroacetic acid. It was shown that in all cases the yield of plastein has a maximum at a substrate concentration between 30 and 40%. At substrate concentrations less than 6–8%, the substrate hydrolyses[18,19].

Analogous results were obtained in studies[23,44] involving the formation of plastein under the influence of pepsin from a pepsin hydrolysate of zein and in studies[20,21] on the preparation of plastein under the influence of pepsin and papain from the pepsin and papain hydrolysates of egg protein. According to modern views on the mechanism of plastein formation, the conclusion that the optimum substrate concentration for plastein formation is 30–40% and that plastein formation does not occur at a substrate concentration below 6–8% is probably common to plasteins obtained from any proteins under the influence of any enzymes.

4. The Influence of the Enzyme and Its Concentration on the Efficiency of Plastein Formation

As already mentioned, a very large number of proteolytic enzymes of different origin have been used in the plastein reaction. The only feature which these enzymes have in common is that they are all endopeptidases. The efficiencies of plastein formation under the influence of various enzymes have been compared systematically[97]. The data compiled in Table 10 show that α-chymotrypsin is most effective in the plastein reaction, while other enzymes are less effective. One should note that the efficiencies of plastein formation listed in Table 10 for a series of enzymes (for example papain and pepsin) conflict with the wide use of these enzymes for the preparation of plasteins.

Table 10. Comparative efficiencies* of various enzymes in the plastein reaction[97].

Enzyme	Yield of plastein, %	Enzyme	Yield of plastein, %
Endopeptidases:		Microbiol proteases:	
α-chymotrypsin	95.0	bioprase	85.5
bromelain	29.0	coronase	52.1
papain	26.8	molsin	21.3
pepsin	20.0	pronase	36.3
trypsin	21.9	prozime	77.0
Exopeptidases:		rapidase	20.0
aspergillocarboxypeptidase	20.0	thermoase PC-10	32.3
carboxypeptidase A	26.5		20.0
leucine aminopeptidase	22.1		

*The plasteins were synthesised from the pepsin hydrolysate of soya-bean protein. The efficiency of plastein formation was estimated from the weight of the plastein fraction precipitated in 10% trichloroacetic acid solution.

The absence of plastein-forming activity in exopeptidases can be explained by the fact that the linkage between peptides is thermodynamically more favourable than the linkage between a peptide and an aminoacid. The different plastein-forming activities of different endopeptidases can be explained only by the fact that at the instant of the measurement the yield of the plastein reaction is still far from equilibrium, because the enzyme, acting as a catalyst, cannot influence the equilibrium position in the system. The reason for the absence of plastein-forming activity of trypsin was examined above.

The influence of enzyme concentration on the efficiency of plastein formation has been studied[20,31,33,47,53]. It was shown that, firstly, in the plastein reaction the enzyme concentration can be approximately the same as the hydrolysis of proteins – up to 1 wt.%, and secondly, that the efficiency of plastein formation depends only very slightly on the enzyme concentration. Thus with increase of the concentration of the enzyme (pepsin) from 0.1 to 8%, the amount of the plastein fraction derived from the pepsin hydrolysate of egg albumin and insoluble in the reaction mixture increases from 13.1 to only 33.3%.[53] In a study of the synthesis of plastein by this procedure[31] a relation was found between the weight of the insoluble fraction and the weight of the enzyme employed: $P = 13.9E^{0.213}$, where P is the weight of the plastein fraction obtained and E the weight of the enzyme employed. An analogous result was obtained in a study[47] where plastein formation from the pepsin hydrolysate of zein under the influence of pepsin was investigated. The efficiency of plastein formation was estimated in this instance from the decrease of the content of amino-nitrogen, determined by the copper complex method[116].

The influence of enzyme concentration on the rate of plastein formation was hardly considered. It has only been stated in one study[20] that the rate of the plastein reaction, determined as the increase with time of the amount of nitrogen precipitated from a 2.5% solution of trichloroacetic acid, is proportional to the square root of enzyme concentration.

Substances which inhibit the activity of the enzyme employed retard or altogether terminate plastein formation[20,25,78,117].

When the influence of enzymes on the plastein reaction is considered, the following factors must be taken into account. It is known that all enzyme preparations contain a certain amount of inactive protein; the concentration of enzymes in solution, found from their weight concentrations, does not therefore represent their true concentration (normality) in solution. In order to determine the normality of enzyme solutions, it is necessary to find the concentrations of their active centres. However, no studies have been made on plastein formation with enzymes of known normality.

5. Dependence of the Efficiency of Plastein Formation on the pH of the Reaction Mixture

The dependence of the efficiency of plastein formation on the pH of the reaction mixture has been studied[22,23,31-33] The dependence of the plastein reaction on the pH of the solution was first investigated for the plastein synthesised using pepsin from the pepsin hydrolysate of egg albumin[31]. The efficiency of plastein formation was determined from the weight of the filtered fraction. It was shown that in this case the insoluble plastein fraction is formed most effectively at pH 4.0. The same pH optimum was found for the plastein reaction catalysed by pepsin[23].

The pH dependence of the rate of plastein formation from a pepsin hydrolysate of soya-bean protein has been investigated for different enzymes[22,32,73]. The rate of plastein formation was determined from the increment in the fraction precipitated in a 10% solution of trichloroacetic acid along the linear section of the kinetic curve. It was shown that, whereas the optimum in the hydrolytic effect of the enzymes employed is in the pH range from 2 to 11, the optimum for plastein formation using the same enzymes is the pH range between 3 and 7 and for the majority of enzymes between 4 and 6. Thus it was found that the optimum pH for the hydrolysis of α-chymotrypsin is 8.0 and that for plastein formation is 5.3. If the difference between the optimum pH values for plastein formation and hydrolysis is denoted by Δ pH then all the enzymes investigated can be divided into three groups: the pepsin type with $\Delta\,\mathrm{pH} > 0$, the chymotrypsin type with $\Delta\,\mathrm{pH} < 0$, and the papain type with $\mathrm{pH} = 0$. Trypsin, which does not exhibit a plastein-forming activity over the entire pH range, constitutes an exception. The values of Δ pH are as a rule greater for enzymes belonging to the chymotrypsin type.

However, there are data showing that chymotrypsin is most effective in the plastein reaction at pH 7.3.[57] The efficiency of plastein formation was estimated in this case from the weight of the filtered fraction. The cause of this discrepancy between the data of different workers remains obscure. Despite this, the fact that the dependence of the efficiency of plastein formation on pH does not coincide with the corresponding pH dependence of the hydrolysis of proteins for all the enzymes investigated leads to the conclusion that the ionic nature of the substrate is an important factor influencing the formation of plasteins.

6. The Influence of Temperature on Plastein Formation

The study of the influence of temperature on plastein formation showed that the weight of the fraction insoluble in the reaction mixture and in 10% trichloroacetic acid solution increases appreciably up to the enzyme denaturation temperature at 60–65°C [29,33,118,119]. The causes of the change in the yield of the plastein reaction when the temperature is altered are not entirely clear. It has been suggested[118] that it is due to the extremely low free energy of the synthesis of polypeptides in the plastein reaction. In the light of present knowledge about the mechanism of plastein formation and its thermodynamics, this explanation is hardly valid. The reason is most probably that an increase of temperature to 55–60°C entails an increase of the energy of the hydrophobic interactions[82,83] responsible for the formation of the gel in the plastein reaction, which leads to an increase of the amount of the fraction sparingly soluble in water.

7. The Influence of the Ionic Strength of the Solution on Plastein Formation

The ionic strength of the solution can influence plastein formation either by altering the activity of the enzyme employed or by affecting the solubility of plastein and desplacing thereby the equilibrium position in one direction or another. The importance of ionic strength in plastein formation is indicated by the finding that the possibility of the formation of gels has been demonstrated on treating a 4% solution of the pepsin hydrolysate of egg albumin at pH 7.3 with chymotrypsin, provided that the solution contains 26% NaCl.[49] As already stated, without the addition of NaCl, plasteins are not formed at this substrate concentration.

A detailed study of the influence of ionic strength on the rate of plastein formation has been carried out in relation to the formation of plastein from egg albumin obtained with the aid of α-chymotrypsin and neutral bacterial protease resistant to the action of high salt concentration[78]. It has been found that different salts act on plastein formation in different ways at a concentration of 1 M. The strength of their influence increases with increase of the charge of the salt cation. The addition of sodium, potassium and lithium chlorides increases the rate of plastein formation by 10%, while the addition of iron, aluminium, and zinc chlorides to the reaction mixture reduces the rate of the plastein reaction by 80–95%. The dependence of the rate of plastein formation on ionic strength, established with the aid of NaCl when α-chymotrypsin is used, is represented by a curve with two maxima of approximately equal height (20–30%) at ionic strengths of 0.1 and 0.8; after the second maximum, there is a sharp decrease of the rate of plastein formation. When a protease which does not lose its activity in concentrated solutions was used, it was shown that the rate of plastein formation increases with increasing ionic strength and that in 3 M NaCl solution it increases by a factor of 2 relative to the initial value.

These studies, combined with studies of the dependence of the activity α-chymotrypsin on the solubility of the plasteins obtained in NaCl solutions at different concentrations, suggest that ionic strength acts on the rate of plastein formation via different mechanisms at different salt concentrations. At low salt concentrations the rate of plastein formation increases owing to the increase of the activity of the enzyme. At high salt concentrations plastein is salted out, which promotes an increase of the rate of its formation, but the enzyme can then lose its activity. If the enzyme does not lose its activity, the rate of the plastein reaction increases; if the enzyme is inactivated, the plastein is formed at a lower rate.

V. INCORPORATION OF VARIOUS AMINOACIDS IN PLASTEINS

The problem of the possible alteration of the aminoacid composition of high-molecular-weight fraction of plasteins in a desired direction has been studied on a fairly wide scale[12,42,52,60,61,63,70,71,100,120-124]. The possibility of increasing the content of all the essential aminoacids in the high-molecular-weight fraction relative to their content in the initial protein was demonstrated. The enrichment can occur on both laboratory and semi-industrial scales[120]. It has been shown that free aminoacids are virtually not incorporated in plasteins[42,52,100,121]. For the successful introduction of a particular aminoacid into a plastein, it is necessary to use aminoacid derivatives. The data in Table 11 show that the amount of the high-molecular-weight fraction of plasteins does not change when different enzymes are used for their synthesis, but the menthionine content in the resulting plastein depends significantly on the enzyme employed. Evidently different methionine derivatives have significantly different abilities to increase the content of this aminoacid in a plastein. Methionine is not incorporated at all if the amino-group is protected by the acetyl group. The incorporation of methionine into a plastein takes place somewhat more successfully if methionineamide is used as the source of the aminoacid.

Table 11. Efficiency of plastein formation and of the incorporation of methionine into plasteins synthesised with the aid of various enzymes using different sources of methionine*.

Enzyme	Yield of plastein reaction	Methionine content in the plastein fraction investigated (in wt.%) after addition of the following methionine derivatives into reaction mixture:				
		Met	AcMet	$MetNH_2$	MetOEt	Met—Met
—	—	1.15	1.44	1.57	2.10	1.50
Ficin	71.68	1.05	1.47	1.32	—	—
Molsin	68.30	1.18	1.53	2.09	3.87	2.70
Nagarse	75.00	1.20	1.22	3.12	7.22	5.10
Papain	78.20	1.15	1.32	1.43	—	—
Pronase	70.10	1.25	1.22	1.25	1.23	1.27
—	—					

*The yield of plastein was determined relative to the non-dialysable fraction of the total mixture by weight.

This shows that the amino-group of the incorporated aminoacid is directly involved in the reaction when methionine is incorporated into a plastein. The methionine content in the plastein increases appreciably when dimethionine and particularly the ethyl ester of methionine are used as the source of methionine. This shows that, although the carboxy-group of the aminoacid is not directly involved in the reaction, its preservation in an active form is essential for the successful incorporation of methionine in a plastein.

From the practical point of view, the possibility of enriching the high-molecular-weight fraction of plasteins in glutamic acid is of considerable interest[123]. Studies have been undertaken on the comparative efficiencies of various glutamic acid esters as a source of glutamic acid in the plastein reaction catalysed by papain[42]. The results of the investigations are presented in Table 12, which shows that the glutamic acid content in the high-molecular-weight plastein fraction can be greatly increased by employing the hydrophobic α,γ-diethyl ester as the source of the aminoacid. The hydrophobic nature of the diethyl ester is almost the same as that of leucine[12].

Table 12. Comparative efficiencies of the employment of various glutamic acid esters as sources of glutamic acid in the plastein reaction catalysed by papain[12]*.

L-Glutamic acid and its esters	Yield, wt.%		Glutamic acid content, wt.%
	w.r.t. hydrolysate	w.r.t. substrate	
Glu-α,γ-OEt_2	95.7	63.8	41.93
Glu-α-OEt	54.3	36.3	32.18
Glu-γ-OEt	58.1	38.7	25.34
Glu	56.9	37.9	25.00
—	60.0	60.0	24.81

*Hydrolysate = pepsin hydrolysate of soya-bean protein; substrate = 2 : 1 mixture (by weight) of hydrolysate and glutamic acid derivative.

In order to investigate the enrichment in lysine of the plastein derived from the pepsin hydrolysate of gluten, synthesised with the aid of papain, a study was made of the influence of the ratio of the weight concentrations of the ethyl ester of lysine and the gluten hydrolysate on the effectiveness of the incorporation of lysine in the plastein. It was found that the maximum degree of incorporation of lysine is reached for a 1 : 2 ratio of the concentrations of the ethyl ester of lysine and the gluten hydrolysate[19]. Similar studies on the enrichment of plasteins in other aminoacids have not been made, but in most investigations the above ratio of the weight concentrations of the aminoacid ester and the protein hydrolysate was in fact used.

A study was made of the dependence of the rate and degree of incorporation of various aminoacids, added to the reaction mixture as aliphatic alcohol ethers of various structure, in plasteins whose formation was catalysed by papain[19,70]. It was found that, when use was made of derivatives of aminoacids with respect to which papain is non-specific (glycine, alanine), the amount of aminoacid ethyl ester incorporated in the plastein increases linearly with the plastein formation reaction time in the presence of the aminoacid ester, amounting to 20% of the total quantity of ester employed in the reaction after 6 h. When the ethyl esters of aminoacids to which papain is specific (L-α-aminobutyric acid, norvaline, norleucine) are used, the incorporation of the aminoacids under virtually the same conditions terminates 2 h after the start of plastein formation; under these conditions, between 50 and 80% of the initial amount of the aminoacid ester is involved in the reaction. The degree of plastein formation after 2 h is only 50%. A distinct correlation has been found between the hydrophobic properties of the side chain of the aminoacids and the rate of their incorporation in the plastein when their ether esters are used. The degree of incorporation of glutamic acid, employed in the form of its diether ester, is the same as for norleucine. Aminoacids branched in the β-position (valine and isoleucine) constitute an exception. For a successful incorporation of the aminoacid, the alcohol with which it is esterified must have an unbranched structure. This requirement is particularly important when aminoacids with respect to

which papain is non-specific are incorporated. The incorporation of any aminoacid is faster the longer the aliphatic chain of the alcohol esterifying the aminoacid. Methionine is linked to the plastein polypeptide chains via peptide bonds[122] and this does not entail the formation of sections of chains consisting exclusively of methionine residues. D-Aminoacids are never incorporated in the plastein.

Thus the structure of the side chain of aminoacids influences primarily the degree and rate of their incorporation in the plastein. The structure of the alcohol esterifying the aminoacid has a smaller influence. The following remarks may be made concerning the mechanism of the incorporation of methionine. Analysis of the terminal amino-groups of the plastein molecules enriched in methionine showed that the methionine residue is located mainly close to the *C*-end of the polypeptide chain of the plastein molecule[61,122]. A three-stage mechanism of the catalysis, involving the formation of an acyl derivative of the enzyme, may be regarded as demonstrated for papain[125]. In this case the similarity of the distribution of methionine residues suggests that the incorporation of methionine in the polypeptide chain involves the formation of a peptidyl derivative of the enzyme, which undergoes nucleophilic attack by the amino-group of the esterified methionine with liberation of free papain and the elongation of the chain by one methionine residue. Subsequently the alcohol molecule is split off and the process can be repeated. Esterification of the carboxy-group promotes in this instance the enhancement of the nucleophilic properties of the methionine amino-group. Any modification of the carboxy-group, for example, the conversion of methionine into the amide of the formation of a dipeptide, has a similar influence on the reactivity of the methionine amino-group, but alcoholic groups are readily split off, which permits the repetition of the process. An alternative mechanism involves the formation of methionine-papain and nucleophilic attack by the peptide amino-group.

The first mechanism, involving the formation of a peptidyl derivative of the enzyme, is supported also by the distribution of the methionine residues preferentially at the *C*-end of the peptide chains and the absence of the incorporation of methionine in the chain when methionine derivatives with a protected amino-group are used as a source of methionine. The same mechanism of the addition of methionine is also supported by the finding that no free methionine, which would have been formed inevitably as a result of the hydrolysis of methionine-papain, has been

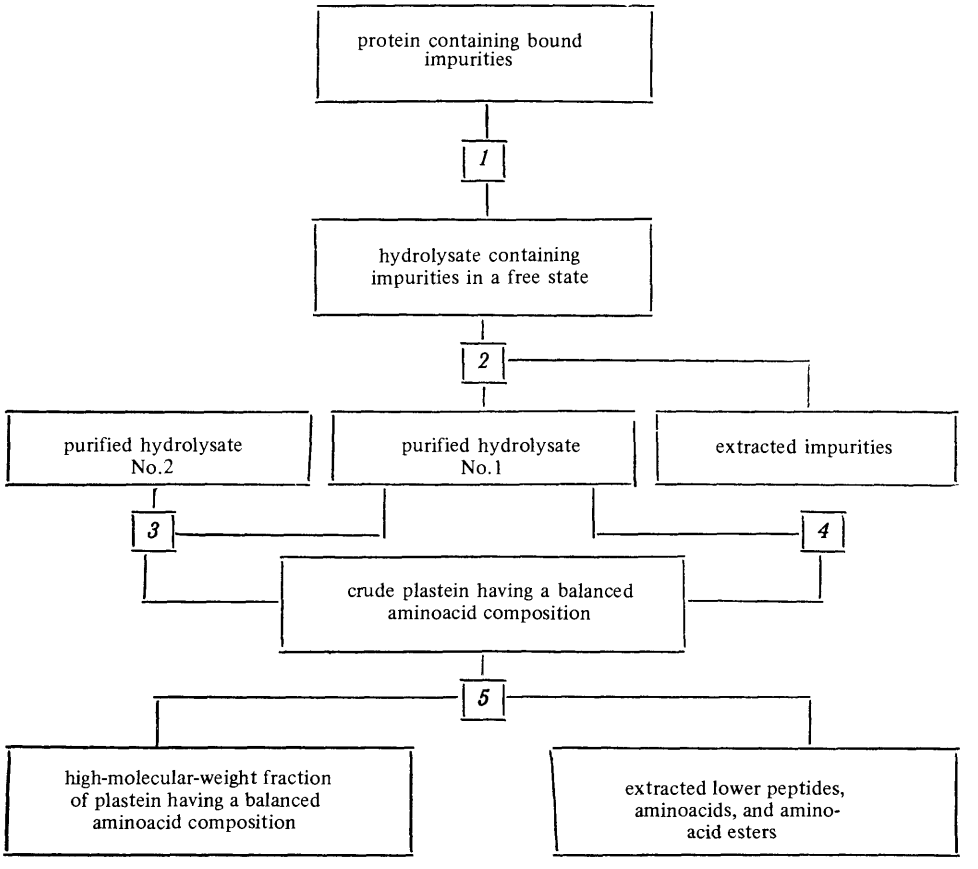

Figure 1. Synthesis of a plastein having a balanced amino-acid composition. Numerals 1 - 5 denote the following operation; 1) hydrolysis by endopeptidases; 2) treatment with organic solvents; 3) addition of endopeptidase; 4) addition of esters of essential aminoacids and endopeptidase; 5) treatment with aqueous ethanol.

found in the reaction mixture. If the reaction mechanism involving the formation of a peptidyl derivative of the enzyme is valid, the observed differences between the rates of incorporation of various aminoacids used in the form of their esters can be attributed to the differences between the binding of different parts of the aminoacid ester molecule to the subcentres S_1 for the aminoacid side chain and S_2 for the alcohol chain[125,128].

Studies on the mechanism of the incorporation of other aminoacids in plasteins under the influence of other enzymes have not been made. One can only postulate, on the basis of general information about the mechanism of the action of endopeptidases[107-111,113,125], that the mechanism of incorporation in such cases is analogous to that examined above. One should note that in many instances a mechanism involving the acylation of the enzyme by the aminoacid derivative is extremely probable. This is indicated by the appreciable incorporation in a plastein of phenylalanine and lysine when the latter are used in the form of ethyl esters with a protected amino-group[52,63,121].

In the enrichment of plasteins by aminoacids side reactions were noted solely in the enrichment of plasteins in lysine catalysed by papain[63]. An appreciable amount of lysine, dilysine, trilysine, and the ethyl ester of dilysine was detected in the reaction mixture only $1\frac{1}{2}$ h after the start of the reaction.

VI. THE USE OF PLASTEINS IN NUTRITION

1. Purification of Proteins and the Preparation of Protein Products with the Required Aminoacid Composition

Numerous studies[19,42,52,60,61,63,70-72,100,120-122,129-132] have shown that protein products with a high food value can be obtained with the aid of the plastein reaction from proteins containing toxic and other undesirable impurities or an unbalanced aminoacid composition. The content of aminoacids in the plasteins obtained is close to ideality under these conditions[1,2]. A scheme for the process is illustrated in Fig. 1. Naturally, protein products with a balanced aminoacid composition can be obtained by simply mixing in definite proportions proteins which are unbalanced with respect to different aminoacids. However, such proteins are by no means always available in a pure form. It is much simpler to purify the hydrolysates than the initial proteins, because the impurities in proteins are incorporated in a network of polypeptide chains. The use of enzymatic protein hydrolysates in food is difficult, because they have a bitter taste and the employment of solid protein products is more customary for man. The main aim of the use of the plastein reaction in this instance is therefore to obtain with its aid protein-like substances from purified hydrolysates. Furthermore, it is naturally important that the enrichment should be by aminoacids synthesised chemically, the latter being introduced into the mixture in the form of ethyl esters.

Studies have shown that plasteins do not have toxic or other undesirable properties and that their nutrient properties are at any rate not inferior to those of the initial proteins and those of plasteins enriched in essential aminoacids are actually superior[72].

Protein-like products with a reduced content of any aminoacid, for example phenylalanine, can be obtained with the aid of the plastein reaction[124,129]. The use of such protein products is the only way of providing protein to persons suffering from phenylketonuria. A scheme for the preparation of plasteins with a low content of phenylalanine is present in Fig. 2. Successive hydrolysis with pepsin and pronase § was essential to ensure that aromatic aminoacids were present in the hydrolysate in a free state. It was found that it is possible to select gel filtration conditions under which aromatic aminoacids are removed from solution almost quantitatively. In order to restore in the resulting plasteins the required levels of tyrosine and tryptophan, the reaction mixture was treated, before plastein formation, with the ethyl esters of the above aminoacids. The subsequent operations involve the purification and more complete isolation of the plastein. As a result of the above process, the phenylalanine content is reduced from 4-5% to 0.05-0.20%, while the content of all the remaining essential aminoacids remains high.

2. Elimination of the Bitter Taste from Enzymatic Hydrolysates

As already mentioned, one of the reasons why enzymatic protein hydrolysates cannot be used in food is their bitter taste[97]. The conclusion that bitter peptides are formed in the enzymatic hydrolysis of proteins can probably be regarded as general for all proteins and all endopeptidases. Bitter peptides with various structures have been isolated from the pepsin hydrolysate of soya-bean protein[133-141]. A characteristic feature of these peptides is the presence of the leucine residue at the ends of the molecule, particularly at the C-end. The important role of hydrophobic terminal aminoacids in the generation of the bitter taste of peptides has been generally observed.

In order to eliminate the bitter taste of enzymatic protein hydrolysates, one can use various procedures. When protein hydrolysates are passed through a charcoal column, the bitter peptides are absorbed preferentially on the charcoal[142]. The bitter taste of enzymatic protein hydrolysate is reduced when the latter are treated with exopeptidases[135,138,139]. However, this method suffers from definite limitations, because, on treatment of the hydrolysates with exopeptidases, free aminoacids are liberated in considerable amounts, which can influence the food value of the hydrolysates.

The plastein reaction proved to be a convenient means for the elimination of the bitter taste from enzymatic protein hydrolysates. It has been found that, when the bitter hydrolysates are used as substrates of the plastein reaction, the resulting products are tasteless[59,97,133,143]. It has been shown that the disappearance of the bitter taste in the plastein reaction is associated with the formation of longer peptides in which the bitter peptides are constituents[73]. Enzymatic hydrolysis of plasteins results in the reappearance of the bitter taste.

The influence of an increased content of glutamic acid on the taste of enzymatic hydrolysates and plasteins is of interest. Plasteins enriched in glutamic acid have no taste, like ordinary plasteins. However, if plasteins with an increased glutamic acid content are hydrolysed by endopeptidases, the bitter taste does not reappear[42,60]. Such a hydrolysate contains peptides of three types: basic, neutral, and acid. The peptides of the first two types are bitter, while those of the third type have no taste. If the tasteless peptides are mixed with peptides of the first two types (jointly or separately), the bitter taste vanishes[42].

---

§ Alkaline bacterial protease from *Streptomyces griseus*.

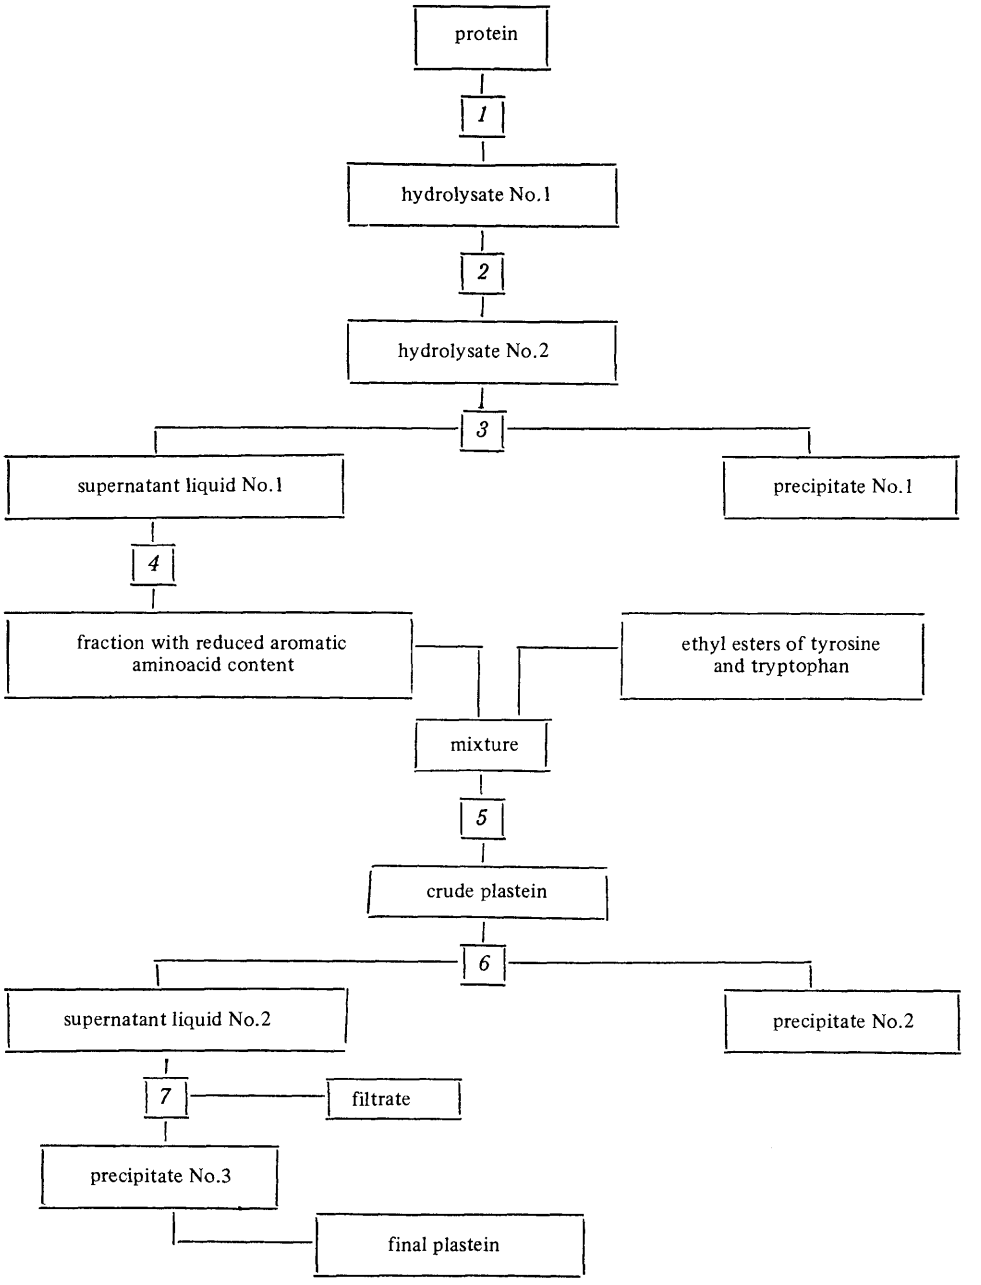

Figure 2. Synthesis of a plastein with a low phenylalanine content. Numerals 1–7 denote the following operations: 1) hydrolysis with pepsin; 2) hydrolysis with pronase; 3) centrifugation; 4) gel filtration; 5) synthesis with papain; 6) centrifugation; 7) ultrafiltration.

The principal component of the peptides of the first type is diglutamic acid. It has been found that diglutamic acid is capable of masking the bitter taste not only of peptides but also of other bitter substances such as $MgCl_2$, caffein, phenylthiourea, and brucine[130]. Consequently in this case the bitter taste disappears as a result of the masking activity of diglutamic acid and not as a result of the formation of new peptides.

Thus the plastein reaction can be useful not only for the preparation of protein-like substances with a high food value from proteins with an unbalanced aminoacid composition but also in the preparation of tasteless enzymatic protein hydrolysates from bitter hydrolysates.

3. Preparation of Protein Pastes and Gels with a High Food Value for Use as Fillers and as Products with an Independent Nutrient Value

The possibility of using plasteins in this way arises from their suitable rheological properties. The problem of the nutrient value of such protein pastes and gels was examined above.

4. Preparation of Mixtures of Peptides with a Particular Smell, Taste, and Other Characteristics for use as Food Additives and Flavours

As already mentioned, plasteins are usually tasteless. It has been shown that enzymatic hydrolysates of plasteins enriched in glutamic acid have the smell and taste of meat[42]. One cannot rule out the possibility that, under certain conditions, one can obtain plasteins or their hydrolysates with any other smell, or taste, but systematic studies on this problem have not been made.

---o0o---

Summarising the studies carried out in the field of plastein formation, the following points must be noted. The principal practical applications of plasteins have now been outlined. It has been shown that with their aid one can use in food proteins derived from non-traditional sources and chemically synthesised aminoacids. However, the mechanism of the plastein reaction has so far been established only in a very broad outline. The determination of the mechanism of plastein formation is of interest not only from the theoretical but also from the practical point of view, because this can lead to new ways for the preparation and application of plasteins, which will increase the raw material base of the food industry.

Dynamics of Elementary Processes in Liquids

A.L.Buchachenko

The dynamics and mechanism of the basis elementary processes in a liquid have been examined, and their characteristic times (in the range 10^{-13}-10^{-6} s) compared. The relationship between these processes and their influence on the kinetics of chemical reactions has been discussed. The bibliography contains 120 references.

I. DYNAMICS OF VIBRATIONAL RELAXATION

Information on the dynamics of the relaxation of vibrational energy in a liquid is obtained by analysing the line widths in the Raman and infrared absorption spectra or from molecular-acoustic ultrasonic absorption data. In the first case, a significant contribution to the line width is made by the rotational motion of the molecules; the procedure for taking account of this contribution and distinguishing the natural line width (which is determined by the lifetime of the vibrational quantum) is difficult and unreliable. Molecular-acoustic methods are also unreliable, since the absorption of high-frequency sound by the excitation of vibrational degrees of freedom is accompanied by the excitation of conformational transitions in molecules. For this reason, only data obtained for conformationally rigid molecules can be accepted with any confidence. The methods of acoustic and vibrational spectroscopy have established only that the vibrational relaxation times in a liquid lie in the picosecond range [1,2].

Direct measurements of the vibrational relaxation times in a liquid became possible with the appearance of lasers generating powerful single pulses of picosecond duration [3-11]. The principle of the measurement is as follows. A picosecond pulse of frequency ν_L, passing through the liquid being studied, undergoes Raman scattering, exciting intramolecular vibrations with frequency ν_M; the intensity of the scattered Stokes component of the radiation with frequency $\nu_L - \nu_M$ increases as the pulse passes through the substance. The concentration of

vibrationally excited molecules increases simultaneously for each photon of Stokes frequency $\nu_L - \nu_M$ there is one molecule in the first vibrationally excited state $v = 1$. The population of the state $v = 1$ after the passage of the exciting pulse reaches a value of $\sim 10^{-3}$, which is greater by 3–4 orders of magnitude than the thermodynamically equilibrium population. Subsequently, as a result of vibrational relaxation processes $v = 1 \rightarrow v = 0$, the above equilibrium population of the state $v = 1$ disappears with a characteristic time τ_1.

The kinetics of the change in the population of the state $v = 1$ are observed by means of a series of delayed probing picosecond pulses of low intensity and frequency νl. The intensity of the Antistokes component of the radiation with frequency $\nu l + \nu_M$, which is proportional to the population of the vibrationally excited level $v = 1$, is measured. The experimentally measured time corresponding to the decay of the Antistokes radiation is the vibrational relaxation time of the excited molecule.

Experiments of this type are usually carried out using the single picosecond pulse of a neodymium laser, which is divided into two parts. The more powerful part of the pulse passes through a KDP crystal to double the frequency and is used to excite molecular vibrations and Raman scattering in the liquid being studied. The second, weaker part of the pulse passes along a delay line consisting of an echelon—a series of plates of different thickness. The echelon forms a series of probing pulses delayed in time to detect the Antistokes radiation in the molecular vibrations generated by the main (exciting or pumping) pulse. In this version of the experiment, $\nu_L = 2\nu l$. It is also possible to double the frequency of the probing pulses, leaving the frequency of the pumping pulse unchanged, equal to the frequency of the neodymium laser; in this case, $\nu l = 2\nu_L$.

The picosecond pumping pulse ν_L and the Stokes radiation $\nu_L - \nu_M$ generated by it are coherent, so that the vibrational excitation of the molecules is also coherent. In other words, definite phase relationships exist between the vibrations of the excited molecules: they all vibrate in step, in the same phase. The phase synchronism of the vibrations gradually breaks down with a characteristic time τ_2; this leads to the loss of the coherence of the vibrations and the Antistokes radiation and is detected as a change in the coherence of the probing picosecond pulses.

There are thus two relaxation processes: the first characterises the loss of vibrational energy and takes place in a time τ_1; the second characterises the loss of the phase synchronism (coherence) of the vibrations and takes place in a time τ_2. Both are detected by the probing pulses from the intensity of the Antistokes radiation; the non-coherent part of this radiation is used for the former, and the coherent part for the latter. The non-coherent radiation is scattered isotropically and is usually measured at an angle of 90° to the direction of the pumping pulse; the coherent radiation is propagated and detected along the direction of the pumping pulse.

The experimental data on the dynamics of the vibrational relaxation of molecules in the ground electronic state can now be examined. For the N_2 molecule at −196°C with a fundamental vibrational frequency of 2336 cm^{-1}, $\tau_2 = 75 \pm 8$ picosecond (ps),[4] which agrees with the value 79 ± 8 ps found by analysing the width of the Raman line[12]. For the C–Cl symmetric stretch with frequency 459 cm^{-1} in CCl_4, $\tau_2 = 4 \pm 0.5$ ps,[13] which also coincides with the value 4 ps obtained from the Raman spectra. Thus the vibrational relaxation times measured from the Raman spectra are in fact the phase relaxation times.

The dynamics of the vibrational relaxation of the totally symmetric stretches of the CH_3 groups in CH_3-CCl_3 (frequency 2939 cm^{-1}) and in CH_3CH_2OH (frequency 2928 cm^{-1}) have been studied[14] at 300 K. With increase in the delay time of the probing pulses, the intensity of the Antistokes scattering increases at first, reaches a maximum, and then decreases exponentially (Fig. 1). The increase in intensity is due to pumping, and the decrease is due to vibrational relaxation. The coherent radiation decays much more rapidly than the non-coherent radiation: $\tau_1 = 5.2$ ps, $\tau_2 = 1.3$ ps (for CH_3CCl_3); $\tau_1 = 22$ ps, $\tau_2 = 0.26$ ps (for CH_3CH_2OH). Thus the ratios τ_1/τ_2 are 4 and 80 in CH_3CCl_3 and CH_3CH_2OH respectively. For N_2 in liquid nitrogen, $\tau_1 \simeq 1$ s, and the ratio τ_1/τ_2 is even greater ($\sim 10^{10}$).[15] This value is anomalously high; for most vibrations of polyatomic molecules studied in a liquid at room temperature, τ_1/τ_2 has values in the range 10–100.[5]

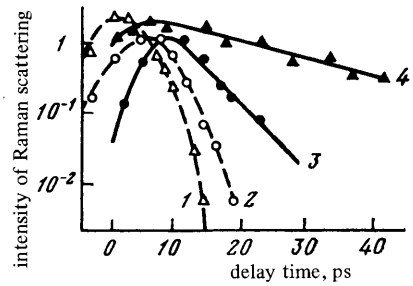

Figure 1. Kinetics of the phase (*1*, *2*) and energy (*3*, *4*) relaxation of the CH_3 stretching vibrations in CH_3CCl_3 (*2*, *3*) and in CH_3CH_2OH (*1*, *4*).[14]

This marked difference in the rates of the phase and energy relaxation is due to the difference in their physical mechanisms. Phase relaxation (loss of coherence of the excited vibrations) takes place as a result of the resonance transfer of a vibrational quantum from an excited to a non-excited molecule. Since the phases of the vibrations of the non-excited molecules are arbitrary and random, this transfer of vibrational energy is accompanied by phase correlation losses, that is loss of coherence. The vibrational quantum does not disappear, but is merely transferred from one molecule to another; its disappearance, that is its transfer to external degrees of freedom of the molecule, is a much slower process. Thus the times τ_2 and τ_1 characterise respectively the kinetics of the processes of the resonance transfer of vibrational energy and its relaxation into the lattice.

The results of experiments which show how the energy relaxation takes place can now be discussed. The energy of the stretching vibrations of the C–H bond correspond to a frequency $\nu_H \simeq 3000$ cm^{-1}, and the energy of the bending vibrations corresponds to a frequency $\delta_H \simeq 1500$ cm^{-1}, that is to half the energy of the stretching vibrations.

The simultaneous measurement of the kinetics of the population of the vibrationally excited states with frequencies 3000 cm^{-1} and 1500 cm^{-1} for the CH_3CCl_3 molecule have shown that excitation of the 3000 cm^{-1} vibration is accompanied by excitation of the 1500 cm^{-1} vibrations.

This means that the population of the excited levels of the bending vibrations takes place through the excited levels of the stretching vibrations. In other words, the relaxation of the 3000 cm^{-1} vibrational quantum takes place by its "exchange" for 1500 cm^{-1} vibrational quanta; the efficiency of this exchange is close to unity[16].

An even more illustrative example is provided by the CH_3CH_2OH molecule[17], which has 21 normal vibrations, five of them in the range 2972–2877 cm^{-1}. The picosecond pumping pulse excited the stretching vibration at 2928 cm^{-1}, and the probing pulses detected the Antistokes scattering on levels in the band 2830–3000 cm^{-1}. It was found that the excitation spectrum was fairly broad (~150 cm^{-1}) and covered almost the entire band of the levels 2830–3000 cm^{-1}. Excitation of the 1550 cm^{-1} and 1350 cm^{-1} levels, which correspond to bending vibrations in the first and second vibrational levels respectively, was also detected.

These results show that the excitation of one stretching vibration (at 2928 cm^{-1}) is very rapidly (in 0.5–1 ps) redistributed between closely situated vibrational levels (in the band 2830–3000 cm^{-1}). It is then transferred slowly (in 22 ps) to vibrational levels of the bending vibrations; from these levels the energy undergoes relaxation into the lattice even more slowly (in ~40 ps).[17]

Data[18] on the excitation of the stretching vibrations of the C–H bonds in hydrocarbons in a band of width 140 cm^{-1} close to 2900 cm^{-1} agree with these conclusions; the relaxation of the population of the excited vibrations was measured. The results are given in Table 1. If τ is normalised to the relative number of methyl groups in the molecule, the values of τ_{norm} obtained remain surprisingly constant in the hydrocarbon series (in particular, in n-heptane there are two methyl groups and seven carbon atoms, so that τ_{norm} = (11.0 ps. 2/7) = 31.14 ps).

Table 1. Vibrational relaxation times in hydrocarbons[18].

Compound	°C	τ, ps	τ_{norm}, ps
n-Heptane	20	11.0	3.14
	−25	14.0	
	−70	16.0	
n-Decane	20	16.0	3.20
	−25	21.0	
Isodecane	20	10.8	3.24
n-Tridecane	20	21.0	3.23
n-Pentadecane	20	24.5	3.27
Hept-1-ene	20	21 0	3.00
Dec-1-ene	20	33.5	3.35
Hepta-1,6-diene	20	60.0	—

This regular feature can be regarded as a consequence of the fact that the vibrational energy rapidly undergoes intramolecular redistribution and is lost through the methyl groups (preferentially through two quanta of the 1450 cm^{-1} bending vibrations).

Data on the transfer of vibrational energy between different molecules can now be examined. Laubereau and coworkers[16] studied relaxation in CH_3CCl_3 + CD_3OD mixtures. On excitation of the stretching vibrations ν(C–H) 3000 cm^{-1} in CH_3CCl_3, it was found that the vibrations ν(C–D) ≃ 2200 cm^{-1} of the CD_3OD molecule are excited, that is intermolecular transfer of a vibrational quantum takes place. Its efficiency depends on the composition of the mixture; the transfer of energy requires the interaction of three particles: an excited CH_3CCl_3 molecule, a non-excited CH_3CCl_3 molecule, and a non-excited CD_3OD molecule. It is assumed that this complex interaction is required in order to establish quasi-resonance conditions for the transfer of energy, since ν(C–H) ≃ ν(C–D) + ν(C–Cl). To satisfy this condition, however, the bimolecular interaction CH_3CCl_3 + CD_3OD is sufficient, since the excess vibrational quantum, equal to ν(C–H) − ν(C–D) may undergo intramolecular transfer to a C–Cl bond of the original CH_3CCl_3 molecule excited in the C–H vibration. A role in the transfer of the vibrational quantum may be played by the bimolecular interaction of the excited CH_3CCl_3 molecule with a van der Waals molecule (CH_3CCl_3 + CD_3OD) (for van der Waals molecules see part V).

In a mixture of CH_3CCl_3 and CD_3OD (60 : 40), the transfer of energy to CD_3OD takes place with $\tau_1 \simeq 13$ ps and with a probability of 0.5; the other half of the vibrational energy of CH_3CCl_3 undergoes intramolecular relaxation through the bending vibrations of the CH_3 group.

In CH_3CCl_3 + CCl_4 mixtures with mole fractions of CH_3CCl_3 (x) equal to 1, 0.8, 0.6, and 0.4, the relaxation time of the vibration ν(C–H) ≃ 3000 cm^{-1} in CH_3CCl_3 increases from 5.2 ps to 29 ps according to the law $\tau^{-1} \sim x^2$ with decrease in x from 1 to 0.4;[16] that is in this case the relaxation of the vibrational energy is a termolecular process: one excited CH_3CCl_3 molecule interacts with two non-excited molecules; the CCl_4 molecules are inert and do not take part in the vibrational relaxation, since the vibrational quantum of the C–Cl bond ($\lesssim$800 cm^{-1}) is small compared with the quantum being relaxed (~3000 cm^{-1}). In this case the relaxation of the energy possibly involves the van der Waals molecule (CH_3CCl_3 + CH_3CCl_3).

The lifetime of the vibrationally excited level of benzene with frequency 991 cm^{-1} (a totally symmetric vibration) is 5 ps, and increases to 8 ps when benzene is diluted with deuterobenzene[19].

The dynamics of vibrational relaxation in electronically excited states of molecules can now be examined. The fluorescence of Rhodamine 6G is delayed relative to an exciting laser pulse[20,21]. The delay is due to the fact that the exciting pulse populates high-lying vibrational levels of an excited singlet state of the molecule, and the fluorescence takes place from the ground vibrational level. These two events—excitation and fluorescence—are separated by a time interval τ, during which the vibrational relaxation of the excited singlet takes place, that is the molecule "descends" from the excited vibrational levels into the ground vibrational level of the electronically excited singlet state.

Quantitative measurements of τ have been carried out for several molecules[22]. A picosecond pulse of frequency ν_L excited the Rhodamine 6G molecule into high vibrational levels of the excited singlet, after which the probing picosecond pulses detected the intensity of the fluorescence from lower-lying vibrational levels at a frequency $\nu_l < \nu_L$ (ν_l usually coincided with the frequency of the centre of the fluorescence band). Thus an inverted population of the vibrational levels of the excited singlet is first created, after which vibrational relaxation restores the normal distribution of the populations; the kinetics of the restoration are detected from the increase in the intensity of the probing picosecond pulses with the passage of time. For Rhodamine 6G in ethanol, the restoration time (that is the vibrational relaxation time in the excited singlet) was 8.3 ps.[22] For the molecules of Erythrocin B, this time was much smaller ($\tau < 2$ ps) and could not be measured[23]. For the molecule of azulene, excited into vibrational levels

lying ~5000 cm^{-1} above the ground level, relaxation to the ground vibrational level takes place with a characteristic time of 7.4 ps;[24] for the vibrational levels lying 500 cm^{-1} above the ground level, this time is 4 ps.[25]

Thus vibrational relaxation in electronically excited states of molecules takes place in a time comparable with or slightly shorter than the vibrational relaxation time of the molecules in the ground electronic state.

II. ROTATIONAL MOLECULAR MOTION

Both physicists and chemists have carried out extensive and successful studies of the rotational–orientational dynamics of molecules in a liquid. Only the most fundamental results will be examined here: 1) the relationship between molecular rotation and the macro-properties of a liquid (in particular, the macro-viscosity); 2) the way in which rotation and reorientation of the molecules take place, and models of this motion; 3) the problem of whether there is a correlation between the rotational and translational motion, and the nature of their relationship; 4) the reorientation of the vector of the angular momentum of rotation; 5) and 6) the quantitative scale of the rotational frequencies.

Before discussing these questions, the physical phenomena on which methods for studying rotational motion are based can be examined. The thermal motion of the molecules in a liquid produces fluctuations in the anisotropy of the polarisability, when the molecules in a small element of volume are randomly found in identical orientations. This fluctuation represents the optical non-uniformity on which scattering of light takes place. Since the fluctuations themselves are oriented randomly, the vectors of their polarisabilities are also directed randomly; this means that the scattered light will be depolarised. The creation and disappearance of fluctuations in the anisotropy take place as a result of the orientational–rotational movements of the molecules, so that the scattered light will be modulated by the frequency of these movements; information on the frequency of the modulation is obtained from an analysis of the line shape in the scattering of the depolarised light. This phenomenon is known as Rayleigh light scattering[26].

Another optical method for studying the rotation of molecules is based on the depolarisation of fluorescence. If isotropically distributed molecules are excited by linearly polarised light, only those molecules will be excited which are oriented in such a way that the dipole moment of their optical transition is directed along the vector of the electric field of the exciting light. Thus the electronically excited molecules have a non-uniform distribution of orientations. If the molecules were stationary, the emission of the fluorescence would have the same polarisation as the exciting light. Molecular rotation, however, leads to random distribution of the orientations of the excited molecules and to depolarisation of the fluorescence. The degree of depolarisation is directly related to the frequency of the molecular rotation.

Both stationary and pulse methods of magnetic radio-frequency spectroscopy (EPR and NMR) are widely used to study rotational dynamics in a liquid. Information on the dynamics is obtained from an analysis of the EPR or NMR line widths and from the electronic or nuclear relaxation times. Both the line widths and the magnetic relaxation times are determined by the intramolecular dipole or quadrupole interactions, the magnitude of which depends on the orientation of the molecule or radical in the magnetic field. Molecular rotation changes the orientations of the particles and modulates the extent of the magnetic interactions; in other words, the molecular rotation modulates the magnitude and direction of the local magnetic fields acting on the electron or nucleus. The line widths and relaxation times depend on the magnitude of the magnetic interactions and the frequency of their fluctuations; if the magnitude of the interaction is known (this is usually the case), the experimentally measured line widths or relaxation times are used to calculate the characteristic times of the rotational–orientational movements.

Mention may also be made of the classical methods of dielectric relaxation, which measure the reorientation times of the electric dipoles of the molecules, and also the methods of Raman light scattering and infrared (vibrational) spectroscopy. In the last two cases, information on the dynamics of rotation is obtained from an analysis of the width of the line and its wings. Finally, the new methods of picosecond spectroscopy may be mentioned.

The questions listed at the start of this section can now be discussed.

1. Relationship Between Molecular Rotation and the Macro-properties of a Liquid

The coefficient of rotational diffusion D_{rot} is determined by the classical relationship

$$D_{rot} = kT/\xi, \tag{1}$$

where ξ is the coefficient of friction experienced by the rotating molecule. In the Debye theory of dielectric relaxation, the coefficient of friction for spherical molecules was calculated from the equations of classical hydrodynamics[27,28]:

$$\xi = 8\pi\eta a^3, \tag{2}$$

where a is the radius of the rotating particle, and η the viscosity of the medium.

On the other hand, molecular rotation is a random stochastic process; it follows from the theory of these processes that the characteristic time of rotational reorientation τ_θ is related to D_{rot} by the following expression:

$$\tau_\theta = (6D_{rot})^{-1}. \tag{3}$$

Substitution of Eqns. (1) and (2) in Eqn. (2) gives the familiar Debye–Stokes–Einstein relationship

$$\tau_\theta = \frac{V\eta}{kT}, \tag{4}$$

which establishes the relationship between the rotational reorientation time of the molecules and the macroscopic viscosity of the medium. This approach was later extended by Perrin[29] to the rotation of ellipsoidal molecules.

A large number of studies have established reliably that the linear relationship between τ_θ and η/T, predicted by this expression, is always observed, but the volumes of the molecules V calculated in this way often do not agree with the actual dimensions of the molecules. In other words, Eqn. (4) gives unsatisfactory quantitative results. Thus depolarised Rayleigh light scattering for the molecules of benzene, toluene, and xylene in different isotropic non-solvating solvents showed[30] that τ_θ obeys the equation

$$\tau_\theta = C\eta + \tau_0, \tag{5}$$

where the constant C was smaller by a factor of 2–6 than that predicted by Eqn.(4); the value of τ_θ, as expected, is close to the period of rotation of the free classical rotator τ_R:

$$\tau_\theta \simeq \tau_R = \frac{2\pi}{9}(I/kT)^{1/2}. \quad (6)$$

In the great majority of cases, Eqn.(4) predicts values of τ_θ which are greater by an order of magnitude than the experimental values. Moreover, the activation energies of rotation (E_θ) are also frequently found to be smaller than the activation energies of the viscosity (E_η), although Eqn.(4) predicts that $E_\theta = E_\eta + RT$. Finally, Eqn.(4) predicts that the dependence on the hydrostatic pressure should be the same for τ_θ and η, whereas the experimentally measured relationships are different [31].

Eqns.(2) and (4) were derived from the equations of classical hydrodynamics for a sphere of volume V, rotating in a continuous medium; clearly, they do not take account of the molecular structure of the liquid, so that in principle it cannot be required that Eqn.(4) give the rotational dynamics quantitatively. In order to "adapt" Eqn.(4) for a correct description of the experimental results, the concept of micro-viscosity η^* was introduced. The quantity η^* is related to the macro-viscosity by the expression $\eta^* = f\eta$, where the coefficient f is a correction for the micro-viscosity. Gierer and Wirtuz [32], in the quasi-stationary approximation, calculated the rotational moments acting on a rotating molecule of radius a from neighbouring molecules of radius b, and determined the coefficient

$$f = \left[6\left(\frac{b}{a}\right) + \left(1 + \frac{b}{a}\right)^{-3}\right]^{-1}. \quad (7)$$

In the simplest case, $b = a$, so that $f = 0.16$; in general, $f \leq 0.16$ (for example, for benzene, dioxan, and cyclohexane, $f \simeq 0.06-0.08$). [32] The correction for the micro-viscosity is introduced semi-empirically, and must be determined experimentally for each rotating molecule–solvent pair.

Considerable progress was made by Steele [33], who developed a theory for calculating the coefficient of friction not from hydrodynamics but at a molecular-kinetic level. It is assumed that the particle moves under the influence of a randomly fluctuating rotational moment; the fluctuations are due to the angular dependence of the intermolecular potential. Since the intermolecular potential of a particle in the environment created by its neighbours is in general anisotropic, the coefficient of friction ξ in Eqn.(1) becomes a tensor quantity; the calculation of the components of the tensor in terms of the parameters of the intermolecular potential is a complex unsolved problem. For the particular case of molecules of the spherical top type, Steele [33] obtained the expression

$$\xi_{ii}^2 = \frac{2I}{\pi}\left\langle \frac{\partial^2 W(R, \Psi)}{\partial \psi_i^2} \right\rangle, \quad (8)$$

where ξ_{ii} is a component of the tensor ξ, I the moment of inertia, and $W(R, \Psi)$ the potential, which is a function of the distance and the angle; the averaging is carried out over all the other variables; in the laboratory system of coordinates, $i = x, y, z$. Eqn.(8) shows that the principal components of the tensor ξ (ξ_{xx}, ξ_{yy}, ξ_{zz}) are proportional to the second derivative of the intermolecular potential with respect to the angle of rotation about the chosen axis.

In recent years there has been a new approach to the calculation of τ_θ within the framework of hydrodynamics [34]. In the derivation of Eqn.(4) it was assumed that the sphere rotates in the continuous medium together with the boundary layer; in other words, it was assumed that the sphere is rigidly bonded to the boundary layer. In fact, this condition is not necessary: the particle may slip relative to the boundary layer. This is equivalent to a decrease in the coefficient of friction and a decrease in τ_θ. The same approach was also deveoped for calculating the coefficient of friction for the rotation of ellipsoids [34] and molecules of arbitrary shape [36]. In particular, for a symmetrical ellipsoid

$$\xi_{xx}^* = \frac{32\pi\eta a^3}{25} e^2 \left(1 - \frac{74}{25} e\right), \quad (9)$$

where a is the length of the semi-axes x and y, and c the length of the semi-axis z; $e = (a/c)^2 - 1$. Fig.2 shows that the ratio ξ_{xx}^*/ξ_{xx} depends on the form of the ellipsoid; here ξ_{xx}^* is determined by Eqn.(9) in the model involving slip, and ξ_{xx} is calculated from the Perrin equations in the hydrodynamic model (without slip). It can be seen that the differences in the coefficients of friction in these two models depend to a marked extent on the shape of the molecules. For an ideal spherical molecule ($a/c = 1$), the model involving slip gives $\xi_{xx} = 0$, that is it predicts free rotation.

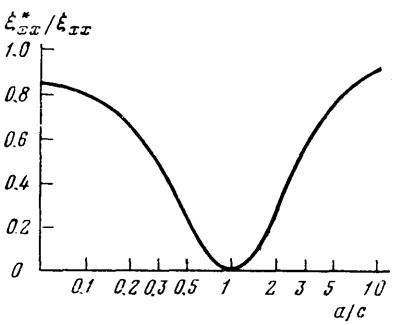

Figure 2. Plot of ξ_{xx}^*/ξ_{xx} against a/c. [37]

This result agrees with Steele's theory: if the intermolecular potential is spherically symmetrical, it follows that $(\partial W/\partial\psi) = 0$, so that from Eqn.(8) it follows that $\xi_{xx} = 0$. In actual fact, molecules with an ideally symmetrical spherical potential do not exist, although many real molecules (CH_4, CCl_4, etc.) have a potential which is almost symmetrical, so that their rotation is restricted to only a slight extent. The hydrogen molecules also undergoes free rotation about the axis directed along the H–H bond, since $\xi_{HH} \simeq 0$. Bauer and coworkers [38] compared the experimental $\tau_\theta(\eta)$ relationships obtained for different molecules by Rayleigh light scattering and NMR relaxation with the theoretical values. It was found that the model including slip reproduces the experimental $\tau_\theta(\eta)$ relationships with good accuracy (±20%).

An interesting feature is that the best agreement is obtained in systems in which there are no solvation effects. In systems where there is strong solvation (for example strong hydrogen bonds), the experimental results are best reproduced by Eqn.(4), that is by the model with rigid binding. Physically, this tendency is wholly reasonable: clearly, solvation will not influence molecular rotation if the lifetime of the complex (or coordination solvate sphere)

is much smaller than τ_θ. On the contrary, stable complexes will rotate as a whole. The dimers of carboxylic acids rotate as a whole in CCl_4;[39] on the other hand, t-butyl alcohol does not influence τ_θ for nitrobenzene[40], since complex formation in this system is weak.

EPR and NMR have been used[41] to study the rotational dynamics of the complex of the stable nitroxide radical with chloroform in various alcohols. A correction for the micro-viscosity was introduced experimentally, and it was shown that the comparatively stable radical–chloroform complex pairs rotate in alcohol as a whole, and the calculated volumes of the rotating particles correspond to their geometric dimensions.

The hydrodynamic model of rotation with slip describes satisfactorily not only the viscosity relationships $\tau_\theta(\eta)$ but also the temperature dependence $\tau_\theta(T)$. As a rule, in systems with slip, $\epsilon_{rot} < \epsilon_\eta$, whereas in systems without slip, $\epsilon_{rot} \simeq \epsilon_\eta$.

2. Models of the Rotation of Molecules in a Liquid

The orientational–rotational movement of a molecule is accompanied by a change in the angular orientation of its axes. It may be assumed that in a time τ_θ the change in the angle is θ; this change may take place either by continuous slow rotation or by a single instantaneous abrupt rotation through an angle θ. Thus in principle it is possible to picture two models of molecular rotation: Brownian diffusion, when the reorientation of the axis of the molecule takes place continuously and randomly, and discontinuous abrupt large-amplitude diffusion. Brownian rotational diffusion can also be regarded as a continuous sequence of abrupt movements of infinitely small amplitude; the difference between the two models of the motion then reduces to a difference in the amplitudes of the elementary abrupt rotational movements.

It is not difficult to understand the physical mechanism of Brownian diffusion (even within the framework of hydrodynamic ideas); it is more difficult to determine the causes and mechanism of abrupt movements of large amplitude. One mechanism[42] assumes that a molecule in a liquid rotates only at those moments when a random fluctuation gives a sufficiently large free volume around it; at these moments the movement of the molecule is regarded as the rotation of a free rotator. When the fluctuation in the free volume disappears, the environment around the molecule contracts, and it remains until the next fluctuation. Theoretical analysis of this mechanism leads to a number of conclusions. Firstly, the activation energy of the rotation must be close to the work of forming the fluctuation of the free volume; this is usually a small quantity, smaller than the activation energy of the viscosity. Secondly, since the rotating molecule is regarded as a free rotator, τ_θ in this model should depend on the moment of inertia of the molecule, so that for isotopically substituted molecules, an isotopic effect in τ_θ should be observed. Atkins and coworkers[42] found that the ratio of τ_θ for the ND_3 and NH_3 molecules is 20% greater than that expected from Eqn.(4); the ratio $\tau_\theta(ND_3)/\tau_\theta(NH_3)$ was found to be close to the ratio $[I_\perp(ND_3)/I_\perp(NH_3)]^{1/2}$, where $I_\perp$ is the component of the moment of inertia perpendicular to the axis of symmetry of the molecule. This is the isotope effect predicted by the theory.

Another mechanism[43,44] assumes that the immediate environment of the molecule has the structure of the crystal lattice, so that the molecule may undergo a reorientation of large amplitude only with the condition that a structural defect or vacancy is created around it, as a result of the displacement of one of the neighbouring molecules into an adjacent lattice site. In this theory, the activation energy of rotation includes the work of formation of the vacancy, and the volume of activation includes the volume of activation for translational diffusion. The first quantity should be close to the molar heat of volatilisation, and the second should be close to the molar volume of the vacancy. The experimentally determined values of these quantities are respectively only 17% of the molar heat of volatilisation and 26% of the molar volume of the vacancy.

Thus the model of the fluctuating free volume shows better agreement with experiment; as will be seen later, this model is also confirmed by the pressure dependence of τ_θ.

How is it possible to establish whether the particle is rotating by a Brownian diffusion mechanism or in abrupt movements? Before answering this question, it is necessary to consider the determination of the coefficient of rotational diffusion D_{rot}.

Eqn.(3) represents a particular definition of D_{rot}; in the general case,

$$D_{rot} = 1/l(l+1)\tau_\theta. \qquad (10)$$

The quantity D_{rot} is a universal characteristic, and is determined by the properties of the rotating particle–medium system; D_{rot} is independent of the physical method of measuring τ_θ. Different methods measure different values of τ_θ, however, and therefore correspond to different values of l (see later).

This important question must be dealt with briefly. All physical methods (mentioned at the start of this section) measure the time dependence of some interaction; usually, the interaction is a random function of time, and its time dependence is described by introducing a correlation function, which characterises the rate at which the "memory" of the magnitude of the initial interaction is lost. It is usually assumed that the correlation function decreases exponentially with a characteristic time τ_θ. In other words, τ_θ is the time in which the magnitude of the interaction changes by a factor of e as a result of molecular rotation. It may be assumed that in this time the "memory" of the magnitude of the initial interaction is lost, that is the correlation disappears; for this reason, τ_θ is called the correlation time of the rotational motion.

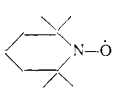
The correlation function is expressed in terms of special functions—spherical harmonics of rank l. For interactions of the vector type, $l = 1$; these include the interaction of a constant dipole electric moment with an electric field. For interactions of the tensor type, $l = 2$; these include the dipolar interaction of the nuclei (in NMR), electron–nuclear dipolar interaction (in EPR), and polarisability (in Rayleigh light scattering). Eqn.(3) is obtained from Eqn.(10) for $l = 2$; for dielectric relaxation, $l = 1$ and $\tau_\theta = (2D_{rot})^{-1}$.

From the definition (10) it now follows immediately that for Brownian diffusion

$$\tau_\theta(l=1)/\tau_\theta(l=2) = 3\ . \qquad (11)$$

In other words, if τ_θ is measured in a given system by two different methods, the ratio of τ_θ obtained should be equal to 3. One of the methods should measure an interaction of the vector type (for example from the dielectric relaxation or from an analysis of line shape in the infrared vibrational spectrum), and the other method should use an interaction of the tensor type (for example EPR, NMR, or Rayleigh or Raman light scattering).

The physical significance of Eqn.(11) is that in the rotation of the molecule, the tensor interaction changes more rapidly, so that the change in this interaction takes place e times more rapidly, in a shorter time τ_θ.



If the molecule rotates in abrupt movements with an amplitude which is sufficiently large for any interaction to change by a factor of not less than e, it follows that in this case τ_θ will be independent of the physical method of measurement; in this case

$$\tau_\theta(l = 1)/\tau_\theta(l = 2) = 1 . \qquad (12)$$

Eqn.(11) is applicable for Brownian diffusion, and Eqn.(12) for diffusion by abrupt movements; by determining the ratio $\tau_\theta(l = 1)/\tau_\theta(l = 2)$ experimentally, it is possible to reach conclusions regarding the mechanism of rotational diffusion. This approach, and a rigorous theory, were developed by Valiev and Ivanov[45].

The mechanism by which rotation of the molecule takes place can now be examined. Gershon and coworkers[46] determined τ_θ by Rayleigh light scattering in a number of liquids, and compared the results with the dielectric relaxation times. It was found that in quinoline, nitrobenzene, chlorobenzene, aniline, and pyridine at 25°C, the ratio of these times is close to unity. It was therefore concluded that the rotation of the above molecules takes place in abrupt movements with a large amplitude (~1–1.5 radian). On the other hand, the rotation of the molecules of nitrobenzene and camphor in CCl_4 and CS_2 takes place by a diffusion mechanism: for these molecules, the ratio $\tau(l = 1)/\tau(l = 2)$ is 3 ± 0.5.[45]

Recently, particular attention has been paid to the study of the rotation of nitroxide radicals, which are widely used as spin markers and probes[47,48]: the form of their EPR spectrum is sensitive to the model of rotation. It was found that the radical $(SO_3)_2^{2-}NO$ in aqueous glycerol rotates in almost abrupt movements[49], whereas the rotation of the molecule of spin-labelled haemoglobin is more effectively described by a continuous diffusion model[50]. In a study of a number of radicals of different shape and size, Kuznetsov[51] showed that the rotation of small radicals is described more effectively by the model of diffusion by abrupt movements, whereas that of large and unsymmetrical radicals is described more effectively by the continuous diffusion model[51]. For the radical

the conclusion that it undergoes abrupt movements was confirmed by comparing the values of τ_θ obtained from dielectric relaxation and from the EPR spectra[52]; their ratio being close to unity. A general tendency is for large and asymmetric molecules in viscous solutions to rotate by continuous diffusion; small molecules in non-viscous solutions generally rotate by abrupt movements.

In general, in a liquid, rotational movements of different frequency, scale, and amplitude are allowed, but movements of particular frequencies and amplitudes predominate, depending on the viscosity, temperature, size, and shape of the molecules. The movement of large molecules at high viscosities takes place with a low amplitude, and rotation through a large angle is made up of a large number of rotations through small angles; this is the case of continuous diffusion. With decrease in the viscosity, movements with large amplitude begin to predominate, and in the limit these can be regarded as abrupt movements. Situations intermediate between these two limiting cases are possible.

3. Relationship Between Rotational and Translational Motion

Data on the relationship between rotational and translational molecular motion in a liquid can be obtained by NMR relaxation. Studies of this kind have been carried out by Jones and coworkers[31], who studied the pressure dependence of the intramolecular dipole contribution to the relaxation of the protons of the molecules of acetone, benzene, chlorobenzene, toluene, and other derivatives of benzene, dissolved in the corresponding deuterated compounds. The intramolecular dipole contribution to the nuclear relaxation is determined only by the rotation of the molecules, and its pressure dependence shows unambiguously that the rotation depends on pressure.

The proton relaxation times of acetone and benzene are independent of pressure up to pressures of several kilobars. This means that the freezing of the translational mobility of the molecules at high pressures does not influence their rotational mobility, that is the rotation of these molecules is autonomous and independent of their translation. The physical cause lies in the fact that in these molecules the main contribution to the nuclear relaxation is made by rotations of the methyl groups (in acetone) and rotation of the benzene molecules about the C_6 symmetry axis; these movements also take place in the solid.

In substituted benzenes, where the symmetry of rotation is destroyed, the intramolecular dipole contribution to the nuclear relaxation shows a marked pressure dependence. In these molecules, rotation is related to translational motion; the relationship is stronger, the greater the van der Waals radius of the substituent in the aromatic ring.

Thus in the relationship between rotation and translation, the principal role is played by the shape of the molecules: for symmetrical molecules, rotation is practically autonomous, whereas for asymmetric molecules there is a marked correlation between these two types of molecular motion. This conclusion is confirmed by data on the scattering of slow neutrons by the liquid; in this case the theory which does not take account of statistical correlation of rotational and translational motion provides a poor description of the experimental data[53].

The correlation of the rotational and translational motion is quite natural; for a given molecule to rotate, it is necessary to have a fluctuation of the free volume around it, and this fluctuation is impossible without rotational–translational movement of its neighbours.

4. Behaviour of the Rotational Moments of Molecules

Exceptionally important information on the dynamics of molecular motion is given by NMR in those cases where the nuclear relaxation takes place as a consequence of spin–rotational coupling. A randomly rotating molecule is a system of moving charges, and therefore creates its own randomly varying electromagnetic field, the magnetic component of which induces the relaxation of the nuclei of the molecule. The correlation time of this spin–rotational coupling is the time corresponding to the change in the angular momentum of the molecule τ_J; in fact, this is the time which is necessary for the molecule to lose the "memory" of its original angular momentum or, in other words, it is the time between the collisions of the molecules in the liquid. The determination of the relationship

between the times τ_θ and τ_J is of particular importance for an understanding of the mechanism of molecular motion.

The behaviour of the angular momentum can be described by two different models[54]. One of these (the J-model) assumes that τ_J is the average time between instantaneous molecular collisions in which there are simultaneous changes in the magnitude and direction of the angular momentum. The other (the M-model) assumes that only the direction of the momentum changes, and that its magnitude (and hence the rotational energy) does not change. The results of the theoretical calculation of τ_J and τ_θ for these models are given in Fig. 3.[55]

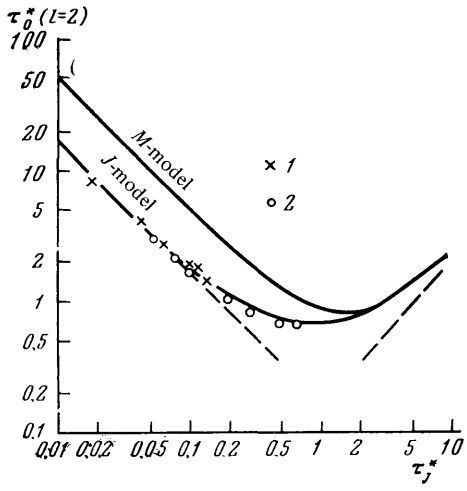


Figure 3. Relationship between τ_θ^* ($l = 2$) and τ_J^* in the J- and M-models[55]. The points give the experimental data: *1*) CS_2 (167–308 K), *2*) ClO_3F (140–368 K); $\tau^* = \tau(kT/I)^{1/2}$.

In the range of Brownian continuous diffusion $\tau_J \ll \tau_\theta$, and they are related by the expressions

$$\tau_J\tau_\theta = I/l(l+1)kT \qquad (13)$$

for the J-model and

$$\tau_J\tau_\theta = 3I/l(l+1)kT \qquad (14)$$

for the M-model (I is the moment of inertia of the molecule). These relationships are also obtained from the Langevin equations for the classical mechanics of a rotator[37]; Eqns. (13) and (14) also lead to the characteristic of Brownian diffusion already discussed [Eqn. (11)].

In the range of diffusion by abrupt movements, Eqns. (13) and (14) no longer apply (as expected), and τ_J is comparable with τ_θ; the physical significance of this result corresponds to the definition of diffusion by abrupt movements. This region lies close to the critical conditions for the existence of the liquid, and in this region the two models (J and M) give similar results. In the gaseous phase, according to kinetic theory, $\tau_\theta \sim \tau_J$ (Fig. 3).

The points in Fig. 3 give the experimental results for the ClO_3F and CS_2 molecules[56,57]. For ClO_3F, the value of τ_θ was determined from the relaxation of ^{35}Cl nuclei, induced by quadrupole coupling ($l = 2$), and τ_J was obtained from the relaxation of ^{19}F nuclei, taking place as a result of spin–rotational coupling[56]. At low temperatures, $\tau_\theta \gg \tau_J$, and Eqn. (13) is fulfilled, that is the rotation of the molecule takes place by the Brownian mechanism; at high temperatures, τ_θ is comparable with τ_J, and rotation takes place by abrupt movements. In CS_2, the relaxation of the ^{13}C nuclei takes place as a result of spin–rotational coupling and the anisotropy of the chemical shift[57]; both contributions have been measured, and the values of τ_θ and τ_J given in Fig. 3 obtained.

Similar measurements of τ_θ and τ_J have been carried out for the molecules of fluorobenzene, fluorine, CF_4, CCl_3F, HCl, SF_6, HBr, PH_3, CH_4, etc.[55] In all cases the J-model is applicable, that is paired collisions of the molecules are accompanied by simultaneous changes in the magnitude and direction of the angular momentum; the actual collisions take place randomly, and are not correlated. The applicability of the J-model confirms the view that there is a high efficiency of exchange of energy between the rotational and translational degrees of freedom.

The temperature dependence of τ_J is of interest. Since increase in temperature leads to an increase in the thermal velocities, it was expected that the time between the collisions of the molecules in the liquid should decrease, that is τ_J should decrease. Experiment reveals the opposite tendency. Thus for liquid fluorine at 56 K (m.p. 53.5 K), $\tau_J = 9.5 \times 10^{-14}$ s and increases with increase in temperature with an activation energy of 300 cal mole^{-1}.[58]

For fluorobenzene, τ_J also increases with increase in temperature, even at a constant density, that is for a constant intermolecular distance (experiments at high pressures)[31]; a similar increase in τ_J has been observed for CF_4, ClO_3F, etc. To explain this phenomenon, it was necessary to assume that the radius of the particles decreases with increase in temperature. In other words, with increase in the kinetic energy of the molecules, the distance of their maximum approach on collision decreases, that is more extensive overlap of the electron clouds of the colliding particles takes place. This corresponds to an increase in the free path of the molecules and hence to an increase in τ_J.

Eqns. (10) and (13) can be used to obtain the equation

$$D_{rot} = \left(\frac{kT}{I}\right)\tau_J, \qquad (15)$$

in which (kT/I) is the square of the angular velocity of the rotation, and τ_J the time between the collisions which lead to a change in the rotational moment and angular velocity.

The results given in Fig. 3 and in Eqns. (13) and (14) are of particular practical importance. They make it possible to estimate the values of D_{rot} and τ_θ from τ_J; τ_J in turn can be estimated from the thermal velocity of the molecules v and from the intermolecular distance d: $\tau_J \simeq dv^{-1}$. Here, $d = \bar{r} - \sigma$, where $\bar{r}$ is the average distance between the centres of the molecules, and σ the diameter of the molecule, which can be found from data on the elastic scattering, from molecular models, or from the molar volume of the solid:

$$\bar{r} = \left(\frac{V\sqrt{2}}{N}\right)^{1/3}; \quad v = \left(\frac{8kT}{\pi m}\right)^{1/2};$$

V is the molar volume of the liquid, and N Avogadro's number. For a molecule of the benzene type, $\sigma \simeq 5.2$ Å, $\bar{r} \simeq 6.0$ Å, $v \simeq 6 \times 10^4$ cm s^{-1}, and $\tau_J \simeq 1 \times 10^{-13}$ s.

5. Anisotropy of the Molecular Rotation

Spherical molecules rotate isotropically, whereas the rotation of non-spherical molecules must be characterised by a rotational diffusion tensor. From the definition (8) of the components of the tensor coefficient of friction it follows that there are two factors responsible for the anisotropy of the rotation: the anisotropy of the force potential $\partial W/\partial\psi$ and the anisotropy of the moment of inertia I, the components of which, I_{xx}, I_{yy}, and I_{zz}, may in general be different.

The axes of symmetry of a molecule usually coincide with the axes of symmetry of its force field and the axes of the tensor of the moment of inertia, so that the principal components of the tensor of the rotational diffusion are the frequencies of rotation about the axes of symmetry. If the molecule has no axes of symmetry, the principal axes of the tensor of the rotational diffusion usually coincide with the principal axes of the tensor of the moment of inertia (with the condition that the molecule is not involved in any strong intermolecular interaction creating a marked anisotropy of the potential; in this case the axes of rotation coincide with the axes of the potential).

In general, rotation must be defined by three correlation times (relative to each of the three axes), but for molecules of the symmetric top type there are only two times, $\tau_{\parallel}$ and $\tau_{\perp}$ (rotation relative to the axis of highest order symmetry and about axes perpendicular to it).

The anisotropy of molecular rotation can be successfully studied using the NMR relaxation of nuclei exhibiting a quadrupole moment; it is necessary that the molecules contain not less than two nuclei which exhibit quadrupole moments and which do not lie on the same molecular axis[59] For example, for the CD_3CN molecule the rotational correlation time calculated from the rate of relaxation of ^{14}N nuclei describes the motion at right angles to the axis of symmetry of the molecule, since the gradient of the electric field inducing the relaxation of the nucleus is directed along the C≡N bond; this time is 1.2 ps. The time 0.14 ps, calculated from the rate of relaxation of the deuterium nucleui, characterises the rotation about all three axes, although the predominant contribution is made by the rotation about the axis of symmetry. Thus for CD_3CN at 25°C, $\tau_{\parallel} = 0.14$ ps, $\tau_{\perp} = 1.2$ ps. The activation energies of rotation about different axes are also different: $\epsilon_{\parallel} = 0.8$ kcal mole^{-1}, $\epsilon_{\perp} = 1.7$ kcal mole^{-1}.[59]

The pressure dependence of $\tau_{\parallel}$ and $\tau_{\perp}$ has been studied [60]; at 23°C, $\tau_{\parallel}$ is almost independent of pressure (up to 2 kbar), whereas $\tau_{\perp}$ increases by a factor of almost 3. The activation volumes are $V_{\parallel} \leq 2$ cm^3 mole^{-1} and $V_{\perp} = 8.5$ cm^3 mole^{-1}; these quantities have the significance of the fluctuations of the free volume required to unfreeze rotation. It is obvious that for rotation about a perpendicular axis it is necessary to create a fluctuation of a large volume, whereas rotation about an axis of symmetry requires almost no additional volume. These results agree with the theoretical models of rotation previously examined.

A similar relationship has been found for CD_3I (at 23°C, $V_{\parallel} < 2$ cm^3 mole^{-1}, $V_{\perp} = 10.0$ cm^3 mole^{-1}), and for toluene and other molecules [31]. The rates of relaxation of the quadrupolar nuclei D and ^{35}Cl have been used to determine $\tau_{\parallel}$ and $\tau_{\perp}$ for $CDCl_3$;[59] at 20°C the values are 1 ps and 2 ps, and the activation energies are 0.8 kcal mole^{-1} and 1.6 kcal mole^{-1} respectively.

For BCl_3, the ratio $\tau_{\perp}/\tau_{\parallel} \simeq 0.75$, and for $VOCl_3$ and CCl_3CN these ratios are 1.4 and 2 respectively (20°C); for pyridine, the value of $\tau_{\perp}/\tau_{\parallel}$ changes considerably with temperature (it is equal to 3 at −20°C and 1 at 90°C).[61] The anisotropy of the rotation of the nitroxide radicals used as spin markers and probes is of considerable interest. The anisotropy of their rotation was first studied by Vasserman and coworkers[62]. The rotation of the radical $(SO_3)_2^{2-}NO$ is anisotropic[49,51,62]: it is most rapid about the axis perpendicular to the N–O bond and the $2p\pi$-orbital of the unpaired electron; the ratio of the frequencies of rotation in water and in glycerol has the values 2.9 and 4.7. The anisotropy of the rotation depends on temperature only for small radicals[51]. The temperature dependence of the anisotropy of rotation is an important characteristic: its existence indicates that the anisotropy of the rotation is due to the anisotropy of the force potential, and its non-existence indicates that the rotational anisotropy is due to the anisotropy of the moment of inertia.

For benzene, toluene, nitrobenzene, and mesitylene, the correlation times $\tau_{\parallel}$ and $\tau_{\perp}$ obey Eqn.(5), but the dependence of these times on the viscosity is strongly anisotropic, that is the proportionality coefficients $C_{\parallel}$ and $C_{\perp}$ differ considerably[63]. This indicates that the simple hydrodynamic model is unsuitable for the description of the mechanism of the elementary movements.

6. Molecular Rotation Frequency Scales

The molecular movements of highest frequency in a liquid are those movements which lead to a change in the moment of inertia; their characteristic times τ_J are of the order of 10^{-13} s or less, and coincide with the times obtained from an analysis of the far edge of the Rayleigh scattering line[64]. If the liquid is regarded as a quasi-crystalline solid, this time can be identified with the period of the oscillations in the lattice sites.

The rotational reorientations of molecules take place much more slowly (see Table 2); even small and symmetrical molecules undergo reorientations in times of ~2–10 ps, and the rotation of large and unsymmetrical molecules in viscous solvents takes place in times of 10^{-10}–10^{-9} s.

Table 2. Rotational correlation times of various molecules in liquids.

Molecule	°C	τ_0, ps	Refs.
HF	25	0.8	65
CS_2	20	2	66
C_6H_6	20	4	61
Cyclopentane	20	1.3	67
ClO_3F	−143÷95	0.06 exp (900 RT)	58
F_2	−217	6.8	65
Bromobenzene	23	13	64
Nitrobenzene	25	32	66
Toluene	20	14	64
m-Nitrotoluene	23	44	64
Rhodamine 6G in octanol	20	1600	68
Rhodamine 6G in $CHCl_3$	20	100	68
Bengal Pink in CH_3OH	20	180	69
Bengal Pink in iso-C_3H_7OH	20	890	69
Eosin in water	20	550	69
Macromolecules (mol.mass ~10^6)	20	~10^8	–

The activation energies of rotation for small and symmetrical molecules are 1–3 kcal mole^{-1}, and for large and anisotropic molecules they may reach 5–7 kcal mole^{-1} and sometimes more. An interesting feature is that the pre-exponential factors for the rotational correlation times amount to ~10^{-13} s and coincide with τ_J.

New possibilities for the study of quantitative dynamics were opened up by picosecond spectroscopy (the data for dyes given at the end of Table 2 were obtained by direct observation of the depolarisation of the fluorescence by picosecond spectroscopy).

The phenomenon of optically induced birefringence (optically induced Kerr effect) is of particular interest. The electric field of a powerful laser pulse passing through the liquid brings about partial orientation of electrically anisotropic molecules. After the passage of the light pulse, the system exhibits the property of birefringence, which disappears with a characteristic time τ_θ. The action of super-fast shutters (Kerr cells) is based on this phenomenon.

III. DYNAMICS OF TRANSLATIONAL MOTION

A macroscopic characteristic of translational dynamics is the diffusion coefficient

$$D_t = \frac{\langle l^2 \rangle}{6\tau}, \qquad (16)$$

where τ is the time in which a particle, on the average, is displaced through a distance l. A familiar expression is the Stokes–Einstein relationship

$$D_t = \frac{kT}{6\pi a\eta}, \qquad (17)$$

which is obtained from the hydrodynamic equations for the movement of a sphere of radius a in a continuous medium with a viscosity η. As in the case of rotational diffusion, this macroscopic description is inadequate; the experimental values of D_t are usually greater than the predicted values, particularly in viscous liquids, polymer solutions, etc. In order to adapt Eqn.(17) for the description of the experimental results, the concept of the micro-viscosity η^* ($\eta^* = f_t\eta$) was introduced [32], with micro-viscosity coefficient

$$f_t = 0.16 + 0.4\,(a/a_L), \qquad (18)$$

where a_L is the radius of the molecules of the solvent. With this correction, Eqn.(17) in most cases reproduces the experimental results satisfactorily (to within 20–30%).

Strictly speaking, Eqn.(17) is not applicable for the description of the micro-dynamics of diffusion. It is often used, however, with the assumption that $\langle l^2 \rangle \simeq \langle a^2 \rangle$ and $\tau = \tau_t$, where τ_t is the time corresponding to a displacement through a distance of the order of the molecular diameter. The particle can cover this distance either by continuous Brownian movement or by abrupt movements.

Existing theories of the molecular mechanism of translational movements are based on the concepts of fluctuations of the free volume and their migration, and in fact represent a development of Frenkel's ideas [70]. The theories predict the Arrhenius temperature dependence of the diffusion coefficient $D = D_0 \exp(-\epsilon_D/RT)$ with ϵ_D close to the activation energy of viscous flow. For some atoms and molecules (of the type Ar, O_2, etc.), however, diffusion takes place without activation, and the diffusion coefficient is proportional to temperature and independent of viscosity [71]. The Arrhenius relationship usually applies in a narrow temperature range; the study of diffusion over a wide temperature range shows that ϵ_D itself depends on temperature. The activation volume of diffusion (which is obtained from the pressure dependence of D) also is not constant and depends on temperature [31]. This indicates that translational molecular movement is not an elementary process, and although different theories give different aspects of this process satisfactorily, there is no complete rigorous theory of both rotational and translational diffusion.

The most extensive information on translational dynamics is obtained by measuring the magnetic relaxation of nuclei and electrons (NMR and EPR). The diffusion coefficients are determined by the spin echo method; the correlation time τ_t and the amplitude of the translational displacement are calculated from the intermolecular dipole contribution to the relaxation of the nuclei (in NMR) or electrons (in EPR).

An example is provided by data [72] on the relaxation times of the protons of chloroform diluted with deuterochloroform. The relaxation time depends on the diffusion coefficient, the distance of closest approach of the nuclei when the molecules come into contact, and the amplitude of the displacement. If the approach distance is taken as 4.1 Å (from molecular models), the amplitude of the displacement is found to be 4.6–5.5 Å. On the other hand, if it is assumed that diffusion takes place by a Brownian mechanism, that is if it is assumed that the amplitude of the displacement is infinitely small, the approach distance is 2.3 Å, which is a physically unrealistic value. From this it may be concluded that translation in chloroform takes place by abrupt movements, with an amplitude of 4.6 to 5.5 Å.

The correlation time τ_t is calculated from the experimentally determined diffusion coefficients using Eqn.(16), where l = 4.6–5.5 Å:

$$\tau_t = 4 \cdot 10^{-13} \exp(-2300/RT).$$

The pre-exponential factor is close to the value of τ_J, and characterises the period of the vibrations of the molecule in the equilibrium position. In liquid HF at 25 °C, it was found that $D = 10^{-4}$ cm^2 s^{-1}, τ_t = 2.3 ps (from NMR data) or 4.0 ps (from neutron scattering); the amplitude l = 3.7 Å (NMR) or ~5 Å (neutron scattering) [65]. For cyclopentane and cyclohexane at 20 °C, the amplitudes of the rotations, calculated from the scattered neutron spectra, are 0.3–0.6 Å (the displacement of a point along the surface of the sphere of rotation); the amplitudes of the vibration of the centre of gravity of the molecules are 1.3–1.9 Å in the temperature range from the melting point to the boiling point [67].

The quasi-elastic scattering of cold (low-energy) neutrons is becoming a powerful experimental method for studying the molecular dynamics of liquids. The energy spectrum of scattered neutrons gives the frequency spectrum of the atomic–molecular movements with characteristic times 10^{-4}–10^{-11} s and amplitudes of the atomic–molecular displacements 0.1–10 Å.

Neutron scattering data show that both the orientational and the translational movements contain as components displacements of both small amplitude and large amplitude. Their relative proportions depend on the shape of the molecules, temperature, and the viscosity of the liquid.

In recent years, fairly exact mathematical methods have been developed for calculating the coefficients of rotational and translational diffusion. These methods are based on the view of a liquid as a system of close-packed rigid spherical (or almost spherical) particles. These

ideas effectively give the static structure of a liquid. It is assumed[73] that they can also be used to describe its dynamics. A dynamic theory has been developed[74], based on the fact that single-particle movement in a liquid is controlled by the forces of intermolecular repulsion (the steep branch of the intermolecular potential). The dynamics of this system are close to the dynamics of a system of rigid particles[74]. It is assumed that the long-range (changing slowly with distance) intermolecular forces can be neglected. This approximation is applicable to the description of single-particle movement, but is naturally inapplicable to the examination of the collective correlated movement of several particles (for example in liquid crystals).

Thus the one-particle approximation works satisfactorily, and makes it possible to calculate the coefficients of rotational and translational diffusion with good accuracy.

Direct proof that the dynamic processes in a liquid are controlled by short-range forces of repulsion has been obtained[75] by calculating the correlation functions for the velocity of particles in a model liquid, in one case taking account of the entire intermolecular Lennard–Jones potential, and in the second case taking account of only its repulsive part; the correlation functions were found to be the same in both cases.

The same method (computer modelling of the dynamic processes) showed that the diffusion coefficients in a model liquid consisting of rigid spheres coincides to within 10 units with the diffusion coefficients in a liquid in which the entire Lennard–Jones potential is taken into account, that is long-range forces of attraction do not play a significant role in the molecular dynamics of a liquid, although these forces play a decisive role in the thermodynamics of liquids.

IV. MOLECULAR DYNAMICS OF PAIRS

All bimolecular chemical and physicochemical processes take place in pairs of interacting particles (chemical reactions, energy transfer, quenching of excited states, complex formation, etc.); the probability that a process will take place in a single encounter of the reacting particles is determined to a considerable extent by the dynamics of the pair. These dynamics can be examined for the case of a pair of radicals; this reproduces all the characteristic features of the behaviour of any molecular pair of uncharged particles.

A radical pair is a dynamic system in which the partners may diffuse into the volume, move apart, and return again to the original pair, undergoing diffusion journeys along random trajectories of different length and duration. The probability of return gradually decreases with increase in the length of the trajectory; this probability will be defined by a function $f(t)$. In other words, $f(t)$ is a function of the distribution of the pairs with respect to lifetime, that is the probability that a pair survives to the instant of time t; this means that the partners leaving a pair at the instant $t = 0$ return again to the pair at the instant t with a probability $f(t)$.

The probability of reaction in a pair (for example recombination) consists of two terms:

$$P = \varepsilon + (1-\varepsilon)\int_0^\infty \varepsilon f(t)\,dt\,. \qquad (19)$$

The first term takes account of primary recombination, which has a probability ϵ; it is due to the "collapse" of those pairs in which the radicals have been unable to move apart before the instant t. The second term expresses the probability of secondary recombination, due to the repeat encounters of radicals which have left the pair at the instant $t = 0$ and returned to it at the instant t.

From the theory of the random diffusion of particles in a liquid[77], the following expression was proposed for the function $f(t)$:

$$f(t) = mt^{-3/2}\exp\left(-\frac{\pi m^2}{p^2 t}\right), \qquad (20)$$

where $p = \int_0^\infty f(t)dt$ is the probability that the pair undergoes at least one secondary encounter ($1 - p$ is the probability that the radicals never return to the original pair); usually, $1/2 < p < 1$. The values of p and m are determined by the following expressions[78]:

$$p \simeq 1 - (1/2 + 3\rho/2\sigma)^{-1}$$
$$m = 1.036\,(1-p^2)\,(\rho/\sigma)^2\,\nu^{-1/2},$$

where ρ is the diameter of the contact pair, σ the step of the mean-square diffusion displacement of the radicals ($\sigma^2 = 6D\nu^{-1}$), and ν the frequency of the diffusion displacements.

The function $f(t)$ in the form of Eqn. (20) describes the molecular dynamics of any pair of neutral particles. Substituting Eqn. (20) in Eqn. (19) gives the probability of reaction in the pair:

$$P = \varepsilon + \varepsilon\,(1-\varepsilon)\,p^{\cdot}. \qquad (21)$$

This equation in fact determines the magnitude of the cage effect. It is applicable with the condition that the lifetime of the isolated radicals is infinite. In fact, the radicals have a finite lifetime: within the diffusion time they may be transformed into other radicals (by decomposition, isomerisation, or replacement). As a result, chemical dynamics are superimposed on the diffusion dynamics of the pair; the function $f(t)$ must be modified in such a way that it takes account of the diffusion trajectories and return of only the surviving radicals. If the rate constant of the chemical transformation is k, the probability of "survivial" of the radicals until time t in the pair is equal to $\exp(-kt)$; the dynamics of a pair of surviving radicals are then described by the function

$$\varphi(t) = f(t)\exp(-kt). \qquad (22)$$

This function describes the dynamics of any pair of particles having a finite lifetime $\tau = k^{-1}$; for processes involving the bimolecular quenching or transfer of energy (vibrational or electronic), k is the rate constant of the radiative or non-radiative unimolecular deactivation of the excited particle. For processes involving radicals, the function (22) describes the dynamics of not only chemical but also physical transformations (inversion, rotation, *cis-trans* isomerisation); it can then be used to calculate the degree of preservation of the stereochemical configuration or optical activity in the product formed.

Substituting the function $\varphi(t)$ in Eqn. (19) in place of $f(t)$ gives

$$P = \varepsilon + \varepsilon\,(1-\varepsilon)\,p\cdot\exp\left[-(2m/p)\sqrt{\pi k}\right]. \qquad (23)$$

For processes involving the recombination of radicals, P is the probability of formation of the product in the radical pair, and ϵ the probability of recombination in each contact of the partner. For preservation of the stereochemical configuration, P is the probability of preservation,

and k the frequency of the inversion or spatial reorientation of the particles in the diffusion journeys. For processes involving excited particles, P is the probability of the quenching or transfer of energy in the pair formed by the excited molecule and the quenching agent (or energy acceptor), and ϵ the probability of this process in each contact of the partners.

The dynamics of radical pairs exhibits another remarkable feature: in addition to diffusion and chemical dynamics, it exhibits spin dynamics, that is the dynamics of the evolution of spin states, or singlet–triplet transitions. Spin dynamics are controlled by the magnetic interactions in the radicals and depend on the difference in the Zeeman energies of the radicals (and hence on the external magnetic field intensity), the energy of the hyperfine electron–nuclear interaction, and the magnitude of nuclear spin of the radicals. This leads to magnetic effects in radical reactions, the importance of which was understood and evaluated only in recent years [79,81]. These include the chemical polarisation of nuclei and electrons, the magnetic isotope effect, and the influence of a magnetic field on chemical reactions [80]; a complete review of studies in this field has been published [82].

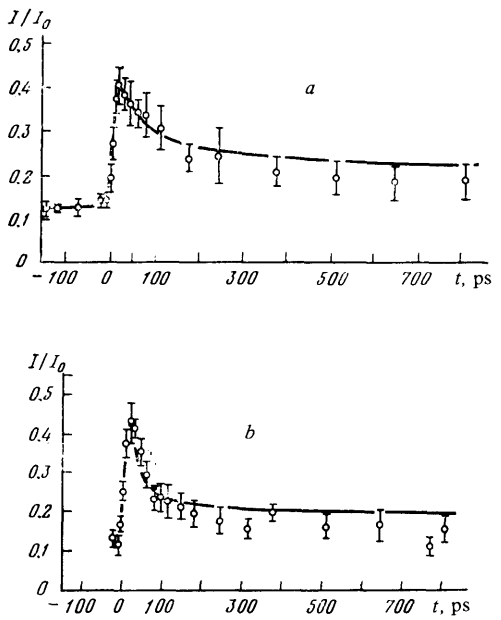

Figure 4. Kinetics of the cage recombination of iodine atoms: *a*) in CCl_4; *b*) in hexadecane [84]. The points give the experimental results, and the lines the results of the calculation using the Noyes model; the moment $t = 0$ corresponds to the end of the exciting pulse.

The dynamics of molecular pairs of free uncharged particles has been discussed; its experimental verification can now be examined.

Firstly, quantitative studies of magnetic effects (in particular, the chemical polarisation of nuclei) have shown that the function $\varphi(t)$ in the form of Eqn.(22) effectively describes the experimental results. The polarisation of nuclei takes place in a pair as a result of singlet–triplet transitions with a characteristic time of $10^{-8}-10^{-10}$ s; the main contribution to the polarisation is therefore made by long diffusion trajectories, the duration of which is comparable with the time of singlet–triplet transitions. In other words, the main contribution to the polarisation of nuclei is made by diffusion displacements with a duration $t \gg m^2/p^2 \simeq 10^{-12}-10^{-11}$ s. With this condition, the function $f(t)$ has the simple form

$$f(t) \simeq mt^{-3/2} \qquad (24)$$

and describes the large-scale diffusion dynamics of long-lived particles.

Secondly, computer calculations of the molecular dynamics of pairs (so-called machine experiments) have confirmed the general form of the function $f(t)$ given by Eqn.(20) and have shown that the probability of a secondary encounter of the particles in a pair decreases with time as $t^{-3/2}$, in agreement with Eqn.(24). [83]

Finally, direct confirmation of the form of the function $f(t)$ has been obtained by picosecond spectroscopy [84]. A solution of I_2 in CCl_4 and $C_{16}H_{34}$ was irradiated by a powerful 5300 Å laser pulse of duration ~5 ps. At this frequency, I_2 is excited into the state $^3\Pi_{0_u^+}$, from which collision-induced predissociation to two atoms in the state $^2P_{3/2}$ takes place. The iodine atoms recombine in the pair (in the cage) or move apart and recombine in diffusion encounters with other atoms, avoiding cage recombination. The formation of I_2 molecules from the atoms is detected by probe laser pulses which measure the transmission at a wavelength absorbed by I_2 (5300 Å); the results are shown in Fig. 4.

After the passage of the exciting pulse, the transmission of the solution at first increases as the I_2 molecules dissociate into atoms, and then decreases, when the iodine atoms begin to recombine, and reaches a stationary value after ~800 ps. The stationary value of the transmission does not coincide with the initial transmission; the difference corresponds to the number of iodine atoms which have avoided cage recombination and moved into the volume. Their recombination in the volume is limited by diffusion, and takes place in a time of $\sim 10^{-8}$ s. The fraction of atoms leaving the cage is 25% in CCl_4, and 5% in hexadecane [84].

The characteristic time of the cage recombination of iodine atoms is ~140 ps in CCl_4, and ~70 ps in hexadecane [84]; this time can in fact be regarded as the lifetime of the cage in the liquid. The kinetics of the recombination are described satisfactorily by Eqn.(20); the best agreement between theory and experiment is obtained for the following values of the parameters: frequency of the abrupt diffusion movements $(1-5) \times 10^{12}$ s^{-1} in CCl_4 and $(2-20) \times 10^{12}$ s^{-1} in $C_{16}H_{34}$; amplitude of the elementary diffusion displacement 0.5–1.0 Å in CCl_4 and ~0.1 Å in $C_{16}H_{34}$. [84] These values are of course approximate, but they give the correct order of magnitude and are physically reasonable.

The function $f(t)$ characterising the dynamics of pairs of oppositely charged particles should describe the diffusion movement of the particles in the Coulombic field of mutual attraction. The problem of the behaviour of a

pair of this kind has been solved in radiation chemistry [85,88], where it is necessary to calculate the probability of the return of a thermalised electron or negative ion to the original positive ion.

Finally, mention may be made of the dynamics of combined pairs, in which the interacting centres are joined by a chain of atoms and chemical bonds. The dynamics of pairs of this kind represents essentially conformational and not diffusion dynamics. If however the connecting chain is sufficiently long, diffusion will influence the rate of the conformational transitions. An example of systems of this kind is provided by nitroxide biradicals, in which two paramagnetic nitroxide fragments are joined in a single molecular system [47]. The exchange interaction of the unpaired electrons in these biradicals takes place chiefly in intramolecular collisions of the paramagnetic centres, so that it depends on the flexibility of the connecting bridges, the number of chemical bonds, and the solvent[87]. The encounter frequency and rate of spin exchange are controlled by the conformational dynamics of the connecting bridge.

A study of the frequency of the intramolecular transfer of an electron between two α-naphthyl groups joined by a polymethylene chain [88] showed that the frequency of transfer decreases according to the law $(n+1)^{3/2}$ for $n \geq 6$ (n is the number of methylene groups in the chain). The activation energy of transfer is small, and independent of n.

The disproportionation of the biradicals

$$\dot{C}H_2-(CH_2)_n-\dot{C}O \rightarrow CH_2=CH-(CH_2)_{n-1}-C\overset{O}{\underset{H}{\diagdown\!\!\diagup}}$$
$$(n = 7-11)$$

is an intramolecular process; the disproportionation product is found to show polarisation of the nuclei, which depends on the magnetic field intensity [80]. The polarisation is produced as a result of $S-T_{-1}$ transitions in the biradical at the moments at which the ends of the biradical, in their random movement, pass through a position in which the condition $2J \simeq g\beta H_0$ is satisfied (when the exchange energy of the electrons is equal to the Zeeman energy). In this position, the energy levels of the singlet (S) and one of the triplet (T_{-1}) states intersect; the magnitude of the polarisation depends on the frequency with which the system passes through this point.

Quantitative calculations of the nuclear polarisation [90] have shown that the probability of passage through the point of intersection of these levels is given satisfactorily by the Treloar function for a freely connected chain.

In both of these examples, the molecular dynamics of the combined pairs is controlled chiefly by the conformational dynamics of the connecting bridges.

V. DYNAMICS OF VAN DER WAALS MOLECULES

Van der Waals molecules (VM) are weakly bonded complexes of atoms, radicals, or molecules, which exist as a result of intermolecular attraction. Dimers of the atoms of the inert gases (Ne_2, Ar_2, Kr_2, Xe_2), and also the complexes $Ne-H_2$, $Ar-H_2$, $Kr-H_2$, $Xe-H_2$, $Ar-N_2$, $Ar-O_2$, $Ar-HF$, $(H_2)_2$, $(O_2)_2$, H_2-N_2, $(NO)_2$, $(CO_2)_2$, etc., are known and have been extensively studied. The properties of VM have been reviewed [91]. Van der Waals molecules have characteristic vibrational–rotational spectra and are detected by infrared and microwave spectroscopy, in experiments on molecular scattering, and in molecular beams.

The main contribution to the energy of formation of VM is made by dispersion interaction (equilibrium distances 3.5–4.5 Å). The dissociation energies of VM are comparable with their kinetic thermal energy and amount to 0.2–0.9 kcal mole^{-1}, so that almost every collision with a foreign molecule leads to decomposition of the VM. At room temperature and a pressure of 1 atm, the time between molecular collisions is $\sim 10^{-10}$ s; the lifetime of the VM is approximately the same. Decrease in temperature increases the lifetime and concentration of VM, and increase in pressure decreases the VM lifetime.

The formation of VM is revealed in the macro-properties of gases, changing the form of the $p-V-T$ diagram, the magnitude of the second virial coefficient, the viscosity, etc. It is assumed [91] that VM take part in processes involving the transfer of its energy, translational–rotational exchange, the spin–rotational relaxation of electronic spin in quantum generators with optical pumping. In addition, VM induce processes of gas condensation; it is suggested [91] that various gaseous chemical reactions may take place with the participation of VM; these reactions may have a negative temperature coefficient (for example the oxidation of NO).

An interesting role is played by VM in reactions taking place in molecular beams. The angular distribution of the reaction products indicates unambiguously that many reactions include the formation of an intermediate complex, the lifetime of which is greater than or comparable to the period of rotation of the complex ($\tau \geq 10^{-12}$ s).[92] This lifetime is much greater than the duration of the collision of the reagent molecules. These reactions include: $Cs + RbCl \rightarrow CsCl + Rb$; $Cl + BrI \rightarrow ClBr + I$; $Cl + I_2 \rightarrow ClI + I$; $D + H_2 \rightarrow DH + H$, etc.[92] The intermediate complexes in these reactions can be regarded as VM, since they can hardly involve any specific interaction other than van der Waals interaction (for example the complex D–H–H, which precedes the reaction $D + H_2 \rightarrow DH + H$).

VM must undoubtedly also exist in a liquid, although their lifetime, other conditions being equal, should be shorter than in the gaseous phase. It is possible to detect VM from the increase in the correlation time of rotational motion in a liquid; the measured time is a complex function of the reorientation time of single molecules and their pairs [93]. This is revealed experimentally by an increase in the rotational correlation time of the molecules with increase in their concentration (at constant viscosity).

These effects are usually investigated by studying the dependence of τ_θ on viscosity at different concentrations of the molecules. The $\tau_\theta(\eta)$ relationship obeys Eqn. (5) at all concentrations, but at η = const. the time τ_θ is greater at higher concentrations of the molecules, that is for a greater contribution of pairs to the measured light scattering. An increase is shown not only by the values of τ_θ but also by their values extrapolated to $\eta = 0$, which are close to the periods of rotation of free rotators in the gaseous phase. This effect has been observed for solutions of benzene, toluene, nitrobenzene, perfluorobenzene, and chloroform [30,40]. Thus for nitrobenzene in an infinitely dilute solution in CCl_4 the time τ_θ is 2.4 ps, and reaches 5.6 ps with increase in the concentration of nitrobenzene to 50% (at the same viscosity). It was concluded that the nitrobenzene molecules are "joined" in pairs in such a way that their planes are arranged in parallel [93]. The pairs of benzene molecules are "joined" with their planes at right angles; the same relative orientation of neighbouring molecules is observed in solid and liquid benzene (from X-ray scattering data [94]). The recently

detected[94] dimers of benzene in the gaseous phase apparently have the same structure, since they exhibit a dipole moment.

The dimers of molecules are short-lived species; their lifetime τ is shorter than the period of rotational reorientation in the liquid τ_θ, but greater than the period of free rotation in the gaseous phase, and amounts to several picoseconds. Thus the dimers can be regarded as van der Waals molecules. The depolarisation of the Rayleigh light scattering in benzene + perfluorobenzene and perfluorobenzene + mesitylene mixtures has revealed pairs of these molecules[95]: the value of τ_θ for the mixtures is 2–4 times τ_θ for the isolated molecules (at a constant viscosity in the same inert solvent, for example in CCl_4). In this case also, the molecular pairs can be regarded as VM with a lifetime $\tau \lesssim \tau_\theta$.

As noted earlier, Rayleigh scattering is observed in solutions of optically anisotropic molecules in optically isotropic solvents. The molecules of these solvents are symmetrical and do not exhibit anisotropy of the polarisability (for example CCl_4). In molecular collisions, however, the electronic structure of the interacting particles changes, with a consequent breakdown of the symmetry of the electron cloud and the production of short-lived fluctuations in the anisotropy of the polarisability. For this reason, symmetrical molecules (and even atoms) also show Rayleigh scattering; the line corresponding to this scattering is usually very broad, and is superimposed on the narrow line corresponding to the ordinary Rayleigh scattering of optically anisotropic molecules.

Rayleigh scattering induced by collisions has been observed in gases (He, Ne, Ar, Xe, H_2); it has been shown that it is due to van der Waals molecules $(He)_2$, $(Ne)_2$, etc.[91] The same scattering has been observed in liquids (Xe, Ar, $SnBr_4$, CCl_4); the correlation times of the paired interactions inducing the Rayleigh scattering amount to 1–3 ps.[96] These times are obviously too long to be regarded as the duration of the collision. In a liquid, the light scattering is most probably due to VM, in which the anisotropy of the optical polarisability is revealed; the lifetime of these VM is ~1–3 ps and is shorter than the period of rotational reorientation.

The problem of possible complex formation by the most important chemical reagent—molecular oxygen—is of particular interest. Evans[97] was the first to observe singlet–triplet absorption by benzene in the presence of oxygen; it was assumed that oxygen removes the spin-forbidden character of the singlet–triplet transition in benzene, and hence interacts somehow with the electron cloud of the benzene molecule. It was later found[98] that in the presence of oxygen, new absorption bands appear in the electronic spectra of hydrocarbons, alcohols, and aromatic molecules; they were assigned to charge-transfer complexes. The equilibrium constants for complex formation were small, however, and the bond energies $\lesssim$300 cal mole^{-1}. The results were often contradictory and indefinite; the formation of the complex $C_6H_6 + (O_2)_2$ was also suggested[98]. A displacement of the $^1\Sigma_g^+ \longleftrightarrow {}^3\Sigma_g^-$ absorption band of molecular oxygen from 760 nm (in the gas) to 630 nm (in water) is also observed[99]. All these facts have been regarded as signs of the interaction of the electron clouds of molecular oxygen and organic molecules

Convincing proof of this interaction was obtained by NMR: in the presence of molecular oxygen, dissolved under a pressure of 3–50 atm in the liquid, the NMR lines of most molecules studied (water, alcohols, dioxan, amines, acetone, cyclohexene, phenylacetylene, chloroform, benzene and its derivatives, anthracene, etc.) undergo paramagnetic shifts and broadening[100,101]. The paramagnetic shifts show unambiguously that in the interaction of the oxygen molecule with dissolved molecules, overlap of their electron clouds and partial transfer of the unpaired electrons of oxygen to the organic molecules take place.

This "collectivisation" of electrons can be regarded as a sign of the participation of oxygen in a complex, but the equilibrium constants of complex formation are very small and do not exceed 10^{-2} litre mole^{-1}.[101] The bond energies in the complex are also small, and different for different groups of a given molecule. Thus the bond energy measured from the temperature dependence of the paramagnetic shift of the protons of the CH_3 group in toluene is 1.7 kcal mole^{-1}, whereas that measured from the protons of the aromatic ring is close to zero; in methanol, the bond energy measured from the protons of the CH_3 group is close to zero, whereas that measured from the hydroxyl protons is 0.5 kcal mole^{-1}.[101] Thus different fragments of the same molecule interact in different ways with oxygen.

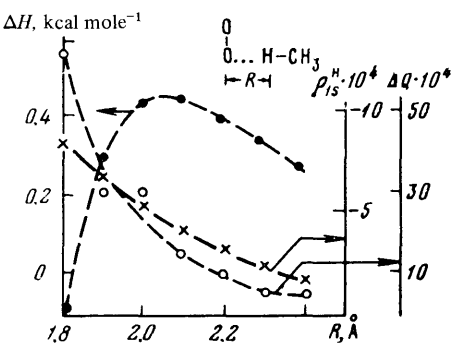

Figure 5. Dependence of ΔH, ρ^H_{1S}, and ΔQ on the distance between the partners of the complex $O_2 \ldots CH_4$.

In binary or ternary mixtures, the paramagnetic shifts depend little or not at all on the composition of the mixtures; this means that there is practically no competition between different molecules for a position in the coordination sphere of oxygen[101]. All these facts show that oxygen forms very weak complexes, which must be regarded as van der Waals molecules. Some results of a quantum-chemical calculation of the most stable configuration of the system $O_2 + CH_4$ are given in Fig. 5; the calculated equilibrium distance is ~2.05 Å, the bond energy $\Delta H \simeq 400$ cal mole^{-1}; the charge ΔQ transferred from oxygen to the methane molecule is $\sim 2 \times 10^{-3}$; the spin density ρH_S on the hydrogen atom attached to the p_z orbital of oxygen is $\sim 3 \times 10^{-4}$. The calculated values of the bond energy and the transferred spin density are close to the experimental values.

The equilibrium constant (~10^{-2} litre mole^{-1}) can be used to estimate the lifetime of VM involving oxygen: the value is ~10^{-12} s. The paramagnetic broadening of NMR lines is completely determined by the intermolecular contribution[101]; the intramolecular contribution, due to the dipole electron–nuclear interaction within the VM, is

negligible. This means that the lifetime of the VM is shorter than the period of its rotational reorientation, that is $\tau \leqslant (1-5) \times 10^{-12}$ s.

In general it should be noted that it is almost impossible to distinguish a distinct boundary between van der Waals molecules and weak short-lived complexes. Neither the lifetime nor the bond energy nor even the transfer of spin (electron) density can serve as unambiguous criterion of the difference between these particles. The only difference between a complex and a VM is the nature of the forces holding the partners in the complex or in the van der Waals molecule; it is fairly difficult, however, to detect this difference experimentally. The partners in VM are held by van der Waals (mainly dispersion) forces; in contrast to the case of the forces responsible for specific interactions in a complex, it should be impossible to saturate dispersion forces; in other words, the coordination number for VM may be large (up to 4–6). It is impossible in practice, however, to reach the concentration range in which this characteristic feature of VM might be detected.

VI. PROCESSES OF COMPLEX FORMATION AND SOLVATION

Complex formation by particles is generally accompanied by the partial overlap of the electron clouds of the partners, which changes the reactivity of the particles in the complex. In the study of complex formation by organic molecules in a liquid, the following principal problems arise: what types of complex exist, what orbitals are used by the partners for complex formation, in what combinations are these orbitals used, how are the orbitals oriented in space, what are the interatomic distances in the complexes, and what are the lifetimes of the complexes? Extensive information on complexes has been obtained by the classical methods of optical spectroscopy, NMR, and dielectric measurements [102]. In recent years, NMR studies of paramagnetic complexes of the type $\dot{R}\ldots L$ (where $\dot{R}$ is an organic radical, and L an organic ligand molecule) [47] have revealed a number of important regular features of complex formation. An advantage of complexes of the type $\dot{R}\ldots L$ is that they have an unpaired electron, which is situated in collectivised molecular orbitals of the complexes. The unpaired electron is transferred with a definite probability (measured by NMR) to the ligand atoms, and reflects all the interactions taking place in the complex.

The theory of the paramagnetic shifts and broadening of the NMR lines in paramagnetic complexes has been developed, the dependence of these spectral changes on the concentration of the complexes in the solution studied, and an approach to the extraction of information on the structure and dynamics of these complexes formulated [103-105]. The basic idea behind this approach is to organise competition between different ligand molecules for the orbitals of the radical. Thus for example the paramagnetic fragment of a nitroxide radical (Fig. 6) uses its π- and n-orbitals for complex formation with the ligand. If the solution contains two types of ligand, one of which reacts using the π-orbital while the other reacts using the n-orbital, the paramagnetic shifts of each of these ligands will be independent of the concentration of the other. Each ligand may add on independently to different orbitals of the radical, forming a two-coordinated complex. In this case there is no competition between the ligands for the orbitals of the radical. On the other hand, if both ligands add on to the same orbital of the radical forming complexes of the same type, the mole fractions of the complexes with each of these ligands (and hence their paramagnetic shifts) will depend on the concentration of the corresponding ligand. In this case the ligands compete for the same orbital of the radical.

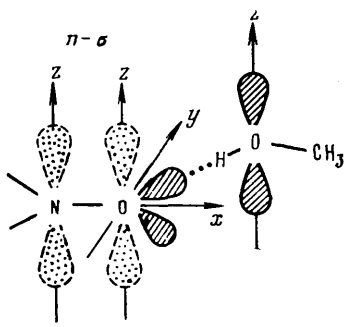

Figure 6. Participation of the orbitals of the paramagnetic fragment of a nitroxide radical in the formation of $n-\sigma$ complexes.

Table 3. Ligands competing with solvent molecules for the orbitals of a radical [105].

Ligand	Functional group (atoms to which the NMR signal relates)	Solvent	Type of complex	K, litre mole^{-1}	ρ_{1s}^{H} or ρ_{2s}^{13C}*
H_2O	OH (protons)	C_6H_5OH	$n-\sigma$	0.7	$1\cdot10^{-3}$
$CHCl_3$	CH (protons)	CH_3OH	$n-\sigma$	0.6	$0.8\cdot10^{-3}$
$(CH_3)_3CNH_2$	NH_2 (protons)	CH_3OH	$n-\sigma$	—	—
	CH_3 (^{13}C)	C_6H_{12}	$\pi-\sigma$	0.1	$1.3\cdot10^{-4}$
CCl_4	CCl (^{13}C)	C_6H_{12}	$\pi-n$	0.5	$1.8\cdot10^{-3}$
C_6H_{12}	CH_2 (^{13}C)	CCl_4	$\pi-\sigma$	0.05	$2.6\cdot10^{-4}$
$H_3CCH_2CH_2-C\equiv$	CH_3, CH_2 (^{13}C)	C_6H_{12}	$\pi-\sigma$	—	—
$H_3CCH_2CH_2-C\equiv$					

*ρ_{1s}^{H} is the spin density in the 1s orbital of the hydrogen atom forming the hydrogen bond; ρ_{2s}^{13C} is the spin density in the 2s orbital of the carbon atom.

This principle has been widely used to determine the structures of the complexes of nitroxide radicals [105]; the chief results of the experimental studies are summarised in Tables 3 and 4.

Molecules containing hydroxyl or amino-groups form complexes of the $n-\sigma$ type; in these, the radical provides a n-orbital, to which the σ-bond O–H (or N–H) of the ligand is attached (see Fig. 6). These are ordinary hydrogen-bonded complexes; the ligands forming the hydrogen bond (H_2O, alcohols, amines, chloroform, organic acids, etc.) compete with one another for the n-orbital of the radical (Table 3). The hydrogen bond joins the radical and the ligand with the formation of a single quasi-π-system, in which ~1% of the density of the unpaired electron is transferred to the π-orbital of the ligand; this spin density subsequently extends to the ligand atoms by a

hyperconjugation or spin polarisation mechanism, leading to the appearance of spin density of different sign in the σ-electronic system of the ligand[106]. Various properties of complexes of radicals with a hydrogen bond are given in Table 5.

Table 4. Ligands not competing with solvent molecules for the orbitals of a radical[105].

Ligand	Functional group (atoms to which the NMR signal relates)	Solvent	Type of complex	K, litre mole^{-1}	ρ_{1S}^{H*}
CH_3OH	OH (protons)	CCl_4, C_6H_{12}	$n-\sigma$	3	$1\cdot10^{-3}$
C_2H_5OH	OH (protons)	CCl_4, C_6H_{12}	$n-\sigma$	0.7	$0.7\cdot10^{-3}$
$(CH_3)_3CNH_2$	NH_2 (protons)	C_6H_{12}	$n-\sigma$	—	—
$CHCl_3$	CH (protons)	CCl_4	$n-\sigma$	0.6	$0.8\cdot10^{-3}$
$C_6H_5OCH_3$	CH_3 (^{13}C)	CH_3OH	$\pi-\sigma$	—	—

*See footnote to Table 3.

Table 5. Equilibrium constants K, lifetimes τ_l, distances $r_{O\ldots H}$, and spin densities ρ_{1S}^{H} on the hydrogen atoms in complexes.

Ligand	K, litre mole^{-1}	τ_l, s	$r_{O\ldots H}$, Å	$\rho_{1S}^{H}\cdot10^3$
CH_3OH	3.5	$4\cdot10^{-11}$	1.75	−9.6
$CHCl_3$	0.6	$2.6\cdot10^{-11}$	1.77	−7.7
$C_6H_{11}OH$	—	$1.1\cdot10^{-10}$	1.45	−1.75
$(CH_2OH)_2$	—	$3\cdot10^{-11}$	1.74	−8.2

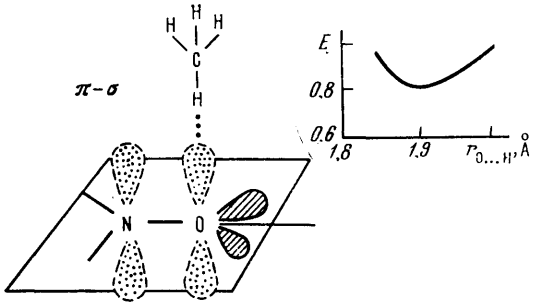

Figure 7. Molecular model of the $\pi-\sigma$ complex of methane and the potential energy curve for the complex; the spin density on the hydrogen atom of the ligand, attached to the π-orbital of the radical, is 3×10^{-4}, and that on the 2*s* orbital of the carbon atom is 1×10^{-3}.

Complexes of the $\pi-\sigma$ and $\pi-n$ type are of particular interest; they are formed using the π-orbital of the unpaired electron and the σ-bond C−H ($\pi-\sigma$ complexes) or with the participation of the unshared pairs of the ligands ($\pi-n$ complexes). The first are formed with saturated hydrocarbons using the CH_2 or CH_3 groups and are detected from the paramagnetic shifts of the ^{13}C nuclei[105]; a model of such a complex is shown in Fig. 7.

The $\pi-\sigma$ complex obviously lies on the reaction coordinate for the transfer of a hydrogen atom and precedes the activated complex, so that the distribution of the spin density and the mechanism of its propagation in $\pi-\sigma$ complexes is of theoretical interest.

Molecules forming complexes of the $\pi-n$ type compete with molecules forming $\pi-\sigma$ complexes for the π-orbital of the radical (see Tables 3 and 4). They do not compete, however, with molecules forming $n-\sigma$ complexes. The $\pi-\sigma$ and $\pi-n$ complexes are generally much less stable than the $n-\sigma$ complexes; their equilibrium constants and lifetimes are an order of magnitude smaller than those for $n-\sigma$ complexes. They are not van der Waals molecules, however, since their formation involves rigorously defined localised interactions: each partner provides its own particular orbitals, which exhibit regular relative orientations and arrangements.

If the molecule contains different functional groups, they may take part in the formation of different complexes. Thus t-butylamine gives a $n-\sigma$ complex involving the NH_2 group, and a $\pi-\sigma$ complex involving the CH_3 groups; $CHCl_3$ gives $n-\sigma$ and $\pi-n$ complexes involving the C−H and C−Cl bonds respectively; n-propylacetylene forms complexes of the $n-\sigma$ type (involving the acetylenic C−H bond) and of the $\pi-\sigma$ type (involving the CH_2 and CH_3 groups), etc. (see Tables 3 and 4).

It is comparatively simple to distinguish these complexes: $n-\sigma$ interaction generally leads to strong paramagnetic shifts on the protons, whereas $\pi-\sigma$ and $\pi-n$ interactions make a large contribution to the paramagnetic shift on carbon nuclei and a small contribution to the paramagnetic shift on protons. Aromatic molecules and alkene groups add on to radicals chiefly to give complexes of the $n-\sigma$ type (involving C−H bonds); interactions of the $\pi-\pi$ type are practically never observed, and apparently involve repulsion.

These regular features of complex formation have been confirmed for phenoxide and verdazyl radicals[107]; the complexes of nitroxide and phenoxide radicals with phenols have been extensively studied[108].

Complex formation by radicals changes the hyperfine interaction constants and the values of the g-factor[106]; this aspect is of particular importance when nitroxide radicals are used as spin tracers and probes. A situation is often realised in which a radical in two states—free and bound in a complex—has different frequencies of rotation and in addition is transferred from one state to another with a definite frequency. This dynamic problem has been solved[109]; the theoretical EPR spectra for different frequencies of exchange and rotation have been published[110].

Complex formation is also revealed in the rotational dynamics of molecules: the rotation about different axes is retarded indifferent ways, depending on how the molecules are attached to one another. Thus complex formation alters primarily the anisotropy of rotation. The rotation of the $CDCl_3$ molecule about the C_3 axis in benzene solution remains unchanged relative to the rotation in pure chloroform, but the rate of the rotation about the perpendicular axes is decreased by a factor of four[59]. This agrees with a structure of the complex in which the C−H bond of chloroform is adjacent and perpendicular to the plane of the benzene ring. In addition, the frequencies of the rotation of the molecules of benzene and chloroform in the complex about the common axis C_3-C_6 coincide,

that is the complex rotates as a whole, and there is no internal rotation about the C_3-C_6 axis[59].

The attachment of Ag^+, Na^+, or Li^+ ions to the CD_3CN molecule does not influence $D_\parallel$ but decreases $D_\perp$, that is the ions are attached to the CN group along the C_3 axis[59].

In conclusion, mention may be made of the measurement, by picosecond spectroscopy[111], of the characteristic time in which a free electron in water creates an equilibrium solvation layer, dropping into a potential well. This time is 4 ps, and corresponds to the rotational orientation time of dipolar molecules.

VII. INFLUENCE OF MOLECULAR DYNAMICS ON THE KINETICS OF CHEMICAL REACTIONS

The rate constant of a diffusion-controlled reaction k is equal to the product $k_{diff}P$, where k_{diff} is the rate constant of the encounters of the reacting particles, and P the probability of reaction in the pair. The quantity k_{diff} is determined entirely by the dynamics of the translational motion, and is usually estimated from the Smolukhovskii relationship[28]: $k_{diff} = 4\pi(r_A + r_B)(D_A + D_B)$, where r and D are the radii and diffusion coefficients of the interacting particles A and B.

The quantity P is determined by the molecular dynamics of the pair and is calculated from Eqn.(23), which contains the parameters of the diffusion (p, m) and chemical (k, ϵ) dynamics. The relative proportion of the primary and secondary reactions in the pair [first and second terms in Eqn.(23)] depends on the values of the constants k and ϵ; for large k and ϵ, the proportion of the primary reaction (that is reaction at the moment of first contact of the particles) is large; for small k and ϵ, an appreciable contribution to the probability of the reaction is made by the secondary encounters of the partners in the pair. The value of P also determines the cage effect in radical reactions; the same considerations apply to the primary and secondary recombination of the radicals in the pair. The cage effect and diffusion kinetics will not be discussed here; these topics have been dealt with in a number of reviews and monographs (see for example Refs.112 and 113).

The parameter ϵ (that is the probability of reaction in a contact pair) depends on the competition of the rotational and translational mobilities of the particles. It is usually described effectively using the black spot model. It is assumed that the reacting particles are spheres with marked anisotropy of the reactivity; in other words, the reaction centre occupies only a small fraction (the "black spot") of the surface of the sphere. If contact between two such spheres is to be accompanied by reaction, it is necessary that their relative orientation lead to the coincidence of the two "black spots". This model has been examined in detail[114]; the probability of reaction depends on the ratio of the frequencies of rotation and translation and on the size of the "black spot".

The "black spot" model has been confirmed by recent data[115] The disappearance of t-butyl radicals in C_7-C_{16} hydrocarbons is a diffusion-controlled process with rate constant 10^8-10^9 litre $mole^{-1}$ s^{-1}; the ratio of the yields of the disproportionation and recombination products (f_d/f_c) decreases with increase in temperature and decrease in the viscosity of the solvent. This dependence is explained as follows. For t-butyl radicals, disproportionation takes place in the pair for many relative orientations; in other words, the set of states from which disproportionation takes place is large, that is the "black spot" is large for disproportionation and small for recombination (the ratio of their areas is ~20). Increase in temperature and decrease in viscosity lead to an increase in the frequency of the rotations and an increase in the probability of contact of the "black spots" responsible for recombination; the probability of recombination therefore increases more rapidly than the probability of disproportionation. The ratio f_d/f_c should therefore decrease until it is determined purely by the chemical reactivity ($k_d/k_c \simeq 3$).

This dependence of f_d/f_c on temperature and viscosity, predicted by the "black spot" model, agrees with the experimental results. For reactions controlled by activation, that is taking place under kinetic conditions, molecular dynamics does not play a significant role; it may be revealed only in exceptional cases (in very viscous solutions or in reactions involving macro-molecules). For solid-phase reactions, on the other hand, even under kinetic conditions, the chemical kinetics are controlled by the molecular dynamics[116]; this is the fundamental difference between solid-phase and liquid-phase reactions.

Complex formation and solvation influence the kinetics of reactions controlled by both activation and diffusion. For reactions controlled by activation, the difference in the reactivities of the free and solvated particles is significant; the relative contributions of each to the reaction are determined by the corresponding rate constants and the solvation equilibrium constant[117]. Extensive data on the influence of solvation on the kinetics of reactions have been published[118,119]. For reactions controlled by diffusion, complex formation and diffusion influence both k_{diff} (via the translational dynamics) and P (via the reactivity and dynamics of the pair).

Thus solvation decreases the magnitude of the rate constant for the recombination of t-butoxide and peroxide radicals[119]. The diffusion coefficients of hydrocarbon molecules RH are much greater than the diffusion coefficients of the corresponding alkyl radicals R; it is suggested that this is due to solvation of the radicals[120]. The situation is particularly complicated when the solvated particles do not react, and the lifetime of the solvates is comparable with the lifetime of the pair; it is then necessary, in calculating P, to take simultaneous account of the dynamics of the pair and the dynamics of solvation.

---o0o---

The dynamics of elementary processes in a liquid is part of chemical dynamics. It determines the competition of the elementary processes in pairs of reacting particles, diffusion kinetics, the efficiency of initiation in thermal, photochemical, and radiation-chemical processes, the efficiency of the utilisation and transformation of energy in chemical reactions, etc. The completeness of its description is of course still far from that for gaseous reactions (for example reactions in molecular beams), but it is being developed rapidly. The greatest contribution to the further development of this field is expected from picosecond spectroscopy.

Structure of the Electrical Double Layer in Non-aqueous Solvents

B.B.Damaskin and R.V.Ivanova

Systematic quantitative studies of the structure of the electrical double layer in non-aqueous solvents published during the past 10 years are reviewed. Methods for studying quantitatively the adsorption of ions at the electrode-solution (non-aqueous) interface are described, and the main experimental results on the specific adsorption of ions from non-aqueous media are summarised and compared with theoretical adsorption isotherms. The factors which determine the energy of adsorption and its dependence on the nature of the solvent, on the charge on the electrode, and on the number of pre-adsorbed particles are discussed. Existing models of the ionic double layer are tested for their ability to describe the specific adsorption of ions from non-aqueous solutions. Theoretical models of the fixed part of the electrical double layer are considered (in the absence of specific adsorption of ions), and used to interpret differential capacity curves in various solvents. 105 references.

I. INTRODUCTION

Important new developments, associated with the use of non-aqueous solvents, have occurred in the last few years in both experimental and theoretical electrochemistry. In applied electrochemistry the practical aim of this work is to develop new cells in which the electrolyte consists of a non-aqueous solution. The electro-synthesis of organic compounds can also be carried out conveniently in non-aqueous solvents, since both organic and inorganic compounds are readily soluble in many non-aqueous solvents. Non-aqueous solutions are used in new electrochemical information-processing devices. The technical application of various solvents invariably leads to corrosion problems, and special studies of the corrosion of metals in contact with non-aqueous solvents have been reported. This work in applied electrochemistry underlines the importance of theoretical advances in our understanding of the kinetics and mechanisms of electrochemical reactions in non-aqueous media. Studies of the structure and properties of the electrical double layer and of adsorption phenomena at the electrode-non-aqueous solvent interface are an essential part of this type of work.

The first studies of the structure of the electrical double layer in non-aqueous solutions, based on measurements of electrocapillarity, were reported by Gouy[1] and by Frumkin[2,3]. Gouy measured the surface tension maxima of mercury in a series of non-aqueous solvents, and Frumkin plotted the full electrocapillary curves of the mercury electrode in methanol and ethanol, in pyridine, and in acetone. From these results Frumkin calculated the average double layer capacity for a negatively charged electrode, and he concluded that the effective dielectric constant within the electrical double layer bears little relation to the dielectric constant in the bulk of the solution[2,3]. Renewed interest in non-aqueous solvents in the early 1950's resulted in a series of publications on the electrochemistry of non-aqueous solutions and in particular on the structure of the electrical double layer. However most of this work is qualitative or, at best, semi-quantitative.

The first stage in the collection of qualitative data on the structure of the electrical double layer at the electrode-non-aqueous solvent interface was essentially completed in 1970. The results were fully reviewed by Payne[4,5]. The main conclusions can be summarised as follows.

1. There is a qualitative analogy between the mercury-water and the mercury-non-aqueous solvent interface. This analogy is most evident in the relative position of the electrocapillary and the differential capacitance curves for solutions of a series of surface-active anions[2-5].

2. The Gouy-Chapman-Grahame theory[6] of the diffuse part of the double layer is also applicable to non-aqueous solutions of surface-inactive electrolytes. In dilute solutions of these electrolytes a minimum appears in the differential capacitance curve near the zero charge potential, and the capacitance at the minimum varies with electrolyte concentration as predicted by the theory of the diffuse part of the electrical double layer[6]. This was first demonstrated by Grahame for NaF solutions in methanol[7], and later confirmed for other solvents[4,5,8,9].

3. General thermodynamic relationships (including those derived from the basic electrocapillarity equation) are applicable to the structure of the electrode-non-aqueous solvent interface. In particular, comparison of experimental electrocapillary curves with those calculated by double integration of the differential capacitance curves confirms the validity of the expression

$$C = -\partial^2\sigma/\partial E^2, \qquad (1)$$

where C is the double-layer capacitance, σ is the interfacial tension, and E is the potential[8-11].

4. The double-layer capacitance can be correlated with the thickness of the electrical double layer, determined by the size and shape of the solvent molecules[4,5,12], but it cannot be correlated with the bulk dielectric constant of the solvent.

Since Payne's review deals mainly with the boundary between a mercury electrode and the solution we shall discuss the above conclusions by considering the bismuth electrode, on which extensive experimental data have been

obtained in recent years by Pal'm and his colleagues of the Tartu State University (reviewed in Refs. 13 and 14).

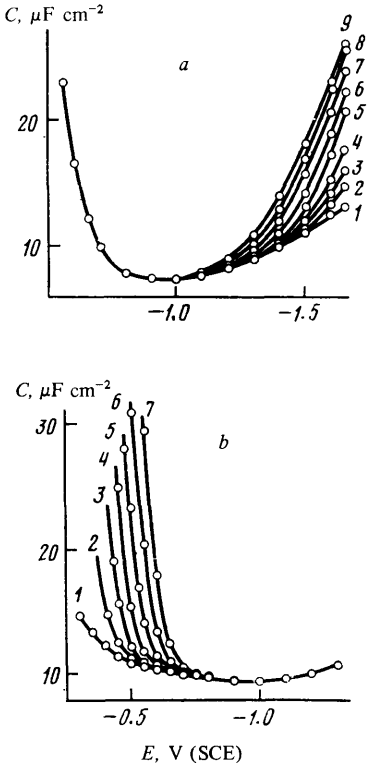

Figure 1. Differential capacitance curves for the Bi/C_2H_5OH interface in the following systems: (*a*) m*c* KSCN + $(1-m)c$ LiSCN for $c = 0.1M$ and the following values of m[*1*) 0, *2*) 0.005, *3*) 0.01, *4*) 0.02, *5*) 0.05, *6*) 0.1, *7*) 0.2, *8*) 0.5, *9*) 1.0]; (*b*) m*c* KCN + $(1-m)c$ KF for $c = 0.1M$ and the following values of m[*1*) 0, *2*) 0.003, *3*) 0.01, *4*) 0.03, *5*) 0.1, *6*) 0.3, *7*) 1.0] (from Ref. 14).

Fig. 1 shows the differential capacitance curves for the Bi/ethanol interface in mixtures of two salts at constant ionic strength[14]. The first of the two systems illustrates the replacement of the surface-inactive Li^+ cation by the surface-active K^+ cation, and the second illustrates the analogous replacement of the F^- by the CN^- anion. It can be seen from Fig. 1 that the capacity increases with the concentration of the surface-active component. A similar behaviour had been observed previously at a mercury electrode in aqueous solutions, for which the transition from an inactive to an active ion is accompanied by an increase in double-layer capacitance[15]. By using the reverse integration method[16] together with Eqn. (1) we can obtain two series of electrocapillary curves for the above systems to the precision of a single integration constant; in these curves an increase in the relative amount of surface-active ion is accompanied by a decrease in σ and a shift in the position of the electrocapillary maximum.

Fig. 2 shows the differential capacity curves of a bismuth electrode in ethanol solutions of the surface-inactive electrolyte $LiClO_4$.[17] In dilute solutions a characteristic minimum appears near the zero-charge potential (Fig. 2*a*). A plot of the reciprocal of the measured capacitance against the reciprocal of the calculated capacitance of the diffuse part of the double layer gives a straight line of unit slope, as expected from the theory of the electrical double layer (Fig. 2*b*).

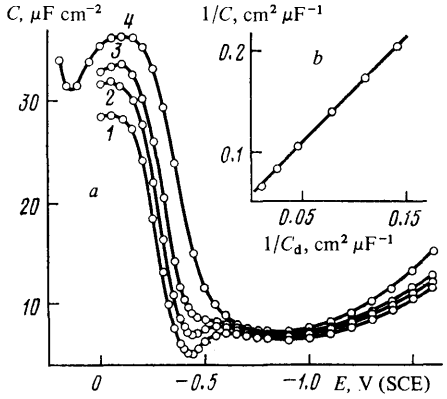

Figure 2. Differential capacitance of a bismuth electrode in standard solutions of $LiClO_4$: (*a*) capacitance against potential for various concentrations of $LiClO_4$ [*1*) 0.003, *2*) 0.01, *3*) 0.03, *4*) 0.5 *M*]; (*b*) reciprocal capacitance against reciprocal diffuse layer capacitance at zero surface charge (from Ref. 14).

The second stage in the study of the electrical double layer in non-aqueous solvents, with which the present review is mainly concerned, is characterised by quantitative studies of the adsorption of ions at the interface between the metal and the non-aqueous solvent. Quantitative data on the structure of the electrical double layer are needed to study the relationship between these results and the model structure of the double layer, to choose an isotherm which adequately describes the adsorption of ions, and to interpret the role of the non-aqueous solvent in determining the structure of the electrical double layer.

II. METHODS OF QUANTITATIVE STUDY OF THE ELECTRODE–NON-AQUEOUS SOLVENT INTERFACE

All the basic data on the structure of the electrical double layer at the boundary between *s,p* metals and aqueous solutions have been obtained by measurements of surface tension and differential capacity. However, the measurement of electrocapillary curves in non-aqueous solutions presents a number of difficulties. In experiments with the Gouy capillary electrometer[18,19] the non-aqueous solution often fails to wet the area between the mercury and the wall of the capillary (unlike aqueous solutions, which have a good wetting action). Thus the condition of full-wetting (which is essential in the capillary electrometer

method) is infringed, leading to unsatisfactory experimental results. In another method of measuring surface tension, based on squeezing a mercury drop from a U-shaped capillary[20], measurements in non-aqueous solutions are complicated by the need to achieve full wetting of the capillary tip whilst avoiding seepage of the solution into the capillary. In the case of aqueous solutions the combined requirements are met by making the capillary hydrophobic over its entire length before cutting off the capillary tip (which thus remains hydrophilic). In non-aqueous solvents this method is not applicable because the wetting powers of organic solvents towards hydrophobic and towards clean glass surfaces are almost identical. Thus, in spite of the large number of published studies of the double layer at the mercury/non-aqueous solution interface based on measurements of electrocapillary curves[8-11,21-27], the number of systems to which the method can legitimately be applied is limited by the above considerations. We should also note that the electrocapillary curve method cannot be used with solid electrodes. Therefore the most important method of studying the electrode/non-aqueous solution interface experimentally is the measurement of the differential capacitance of the electrical double layer.

Differential capacitance data can be used in two ways, which have been termed the binary electrolyte method[28-30] and the mixed electrolyte method[15,31]. In the case of a binary 1,1 electrolyte the surface excess of anions (Γ_-) for a given electrode charge q is calculated by the equation

$$\Gamma_- = (\Gamma_-)_{q=q^*} + (q - q^*)\left(\frac{\partial \Gamma_-}{\partial q}\right)_{q=q^*} - \frac{1}{2RT}\int_{q^*}^{q}\int_{q^*}^{q}\left[\frac{\partial (1/C)}{\partial \ln a_\pm}\right]_q dq^2, \qquad (2)$$

where q^* is the negative charge on the electrode (large enough to suppress the specific adsorption of anions), and $a_\pm$ is the mean activity of the electrolyte. The quantities $(\Gamma_-)_{q=q^*}$ and $(\partial\Gamma_-/\partial q)_{q=q^*}$ in Eqn. (2) are calculated by the formulae of the theory of the diffuse layer[29,30]. In order to use Eqn. (2) we must first of all determine the charge on the electrode by numerical integration of the C,E curves and plot $1/C$ against $\ln a_\pm$ for different (constant) values of q. The differentials $[\partial(1/C)/\partial \ln a_\pm]_q$ are then found by numerical or graphical differentiation of these curves.

The binary electrolyte method can be used if the following conditions are met. Firstly there must be a region of charge such that the charge of specifically adsorbed ions is $q_1^- = 0$. Secondly we must assume that the specific adsorption of counter-ions is negligible, and therefore that the charge q_1^+ of these ions in the fixed part of the double layer is zero. The condition $q_1^+ = 0$ must be met in the presence as well as in the absence of specific adsorption of anions. This is equivalent to assuming that the specifically adsorbed anions do not "drag" cations from the base electrolyte into the fixed part of the electrical double layer.

The second method relies on the use of a mixed electrolyte of constant ionic strength. To study the adsorption of the surface-active anion A* we use the system

$$mc\,\mathrm{KA^*} + (1-m)\cdot c\,\mathrm{KA}, \qquad (3)$$

where c is the total concentration of the solution, and m is the mole fraction of the surface-active anion A^* in the mixture with the inactive anion A. To study the adsorption of the surface-active cation K^* we use the system

$$mc\,\mathrm{K^*A} + (1-m)\cdot c\,\mathrm{KA}, \qquad (4)$$

where K is the surface-inactive cation. The characteristic C,E curves for systems (3) and (4) are shown in Fig. 1.

When the mixed electrolyte method is used to treat the experimental results there are two possible approaches. The first approach, used almost exclusively in the work reported so far, consists in the following. The q,E curves are first calculated by the reverse integration method, and then the change in the reciprocal of the differential capacitance $\Delta(1/C) = 1/C_0 - 1/C$ as between the inactive and the active electrolyte is calculated for a given charge on the electrode. The following equation is used:

$$q_1 = (zF/RT)\frac{\partial}{\partial \ln m}\int_{q^*}^{q}\int_{q^*}^{q}\Delta\left(\frac{1}{C}\right)\mathrm{d}\,q^2, \qquad (5)$$

where F is the Faraday and z is the charge on the ion. The second method of treating the experimental data in the mixed electrolyte method is proposed in Ref. 32, but it does not appear to have been used to date. It consists in plotting the reciprocal of the capacitance against the logarithm of the mole fraction in the mixture for q = const: these plots are then differentiated, and the differential is integrated twice with respect to charge:

$$q_1 = -(zF/RT)\int_{q^*}^{q}\int_{q^*}^{q}[\partial(1/C)/\partial \ln m]_q\,\mathrm{d}\,q^2. \qquad (6)$$

In principle Eqns. (5) and (6) should give the same value for the charge of specifically adsorbed ions (q_1).

The following assumptions are implicit in the mixed electrolyte method: 1) the surface-inactive reference ion can exist over the whole of the range of charges[31,33,34]; 2) the degrees of dissociation of the inactive and the active electrolyte are equal (note that substantial errors can arise if this assumption is not valid[35]); 3) the activity coefficients of the two electrolytes in the mixture are approximately equal[15,31] (the errors associated with the infringement of this condition, and ways of applying suitable corrections, are discussed in Refs. 36 and 37).

In order to describe the adsorption of ions we must not only determine the surface activity of various types of particle but also evaluate the adsorption characteristics of the double layer such as the ion–electrode interaction (the free energy of adsorption ΔG_A) and the ion–ion interaction in the adsorption layer (the repulsion interaction coefficient B). Hence the measured charge of specifically adsorbed ions is usually compared with the values calculated by using the adsorption isotherms. A detailed examination of experimental data and a theoretical discussion of the various types of isotherm[38-42] suggest that the most appropriate equation for the binary electrolyte is

$$\ln(q_1/zc) + zF\psi_0/RT = \ln\beta - 2Bq_1/z \qquad (7)$$

whereas the analogous isotherm

$$\ln(q_1/zmc) + zF\psi_0/RT = \ln\beta - 2Bq_1/z \qquad (8)$$

is the best for the mixed electrolyte. In these expressions the quantity $\ln\beta$, which is usually a linear function of the charge, i.e.

$$\ln\beta = a + bq, \qquad (9)$$

characterises the free energy of adsorption. The quantity ψ_0 is the potential of the outer Helmholtz plane, which can be calculated by the theory of the diffuse double layer. Thus for a 1,1 electrolyte we have

$$\psi_0 = (2RT/F)\,\mathrm{arcsinh}\left(\frac{q+q_1}{2Ac^{1/2}}\right), \qquad (10)$$

where $A = (\epsilon RT/2\pi)^{\frac{1}{2}}$ and ϵ is the dielectric constant of the solvent. The quantity B in Eqns. (7) and (8) is a measure of the repulsion interaction between the specifically adsorbed ions.

Eqns. (7) and (8) are a variant of the virial isotherm equation with the concentration of the ion in the bulk of the solution replaced by the concentration of the same ion in the outer Helmholtz plane. Thus the isotherm takes account of the so-called buffer action of the diffuse part of the electrical double layer, consisting in a contribution to the energy of an ion passing from the solution to the surface (since such an ion has to pass through the potential jump in the diffuse layer).

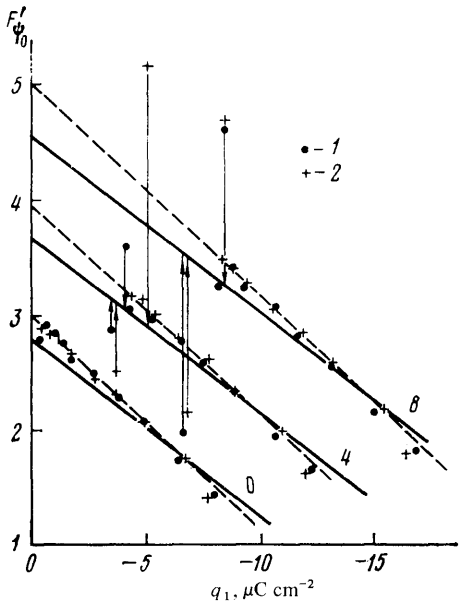

Figure 3. Plots of the quantity $F'_{\psi_0} = [\lg(q_1/zc) + zF\psi_0/2.3RT]$ against charge of specifically adsorbed anions for different electrode charges (stated against each curve in μC cm^{-2}). Full lines are theoretical plots obtained from Eqn. (7) with $a = 6.4$, $b = 0.51$, $B = 0.175$; the points and the broken curves are calculations by Eqn. (2) assuming the following uncertainties in the capacitance values: *1*) 0.1, *2*) 0.01 μF cm^{-2} (from Ref. 43).

The precision of the various methods has been assessed[32,43] by using Eqns. (7) and (8) under conditions of a charge of specifically adsorbed ions in excess of the charge on the electrode (in absolute value). As had already been pointed out[44,45], under the opposite conditions (i.e. $|q_1| < |q|$) the binary electrolyte method cannot be used to determine the specific adsorption of ions, and only the mixed electrolyte method offers reliable results. Hence it was interesting to compare the two methods under the condition $|q_1| > |q|$. This was done by assigning arbitrary values to the parameters a, b, and B, and using Eqns. (7) and (8) to calculate (on a computer) the variation of q_1, with q for various concentrations of the active component in the binary[43] or the mixed[32] electrolyte. The equation[43]

$$1/C = 1/C_{02} + (RT/FM)\left[2 - \frac{(2 - zbM)^2}{2 + M(z/q_1 + 2B)}\right] \qquad (11)$$

(where $M = [4A^2c + (q + q_1)^2]^{\frac{1}{2}}$ and C_{02} is the differential capacitance of the fixed layer at $q_1 = 0$) was then used to calculate the differential capacitance curves. The C values were rounded off to within 0.1 or 0.01 μF cm^{-2}, and the capacitance curves were then interpreted by the method described above[32,43]. This enabled the theoretical values of the parameters to be compared objectively with those obtained from the differential capacitance curves.

Table 1. Comparison of standard and calculated values of the parameters a, b, and B.

Parameter	Binary electrolyte method		Mixed electrolyte method	
	given	found	given	found
a	6.400	6.79	8.1500	8.24
b, cm^2 μC^{-1}	0.510	0.59	0.5900	0.61
B, cm^2 μC^{-1}	0.175	0.22	0.2125	0.23

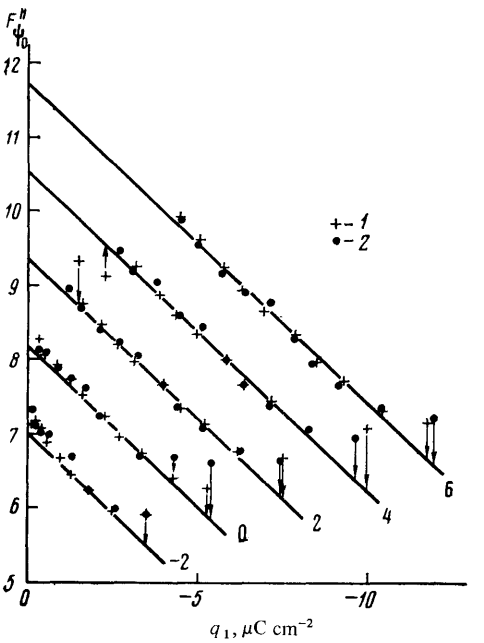

Figure 4. Plots of $F''_{\psi_0} = [\ln(q_1/zmc) + zF_{\psi_0}/RT]$ against charge of specifically adsorbed anions for different electrode charges (stated against each curve in μC cm^{-2}). Full lines are theoretical plots obtained from Eqn. (8) with $a = 8.15$, $b = 0.59$, $B = 0.2125$, and $c = 0.1$; the points were calculated by the mixed electrolyte method [*1*) by Eqn. (5), *2*) by Eqn. (6)] (from Ref. 32).

Fig. 3 shows plots of F'_{ψ_0} against q_1, where F'_{ψ_0} is the left-hand side of Eqn. (7), based on results obtained for a binary electrolyte[43]. The full lines are the initial plots,

corresponding to given values of the parameters a, b, and B, and the points were obtained from the C,E curves by the binary electrolyte method. Points *1* and *2* denote two different levels of precision in rounding off the differential capacitance values. We note a strong deviation of the "experimental" points from the ideal straight line, irrespective of the rounding off precision. Even the points which lie near the straight lines can be seen to fall on different straight lines, with a different slope and a different intercept. In other words, the binary electrolyte method can lead to serious errors in the determination of the parameters a, b, and B. We have shown[43] that the error of the binary electrolyte method can be minimised by increasing 1.5–2-fold the number of concentrations for which the differential capacitance curves are determined. Analogous data for a mixed electrolyte[32] are shown in Fig. 4. Though some of the points lie well away from the straight lines, most of the points lie exactly on the lines, and the experimental values of the parameters a, b, and B agree very well with the values assumed in the theoretical plots.

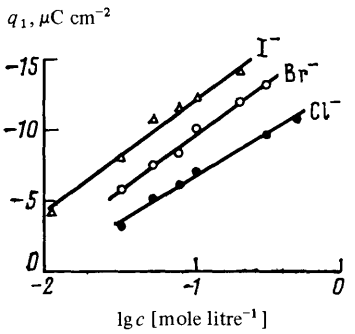

Figure 5. Specific adsorption isotherms of the Cl^-, Br^-, and I^- anions on a mercury electrode at a charge of +2 μC cm^{-2} from binary solutions in DMSO (from Ref. 30).

Our estimates of the precision of the binary electrolyte and the mixed electrolyte method are summarised in Table 1. We note that when $|q_1| > |q|$ the specific adsorption of ions is more accurately described by the mixed electrolyte method. Thus its use is recommended if the necessary conditions are met. In this respect the bismuth electrode has an important advantage, since it is easier to select a surface-inactive reference ion for the bismuth electrode than for the mercury electrode. This is due partly to the semiconductor properties of bismuth (which tend to lower the affinity of bismuth towards all anions) and partly to the fact that oxygen-containing solvent molecules are more strongly adsorbed on bismuth[13,14]. In the case of the mercury electrode there are systems for which no surface-inactive reference ion can be chosen[46]. Thus the results obtained on a bismuth electrode are currently the most appropriate for quantitative comparison of the specific adsorption of ions from non-aqueous solvents.

III. SPECIFIC ADSORPTION OF IONS AT THE METAL–NON-AQUEOUS SOLVENT INTERFACE

Let us examine first of all some experimental results. Fig. 5 shows the specific adsorption isotherms of the anions Cl^-, Br^-, and I^- at the interface between mercury and dimethylsulphoxide (DMSO) for $q = +2$ μC cm^{-2}. The isotherms have the characteristic semilogarithmic form, the surface activity of the anions increasing in the sequence $Cl^- < Br^- < I^-$ (i.e. as in aqueous solutions). Fig. 6 shows the specific adsorption isotherms of the Br^- anion for a range of solvents and an uncharged mercury surface.

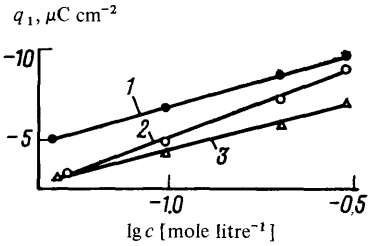

Figure 6. Specific adsorption isotherms of the Br^- anion on an uncharged mercury surface from binary solutions in different solvents: *1*) DMSO,[103] *2*) water[104], *3*) DMFA.[47]

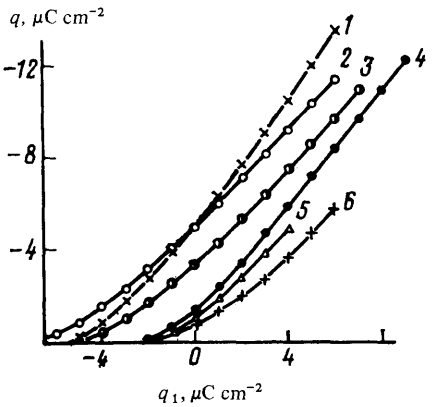

Figure 7. Charge of specifically adsorbed Br^- anions against charge of the Bi electrode (at $m = 0.1$) for the following solvents: *1*) AN, *2*) DMFA, *3*) DMSO, *4*) ethanol, *5*) methanol, *6*) water (from Ref. 14).

We note that the surface activity of Br^- increases from dimethylformamide (DMFA) to water and to DMSO, but the differences are not very large. Fig. 7 shows plots of q_1 against q for the adsorption of Br^- anions on Bi from six different solvents. We can see that for sufficiently high values of $q > 0$ the adsorbability of Br^- anions increases in the sequence water < methanol < ethanol < DMSO < DMFA < acetonitrile (AN).

In Figs. 8 and 9 we show some measurements of the specific adsorption of Cs^+ cations from various solvents on a negatively charged surface of bismuth or mercury. We note that the surface activity of the Cs^+ cations is greater at the mercury than at the bismuth interface for all solvents, i.e. that the nature of the metal has a marked effect. On the other hand the specific adsorption of Cs^+ on both metals (bearing a sufficiently negative surface charge) increases on going from water to DMFA, methanol, and ethanol. These results should be interpreted in conjunction with the changes in double-layer capacitance of sodium and caesium salts in various solvents. By comparing Figs. 9 and 10 we see that the increase in capacitance can be correlated qualitatively with the specific adsorption of caesium cations at the appropriate interface.

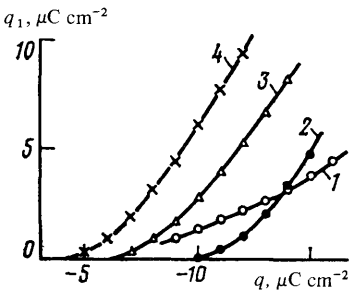

Figure 8. Charge of specifically adsorbed Cs^+ cations against charge of the Bi electrode (at $m = 0.1$) for the following solvents: *1*) water, *2*) DMFA, *3*) methanol, *4*) ethanol (from Ref. 14).

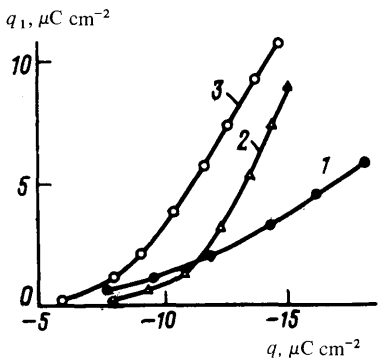

Figure 9. Charge of specifically adsorbed Cs^+ cations against charge of the Hg electrode (at $m = 1$) for the following solvents: *1*) water,[57] *2*) DMFA,[105] *3*) methanol[60].

It is interesting to consider the factors which determine the adsorption energy of the ions and the way in which this energy varies with the nature of the metal, that of the solvent, the charge on the electrode, and lastly the amount of adsorption already present on the electrode. A general solution of this problem must take account of the following interactions: metal and ion, metal and solvent, ion and solvent, adsorbed ions with themselves, and solvent molecules with themselves. We must also allow for the influence of the field due to the electrical double layer on all these interactions. Thus we can expect any general solution to be rather cumbersome.

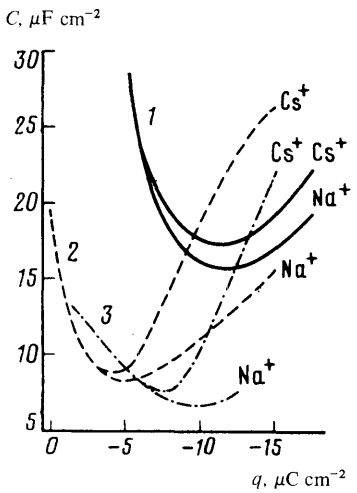

Figure 10. Cathodic portions of the plots of differential capacitance against electrode charge in 0.1 N solutions of sodium and caesium salts at the following interfaces: *1*) Hg/H_2O (chlorides)[57], *2*) Hg/CH_3OH (chlorides)[60], *3*) Hg/DMFA (perchlorates)[44].

Let us examine in detail the factors which influence the adsorbability of ions in different solvents. Since the specific adsorption of anions causes solvent molecules to be displaced from the surface, we can treat the adsorption process as a reaction in which solvent molecules are replaced by ions:

$$n\,S_{ads} + A_{bulk} \rightarrow A_{ads} + n\,S_{bulk}, \qquad (12)$$

where S denotes a solvent molecule, A is a specifically adsorbed ion (anion in this case), and n is the average number of solvent molecules displaced from the surface by one ion ($n \neq 1$). Evidently, the energy of adsorption of the ion from a given solvent ($\Delta G_{ads}^{(S)}$) will be greater, the stronger the interaction between the metal and the ion (ΔG_{M-A}), and it will be smaller, the stronger the interaction between the metal and the solvent (ΔG_{M-S}) as a result of the displacement of solvent molecules from the surface. It will also be smaller, the stronger the interaction between the ion and the solvent (ΔG_{A-S}), because the bonds between the ion and the solvent molecules are partially broken, and it will be greater, the stronger the interaction between the solvent molecules themselves (ΔG_{S-S}), because of the interaction between the displaced solvent molecules when they are transferred to the bulk of the solution. Thus the energy of adsorption of the ion A from the solvent S_1 can be written, according to Eqn. (12),

$$\Delta G_{ads}^{(S_1)} = \Delta G_{M-A} - n_1 \Delta G_{M-S_1} - \Delta G_{A-S_1} + n_1 \Delta G_{S_1-S_1}. \qquad (13a)$$

An analogous expression can be written for the solvent S_2 on the assumption that the quantity ΔG_{M-A} is independent of the solvent:

$$\Delta G_{ads}^{(S_2)} = \Delta G_{M-A} - n_2 \Delta G_{M-S_2} - \Delta G_{A-S_2} + n_2 \Delta G_{S_2-S_2}. \quad (13b)$$

We shall characterise the quantity ΔG_{M-S} by the work of adhesion referred to the limiting adsorption of solvent ($\Gamma_\infty^{(S)}$).[4,5] Using the Dupre equation we have

$$\Delta G_{M-S} = (\sigma_M + \sigma_S - {}_M\sigma_S)/\Gamma_\infty^{(S)}, \quad (14)$$

where σ_M is the surface tension (reversible surface work of the metal M), σ_S is the surface tension of the solvent S, and ${}_M\sigma_S$ is the interfacial tension (reversible surface work) of the M/S interface. If we equate[4,5] the quantity ΔG_{S-S} to one-half of the work of cohesion, also referred to $\Gamma_\infty^{(S)}$, we have

$$\Delta G_{S-S} = \sigma_S/\Gamma_\infty^{(S)}. \quad (15)$$

Subtracting (13b) from (13a), and using (14) and (15), we obtain

$$\Delta(\Delta G_{ads})^{(S_1-S_2)} = (\Delta G_{A-S_2} - \Delta G_{A-S_1}) + n_2(\sigma_M - {}_M\sigma_{S_2})/\Gamma_\infty^{(S_2)} - n_1(\sigma_M - {}_M\sigma_{S_1})/\Gamma_\infty^{(S_1)}. \quad (16)$$

But since $\Gamma_\infty^{(S_1)}/n_1 = \Gamma_\infty^{(S_2)}/n_2 = \Gamma_\infty^{(A)}$, where $\Gamma_\infty^{(A)}$ is the limiting adsorption of the anion A, Eqn. (16) simplifies to

$$\Delta(\Delta G_{ads})^{(S_1-S_2)} = (\Delta G_{A-S_2} - \Delta G_{A-S_1}) + ({}_M\sigma_{S_1} - {}_M\sigma_{S_2})/\Gamma_\infty^{(A)}. \quad (17)$$

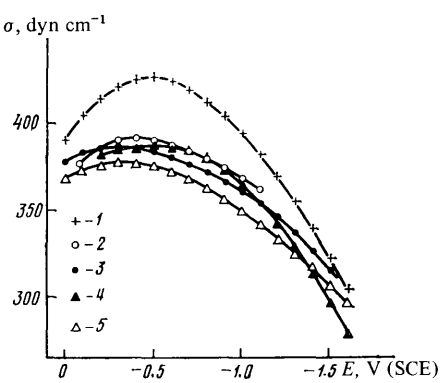

Figure 11. Electrocapillary curves of the mercury electrode for 0.1 *N* solutions of: *1*) Na_2SO_4 in water[18], *2*) NaCl in methanol[2], *3*) $NaClO_4$ in ethanol[2], *4*) KF in formamide[9], *5*) $NaClO_4$ in DMFA.[44]

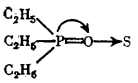
Thus to the approximation of our present model the change in energy of adsorption of an ion on going from one solvent to another is determined by two factors: the difference in solvation energy and the different in surface tension of the metal in the two solvents, referred to the limiting loading of the surface by adsorbate. This conclusion had been arrived at earlier[47] for the transition from water to DMFA, but equality of the areas occupied by the ion and by the solvent molecule had been assumed (i.e. $n_1 = n_2 = 1$). The above argument does not rely on this assumption. Thus the use of Eqn. (17) to discuss the influence of the solvent on the adsorption energy of ions seems to be fully justified.

Let us consider first of all the effect of changes in interfacial tension. Fig. 11 shows the electrocapillary curves for a mercury electrode in solutions of various salts in water, methanol, ethanol, formamide, and DMFA. The σ, E curve for water (at low surface charges) lies significantly higher than the curves for the other solvents. Thus if we consider only the second factor we conclude that anions should be more readily adsorbed from aqueous than from non-aqueous solutions. However we see from Figs. 6 and 7 that this conclusion does not agree with experiment, and therefore the energy of solvation of the ions appears to play the predominant role.



This result is not surprising if we remember that the change in energy of solvation of anions between water and various polar solvents is usually between 2 and 12 kcal mole^{-1}.[48] At the same time, putting $\Gamma_\infty^{(A)} \simeq 5 \times 10^{-10}$ mole cm^{-2} and noting from Fig. 11 that ${}_{Hg}\sigma_{H_2O} - {}_{Hg}\sigma_S \leq 40$ dyn cm^{-1}, we conclude that the ratio $({}_{Hg}\sigma_{H_2O} - {}_{Hg}\sigma_S)/\Gamma_\infty^{(A)}$ cannot be greater than 1.9 kcal mole^{-1}. On the other hand if we consider the adsorption of cations, which is most marked at high negative charges (when the surface tension is approximately the same in different solvents), we find that the second factor can be ignored to a first approximation. In this case the adsorption is determined only by the difference in solvation energy.

Let us examine the factors which determine the energy of solvation of ions and its change as between different solvents. The major part ($\geq 80\%$) of the energy of solvation accompanying the transfer of the ion from the gas phase into the solvent consists of the Born term, i.e. the energy gain due to purely electrostatic interactions between the charged particle and the medium (whose dielectric constant is substantially greater than unity[49]). However we are not concerned with the overall solvation energy, but with the difference in solvation energy as the ion is transferred from one solvent to another. The contribution of the Born term to this difference is quite small. Indeed, the well known Born formula for the solvation energy[50] gives the relative change in solvation energy on transferring the ion from a solvent of dielectric constant ϵ_1 to a solvent of dielectric constant ϵ_2 as $(1/\epsilon_2 - 1/\epsilon_1)$. .100%, i.e. less than 4% if the dielectric constants are greater than 25.

Thus the most important contribution to the change in solvation energy on transferring an ion from one polar solvent to another must come from factors other than the Born term. These could include, for example, hydrogen bond formation with anions in protonic solvents, whose effect should be most marked when the ion is transferred to an aprotic solvent (in which this factor is absent). Another relevant factor is the effect of the ion on the structure of the solvent, which may give rise to energy effects and thus contribute to the difference in solvation energy of the ion between two different solvents. Lastly we must allow for donor–acceptor interactions between the ion and the solvent molecule.

Up to recently it has been customary to characterise donor–acceptor interaction with allowance for hydrogen bond formation in terms of the donor number *DN*. According to Gutmann[48,51] the donor number is determined by the enthalpy of the reaction between a solvent molecule and $SbCl_5$ (i.e. of the reaction S + $SbCl_5$ = S.$SbCl_5$), in which the solvent S acts as a donor and $SbCl_5$ as an acceptor of electrons, thus: $DN \equiv -\Delta H_{S \rightarrow SbCl_5}$. However the experimental information most commonly available in studies of the specific adsorption of ions from non-aqueous solvents

concerns the adsorption of anions, which are themselves electron donors. Therefore the donor number is not a convenient way of comparing the adsorption of anions, and we prefer to use the acceptor number *AN*, recently proposed by Gutmann and coworkers[52,53]. The acceptor number can be determined by considering the interaction between solvent molecules and triethylphosphine oxide, which is an electron donor. As a result of donor–acceptor interactions of the type of

we observe a chemical shift of the ^{31}P signal in the NMR spectrum: it is suggested that the *AN* is proportional to $\delta^{31}P$. The acceptor number is normalised by the condition that the chemical shift $\delta^{31}P$ for the reaction $(C_2H_5)_3$. .PO + $SbCl_5$ corresponds to *AN* = 0 in hexane and *AN* = 100 in dichloroethane.

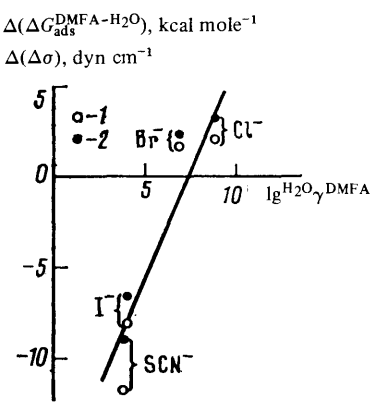


Figure 12. Change in surface activity of the anions Cl^-, Br^-, I^-, and SCN^- when transferred from water to DMFA against distribution coefficient of the ions between these two solvents. The surface activity of the anions on a mercury electrode is characterised by: *1*) the energy of adsorption at zero charge for $\Gamma_- \to 0$, *2*) the decrease in surface tension at the electrocapillarity maximum for $c = 0.1\ M$.

Gutmann has pointed out[52] that the acceptor number shows a good correlation with the energy of transfer of a chloride ion from acetonitrile to 12 different solvents. This observation confirms the validity of the acceptor number as an indicator of the change in solvation energy of a given ion on being transferred to different solvents. Of course, the donor–acceptor interaction is characterised by the properties of the ion as well as by those of the solvent (charge on the ion, and structure of the electronic shells[48,49]). Therefore the change in solvation energy of different ions being transferred from one solvent to another is not identical, and hence the corresponding change in the energy of adsorption of the ions is also not identical.

The change in solvation energy of ions of a given type being transferred from one solvent to another is conveniently characterised by the distribution coefficient of the ions between the two solvents. Fig. 12 shows a plot of the change in energy of adsorption of different ions on an uncharged mercury surface between water and DMFA against the logarithm of the distribution coefficient the ions between the same two solvents. These results suggest a good correlation between the change in solvation energy and the change in adsorption energy under the condition $M^{\sigma}S_1 - M^{\sigma}S_2 = \text{const}$. As Fig. 12 shows, the quantity $\Delta(\Delta G_{ads})^{(DMFA-H_2O)}$ on the vertical axis can be replaced by the change in the lowering of surface tension $\Delta(\Delta\sigma)$ produced by the ion at the maximum of the electrocapillary curve. If the vertical scale is properly chosen the plot against $lg\ S_{1\gamma}S_2$ is practically unchanged.

Unfortunately the distribution coefficients are not available for all the ions (and certainly not for all the solvents). Therefore we should look for a more general correlation between the energy of adsorption of the ion on the given electrode at $q = 0$ and the *AN* value of the solvent. If the potential of the outer Helmholtz plane (ψ_0) does not vary appreciably at $q = 0$ when the ion is transferred to a different solvent we can combine the term $zF\psi_0/RT$ in Eqns. (7) and (8) with the parameter $a_b = a + zF\psi_0/RT$, and use the latter parameter (a_b) to characterise the adsorption energy of the ion. Values of the parameter a_b for the adsorption of various ions on a bismuth electrode from various solvents are plotted in Fig. 13 against the acceptor number of the solvent. We note a good correlation between the change in adsorbability of the ion on bismuth and the acceptor number of the solvent, the difference in adsorbability between water and DMFA being greatest for the Cl^- anion and decreasing in the sequence

$$Cl^- > Br^- > I^- > SCN^-,$$

which reflects the effect of the nature of the ion. The small Cl^- anion is strongly solvated in aqueous solution as a result of hydrogen bond formation, whereas in aprotic solvents this ion is poorly solvated. As the size of the ion increases, so does its polarisability in dipolar aprotic solvents, thus compensating the solvation effects accompanying the transfer of the ion from water to DMFA. In the case of the large SCN^- anion the compensation is almost complete (see Fig. 13).

As expected, the adsorbability of anions increases as the acceptor number decreases. For the Cs^+ cations we note the opposite relationship (Fig. 13): the adsorption energy decreases on going from water to DMFA. Since a decrease in acceptor number should increase the solvation energy of cations, this result is not unexpected. However a comparison of the change in adsorbability of cations at zero charge with the results given above for high negative charges (Figs. 8–10) produces an apparent contradiction: the results for an uncharged surface are consistent with the change in acceptor number, whereas those for high negative surface charges are not. This discrepancy arises because the adsorption energy depends on the charge on the electrode as described in formula (9), where the parameter *b* is related to the structure of the electrical double layer.

Using the simple model of Grahame and Parsons[54,55] we obtain the following expression for the parameter *b* (see Ref. 38):

$$b = -zF/RTK_{12}, \qquad (18)$$

where K_{12} is the integral capacity of the space between the outer and the inner Helmholtz plane. Replacement of water by an organic solvent causes a relative displacement of the charged planes of the double layer, and K_{12} decreases whilst b increases. Therefore at high negative charges the adsorbability of cations in organic solvents can be greater than in H_2O, in spite of the smaller value of the a parameter. This effect is illustrated in Table 2 for the special case of the adsorption of Cs^+ cations at the Bi/H_2O and Bi/CH_3OH interfaces.

Table 2. Adsorption energy of Cs^+ and parameters of the double layer at the Bi/H_2O and Bi/CH_3OH interfaces for $q \leqslant 0$.

Interface	$a = (\ln \beta)_{q=0}$	K_{12}, $\mu F\ cm^{-2}$	b, $cm^2\ \mu C^{-1}$	$(\ln \beta)_{q=-15}$
Bi/H_2O	−1.4	93	−0.42	4.9
Bi/CH_3OH	−1.6	46	−0.85	11.2

Thus by allowing for the effect of the electric field on the adsorption energy of the ions we find that the changes in adsorption energy between different solvents are determined not only by the factors which appear in Eqn. (17) but also (and to a large extent) by a geometric factor: the relative size of the solvent molecules.

We should note that geometry considerations apply not only to the change in adsorption energy but also to the repulsion interaction between specifically adsorbed ions located in the inner Helmholtz plane. In practice the counter-ions reside in the outer Helmholtz plane, where they partially screen this repulsion effect, so that the screening effect is greatest (and the repulsion between the specifically adsorbed ions is weakest) when the inner and the outer Helmholtz plane are closest together. Since the molecules of non-aqueous solvents are larger than water molecules we expect the strongest repulsion effects in non-aqueous solvents[56]. As Fig. 14 shows, this expectation is borne out in a large number of systems[13,14]: the Figure is a plot of the virial coefficients B (which characterise the repulsion interaction in the adsorption of anions and cations on a Bi electrode from a number of solvents) against the quantity $(x_2-x_1)/x_2$, where x_1 and x_2 are the distance from the electrode surface to the inner and the outer Helmholtz plane respectively. Since the parameter B allows for the variation of the adsorption energy with the amount of pre-adsorbed particles this dependence of B on the ratio $(x_2-x_1)/x_2$ demonstrates one aspect of the influence of the nature of the solvent on the adsorption energy of ions.

Thus we have a fairly complex relationship between the specific adsorption energy of ions and the nature of the solvent, determined by the interaction of the solvent with the electrode surface, by ionic solvation effects, and by the geometry of the solvent molecules.

IV. SPECIAL FEATURES OF THE DOUBLE-LAYER MODELS FOR NON-AQUEOUS SOLUTIONS

As we have already pointed out, the isotherm which most rationally describes the adsorption of ions is one which allows for the buffer action of the diffuse double layer [see Eqns. (7) and (8)]. This can be illustrated by

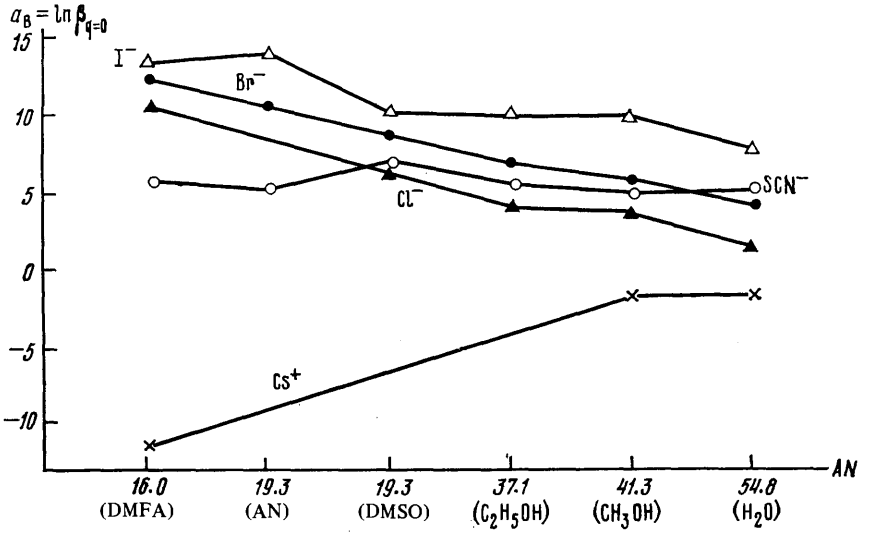

Figure 13. Adsorption of various ions on an uncharged bismuth surface against the acceptor number (AN) of the solvent. (a_b values taken from Ref. 14, AN values from Ref. 52).

considering the adsorption of caesium cations at the Hg/H_2O interface[38,57]. If we ignore the diffuse layer the adsorption isotherms in co-ordinates of $\ln(q_1/zmc)$ against q_1 give straight-line plots (Fig. 15). However these straight lines are not indistinguishable for systems with different ionic strength, and therefore the free energy of adsorption at $q_1 \to 0$ is a function of the concentration of the solution. This conclusion lacks physical significance, since there can be only one value of the energy of adsorption (which defines the system) for each value of the surface charge. However if we introduce a correction for the diffuse layer as in Eqn. (8) all the experimental points for systems with different ionic strength fall on a single straight line, and we obtain a unique value of the free energy of adsorption for each surface charge (Fig. 16). Similar results were obtained for the adsorption of K^+ and Rb^+ cations at the Bi/CH_3OH and Bi/C_2H_5OH interfaces[58].

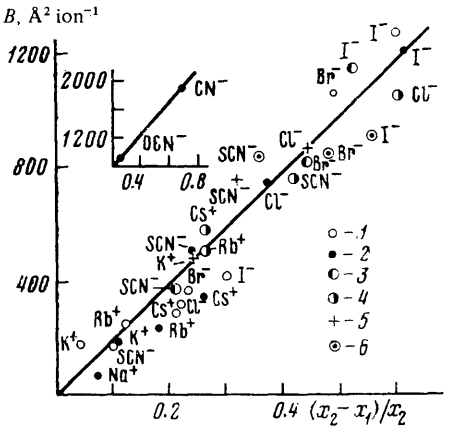

Figure 14. Plot of the second virial coefficient against the ratio $(x_2 - x_1)/x_2$ for the adsorption of various ions on the surface of a Bi electrode from the following solvents: *1*) water, *2*) methanol, *3*) AN, *4*) DMFA, *5*) ethanol, *6*) DMSO (from Ref. 14).

However complications arising from the incorporation of counter-ions into the fixed part of the double layer are often encountered in non-aqueous solvents. This process is favoured by the relatively smaller difference in dielectric constant (as compared with an aqueous medium) between the fixed and the diffuse part of the double layer, which allows ion pairs to be formed not only in the bulk but also within the fixed part of the double layer. The incorporation of counter-ions into the fixed part of the double layer can be illustrated by the adsorption of Cl^- on a bismuth electrode from ethanol[59]. The application of the isotherm equation (8) to the experimental results is shown in Fig. 17. We note that in the absence of a correction for the diffuse layer the plots of $\ln(q_1/zmc)$ against q_1 are rectilinear, but the straight lines for different concentrations do not coincide, and therefore different values of the adsorption energy are obtained for different concentrations at $q_1 \to 0$. On the other hand if the diffuse layer correction is applied, as in Fig. 17, the adsorption energy at $q_1 \to 0$ ceases to be a function of the ionic strength of the solution, though serious deviations from linearity are introduced.

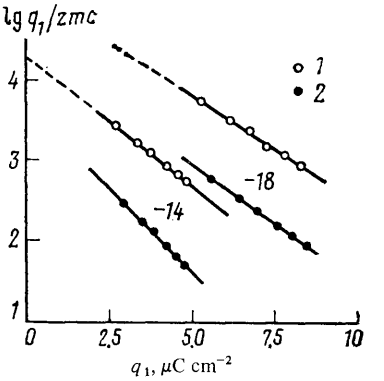

Figure 15. Plots of $\lg(q_1/zmc)$ against charge of specifically adsorbed Cs^+ cations in the system mc CsCl + $(1-m)c$ LiCl at the Hg/H_2O interface: *1*) $c = 0.01$ *M*, *2*) $c = 0.1$ *M*. The numbers against the curves denote the electrode charge in $\mu C\ cm^{-2}$ (from Ref. 57).

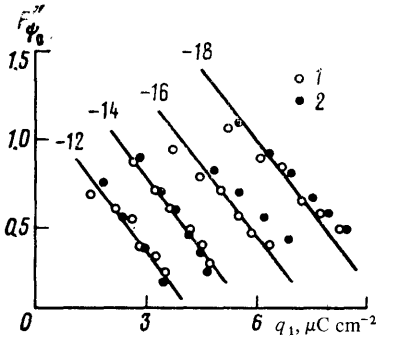

Figure 16. Plots of $[\lg(q_1/zmc) + zF\psi_0/2.3RT] = F\psi_0''$ against charge of specifically adsorbed Cs^+ cations for the system mc CsCl + $(1-m)c$ LiCl (from Ref. 38).

These deviations from linearity can be explained by postulating that counter-ions (in this case Li^+ cations) are attracted into the fixed layer by the specifically adsorbed Cl^- anions. In the calculation of the potential of the outer Helmholtz plane (ψ_0) which appears in Eqn. (8) we had assumed that $q_i^+ = 0$, i.e. that the Li^+ cations are not attracted into the fixed layer. This assumption appears to be unjustified. We shall now assume that the system is correctly described by Eqn. (8), and that the deviations from linearity are due to the incorporation of Li^+ cations into the fixed part of the double layer. We can therefore calculate the true potential of the outer Helmholtz plane from the magnitude of these deviations, and hence arrive

at the value of q_1^+. The number of cations (calculated in this way) is plotted in Fig. 18 against the number of specifically adsorbed anions. We can see that the points corresponding to different charges on the electrode all lie on the same curve, i.e. a definite relationship exists between the incorporation of cations and the specific adsorption of anions. This observation confirms the validity of our previous assumption, i.e. that the deviations from linearity of the plots of $[\ln(q_1/zmc) + zF\psi_0/RT]$ against q_1^- are due to the incorporation of counter-ions into the fixed part of the electrical double layer. This assumption stems directly from the concept of ion pair formation in the fixed layer, noting that the formation of ion pairs requires a definite stoichiometry of cations and anions.

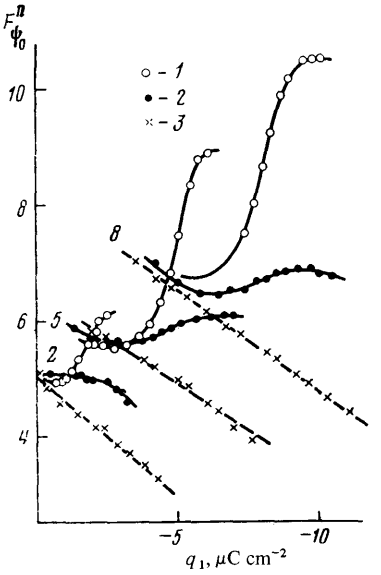

Figure 17. Plots of $[\ln(q_1/zmc) + zF\psi_0/RT] = F\psi_0''$ against charge of specifically adsorbed Cl^- anions in the system mc LiCl + $(1-m)c$ $LiClO_4$ at the Bi/C_2H_5OH interface: *1*) $c = 0.01$, *2*) $c = 0.1$, *3*) $c = 0.5$ *M*. The numbers against the curves denote the electrode charge in μC cm^{-2} (from Ref. 59).

The validity of our assumption can be demonstrated also by calculating the total surface excess of anions (Γ_-) in the double layer. The quantity Γ_- can be evaluated, in the first instance, by adding the charge of specifically adsorbed anions (q_1^-) and the charge due to the anions in the diffuse layer (q_2^-). The quantity q_2^- is calculated either by ignoring the incorporations of cations ($q_1^+ = 0$) or by allowing for the q_1^+ values (as shown in Fig. 18). Alternatively, the total surface excess Γ_- can be calculated by an independent method (the binary electrolyte method). By comparing the two methods we conclude[59] that the agreement between the plots of Γ_- against q is much better when allowance is made for the incorporation of cations in the fixed part of the double layer.

Similar irregularities in the plot of $F\psi_0'' = [\ln(q_1/zmc) + zF\psi_0/RT]$ against the charge due to specific adsorption can be observed in other systems, and in particular for the adsorption of Cs^+ cations at the Hg/CH_3OH interface[60].

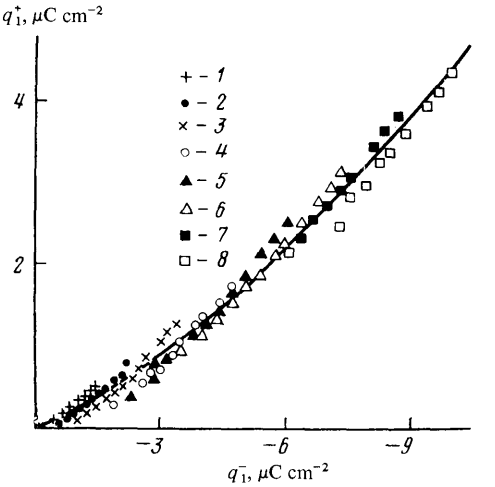

Figure 18. Charge of Li^+ cations incorporated into the fixed layer against charge of specifically adsorbed Cl^- anions in the system mc LiCl + $(1-m)c$ $LiClO_4$ at the Bi/C_2H_5OH interface for $c = 0.01$ *M*. The numbers denote the charge in μC cm^{-2} to which each type of point refers (from Ref. 59).

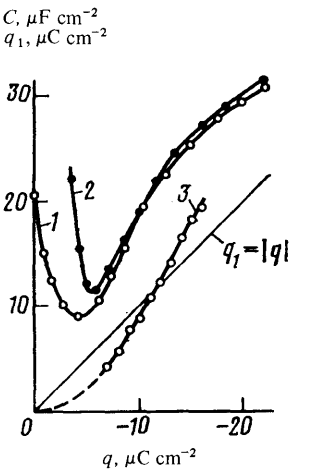

Figure 19. Differential capacity of a mercury electrode in 0.1 *N* methanolic solutions of (*1*) CsCl and (*2*) CsI, and charge of specifically adsorbed Cs^+ cations (*3*) in the same systems as a function of electrode charge.

As in the case of the adsorption of Cl^- ions at the Bi/C_2H_5OH interface, this system shows a surface overcharging effect, and therefore we may suggest that the deviations are due to the incorporation of anions into the fixed part of the

double layer. However the iodide anions attracted by the specifically adsorbed caesium cations could be expected to produce a greater increase in double-layer capacitance than the chloride anions. It is clear from Fig. 19 that this effect is not observed: at high negative charges the experimental C, E curves for 0.1 M methanolic solutions of CsCl and CsI are practically indistinguishable.

We can suggest two possible explanations: either the Cs^+ cations specifically adsorbed at the Hg/CH_3OH interface do not attract anions into the double layer (in which case we must look for another explanation of the deviation from linearity of the plot of $F\psi_0''$ against q_1), or the I^- and Cl^- anions have practically no effect on the capacity of the double layer when incorporated into the fixed layer. Anion adsorption (Cl^- or I^-) usually causes a sharp increase in capacitance when these anions are able to approach the surface, whereas the cations remain in the outer plane or are only partly attracted into the fixed layer. At high negative surface charges the caesium cations are apparently closer to the surface than the anions attracted into the fixed layer. If we ascribe the normal increase in capacity in the presence of iodide anions to partial charge transfer during adsorption[61,62], we cannot expect a large change in capacity to result from the incorporation of I^- anions into the fixed layer when the electrode is in the cathodic region and no charge transfer occurs during the adsorption of iodine. However the only rational criterion for choosing between the two alternative explanations is a direct programme of electrocapillary measurements. The problem remains unresolved at the moment.

The incorporation of counter-ions into the fixed part of the double layer cannot fail to complicate the model of the double layer, since the plane in which the counter-ions are located does not coincide (in general) with the plane of the specifically adsorbed ions. Hence we must consider two inner Helmholtz planes: one for the cations and one for the anions. These planes are situated at distances x_1^+ and x_1^- respectively from the electrode surface. This model of the electrical double layer is discussed in Refs. 63 and 64. Assuming additivity of the potential jumps associated with the charges q, q_1^+, and q_1^- we obtain the following expression[63,64] for the total potential jump in the fixed layer (ψ_u):

$$\psi_u = q/K_{02} + q_1^+/K_{1^+2} + q_1^-/K_{1^-2}, \qquad (19)$$

where K_{02} is the integral capacity of the whole of the fixed layer (from $x = 0$ to $x = x_2$), and K_{1^+2} and K_{1^-2} are the integral capacities of the regions between the outer Helmholtz plane ($x = x_2$) and the planes $x = x_1^+$ and $x = x_1^-$ respectively.

Assume that the specific adsorption consists of cations (for example, Cs^+ cations[64]), and that the charge q_1^- is due to incorporated counter-ions. Under these conditions $q_1^+ > |q_1^-|$ (for example, according to Palm and coworkers[64] $|q_1^-|/q_1^+ = 0.27$), and $x_1^+ < x_1^-$, so that

$$K_{1^-2} = \frac{\varepsilon}{4\pi(x_2 - x_1^-)} > K_{1^+2} = \frac{\varepsilon}{4\pi(x_2 - x_1^+)}.$$

Therefore Eqn. (19) can be re-written

$$\psi_u = \frac{q}{K_{02}} + \frac{q_1^+}{K_{1^+2}}(1 - \alpha_+), \qquad (20)$$

where the quantity $\alpha_+ = K_{1^+2}|q_1^-|/K_{1^-2}q_1^+$ is much smaller than unity. An analogous formula is obtained for the specific adsorption of anions:

$$\psi_u = \frac{q}{K_{02}} + \frac{q_1^-}{K_{1^-2}}(1 - \alpha_-), \qquad (21)$$

where the quantity $\alpha_- = K_{1^-2}q_1^+/K_{1^+2}|q_1^-|$ is also much smaller than unity, since under these conditions $q_1^+ < |q_1^-|$, and $K_{1^-2} < K_{1^+2}$.

Thus to a first approximation we can replace Eqn. (19) by the simpler expression of the Grahame–Parsons model[54]

$$\psi_u = q/K_{02} + q_1/K_{12}. \qquad (22)$$

For the specific adsorption of cations we now have $q_1 = q_2^+$ and $K_{12} = K_{1^+2}/(1-\alpha_+)$, and for the specific adsorption of anions $q_1 = q_1^-$ and $K_{12} = K_{1^-2}/(1-\alpha_-)$. It follows that K_{12} as defined in the Grahame–Parsons model[54] under conditions resulting in the incorporation of counter-ions in the fixed layer describes an effective capacity, slightly greater than the true capacity K_{1^+2} or K_{1^-2}. Therefore the simple Grahame–Parsons model can give a formal description of systems in which the specific adsorption of ions is accompanied by the incorporation of counter-ions into the fixed part of the double layer.

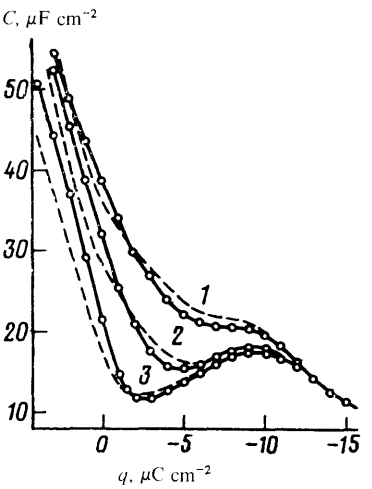

Figure 20. Differential capacity curves for a mercury electrode in *N*-methylformamide solutions of KBr of the following concentrations: *1*) 0.74, *2*) 0.1, *3*) 0.05 *M*. The full curves are experimental, the broken curves are calculated by Eqn. (11) for $a = 6.39$, $b = 0.72$ cm^2 μC^{-1}, and $B = 0.144$ cm^2 μC^{-1} (from Ref. 65).

As an example, we show in Fig. 20 a comparison of experimental C, q curves with the corresponding curves calculated by Eqn. (11) under conditions of specific adsorption of Br^- anions at the mercury/*N*-methylformamide (NMF) interface[65]. As we have already pointed out, Eqn. (11) was derived[43] from the Grahame–Parsons model. Hence the good agreement between experiment and calculation in Fig. 20 shows that the Grahame–Parsons model is formally applicable to the Hg/KBr in NMF system. On the other hand the incorporation of K^+ cations into the fixed part of the double layer through the specifically adsorbed Br^- anions cannot be excluded in this system. In other words, consistency between experimental results

and the Grahame–Parsons model cannot be taken as a general criterion for the absence of incorporated counter-ions in the fixed part of the double layer. A more detailed analysis is needed to establish the absence of counter-ions in the fixed layer[59].

V. SHAPE OF THE DIFFERENTIAL CAPACITY CURVES AND DISTRIBUTION OF SOLVENT MOLECULES IN THE FIXED PART OF THE LAYER IN THE ABSENCE OF SPECIFIC ADSORPTION OF IONS

The differential capacity curves of the fixed layer measured in different solvents can be arbitrarily classified into three groups[66]. The first group is characterised by a single maximum (or "hump"). C,q curves of this shape are obtained in water[67], formamide[9,68], and N-methylformamide[69], with a characteristic increase in capacity in the anodic region. To this group can also be assigned the C,E curves obtained in carbonates, lactones, and in sulpholane[26,70], in which the electrochemical process sets in before the anodic rise in capacity. The second group includes the C,E curves with a minimum, which do not show a "hump". Curves of this shape are typical of methanol[7], DMFA,[68] liquid ammonia[71], and some other solvents. Lastly we have the C,E curves with two "humps", observed in N-methylacetamide and N-methylpropionamide[4] (see curve *2* of Fig. 21).

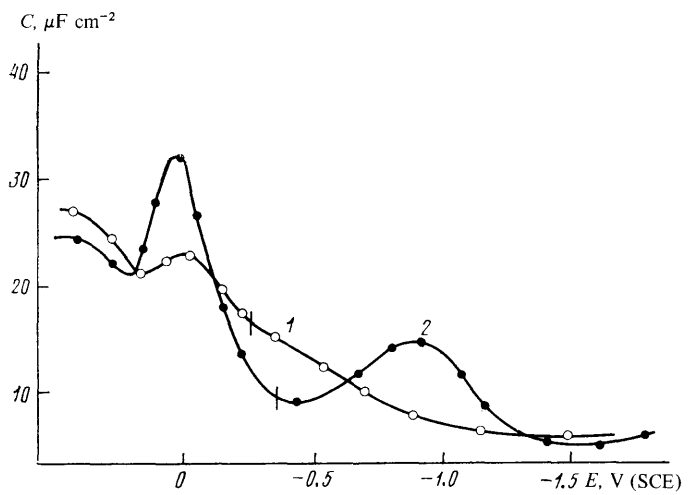

Figure 21. Differential capacity curves for a mercury electrode in 0.1 M solutions of KPF_6 in: *1*) dimethylacetamide, *2*) N-methylpropionamide. The vertical lines denote the position of the zero-charge potential (from Ref. 4).

The models of the fixed layer have been developed primarily for the interface between a metal and an aqueous solution. Thus, several workers[72–77] have discussed the presence of dipoles from the solvent on the electrode surface in two opposite orientations: with their negative pole or their positive pole pointing towards the surface. The relative number of dipoles in the two orientations depends on the charge on the electrode, and the "hump" on the C,q curve denotes equal numbers of dipoles in the two orientations.

Frumkin and coworkers[78,79] proposed a different model to explain the C,E curves of the gallium electrode. They assumed that solvent dipoles are chemisorbed with their negative pole pointing towards the surface: this would explain the experimentally observed increase in capacitance as the potential is made more positive.

Lastly, Damaskin and Frumkin[80] have described a model which combines the assumptions of the two previous models. They suggest that solvent particles can exist on the metal surface in two conditions: either as particles which can be freely oriented by the field of the double layer or as chemisorbed dipoles. Since the freely oriented particles and the chemisorbed dipoles cannot be identical, it is further suggested that the former consist of groups of several (usually three) associated molecules of water. The model was subsequently modified and improved[81–83]. In its most recent form the model describes in a quantitative way the dependence of the capacitance of the double layer on the electrode charge for the case of aqueous solutions of surface-inactive electrolytes on mercury, bismuth, and cadmium electrodes, and it correctly describes the temperature dependence of the capacity of the mercury electrode.

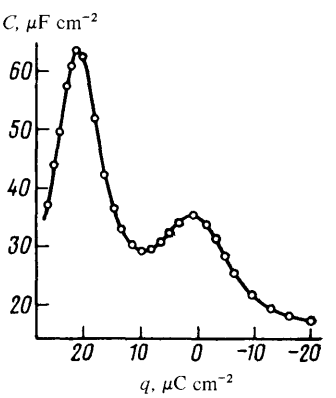

Figure 22. Differential capacity of the fixed part of the double layer against electrode charge according to a model which allows for the simultaneous presence of chemisorbed solvent dipoles and associated groups of dipoles able to orient themselves freely in the field of the double layer (from Ref. 83).

It is easy to show that this model (and none of the other models proposed so far) can account for all three types of differential capacitance curves in non-aqueous solvents[66]. Fig. 22 shows a C,q curve calculated by this model for a wide range of surface charge. If the region of the left-hand peak is not experimentally accessible as a result of electrochemical metal dissolution or solvent oxidation reactions this theoretical curve describes the variations in capacitance in the solvents of our first group. If the ideal polarisability region is even shorter, and only the middle part of the theoretical curve (between the two peaks) is experimentally accessible, the theoretical curve

describes the C,q curves of the second group of solvents. Lastly, for the general case the theory predicts a differential capacitance curve with two peaks as observed in *N*-methylacetamide and in *N*-methylpropionamide (see Fig. 22).

The following observations are also relevant. The position of the theoretical C,q curve along the horizontal axis is determined (if the associated groups of molecules can be freely oriented by the field) exclusively by the difference in energy level between a single solvent molecule forming part of the grouping and the same molecule present as a chemisorbed dipole. Under these conditions the right-hand maximum (or "hump") of the theoretical C,q curve is always found near $q = 0$. In order to shift the theoretical C,q curve towards more negative charges and thus align it with the experimental differential capacitance curves observed in amides we must make the further assumption that the associated groups have different stabilities in the two positions. The physical significance of this assumption is that the orientation of the associated groups depends both on the electric field of the double layer and on the structure of the solvent on the solution side. The structural orientation of the solvent dipoles determines the surface potential at the solution/air interface. The transition from the solution/air to the solution/metal interface causes a change in this surface potential, due both to the field of the double layer and to the specific interaction of the solvent molecules with the metal.

Thus the dipole component of the potential jump at the electrode/solution interface arises not only from the interaction of the solvent molecules with the electrode surface but also from the interaction of these molecules with similar molecules in the bulk of the solution. The work of Bagotskaya and Dubova[94] leads to the same conclusion: these workers compared the change in zero-charge potential of various metals and the change in adsorption-induced potential jump at the solution/air interface[85] for electrodes in water and in non-aqueous solvents respectively.

Studies of the adsorption of thiourea at the non-aqueous solvent/metal interface have helped to establish the structure of this interface. A great deal of information on the adsorption of thiourea on mercury and on bismuth from different solvents is now available[86–91]. However it is difficult to generalise these results because different models were used[86,89,91–93] in their theoretical analysis.

VI. CONCLUSIONS

This review shows that the quantitative study of the structure of the electrical double layer and of ionic adsorption at the metal/non-aqueous solvent interface has allowed us to reach some important conclusions as to the factors which determine the adsorption energy and the charge of specifically adsorbed ions, and also on some special features of the structure of this interface. Nevertheless workers in this field are still faced by many unsolved problems. The following are some of the most important problems currently being examined in the field of the structure of the electrical double layer and of adsorption phenomena at the interface between an electrode and a non-aqueous solution.

1. Further studies of mixed electrolyte systems in the region of $m \to 1$, where anomalous behaviour is sometimes reported (capacitance in a solution with $m = 1$ lower than in a solution with $m < 1$ for the same electrode charge[33,94]).

2. More extensive study of the effects arising from incorporation of counter-ions into the fixed part of the double layer; clarification of the role of the nature of the counter-ion and of the solvent[37,95]; influence of the adsorption of I^- anions (in the second layer) on the measured double layer capacity.

3. Development of a detailed model of the electrical double layer with two inner Helmholtz planes, to take account of the recent theoretical advances in this area[96,97].

4. Acquisition of additional experimental information on the adsorption of thiourea molecules at the metal–non-aqueous solvent interface, especially in dilute solutions (which sometimes show deviations from the classical theory of the diffuse layer[98]); generalisation of existing data on the adsorption of thiourea at various interfaces.

5. Detailed study of the structure of the fixed part of the double layer at the metal–non-aqueous solvent interface in the absence of specific adsorption of ions (measurement of capacity as a function of temperature, application of new relaxation methods with time constants of the order of nanoseconds, quantitative comparison of experimental data with model calculations).

6. Study of systems in which adsorption of ions is in competition with adsorption of solvent dipoles under conditions of strong specific interaction with the electrode surface, where interesting kinetic phenomena have been observed[99] but not fully investigated.

7. Study of systems with very strong chemisorption of solvent molecules on the electrode (for example, Pt or Ni). Only tentative results have so far been obtained[100–102] for systems of this type.

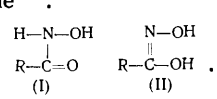
Hydroxamic Acids and Their Metal Complexes

Y.K.Agrawal



The chemical properties and thermodynamic characteristics of hydroxamic acids and their metal complexes are examined and Tables of proton-ligand and metal-ligand stability constants are presented. The influence of various factors on the dissociation of hydroxamic acids and their complexes is discussed.
The bibliography includes 123 references.

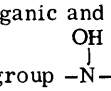
I. INTRODUCTION

Hydroxamic acids is the name given to *N*-acyl derivatives of hydroxylamine[1-3]:

(I) (II)



On the other hand, they can be regarded as *N*-hydroxy-derivatives of acid amides or as oximes of carboxylic acids[4]. The substitution of one or both hydrogen atoms in (I) or (II) by hydrocarbon or acyl groups yields compounds having the general formula

(III)

Here R_1 = H, phenyl, *o*-tolyl-, *m*-tolyl, *p*-tolyl, or *p*-chlorophenyl and R_2 consists of carboxylic or aliphatic acid derivatives.

Different terminologies are used for hydroxamic acids in the literature[1,3,5]. Thus in the publications of certain European workers a distinction is drawn between compounds designated above by odd and even numbers: the former are called "hydroxamic" acids and the latter are referred to as "hydroximic" acids. On the other hand, in certain American publications, including Chemical Abstracts[6-8], no such distinction is made and the general term "hydroxamic acids" is used for all compounds (I)-(III).

Hydroxamic acids are used in a wide variety of ways as reagents in organic and inorganic analysis. They contain the bidentate group  , which meets all the requirements necessary for the formation of metal complexes.

Complexes are usually formed via the substitution of a hydrogen atom of hydroxylamine by a metal cation and ring closure via the carbonyl oxygen atom:

The formation of metal chelates via this mechanism has for a long time constituted the basis of a wide variety of analytical methods[9-25]. Because of the non-ionic nature of such metal complexes (or inner complexes), they can be extracted in all cases from aqueous solutions or suspensions with the aid of solvents immiscible with water, such as benzene, chloroform, carbon tetrachloride, higher alcohols, or dichlorobenzene; separation processes involving solvent extraction are based on this feature. If such inner complexes are very sparingly soluble in water, are fairly stable, and have a constant composition, they can be used in gravimetric methods.

The study of the possible analytical applications of hydroxamic acids requires the knowledge of their ionisation constants[26,27]. In the search for reagents with improved analytical properties, numerous analogous compounds have been synthesised in recent years by introducing various substituents in different positions. For such specific synthesis to be successful, it is desirable to know the physicochemical properties of the reagents and their metal complexes; this would lead to a better understanding of the causes of the selectivity and sensitivity of the corresponding analytical reactions.

II. PROTON-LIGAND STABILITY CONSTANTS OR IONISATION CONSTANTS (pK_a)

The thermodynamic dissociation constants K_a(aq) of hydroxamic acids HA (dissociation via the reaction $HA \rightarrow H^+ + A^-$) in an aqueous medium are defined by the

formula

$$K_a(\text{aq}) = \frac{[H^+]\cdot[A^-]}{[HA]}\cdot\frac{Y_{H^+}\cdot Y_{A^-}}{Y_{HA}}, \quad (1)$$

or

$$p\,K_a(\text{aq}) = \lg[H^+] + \lg\frac{[HA]}{[A]} + 2\lg\frac{1}{Y_\pm}, \quad (2)$$

where $Y_\pm$ is the activity coefficient of a univalent ion ($Y_{H^+} + Y_{A^-} = Y_\pm$) at a given temperature and in a given medium; it is assumed that the activity coefficient of the unionised acid Y_{HA} is unity.

If the medium is altered by the addition of water, then, according to Van Uitert and Hass, the stoichiometric hydrogen ion concentration $[H^+]$ can be obtained from instrumental readings (B) with the aid of the equation

$$\lg[H^+] = B + \lg U_H^0 - \lg\frac{1}{Y_\pm}. \quad (3)$$

The values of $\lg U_H^0$ have been determined experimentally[28] and are listed in Table 1 for the dioxan–water medium.

Table 1. The values of $\lg U_H^0$ for water–dioxan media of different composition.

Dioxan concentration		$\lg U_H^0$ at 25°C		$\lg U_H^0$ at 30°C			$\lg U_H^0$ at 35°C
vol.%	mole fraction	this work	Ref.96	this work	Ref.97	Ref.96	this work
0	0	0.00	0.00	0.00	0.00	0.00	0.00
10	0.023	0.01	0.01	0.01	—	0.03	0.01
20	0.050	0.02	0.04	0.02	0.02	0.06	0.02
30	0.083	0.04	0.06	0.05	0.05	0.10	0.06
40	0.123	0.08	0.11	0.09	0.09	0.16	0.10
45	0.147	0.12	0.16	0.13	0.13	0.20	0.14
50	0.174	0.20	0.22	0.22	0.22	0.26	0.24
60	0.240	0.40	0.44	0.39	0.40	—	0.42
70	0.330	0.80	0.85	0.80	0.80	—	0.83

We have from Eqns. (2) and (3)

$$p\,K_a = B + \lg U_H^0 + \lg\frac{[HA]}{[A^-]} + \lg\frac{1}{Y_\pm}, \quad (4)$$

or

$$p\,K_a = B + \Delta, \text{ where } \Delta = \lg U_H^0 + \lg\frac{[HA]}{[A]} + \lg\frac{1}{Y_\pm}. \quad (5)$$

The values of Δ are listed in Tables 2 and 3.

III. THERMODYNAMIC FUNCTIONS FOR IONIC EQUILIBRIA

The standard free energy ΔF° of the ionisation reaction $HA \rightleftharpoons H^+ + H^-$ can be determined from the equation

$$\Delta F^0 = 2.303RT\ p K_a, \quad (6)$$

which can be written in a simplified form:

$$\Delta F^0(298.2°) = 1.365 p K_a \text{ (kcal)}; \quad (7)$$

$$\Delta F^0(308.2°) = 1.411\ p K_a \text{ (kcal)}. \quad (8)$$

The expression for the standard enthalpy of reaction ΔH° is obtained by integrating the van't Hoff equation for two temperatures T_1 and T_2:

$$\lg\frac{K_2}{K_1} = \frac{\Delta H^0(T_2 - T_1)}{4.576 T_1 T_2}. \quad (9)$$

Eqn. (9) is approximate, since ΔH° varies with temperature. However, for similar temperatures of the kind considered above (25° and 35°C), ΔH° can be assumed to be constant and Eqn. (9) can be written in the form

$$\Delta H^0 = 42.07 \Delta p K_a \text{ (kcal)}, \quad (9a)$$

where

$$\Delta p K_a = p K_a(25°) - p K_a(35°).$$

Table 2. The values of Δ at 25°C.

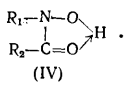
Note. 0.01 M acid is titrated with 0.1 M alkali added in ten equal portions; each portion corresponds to the neutralisation of one tenth of an equivalent of the acid.

The standard entropy of reaction $-\Delta S^\circ$ is usually calculated from the Gibbs–Helmholtz equation



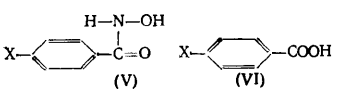
$$-\Delta S^0 = \frac{\Delta F^0 - \Delta H^0}{T}, \quad (10)$$

or

$$-\Delta S^0(25°) = 3.354 \cdot 10^{-3}(\Delta F^0 - \Delta H^0) \text{ (kcal)};$$
$$-\Delta S^0(35°) = 3.244 \cdot 10^{-3}(\Delta F^0 - \Delta H^0) \text{ (kcal)}.$$

IV. PROTON–LIGAND STABILITY CONSTANTS IN AN AQUEOUS MEDIUM

The ionisation constants of many substituted hydroxamic acids are listed in Table 4. These compounds are weak acids and, as has been observed for amides, the basicity of their nitrogen atom is also suppressed. In an aqueous medium and in dioxan–water mixtures the OH groups may be largely responsible for the acidity of hydroxamic acids. The suppression of the acid nature of these groups can then be accounted for by the intermolecular hydrogen bond formed by the compound. The formation of structure (IV) with intermolecular hydrogen bonds has been confirmed in several cases by infrared spectroscopy[30–33]:



(IV)

Table 4. Proton–ligand thermodynamic stability constants (in an aqueous medium at 25 °C).

Hydroxamic acid	pK_a	Hydroxamic acid	pK_a

Phenylaceto-	9.33		

*All the substituted *N*-*p*-chlorophenylbenzohydroxamic acids, obtained from *p*-fluoro-, *p*-chloro-, *p*-bromo-, and *p*-iodo-benzoic acids, are insoluble in water.

The thermodynamic ionisation constants of *p*-substituted benzohydroxamic acids listed in Table 5 are satisfactorily correlated with the Hammett constants:

(V) (VI)

X = H, CH_3, OCH_3, F, Cl, Br, I, NO_2, NH_2, or CN .

Table 5 shows that the pK_a values found experimentally and calculated from the Hammett equation and by the method of least squares agree satisfactorily, the maximum difference amounting to 0.03 pK_a unit.

Plots of the pK_a of hydroxamic acids (V) against the pK_a of benzoic acids (VI) and against the constants σ are presented in Figs. 1 and 2 respectively. The plots are linear and the following equation can be fitted by least squares:

$$pK_a = 1.02X + 4.62, \quad (11)$$

where X is the pK_a of the substituted benzoic acid. Similarly the plot of the pK_a of *p*-substituted benzohydroxamic acids (V) against the Hammett function σ is linear and has a slope of 1.00, which agrees satisfactorily with experimental values. The relation between acidity and the effect of the substituent introduced into the benzene ring is expressed by the constant ρ, whose values, derived from different plots (Figs. 1 and 2), are the same.

Table 5. Thermodynamic ionisation constants and Hammett constants for substituted benzohydroxamic acids.

No.	Benzohydroxamic acid		σ	pK_a (calc. by Eqn.(11))*	pK_a (calc. by Hammett Eqn.)	ΔpK_a**	pK_a for benzoic acid
	X	pK_a (expt.)					
1	H	8.91	—	8.91	—	±0.00	4.21
2	CH_3	9.05	−0.170	9.05	9.08	±0.00	4.34
3	OCH_3	9.15	−0.268	9.18	9.18	−0.03	4.47
4	F	8.81	+0.062	8.84	8.85	−0.03	4.14
5	Cl	8.70	+0.227	8.69	8.69	+0.01	3.99
6	Br	insoluble	+0.232	8.70	8.68	—	4.00
7	I	insoluble	+0.276	8.63	8.63	—	—

9	NH_2	9.42	−0.660	—	—	—	—
10	CN	8.26	+0.660	8.24	8.25	0.02	3.55

*Obtained by the method of least squares as the average of nine values: $pK_a = 1.02X + 4.62$.
**ΔpK_a is the difference between the values of pK_a obtained experimentally and found from Eqn. (11).

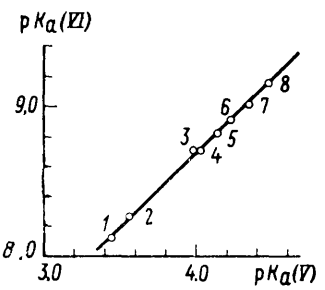

Figure 1. Relation between the pK_a values for benzoic acid (V) and benzohydroxamic acids (VI); substituent X: 1) NO_2; 2) CN; 3) Cl; 4) Br; 5) F; 6) H; 7) CH_3; 8) OCH_3.

The introduction of substituents into organic chelating compounds frequently alters their ability to form chelates and also influences other chemical and physical properties. Such changes in the acids have been studied on the basis of changes in their polarity, hydrogen bonding, and resonance and inductive effects.

In order to understand the relation between the molecular structure of hydroxamic acids and their pK_a values, it is necessary to investigate the pK_a of the initial carboxylic acids. All the hydroxamic acids (V) considered here were obtained from substituted benzoic acids (VI). Table 5 shows that the pK_a values for

hydroxamic acids form the same sequence as the pK_a for benzoic acids:

$$NH_2 > OCH_3 > CH_3 > F > Cl \simeq Br > NO_2 .$$

The introduction of the methyl group (X = CH_3), which has positive inductive and tautomeric effects, into (V) reduces the acidity. For the methoxy-group (X = OCH_3), which is an electronegative substituent[35], the positive tautomeric effect is much stronger than the inductive effect, which leads to a further decrease of acidity: $pK_a(OCH_3) > pK_a(CH_3)$. The strong influence of the nitro- and halogeno-substituents can be accounted for[36,37] by the mesomeric effect arising owing to the resonance between the benzenoid forms; in terms of this effect, halogens can be arranged in the sequence $F > Cl$; $Br > I$. Hydroxamic acids (Table 5) form the same sequence: compound 4 > compound 5; compound 6 > compound 7.

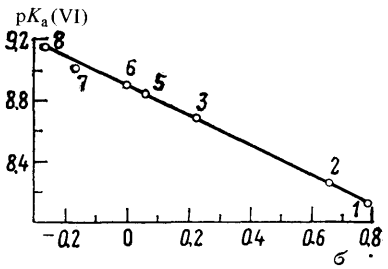

Figure 2. The Hammett relation for the pK_a values for benzohydroxamic acid; the significance of the circles is the same as in Fig. 1.

The nitro-group is a powerful *meta*-directing substituent with distinct electron-accepting properties, which increases the strength of benzoic acid, since pK_a(Hal) > $pK_a(NO_2)$; accordingly, the pK_a values for the compounds form the sequence 4–7 > 8 (Table 5).

V. PROTON–LIGAND STABILITY CONSTANTS IN MIXED AQUEOUS MEDIA

N-Arylhydroxamic acids are usually insoluble in water and readily dissolve in alcohol, dioxan, chloroform, etc. Their stability constants were therefore determined in dioxan–water mixtures of different compositions (10–70%) and were then extrapolated to the aqueous medium. The thermodynamic ionisation constants for certain hydroxamic acids are listed in Tables 6–8.

1. The Influence of Temperature

The ionisation constant of a weak acid is a function of temperature and usually has a maximum [K_a(max) or pK_a(min)] at approximately 25°C.[38] The data in Table 6 show that the pK_a for all hydroxamic acids in all solvents are lower at 35°C than at 25°C. The temperature corresponding to the maximum K_a can be found by determining pK_a at several temperatures, but it is evident that this temperature (T_{max}) must be higher than 25°C.

2. The Influence of the Medium

Agrawal and Tandon[39] observed that, with increase of the mole fraction of dioxan, the pK_a for hydroxamic acids also increases. This entails an intensification of the electrostatic interaction between the ions in a solvent with a low dielectric constant and facilitates the formation of molecular species. Gurney[40] and other workers[41,42] found that the change in standard free energy accompanying proton transfer ΔF°_{diss} can be represented by a sum of two components—electrostatic (ΔF°_{el}) and non-electrostatic (ΔF°_{nel}):

$$\Delta F^0_{diss} = \Delta F^0_{el} + \Delta F^0_{nel}, \qquad (12)$$

The electrostatic contribution to the free energy change can be estimated with the aid of the Born equation:

$$\Delta F^0_{el} = \frac{Ne^2}{2D}\left(\frac{1}{r^+} + \frac{1}{r^-}\right). \qquad (13)$$

For dilute solutions, D can be assumed equal to the dielectric constant of the solvent[43,44]; hence

$$pK_a = \frac{\Delta F^0_{nel}}{2.303RT} + \frac{Ne^2}{4.606RT}\left(\frac{1}{r^+} + \frac{1}{r^-}\right). \qquad (14)$$

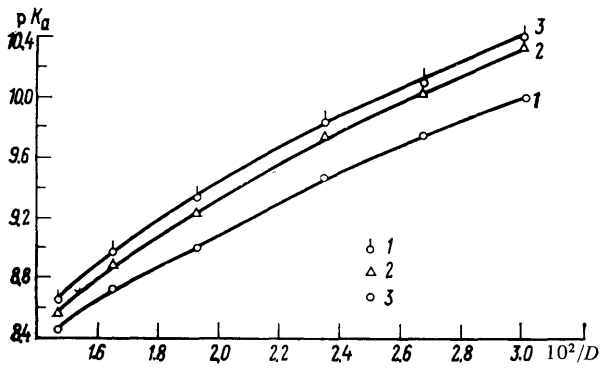

Figure 3. Dependence of pK_a on the dielectric constant (25°C): 1) *N*-*o*-tolylnitrobenzohydroxamic acid; 2) *N*-*m*-tolylnitrobenzohydroxamic acid; 3) *N*-*p*-tolylnitrobenzohydroxamic acid.

If it is assumed that ΔF°_{nel} is independent of the solvent, it is possible to plot pK_a against $1/D$. In certain cases, particularly for water-rich media, linear relations have been obtained[45–48], although deviations from linearity are not unusual either[49]. When such plots were constructed, it was observed that their curvature can vary. This is illustrated by typical curves in Fig. 3. Evidently non-electrostatic factors have a considerable influence on the dissociation of hydroxamic acids. Furthermore, a change in the dielectric constant and the consequent change in the shape and size of individual ions, hydrogen bonding, and other specific forms of solvent–solute interaction also have an appreciable influence on the dissociation of hydroxamic acids.

Table 6. Proton–ligand and metal–ligand stability constants for hydroxamic acids*.

* The following notation is used in Table 6 (and also in Tables 7 and 8): a = acetone; Aq = aqueous medium; d = dioxan (20 denotes a 20% dioxan solution); dis = distribution method; e = methods of measurement differing from those enumerated below; gl = potentiometric method using a glass electrode; ins = insoluble; pH = potentiometric titration method; sp = spectrometric method; *T* = thermodynamic constant; $k_1 = \lg k_1$ = logarithm of stability constant; "–" data not presented in given study. The horizontal rows present the following data: method, ionic strength/thermodynamic constant, temperature, medium, stability constants, reference; for example: gl (method; *T* (thermodynamic constant); 25 (temperature); 20d (medium consisting of a 20% dioxan solution); k_1 = 10.49 (logarithm of stability constant); [61] (reference).

3. The Mole Fraction of Dioxan

When the mole fraction of dioxan is altered, an appreciable change in the pK_a is observed for all hydroxamic acids. The difference between the pK_a in water ($n_2 = 0$) and in a 70% dioxan–water mixture ($n_2 = 0.33$) is more than 4 pK_a units. The plot of the pK_a for hydroxamic acids against dioxan concentration is linear (Fig. 4). The

experimental values of the pK_a for almost all hydroxamic acids deviate from linearity by not more than 0.05 of a pK_a unit (i.e. by approximately 0.5%).

It is of interest to determine the accuracy of the pK_a values obtained by extrapolation to zero dioxan concentration (i.e. for $n_2 = 0$). In the case of hydroxamic acids for which data can be obtained in an aqueous medium it is possible to compare the extrapolated and experimental values. Table 9 shows that the agreement between them is satisfactory.

It is noteworthy that the validity of the extrapolation depends greatly on the availability of pK_a data in the region of low dioxan concentrations. The insolubility of the hydroxamic acid in 10 and 20% dioxan can hinder the extrapolation.

Table 9. Ionisation constants of hydroxamic acids in an aqueous medium.

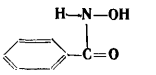
[a] This work.

[b] Priyadarshi[19] quotes pK_c values of 8.75 in 0.1 M KCl and 8.80; the calculated values of T_pK are 8.85 and 8.84 respectively.

[c] Taken from Priyadarshi[19].

[d] Taken from Shukla and Tandon[61].



[e] According to the data of Dutta and Seshadari[99], pK_c = 8.08 at I = 0.1 M and 30°C; the calculated value is T_pK = 8.19.

[f] According to Dutta and Seshadari[99], pK_c = 7.60 at I = 0.1 M and 30°C; the calculated value is T_pK = 7.71.

4. Thermodynamic Functions

The pK_a values can be determined to within 0.02–0.03, whence the error of the determination of ΔF° is estimated as 0.03–0.04 kcal. The temperature coefficient method, normally employed for the calculation of ΔH°, can lead to a large error, because (1) the enthalpy of ionisation of acids is low and (2) the pK_a values have not been determined at many temperatures, which necessitates a more accurate graphical method for their estimation[50]. Eqn.(9a) shows that an error of 0.01 of a pK_a unit leads to an error in ΔH° of 0.42 kcal; the error in the determination of pK_a depends on the mutual cancelling or addition of errors in the pK_a values determined at two temperatures. Owing to the inherent deficiencies of the method, it is impossible to observe any definite tendencies in the variation of ΔH° as the medium is altered. This is illustrated by the data in Table 10 for benzohydroxamic acid (columns 4 and 5). It follows from the foregoing that ΔH° is best determined with the aid of the more accurate calorimetric method.

Table 10. The pK_a values for benzohydroxamic acid (BHA) calculated with the aid of thermodynamic functions*

Dioxan concn. vol.%	pK_a 25°	pK_a 35°	ΔpK_a	ΔH°
0	8.91	8.79	0.12	5.1
10	9.17	9.02	0.15	6.3
20	9.45	9.29	0.16	6.7
30	9.79	9.64	0.15	6.3
40	10.14	10.03	0.11	4.6
45	10.41	10.26	0.15	6.3
50	10.69	10.57	0.12	5.1
60	11.34	11.21	0.13	5.5
70	12.25	12.12	0.12	5.1

*Here $\Delta pK_a = pK_a(25^\circ) - pK_a(35^\circ)$; $pK_a(25^\circ) = 10.10n_2 + 8.92$; $r = 0.999$; $pK_a(35^\circ) = 10.10n_2 + 8.79$; $r = 0.999$ (r = correlation coefficient).

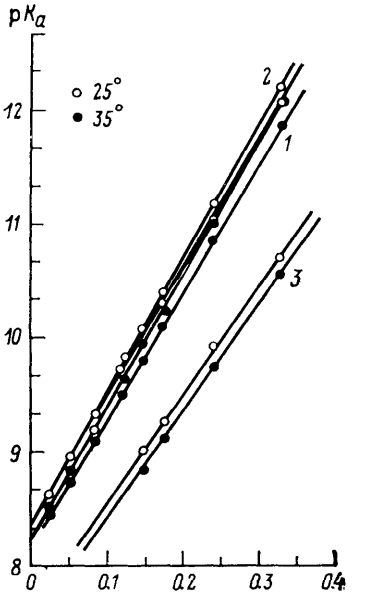


Figure 4. Dependence of pK_a on the mole fraction of dioxan: 1) *N*-phenylbenzohydroxamic acid; 2) *N*-*o*-tolyl-*m*-nitrobenzohydroxamic acid; 3) *N*-*m*-tolyl-*m*-nitrobenzohydroxamic acid.

Despite the relatively large errors in the values of ΔH° calculated by the temperature coefficient method, these data are very important, because they permit many important conclusions. At any rate, there is no doubt about the positive values of ΔH° found for all hydroxamic

acids in all solvents. This means that the ionisation reaction is endothermic below 25°C and becomes exothermic only above T_{max}. Furthermore, there is no doubt that the changes in ΔH° when the medium is altered are relatively small and are within the limits of experimental error. This is why the slopes of the linear plots of pK_a against n_2 are the same or almost the same at two temperatures for individual hydroxamic acids (Tables 6–8).

In the light of the foregoing, it would be correct to assume that ΔH° is to a first approximation independent of the medium, at least in the range of dioxan mole fractions 0–0.33.

*Here ΔF° and ΔH° are expressed in kcal mole^{-1} and ΔS° is expressed in cal mole^{-1} K^{-1}; the first value refers to 25°C and the second to 35°C. The values given in brackets have been obtained by extrapolation.

On this hypothesis, the values of ΔH° were calculated for different hydroxamic acids; they are equal to the difference between the intercepts made by the parallel lines on the pK_a axis multiplied by 42.07. The values of ΔH° calculated in this way are listed in Table 10, while the values calculated for each dioxan concentration have been deliberately omitted for reasons stated previously.

The errors in the determination of ΔF° and ΔH° are reflected in the values of ΔS°. Taking into account the considerations described in the preceding paragraphs, the values of ΔS° listed in Table 11 were calculated on the assumption that ΔH° is independent of solvent composition. It must be emphasised that ΔH° should change when the medium is altered. However, in the present study the influence of this factor was not observed and the simplifying assumption was made that ΔH° is independent of medium composition.

The usual tendency towards an increase of ΔS° with increasing content of dioxan in the solvent was noted. This tendency appears to be reliable and is observed also in the calculation of ΔS° from calorimetric values of ΔH°. If the acid ionises in two media—in water and in dioxan–water mixtures—the equations can be formulated as follows:

$$HA\,(aq) \rightleftarrows H^+\,(aq) + A^-\,(aq),$$
$$\Delta F^0\,(aq) = 2.303RT\,p K_a\,(aq). \qquad (15)$$

For mixed media, we have

$$HA \rightleftarrows H^+ + A^-,$$
$$\Delta F^0 = 2.303RT\,p K_a. \qquad (16)$$

Hence we have for the transfer reaction

$$HA + H^+\,(aq) + A^-\,(aq) \rightleftarrows HA\,(aq) + H^+ + A^-,$$
$$\Delta F^0 - \Delta F^0\,(aq) = 2.303RT\,(p K_a - p K_a\,(aq)) = 2.303RT\Delta p K_a. \qquad (17)$$

Thus, as shown above, the free energy ΔF° of the transfer reaction is proportional to the difference between the pK_a values in the aqueous and aqueous dioxan media. Hence it is readily seen that, since ΔH° is independent of the medium and is consquently zero for the transfer reaction, the changes in ΔF° are due to the changes in ΔS°. This can be illustrated in relation to benzohydroxamic acid for which ΔF°(aq) = 12.15 kcal mole^{-1} and $\Delta F^\circ(n_2 = 0.174)$ = 14.58 kcal mole^{-1}. Thus the transfer reaction entails a change in ΔF° by 2.43 kcal mole^{-1} due to the change in ΔS by 30.6 – 22.4 = –8.2 cal mole^{-1} K^{-1}.

VI. METAL–LIGAND STABILITY CONSTANTS

The stepwise formation of the hydroxamic acid complex (a 1 : 2 complex) can be represented as follows:

$$M^{n+} + HA \rightleftarrows MA^{(n-1)+} + H^+, \qquad (18)$$
$$MA^{(n-1)+} + HA \rightleftarrows MA_2^{(n-2)+} + H^+. \qquad (19)$$

The corresponding stability constants are defined in the following way:

$$k_1 = \frac{\{MA^{(n-1)+}\}}{\{M^{n+}\}\{A^-\}} = \frac{[MA^{(n-1)+}]}{[M^{n+}]\cdot[A^-]} \cdot \frac{Y_{MA}}{Y_{M+}\cdot Y_{A^-}} = k_1 \cdot \frac{Y_{MA}}{Y_M \cdot Y_A}; \qquad (20)$$

$$k_2 = \frac{\{MA_2^{(n-2)+}\}}{\{MA^{(n-1)+}\}\cdot\{A^-\}} = \frac{[MA_2^{(n-2)+}]}{[MA^{(n-1)+}][A^-]} \cdot \frac{Y_{MA_2}}{Y_{MA^+}Y_{A^-}} = k_2 \frac{Y_{MA_2}}{Y_{MA^+}Y_{A^-}}, \qquad (21)$$

where the symbols in curved brackets represent activities, Y are activity coefficients, and the symbols in square brackets are concentrations. The expressions for the constants K_1 and K_2 can be formulated thus:

$$\lg K_1 = \lg k_1 + 4\lg\frac{1}{Y_\pm}, \qquad (22)$$

$$\lg K_2 = \lg k_2 + 2\lg\frac{1}{Y_\pm}. \qquad (23)$$

where K_1 and K_2 are the thermodynamic stability constants and k_1 and k_2 are the molar contributions to the reversible reactions (18) and (19) respectively. Eqns. (22) and (23) can be obtained on the assumption that the activity coefficients of neutral species are unity and those of univalent negative and positive ions are approximately equal to the mean activity coefficient $Y_\pm$ of hydrochloric acid. In the limiting case where the Debye–Hückel law is applicable, we have $\lg Y_M^{2+} = 4 \lg Y_\pm$ (1 : 1).

In the study of equilibrium solutions it is customary to carry out measurements of concentration coefficients in media containing supporting salts at constant and high concentrations, which ensures a fixed ionic strength of the solution, so that the activity coefficients remain constant. Thus the concentration coefficients can be regarded as conventional constants applicable to solutions with the same supporting salt compositions as those used in the measurement of these constants.

There are three ways of obtaining experimental data for the calculation of thermodynamic constants: (1) experiments are performed in solutions which are sufficiently dilute for the concentrations to be set equal to the activities; (2) experiments are performed at different ionic strengths and the concentration coefficients are extrapolated to zero ionic strength; (3) corrections are applied for activity coefficients on the basis of the Debye–Hückel theory.

VII. DETERMINATION OF STABILITY CONSTANTS

Hydroxamic acids are weak acids and, when a complex is formed, there is competition between protons and metal ions for the ligand; the stability constant can be obtained by measuring the pH. pH measurements for the determination of stability constants are carried out by one or both methods presented below: (a) pH is measured as a function of ligand concentration; (b) pH is measured as a function of the amount of added acid (or base) at a constant metal ion and ligand concentration. In the second case the concentration of the free ligand, in excess relative to the amount required for complex formation, can be varied within wider limits than in the first case.

The stability constants can be calculated by the Bjerrum method[51] as developed by Calvin and Wilson[52]. The Bjerrum method has been examined theoretically by several workers[53–56].

The formation function $\bar{n}$, equal to the average number of coordinated groups per metal ion, is given by

$$\bar{n} = \frac{[MA] + 2[MA_2] + \ldots + N[MA_N]}{[M] + [MA] + [MA_2] + \ldots + [MA_N]} . \quad (24)$$

Using the expressions for the stability constant, it can be shown that $\bar{n}$ is a function of the free ligand concentration.

The values of $\bar{n}$ can be calculated in two ways. In the first procedure two titrations are carried out: initially, at a high concentration of added electrolyte the ligand is titrated with a standard solution of alkali, the pH change after each successive addition of alkali is noted, and the corresponding curve is plotted. One then titrates with alkali a mixture of the metal ions and the ligand in the presence of the same electrolyte and a plot is again constructed. The second titration curve lies significantly below the curve for the ligand alone; the decrease in pH shows that complex formation leads to neutralisation of the solution. The distance between the two titration curves in the horizontal direction yields the total number of ligand linkages and its division by the total concentration of metal ions makes it possible to obtain $\bar{n}$.

In the second case the free ligand concentration is calculated from the principle of electroneutrality. Substitution of this concentration in Eqn. (5) gives $\bar{n}$:

$$\bar{n} = \frac{A^0 - [A^-]}{M^0} , \quad (25)$$

where $[A^-] = 1 + [H^+]/k_1 + [H^+]^2/k_1k_2 + \ldots + [H^+]^n/k_1k_2 \ldots k_n$ and A^0 and M^0 are the total ligand and metal ion concentrations respectively.

The free ligand concentration can be determined as follows: the concentration of undissociated acid is equal to the difference between the total acid concentration ions and the concentration of acid which has reacted and dissociated:

$$[HA] = A^0 - C_{OH} - [H^+] - [OH^-]. \quad (26)$$

We have from Eqn. (1)

$$K_a = \frac{1}{q_H} \cdot Y_\pm^2,$$

where

$$q_H = [HA]/[H^+]\,[A^-]$$

or

$$\lg q_H = \mathrm{p}K_a - 2 \lg \frac{1}{Y_\pm} .$$

On substituting the expression for [HA] in Eqn. (26), we obtain

$$[A^-] = \frac{A^0 - C_{OH} - [H^+] - [OH^-]}{q_H [H^+]} . \quad (27)$$

The stability constants are calculated for different values of $\bar{n}$ and the corresponding values of $[A^-]$ by solving a system of N equations. Block and McIntyre[57] obtained equations for different values of N; thus the expressions for $N = 2$ are

$$k_1 = \frac{\bar{n}\,J_2' - \bar{n}J_2}{J_1\,J_2' - J_2'\,J_2} , \quad (28)$$

$$k_2 = \frac{\bar{n}'J_1 - \bar{n}J_1'}{\bar{n}J_2 - \bar{n}'J_2} \quad (29)$$

where

$$J_n = (n - \bar{n})\,[A^-]^n, \quad (30)$$

$$J_n' = (n' - \bar{n}')\,[A^-]'^n . \quad (31)$$

This method has been used by the majority of workers who have investigated the metal complexes of hydroxamic acids[58–62].

If $K_1 \gg K_2$, it is possible to obtain a plot of $\bar{n}$ against $[A^-]$ and find from the latter the stability constants at half-integral values of $\bar{n}$:[63]

$$\bar{n} = 1/2,\ k_1 = 1/[A^-]; \quad (32)$$

$$\bar{n} = 3/2,\ k_2 = 1/[A^-]; \quad (33)$$

$$\bar{n} = 1,\ \sqrt{k_1k_2} = k = 1/[A^-]. \quad (34)$$

Other methods for the calculation of the constants have been summarised by Beck[53]. The most important is the method according to which the relation between $\bar{n}$ and $[A^-]$ is transformed in such a way that the plot of $\bar{n}/(1 - \bar{n})[A^-]$ against $(2 - \bar{n})[A^-]/(1 - \bar{n})$ is represented by a straight line which makes an intercept on the ordinate axis equal to k_1 and which has a slope equal to k_1k_2.

Agrawal et al.[64] developed a computer program based on the method of least squares and using all experimental data.

VIII. LINEAR FREE ENERGY RELATIONS

The standard free energy of reaction ΔF° can be represented as a function of a large number of independent variables w, x, y, and z, whereupon ΔF° is described by the equation

$$d(\Delta F^0) = (\partial \Delta F^0/\partial w)_{x,y,z}\, dw + (\partial \Delta F^0/\partial x)_{w,y,z}\, dx + \ldots \quad (35)$$

An expression whereby the standard free energies of related reactions can be compared has been obtained from Eqn. (35) by regarding $d(\Delta F^\circ)$ as a function of independent variables. Wells[65] used this approximation to derive empirical equations of the Hammett type. Equations involving the metal complex stabilisation factor have also been obtained[66] by regarding the free energy of formation of the complex as a function of a single variable. However, Nieboer and McBryde[67] believe that the standard free energy of formation of metal complexes in a series of reactions is a function of two variables; their reasoning is examined below.

We assume that only a 1 : 1 complex is formed and the following equations are formulated:

$$M + A \overset{K_{MA}}{\rightleftharpoons} MA \quad , \quad (36)$$

$$M_s + A_o \overset{K_{M_sA_o}}{\rightleftharpoons} M_sA_o \quad . \quad (37)$$

$$\Phi = \lg (K_{MA}/K_{M_sA_o}), \quad (38)$$

$$M_s + A \overset{K_{M_sA}}{\rightleftharpoons} M_sA \quad , \quad (39)$$

$$\sigma = \lg (K_{M_sA}/K_{M_sA_o}) \quad , \quad (40)$$

$$M + A_o \overset{K_{MA_o}}{\rightleftharpoons} MA_o \quad , \quad (41)$$

$$\theta = \lg (K_{MA}/K_{M_sA_o}) \quad . \quad (42)$$

The subscripts s and o refer respectively to the metal and the ligand chosen as reference standards. Furthermore, it is readily seen that σ and θ are logarithms of the equilibrium constants for the following substitution reactions:

$$M_sA_o + A \rightleftarrows M_sA + A_o \quad , \quad (43)$$

$$\sigma = \lg K_A \quad , \quad (44)$$

$$M_sA_o + M \rightleftarrows MA_o + M_s \quad , \quad (45)$$

$$\theta = \lg K_M \quad . \quad (46)$$

We assume that Φ is a function of the dependent variables σ and θ and Eqns. (39) and (41) therefore represent series of reactions to be compared. A series of ligands react with the standard or reference metal M_S via reaction (39). It is next assumed that the parameter σ depends only on the nature of the ligand, which is equivalent to a ligand-dependent contribution to Φ. Eqn. (39) now describes a ligand-dependent standard reaction series and Eqn. (41) represents a metal-dependent standard reaction series. In Eqn. (41) the only variable factor is the metal ion M, and A_O is the standard or reference ligand. The assumption is made that the parameter θ depends only on the nature of the metal ion and that a metal-dependent contribution to Φ corresponds to it. Having made these assumptions, we shall subject them to a critical examination.

The changes in Φ caused by the increase in $d\sigma$ and $d\theta$ can be expressed in a differential form by the formula

$$d\Phi = (\partial\Phi/\partial\sigma)_\theta\, d\sigma + (\partial\Phi/\partial\theta)_\sigma\, d\theta \quad . \quad (47)$$

We denote $(\partial\Phi/\partial\sigma)_\theta$ by B and $(\partial\Phi/\partial\theta)_\sigma$ by C. Since $K_{M_SA_O}$ does not vary for any reaction series, it follows that $d \lg K_{M_SA_O} = 0$. Consequently, $d\Phi = d \lg K_{MA}$, $d\sigma = d \lg K_{M_SA}$, and $d\theta = d \lg K_{MA_O}$ and the quantities B and C can be expressed as follows:

$$B = (\lg K_{MA}/\lg K_{M_sA}), \quad (48)$$

$$C = (\lg K_{MA}/\lg K_{MA_o}). \quad (49)$$

MA can be obtained from M_S and A_O in two ways:

(1) $M_sA_o \rightarrow MA_o \rightarrow MA$;
(2) $M_sA_o \rightarrow M_sA \rightarrow MA$.

In the first procedure integration of Eqn. (47) leads to the expression

$$\Phi = B\sigma + \theta \quad (50)$$

and in the second we have

$$\Phi = \sigma + C\theta. \quad (51)$$

In order that Φ is a function of σ only, it must not depend on θ or it must depend on the ligand alone. Putting

$$\Phi' = \lg (K_{MA}/K_{MA_o}), \quad (52)$$

we obtain

$$\Phi' = \Phi - \theta = B\sigma. \quad (53)$$

When $M_S = H^+$, Eqn. (53) is a Hammett type equation, although the quantity σ involved in it is not equal to the Hammett factor. If Φ, σ, and θ are expressed in terms of the corresponding equilibrium constants, then Eqn. (53) can be written in the following form:

$$\lg K_{MA} = B \lg K_{M_sA} + [\lg K_{MA_o} - B \lg K_{M_sA_o}]. \quad (54)$$

Eqns. (53) and (54) describe the substitution effect. With their aid, it is possible to compare the stabilities of the complexes of two metals (M and M_S) for a series of related ligands A. The series of ligands A (hydroxamic acids) usually consists of the initial reagent and its substituted derivatives. Hence σ is a measure of the effect of substitution of the ligand in the ligand-dependent standard reaction series and Φ' is a measure of this effect in the test reaction.

In order that Φ is a function of θ alone, it must depend solely on the metal ion. Defining a new variable Φ'', i.e.

$$\Phi'' = \lg (K_{MA}/K_{M_sA}), \quad (55)$$

we obtain

$$\Phi'' = \Phi - \sigma = C\theta. \quad (56)$$

Substitution of the corresponding values in Eqn. (56) leads to the expression

$$\lg K_{MA} = C \lg K_{MA_o} + [\lg K_{M_sA} - C \lg K_{M_sA_o}]. \quad (57)$$

With the aid of Eqns. (56) and (57), it is possible to compare the stabilities of the complexes of two ligands (A and A_O) with a series of metal ions M and to describe a quasi-substitution effect. The parameters Φ and Φ'' are a measure of the quasi-substitution effect in the metal-dependent standard reaction series and in the test reaction respectively.

The results of the tests of Eqns. (54) and (57) (Fig. 5) with the aid of data for the reactions of *ortho*-substituted *N*-phenylbenzohydroxamic acids with certain metal ions are summarised in Table 12. The existence of two fundamentally different types of behaviour has been noted[67]. In the first case there is a simultaneous dependence of B on the metal ions and of C on the ligands, and in the second case all the values of B and C are unity regardless of the nature of the metal ion and the ligand. The cause of these differences is still obscure.

Table 12. The values of B for *N*-phenylbenzohydroxamic acids.

Ion	B	r	C. I., %	$-\theta$ *
H^+	1.00	1.00	100	0.00
Cu^{2+}	0.90	1.28	99.3	0.67
Zn^{2+}	0.62	0.99	99.9	3.25
Ni^{2+}	0.56	1.11	99.2	3.76

* Here $\theta = \lg K_{MA} - pK_0$; $M_S = H^+$; A_0 = phenylbenzohydroxamic acid.

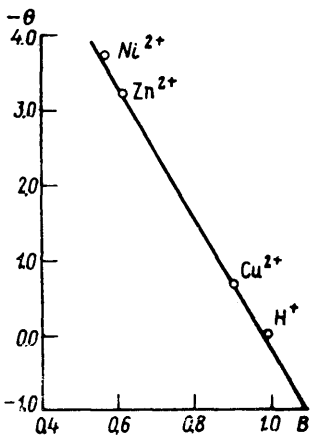

Figure 5. Test of the accuracy for a series of *N*-phenylbenzohydroxamic acids.

IX. THE SOLVENT EFFECT

The stability constants of metal complexes increase with increasing dioxan content. Since the dielectric constant of the medium decreases under these conditions, the ion–ion interaction between the metal ion and the oxygen anion of the ligand intensifies to a greater extent than the ion–dipole interaction between the metal ion and solvent molecules. The plot of $\lg k_1$ against the mole fraction of dioxan for copper(II), zinc(II), nickel(II), and manganese(II) is linear (Fig. 6). According to Irving and Rossotti[68], the dependence of the stability constants of metal complexes of hydroxamic acids in 60% dioxan solution on the stability constants of the metal ions at other dioxan concentrations (50 and 70%) is also linear and the slope of the straight lines is unity (Fig. 6). The same type of dependence has been found in many instances by Van Uitert et al.[69]

X. CORRELATION BETWEEN IONISATION CONSTANTS AND THE STABILITY OF THE COMPLEX

Approximately linear relations between the logarithms of the stability constants of a series of complexes of the same metal ion with a series of closely related ligands have been noted in several studies[68-74]. On this basis, it was expected that more basic ligands should give rise to more stable complexes.

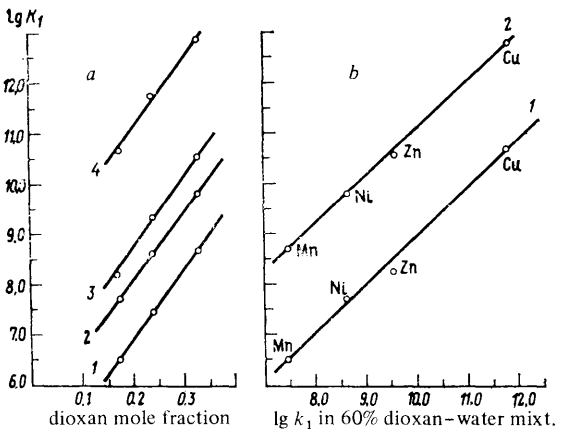

Figure 6. *a*) Dependence of $\lg K_1$ on dioxan concentration [1) Mn^{2+}; 2) Ni^{2+}; 3) Zn^{2+}; 4) Cu^{2+}]; *b*) dependence of $\lg K_1$ in a 60% dioxan–water mixture on $\lg K_1$ in 50% (line *1*) and 70% (line *2*) dioxan–water mixtures (*N*-*m*-tolyl-*m*-methylbenzohydroxamic acid).

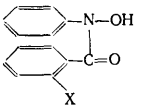
If the hydrogen ion is adopted as the standard ion, Eqns. (54) and (57) can be formulated as follows:

$$\lg K_{MA} = B_p K + [\lg K_{MA} - B\,p K_0], \quad (58)$$



$$\lg K_{MA} = C \lg K_{MA_0} + [pK - C_p K_0]. \quad (59)$$

Eqn. (58) refers to those cases where the stability constants of complexes of one metal ion with a series of ligands substituted in the same position are considered. Eqn. (59) makes it possible to compare the stability constants of complexes of two closely related ligands with a series of metal ions. It has been shown[75] that there is a linear relation between the stability constants and the pK values for copper complexes of *N*-arylhydroxamic acids:

$$\lg K_1 = 0.73\,p K_a + \text{const}. \quad (60)$$

The slope of this straight line is less than unity, which shows that copper(II) has the properties of a π-donor. Agrawal and Tandon[63] showed that the slope of this straight line depends on the nature of the metal ion.

However, in the case of *ortho*-substituted hydroxamic acids (VII) a linear relation between pK_a and $\lg K_1$ was not observed for any metal ion:

(VII)

X=H, CH_3, CH_3O, F, Cl, Br, I, or NO_2 .

Fig. 7 presents typical curves for Cu^{2+}, Zn^{2+}, Ni^{2+}, and Mn^{2+}; evidently the deviations from the straight line are considerable for at least two ligands. The absence of a linear relation can probably be caused by the steric hindrance arising owing to the presence of *ortho*-substituents; electronic effects can also play a role. Such deviations from linearity, due to the perturbing influence of steric hindrance, have been demonstrated for certain types of ligands[68].

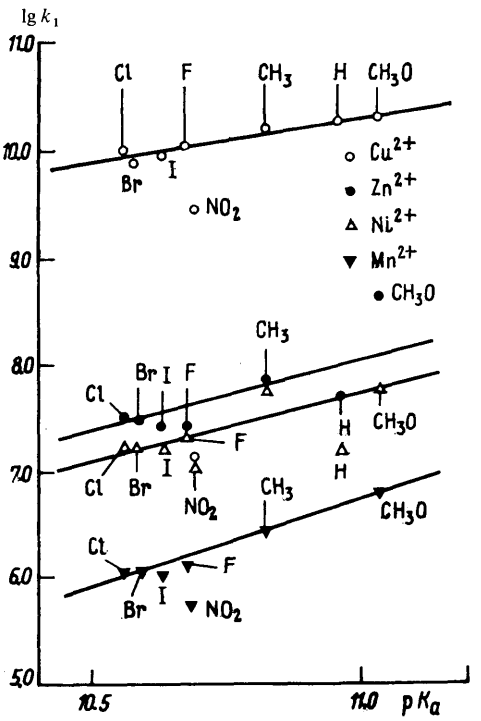


Figure 7. Dependence of $\lg K_1$ on pK_a for *ortho*-substituted *N*-phenylbenzohydroxamic acid derivatives.

The absence of a correlation between pK_a and $\lg K_1$ has been discussed from the standpoint of thermodynamics[73]. The authors established that the linearity of the relation between $\lg K_H(pK_a)$ and $\lg K_{MA}(\lg K_1)$ is not a general property owing to the differences between the ways in which π-donor (or π-acceptor) properties affect pK_a and $\lg K_1$. For beryllium complexes of *para*-substituted hydroxamic acids, the system of linear equations is of the form[76]

$$\lg K_1 = 1.44\, pK_a - 6.99. \qquad (60a)$$

Eqn. (60) has not so far been tested against the stability constants of hydroxamic acids.

XI. THE SEQUENCE OF STABILITY CONSTANTS

The sequence of the stabilities of the copper(II), zinc(II), nickel(II), and manganese(II) complexes of hydroxamic acids can be accounted for by inspecting the ionic radii or the electronegativities determined in terms of the ionisation potentials and ligand field stabilisation energies. The usual stability series for the bivalent ions of 3*d* transition metals, quoted by Maley and Mellor[77] and later by Irving and Williams[78], is

$$Mn^{2+} < Ni^{2+} < Cu^{2+} < Zn^{2+}.$$

The stability constants of hydroxamic acid complexes can be arranged in the sequence:

$$Mn^{+2} < Ni^{+2} < Zn^{2+} < Cu^{2+}.$$

The dependence of $\lg K_1$ on the atomic number, ΔF°, and ΔH° follows from the above sequence.

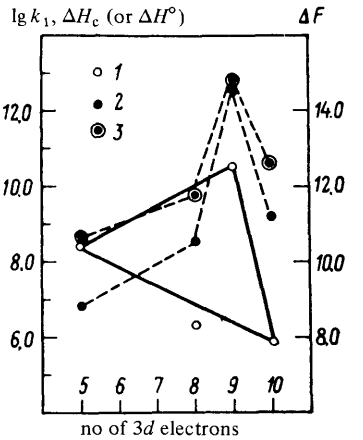

Figure 8. The values of ΔH_C (*1*), ΔF° (*2*), and $\lg K_1$ (*3*) (for *N*-*m*-tolyl-*p*-methylbenzohydroxamic acid) at 25°C in 70% dioxan–water mixtures.

The sequence of the stability constants is the same also in the case of $\lg K_1$ ($\lg K_2$ or $\lg \beta_2$) for hydroxamic acids and bivalent ions of 3*d* transition metals (Fig. 8). Beyond manganese, the constants increase with increasing atomic number, reaching a maximum for $3d^9$ [copper(II)] and then decrease for $3d^{10}$ [zinc(II)]:

$$Mn\ (II) < Ni\ (II) < Cu\ (II) > Zn\ (II)\ .$$

One may note the unusually high stabilities for $3d^9$ [copper(II)], while the stability of $3d^8$ [nickel(II)] is minimal. There is also a correction for the crystal field, which is a maximum for copper and falls rapidly to zero for zinc[79,80]. It is also seen that the stability constants

for zinc(II) are higher than for nickel(II), while those for copper(II) are appreciably higher.

The relative decrease in the stability of nickel(II) chelates may be due to steric hindrance, which prevents the formation of a square planar structure. The same picture was observed also for nickel chelates with other ligands[81,82]. The hydrolysis constants for zinc are lower than those for nickel, which implies a greater affinity of the Zn^{2+} ion for OH groups. Hydroxamic acids containing the –C(O)–N–OH functional group resemble acids with an OH group, because both these groups have a negatively charged oxygen atom. One may expect that, on formation of a bond, the smaller ion (i.e. Zn^{2+}) [83] would give rise to more stable complexes than Ni^{2+}, which is indeed the case.

XII. IONIC CHARGES AND RADII

The stability constants of the metal complexes of hydroxamic acids available at present as a rule increase with increasing ionic potential (i.e. with the charge/radius ratio).

It has been shown[42] that the energy of solution of gaseous ions should be expressed by Eqn. (13) (if it is assumed that they are spherical). Since K is directly related to energy, presumably the ratio of the spherical charge to the radius or to the reciprocal of the radius or the ratio of the charge to the radius should be directly proportional to the stability of the metal chelates with the same ligand. The plot of the stabilities of various metal chelates ($\lg K_1$) against the reciprocals of the ionic radii is linear for all known hydroxamic acids.

XIII. THE IONISATION POTENTIAL AND ELECTRONEGATIVITY

A number of attempts have been made to correlate the stability constants of a series of hydroxamic acid complexes and the ionisation potentials of metals[58–60,63,84,85]. Approximately linear relations have been observed. Other parameters have also been proposed in the literature for correlations. For example, linear relations between $\lg K_1$ and the electronegativities of metal ions X_M (on the Pauling scale) were obtained for the first time by Fernelius and coworkers[86–88] for a series of complexes of a large number of cations with the usual ligands. Normally, individual linear correlations were obtained for univalent, bivalent, and tervalent central metal ions. However, Van Uitert and Fernelius[87] found that a single correlation can be obtained for benzoylmethanates by plotting $\lg K_1$ against the product of X_M and a quantity which was initially referred to as the bond strength and was later identified as the ionic charge z.

In order to characterise individual metal ions, Craig and Nyholm[89] proposed the parameter $R = \Sigma I_M(r_M+r_L)/z^2$, where ΣI_M is the sum of the ionisation energies of the metals up to a charge z and r_M and r_L are the ionic radii of the metal and the ligand respectively. A numerical correlation index Q has been introduced[90]:

$$Q = (a\delta z X_M + b X_M^2)/(a+b) , \qquad (61)$$

where X_M is the Albert electronegativity[57] of the metal ion, a and b are integral weight coefficients (0, 1, 2, ...), and δ is a parameter calculated with the aid of Slater atomic shielding constants[92] and designed to compensate the marked increase of the electronegativities of certain elements due to the small size of their atoms or the marked covalent nature of their bonds. For certain metal ions, the set of parameters a, b, and δ depends on the type of ligand with which the metal forms a complex. Nieborer and McBryde[90] obtained linear relations between $\lg K_1$ and Q for complexes of different metals with more than thirty ligands.

Fig. 9 presents plots of the stability constants of metal complexes of hydroxamic acids against the ionisation potentials of the metal ions. Evidently straight lines were obtained in all cases. The points corresponding to the copper(II) complexes of all the ligands do not fit on these lines and are always above them. The high stability constants of the copper complexes can be accounted for[58–60] by the unusual electronic configuration of the Cu^{2+} ion, for which there is a possibility of additional stabilisation of the complexes due to the tetragonal distortion of the octahedral symmetry as a result of the Jahn–Teller effect. For the Cu^{2+} ion with its d^9 configuration, this distortion is manifested to an appreciable degree.

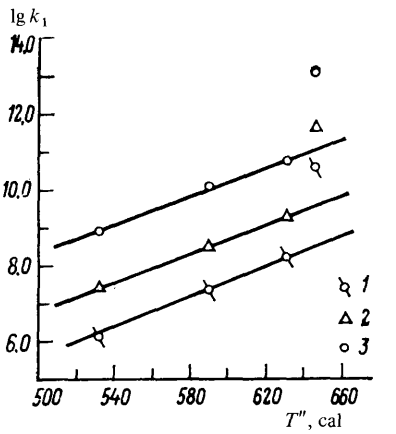

Figure 9. Dependence of $\lg K_1$ (for N-p-tolyl-p-methylbenzohydroxamic acid) on the field ionisation potential I'' in dioxan–water mixtures with different percentages of dioxan: 1) 50; 2) 60; 3) 70.

XIV. THE LIGAND FIELD STABILISATION ENERGY

The stability constants of complexes are related to the free energy change and hence to the temperature-independent heat of reaction:

$$RT\ln K = \Delta F^0 = \Delta H^0 - T\Delta S^0 .$$

These quantities are presented in Fig. 8 and in Tables 13 and 14. The values of $\Delta H_C(\Delta H^\circ)$ for bivalent ions of $3d$ transition metals fit on a curve with a maximum. The latter can be interpreted, as was done above, from the standpoint of ionisation potentials whose curve has a similar shape. The lower line in Fig. 8 represents the same values but with a correction for the orbital stabilisation energy obtained by applying the ligand field theory to the complexes. The curves indicate a constant increase of ΔH_C with increase of the atomic number.

According to the ligand field theory, the thermodynamic properties of metal chelate compounds vary as a function of the inner shells of the transition metal ions and the splitting of the orbitals in the ligand field leads to the stabilisation of the inner electrons compared with the energy which they would have had in the absence of the ligand field[93]. The contraction energy E_r has been determined[94] for a series of transition metals (Mn–Zn) as the heats of the reaction

$$Zn^{2+}_{(g)} + MnA^{2+}_{(aq)} \rightarrow ZnA^{2+}_{(aq)} + Mn^{2+}_{(g)}. \quad (62)$$

E_r can be calculated from the equation

$$E_r = -[\Delta H_H(Zn^{2+}) + \Delta H_c(Zn^{2+})] + [\Delta H_H(Mn^{2+}) + \Delta H_c(Mn^{2+})], \quad (63)$$

where $\Delta H_H(M^{2+})$ is the heat of hydration of the transition metal ion, i.e. the heat of the reaction $M^{2+}_{(g)} = M^{2+}_{(aq)}$, $\Delta H_c(\Delta H^\circ)$ the heat of formation of the complex, and E_r the contraction energy for the series from Mn to Zn ($3d^5$–$3d^{10}$).

*Here ΔF° and ΔH° are expressed in kcal mole^{-1} and ΔS° is expressed in cal mole^{-1} K^{-1}; the first value refers to 25 °C and the second to 35 °C.

The ligand field stabilisation energy δH for complexes of $3d^n$ transition metal ions M^{2+} can be obtained knowing the enthalpy if one assumes that all the complexes of metal ions ranging from Mn^{2+} to Zn^{2+} have the same symmetry, namely octahedral or tetrahedral[94]. Then

$$\delta H_i(M^{2+}) = \Delta H_c(M^{2+}) - \left(\frac{n-5}{5}\right)E_r - \Delta H_c(Mn^{2+}) - \Delta H_H(M^{2+}),$$

where n is the number of d electrons.

A plot of $\Delta H_H + \Delta H_c$ against the number of $3d$ electrons in the metal ion for complexes of p-methyl-N-m-tolylbenzohydroxamic acid is presented in Fig. 9. The hydration energies ΔH_H were taken from George and McClure[94]. The stabilisation energy of the complexes δH was calculated as the difference between the true value and the corresponding value obtained from the interpolation curve. The stabilisation energy thus increases from $3d^5$ to $3d^8$ and falls for the $3d^{10}$ ion, following the sequence of increasing field stabilisation energy—it is higher for Ni^{2+} than for Cu^{2+}.[95]

Table 14. The ligand field stabilisation energies for bivalent metal ions (N-m-tolyl-p-methylbenzohydroxamic acid)*.

Transition metal	$3d^n$	ΔH_H	ΔH_c	$\Delta H_H + \Delta H_c$	$(n-5)/5$	δH
Mn(II)	$3d^5$	654.0	8.40	662.40	0	
Ni(II)	$3d^8$	716.0	6.31	722.31	26.75	33.30
Cu(II)	$3d^9$	716.9	10.51	727.41	35.67	29.25
Zn(II)	$3d^{10}$	701.1	5.89	706.99	—	

*The contraction energy for the series from Mn to Zn is E_r(Mn–Zn) = 44.59.

Since the ability of the metal ion to interact with the ligand is proportional to the number of vacant sites, the ratio of the successive stability constants is to some extent determined by statistical factors[51]. For anionic ligands, the Coulombic attraction to Mn^{2+} is greater than for MA^+. The quantity lg K_1 – lg K_2 itself is usually positive[96]. The study of hydroxamic acid complexes established that the difference lg K_1 – lg K_2 is greater than zero for all the systems and lies in the range from 1 to 2.5 (in terms of logarithmic units).

Mixed Organic Derivatives of Mercury and Silicon

M.G.Voronkov and N.F.Chernov

The methods of synthesis and properties of all types of mixed organic derivatives of mercury and silicon are examined and certain examples of these compounds are quoted.
The bibliography includes 224 references.

I. INTRODUCTION

Among the numerous classes of organosilicon derivatives incorporating other elements [1], organosilicon derivatives of mercury are of particular interest owing to the unusual nature of their structure and reactivity and because of definite prospects for their practical applications.

The chemistry of organosilicon derivatives of mercury was first surveyed in 1966 in a monograph [1]. This book was followed by reviews in which organosilicon derivatives of mercury containing an Si–Hg bond were examined [2-6]. In the last twelve years the chemistry of organosilicon derivatives of mercury has developed so vigorously that it has become necessary to carry out another survey of the extensive structural data accumulated in the world literature. This is in fact the aim of the present review, which deals with studies published up to the middle of 1977.

II. COMPOUNDS CONTAINING THE Si–Hg BOND

Compounds containing an Si–Hg bond constitute the class of organosilicon derivatives of mercury which has been most thoroughly investigated. The presence of these compounds was founded mainly as a result of the investigations of Razuvaev, Vyazankin, Wiberg, and Neuman [2,4-7].

1. Methods of Preparation

The first attempt at the synthesis of organosilicon derivatives of mercury containing the Si–Hg bond was unsuccessful [8]. The reaction of triphenylsilyl-lithium with mercury halides, phenylmercury halides, or diphenylmercury was used for this purpose.

The reaction involving $HgCl_2$ leads to the formation of chlorotriphenylsilane, mercury, Hg_2Cl_2, and hexaphenyldisilane (in 45% yield). When $HgBr_2$ is used, the yield of hexaphenyldisilane increases to 63%. Hg_2Cl_2 reacts similarly. The results have been explained by the exchange reaction

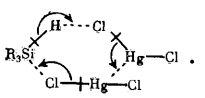
$$R_3SiLi + HgX_2 \rightarrow R_3SiX + [LiHgX] \rightarrow LiX + Hg\ ,$$
$$R_3SiLi + R_3SiX \rightarrow R_3SiSiR_3 + LiX\ .$$

When triphenylsilyl-lithium reacts with phenylmercury bromide or diphenylmercury, the main product is tetraphenylsilane:

$$Ph_3SiLi + PhHgX \rightarrow Ph_4Si + Hg + LiX\ ;\quad X = Br, \text{ or } Ph.$$

In this case it was necessary to postulate that an unstable phenyl(triphenylsilyl)mercury salt is formed as an intermediate:

$$Ph_3SiLi + PhHgX \rightarrow Ph_3SiHgPh + LiX\ ,$$
$$Ph_3SiHgPh \rightarrow Ph_4Si + Hg\ .$$



The most convenient method for the synthesis of organosilicon derivatives of mercury containing the Si–Hg bond was discovered in 1964 by Vyazankin and Razuvaev [9]. It is based on the interaction of triorganylsilanes with dialkylmercury derivatives. It had been known previously that the reaction of triorganylsilanes with mercury salts proceeds as a reduction process [9,10-19]:

$$R_3SiH + 2HgX_2 \rightarrow R_3SiX + Hg_2X_2 + HX$$

or

$$R_3SiH + HgX_2 \rightarrow R_3SiX + Hg + HX\ .$$

The intermediate formation of a six-membered cyclic complex in this reaction was postulated:

The reduction to univalent or metallic mercury is determined by the nature of the anion X and the solvent employed. In the reaction of triorganylsilanes with organylmercury halides the latter are also reduced [20]:

$$R_3SiH + R'HgCl \rightarrow R_3SiX + HR' + Hg\ .$$

In contrast to this, in the course of the slow reaction of triethylsilane with diethylmercury (117 h at 130-140°C) the products are compounds with the Si–Hg bond [9,21]:

$$Et_3SiH + Et_2Hg \rightarrow Et_3SiHgEt + C_6H_6\ , \quad (1)$$

$$2Et_3SiH + Et_2Hg \rightarrow (Et_3Si)_2Hg + 2C_6H_6\ . \quad (2)$$

Together with ethyl(triethylsilyl)mercury, one obtains bis(triethylsilyl)mercury, albeit in a low yield (~ 3%), possibly as a result of symmetrisation (disproportionation):

$$2Et_3SiHgEt \rightarrow (Et_3)_2Hg + HgEt_2 .$$

Indeed, when ethyl(triethylsilyl)mercury is heated for 11 h at 170°C, it is converted to a fairly large extent (70%) into bis(triethylsilyl)mercury. The low yields of triethylsilyl derivatives of mercury in reactions (1) and (2) can be explained by their secondary decomposition processes, which is indicated by the high content of metallic mercury in the reaction products[9].

Trichlorosilane reacts slowly with diethylmercury at 20°C for several days, forming ethyl(trichlorosilyl)mercury in 71.8% yield[22,23]. Bis(trichlorosilyl)mercury, which is also formed in this reaction, is a product of the symmetrisation of $EtHgSiCl_3$. Very pure $(Cl_3Si_2)Hg$ can be obtained by the ultraviolet irradiation of a mixture of bis(trimethylsilylmethyl)mercury and trichlorosilane[23]:

$$(Me_3SiCH_2)_2Hg + 2HSiCl_3 \rightarrow 2Me_4Si + Cl_3SiHgSiCl_3 .$$

In the analogous reaction of Me_3SiHCl_2 or $(Me_3)_2SiHCl$ the products are $(Cl_2MeSi)_2Hg$ and $(ClMe_2Si)_2Hg$ respectively, which decompose spontaneously above −79°C with liberation of mercury and substituted disilanes[23]. However, the reactions of $ClMe_2SiH$ and Cl_2MeSiH with di-(t-butyl)mercury at 85°C gave rise to bis(chlorodimethylsilyl)- and bis(dichloromethylsilyl)mercury, which are thermally stable (they sublime *in vacuo* at 80°C).[24] The difficulties experienced by earlier workers[23] can probably be accounted for by the use of radiation, which decomposes these compounds.

When triorganylsilanes interact with di-(t-butyl)mercury[25] or dibenzylmercury[26], the corresponding organosilicon derivatives of mercury, containing the Si–Hg bonds, are formed under mild conditions and in high yields.

The nature of the substituents at the silicon atom in triorganylsilanes affects not only the reactivity of the latter, but also the stability of the organosilicon derivatives of mercury obtained from them. Thus pentaethyldisilane reacts with diethylmercury more vigorously than does triethylsilane[27]. The yield of mono- and di-substituted pentaethyldisilyl derivatives of mercury is higher than that of the analogous triethylsilyl derivatives.

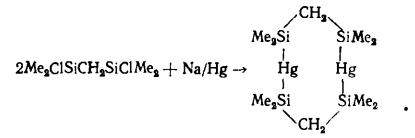
The reaction of triorganylsilanes with diorganylmercury makes it possible to obtain a wide assortment of compounds containing the Si–Hg bond with various substituents at the silicon atom. $[Me_2(n\text{-}Pr)Si]_2Hg$, $(MeEt_2Si)_2Hg$,[28] $(PhMe_2Si)_2Hg$, $(Ph_2MeSi)_2Hg$, $(Ph_3Si)_2Hg$,[29] $[(Me_3SiCH_2)_2Me_2Si]_2Hg$, $[(Me_3Si)_3Si]_2Hg$, $[Me_2(PhCH_2)Si]_2Hg$, and optically active bis(methylphenylsilyl-1-naphthyl)mercury were synthesised by this method. When a 2 : 1 mixture of ethylbis(triethylgermyl)silane and diethylmercury was heated in an evacuated sealed tube (14 h at 150°C), bis[ethylbis(triethylgermyl)silyl]mercury was obtained in 65.9% yield together with ethane[30]. Bis[diethyl(triethylgermyl)silyl]mercury, bis[tris(triethylgermyl)silyl]mercury, and bis[ethylbis(triethylsilyl)]mercury were synthesised under analogous conditions but after more prolonged heating (21–35 h)[30]:

$$2Et_{3-n}(Et_3E)_nSiH + Et_2Hg \rightarrow [Et_{3-n}(Et_3E)_nSi]_2Hg + 2EtH ;$$
$$E = Si \text{ or } Ge;\ n = 1-3 .$$

Ethyltriethylsilylmercury[31] and bis-(*N*-hexamethyldisilazanyl)mercury can be used instead of diorganylmercury[32,33]:

$$Ph_3SiH + EtHgSiEt_3 \rightarrow Ph_3SiHgSiEt_3 + EtH$$
$$\downarrow$$
$$^1/_2(Ph_3Si)_2Hg + ^1/_2(Et_3Si)_2Hg ,$$
$$2(C_6F_5)_3SiH + [(Me_3Si)_2N]_2Hg \xrightarrow{150-170°} 2[(C_6F_5)_3Si]_2Hg + 2(Me_3Si)_2NH .$$

The attempt to use the Wurtz reaction for the synthesis of disilane derivatives by treating halogenotrimethylsilanes with liquid sodium amalgam led to the formation of bis(trimethylsilyl)mercury[7]:



$$2Me_3SiX + 2Na + Hg \rightarrow (Me_3Si)_2Hg + 2NaX ;$$
$$X = Cl \text{ or } Br.$$

The analogous reaction with bromodimethylsilane apparently leads to the formation of $Hg(SiMe_2H)_2$, but this compound could not be isolated because of its instability[7].

Chlorodimethyl(pent-4-en-1-yl)silane gives rise to the corresponding mercury derivative[34]:

$$2H_2C{=}CH(CH_2)_3Me_2SiCl + Na/Hg \rightarrow Hg[SiMe_2(CH_2)_3CH{=}CH_2]_2 .$$

$[CH_2 = CHCH_2Me_2Si]_2Hg$, $(EtMe_2Si)_2Hg$, and $(Et_3Si)_2Hg$ were obtained similarly[28]. The interesting heterocyclic compound 2,2,4,4,6,6,8,8-octamethyl-2,4,6,8-tetrasila-1,5-dimercuracyclo-octane is formed from 2,4-dichloro-2,4-dimethyl-2,4-disilapentane (20°C, 1 month)[35]:

Bis(triphenylsilyl)mercury has been obtained in a yield up to 70% by treating with mercury acetate the ternary complex of ethylbis(triphenylsilyl)aluminium with lithium bromide and tetrahydrofuran (THF)[36]:

$$2Ph_3SiAl(Et)SiPh_3 \cdot 2LiBr \cdot 2THF + 3Hg(OAc)_2 \rightarrow 2(Ph_3Si)_2Hg + Et_2Hg + 2Al(OAc)_3 +$$
$$+ 4LiBr + 4THF.$$

The reaction of bis(trimethylsilyl)mercury with bromosilane (SiH_3Br) makes it possible to obtain silyl(trimethylsilyl)mercury[37]:

$$(Me_3Si)_2Hg + BrSiH_3 \rightarrow Me_3SiHgSiH_3 + Me_3SiBr .$$

$(SiH_3)_2Hg$ and $Me_3SiHgGeH_3$ have been obtained similarly.

2. Physical Properties

According to X-ray diffraction, the $(R_3Si)_2Hg$ molecule has a linear structure, the Si–Hg bond length amounting to 2.500 ± 0.005 Å.[38] The infrared spectra of compounds of this type show an intense absorption band with $\nu_{as}(Hg\text{–}Si)$ = 318 cm^{-1} and $\nu_S(Hg\text{–}Si)$ = 312 cm^{-1}.[7,38] The 474 cm^{-1} frequency corresponds to the stretching vibration of the Hg–C bond in the spectra of compounds of the type $R_3SiHg\text{–}R'$.[39]

The presence of a mercury atom at the silicon atom increases the $\nu(Si\text{–}C)$ frequency[40,41]. Thus $\nu_S(Si\text{–}C)$ = 569 cm^{-1} for hexamethyldisilane and 583 cm^{-1} for bis(triethylsilyl)mercury. This is apparently associated with the greater electronegativity of the $-Hg\text{–}Si(Et)_3$ fragment compared with $-SiEt_3$. When $(Et_3Si)_2$ is replaced by $(Et_3Si)_2Hg$, a new long-wavelength maximum (335 nm) appears in the electronic absorption spectra[42].

The ^1H NMR[43–46] and ^{199}Hg NMR[46] spectra of organosilicon derivatives of mercury of the type R_3SiHgR' and $(R_3Si)_2Hg$ have been investigated. The chemical shift of the protons in the Me_3SiHg group is τ = 9.83 p.p.m. and the spin–spin coupling constant $J(^{199}Hg\text{–}Si\text{–}C\text{–}^1H) = 40.8$ Hz for $(Me_3Si)_2Hg$;[43] τ_{CH_2} = 9.23 p.p.m. and τ_{CH_3} = 8.94 p.p.m. for the Et_3SiHg group in $(Et_3Si)_2Hg$.[44] For asymmetric organosilicon derivatives of mercury of the type Me_3SiHgR,

where R = Me, $CH=CH_2$, $\overline{CH-CH_2-CH_2}$, Ph, or CH_2Ph, the long-range spin–spin coupling constants $J(^{199}Hg-Si-C-^1H)$ increase with increasing electronegativity of the substituent R.[45] They are related to the spin–spin coupling constants for the corresponding organomercury compounds of the MeHgR series by the linear expression $0.453\,J(^{199}Hg-C-^1H) + 6.0 = J(^{199}Hg-Si-C-^1H)$. The existence of this relation shows that the nature of the spin–spin coupling in the two series of compounds is the same.

According to calorimetric data[47], the enthalpy of the Si–Hg bond is $\Delta H^\circ_S(liq.) = 42 \pm 1$ kcal mole^{-1} and its average dissociation energy is $\bar{D} = 20 \pm 3$ kcal mole^{-1}.

In the study of compounds containing the Si–Hg bond mass-spectrometry was used to determine their molecular weights[26,34,48] and only a few communications[28,35,49] have been devoted to their fragmentation. Under electron impact, all the compounds investigated give rise to a molecular ion and subsequently undergo fragmentation with ejection of mercury either as a result of electron impact or in consequence of pyrolytic decomposition[28]. Between 1 and 6% of the overall ionic current corresponds to the molecular ion, amounting to 15.6% only for bis(trimethylsilyl)mercury. The mass spectrum of the latter involves a considerable contribution of three ions containing mercury and silicon: $Me_5Si_2Hg^+$ (5.5%), Me_3SiHg^+ (2.16%), and Me_2SiHg^+ (0.38%). On partial or complete replacement of methyl groups by higher alkyl groups (ethyl and n-propyl), the concentration of ions containing the Si–Hg bond decreases significantly. This is also observed on passing from $(Me_3Si)_2Hg$ to $(Me_2PhSi)_2Hg$. The $(MePh_2Si)_2Hg$ and $(Ph_3Si)_2Hg$ ions, which contain the Si–Hg bond, have not been detected in the mass spectra with the exception of the molecular ions. The replacement by the alkenyl groups $CH_2=CH(CH_2)_n$ ($n = 1-3$) leads to a decrease of the concentration of the molecular ions and to the absence of other ions with the Si–Hg bond, which indicates a destabilising effect of the alkenyl groups on this bond.

Successive substitution of the methyl groups in $(Me_3Si)_2Hg$ by chlorine atoms entails an increase of the concentration of ions with the Si–Hg bond, which shows that the presence of chlorine atoms at the silicon atom stabilises the Si–Hg bond[28].

Under electron impact, 2,2,4,4,6,6,8,8-octamethyl-2,4,6,8-tetrasila-1,5-dimercuracyclo-octane gives rise to a molecular ion and ions corresponding to the successive loss of one or two mercury atoms[28,35].

3. Chemical Properties

Organosilicon derivatives of mercury containing the Si–Hg bond are highly reactive. The vast majority of the chemical reactions lead to the cleavage of the covalent Si–Hg bond with preservation of the R_3Si- fragments. On the other hand, these compounds are fairly stable and usually can be vacuum distilled in the absence of atmospheric oxygen without appreciable decomposition. The thermal stability of pentaethyldisilyl derivatives of mercury is higher than that of the analogous triethylsilyl derivatives[27]. Bis(tribenzylsilyl)mercury is also very stable[50,51]. Metallic mercury and the corresponding hexaorganyldisilane are formed quantitatively in the thermal decomposition of bis(triorganylsilyl)mercury[7,22,23]:

$$(R_3Si)_2Hg \rightarrow (R_3Si)_2 + Hg .$$

The thermal decomposition of bis(trimethylsilyl)mercury in solution proceeds via a free-radical mechanism[26,52–55]. The $Me_3Si^\cdot$ radicals formed can not only dimerise to hexamethyldisilane but can also react with the solvent. In aromatic solvents (benzene, toluene, and anisole) this leads to aromaric homolytic substitution products[56–59].

All the compounds containing the Si–Hg bond are sensitive to light. Photolysis of bis(trimethylsilyl)mercury leads to the formation of mercury and $Me_3Si^\cdot$ radicals. The very short-lived $Me_3SiHg^\cdot$ radicals have been identified together with the above species[9,60–62]:

$$(Me_3Si)_2Hg \rightarrow Me_3Si^\cdot + {}^\cdot Hg-SiMe_3 \rightarrow Hg + 2Me_3Si^\cdot$$
$$Me_3Si^\cdot + Hg(SiMe_3)_2 \rightarrow Hg + (Me_3Si)_2 + {}^\cdot SiMe_3 .$$

Compounds with the Si–Hg bond are very readily oxidised by atmospheric oxygen. Oxidation of ethyl(triethylsilyl)mercury is a free-radical chain process initiated at the beginning by the $Et_3SiHg^\cdot$ and $Et_3Si^\cdot$ radicals formed[9,25,63,64]:

$$2R_3SiHgR \rightarrow R_2Hg + R_3SiHg^\cdot + R_3Si^\cdot ,$$
$$R_3Si^\cdot + O_2 \rightarrow R_3SiOO^\cdot ,$$
$$R_3SiHg^\cdot \rightarrow R_3Si^\cdot + Hg ,$$
$$R_3SiOO^\cdot + R_3SiHgR \begin{cases} \rightarrow R_3SiOHgR + R_3SiO^\cdot \\ \rightarrow (R_3SiO)_2 + RHg^\cdot \end{cases} ,$$
$$R_3SiO^\cdot + R_3SiHgR \rightarrow (R_3Si)_2O + RHg^\cdot ,$$
$$RHg^\cdot + O_2 \rightarrow CH_3CHO + {}^\cdot HgOH ,$$
$$^\cdot HgOH + R_3SiHgR \rightarrow R_3SiOH + RHg^\cdot + Hg^\cdot ,$$
$$2R_3SiOH \xrightarrow[-H_2O]{} (R_3Si)_2O ;$$
$$R=Et .$$

The oxidation is accelerated severalfold in the presence of traces of Lewis bases capable of forming complexes with organomercury compounds, (ammonia, amines, triphenylphosphine, etc.)[64–66].

Under the usual conditions, bis(triorganylsilyl)mercuranes $(R_3Si)_2Hg$ are resistant to hydrolysis and alcoholysis, but these reactions take place readily in a homogenising solvent. Thus, when bis(triphenylsilyl)mercury is acted upon by moist benzene, there is very rapid formation of mercury (quantitative), triphenylsilanol, and hydrogen[26]:

$$\begin{array}{l} Ph_3Si-Hg-SiPh_3 \\ \quad\vdots\quad\vdots \\ \quad HO-H \end{array} \rightarrow Ph_3SiOH + HHgSiPh_3 ,$$
$$HHgSiPh_3 + H_2O \rightarrow Ph_3SiOH + [H_2Hg] \rightarrow H_2 + Hg + Ph_3SiOH .$$

In addition, small amounts of triphenylsilane, hexaphenyldisiloxane, and hexaphenyldisilane are produced. The alcoholysis of $(R_3Si)_2Hg$ can proceed via two pathways[67]:

$$\begin{array}{l} Ph_3Si-Hg-SiPh_3 \\ \quad\vdots\quad\vdots \\ \quad RO-H \end{array} \rightarrow Ph_3SiOR + HHgSiPh_3 \rightarrow Ph_3SiOR + Hg + HSiPh_3 ,$$
$$\begin{array}{l} HHg-SiPh_3 \\ \quad\vdots\quad\vdots \\ \quad H\ -OR \end{array} \rightarrow Ph_3SiOR + [H_2Hg] \rightarrow Ph_3SiOR + H_2 + Hg ,$$
$$\begin{array}{l} Ph_3Si-Hg-SiPh_3 \\ \quad\vdots\quad\vdots \\ \quad HO-R \end{array} \rightarrow Ph_3SiOH + RHgSiPh_3 .$$

The interaction of organosilicon derivatives of mercury containing the Si–Hg bond with acids leads to the quantitative formation of mercury and can serve as a method for the analysis of these compounds[7,25,50]:

$$(R_3Si)_2Hg + HX \rightarrow R_3SiH + Hg + R_3SiX ;$$
$$R=Me,\ Et\ or\ Ph;\ X=Cl\ or\ OAc .$$

Bis(trimethylsilyl)mercury reacts with CO_2 only in hexamethylphosphoramide (HMPT) to form CO and hexamethyldisiloxane[68]:

$$(Me_3Si)_2Hg + CO_2 \xrightarrow[-Hg]{} \begin{array}{l} SiMe_3 \\ | \\ O=C-OSiMe_3 \end{array} \rightarrow (Me_3Si)_2O + CO .$$

The reaction with carbon disulphide proceeds via a similar mechanism:

$$(Me_3Si)_2Hg + CS_2 \xrightarrow{-Hg} S{=}C(SiMe_3){-}SSiMe_3 \rightarrow (Me_3Si)_2S + 1/n\,(CS)_n .$$

The interaction of SO_2 with bis(trimethylsilyl)mercury at 20°C proceeds via the mechanism[68]

$$(Me_3Si)_2Hg + SO_2 \xrightarrow{-Hg} Me_3Si{-}O{-}S{-}O{-}SiMe_3 .$$

The bis(trimethylsilyl)sulphoxylate formed decomposes at room temperature into hexamethyldisiloxane and sulphur, which reacts with mercury to form HgS.

Acyl peroxides (but not t-butyl peroxide[2]) react vigorously with compounds containing the Si–Hg–Si[2,25,69] or Si–Hg–C[9] groups:

$$(Et_3Si)_2Hg + (PhCOO)_2 \rightarrow Hg + 2Et_3SiOCOPh ,$$
$$2Et_3SiHgEt + (PhCOO)_2 \rightarrow Et_2Hg + 2PhCOOSiEt_3 + Hg .$$

Aliphatic aldehydes interact with bis(trimethylsilyl)mercury very slowly in benzene. On the other hand, aromatic aldehydes interact rapidly even at 20°C, forming bis(trimethylsiloxy)hydrobenzoin[70,71]:

$$(Me_3Si)_2Hg + 2RCHO \xrightarrow{-Hg} R{-}CH(OSiMe_3){-}CH(OSiMe_3){-}R ,$$

where **R** = aryl.

2,2-Dichlorovinyloxytrimethylsilane is formed from chloral via an exothermic reaction[71]:

$$(Me_3Si)_2Hg + CCl_3CHO \xrightarrow{-Hg} Me_3SiOCHCCl_3 \rightarrow Me_3SiCl + Me_3SiOCH{=}CCl_2 .$$
($SiMe_3$ on the CHCCl$_3$ carbon)

Bis(trimethylsilyl)mercury reacts vigorously at room temperature with ketones and quinones such as acetone[72-74], hexafluoroacetone[75], cyclohexanone[72,73], 9-fluorenone[76], acetophenone[70,72,73], benzophenone[72,73], 1,4-naphthoquinone, 1,2-naphthoquinone, and anthraquinone[70], forming the intermediate $R_2COSiMe_3$ radical, which then dimerises or disproportionates:

$$(Me_3Si)_2Hg + R_2CO \xrightarrow{-Hg} R{-}C(R)(OSiMe_3){-}\cdot \rightarrow R{-}C(R)(OSiMe_3){-}H + RCH{=}C(R)(OSiMe_3)$$
$$\rightarrow R{-}C(R)(OSiMe_3){-}C(R)(OSiMe_3){-}R .$$

1,2-Diketones react via the mechanism[71]

$$(Me_3Si)_2Hg + RCOCOR \xrightarrow{-Hg} R{-}C(OSiMe_3){=}C(OSiMe_3){-}R ,$$

where **R** = Me or Ph.

The following reactions occur when bis(trimethylsilyl)-mercury interacts with diorganylketones[68,70]:

$$(Me_3Si)_2Hg + 2R_2C{=}C{=}O \xrightarrow{-Hg} R_2C(SiMe_3){-}CO{-}C(OSiMe_3){=}CR_2 ,$$
$$R_2C{=}C(OSiMe_3){-}CR_2{-}COSiMe_3 ,$$
$$R_2C{=}C(OSiMe_3){-}C(OSiMe_3){=}CR_2 .$$

where **R** = Me or Ph.

The reaction with aryl isocyanates in HMPT leads to the formation of *N*,*N'*-diaryl-*N*,*N'*-bis(trimethylsilyl)urea and carbon monoxide[68,70]:

$$(Me_3Si)_2Hg + 2R{-}N{=}C{=}O \xrightarrow[-Hg]{-CO} R{-}N(Me_3Si){-}C(=O){-}N(SiMe_3){-}R ,$$

where **R** = Ph, 4-$CH_3C_6H_4$, or 1-$C_{10}H_7$.

Diphenylcarbodiimide reacts rapidly[68] with bis(trimethylsilyl)mercury in HMPT via the mechanism

$$(Me_3Si)_2Hg + PhN{=}C{=}NPh \xrightarrow{-Hg} Ph{-}N(SiMe_3){-}C{=}NPh .$$

1,4- and 1,6-additions take place in the reaction of bis(trimethylsilyl)mercury with maleate or fumarate esters[71,78]:

$$(Me_3Si)_2Hg + \begin{matrix}HC{-}COOEt\\ \|\\ HC{-}COOEt\end{matrix} \xrightarrow{-Hg} \begin{matrix}HC(OSiMe_3){=}C{-}OEt\\ |\\ HC{-}SiMe_3\\ |\\ COOEt\end{matrix} + \begin{matrix}HC(OSiMe_3){=}C{-}OEt\\ |\\ HC{=}C{-}OEt\\ |\\ OSiMe_3\end{matrix} .$$

On heating or under ultraviolet irradiation, bis(trimethylsilyl)mercury cleaves the isoxazole ring[79]:

$$6\,(Me_3Si)_2Hg + 2N{=}CRCH{=}CR'O \xrightarrow{-3Hg} [(Me_3Si)_2NCR{=}CHCR'OSiMe_3]_2 ;$$
R, R'=H or Me.

The reaction of bis(trimethylsilyl)mercury with pyridine and its derivatives leads to *N*,*N'*-bis(trimethylsilyl)tetrahydro-4,4'-bipyridyls[80,81-83]:

$$(Me_3Si)_2Hg + 2N{=}C_5H_4(X) \xrightarrow{-Hg} Me_3SiN(X){-}(X)C_5H_4NSiMe_3 ;$$
X=H, 2-Me, 3-Me, 3-CN, 3-COOMe, 4-COOMe, or 4-Ac.

When an equimolar mixture of $(Me_2Si)_2Hg$ and a pyridine derivative containing the carbonyl group in the 4-position is irradiated with ultraviolet light, the α-trimethylsiloxy-*N*-trimethylsilyl derivatives of 4-methylenedihydropyridines are formed[84]:

$$(Me_3Si)_2Hg + N{=}C_5H_4{-}C(=O)R \xrightarrow{-Hg} Me_3SiN(H){-}C(OSiMe_3){=}CR ;$$
R=H, Me, or Ac.

Bis(trimethylsilyl)mercury reacts with azo-compounds as a nucleophile, adding to the azo-group[78,82]:

$$(Me_3Si)_2Hg + R{-}N{=}N{-}R \rightarrow R{-}N(HgSiMe_3){-}N(SiMe_3){-}R \xrightarrow{-Hg} R{-}N(SiMe_3){-}N(SiMe_3){-}R ;$$
R=EtOCO, Ph, or 2-C_5H_4N.

$(Me_3Si)_2Hg$ interacts with aryl azides via a radical mechanism to form nitrogen and *N*,*N'*-bis(trimethylsilyl)-anilines[68]:

$$(Me_3Si)_2Hg + R{-}N{=}N{-}N \xrightarrow{-Hg} (Me_3Si)_2N{-}N{=}NR \xrightarrow{-N_2} (Me_3Si)_2NR ;$$
R=Ar .

The reaction of t-butyl(trimethylsilyl)mercury with substituted benzylidenemalonodinitriles leads to *N*-trimethylsilylketenimines[85]:

$$Me_3SiHgCMe_3 + XC_6H_4CH{=}C(CN)_2 \rightarrow XC_6H_4CH(CMe_3)C(CN){=}C{=}NSiMe_3 ;$$
X=H, Me, MeO, Cl, or NO_2.

t-Butyl(trimethylsilyl)mercury adds to 4-$MeOC_6H_4CH{=}C(CN)COOEt$ to form *O*-silylketen acetal[85].

In the interaction of bis(trimethylsilyl)mercury with an olefin under the conditions of photolysis trimethylsilyl radicals add to the double bond[86]:

$$(Me_3Si)_2Hg + CH_3CH(CH_3)CH{=}CHCH_3 \xrightarrow{-Hg} CH_3CH(CH_3)\underset{Me_3Si}{CH}{-}\underset{SiMe_3}{CH}CH_3 .$$

The attempts to achieve the transfer of the trimethylsilyl radical from $(Me_3Si)_2Hg$ to zinc or aluminium were unsuccessful[7]. Bis(trimethylsilyl)mercury interacts with zinc only at a high temperature, liberating dimethylmercury. The interaction with aluminium results in the liberation of metallic mercury and the formation of a mixture of compounds not containing the Si–Al bond. On the other hand, lithium reacts with bis(triethylsilyl)mercury and ethyl(triethylsilyl)mercury in THF with formation of triethylsilyl-lithium[87,88]:

$$(Et_3Si)_2Hg + 2Li \rightarrow Hg + 2Et_3SiLi ,$$
$$Et_3SiHgEt + 2Li \rightarrow Hg + Et_3SiLi + EtLi .$$

This reaction is convenient for the synthesis of Alk_3SiLi.

Bis dimethyl(pent-4-en-1-yl)silyl mercury reacts with lithium to form the corresponding lithio-derivative which cyclises and gives rise to 1,1,2-trimethyl-1-silacyclopentane after hydrolysis[34]:

$$(CH_2{=}CHCH_2CH_2CH_2Me_2Si)_2Hg + Li \xrightarrow{-Hg} 2CH_2{=}CHCH_2CH_2CH_2Me_2SiLi \rightarrow$$
$$\rightarrow \underset{Me\quad Me}{\overset{}{Si}}{-}CH_2Li \xrightarrow{H_2O} \underset{Me\quad Me}{\overset{}{Si}}{-}CH_3 .$$

The reaction of $(Et_3Si)_2Hg$ with metallic potassium or sodium in an aromatic solvent results in the formation of triethylsilylpotassium and triethylsilylsodium, but the reaction with the solvent predominates in this case[89]: it may be that Et_3SiM is a reaction intermediate, which interacts with the solvent to form Et_3SiPh and MH:

$$(Et_3Si)_2Hg + 2M \xrightarrow{C_6H_6} 2Et_3SiM + Hg ,$$
$$Et_3SiM + C_6H_6 \rightarrow Et_3SiH + PhM ,$$
$$PhM + Et_3SiH \rightarrow PhSiEt + M ;$$
M = K or Na.

Triethylsilylpotassium can be obtained by treating $(Et_3Si)_2Hg$ with potassium using triethylsilane as a solvent[89].

Bis(trimethylsilyl)mercury interacts with alkali metals in 1,2-dimethoxyethane, forming dimetallo-organosilicon complexes[90,91]:

$$2(Me_3Si)_2Hg + 2M \rightarrow (Me_3Si)_4HgM_2 + Hg ;$$
M = K or Na.

The analogous lithium compounds have been obtained by the direct interaction of bis(trimethylsilyl)mercury with Me_3SiLi:

$$(Me_3Si)_2Hg + Me_3SiLi \rightarrow (Me_3Si)_2HgLi ,$$
$$(Me_3Si)_2Hg + 2Me_3SiLi \rightarrow (Me_3Si)_4HgLi_2 .$$

The formation of $K_2Hg(SiEt_3)_4$ has been observed in the reaction of bis(triethylsilyl)mercury with potassium cyanide in THF in the presence of a crown-ether[92]:

$$3(Et_3Si)_2Hg + 2KCN \rightarrow (Et_3Si)_4HgK_2 + 2Hg + 2Et_3SiCN .$$

Organosilicon derivatives of mercury containing the Si–Hg bond are capable of exchanging the trialkylsilyl fragment for the anions of a number of metal salts. For example, the interaction with mercury salts proceeds via the general mechanism[92-96]

$$(R_3Si)_2Hg + HgX_2 \rightarrow 2R_3SiX + 2Hg ;$$
X=Cl, Br, I, CN, $Co(CO)_3$, $Cr(CO)_3C_6H_5$, $W(CO)_3C_6H_5$, or $Mo(CO)_3C_5H_5$.

The intermediates in this reaction are probably compounds of the type R_3SiHgX, which immediately decompose to mercury and R_3SiX.

The products of the reaction of bis(triethylsilyl)mercury with alkylmercury chlorides in the absence of a solvent in atmospheric oxygen give rise to the corresponding alkyl(trialkylsilyl)mercuranes together with mercury and a trialkylchlorosilane[61,97-98]:

$$(Et_3Si)_2Hg + RHgX \rightarrow Et_3SiHgR + Et_3SiX + Hg ,$$
R=Me, Et, Pr, iso-Pr, t-Bu; X=Cl .

The reactions of $(R_3Si)_2Hg$ with organomercury compounds of the type HgR'_2, where R′ is a hydrocarbon or a polyfluoro-hydrocarbon radical [Me_2, iso-Pr, $CH{=}CH_2$, Ph,[45] $-C-C-Ph$ (bonded to $B_{10}H_{10}$),[99] CF_3, CH_2CF_3, $CHFCF_3$, CF_2CF_3, $CFClCF_3$, $CH(CF_3)_2$, and $CF(CF_3)_2$[95,100]] in aprotic solvents (benzene, toluene) lead to the corresponding trialkylsilylorganylmercuranes:

$$(Et_3Si)_2Hg + HgR'_2 \rightarrow 2Et_3SiHgR' .$$

$(R_3Si)_2Hg$ reacts via a similar mechanism with dimetallo-organic compounds of the type HgR'_2, where R = $SnMe_3$, $GeMe_3$, or $SiMeCl_2$.[43,49] Other reactions of bis(trialkylsilyl)mercuranes are listed in the Table.

Organosilicon derivatives of mercury containing the Si–Hg bond are used in the synthesis of organosilicon derivatives which are difficult to obtain otherwise and also as catalysts in the polymerisation of styrene[29,135] or ethylene[136] and in the hydroxylation of unsaturated compounds (in combination with ultraviolet irradiation)[137]. However, the considerable lability of the Si–Hg bond limits the scope of the industrial utilisation of compounds of this class.

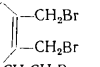
III. COMPOUNDS CONTAINING THE Si–(–C–)$_n$–Hg GROUP

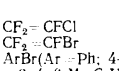
Compounds containing the Si–(–C–)$_n$–Hg group have been known much longer than those discussed above but have been investigated in much less detail.

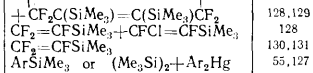
1. Methods of Synthesis

(a) Organometallic synthesis. The first compound containing the Si–(–C–)$_n$–Hg group was obtained in 1945 by Whitmore and Sommer[138] by treating trimethylsilylmethylmagnesium chloride with mercury(II) chloride:

$$Me_3SiCH_2MgCl + HgCl_2 \rightarrow Me_3SiCH_2HgCl + MgCl_2 .$$







The compounds RHgCl, where R = $Me_3CSiMe_2CH_2$,[139] $PhMe_2SiCH_2$,[140-143] $Me_3SiCHMe$,[144] $Me_3SiSiMe_2CH_2$, $EtMe_2SiSiMe_2CH_2$, or $(Me_3Si)_2CH$,[139] were subsequently synthesised by a similar procedure.

The reaction of 2 moles of Me_3SiCH_2MgCl with 1 mole of $HgCl_2$ leads to the formation of bis(trimethylsilylmethyl)mercury in yields up to 50%:[145,146]

$$2Me_3SiCH_2MgCl + HgCl_2 \rightarrow (Me_3SiCH_2)_2Hg + 2MgCl_2 .$$

Symmetrical organosilicon derivatives of mercury of the type R_2Hg (for the significance of R, see above) have been obtained in the same way.

Reactions of $(R_3Si)_2Hg$ with organic and organometallic compounds.

R_2	Reagent	Reaction product	References
Et_3, $MePh_2$	$Hg[C(N_2)COCH_3]_2$	$R_3SiC(N_2)COCH_3$	101

The mercuration of Me_3SiCH_3MgCl by organylmercury chlorides R'HgCl leads to compounds of the type Me_3SiCH_2HgR' [R' = Me, n-C_6H_{13}, Ph,[138] $CH_2SiMe_2CMe_3$,[139] CH_2GeMe_3,[147] $CH_2Me_2SiSiMe_3$, $CH_2Me_2SiSiMe_2Et$, or $CH(SiMe_3)_2$ [139]].

Dimethylmercury reacts with trichloromethylsilane or dichlorodimethylsilane at 450°C to form $(Cl_3SiCH_2)_2Hg$ and $(Cl_2CH_3SiCH_2)_2Hg$ respectively [148]:

$$2(CH_3)_nSiCl_{4-n} + (CH_3)_2Hg \rightarrow [(CH_3)_{n-1}Cl_{4-n}SiCH_2]_2Hg + 2CH_4 .$$

These compounds were not isolated in a pure form but were identified as their methyl derivatives, obtained by treatment with methylmagnesium bromide.

Organozinc synthesis can also be used to prepare certain organosilicon derivatives of mercury, for example [149]:

$$2Me_3SiCHIZnI + HgCl_2 \rightarrow (Me_3SiCHI)_2Hg + 2IZnCl .$$

The yield of bis[iodo(trimethylsilyl)methyl]mercury is then 45% (traces of $Me_3SiCHIHgI$ were also found).

The reaction of dichloromethyl(trimethylsilyl)lithium with mercury(II) bromide at 135°C has been used to synthesise dichlorobis(trimethylsilyl)methylmercury, which serves as a source of chlorotrimethylsilylcarbene [150–152]:

$$2Me_3SiCCl_2Li + HgBr_2 \rightarrow (Me_3SiCCl_2)_2Hg + 2LiBr .$$

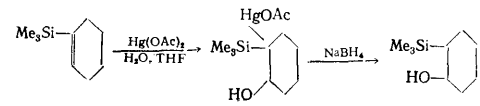
For an initial reactant ratio of 1 : 1, up to 5% of Me_3SiCCl_2.HgBr is formed together with the symmetrical compound (yield 44%). When $HgBr_2$ is replaced by $HgCl_2$, the yield of $(Me_3SiCCl_2)_2Hg$ falls to 23% and up to 17% of Me_3SiCCl_2.HgCl is formed.

Trimethyl[(methylmercuri)(trimethylsilyl)methylene]-phosphorane has been obtained by the reaction of the lithium derivative of trimethyl(trimethylsilylmethylene)phosphorane with methylmercury chloride [153]:

$$Me_3P(CH_2Li)=CHSiMe_3 + Me_3HgCl \rightarrow Me_3P=C(HgMe)(SiMe_3) + LiCl .$$

(b) Mercuration of unsaturated organosilicon compounds. The addition of mercury salts to the double bonds of unsaturated organosilicon compounds was first achieved in 1959 [154]:

$$Me_3SiCH=CH_2 + Hg(OAc)_2 \xrightarrow[-CH_3COOH]{H_2O} Me_3SiCH(HgOAc)CH_2OH .$$



The reduction of the product with sodium amalgam led to (2-hydroxyethyl)trimethylsilane, which confirmed the above anomalous mode of reaction [the mercuration of olefins of the type $RCH=CH_2$ with mercury acetate usually proceeds in accordance with the Markovnikov rule, leading to $RCH(OH)CH_2HgOAc$ [155]]. The unusual mode of mercuration in this case is due to the interaction of the π electrons of the vinyl group with the vacant 3*d* orbitals of the silicon atom (the effect of the $d\pi - p\pi$ conjugation), which predominates over the opposed inductive effect of the trimethylsilyl group, which reduces the electron density at the β-carbon atom.

When trimethylallylsilane is acted upon by mercury salts, only the products of the cleavage at the $Si-CH_2$ bond are formed, which is apparently due to the β-decomposition of the adduct formed initially [156–158]. The study of the kinetics of this process showed that its mechanism does not fit within the framework of simple bimolecular electrophilic substitution [158]. The reaction proceeds in several stages, the rate of the process being determined by the cleavage of the adduct to $(CH_3)_3SiX$ and $CH_2=CHCH_2HgS$.

The addition of bis(trinitromethyl)mercury to trimethylvinylsilane in water, alcohol, benzene, and carbon tetrachloride leads to bis[(3,3,3-trinitro-1-trimethylsilyl)propyl]mercury (in 90% yield) [156,157]:

$$2Me_3SiCH=CH_2 + Hg[C(NO_2)_3]_2 \rightarrow Hg[-CH(SiMe_3)CH_2C(NO_2)_3]_2 .$$

The interaction of mercury acetate with 1-trimethylsilylcyclohexane in an aqueous medium gives rise to an addition product, whose reduction with sodium tetrahydroborate results in the formation of 1-trimethylsilyl-2-cyclohexanol [159]:

The mode of addition of the HgOAc group in the mercuration of unsaturated compounds of the type $RCH=CH(CH_2)_nSiX_3$ (R = H, Me, or Ph; X = Me, Et, Me, Et, or Ac)

depends on the nature of the substituents at the double bond (**R**) and at the silicon atom (**X**) as well as the position of the double bond[160]. It has been established by ^1H NMR that, in the reaction of mercury acetate with trimethylvinylsilane in both alcoholic and acetic acid media, the HgOAc group adds only to the α-carbon atom:

$$Me_3SiCH{=}CH_2 + Hg(OAc)_2 \xrightarrow[-AcOH]{R'OH} Me_3SiCH(HgOAc)CH_2OR';$$
$$R' = Me, \text{ or } Ac.$$

The addition of mercury acetate to trimethylpropenylsilane and trimethyl-β-styrylsilane is no longer selective. In both instances the HgOAc group adds to both α- and β-carbon atoms:

$$Me_3SiCH{=}CHR + Hg(OAc)_2 \xrightarrow[-AcOH]{R'OH} \begin{cases} \rightarrow Me_3SiCH(HgOAc)CH(R)OR' \\ \rightarrow Me_3SiCH(OR')CH(R)HgOAc \end{cases}.$$

The ratio of the α- and β-adducts is 7 : 3 for **R** = Me and 1 : 1 for **R** = Ph. The breakdown of selectivity in the addition reaction is due to the enhanced electron density at the β-carbon atom owing to the $+I$ effect of the methyl group or the incorporation of the phenyl group in the conjugation chain.

Contrary to data published previously[161], the addition of mercury acetate to alkenyltrialkoxysilanes in an alcoholic medium is in all cases quantitative and vigorously selective with formation of α-mercurated adducts alone[160]:

$$(MeO)_3SiCH{=}CHR + Hg(OAc)_2 \xrightarrow{MeOH} (MeO)_3SiCH(HgOAc)CH(R)OMe + AcOH;$$
$$R = H, Me, \text{ or Ph}.$$

On the other hand, only the γ-mercuri-derivative has been obtained from trialkoxyallylsilane:

$$(EtO)_3SiCH_2CH{=}CH_2 + Hg(OAc)_2 \xrightarrow[-AcOH]{EtOH} (EtO)_3SiCH_2CH(OEt)CH_2HgOAc.$$

The adducts formed in both cases are fairly stable.

In nitromethane or chloroform mercury acylates add smoothly to vinylsilanes with formation of the corresponding α-acyloxymercuri-derivatives[160]:

$$X_3SiCH{=}CH_2 + Hg(OCOR)_2 \rightarrow X_3SiCH(HgOCOR)CH_2OCOR;$$
$$X = Et, Me, \text{ or AcO}; R = Me, \text{ or Ph}.$$

When trialkylethynylsilanes are acted upon by mercury salts, the acetylenic hydrogen atom is substituted instead of the addition to the triple bond[162]:

$$Me_3SiC{\equiv}CH + XHgOAc \rightarrow Me_3SiC{\equiv}CHgX + AcOH;$$
$$X = I, \text{ or OAc}.$$

The reaction of mercury(II) chloride with 1-triethylsilyl-2-tripropylstannylethylene leads to the cleavage of the bond between tin and the unsaturated group[163]:

$$Et_3SiCH{=}CHSnPr_3 + HgCl_2 \rightarrow Et_3SiCH{=}CHHgCl + ClSnPr_3.$$

The interaction of methylmercury chloride with trimethyl(trimethylsilylmethylene)phosphorane leads to trimethyl[(methylmercuri)(trimethylsilyl)methylene]phosphorane[153,164]:

$$MeHgCl + Me_3P{=}CHSiMe_3 \rightarrow (Me_3\overset{+}{P}{-}\underset{\displaystyle SiMe_3}{\underset{|}{CH}}{-}HgMe)\,Cl^- \xrightarrow{Me_3P=CHSiMe_3} \rightarrow Me_3P{=}C\begin{matrix}HgMe\\SiMe_3\end{matrix} + (Me_3\overset{+}{P}CH_2SiMe_3)\,Cl^-.$$

(c) The cleavage of sila- and 1,3-disilacyclobutanes with mercury salts. When 1,1-dialkylsilacyclobutanes are acted upon by mercury salts in an aqueous or alcoholic medium, the endocyclic Si–C bond is cleaved[165–168]. This results in the smooth formation of γ,γ'-mercurated 1,1,3,3-tetraorganyl-1,3-dipropylsiloxanes:

$$R_2Si\begin{matrix}CH_2\\CH_2\end{matrix}CHR' + HgX_2 \rightarrow XSiR_2CH_2CHR'CH_2HgX \xrightarrow{R''OH} \rightarrow R''OSiR_2CH_2CHR'CH_2HgX \rightarrow O(SiR_2CH_2CHR'CH_2HgX)_2.$$

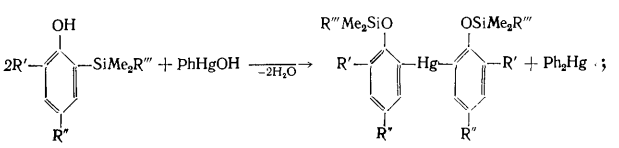
In an alcoholic medium these compounds are apparently formed as a result of heterofunctional condensation catalysed by mercury salts:

$$\equiv SiX + R''OSi{\equiv} \xrightarrow{HgX_2} \equiv Si{-}O{-}Si{\equiv} + R''X.$$

Mercury salts cleave 1,1,3,3-tetramethyl-1,3-disilacyclobutane even more readily (the rate of its cleavage by $HgCl_2$ is four times greater than the rate of cleavage of 1,1-dimethylsilacyclobutane)[165–168]:

$$Me_2Si\begin{matrix}CH_2\\CH_2\end{matrix}SiMe_2 + HgX_2 \rightarrow XSiMe_2CH_2SiMe_2CH_2HgX \xrightarrow{R''OH} \rightarrow R''OSiMe_2CH_2SiMe_2CH_2HgX \rightarrow O[SiMe_2CH_2SiMe_2CH_2HgX]_2.$$

The homogeneous reaction of sila- and 1,3-disila-cyclobutanes with $Hg(NO_3)_2$ in an alcoholic medium proceeds in the same direction as for $HgCl_2$ or $HgAc_2$, but in a heterogeneous medium (when aqueous mercury nitrate solutions are used) oligomeric (telomeric) mercuration products are formed[169,170] probably via the mechanism

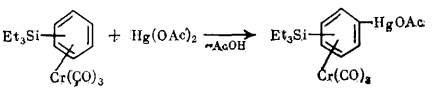


$$R_2Si\begin{matrix}CH_2\\CH_2\end{matrix}R' + Hg(NO_3)_2 \xrightarrow{H_2O} [O_3NSiR_2CH_2R'CH_2HgNO_3] \xrightarrow{nR_2Si\diamondsuit R'} \rightarrow \{O_3N[SiR_2CH_2R'CH_2]_{n+1}HgNO_3\} \xrightarrow{H_2O} HO[SiR_2CH_2R'CH_2]_{n+1}HgNO_3 \rightarrow O\{[SiR_2CH_2R'CH_2]_{n+1}HgNO_3\}_2;$$
$$R = Me, \text{ or Ph}; R' = CH_2, \text{ or } SiR_2.$$

Evidently in this case the primary cleavage product, containing the labile Si–O–NO_2 group, is itself capable of breaking the sila- or 1,3-disila-cyclobutane ring, which leads to the formation of oligomeric compounds.

Five-membered heterocycles with one or two silicon atoms in the ring do not react with mercury salts[167]. It has been suggested that the rate of these reactions is controlled by the electrophilic attack by the HgX^+ cation.

(d) Mercuration of aromatic organosilicon derivatives. The reactions of mercury salts with organosilicon compounds in which the silicon atom is linked directly to an aromatic ring lead in all cases to the dissociation of the Si–Ar bond and not to the mercuration of the ring[171–176].



Sterically hindered *o*-trialkylsilylphenols react with PhHgOH or Ph_2Hg, forming the corresponding bis-(2-trialkylsiloxyphenyl)mercuranes[177–180]:

$R' = R'' = CMe_3$, $R''' = Me$; $R' = SiMe_3$, $R'' = CMe_3$, $R''' = Me$; $R' = CMe_3$, $R'' = SiMe_3$, $R''' = Me$; $R' = R'' = CMe_3$, $R''' = Ph$.

When PhHgOH interacts with *o*-trialkylsilylphenols containing a less hindered OH group, polymeric arylmercury oxides which do not contain silicon are formed[178]. If the trialkylsilyl group is in the *para*-position relative to the hydroxy-groups, mercuration does not occur[181] and oxidation of the organosilicon phenols is observed.

The interaction of triethylsilylbenzenechromium tricarbonyl by mercury acetate in glacial acetic acid leads to mercuration in the aromatic ring without the elimination of the triethylsilyl group [182]:

The separation of the silicon atom from the aromatic ring by the $-(CH_2)_nO$-group permits the smooth mercuration of the ring [183]:

$$X_3Si(CH_2)_nOC_6H_4Y + Hg(OAc)_2 \xrightarrow{-AcOH} X_3Si(CH_2)_nOC_6H_3Y(HgOCOCH_3);$$

X = Me, MeO, or EtO;

Y = H, OMe-*o*, Me-*p*; $n = 1, 3$.

Using an excess of mercury acetate, it is possible to convert compounds of the type $X_3Si(CH_2)_nOPh$ into [bis(acetoxymercuri)phenoxyalkyl]trialkyl- or [bis(acetoxymercuri)phenoxyalkyl]trialkoxy-silanes $X_3Si(CH_2)_nOC_6H_3 \cdot (HgOAc)_2$. [183]

2. Properties

Organomercury compounds containing the $Si-(-C-)_n-Hg$ group are fairly resistant to the action of atmospheric oxygen, moisture, and light, in contrast to compounds with the Si–Hg bond. They also exhibit a comparatively high thermal stability. Thus many compounds of the type R_3SiCH_2HgR' can be distilled *in vacuo* without appreciable decomposition and can be successfully separated by the gas–liquid chromatography (GLC) [139]. Bis(trimethylsilylmethyl)mercury decomposes slowly only at 200°C (to the extent of 5% after 100 h) [145], forming mercury, tetramethylsilane, and $Me_3SiCH_2HgCH_2SiMe_2CH_2CH_2SiMe_3$.

However, in the photolysis of $(Me_3SiCH_2)_2Hg$ vigorous decomposition is observed with formation of mercury, methane, tetramethylsilane, and small amounts of $Me_3SiCH_2HgCH_2SiMe_2CH_2CH_2SiMe_3$, $Me_3SiSiMe_3$, $(Me_3SiSiMe_2)_2$, and $(Me_3SiCH_2CH_2SiMe_2CH_2)_2$. [145] When bis[tris(trimethylsilyl)methyl]mercury is acted upon by light, the relatively stable free radicals $[(CH_3)_3Si]_3Si^{\cdot}$ are generated [184]. They are only slightly less stable than $(Ph_3C^{\cdot})$:

$$[(Me_3Si)_3C]_2Hg \rightarrow 2(Me_3Si)_3C^{\cdot} + Hg .$$

The products of the mercuration of Si-substituted alkenylsilanes and organosilicon derivatives of mercury, formed when sila- or 1,3-disila-cyclobutanes are cleaved by mercury salts, exhibit an inadequate thermal stability. They do not distill *in vacuo*, since they readily eliminate metallic mercury.

Treatment of organosilicon derivatives of mercury of the type $Me_3SiCH(HgOAc)CH_2OH$ with saturated solutions of alkali metal halides leads to the exchange of the acetoxy-group at the mercury atom for the halogen [154]:

$$Me_3SiCH(HgOAc)CH_2OH + MX \rightarrow Me_3SiCH(HgX)CH_2OH + MOAc;$$

M = K or Na; X = Cl, Br, or I.

The amorphous halogenomercuri-derivatives formed under these conditions exchange the HgX group for the halogen in reactions with the latter [154,156]:

$$Me_3SiCH(HgX)CH_2OH + X_2 \rightarrow Me_3SiCHXCH_2OH + HgX_2 .$$

The reactions of $Me_3SiC{\equiv}CHgOAc$ and $Me_3SiC{\equiv}CHgI$ with iodine lead to the formation of trimethyliodoethynylsilane [162]:

$$(CH_3)_3SiC{\equiv}CHgX + I_2 \rightarrow (CH_3)_3SiC{\equiv}CI + IHgX;$$

X = OAc or I.

[(Phenyldimethylsilyl)methyl]mercury bromide is converted into the corresponding mercury acetate when acted upon by silver acetate [143]; the mercury acetate readily symmetrises under the influence of a 0.02 M perchloric acid solution:

$$PhMe_2SiCH_2HgBr \xrightarrow[-AgBr]{AgOAc} PhMe_2SiCH_2HgOAc \xrightarrow{HClO_4} (PhMe_2SiCH_2)_2Hg + Hg(OAc)_2$$

When acted upon by a saturated solution of hydrogen chloride in ethanol, compounds of the type Me_3SiCH_2HgR are cleaved [138] via the mechanism

$$Me_3SiCH_2HgR + HCl \xrightarrow{C_2H_5OH} \begin{cases} \rightarrow Me_4Si + RHgCl \ (R = Me \text{ or } n\text{-}C_6H_{13}) \\ \rightarrow Me_3SiCH_2HgCl + RH \ (R = Ph) \end{cases}.$$

This reaction made it possible to estimate the relative electronegativities of the substituent R linked to the mercury atom, which decrease in the following sequence:

$$Ph > Me_3GeCH_2 > Me_3SiCH_2 > Me > n\text{-}C_6H_{13} > Me_3CCH_2.$$

The higher electronegativity of the Me_3GeCH_2 group compared with that of the Me_3SiCH_2 group is indicated by the reaction [147]

$$2Me_3SiCH_2HgCH_2GeMe_3 + HCl \rightarrow \underset{(80\%)}{Me_4Ge} + \underset{(85\%)}{Me_3SiCH_2HgCl} + \underset{(20\%)}{Me_4Si} + Me_3GeCH_2HgCl .$$

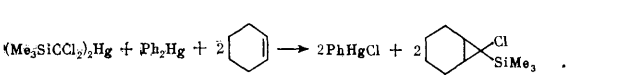
However, all these data concerning the relative ease of elimination of substituents from the mercury atom characterise not only their electronegativity, but also their steric effect. For example, although the $Me_3SiSiMe_2$ group has stronger electron-donating properties than the Me_3Si group, it is eliminated from the mercury atom by hydrogen chloride with greater difficulty owing to steric hindrance [139]. The more bulky $Me_3CSiMe_2CH_2$ and $(Me_3Si)_2CH$ group are also split off from the mercury atom with greater difficulty than the Me_3SiCH_2 group.

Compounds of the type Me_3SiCH_2HgR' are also cleaved by mercury(II) chloride [138]:

$$Me_3SiCH_2HgC_6H_{13} + HgCl_2 \rightarrow Me_3SiCH_2HgCl + C_6H_{13}HgCl .$$

Bis(triorganylsilylmethyl)mercuranes interact with alkali metals, splitting off mercury and forming the corresponding alkali metal derivatives [140–142,185]:

$$(R_3SiCH_2)_2Hg + 2M \rightarrow 2R_3SiCH_2M + Hg ,$$



where M = Li, Na, K, Rb, or Cs.

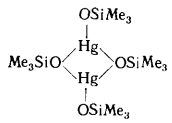
This reaction constitutes a convenient method for the synthesis of organosilicon derivatives of alkali metals.

Tris(trimethylsilylmethyl)aluminium has been obtained similarly [186]:

$$3(Me_3SiCH_2)_2Hg + 2Al \rightarrow 2(Me_3SiCH_2)_3Al + 3Hg .$$

On heating, compounds of the type $(Me_3SiCX_2)_2Hg$ ($X_2 = Cl_2$, HBr, ClBr, or Br_2) give rise to the carbenes Me_3SiCH, Me_3SiCCl, and Me_3SiCBr, [150–152] which are capable of adding to the double bonds of unsaturated compounds:

In view of the high stability of compounds containing the $Si-(-C-)_n-Hg$ group, in contrast to compounds with the Si–Hg bond, the former can find practical applications. Thus compounds having the general formula $ROCOHgCH_2C \cdot (OR')YA_nSi(R'')_a(X)_b$ ($R = R' = R'' =$ alkyl; Y = H or Me; A = alkylene; X = alkoxy- or acetoxy-group; $a = 0-2$; $b = 3-a$) can serve as fungicidal additives to silicone elastomers [161].

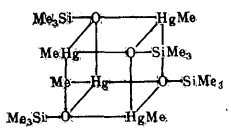


IV. COMPOUNDS CONTAINING THE Si–X–Hg (X = O, S, Se, Te, OR N) GROUP

1. Compounds Containing the Si–O–Hg Group

One of the most widely used methods for the synthesis of compounds containing the Si–O–Hg group involves the reaction of alkali metal triorganylsilanoxides with mercury salts. Mercury(II) chloride reacts with sodium trimethylsilanoxide in dioxan, forming the ether-soluble bis(trimethylsiloxy)mercury, which is extremely sensitive to moisture [187]:

$$2Me_3SiONa \xrightarrow[-2NaCl]{HgCl_2} (Me_3SiO)_2Hg \xrightarrow[-HgO]{H_2O} 2Me_3SiOH \ .$$



This compound sublimes in a high vacuum at 90°C, forming crystals. Determination of the molecular weight revealed its dimeric structure [188]:

At approximately 0°C bis(trimethylsiloxy)mercury slowly decomposes with dissociation of the Si–C bond:

$$(Me_3SiO)_2Hg \rightarrow Me_3SiOHgMe + 1/n\,(Me_2SiO)_n \ .$$

Methyl(trimethylsiloxy)mercury, obtained by treating Me_3SiONa with methylmercury chloride, is more stable and is readily soluble in organic solvents [188–190]. It is associated and has a tetrameric structure in the crystalline state [190,191]:

When $HgCl_2$ interacts with sodium triphenylsilanoxide (in molar proportions of 1 : 2) in ether, sodium chloride precipitates instantaneously and bis(triphenylsiloxy)mercury is formed [192]. However, even when the solvent is removed *in vacuo* (< 20°C), the decomposition of this compound begins. This results in a 34% yield of phenyl(triphenylsiloxy)mercury and a solid polymer which melts in the range 135–250°C:

$$2Ph_3SiONa + HgCl_2 \xrightarrow[-2NaCl]{} [Ph_3SiO]_2Hg \rightarrow Ph_3SiOHgPh + Ph_3SiO\,(Ph_2SiO)_n\,HgPh \ .$$

When the proportions of $HgCl_2$ and PhSiONa are 1 : 1, a similar polymer and PhHgCl are formed, which indicates an analogous process (with dissociation of the Si–C bond):

$$R_3SiONa + HgCl_2 \rightarrow R_3SiO\,(R_2SiO)_n\,HgCl + RHgCl \ .$$

Phenyl(triphenylsiloxy)mercury can be obtained also by another procedure [192]:

$$Ph_3SiOK + PhHgCl \rightarrow Ph_3SiOHgPh + KCl \ .$$

This compound is not hydrolysed by water but is cleaved on treatment with HCl, forming triphenylsilanol and PhHgCl. It is stable at room temperature, but above the melting point decomposes with formation of Ph_2Hg and $Ph_3SiO(Ph_2SiO)_nHgPh$.

Organosilicon derivatives of mercury containing the Si–O–Hg group can be obtained [193] by the reaction of RHgX (R is an organic group and X the hydroxy-group or the residue of an inorganic or acetic acid) with silicon tetrachloride, tetraethoxysilane, metal silicates, and silicic acid. After prolonged refluxing of a mixture of $SiCl_4$ and mercury(II) oxide in a polar solvent (acetonitrile, nitromethane, etc.) in the presence of mercury(II) chloride [194], perchloro-oligosiloxanes $Cl_3Si(OSiCl_2)_nCl$ (n = 1–4), boiling in the range from 190° to 262°C at 15 mmHg, and a solid having the composition $ClHgOSiCl_3$ are formed.

The attempt to obtain polyphenylmercurosiloxanes by the reaction of disodium diphenylsilanedioxide with mercury(II) chloride led only to the formation [195] of octaphenylcyclotetrasiloxane $Ph_2SiOPh_2SiOPh_2SiOPh_2SiO$, but the reaction of diphenylsilanediol with diethylmercury nevertheless made it possible to synthesise the polymeric organosilicon derivative of mercury containing the Si–O–Hg group [195].

The 885 cm^{-1} [192] and 932 cm^{-1} [188] bands in the infrared spectra of triorganylsiloxymercuranes have been assigned to the vibrations of the Si–O–Hg group [188].

2. Compounds Containing the Si–X–Hg Groups (X = chalcogen).

As stated in Section II. 3 (see Table), organosilicon derivatives of mercury containing the Si–X–Hg group are formed when bis(trialkylsilyl)mercuranes interact with sulphur or selenium [50,100,121–123]:

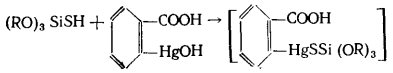
$$(R_3Si)_2Hg + 1/8\,X_8 \rightarrow R_3SiXHgSiR_3 \ ;$$
$$R = Et \text{ or iso-Pr};\ X = S \text{ or Se}.$$

Selective heterolytic cleavage of bis(triethylgermyl)-mercury with triethylsilaneselanol or triethylsilanetellurol leads to the corresponding germanium derivatives [100,196,197]. When the reactants are in proportions of 1 : 2, $(R_3SiX)_2Hg$ is formed together with triethylgermane:

$$(R_3Ge)_2Hg + HXSiR_3 \rightarrow R_3GeHgXSiR_3 + R_3GeH \ ,$$
$$(R_3Ge)_2Hg + 2HXSiR_3 \rightarrow 2R_3GeH + Hg\,(XSiR_3)_2 \ ,$$
$$R = Et;\ X = Se \text{ or Te} \ .$$

Asymmetric compounds containing the Si–X–Hg group readily decompose at room temperature via the mechanism [196,197]

$$R_3GeHgXSiR_3 \rightarrow R_3GeXSiR_3 + Hg \ .$$



On the other hand, the symmetrical derivatives $(R_3SiX)_2Hg$ have a fairly high thermal stability and do not fully decompose in solution even under prolonged heating (7 h, 130°C). Their decomposition products are the mercury chalcogenide and $(R_3Si)_2X$:

$$(R_3SiX)_2Hg \rightarrow (R_3Si)_2X + HgX \ .$$

Trialkoxysilylthiomercuranes, which are relatively soluble in ether and tetrahydrofuran and are stable in the absence of moisture, have been obtained by the interaction of trialkoxysilanethiols with ethylmercury bromide [198]:

$$(RO)_3SiSH' + EtHgBr \rightarrow (RO)_3SiSHgBr + C_2H_6 \ ;$$
$$R = \text{iso-Pr, } Me_3C, \text{ or } (CH_3)_2CHCH_2CH_2 \ .$$

The formation of a compound containing the Si–S–Hg group is observed in the reaction of trialkoxysilanethiols with *o*-hydroxymercuribenzoic acid. However, the product has not been isolated in a free form [199]:

3. Compounds Containing the Si–N–Hg Group

The exothermic reaction of sodium bis(trimethylsilyl)-amide with mercury(II) bromide in ether yielded di[bis(trimethylsilyl)amino]mercurane [153,200,201]:

$$2\,(Me_3Si)_2NNa + HgBr_2 \rightarrow [(Me_3Si)_2N]_2Hg + 2NaBr\ .$$

The reaction product is a colourless crystalline substance, which distills *in vacuo*, does not form adducts with pyridine or tetrahydrofuran, and is readily hydrolysed to $Hg(OH)_2$ and hexamethyldisilazane.

The force constant, indicating that the Hg–N bond is covalent and single, has been calculated from infrared and Raman spectroscopic data [200]. The Hg–N interatomic distance is 2.23 Å. The band at 406 cm^{-1} in the infrared spectrum was assumed to correspond to the $\nu_{as}(N–Hg–N)$ frequency. The 390 cm^{-1} line in the Raman spectrum corresponds to the $\nu_S(N–Hg–N)$ vibration.

Lithium tris(trimethylsilyl)hydrazide reacts exothermically with mercury(II) chloride or bromide in pentane [202], forming the lithium halide and mercury tris(trimethylsilyl)-hydrazide:

$$2\,(R_3Si)_2N–N(Li)–SiR_3 + HgX_2 \rightarrow 2LiX + (R_3Si)_2N–N\begin{matrix}SiR_3\\ \diagdown\\ Hg–N–N–(SiR_3)_2\\ \diagup\\ SiR_3\end{matrix}\ ;$$

$$R = Me,\ X = Cl\ or\ Br\ .$$

This hydrazide is a crystalline substance, which is readily soluble in petroleum ether, benzene, and THF and is sensitive to moisture. According to cryoscopic data, the compound is monomeric. Its infrared spectrum exhibits the intense asymmetric vibration of the N–Hg–N group with $\nu_{as} = 379\ cm^{-1}$ in the region of low frequencies. The ^1H NMR spectrum is a doublet ($\nu = 0.28,\ 0.26$). [202]

The interaction of lithium bis(trimethylsilyl)amide with alkylmercury halides gave *N*,*N'*-bis(trimethylsilyl)alkylmercuramines in yields up to 85% [203]:

$$(Me_3Si)_2NLi + RHgX \rightarrow (Me_3Si)_2NHgR + LiX\ ;$$

$$R = Me\ or\ Et;\quad X = Cl\ or\ Br\ .$$

They are colourless liquids which distill *in vacuo*. ^1H NMR spectra: $\delta(CH_3Hg) = 0.37$ p.p.m., $\delta(CH_3Si) = 0.17$ p.p.m., and $J(^{199}Hg–CH_3) = 157$ Hz were obtained for $CH_3HgN[Si(CH_3)_3]_2$; $\delta(CH_3CHg) = 1.07$ p.p.m., $\delta(CCH_2Hg) = 1.17$ p.p.m., $\delta(SiCH_3) = 0.19$ p.p.m., $J(^{199}Hg–CH_2) = 160$ Hz, and $J(^{199}Mg–CCH_3) = 195$ Hz were found for $C_2H_5HgN.[Si(CH_3)_3]_2$.

Alkyl-*N*,*N'*-bis(triorganylsilyl)mercuramines are useful reagents in the synthesis of many organomercury compounds which are otherwise difficult to obtain. Thus the interaction of $MeHgN(SiMe_3)_2$ with an equimolar amount of water in ether leads to the formation of dimethyldimercury oxide and hexamethyldisilazane in quantitative yields [203]:

$$2\,(Me_3Si)_2NHgMe + H_2O \rightarrow 2\,(Me_3Si)_2NH + MeHgOHgMe\ .$$

The reaction with HN_3 gives rise to mercury azides [203]:

$$(Me_3Si)_2NHgR + HN_3 \rightarrow (Me_3Si)_2NH + RHgN_3\ ;$$

$$R = Me\ or\ Et.$$

The reaction

$$2\,(Me_3Si)_2NHgR + H_2NCN \rightarrow 2\,(Me_3Si)_2NH + (RHg)_2NCN\ ;$$

$$R = Me\ or\ Et.$$

has been used to synthesise bis(organylmercuri)cyanamide. The interaction of *N*,*N'*-bis(trimethylsilyl)methylmercuramine with $HN=P(NMe_2)_3$ yielded tris(dimethylamino)-*N*-(methylmercuri)phosphinimide [204]:

$$(Me_3Si)_2NHgMe + HN=P(NMe_2)_3 \rightarrow (Me_3Si)_2NH + MeHgN=P(NMe_2)_3\ .$$

The reaction with nitroalkanes gives rise to organomercury derivatives of nitronic acids [205]:

$$(Me_3Si)_2NHgR + R'R''CHNO_2 \rightarrow (Me_3Si)_2NH + RHgO\overset{O}{\overset{\|}{N}}=CR'R''\ ;$$

$$R = Me\ or\ Et;\quad R',\ R'' = H\ or\ CH_3.$$

The reaction of $RHgN(SiMe_3)_2$ with diazoacetone or diazoacetophenone is used to synthesise organylmercuridiazoketones and mercuribis(diazoketones) [206]:

$$(Me_3Si)_2NHgR + HC(N_2)COR' \rightarrow (Me_3Si)_2NH + RHgC(N_2)COR'\ ,$$

$$(Me_3Si)_2NHgR + 2HC(N_2)COR' \rightarrow (Me_3Si)_2NH + Hg[C(N_2)COR']_2 + RH\ ;$$

$$R = Me\ or\ Et;\quad R' = Me\ or\ Ph.$$

$[(Me_3Si)_2N]_2Hg$ reacts analogously with 1,3-diketones [201,207,208]:

$$[(Me_3Si)_2N]_2Hg + 2HOCR=CHCOR \rightarrow (Me_3Si)_2NH + Hg(OCR=CHCOR)_2\ ;$$

$$R = Me\ or\ CMe_3.$$

Organyl-*N*,*N'*-bis(trimethylsilyl)mercuramines react with cyclopentadiene to form organylmercuricyclopentadienes [203]:

$$(Me_3Si)_2NHgR + HC_5H_5 \rightarrow (Me_3Si)_2NH + RHgC_5H_5\ ;$$

$$R = Me\ or\ Et\ .$$

Bis(cyclopentadienyl)mercury is formed similarly from $Hg[N(SiMe_3)_2]_2$ [209]:

$$[(Me_3Si)_2N]_2Hg + 2HC_5H_5 \rightarrow 2\,(Me_3Si)_2NH + Hg(C_5H_5)_2\ .$$

Mercury derivatives of tris(pentafluorophenyl)silane and tris(pentafluorophenyl)germane [21,32,210] as well as triphenylstannane [211] have been obtained with the aid of di[bis(trimethylsilyl)amino]mercury [211]:

$$[(Me_3Si)_2N]_2Hg + 2H\Theta(C_6F_5)_3 \rightarrow 2\,(Me_3Si)_2NH + Hg[\Theta(C_6F_5)_3]_2\ ;$$

$$\Theta = Si\ or\ Ge.$$

$$[(Me_3Si)_2N]_2Hg + 2HSnPh_3 \rightarrow 2\,(Me_3Si)_2NH + Hg(SnPh_3)_2\ .$$

The hydrolytic instability of compounds containing the Si–X–Hg group limits their industrial manufacture and practical employment. However, they are extremely useful in the preparative synthesis of organomercury and organosilicon compounds which are otherwise difficult to obtain.

V. COMPOUNDS CONTAINING THE $Si–(–C–)_n–X–Hg$ GROUP

Among compounds of this type, only examples with X = Ge or Sn are known [212,213]. Di[tris(trimethylsilylmethyl)germyl]mercurane has been obtained by treating $(Me_3SiCH_2)_3GeH$ with diethylmercury [213]:

$$2\,(Me_3SiCH_2)_3GeH + Et_2Hg \rightarrow [(Me_3SiCH_2)_3Ge]_2Hg + 2EtH\ .$$

Di[tris(trimethylsilylmethyl)stannyl]mercurane has been synthesised by a similar mechanism [212]:

$$2\,(Me_3SiCH_2)_3SnH + Et_2Hg \rightarrow [(Me_3SiCH_2)_3Sn]_2Hg + 2EtH\ .$$

This compound is one of the products of the exchange reaction of the ester of mercurybisacetic acid with di[tris(trimethylsilylmethyl)stannyl]cadmium [213]:

$$[(Me_3SiCH_2)_3Sn]_2Cd + Hg(CH_3COOMe)_2 \rightarrow [(Me_3SiCH_2)_3Sn]_2Hg + Cd(CH_3COOMe)_2\ .$$

The asymmetric compounds $(Me_3SiCH_2)_3SnHgCH_2COOMe_3$ and $(Me_3SiCH_2)_3SnCdCH_2COOMe$ are then formed as intermediates.

Di[tris(trimethylsilylmethyl)stannyl]mercury exhibits an anomalously high thermal stability compared with its analogues $(R_3Sn)_2Hg$, where R = H, alkyl, or phenyl. This can be explained by the stabilising effect of the Me_3SiCH_2 group.

$[(Me_3SiCH_2)_3Sn]_2Hg$ is a crystalline substance which melts without decomposition. Its reactivity does not differ appreciably from that of bis(triethylsilyl)mercury and similar compounds [212,214-216]. Its solutions in hexane and THF are stable at 20°C. Thermal decomposition in the absence of solvents leads to the formation of mercury, tetrakis(trimethylsilylmethyl)stannane, and tin [221,214], probably via the intermediate formation of hexakis(trimethylsilylmethyl)distannane, which then disproportionates via the mechanism

$$2\,[(Me_3SiCH_2)_3Sn]_2 \xrightarrow{150^\circ,\ 10\ h} 3\,(Me_3SiCH_2)_4Sn + Sn\ .$$

Oxidation with atmospheric oxygen in THF leads to the formation of mercury and hexakis(trimethylsilylmethyl)-distannoxane [218]:

$$[(Me_3SiCH_2)_3Sn]_2Hg + {}^1/_2O_2 \rightarrow [(Me_3SiCH_2)_3Sn]_2O + Hg\ .$$

The exchange reaction with $HgCl_2$ in THF at 20°C is completed after 30 min and leads to the quantitative formation of mercury and $(Me_3SiCH_2)_3SnCl$ [212,214]:

$$[(Me_3SiCH_2)_3Sn]_2Hg + HgCl_2 \rightarrow 2\,(Me_3SiCH_2)_3SnCl + 2Hg\ .$$

The interaction of di[tris(trimethylsilylmethyl)stannyl]-mercury with $Hg[C(CF_3)_3]_2$ leads to the formation of an asymmetric stannylmercury compound, which is demercurated with simultaneous β-decomposition [95,214]:

$$[(Me_3SiCH_2)_3Sn]_2Hg + Hg[C(CF_3)_3]_2 \rightarrow 2\,(Me_3SiCH_2)_3SnHgC(CF_3)_3 \rightarrow$$
$$\rightarrow 2\,(Me_3SiCH_2)_3SnF + 2Hg + 2\,(CF_3)_3C{=}CF_2\ .$$

Elemental iodine readily cleaves the Sn–Hg bond [213]:

$$[(Me_3SiCH_2)_3Sn]_2Hg + 2I_2 \rightarrow 2\,(Me_3SiCH_2)_3SnI + HgI_2\ .$$

Metallic lithium exchanges with mercury to form the corresponding stannyl-lithium derivative [213,217]:

$$[(Me_3SiCH_2)_3Sn]_2Hg + 2Li \rightarrow 2\,(Me_3SiCH_2)_3SnLi + Hg\ .$$

However, when the reaction is carried out in benzene, the main product is hexakis(trimethylsilylphenyl)distannane.

VI. COMPLEXES OF ORGANOSILICON COMPOUNDS WITH MERCURY SALTS

Triorganylsilylmethyl derivatives of phosphorus and arsenic form stable complexes with mercury halides. Thus tris(trimethylsilylmethyl)phosphine and tris(trimethylsilylmethyl)arsine react with mercury(II) chloride to form crystalline adducts [218,219]:

$$(Me_3SiCH_2)_3E + HgCl_2 \rightarrow (Me_3SiCH_2)_3E \cdot HgCl_2$$
$$E = P \text{ or } As.$$

When a solution of methyltris(trimethylsilylmethyl)arsonium iodide is refluxed with mercury(II) iodide in ethanol, methyltris(trimethylsilylmethyl)arsonium iodomercurate is formed [218]:

$$(Me_3SiCH_2)_3AsMeI + HgI_2 \rightarrow [(Me_3SiCH_2)_3AsMe]\,HgI_3\ .$$

The complexes of diphenyl-(*p*-triethylsilylphenyl)arsine with mercury(II) halides [*p*-$(Et_3Si)C_6H_4AsPh_2.HgCl_2$, *p*-$(Et_3Si)C_6H_4AsPh_2.HgBr_2$, and *p*-$(Et_3Si)C_6H_4AsPh_2.HgI_2$] are soluble in benzene and have distinct melting points (188°, 181°, and 139.5°C respectively), so that they can be used for the identification of triorganyl-silylphenylarsines [220].

The interaction of mercury(II) bromide with $[Ph_3PCH_2.SiMe_3]^+Br^-$ in methanol led to a water-soluble phosphonium complex having the composition $[Ph_3PCH_2SiMe_3]^+\,HgBr_3^-$. [221]

The reactions of mercury(II) chloride and methylmercury chloride with $Me_3P{=}CHSiMe_3$ or $Me_3P{=}C(SiMe_3)_2$ lead to the formation of mercurated silylphosphonium salts [153,164] $Me_3P{=}CHSiMe_3.HgCl_2$. When the reactant ratio is 2 : 1, the products are

$$\left[\begin{matrix} Me_3PCHHgCHPMe_3 \\ | \qquad\quad | \\ Me_3Si \qquad SiMe_3 \end{matrix}\right]^{2+} 2X^-,\ X = Cl \text{ or } Br\ .$$

In the reaction of bis(tricarbonylnitrosyliron)mercury with tris(trimethylsilylmethyl)phosphine one of the CO groups is substituted quantitatively [222]:

$$2\,(Me_3SiCH_2)_3P + Hg[Fe(CO)_3(NO)]_2 \xrightarrow[-CO]{} Hg[Fe(CO)_2(NO)P(CH_2SiMe_3)_3]_2\ .$$

On interaction with the same phosphine, bis(tetracarbonylcobalt)mercury forms a complex which undergoes an exchange or disproportionation reaction in the presence of mercury(II) halides [222]:

$$2\,(Me_3SiCH_2)_3P + Hg[Co(CO)_4]_2 \xrightarrow[-CO]{} [(Me_3SiCH_2)_3PCo(CO)_3]_2Hg \xrightarrow{+HgX_2}$$
$$\rightarrow 2\,(Me_3SiCH_2)_3PCo(CO)_3HgX\ .$$

Trialkylsilylmethanethiols react with mercury(II) chloride to form stable crystalline adducts [223]:

$$R_3SiCH_2SH + HgCl_2 \rightarrow [(R_3SiCH_2SH)_2Hg]Cl_2\ .$$

Bis(trimethylsilylmethyl) sulphide reacts with mercury(II) iodide to form $(Me_3SiCH_2)_2S.HgI_2$. [223] Compounds having the general formula $[XC_6H_4Hg]_2SiF_6$, where X = H or a halogen, are obtained by treating a phenylmercury salt with fluorosilic acid [224].

All the facts described above show that further studies in the field of organosilicon derivatives of mercury will prove extremely useful for the development of theoretical and particularly synthetic organic and organoelemental chemistry. There is also no doubt that, apart from the applications already described, new fields of the practical use of these compounds will be discovered.

Molecular Weight Distribution in the Production of Homopolymers

N.S.Enikolopyan and R.G.Gleizer

The principal mathematical methods for the simulation of the molecular weight distributions (MWD) in homopolymers obtained by radical polymerisation are examined. An attempt is made at a survey and a systematic arrangement of mathematical models in terms of kinetic mechanisms, type of reaction apparatus, and the mathematical procedure used.
The bibliography includes 45 references.

I. INTRODUCTION

In studies on polymerisation processes and the properties of polymers much attention is devoted to the investigation of the distribution of polymer and radical chains with respect to molecular weight. Information about the characteristics of the molecular weight distribution (MWD) is necessary for many theoretical and practical problems in polymer chemistry. Nowadays there is an appreciable need to employ MWD in the technology of polymers. The modern principles of the strategy for the simulation of large chemical engineering plants, whereby the process can be optimised from a particular point of view, are of interest also for the technology of polymeric materials. This strategy can be applied to the analytical planning of new large-scale polymerisation processes, their optimisation, and the intensification of the existing processes, but an obligatory condition is always the knowledge of MWD. The initial information required for the solution of problems of this class in relation to polymerisation processes includes, apart from the traditional (for chemistry) mathematical description of the technological process and the set of optimisation criteria, a library of mathematical MWD models. The solution of optimisation problems in the field of industrial polymerisation without the calculation of MWD is impossible, since any optimisation of the polymerisation process must assist the solution of the main problem of polymer chemistry—the synthesis of polymeric materials with specified properties, i.e. ultimately materials having the required set of MWD characteristics.

In the study of a polymerisation process technologists have at their disposal a set of models of various types of reaction apparatus in which polymerisation takes place. In selecting the optimisation factor, the specific features of processes of this kind (the set of requirements which the process must meet is described by several factors and it is important that all such factors be optimised simultaneously) are reflected in the application of multifactor optimisation methods. As regards the use of mathematical MWD models, there is no such clarity. This review is an attempt at a survey and systematic account of mathematical MWD models with respect to the specific mechanism, type of reaction apparatus, and the mathematical procedures employed. The proposed ordered arrangement of the multiplicity of methods for the calculation of distribution functions is designed for a broad class of studies on polymerisation processes with the aim of a rational control of these processes. A systematic arrangement of MWD models is considered in relation to homopolymers obtained in radical polymerisation, although the proposed approach can be used also for branched polymers by extending the set of mathematical methods, for example, by including the method of the theory of graphs developed in topology and introduced for the first time in studies on the chemical kinetics of multistage branched enzymatic catalytic reactions[1-3]. However, the aim of the present review was restricted to the consideration of the MWD in the formation of linear homopolymers by a free radical mechanism.

Table 1. Kinetic scheme for radical polymerisation.

Designation	Reaction mechanism	Reaction rate equation
Initiation		
decompn. of initiator	$I \xrightarrow{k_i} 2R_c$	
start of reaction	$R_c + M \rightarrow R_1$	$w_i = f(I)$
Chain propagation	$R_r + M \xrightarrow{k_p} R_{r+1}$	$w_p = k_p M R_r$
Chain transfer:		
via the monomer	$R_r + M \xrightarrow{k_f} P_r + M^{\cdot}$	$w_f = k_f M R_r$
via the solvent	$R_r + S \xrightarrow{k_{fs}} P_r + S^{\cdot}$	$w_{fs} = k_{fs} S R_r$
Chain termination:		
by recombination	$R_r + R_s \xrightarrow{k_{t_1}} P_{r+s}$	$w_{t_1} = k_{t_1} R_s R_r$
by disproportionation	$R_r + R_s \xrightarrow{k_{t_2}} P_r + P_s$	$w_{t_2} = k_{t_2} R_s R_r$
via the monomer	$R_r + M \xrightarrow{k_{t_3}} P_{r+1}$	$w_{t_3} = k_{t_3} M R_r$
spontaneous	$R_r \xrightarrow{k_{t_4}} P_r$	$w_{t_4} = k_{t_4} R_r$

The generally accepted kinetic mechanism of a free-radical polymerisation process, which includes elementary chain initiation, chain transfer, and chain termination reactions, is presented in Table 1, where the following notation is used: R_C is the primary radical formed on decomposition of the initiator I, R_r and P_r are respectively

the polymer radical and an inactive polymer molecule consisting of r monomer units, M is the monomer molecule, S the solvent molecule, M$^{\cdot}$ and S$^{\cdot}$ are the corresponding low-molecular-weight radicals, w_i and w_p are the rates of chain initiation and propagation, w_f and w_{fs} the rates of chain transfer via the monomer and the solvent, w_{t_1}, w_{t_2}, w_{t_3}, and w_{t_4} the rates of chain termination via recombination, disproportionation, via the monomer, and via a spontaneous mechanism respectively, and k_p, k_f, and k_t the rate constants for the corresponding reactions. In the equations presented for the rates of the elementary reactions and throughout the review, M, R_r, S, and P_r denote the concentrations of the corresponding substances.

Apart from the kinetic mechanism of the polymerisation process and the rates of the elementary reactions determined by it, the characteristics of the MWD of the polymer formed are influenced by the mass-exchange conditions during the reaction, which depend mainly on the type of reaction apparatus used. In the present review we shall consider the following extreme idealisations: continuous operation ideal displacement reactor, periodic-operation mixing reactor, and ideal continuous-operation mixing reactor. The hydrodynamic conditions for reactors of the intermediate type permit their description with the aid of combined models, including as their elements the above idealised reactor types. Evidently in systems of the first type (ideal displacement reactor, periodic-operation mixing reactor) the concentration of the reactants and the characteristics of the MWD are non-stationary (with respect to time for the mixing reactor and with respect to length for the ideal displacement reactor) are satisfactorily described by differential equations in terms of the usual derivatives. In reaction systems of the second type (continuous operation ideal mixing reactor or a cascade of such reactors) the concentration of the reactants and all the MWD characteristics remain constant in time and are described by algebraic equations.

There exist different mathematical approaches whereby analytical MWD models can be obtained. The choice of the method of calculation of the distribution with respect to molecular weights is determined by the kinetic mechanism and, to a greater extent, by the simplifying assumptions adopted concerning the polymerisation kinetics. Frequently the abandonment of one hypothesis entails the necessity to employ a new mathematical procedure. The methods for the calculation of the MWD considered in the present review have a kinetic bias in the simulation of the molecular weight distributions of polymers, which is based on the physical chemistry of the process. The statistical approach to the calculation of the MWD, based on the estimation of the probability of the summation of polymer chains of the given size without an explicit allowance for the process kinetics, described in a number of monographs[4-6], is not considered in this review. The statistical approach is known to be phenomenological in character overall. With the aid of the statistical distribution, it is possible to characterise rapidly the polymerisation mechanism in broad outline and to predict the approximate MWD parameters of the polymer obtained under specified conditions. Furthermore, in the calculation of the MWD at the end of an industrial technological process, organised with the aid of reactors of different types, it is necessary to know the law governing the evolution of this distribution in time in addition to the adoption of a statistical distribution as a set of exponential functions of the same type. On the other hand, in the kinetic approach account is taken not only of the kinetic mechanism of the polymerisation process but also of the way in which the reaction is carried out (the type of reaction apparatus). The physics and chemistry of the process are reflected in the final distribution, which establishes a relation between the MWD and the parameters of the polymerisation process and this makes it possible to regulate the MWD.

II. CLASSICAL METHOD FOR THE CALCULATION OF THE MOLECULAR WEIGHT DISTRIBUTION

The analytical method for the calculation of the MWD in polymers, which can now be properly referred to as classical since it was used in early studies on the calculation of the MWD, [6-9,11] consists of a direct solution of a system of an infinite number of material balance equations for all the components of the polymerisation system.

We shall explain the essential features of this method in relation to the calculation of the MWD in a reaction of the periodic type quoted by Bamford et al.[6]; a radical polymerisation reaction takes place in the reactor via the kinetic mechanism illustrated in Fig. 1, where $k_{t_3} = 0$ and $k_{t_4} = 0$, i.e. chain termination takes place only via recombination and disproportionation. The equations for the rates of change of the concentrations of the active and inactive polymer radicals and the monomer assume the following form in this instance:

$$\frac{dR_1}{dt} = w_i - k_p M R_1 + (k_{fs}S + k_f M)\sum_{i=2}^{\infty} R_i - (k_{fs}S + k_f M)R_1 - (k_{t_1} + k_{t_2})R_1 \sum_{i=2}^{\infty} R_i, \quad (1)$$

$$\frac{dR_r}{dt} = k_p M R_{r-1} - k_p M R_r - (k_{fs}S + k_f M)R_r - (k_{t_1} + k_{t_2})R_r \sum_{i=2}^{\infty} R_i, \quad (2)$$

$$\frac{dM}{dt} = w_i + k_p M \sum_{i=2}^{\infty} R_i + k_f M \sum_{i=2}^{\infty} R_i, \quad (3)$$

$$\frac{dP_r}{dt} = (k_{fs}S + k_f M)R_r + \frac{1}{2}k_{t_1}\sum_{k=1}^{r-1} R_k R_{r-k} + k_{t_2}R_r \sum_{i=2}^{\infty} R_i, \quad (4)$$

$$r = 2, 3, \ldots \infty.$$

Calculation of the MWD from an infinite system of differential equations (1)–(4) without the adoption of any additional simplifications is unduly difficult. The mathematical method for the calculation of the MWD under consideration postulates the use of the following assumptions, normally adopted in the kinetics of radical polymerisation.

Firstly, it is assumed that at low degrees of conversion the rate of formation of radicals becomes at some instant equal to the rate of their disappearance. This assumption makes it possible to set dR_r/dt and dR_1/dt equal to zero which simplifies further mathematical treatment. There exists a criterion of the applicability of the hypothesis of "quasi-stationarity" or the "Bodenstein–Semenov hypothesis": the residence time in the reaction zone τ is incomparably longer than the time required for the polymer radical to attain stationary conditions (τ_{st}). The time τ_{st} agrees fairly accurately with the average lifetime of the polymer radicals[10].

However, in many cases the validity of this hypothesis is doubtful. In the first place caution must be exercised in applying it when one is considering adiabatic polymerisation conditions. It follows from general considerations that, depending on the activation energy for the decomposition of the initiator and the destruction of the radicals, in an adiabatic process an increase of temperature in the system should have different effects on the rates of formation and destruction of macroradicals.

An increase of the temperature of the reaction medium should then have a much greater influence on the rate of decomposition of the initiator because of the much higher activation energy for the initiation reaction. Therefore, over a fairly long reaction temperature range, a case may arise where the application of the hypothesis of quasi-stationary concentrations becomes incorrect. It has been established[13] theoretically that there is an appreciable difference between the quasi-stationary and non-stationary adiabatic polymerisation conditions (Fig. 1). Evidently the application of the Bodenstein–Semenov hypothesis is unjustified also in the case of an extremely low initiator concentration, since the attainment of stationary conditions is then limited by the initiator concentration. However, in the vast majority of cases of isothermal free-radical polymerisation reactions the MWD obtained using the hypotheses of quasi-stationary concentrations and without it agree satisfactorily[8].

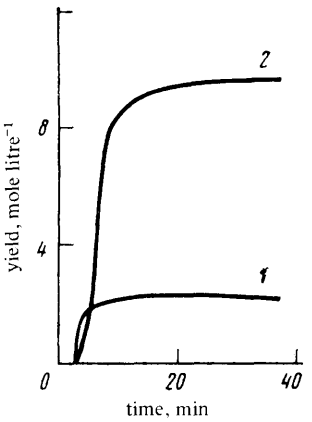

Figure 1. Time variation of the yield of the polymer[13]: 1) with the quasi-stationary hypothesis; 2) without the quasi-stationary hypothesis.

Secondly, the rate constants for the elementary reactions are assumed to be independent of the radical chain length and the degree of conversion of the reaction mixture, which makes it possible to characterise with the aid of a single constant all the steps of elementary reactions of one type. Evidently this assumption greatly simplifies the calculations. However, it has been shown[14] that the hypothesis that the polymerisation reaction rate constants are independent of the length of the macromolecule is in general not justified theoretically and must be proved for each specific case.

Thirdly, it is assumed that, for fairly long chains, the monomer is mainly consumed in the formation of the polymer chain, which makes it possible, by neglecting the consumption of the monomer in initiation and chain transfer, to write instead of Eqn. (3)

$$-\frac{dM}{dt} \cong k_p M \sum_i R_i, \qquad (3')$$

where ΣR_i is the concentration of "living" macromolecules.

Summation of Eqns. (1) and (2), where $r = 2-\infty$, using the hypothesis of quasi-stationary concentrations and the invariance of the rate constants for the elementary reactions, yields the overall concentration of radicals:

$$R = \sum_i R_i = [w_i (k_{t_1} + k_{t_2})]^{1/2}. \qquad (5)$$

On substituting this value of R in Eqns. (1) and (2), we obtain expressions for R_1 and R_r. Integration of the last two equations using the expressions obtained for R_1 and R_r yields the concentration of polymer molecules P_r consisting of r units. Having calculated P_r for various chain lengths r, we obtain the required molecular weight distribution curve. In the general case it is impossible to obtain an analytical expression for P_r by the above procedure. However, in many special cases (in the absence of individual elementary reactions and for constant concentrations of the monomer and other components) it is possible to solve Eqns. (1)–(4) for P_r, i.e. to obtain in an explicit form the equation of the MWD curve.

If the radical polymerisation reaction is carried out in a continuous-operation reaction, the stationary state is described by a system of algebraic equations, each of which represents the material balance with respect to the rth radical, where $r = 1, 2, \ldots$. We shall now explain how the MWD is calculated for a reaction apparatus of this type, following the work of Thiele[9], who considered a kinetic mechanism of radical polymerisation with chain termination via recombination. The material balance equations for the radicals R_1, R_2, R_3, etc. assume the following form in this instance:

$$2k_i f I + k_f M \sum_i R_i = \theta^{-1} R_1 + k_p M R_1 + k_{t_1} R_1 \sum_i R_i, \qquad (1')$$

$$k_p M R_1 = \theta^{-1} R_2 + k_p M R_2 + k_{t_1} R_2 \sum_i R_i + k_f R_2 M, \qquad (2')$$

$$k_p M R_2 = \theta^{-1} R_3 + k_p M R_3 + k_{t_1} R_3 \sum_i R_i + k_f R_3 M, \qquad (2'')$$

where θ is the average residence time of the polymerising system in the reactor $2k_i f I$ the rate of the initiation reaction, and f the efficiency of the initiation. Summation of Eqns. (1'), (2'), ... yields the expression

$$2k_i f I = \theta^{-1} R + k_{t_1} R^2. \qquad (5')$$

We may note that here we are using in essence the assumption that the rate constants for the elementary reactions are independent of chain length. Successive representations of R_r in terms of R_{r-1} yield

$$R_r = \frac{(k_p M)^{r-1} (2k_i f I + k_f M R)}{[\theta^{-1} + (k_p + k_f) M + k_{t_1} R]^r}. \qquad (6)$$

The substitution of the expression for the overall concentrations of macroradicals R from Eqn. (5') in the above formula yields the distribution of active radicals along the chain length. Taking into account Eqn. (6), we obtain the required distribution of polymer chains P_r from the material balance equation for the polymer:

$$\theta^{-1} P_r = \frac{k_{t_1}}{2} \sum_{k=1}^{r-1} R_k R_{r-k} + k_f R_r M. \qquad (7)$$

A considerable mathematical simplification is achieved compared with a periodic-operation reactor, since there is no need to integrate differential equations, which is frequently impossible in terms of quadratures and in the simpler version complex mathematical transformations are needed. This extends the range of models for which it is possible to find an analytical expression of the MWD.

Furthermore, the very expressions for the MWD simplify compared with a periodic-operation reactor as a result of the constancy of the concentrations of all the components of the polymerising system.

If it is assumed that the chain lifetime is short compared with the residence time in the reactor, then evidently the probability that the active radical leaves the reactor before it undergoes chemical reaction and loses its activity is small. This finding is reflected in the initial system of algebraic equations by the relatively low value of the $\theta^{-1}R_r$ terms. The system of algebraic equations for active radicals in a continuous-operation reactor is then identical to the quasi-stationary condition for a periodic-operation reactor and the distributions of radicals with respect to length should be similar for reactors of both types.

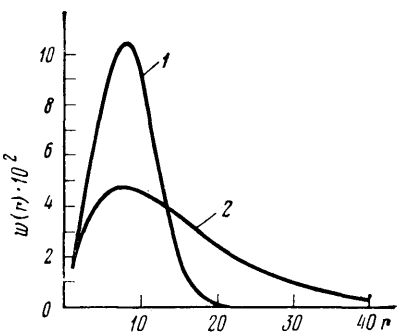

Figure 2. The influence of the type of reactor on the MWD when the lifetime of the active radicals is comparable to the residence time in the reactor[7]: 1) periodic-operation reactor; 2) continuous-operation reactor.

In relation to polystyrene, the lifetime of the growing chain of which is measured in seconds[10,15] while the residence time in the reactor amounts to hours, it has been confirmed[7] that the distribution with respect to the residence time of the species does not affect the MWD of polystyrene. When the residence time of the species in the reaction zone and the chain lifetime are comparable, one must expect a broader MWD for the polymer obtained in a continuous-operation reactor compared with a periodic-operation reactor. This is confirmed by calculations of the MWD [7] (Fig. 2) and can be accounted for by the influence of segregation and micromixing effects on the rate of reaction[16]. Fig. 2 shows a decrease of the homogeneity of the polymer when the process is carried out in a continuous operation reactor compared with a periodic-operation reactor. Analogous results of the calculation of the MWD in the initiated polymerisation of polystyrene, carried out in reactors of both types on the assumption that chain termination takes place as a result of recombination and that there is no chain transfer reaction, have been obtained by Thiele and Hartman[11].

Compared with the large number of theoretical studies on the calculation of the MWD, there are only a few publications presenting the results of the corresponding experimental investigations. In one of the early studies[12] a satisfactory agreement was obtained between experimental and theoretical molecular weight distributions in polystyrene calculated with the aid of the given method. The theoretical MWD curve for suspension polystyrene, obtained in a periodic operation reactor under ideal mixing conditions, has been compared[17] with experimental data. MWD curves have been calculated[18,19] for polystyrene on the assumption that chain termination takes place solely as a result of recombination and that there is chain transfer via the monomer and the solvent. The influence of the solvent concentration was taken into account in the model by a coefficient obtained experimentally[19] as a correction to the rate constant for chain transfer via the monomer. Among a series of experimental results obtained under the conditions of regulated solvent concentration and solution viscosity, best agreement with calculation is observed for low solution viscosities and low solvent concentrations. These results are illustrated in Fig. 3.

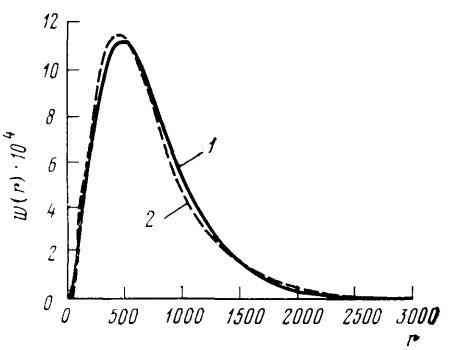

Figure 3. Comparison of the MWD obtained for a low solution viscosity[19]: 1) theoretically; 2) experimentally.

Table 2. Comparison of the calculated and experimental MWD parameters on the basis of the data of Hamielec et al.[19]

MWD parameter	Calculated value	Experimental value
μ_1	48 940	47 460
μ_2	73 920	73 610
μ_2/μ_1	1.51	1.55

The experimental and calculated values of important MWD parameters proved to be very similar under these conditions (Table 2). An experimental characteristic of the MWD (average degree of polymerisation) has been used[17] to determine the elementary reaction constants, which were calculated by minimising the sum of squares of the differences between the measured and calculated average degrees of polymerisation and conversion of styrene.

III. METHOD OF GENERATING FUNCTIONS

The method of generating functions from the theory of random functions has been used in the mathematical simulation of radical polymerisation processes. Liu and Amundson[20] were the first to introduce the above method in the study of processes of this kind. In the investigation of discrete distributions use is frequently made of the generating functions representing them[21]. We shall assume that the probability of a quantity ξ, assuming values of 1, 2, ..., is p_r when $\xi = r$. The term generating function of a random quantity ξ is applied to the function $G(s) = \sum_r s^r p_r$, where $s \leqslant 1$. The generating function satisfies the self-evident relations

$$G(0) = 0; \quad G(1) = 1.$$

With the aid of generating functions, it is possible to obtain a simple solution of many problems associated with the summation of independent random quantities. Their use makes it possible to replace the complex operation involving the setting up of the distribution functions of random quantities, which is necessary when the latter are added together, by a product of the generating functions of the components. Suppose for example, that ξ and η are independent random quantities. The generating function of the sum of the random quantities $\varphi = \xi + \eta$ is then expressed as follows in terms of the generating functions of the components:

$$G_\varphi(s) = G_\xi(s) \cdot G_\eta(s).$$

The wide-scale employment of the method of generating functions in the calculation of the fundamental MWD parameters is to a large extent associated with the most important property of generating functions, arising from their differentiability and from the existence of simple relations between the nth order moments of the distributions of the random quantities and the nth differential of the generating function. It appears natural to apply the method of generating functions to the calculation of MWD, since the polymer chain length is a typical discrete random quantity. Indeed, at each step of the propagation process, the radical has a number of possible choices: it can continue to grow by interacting with a monomer molecule, or it can participate in a chain transfer reactor, or it can react with other radicals, which leads to their mutual destruction. The employment of the method of generating functions gives rise to a number of significant advantages compared with the classical method. In the first place it makes it possible to eliminate the quasi-stationary hypothesis, which is important in the simulation of radical polymerisation processes up to high degrees of conversion in a periodic-operation reactor, when the polymerisation process is carried out under adiabatic conditions, and in a number of other instances.

The calculation of the MWD by the method of generating functions begins with the usual mathematical treatment of the kinetic mechanism of the polymerisation process. We shall show how the calculation is carried out for the polymerisation in a periodic-operation reactor, considered by Liu and Amundson[20], where

$$w_i = k_i M^n; \; k_f = k_{fs} = 0; \; k_{t_1} = k_{t_2} = k_{t_3} = 0,$$

for the kinetic scheme presented in Table 1. Eqns. (1)–(4) are then written in the following form:

$$\frac{dM}{dt} = -k_i M^n - (k_p + k_{t_3}) MR, \tag{8}$$

$$\frac{dR_1}{dt} = k_i M^n - (k_p + k_{t_3}) MR_1, \tag{9}$$

$$\frac{dR_r}{dt} = k_p R_{r-1} M - (k_p + k_{t_3}) MR_r, \tag{10}$$

$$\frac{dP_r}{dt} = k_t M R_{r-1}; \quad r = 2, 3, \ldots \infty. \tag{11}$$

On multiplying Eqns. (9) and (10) by s^r and carrying out the summation from $r = 1$ to ∞, we obtain

$$\frac{dG}{dt} = sk_i M^n + (k_p s - k_p - k_{t_3}) MG(s). \tag{12}$$

The solution of Eqn. (12) subject to the initial conditions $G(s, t)|_{t=0} = 0$ (i.e. at the initial instant there are no active radicals) yields

$$G(s) = \int_0^t sk_i M^n \cdot \exp\left[-(k_p + k_{t_3}) \int_{t_1}^t M\,dt_2\right] \cdot \exp\left[k_p s \int_{t_1}^t M\,dt_2\right] dt_1. \tag{13}$$

Subsequent expansion of $s \cdot \exp\left(k_p s \int_{t_1}^t M\,dt_2\right)$ in Taylor's series in terms of powers of s in the vicinity of $s = 0$, yields

$$s \cdot \exp\left[k_p s \int_{t_1}^t M\,dt_2\right] = s\left[1 + \frac{sk_p \int_{t_1}^t M\,dt_2}{1!} + \frac{s^2\left(k_p \int_{t_1}^t M\,dt_2\right)^2}{2!} + \ldots + \frac{s^{r-1}\left(k_p \int_{t_1}^t M\,dt_2\right)^{r-1}}{(r-1)!} + \ldots\right] = \sum_r \frac{\left(k_p \int_{t_1}^t M\,dt_2\right)^{r-1}}{(r-1)!} s^r.$$

We substitute this expression in Eqn. (13) and then compare the latter with the definition of the generating function $G(s, t) = \sum_r s_r p_r$. Setting the coefficients of identical powers of s equal to one another, we obtain

$$R_r = k_i \int_0^t M^n \exp\left[-(k_p - k_{t_3}) \int_{t_1}^t M\,dt_2\right] \frac{\left(k_p \int_{t_1}^t M\,dt_2\right)^{r-1}}{(r-1)!} dt_1. \tag{14}$$

In order to calculate $M(t)$, we make use of Eqns. (8) and (12) and the initial conditions

$$M|_{t=0} = M_0, \quad G(1)|_{t=0} = 0.$$

We obtain for $n = 1$

$$\frac{dM}{dG(1)} = -\frac{k_t + (k_p + k_{t_3}) G(1)}{k_t - k_{t_3} G(1)}.$$

Hence

$$M = M_0 + \frac{k_p + k_{t_3}}{k_{t_3}} G(1) + \frac{k_t (k_p + 2k_{t_3})}{k_{t_3}^2} \lg \frac{k_t - k_{t_3} G(1)}{k_t}. \tag{15}$$

Eqn. (11) yields

$$P_r = k_{t_3} \int_0^t MR_{r-1}\,dt_1. \tag{16}$$

Substitution of the expression for R_r from Eqn. (14) and of M from Eqn. (15) in Eqn. (11) gives the required distribution $P = f(r)$.

The formulae for the calculation of the MWD by the method of generating functions in the given case for other radical polymerisation mechanisms are not as cumbersome as might have been expected when the Bodenstein–Semenov hypothesis is abandoned. The introduction of generating functions made it possible to replace an infinite system of differential equations (9) and (10) in terms of

ordinary derivatives by a single first-order differential equation (12), also in terms of ordinary derivatives. This considerable advantage of the method led to its wide scale employment in studies of the mathematical simulation of radical polymerisation[20,22-24].

The principal statistical characteristics of the distribution—its moments—frequently permit more clear-cut inferences about the form of the distribution than does the knowledge of the analytical expression for the MWD and their calculation is much easier than the calculation of the MWD itself. The relation between the moments of the distribution and the generating function for $s = 1$ in the following way:

$$\mathcal{M}_1 = \sum_r rP_r = \frac{dG}{ds}\Big|_{s=1},$$

$$\mathcal{M}_2 = \sum_r r^2P_r = \mathcal{M}_1 + \frac{d^2G}{ds^2}\Big|_{s=1}.$$

The application of the method of generating functions yields compact analytical expressions for the number-average (μ_1) and weight average (μ_2) molecular weights of the polymers. Suppose that

$$G(s) = \sum_n s^n R_n,$$

$$H(s) = \sum_n s^n P_n$$

are the generating functions of the concentration of free radicals and the polymer. Consider a function $F(s) = G(s) + H(s)$. The number-average and weight-average molecular weights can then be expressed as follows in terms of the derivative functions $F(s)$:

$$\mu_1 = \frac{\sum_n nR_n + \sum_n nP_n}{\sum_n R_n + \sum_n P_n} = \frac{d \ln F(1)}{ds},$$

$$\mu_2 = \frac{\sum_n n^2R_n + \sum_n n^2P_n}{\sum_n nR_n + \sum_n nP_n} = 1 + \frac{d^2F(1)}{ds^2} \Big/ \frac{dF(1)}{ds}.$$

Higher-order moments can be calculated by a similar use of the derivative functions $F(s)$. The function $F(s)$ is found as the solution of a system of equations set up for any reactor (individual or in a reactor cascade) using the technique of generating functions.

IV. THE CONTINUOUS VARIABLE METHOD

The application of the method of generating functions to the calculation of the MWD or a finite number of its moments is limited to the region where the assumption of the invariance of the chain propagation and termination rate constants holds regardless of the length of the molecular chain. The principle of the independence of the reactivity of the terminal or any other group of the polymer molecule of its length does not hold in many instances, for example, in polymerisation in highly dilute solutions.

The continuous variable method makes it possible to calculate the MWD without adopting the drastic simplifying assumption that the rate constants for the elementary reactions are independent of the molecular chain length. The principal idea of the method involves the approximate representation of the mathematical problem with an infinite number of discrete variables by a continuous problem. An attempt at such an approximation would be natural for any mathematical system involving an infinite number of discrete variables. These considerations enabled Zeman and Amundson[25-27] and Thiele et al.[28] to treat the concentration of polymer molecules with a length P_r in the calculation of the MWD not as a function of a discrete variable r but as a function of a continuous variable $P(r)$. From the physical standpoint, this is a very satisfactory approximation, since the change in length by unity can be regarded as fairly small for fairly long chains.

The continuous variable method will be demonstrated in relation to the calculation of the MWD in radical polymerisation[25], where the reaction is carried out in a continuous-operation reactor via the following kinetic mechanism (Table 1).

$$k_f = k_{s_1} = 0, \quad k_{t_1} = k_{t_2} = k_{t_4} = 0, \quad w_i = k_i M.$$

We shall abandon the hypothesis that the rate constants for the chain propagation and termination reactions are independent of chain length. In this case the equations for the stationary state are

$$M_0 - M\left[1 + k_t\theta + \theta\sum_r k_{p_r}R_r + \theta\sum_r k_{t_r}R_r\right] = 0, \tag{17}$$

$$-R_1[1 + \theta k_{p_1}M + \theta k_{t_1}M] + \theta k_i M = 0, \tag{18}$$

$$-R + k_t\theta M - \theta M\sum_r k_{t_r}R_r = 0, \tag{19}$$

$$-P_r + k_{t_{r-1}}\theta M R_{r-1} = 0, \tag{20}$$

$$-R_r + \theta M(k_{p_r}R_r - k_{p_{r-1}}R_{r-1}) - \theta M k_{t_r}R_r = 0,$$
$$r = 2, 3, \ldots \infty. \tag{21}$$

We shall use the fundamental relations of the continuous variable method:

(a) Suppose that the propagation and termination rate constants are known functions of chain length: $k_p = k_p(r)$ and $k_t = k_t(r)$;

(b) A relation between the continuous variable $R(r)$ and a function of the discrete variable R_r is established with the aid of the Euler–Maclaurin formula[29]:

$$R = \sum_r R_r = \int_1^\infty R(r)\,dr + \frac{R(1) + R(\infty)}{2},$$

where $R(1) = R_1$ by definition and $R(\infty) = 0$ from physical considerations; there is a zero probability of the appearance of a concentration of a polymer with an infinite chain length;

(c) The expansion of $R(r-1)$ in Taylor's series, neglecting terms with orders of smallness higher than the first, yields correspondingly

$$R(r-1) = R(r) - \frac{dR(r)}{dr}.$$

After changing to a continuous variable, the system of Eqns. (17)–(21) becomes

$$M_0 - M\left[1 + k_t\theta + \theta\int_1^\infty k_p(r)R(r)\,dr + \theta\int_1^\infty k_t(r)R(r)\,dr + \right.$$
$$\left. + \frac{\theta}{2}[k_p(1) + k_t(1)]R(1)\right] = 0, \tag{17'}$$

$$R(1) = \frac{k_i\theta M}{1 + \theta[k_p(1) + k_t(1)]M}, \tag{18'}$$

$$R = k_i\theta M - \theta M\int_1^\infty k_t(r)R(r)\,dr - \frac{1}{2}\theta k_{t_1}MR(1), \tag{19'}$$

$$P(r) = \theta k_t (r-1)\, MR(r-1), \qquad (20')$$

$$\frac{\mathrm{d}}{\mathrm{d}t}[k_p(r)\,R(r)] + \frac{1+\theta M k_t(r)}{\theta M} R(r) = 0, \quad r \geqslant 2. \qquad (21')$$

Eqn. (21′) can be integrated after obtaining an expression for the distribution of active radicals:

$$R(r) = \frac{k_{p_1}}{k_p(r)} R(1) \exp\left(-\int_1^r \alpha(r)\,\mathrm{d}r\right); \quad r \geqslant 1, \qquad (22)$$

where $\alpha(r) = [1 + \theta k_t(r)M]/\theta M k_p(r)$ and $R(1)$ is defined by Eqn. (18′). After substituting Eqn. (22) in Eqn. (20′), we obtain an expression for the distribution of polymer molecules with respect to chain length:

$$P(r) = \theta M R(1)\, k_{p_1} \frac{k_t(r-1)}{k_p(r-1)} \exp\left[-\int_1^{r-1} \alpha(r)\,\mathrm{d}r\right]; \quad r \geqslant 2\,. \qquad (23)$$

In order to calculate the distribution by Eqn. (23), it is first necessary to find M. For this, one must substitute $R(1)$ from Eqn. (18′) and $R(r)$ from Eqn. (22) in Eqn. (17′) and the resulting expression must then be solved for M. In the given calculation of the MWD one must postulate that the chain propagation and termination rate constants depend on the chain length instead of the assumption that the reactivity of the radicals is constant, which was abandoned at an earlier stage. A linear relation between the activation energies for elementary chain propagation and termination reactions and chain length was adopted[26]. A relation has been proposed[14] between the chain propagation rate constant and the molecular weight of the polymer molecule.

A simple case, where the chain propagation and termination rate constants are independent of chain length, follows from Eqns. (17′)–(21′). Eqns. (17′)–(21′) can then be written as follows:

$$M_0 - M[1 + k_i\theta + \theta(k_p + k_t)R] = 0, \qquad (17'')$$

$$R(1) = \frac{\theta k_i M}{1 + \theta(k_t + k_p)M}, \qquad (18'')$$

$$P(r) = \theta k_t M R(1) \exp[-\alpha(r-2)], \qquad (19'')$$

$$R = \frac{\theta k_i M}{1 + \theta k_t M}, \qquad (20'')$$

$$R(r) = R(1)\exp[-\alpha(r-1)], \quad \alpha = [1 + \theta k_t M]/\theta k_p M. \qquad (21'')$$

Hence we find the distribution of the active radicals and polymer molecules:

$$R(r) = R(1)\exp[-\alpha(r-1)], \qquad (22'')$$

$$P(r) = \theta k_t R(1)\exp[-\alpha(r-2)]. \qquad (23'')$$

The use of the continuous variable method for a periodic-operation reactor will be demonstrated by the following example: suppose that chain termination takes place only via the monomer, i.e. in Table 1 $k_{t_1} = k_{t_2} = k_{t_4} = 0$, there is no chain transfer reaction ($k_f = k_{f_S} = 0$), and the rate constants for the elementary reactions are invariant. The rate equations for the variation of the concentrations of the active polymer radicals assume the following form in the case under consideration:

$$\frac{\mathrm{d}R_r}{\mathrm{d}t} = -k_p M(R_r - R_{r-1}) - k_t M R_r; \quad R_r(0) = 0; \quad r = 2, 3, \ldots \infty. \qquad (24)$$

On changing to a continuous variable, this infinite system of differential equations with ordinary derivatives can be transformed into a single equation in terms of partial derivatives:

$$\frac{\partial R(r,t)}{\partial t} = -k_p M \frac{\partial R(r,t)}{\partial r} - k_t M R(r,t); \quad R(r,0) = 0; \quad R(1,t) = R_1(t); \quad r \geqslant 2. \qquad (25)$$

Similarly the infinite system of differential equations in terms of ordinary derivatives, which describes the rate of change of the concentrations of inactive molecules,

$$\frac{\mathrm{d}P_r}{\mathrm{d}t} = k_t M R_{r-1}, \quad P_r(0) = 0; \quad r = 2, 3, \ldots \infty \qquad (26)$$

is transformed, within the framework of the continuous variable method, into a single partial differential equation:

$$\frac{\partial P(r,t)}{\partial t} = k_t M R(r,t), \quad P(r,0) = 0; \quad r \geqslant 2. \qquad (27)$$

Thus, with the aid of the continuous variable method, the infinite system of algebraic material balance equations for a continuous-operation reactor can be reduced to a single differential equation and the infinite system of differential equations describing the non-stationary state of the polymerising system in a periodic-operation reactor is reduced to several partial differential equations.

V. POLYMERISATION AT HIGH CONVERSIONS

The mathematical methods for the calculation of the MWD examined above are applicable mainly to radical polymerisation processes occurring up to low degrees of conversion of the monomer. At high conversions the analytical relations for the rate of polymerisation, obtained by considering the classical kinetic mechanism, lead to appreciable discrepancies with experiment: virtually none of the mechanisms reproduces the experimental dependence of the rate of polymerisation of styrene on the degree of conversion obtained by one of the present authors and his coworkers[37]. The majority of polymerisation processes, particularly industrial processes, are continued up to high degrees of conversion. At high conversions the rate constants for the elementary reactions can no longer be regarded as constant[6,26,38]. An increase of the viscosity of the reaction medium during polymerisation is known to have a major influence on the rate of the chain termination reaction; however, there is no doubt about the influence of this factor also on the rates of other elementary reactions.

The form of the distribution function associated with the changes in these constants varies with the degree of conversion. At high conversions another simplification postulating that the radical concentrations are quasi-stationary, does not hold either. The point is that at high conversion one should expect a considerable increase of the lifetime of polymer radicals and hence also of their concentration, since radicals become relatively immobile in a highly viscous medium and cannot be destroyed as a result of interactions. The adoption of the Bodenstein–Semenov hypothesis would lead to an appreciable error in this instance. The above factors greatly complicate the kinetic calculation of the MWD at high conversions. On the other hand, polymerisation processes continued up to high degrees of conversion of the monomer are in fact of practical interest for the solution of many problems in the industrial application of the process: in the selection of a

technological scheme and type of reactor and in the calculation of the optimum technological conditions.

Isolated studies concerned with quantitative descriptions of radical polymerisation at high conversions have been carried out recently. One of the methods for the theoretical calculation of the MWD in radical polymerisation at high conversions has been proposed by Graessley et al.[39] It is based on the recognition and allowance for an important factor—the dependence of the rate constants for the elementary reactions on the degree of conversion. In order to simplify the problem, the author disregarded the remaining factors. A parameter, defined as the average number of units contained in the growing chain from the instant of its formation in the initiation of radicals up to deactivation on chain transfer or termination, was introduced:

$$\lambda = \frac{w_p}{w_f + w_{fS} + w_{t_1} + w_{t_2} + w_{t_3} + w_{t_4}}.$$

Since the rate constants for the elementary reactions vary with the degree of conversion, the parameter λ reflects these changes: $\lambda = \lambda(C)$, where C is the degree of conversion of the monomer. This exhausts the kinetic approach and the author[39] turns to a purely statistical treatment. In particular, he assumes that the growing molecules obey an exponential distribution law with respect to lengths:

$$f_r(C) = \frac{1}{\lambda} \exp\left(-\frac{r}{\lambda}\right).$$

In polymerisation in a periodic-operation reactor the total number of chains formed for an increment in the degree of conversion ΔC is proportional to $\Delta C/\lambda(C)$. Then the fraction of molecules with a chain length r, present for a degree of conversion C, is

$$F_r(C) = \int_0^C f_r(\xi) \frac{\mathrm{d}\xi}{\lambda(\xi)} \Big/ \int_0^C \frac{\mathrm{d}\xi}{\lambda(\xi)}.$$

Thus the characteristics of the polymerisation are taken into account exclusively by the parameter λ. The proposed method employs to a significant extent fairly drastic simplifications, which to some extent obliterate the characteristic features of polymerisation at high conversions. The influence of disregarded factors is in no way smaller than the variation of the rate constants for the elementary reactions with the degree of conversion, which has been taken into account.

An interesting approach to a quantitative description of polymerisation has been proposed[40]. Assuming that all the characteristics of the thermally initiated polymerisation of styrene in bulk which lead to discrepancies between theory and experiment at high conversions can be accounted for by changes in the rate constants for the elementary reactions, the constants are calculated on a computer by means of the following equations:

$$w(k_i, k_t, k_p) = w^{\mathrm{emp}}(C, T), \quad (28)$$

$$P_N(k_i, k_t, k_p, k_f) = P_N^{\mathrm{emp}}(T), \quad (29)$$

where $w(k_i, k_t, k_p)$ and $P_N(k_i, k_t, k_p, k_f)$, the theoretical expressions for the rate of reaction and the number-average degree of polymerisation as a function of the rate constants for the elementary reactions, are set equal to the simpler equivalent empirical expressions $w^{\mathrm{emp}}(C, T)$ and $P_N^{\mathrm{emp}}(T)$. An expression from the paper of Gleizer et al.[37] was adopted as the empirical equation for the rate of reaction $w(C, T)$:

$$w(C, T) = k_0 \exp[-E/RT] f(C), \quad (30)$$

where C is the degree of conversion and $f(C)$ an empirical function; the following expression is fitted to the experimental relation $P_N(T)$:

$$P_N(T) = a_N \exp[b_N/T]. \quad (31)$$

The rate constants for the elementary reactions obtained from Eqns. (28) and (29) are introduced into the theoretical equations for all the required MWD moments.

The above approach is analogous to the earlier method[41] for the solution of the converse problem involving the determination of the elementary rate constants as a function of temperature and the degree of conversion by minimising the Bayes factor[42]. The mathematical model of the MWD of the polymer obtained in the thermally initiated polymerisation of styrene was based on the kinetic mechanism for radical polymerisation with chain transfer to the monomer and the adduct, chain termination by recombination, and two different initiation mechanisms (with second and third orders with respect to the monomer). Equations for the rates of variation of the concentration of the active and inactive radicals and the monomer were set up in the traditional manner for the case under consideration. With the aid of the method of generating functions, the infinite system of ordinary differential equations in terms of the rate of variation of the concentration of polymer radicals (active and inactive) was converted into two ordinary differential equations in terms of generating functions of the concentrations of free radicals $[G(s)]$ and the polymer $[H(s)]$. Analytical expressions for the number-average and weight-average molecular weights can be obtained from these equations as a function of the rate constants for the elementary reactions. Empirical formulae relating the latter to the degree of conversion have been proposed. In the determination of the unknown coefficients in these formulae the authors[41] used one of the identification algorithms[42], which was executed using the experimental points representing the changes in the degree of conversion and in the number-average and weight-average molecular weights with time under isothermal conditions.

The essential feature of the method is that one has to find m unknown parameters θ_n ($n = 1, 2, \ldots, m$) from n observed values of Y_{iu} ($i = 1, 2, \ldots, k$; $u = 1, 2, \ldots, n$) (i.e. from n measured degrees of conversion and number-average and viscosity-average molecular weights) of the function $f_i(X_{iu}^g, \theta_n)$, the form of which is known:

$$Y_{iu} = f_i(X_{iu}^g, \theta_n) + \varepsilon_{iu},$$

where X_{iu}^g (with $i = 1, 2, \ldots, k$; $u = 1, 2, \ldots, n$; $g = 1, 2, \ldots, r$) represents r variables corresponding to n observations for each ith constituent vector-function and ϵ_{iu} is the error of the observation.

The relations obtained for the rate constants, which take into account all the characteristics of the polymerisation at high conversions, enabled the authors[41] to carry out a theoretical computer calculation of the MWD of polystyrene obtained in thermally initiated polymerisation. Fig. 4 reveals a fairly satisfactory agreement between the theoretical and experimental MWD curves. Table 3 shows that the fundamental experimental and calculated MWD parameters also proved to be fairly close. The mathematical model for the MWD of a polymer obtained by radical polymerisation (continued up to virtually complete

conversion of the monomer), proposed in the study under consideration, is of undoubted interest for the planning and optimisation of industrial polymerisation processes.

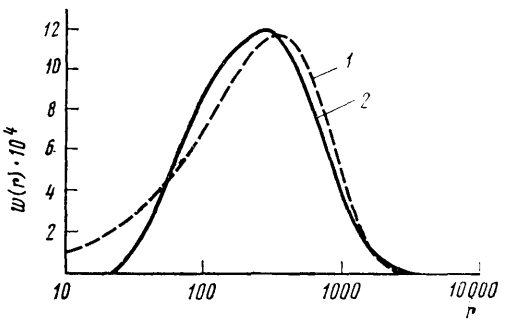

Figure 4. Comparison of the MWD obtained for a high degree of conversion of the monomer under isothermal conditions[41]: 1) calculated; 2) experimental.

Table 3. Comparison of the calculated and experimental MWD parameters at high conversion (X_{calc} = 95.1%, X_{exp} = 95.9%) on the basis of the data of Hui and Hamielec[41].

MWD parameter	Calculated value	Experimental value
M_n	35 000	35 500
M_w	70 600	71 200

VI. CALCULATION OF THE MOLECULAR WEIGHT DISTRIBUTION IN THE PRODUCTION OF HOMOPOLYMERS IN A CASCADE OF REACTORS

The study of the MWD at the output end of a cascade of polymerisation reactors merits particular attention, because a reactor cascade constitutes the most suitable technical means for carrying out polymerisation which permits a stepwise alteration of the temperature and concentration of the reactants, i.e. a stepwise alteration of the polymerisation conditions from the reactor to reactor.

For a cascade of Λ ideal mixing flow reactors, in which the polymerisation reaction takes place in accordance with the mechanism presented in Table 1 with $k_f = 0$ and $k_{t_2} = k_{t_4} = 0$, a system of algebraic equations defining the function $F(s) = G(s) + H(s)$ is set up by the generating function method:

$$M(n) = \frac{M(n-1) - \theta_n k_i(T_n) I_n}{1 + \theta_n \{[k_p(T_n) + k_f(T_n)] G(1, n) - k_f(T_n) R_1(n)\}}$$

$$R_1(n) = \frac{R_1(n-1) + \theta_n \{k_i(T_n) I_n + k_f(T_n) M(n) G(1, n)\} s}{1 + \theta_n \{M(n)[k_p(T_n) + k_f(T_n)] + k_i(T_n) G(1, n)\}}$$

$$G(s, n) = \frac{G(s, n-1) + \theta_n \{k_i(T_n) I_n + k_f(T_n) M(n) G(1, n)\} s}{1 + \theta_n \{M(n)[k_p(T_n)(1-s) + k_f(T_n)] + k_{t_1}(T_n) G(1, n)\}}$$

$$H(s, n) = H(s, n-1) + \theta_n \left\{\frac{k_{t_1}(T_n)}{2} G(s, t)^2 + k_f(T_n) M_n [G(s, n) - sR_1(n)]\right\}.$$

$$n = 1, 2, \ldots N.$$

The elimination of computational difficulties, associated with the calculation of the moments of the MWD function, with the aid of the derivative functions $F(s)$ (see Section III) makes it possible to formulate and solve the problem of the optimisation of ideal mixing polymerisation flow reactors taking into account the quality of the polymer obtained. Ray and coworkers[22,23] made the first attempt at the optimum design of the polymerisation process in a cascade of chemical reactors in order to obtain the required MWD parameters for the polymer. In this case the problem reduces to the determination of the optimum polymerisation conditions by an appropriate choice of the initiator concentration, temperature, and the residence time of the polymerising mass in the reaction system. A linear function of the standard of deviations of the principal MWD parameters and of the degree of conversion from the required values of the latter is adopted as a criterion which determines whether or not optimum conditions have been obtained:

$$f = (\mu_1 - \bar{\mu})^2 + \lambda_1 \left(\frac{\mu_2}{\mu_1} - \bar{S}\right)^2 + \lambda_2 (1 - C)^2,$$

where λ_1 and λ_2 are the weighting factors taking into account the relative importance of the polydispersity and the degree of conversion of the finished product and $\bar{\mu}$ and $\bar{S}$ are the required molecular weight and polydispersity coefficient respectively. The optimum conditions for the polymerisation process were calculated on a computer in relation to the polymerisation of styrene in one flow reactor or in a cascade of two reactors. The calculations were performed for different versions of the requirements imposed on the width of the MWD (for the minimum width of the MWD, $\bar{S} = 1$; for a wider distribution, $\bar{S} = 3$), the weighting factors of the components of the above criterion being varied by altering the ratio λ_1/λ_2. The calculations yielded the optimum values of the technological parameters ensuring the maximum degree of conversion and the minimum polydispersity of the polymer.

The continuous variable method has found extensive applications in calculations of the MWD in radical polymerisation processes in a cascade of reactors of different types. The MWD for polystyrene has been calculated[8] taking into account chain transfer to the monomer and chain termination by recombination in continuous-operation reactors. The authors[8] compared two methods for the theoretical calculation of the MWD and observed that the MWD curve calculated by the continuous variable method virtually coincides with the distribution curve calculated by the classical method. For the same initial conditions and the same average residence time, a comparison was made in the same study of the MWD for one-, two-, and three-cascade polymerisation processes. In the calculation of the MWD for the polymer in a reactor cascade the advantage of the continuous variable method over the classical method is particularly manifest; for a cascade of three isothermal reactors, the classical method is already unsuitable even when computers are used, whereas with the aid of the continuous variable method the computational difficulties can be fully overcome.

Calculations on the cascade method of industrial polymerisation with intermediate injection of the initiator can also be performed by the continuous variable method. The influence of various reaction conditions on the MWD of polystyrene has been calculated in relation to the initiated polymerisation of styrene[30]. The calculations showed that, by altering the process conditions (reaction temperature, residence time of the polymerising mass in the reactors, initial monomer concentration, and the

intermediate supply of the initiator, monomer, and solvent), it is possible to affect the MWD appreciably. Hence we believe that a natural step to take would involve optimum planning of the polymerisation process in order to obtain a finished product with specified properties, subject to the condition that the relation between the physicomechanical properties of the polymer and the MWD [31-36] is expressed in a mathematical form. Although exact correlations between the MWD and the physicomechanical properties of polymers have not as yet been established, there now exist many empirical and qualitative relations which can be used in the optimisation and planning of the industrial technological process under conditions where these properties depend on the MWD.

A combination of theoretical equations for the MWD parameters with empirical equations has been used[43-45] to describe the rate of an industrial polymerisation process in order to optimise the thermally ionised polymerisation of styrene in a continuous-operation apparatus consisting of N series-connected isothermal ideal mixing reactors and a reactor of the column type. The stationary state of thermally initiated block polymerisation of styrene was described, taking into account the non-ideality of the flow of the polymerising mass in the column, by a system of algebraic and differential equations. The mathematical description of the process is based on the representation of the rate of polymerisation by the product of two functions, one of which characterises the dependence of the rate on temperature and the other its dependence on the degree of conversion:

$$w(T, C) = w_0(T) f(C).$$

The term expressing the temperature dependence is described by the Arrhenius law

$$w_0(T) = k_0 \exp(-E/RT),$$

and $f(C)$ is specified by an empirical curve constructed on the basis of experimental data and showing how the rate of polymerisation decreases relative to the initial rate of polymerisation $w_0(T)$ at the same temperature as the degree of conversion increases.

Relations obtained on the basis of the definition of the number-average and weight-average molecular weights as the ratios of the corresponding moments of the MWD function have been proposed for the calculation of the principal characteristics of the MWD (see Section III). The presence of an empirical element in the proposed[43-45] mathematical model of the thermally initiated block polymerisation of styrene in a cascade of industrial reactors of different types deprives this approach of the generality characteristic of a purely theoretical calculation; however, the approach permitted a simple and effective solution of the specific problem of the optimum connection of reactors and of the search for the optimum operating conditions of an industrial polymerisation apparatus. Fig. 5 presents a diagram illustrating the technological conditions calculated using digital computers on the basis of algorithms and models developed by Gleizer and coworkers[37,43-45]. The region with the smallest polydispersity is located in the upper right-hand corner of the diagram. The optimum technological parameters selected from this region (the degree of conversion in the first reactor C_1, the temperature in the first reactor T_1, and the temperature in the second reactor T_2) ensure the minimum residence time of the polymerisation mass in the reactor cascade (τ) and the minimum polydispersity of the final polymer (μ_f) for fixed requirements to be met by the final degree of conversion of the finished product (C_f) and its viscosity-average molecular weight (M_f).

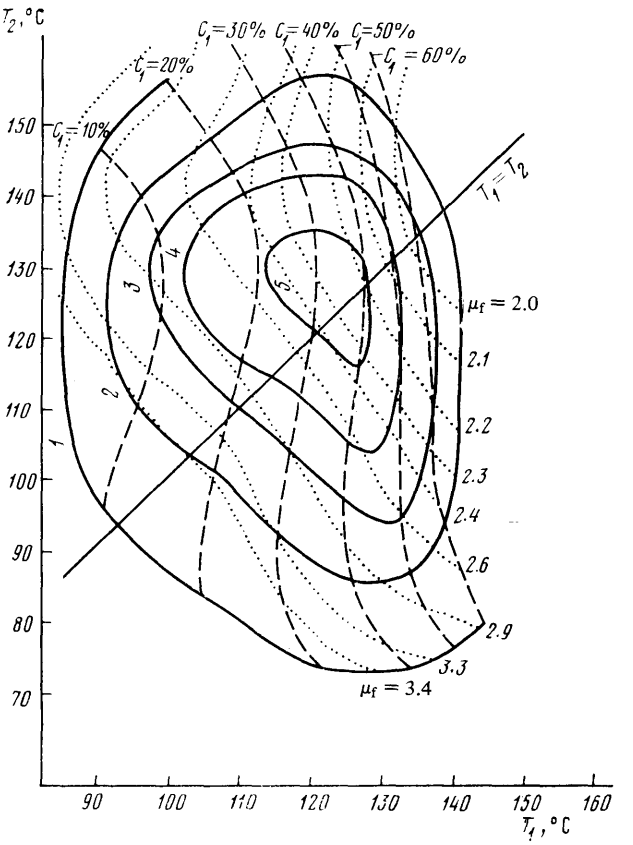

Figure 5. Diagram of technological conditions for the polymerisation of styrene in a cascade of reactors[45] (M_f = 350 000; C_f = 98%): overall residence time of the polymerising mass in the system $\Sigma\tau$ (hours): 1) 15; 2) 10; 3) 8; 4) 7; 5) 6.

Hitherto calculations have been made on polymerisation reactions which can occur both in an individual reactor and in a technological apparatus consisting of series-connected reactors. The type of reactors and the sequence in which the polymerising mass passes through them were assumed to be specified. However, in the development of a technological polymerisation process one of the problems is in fact the selection of the optimum polymerisation system. Evidently the type of reactors and the method of their connection have a significant influence on the degree of reaction of the initial monomer and the composition of the polymer produced. The study where an advance was made towards the next level of the investigation of polymerisation reactors on the basis of their kinetic models—the creation of a polymerisation system of reactors on the basis of a criterion whose optimisation ensures the best functioning of the system—is therefore of interest[24]. This problem must be solved using apparatus for the

polymerisation reaction comprising only one reactor. It is known that, for all reactions (including polymerisation reactions) whose order is positive, a higher degree of conversion of the initial product is attained in a periodic-operation reactor than in an ideal mixing flow reactor with the same reaction volume. The absence of the mixing of the reaction mixture with a fresh stream of the initial monomer in the periodic-operation reactor, of the kind that takes place in a flow reactor, makes the average rate of reaction in the latter always lower than in a periodic-operation reactor. However, in ideal mixing flow reactors processes at higher monomer concentrations take place more effectively. On the other hand, a narrower MWD is frequently obtained in a periodic-operation reactor than in a flow reactor (for example, when the lifetime of the active radical is comparable to the residence time in the reactor[7]).

Industrial polymerisation processes take place up to high conversions and it is desirable to investigate a narrow MWD. Taking into account the nature of the flow of the reaction mixture through the reactors, it is therefore important to arrange them in the following sequence: one or several continuous-operation reactors in the form of fore-polymerisers followed by a displacement reactor (or a periodic-operation reactor) which ensures a high degree of conversion of the monomer. However, even for a system consisting of only two reactors, one of which is of the flow type and the other is of the periodic-operation type, it is not easy to solve the problem of the redistribution of the stream between the reactors, the additional injection of reactants at intermediate stages, and the recycling of part of the stream. Examination of these features from the standpoint of their influence on the degree of conversion and the MWD requires calculations on numerous versions using mathematical models of polymerisation reactors. The addition to a single flow reactor of a further series-connected device, which leads to a higher degree of conversion of the initial monomer, increases sharply the number of versions for which calculations must be made in order to select the optimum conditions. The problem arises of the development of computer algorithms which permit calculations, on the basis of mathematical models of polymerisation reactors, for different versions of the schemes for their connection and a choice of one of them in terms of a criterion.

The scalar function

$$\mathcal{K} = \alpha_1 M + \alpha_2 (\sigma - \bar{\sigma})^2 + \alpha_3 (\Delta - \bar{\Delta})^2,$$

where M is the monomer concentration at the outlet from the polymerisation system, $\bar{\sigma}$ and $\bar{\Delta}$ are the specified degree of dispersion and the mathematical expectation of the MWD function, and α_i (where $i = 1, 2, 3$) are weighting factors, has been proposed as a criterion[24]. The minimisation of the function $\mathcal{K}(M, \sigma, \Delta)$ ensures the attainment of the maximum degree of conversion of the monomer and the minimum deviation of the zeroth, first, and second moments of the MWD from their specified values at the outlet from the system.

We shall now analyse the procedure for the selection of the optimum system of reactors from the multiplicity of permissible systems on the basis of the criterion proposed[24]. For a more detailed analysis of the existing versions and the elucidation of ways of applying the proposed methods, we shall consider initially a technological scheme comprising two series-connected reactors: an ideal mixing flow reactor (FR) and a periodic-operation reactor (POR). We shall consider all possible ways of connecting the FR and the POR for a fixed overall reaction volume of the system. They give rise to a multiplicity of structures of the reaction system and the optimum structure is in this case selected as follows. In the first place, for each stream mixing point, material balance equations with respect to the initiator and the monomer and the equations for the calculation of the MWD moments at the stream merging points from the moments in each of the streams being mixed are set up.

In order to calculate the moments, one sets up with the aid of the generating function method a kinetic model of the initiated radical polymerisation taking into account the chain propagation reaction and chain termination by recombination. The kinetic equations supplemented by stream material balance equations form a universal mathematical model describing various structures of the reaction system. With the recirculation coefficients varied from 0 to 1 (which thus leads to a selection of various structural versions of the reaction system), this model permits computer calculations of all possible structural versions for different requirements to be met by the resulting polymer (by fixing a set of weighting factors for the optimum conditions criterion).

On the basis of these calculations, the structural features of the given reaction system are established. In the first place, it was found that the recirculation of a large proportion of the stream is undesirable, since it leads to an appreciable increase of the target function. The recirculation of very small proportions of the streams in the organisation of the reaction system must be ruled out in view of their insignificant influence on the process, which is expressed by the virtually unchanged values of all the components of the target function. The recirculation of the stream both from the outlet of the FR and from the outlet of the POR to the inlet of the FR is undesirable, since it leads to an increase of the target function owing to the increase of the monomer concentration at the outlet from the system due to the decrease of the overall residence time of the polymerising mass in both reactors. The deviation of the variance and of the mathematical expectation of the MWD function from the specified values then decreases only slightly owing to the mixing of the molecules, emerging from the outlet during the process, with the incoming molecules (the former thus acquire some, albeit small, capacity for growth).

An optimum structural version has been proposed for the polymerisation system under consideration: series-connection of the FR and POR, which are bypassed by a fraction of the streams (0.336 and 0.704 respectively) and in which the ratio of the POR and FR volumes is 0.294. The influence of the changes in the rate constants for the elementary reactions on the polymerisation process has been analysed for the optimum system obtained. A study was also made of the influence of the temperature conditions on the given polymerisation process in this system. For this purpose, the POR was subdivided into two temperature zones. The consequent increase of the target function is associated with the improvement of the MWD parameters.

The methods for the investigation of processes involved in the production of homopolymers, which were considered here on the basis of a mathematical description of the MWD, give rise to considerable possibilities for the analytical development (with the aid of computers) of new polymerisation processes, the theory of calculations on chemical reactors and of the mathematical simulation of the MWD being related to the technological apparatus for the polymerisation processes.

Activators of the Anionic Polymerisation of Lactams

T.M.Frunze, V.V.Kurashev, V.A.Kotel'nikov, and T.V.Volkova

The influence of the structure of activators on the anionic polymerisation of lactams is examined and a classification of activators taking into account the chemical nature of the active centres formed and the side products is proposed. An approach to the specific selection of activating compounds for the regulation of the rate of polymerisation is described and the possibility, in principle, of employing activators with different functionalities for varying the structure and properties of the resulting polyamides is demonstrated. Data are presented on the modification of polyamides using macromolecular activators of the anionic polymerisation of lactams.
The bibliography includes 210 references.

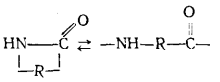
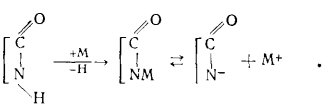
I. INTRODUCTION



Among the industrial methods for the synthesis of polyamides, the polymerisation of lactams occupies a notable place. Thus, one of the most important and widely used examples of the class of polyamides, namely polycaproamide, is obtained on an industrial scale mainly by the hydrolytic polymerisation of ϵ-caprolactam.

When the activating influence of imides, the so-called activators, on the anionic polymerisation of lactams was established, the polymerisation of cyclic amides became even more important. The use of activators in the anionic polymerisation of lactams led to the development of a virtually new method for the synthesis of polyamides and articles made from them—by activated anionic polymerisation. By greatly reducing the energy expenditure, this method makes it possible to obtain articles by chemical moulding involving a "monomer–finished article" procedure. In view of the absence of the processing stage, a unique possibility is created for the formation of large articles of various configurations.

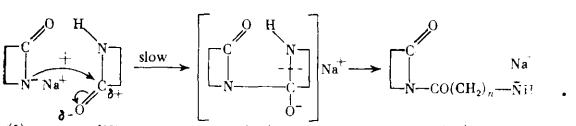
Numerous papers devoted to activating systems in the anionic polymerisation of lactams have been published. The aim of the present review is to give a systematic count of accumulated data, to examine the influence of the chemical structure of compounds of different types on their activating capacity in the anionic polymerisation of lactams, and to consider the possibility of using activators for the regulation of the molecular structure of the polyamides formed.



II. THE POLYMERISATION MECHANISM

The capacity of lactams of different structures for polymerisation is determined by thermodynamic and kinetic factors. It has now been established that the opening of the amide ring at the heterobond

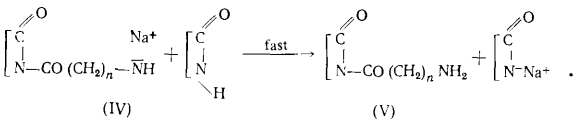
is a thermodynamically favourable process for virtually all the known unsubstituted lactams, although the position of the thermodynamic equilibrium for each monomer depends on its chemical structure [1]. The possibility of obtaining a high-molecular-weight polymer is determined not only by the thermodynamic but also by the kinetic stability of the ring, i.e. its reactivity. The latter depends on a whole series of factors, among which the following may be mentioned: the resonance stabilisation of the amide linkage within the lactam ring, the conformation of the macromolecules (the presence of *cis*- and *trans*-isomers), the possibility of the formation of intermolecular hydrogen bonds, and the basicity of the monomer [1-5]. In addition, the kinetics of the overall polymerisation process depend to a large extent on the nature of the catalytic system used.



Being weak bases, lactams form salts when they interact with alkali metals, alkali metal and alkaline earth metal hydrides and amides, and organometallic compounds:

The anions formed on dissociation of salts catalyse the polymerisation of lactams.

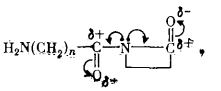
The following mechanism of the anionic polymerisation of lactams can now be regarded as established [5-15]:



(a) The nucleophilic attack by the anion of lactam (I) on the carbonyl carbon atom of the monomer (II) results in the formation of the intermediate carbinolate anion (III), which is stabilised when the ring is opened with formation of the N-anion (IV)

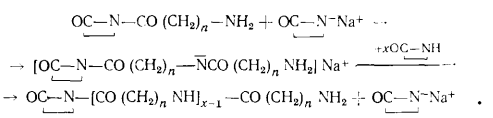
(I) (II) (III) (IV)

(b) In contrast to the lactam anion, the anion of a primary amine is not stabilised. The N-anion (IV) is therefore highly reactive and rapidly reacts with the monomer, abstracting a proton from the latter. The driving force of this reaction is the appreciable difference



between the acidities of the amino- and amido-groups:

(IV) (V)

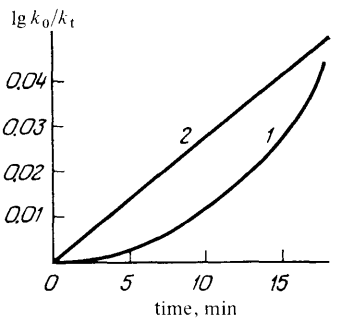


The imide dimer (V) (an *N*-substituted acyl-lactam) formed activates the propagation of the macromolecular chain.

The presence of two carbonyl groups linked to the nitrogen atom in the imide structure leads to a decrease of the resonance stabilisation of the amide linkage within the lactam ring (imide mesomerism):

which promotes an appreciable increase of the activity of the carbonyl group of the cyclic amide in relation to the nucleophilic lactam anion.

(c) Chain propagation is a reaction between the imide molecule and the lactam anion followed by a rapid proton exchange with the monomer, the anion and the terminal imide group of the growing polymer chain being regenerated in each addition step:



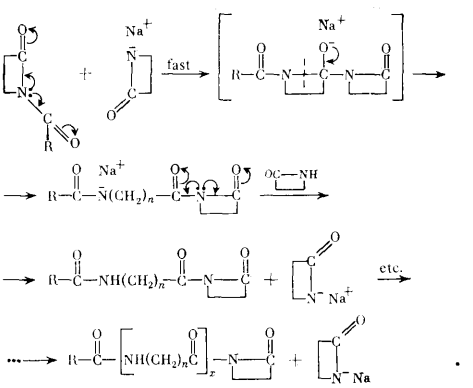


Figure 1. The rate of the anionic polymerisation of ε-caprolactam at 192.6°C in the presence of various additives: 1) 0.5 mole % of the sodium salt of ε-caprolactam; 2) 0.5 mole % of the sodium salt of ε-caprolactam and 0.5 mole % of tetra-acetylhexamethylenediamine[16].

The polymerisation of lactams in the presence of alkaline catalysts takes place with an appreciable induction period[16] (Fig. 1, curve *1*).

Presumably this is associated with the high activation energy for the formation of reactive compounds having the imide structure and the introduction of such compounds into the reaction system should activate the polymerisation process. This hypothesis has been confirmed by Ney and Grouther[17] and then by Šebenda and Kraličeк[16,18], who showed that the use as activators of acyl-lactams, acid chlorides, ethers, and esters, i.e. compounds containing the imide structure or capable of forming it on interaction with the lactam or its anion, eliminates the induction period and increases appreciably the rate of polymerisation of lactams (Fig. 1, curve *2*).

Thus, in the activated anionic polymerisation of lactams, the initial slow stage involving the nucleophilic addition of the lactam anion to the cyclic amide molecule is eliminated. In this case polymerisation begins immediately with rapid interaction of the activator molecules with the lactam anion, which is followed by the same intermediate reactions as in the non-activated polymerisation:

The scheme presented shows that the activated anionic polymerisation of lactams takes place as nucleophilic polyaddition of the lactam anion to the endocyclic carbonyl carbon atom of the imide, formed at the end of the growing macromolecule. One of the characteristic features of the anionic polymerisation of lactams is the absence of the elementary chain termination step. Theoretically, the stepwise addition of the lactam anion to the terminal imide group of the growing macromolecule can continue until the monomer is completely exhausted. However, as in polycondensation processes, this does not occur because of the influence of a number of physical and chemical factors, which include the following: the increase of the viscosity of the reaction medium, the attainment of equilibrium in the monomer–polymer system, and the decrease of catalytic activity. The change in the catalytic activity of the system during the anionic polymerisation of lactams is associated with numerous side reactions, which have been examined in detail in the excellent review by Šebenda[7].

III. CLASSIFICATION OF ACTIVATORS

It follows from the mechanism of the activated anionic polymerisation of cyclic amides examined above that the process activators are compounds having the general formula (I).

where X is an electron-accepting substituent. Evidently the activating capacity of compounds of this type will depend on the nature of the substituent at the nitrogen atom. Table 1 presents an estimate of the electrophilic properties of the substituents X capable of polarising the amide linkage within the ring. In analysing the data in Table 1, one should note that electron-accepting substituents function as a result of the presence of a positive charge on the key atom (Nos. 1 and 2) or in consequence of negative mesomeric and inductive effects (Nos. 3–9). When the

substituents are halogens (Nos. 10–13) or halogenoalkyl groups (No. 14), the strong $-I$ effect is partly compensated by a weak $+M$ effect. The combination of the two effects is reflected by the characteristic numerical Hammett (σ_n^*) and Taft (σ^*) constants.

Table 1. Estimated electrophilic properties of the substituents.

No.	Substituent R	Electronic formula	Conjugation effect	Dipole moment of C_6H_5R (Ref. 19)	σ_n^* substituent in aliphatic compound (Ref. 20)	σ_n (substituent in benzene ring) (Ref. 20)
1	$N(CH_3)_3$		$-I$; $-M$; $(+I_{CH_3})$	—	+0.859	1.90
2	NO_2		$-I$; $-M$	−4.03	+0.778	1.40
3	SO_2CH_3		$-I$; $-M$; $(+I_{CH_3})$	−4.44	+0.728	1.32
4	CN		$-I$; $-M$	−3.94	+0.628	1.30
5	$COCH_3$		$-I$; $-M$	−2.93	+0.516	0.60
6	$CO_2C_2H_5$		$-I$; $-M$; $(+I_{C_2H_5})$	−1.91	+0.522	0.71
7	COOH		$-I$; $-M$	—	+0.265	—
8	CHO		$-I$; $-M$	−2.75	+0.216	—
9	C_6H_5		$-I$; $-M$	—	+0.009	0.215
10	F		$-I$; $+M$	−1.57	+0.062	1.10
11	Cl		$-I$; $+M$	−1.57	+0.227	1.05
12	Br		$-I$; $+M$	−1.55	+0.232	1.00
13	I		$-I$; $+M$	−1.38	+0.276	0.85
14	CF_2		$-I$; $+M$	—	0.551	0.92

When the dipole moments are compared with the Hammett and Taft constants, one is bound to note a general tendency for all the electrophilic substituents listed in Table 1: an increase of the dipole moment corresponds to an increase of the constants σ_n^* and σ^*. The fact that, despite its large negative I effect, fluorine leads to a smaller value of σ_n^* than chlorine can be accounted for by its powerful $+M$ effect owing to conjugation with the benzene ring. The outer $2p$ orbitals of elements in the first Periods of the Periodic System are known[19] to be of approximately the same size as the π orbitals of double-bonded carbon. This leads to a more effective overlap of the orbitals than for heavier substituents (Cl, Br, and I).

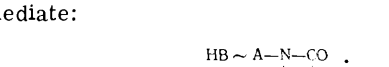
It must be emphasised that the characteristics used to estimate the electrophilicity of substituents refer to substitution in aromatic and aliphatic series. However, the above tendency towards a change in the electrophilic properties of the substituents evidently persists also in the series of *N*-substituted lactams. Thus, it can be assumed

 (I)

that the whole series of compounds having the general formula (I) containing stronger electrophiles as *N*-substituents (Nos. 1–4 and 14) than the acyl group (No. 5), are effective, from the electronic standpoint, centres for the growth of macromolecules in the anionic polymerisation of lactams.

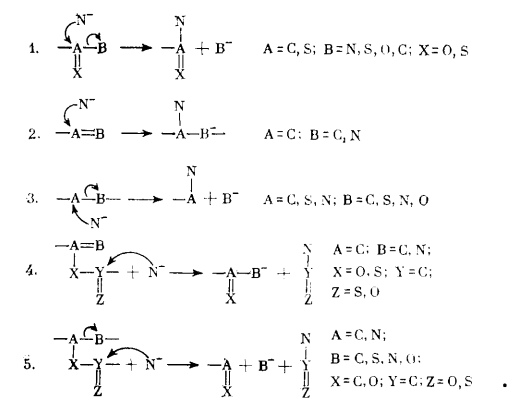
A wide series of both organic and inorganic compounds have been suggested as activators of the anionic polymerisation of lactams (see Table 2 below). Several attempts have been made at a classification of the activating compounds[6,21,22]. The influence of the geometrical and electronic structures of the above compounds on their activating capacity has been examined[8,22] and it has been suggested that activators be divided, on the basis of the nature of their action under the conditions of the anionic polymerisation of lactams, into "direct" activators, with an intrinsic activating capacity, and "indirect" activators, which interact with the lactam or its salt and form the activator.

According to Ikuzo et al.[22], activating compounds of the type A ~ B, where A and B are effective centres of the activator molecule, must meet the following requirements:



(1) A must be sufficiently electrophilic to combine with the lactam anion:

(2) The basicity of B must be sufficiently large to combine with a hydrogen atom linked to the nitrogen of the lactam molecule and thus regenerate the lactam anion:



(3) A must assist in the cleavage of the C–N bond in the intermediate:

(4) The structure of A must be sterically favourable for attack by the lactam anion.

Compounds satisfying the above requirements have been divided into five types in accordance with their structure and the types of reactions leading to their formation[22]. The active centres of these compounds are shown schematically below:

The structures of many of the known types of activators (ethers and esters, *N*-alkylimides, lactaones, etc.) fit within the framework of the above requirements. In addition, Ikuzo et al.[22] tested the activating capacities of a number of other compounds, in particular a wide variety of triazine and pyridazine derivatives, azlactone derivatives, and other similar compounds. With some exceptions, the above compounds proved to be active under the conditions of the anionic polymerisation of lactams. On

Table 2. Classification of activating compounds.

No.	Class of compounds	Refs.	Suggested activation mechanism
1	(a) imides, carbamoyl-lactams, acyl-lactams	23—41	
	(b) isocyanates, isothiocyanates	42—49	$R-N=C=O+\bar{N}-CO \rightarrow R\bar{N}-CO-N-CO$
2	(a) carboxylic acid anhydrides and halides	50—58	$R-COX+\bar{N}-CO \rightarrow RCO-N-CO+\bar{X}$
	(b) halogenated linear and cyclic alkanones	59	$Cl-C-CO-C-Cl+\bar{N}-CO \rightarrow ClCCOC-N-CO+Cl^-$
	(c) organic peroxides	60	$Ar-COOOCO-Ar+\bar{N}-CO \rightarrow ArCOO-N-CO+\bar{O}CO-Ar$
3	(a) organic and inorganic acid esters	17, 60—80	$R-COO-R_1+\bar{N}-CO \rightarrow R-CO-N-CO+\bar{O}R_1$
	(b) lactones, thiolactones	81—90	$COO(CH_2)_n+\bar{N}-CO \rightarrow \bar{O}(CH_2)_n-CO-N-CO$
	(c) urethanes	91	$RNH-COOR_1+\bar{N}-CO \rightarrow RNHCO-N-CO+\bar{O}R_1$
4	(a) amides	92—99	$R-CONR_1R_2+\bar{N}-CO \rightarrow R-CO-N-CO+\bar{N}R_1R_2$
	(b) ureas, thioureas	100—103	$RNHCONHR+\bar{N}-CO \rightarrow RNHCO-N-CO+\bar{N}HR$
	(c) carbonylimidazoles	104, 105	$CH=CHN=CHNCOR+\bar{N}-CO \rightarrow RCO-N-CO+CH=CHN=CHN^-$
	(d) ketoamides	106—108	$RCORR_1R_2CONHR+\bar{N}-CO-\begin{cases}\rightarrow RCOCR_1R_2CO-N-CO+\bar{N}HR\\ \rightarrow RNHCO-N-CO+R_1R_2C=C(\bar{O})R\end{cases}$
	(e) diketones	109—112	$RCOCH_2COR_1+\bar{N}-CO \rightarrow RCO-N-CO+CH_2=C(\bar{O})R_1$
5	(a) nitriles, CN-lactams	113, 114	$R-C\equiv N+\bar{N}-CO \rightarrow RC(=\bar{N})-N-CO$ (или $N\equiv C-N-CO+R^-$)
	(b) CN-halides	115	$R-C\equiv N+\bar{N}-CO\begin{cases}\nearrow N\equiv C-N-CO+R^-\\ \searrow RC(=\bar{N})-N-CO\end{cases}$
	(c) dilactim ethers	116	$(CH_2)_xN=C-O-C=N(CH_2)_y+\bar{N}-CO \rightarrow \rightarrow(CH_2)_xN=C-N-CO+ O^-C=N(CH_2)_y \leftrightarrow OC-N^-(CH_2)_y$
	(d) cyanamides	104, 117	$NH_2-C\equiv N+\bar{N}-CO \rightarrow NH_2-C(=\bar{N})-N-CO$
	(e) carbodiimides, guanidines, imines, iminocarbonates	118—121	$ArN=C=NAr+\bar{N}-CO \rightarrow ArN=C(\bar{N}Ar)-N-CO$
	(f) azides	122	$R-N=N=N+\bar{N}-CO \rightarrow R-\bar{N}-N-CO+N_2$
	(g) triazines, pyridazines, pyrimidines, benzothiazoles	123—130	$N=CR-N=CR-N=CR+\bar{N}-CO \rightarrow N=CR-N=CR-\bar{N}=CR-N-CO$
6	(a) phosphonitrilic compounds $(PNX_2)_3$	131, 132	$N=PCl_2N=PCl_2N=PCl_2 \xrightarrow{+N-CO} N=PCl_2N=PCl_2N=PCl-N-CO+\bar{C}l$
	(b) alkylhalogenophosphines, alkyl halogenophosphites, phosphines, phosphates, phosphorus halides	133—138	$Ar-PX_2+\bar{N}-CO \rightarrow Ar-P(X)(N-CO)+X^-$; $ArPH_2+Na\bar{N}-CO \rightarrow ArP^+(H_2)(Na)\bar{N}-CO$
	(c) P_2O_5	139	$O=P-O-P(=O)-O+\bar{N}-CO \rightarrow O=P-N-CO+\bar{O}P(=O)_2$
7	oxides of Group VI elements, CO, CO_2, CS_2	140—149	$O=C=O+\bar{N}-CO \rightarrow O=C(\bar{O})-N-CO$

the basis of the results obtained, the authors concluded that there is a possibility of the specific synthesis of activators taking into account the above requirements.

However, one should note the difficulty of effecting the classification of activating compounds proposed by Ikuzo et al.[22]; by no means all activators can be described by

the proposed schematic equations (for example, cyanamides, CO, CO_2, sulphur and phosphorus halides and oxide halides, dilactim esters, diketones, etc.).

The classification of activating compounds proposed by Stehliček et al.[21] is based on their chemical structure:

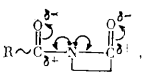
(1) organic and inorganic acid esters and lactones;
(2) carboxylic acid anhydrides and halides;
(3) carboxylic acid amides, nitriles, and cyanamides;
(4) carbodiimides, isocyanates, isothiocyanates, ureas, urethanes, and guanides;
(5) derivatives of sulphonic and phosphoric acids;
(6) metal oxides and chlorides (Friedel–Crafts catalysts);
(7) other compounds such as fluoro-derivatives, organic peroxides, carbon disulphide, aromatic nitro-compounds, aliphatic polyhalides, etc.

In this subdivision of indirect action activators compounds whose interaction with the lactam or its alkali metal salt leads to activating centres and side products (alcohols, acids, amines etc.) of different chemical types are included in a single class. For example, amides and nitriles, combined in a single class, interact with the lactam anion to form activating compounds having different chemical structures; the interaction of isocyanates with lactams does not lead to any side products, while urethanes, which belong to the same class according to Stehliček et al.[21], give rise to alcohols (Table 2).

We attempted to classify activators taking into account the chemical nature of the activating groups and side products formed. Table 2 includes activators of the anionic polymerisation of lactams taken from patent literature. All the compounds have been divided into seven classes, each class being further subdivided into subgroups in view of certain differences between the types of the active compounds formed within each class. Since it is impossible to specify unambiguously the mechanism of the formation of active centres, several versions of the proposed mechanism are quoted in many instances.

Compounds belonging to the first class are direct action activators, which form no side products poisoning the catalytic system and have therefore been considered separately. Compounds belonging to the second, third, and fourth classes form active centres with the same acyllactam structure. Despite this, these compounds have not been combined in a single class, since the side products formed differ in their chemical nature. Among compounds of the fifth class, the active species produced contains a group in which the nitrogen of the lactam ring is linked to an unsaturated system:

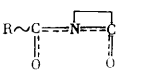
Characteristic side products are not formed for compounds of the fifth class. Phosphorus-containing compounds, forming active centres on interaction with the lactam or its anion, have been combined in the sixth class:



They give rise to acids as side products. The oxides of Group VI elements, CO, CO_2, and CS_2 have been assigned to the seventh class.

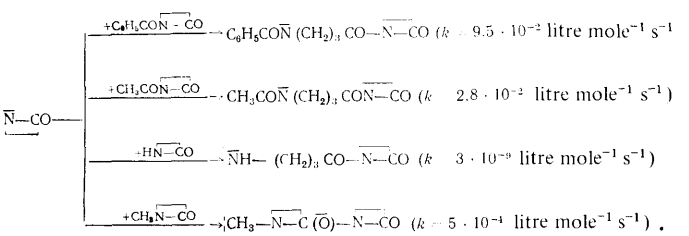
Thus, the classification which we propose for activators takes into account not only the nature of the active centre formed but also the nature of the side products, which have a significant influence on the rate of the anionic polymerisation of lactams. Thus alcohols, amines, acids, and other products arising on formation of the activating compounds lead to many side reactions, which poison the catalyst; among these, mention should be made of the decrease of the alkalinity of the system, the condensation of the aldehydes formed, the aminolysis of the reaction products, etc.

IV. THE INFLUENCE OF THE CHEMICAL STRUCTURE OF ACTIVATING COMPOUNDS ON THEIR EFFICIENCY



The influence of the chemical structure of activators on the rate of the anionic polymerisation of lactams has been considered in the literature mainly in relation to compounds of the acyl-lactam type. According to modern ideas[6,8–10], in the ground state of an *N*-substituted acyllactam the free electron pair of the nitrogen atom of the lactam ring can be involved in a resonance interaction with two neighbouring carbonyl double bonds (imide mesomerism),

which leads to the formation of two mesomeric forms:



Such a resonance system can evidently be regarded as conjugated:

In the conjugated system the electron density in the endocyclic amide bond is reduced compared with a stabilised (also by resonance) lactam molecule. Evidently the electron-accepting properties of the group R tend to increase the polymerisation of the imide group in the direction of the electrophilic substituent, facilitating thereby the nucleophilic attack by the lactam anion on the increased positive charge of the endocyclic carbonyl group.

In order to elucidate the influence of the structure of a substituent at a nitrogen atom, measurements were made [150] of the rate of addition of pyrrolidinonatomagnesium bromide ($\dot{M}gBr^{-}\underline{N-CO}$) to *N*-substituted pyrrolidinones in tetrahydrofuran (THF) solution at 25 °C. The addition rate constants obtained are given below:

This method of estimating the activating capacity is in our view most correct, since it makes it possible to determine the differences in the influence of substituents in the very first stages of the interaction where the difference is most marked. Benzoylpyrrolidinone is more reactive than acetylpyrrolidinone, as can be seen from the addition rate

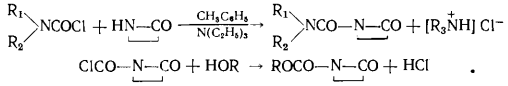
constants, which is probable due to the lower electronegativity of the acetyl group compared with the benzoyl group. For *N*-methylpyrrolidinone, one should expect a a lower value of k than that obtained, since the inductive effect of the CH_3 group acts in the opposite direction. However, the fact that in this instance the ring is not cleared constitutes, according to the authors[150], evidence demonstrating that compounds of this kind cannot be used as activators. The reaction of α-pyrrolidinone with its anion leads to polymerisation, despite the fact that the amine anion $H\overline{N}-(CH_2)_3CON-CO$ is not stabilised, as in the case of *N*-methylpyrrolidinone. The low addition rate constant explains the long induction periods in the non-activated polymerisation of lactams.

Table 3. Polymerisation of ϵ-caprolactam in the presence of *N*-acylcaprolactams as activators at 155°C.[151]*

Acyl group	Hardening time, s	Yield of polymer, %	Logarithmic viscosity, dl g^{-1}**
CH_3——→CO—	138	100	0.74
C_3H_7——→CO—	338	90.0	0.64
	625	81.6	0.65
	1520	18.3	0.52
$C_{16}H_{33}$—CO—	does not harden	4.5	0.25

*The percentage ratio of the activator and catalyst was 1.0:4.2.
**The viscosity was determined in a 0.5% H_2SO_4 solution at 25°C.

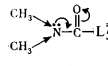
Scelis et al.[151] synthesised a number of *N*-acylcaprolactams, the acyl groups of which had different electronegativities (acetyl, butyryl, benzoyl, and *p*-methoxybenzoyl). The authors assumed that *N*-acyl-lactams having substituents with the most marked electron-accepting properties should exhibit the highest activity. However, the results (Table 3) showed that the size of the substituent has the dominant influence on the rate of the anionic polymerisation of lactams. The highest activity is manifested by *N*-acylcaprolactams with the smallest acyl groups. The effect associated with the electron-accepting properties of substituents is shown, according to authors[151], to a much smaller extent.

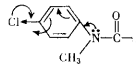


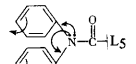
We believe that an estimate of the activating capacity on the basis of parameters such as the time of the onset of thickening, the degree of conversion, and the logarithmic viscosity of a dilute polymer solution is not altogether correct. It follows from the polymerisation mechanism that acyl groups exert the greatest influence on the reactivity of the carbonyl moiety of the imide group of the lactam in the first steps of the addition of the lactam anion.

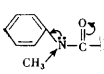
Stehlíček et al.[152] investigated the influence of the structure of the acyl group on the rate of anionic polymerisation of ϵ-caprolactam by measuring the initial rate of polymerisation at a rigorously defined temperature (100° ± 0.2°C) and a concentration of the catalytic system of 0.2 mole %. The relative activating capacity was estimated from the time of the appearance of turbidity in the polymerising system and the following data were obtained for a number of *N*-acyl-lactams:

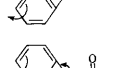
Group	CH_3	C_3H_7	C_4H_9	C_5H_{11}	C_6H_5	$CH_3OC_6H_4$
Time, min	13.8—14.5	14.3	17.2	14.7	14.1—16.3	16.5—17.2

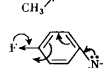


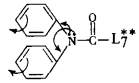






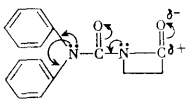






It was noted that anionic polymerisation activated by alkyl-imides obtained from aromatic carboxylic acids is much faster in the first seconds than in the presence of aliphatic acyl-lactams, but 30 s from the start of polymerisation the two rates become virtually equal.

Falkenstein and Dörfel[8] obtained disubstituted carbamoyl-lactams and esters of lactam-*N*-carboxylic acids via the mechanism



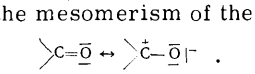
Examples of both classes of compounds proved to be effective activators of the anionic polymerisation of lactams at 120–150°C, and it was possible to vary the activating capacity of disubstituted carbamoyl-lactams and lactam-*N*-carboxylic acid esters within wide limits by the introduction of specific substituents. In order to estimate the efficiencies of the activators obtained, measurements were made of the time from the instant of mixing of the reagents to the onset of thickening and the results were compared with the basicity constants pK_b of the secondary amines used to obtain, *N*,*N*-disubstituted carbamoyl-lactams (Table 4).

Table 4. Dependence of the rate of polymerisation (thickening time) on the chemical structure of disubstituted carbamoyl-lactams[8].

Activator	Thickening time, min		pK_b for initial amine	Activator	Thickening time, min		pK_b for initial amine
	120°	150°			120°	150°	
	—	—	0.5		3.8	0.94	10.5
	—	—	0.9		1.85	0.5	13.4
	10	4.3	8.0		1.45	0.4	14.4
	7.8	2.5	9.1		1.1	0.2	14.4
	7.2	1.8	9.2		1.0	0.15	15

*L_5 = α-pyrrolidinone.
**L_7 = ϵ-caprolactam.

It follows from Table 4 that the activating effect of the compounds under consideration depends significantly on their chemical structure. Carbamoyl-lactams with aliphatic or alicyclic substituents at the exocyclic nitrogen atom (*N*,*N*-dimethyl, piperidinyl) do not activate the anionic polymerisation of lactams at all. The introduction of phenyl substituents leads to the appearance of an activating capacity in carbamoyl-lactams. This influence of the phenyl substituent is attributed [8] to the increase of the polarisation of the carbamoyl-lactam under the influence of the benzene ring in consequence of its negative inductive and mesomeric effects.



The rate of polymerisation depends both on the number of phenyl substituents and on the nature of the substituents in the benzene ring (if such are present).

In lactam-*N*-carboxylic acid ester

the activating effect diminishes with increase of the electronegativity of the substituent X (Table 5). It is believed [8] that the cause of this may be that the electronegative substituent X opposes the involvement of the polar structure in the mesomerism of the carbonyl group:

Thus the C...O bond order increases and the absorption band of the carbonyl group undergoes a bathochromic shift, as can be seen from Table 5. This corresponds to a decrease of the polymerisation of the amide bond in the lactam owing to the inductive effect, which leads to a weakening of the activating influence of the electronegative substituents.

Table 5. Dependence of the rate of polymerisation (thickening time) on the chemical structure of lactam-*N*-carboxylic acids [8].

Activator	Thickening time, min		ν_{CO}, cm^{-1}	Activator	Thickening time, min		ν_{CO}, cm^{-1}
	120°	150°			120°	150°	
ClC_6H_4—O—CO—L_5*	—	—	1726	$C_6H_5CH_2$—O—CO—L_5	1.25	0.25	1720
FC_6H_4—O—CO—L_5	—	—	1725	L_5CO—O—$(CH_2)_4$—O—COL_5	1.15	0.15	1710
$CH_3C_6H_4$—O—CO—L_5	—	—	1725	C_2H_5—O—CO—L_5	1.1	0.15	1717
C_3H_7—O—CO—L_5	1.5	0.5	1718	L_5CO—$O(CH_2)_6$—O—COL_5	1.1	0.1	1710
C_3H_7—O—CO—L_7**	1.4	0.3					
CH_2=CH—CH_2—O—COL_5	1.3	0.3	1720	L_7CO—$O(CH_2)_4$—O—CO—L_7	1.0	0.09	1708

*L_5 = ε-caprolactam.
**L_7 = η-caprinolactam.

Unfortunately Falkenstein and Dörfel [8] did not investigate the activating capacity of lactam-*N*-carboxylic acid esters as a function of the concentration of the catalyst; nor are data available about the isolation of any intermediates in the polymerisation process. The authors' explanation of the mechanism of the action of activators of this kind is therefore not sufficiently well founded. In all probability the activating effect of lactam-*N*-carboxylic acid esters should be sought in the possible interaction of the latter with the lactam or its anion (by analogy with carboxylic acid esters—see Table 2):

which leads to the exhaustion of the alkaline process catalyst. The acidity of the alcoholic residue will then play the main role in interaction with the process catalyst.

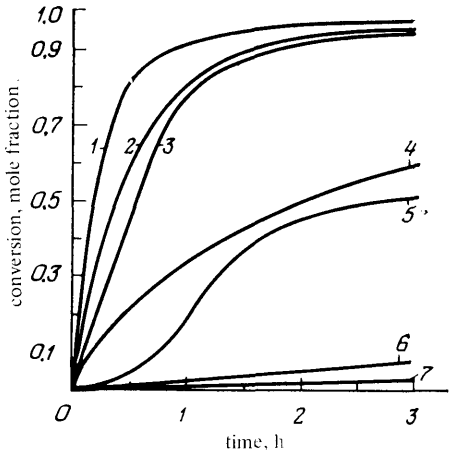


Figure 2. Time variation of the degree of conversion in the anionic polymerisation of ε-caprolactam at 130°C; [155] [NaH] = 0.0067 (mole fraction): 1) *N*-benzoyl-ε-caprolactam; 2) diisopropylcarbodiimide; 3) phenyl isocyanate; 4) *N*-acetyl-ε-caprolactam; 5) 1,3-diphenylurea; 6) 1,3-diethylurea; 7) n-butyl acetate.

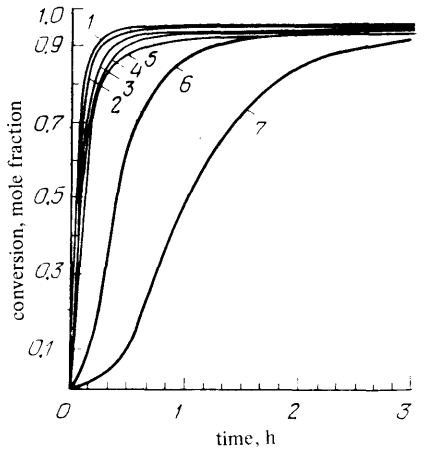
Stehlíček et al. [21] showed in relation to a large class of compounds used as activators that, when the activating compounds interact with the lactam or its anion, the side products formed have an inhibiting influence on the rate of anionic polymerisation of lactams. Among the large number of compounds proposed as activators, only *N*-acyl-lactams and the products of the interaction of mono- and poly-functional isocyanates with lactams have therefore been widely used hitherto [153,154].

It is noteworthy that the conditions in the polymerisation of lactams have an appreciable influence on the nature of the action of activators of both direct and indirect types. A study [155] undertaken to estimate the relative activating capacities of various compounds used in the anionic polymerisation of lactams is of definite interest in this connection. Figs. 2 and 3 present kinetic curves for the variation of the degree of conversion with time in the presence of various activators of the anionic polymerisation of ε-caprolactam at 130° and 180°C. It is seen that the activating capacity of benzoylcaprolactam is higher than that of acetylcaprolactam, particularly at low polymerisation temperatures. The reaction of phenyl isocyanate with ε-caprolactam takes place with formation of phenyl-substituted carbamoyl-ε-caprolactam

by direct addition without the isolation of side products. Despite the intermediate stage, the initiation reaction is in this case (both at 130° and 180°C) appreciably faster than in the reaction involving acetylcaprolactam.



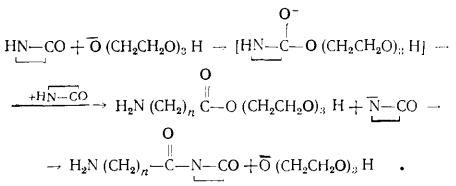


Figure 3. Time variation of the degree of conversion in the anionic polymerisation of ϵ-caprolactam at 180°C;[155] [NaH] = 0.0067 (mole fraction); mole fraction of activator 0.0067: 1) diisopropylcarbodiimide; 2) *N*-benzoyl-ϵ-caprolactam; 3) phenyl isocyanate; 4) *N*-acetyl-ϵ-caprolactam; 5) 1,3-diphenylurea; 6) 1,3-diethylurea; 7) n-butyl acetate.

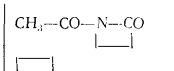
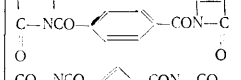
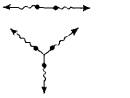
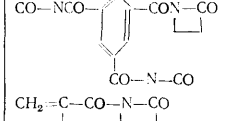
sym-Ureas are known[21] to decompose at high temperatures to isocyanates and amines. The reduced effect of activators of this kind is determined by the basicity of the amined formed. In the case of aniline the free electron pair of the nitrogen atom is stabilised by the $-I$ and $-M$ effects of the benzene ring and the basicity of the amino-group is reduced. *sym*-Diphenylurea is therefore a more effective activator than 1,3-diethylurea, particularly at low polymerisation temperatures.

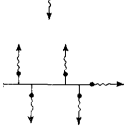
n-Butyl acetate gives rise to a longer induction period both at 130° and at 180°C. However, at the higher polymerisation temperature in the presence of n-butyl acetate it is possible to attain a high degree of conversion, comparable with the values obtained in the presence of *N*-acetyl-ϵ-caprolactam. When the n-butyl group is replaced by the t-butyl, phenyl, or isopropyl group, the activating capacity of the ester increases[21].











According to Stea and Gechell[155], diisopropylcarbodiimide has a high activating capacity over the entire temperature range. Its activating influence can be accounted for in two ways: by the interaction of the carbodiimide with an acid hydrogen atom (traces of water), leading to the formation of *sym*-dialkylureas[156], or by the addition to the carbodiimide of the lactam or its anion with formation of a polar substituent at the lactam nitrogen[21].

The fact that alcohols, which were usually regarded as inhibitors of the polymerisation of lactams, behave at the same time as its activators is of special interest. The use of alcohols as activators of the anionic polymerisation of lactams was first reported by Čefelin et al.[157] and then Mermoud[158] used triethylene glycol as the activator and obtained a product with a high degree of polymerisation. The problem of the use of alcohols for the activation of the polymerisation of lactams was investigated in detail by Sekiguchi[159]. His results show that activation under the influence of alcoholic hydroxyl is due to the imide groups formed as a result of the esterification (decyclisation) of the lactam molecules:

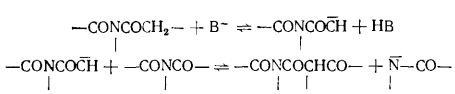
Sekiguchi[6] established experimentally that the activating capacity of alcohols depends to a large extent on the acidity of the alcoholic hydroxyl. Apart from triethylene glycol, an activating capacity is shown, according to his data, by diethylene glycol, 1-octanol, tetradecanol, s- and t-butyl alcohols, etc. We believe that, on the basis of Sekiguchi's mechanism of activation, alcohols should be regarded as catalysts of the anionic polymerisation of lactams, since the growing polyamide chain does not contain an alcoholic radical.

Table 6. The direction of the growth of macromolecular chains in the anionic polymerisation of ϵ-caprolactam in the presence of mono- and poly-functional activators[167].

Activator	Structural formula	Functionality	Schematic illustration of the direction of the macromolecular chain growth
N-Acetyl-ϵ-caprolactam		1	
N,N'-Isophthaloyl-bis-ϵ-caprolactam		2	
N,N',N''-Trimesoyl-tris-ϵ-caprolactam		3	
N-Methacryloyl-ϵ-caprolactam		>3	

V. THE INFLUENCE OF THE FUNCTIONALITY OF ACTIVATORS ON THE MOLECULAR STRUCTURE OF THE POLYMERS FORMED

The activators of the anionic polymerisation of lactams not only accelerate the polymerisation process but also constitute an effective means for the specific regulation of the molecular structure and hence of the properties of the polyamides formed[34,35,160–166].



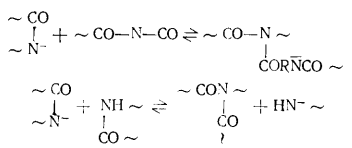
The majority of the activators considered above contain one functional group which ensures the activation and growth of the polymer chain in one direction and this leads to the formation of polymers having a predominantly linear structure. The use in the polymerisation of lactams of

polyfunctional activators, i.e. compounds containing several activating functional groups in their molecule, leads to the formation of polyamides of "star" or "comb" type[165,167]. Thus the direction of growth and the number of growing chains of the macromolecules are related to the disposition and number of the functional groups in the activator molecule. This is illustrated schematically in Table 6.

However, one should note that the polyamides obtained in the presence of monofunctional activators are not linear polymers in the strict sense of the term. It is known[165, 168-171] that the synthesis of polyamides is accompanied by side reactions leading to the formation of polymers with a low degree of branching. The degree of branching of these polyamides is determined in the study of their molecular weight distribution[165,168,169] and from end group analysis[170,171]. It was shown that the number of end groups in the polyamide macromolecules formed in the presence of a monofunctional activator is greater than two[170,171] and that the molecular weight distribution in such polyamides is broad owing to branching reactions occurring at late stages of the process[165,168,169].

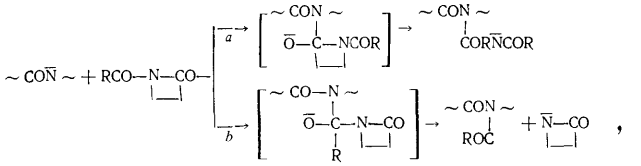
The molecular structure of the polyamides obtained in the presence of polyfunctional activators is more complex. In this case the branching of the polyamides is caused, on the one hand, by the functionality of the activator (Table 6) and, on the other, it is due to the same side reactions which occur also in the formation of polyamides in the presence of monofunctional activators. In the presence of polyfunctional activators the products are polyamides containing, apart from soluble macromolecules, also insoluble macromolecules[34,35,161-166], which is associated with the three-dimensional structure of the latter[165,166,172]. In a study of the molecular structure of soluble specimens of polycaproamide in the initial stages of the polymerisation (up to the instant of gel formation) Pavlova showed[165] that the test specimens contain two groups of fractions—with higher and lower degrees of branching. The molecular weight distribution obtained by Pavlova et al.[165] from fractionation data revealed the presence of two maxima corresponding to narrow and broad distributions. The narrow distribution was explained by the presence in the polyamide chain of macromolecules with non-random branching due to the polyfunctionality of the activator, while the broad distribution was attributed to the presence of macromolecules with random branching[165]. The presence of the above two molecular structures in the polyamides formed—with random and nonrandom branching—can probably be explained by the occurrence of side reactions during the formation of the polyamides.

The reactions which can lead to branching under the conditions of the activated polymerisation of lactams can probably also lead to the formation of cross-linked macromolecules. Wichterle[173] and Šebenda[174] showed in model reactions that in an alkaline medium the imide groups of the compounds undergo the Claisen condensation when the α-carbon atom in the molecule is linked to at least one hydrogen atom:

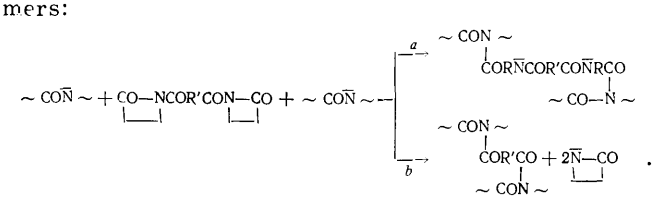


The *N*-acylated β-ketoacid amides (ketoimides), formed as a result of the above reaction, can react with the growing acyl-lactam centres and can lead to the formation of ketoimides of various structures[175,176]. When cyclic ketoimides interact with the lactam anion, they can be converted into ketoamides[176]:

Both ketoamides and ketoimides, containing reactive groups ($>C=O$, $-CH_2-$, $-\underset{|}{C}H-$) can lead to a large number of different compounds under the conditions of the anionic polymerisation of lactams, particularly to hydroxypyridine and uracil derivatives[173], which can serve in their turn as centres for branching and cross-linking in the polymers produced.



Wichterle and coworkers[177,178] and Šebenda[7] suggested that the branching of macromolecules in the anionic polymerisation of lactams can be caused by reactions of the type



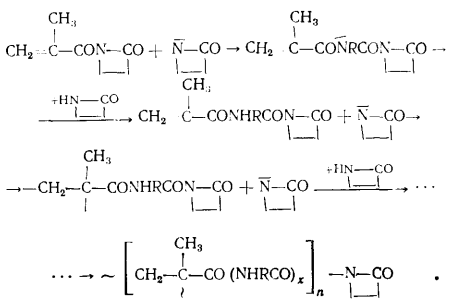
in addition to the side reactions mentioned above.

The above results indicate the possibility of branching and cross-linking in polyamides when the anionic polymerisation of lactams is carried out in the presence of monofunctional and polyfunctional activators. However, when the polymerisation of ϵ-caprolactam was performed in the presence of monofunctional activators (with different proportions of the components of the catalytic systems and at different concentrations) the formation of insoluble polyamides was not observed. Thus the above literature data do not fully explain the cause of the formation of cross-linked polyamides in the presence of polyfunctional activators.

Frunze et al.[172] relate the cause of the formation of cross-linked polyamides to the presence in the growing polyamide macromolecules of terminal acyl-lactam groups capable of reacting with the amide groups of other macromolecules. They showed, for the model reaction of a polyamide (G-669) with mono- and poly-functional activators, simulating the reactive end-groups of the growing polyamide chains, that the reactions of the polyamide with monofunctional activators lead to the formation of *N*-substituted polyamides only:

while the reactions of the polyamide with bifunctional activators result in the formation of cross-linked polymers:

It was shown later[175] that pathways *a* and *b* of the above reactions depend to a large extent on temperature.



The literature data concerning the study of the molecular structures of polyamides, which were examined above, permit the conclusion that in the presence of monofunctional activators the products are linear polyamides with a low degree of branching, while in the presence of polyfunctional activators partially cross-linked polyamides with random branching are formed, the degree of branching increasing with increasing functionality of the activators [165].

N,*N*'-Acylbislactam (*N*,*N*'-isophthaloyl-, *N*,*N*'-terephthaloyl-, *N*,*N*'-adipoyl-, and *N*,*N*'-sebacoyl-biscaprolactams) were first used as bifunctional activators by Korshal et al. [160] in the anionic polymerisation of ε-caprolactam. They established that, depending on the concentration of the catalytic system, soluble or insoluble polyamides are formed and that, when a mixture of the above acylbislactams with a monofunctional activator in different proportions is used, it is possible to regulate fairly readily the molecular weight of the polymers produced [60]. *N*,*N*'-Diacylbislactams have now found extensive applications in the activation of the anionic polymerisation of lactams [32, 100, 114]. Diisocyanates [35-47, 164, 180], in the presence of which soluble polyamides with a high strength are formed, are widely used as bifunctional activators.

N,*N*',*N*''-Trimesoylter-ε-caprolactam, in the presence of which polyamides with randomly branched and partly cross-linked structures are formed, was used for the first time as a trifunctional activator for the polymerisation of ε-caprolactam [35, 161]. It was shown [161] that the polyamides obtained in the presence of the trifunctional activator are more elastic and have a higher impact strength than the polyamides obtained in the presence of a monofunctional activator.

Muller [181] suggested that cyanuric chloride be used as an activator of the anionic polymerisation of α-pyrrolidinone. According to the author, three chlorine atoms in cyanuric chloride are substituted by α-pyrrolidinone and the resulting triazine derivative of α-pyrrolidinone act as an effective trifunctional activator of the anionic polymerisation of the lactam.

The use of acyl-lactams containing unsaturated groups as activators of the anionic polymerisation of lactams is of great interest. Such activators include *N*-methacryloyl-ε-caprolactam [34, 162, 163]. Formally, *N*-methacryloyl-ε-caprolactam can be classified as a monofunctional activator, since its molecule contains only one imide functional group. However, the polyfunctional nature of this activator is manifested in the course of the polymerisation of lactams, as can be seen from the polymerisation mechanism [162, 163]:

It is noteworthy that *N*-methacryloyl-ε-caprolactam does not polymerise in the process involving the double bonds via either a radical or an ionic mechanism [182]. The adduct *N*-methacryloyl-(ε-aminocapryloyl)-ε-caprolactam, formed as a result of the first step in the polymerisation of ε-caprolactam, polymerises via the double bonds, which leads to the formation of a polyfunctional activator [162, 163, 183].

As in the presence of the trifunctional activator *N*,*N*',*N*''-trimesoylter-ε-caprolactam, in the presence of *N*-methacryloyl-ε-caprolactam the products are insoluble polyamides which are randomly branched and partly cross-linked polymers with high strength. Table 7 shows that the physicomechanical properties of the polyamides depend on the functionality of the activator used. The impact strength of the polyamides synthesised using polyfunctional activators is much higher than that of the polymers obtained with *N*-acetyl-ε-caprolactam.

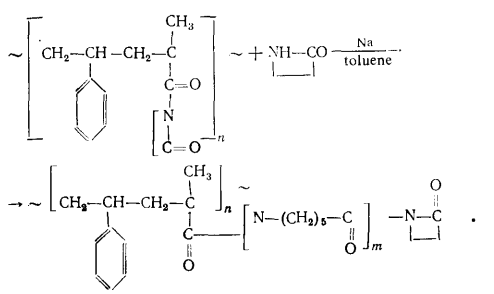


Table 7. Certain physicomechanical characteristics of polycaproamide obtained in the presence of activators with different functionalities relative to lithium Kapron B [162, 163, 184]

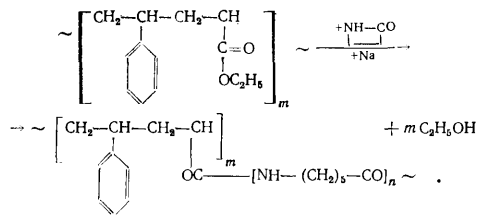
Activator	Content of fraction insoluble in HCOOH, wt.%	Ultimate strength, kgf cm^{-2}		Specific impact strength, kgf cm^{-2}
		on static bending	on compression	
N-Acetyl-ε-caprolactam	0	1300—1500	1100	100—150
N,*N*'-Isophthaloylbis-ε-caprolactam	0	1200—1400	1100	250—350
N,*N*',*N*''-Trimesinoylter-ε-caprolactam	60—70	1200—1400	1000	does not break
	40—50	1400—1500	—	does not break
N-Methacryloyl-ε-caprolactam	0	900	—	150—170
Kapron B				

Thus the data examined above permit the conclusion that the functionality of the activators has a significant influence on the molecular structure and properties of the polymers formed.

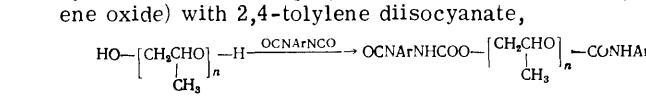


VI. MACROMOLECULAR ACTIVATORS OF THE ANIONIC POLYMERISATION OF LACTAMS

The use of polymeric molecules of different chemical types, containing acyl-lactam, isocyanato-, acid chloride, cyano-, and certain other functional groups, as activators of the anionic polymerisation of lactams leads to the formation of graft and block copolymers. This leads to the possibility of a specific regulation of the properties of the polymeric materials formed. Depending on the positions of the activating groups in the macromolecular chain of the activator, graft or block copolymers are produced. Thus Wichterle and Gregor [182] grafted ε-caprolactam to a copolymer of styrene and *N*-methacryloyl-ε-caprolactam containing acyl-lactam groups:

Korshak and coworkers[185-188] developed a method for the copolymerisation of styrene with ε-caprolactam in bulk to aid the chemical moulding of large articles. According to this method, in the first stage styrene undergoes radical copolymerisation with catalytic amounts of *N*-methacryloyl-ε-caprolactam in solution in ε-caprolactam. In the second stage ε-caprolactam is grafted to the macromolecular activator formed in the reaction mixture. The authors showed that an increase of the content of polystyrene units in the copolymer greatly increases the water resistance of the material but its strength (particularly the specific impact strength) decreases.

Graft copolymers have been obtained[189] by the anionic polymerisation of ε-caprolactam in the presence of a copolymer of styrene with ethyl acrylate, the ester group of which activates the polymerisation of the cyclic amide:



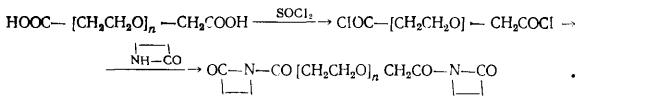
If the styrene–ethyl acrylate copolymer contains more than 1 wt.% of ethyl acrylate, a cross-linked insoluble product is formed, which the authors[190] explain by the presence of a tertiary carbon atom in the α-position relative to the ester group.

The grafting of α-pyrrolidinone[191] and ε-caprolactam[192] to poly(acryloylchloride) has been described:

It was noted that fibres and films with a high strength can be obtained from the graft copolymers of acrylic acid with ε-caprolactam and α-pyrrolidinone thus synthesised.

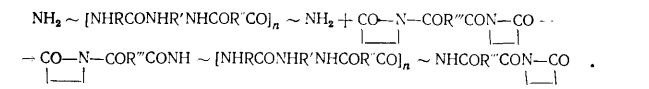
The use of acyl-lactam, acid chloride, isocyanato-, and other groups at the ends of macromolecules of different chemical type for the activation of the polymerisation of lactams in order to obtain block copolymers is known. In this case block copolymers with the structure A–B–A, in which the two outer segments A are polyamide units and the inner segment B is some other polymer, are as a rule obtained. The molecular weight of the inner segments and the ratio of the macromolecular activator and the lactam giving rise to the polyamide units of the outer segments vary within wide limits, which makes it possible to vary also the properties of the block copolymers. The use of polyethers and polyesters[193-196], polythioethers[196], polycarbonates[196], polybutadienes[197-199], polystyrene[197, 200-202], polysulphone[203], and polyamides of other chemical types[204-207] as the inner segments of block copolymers has been reported.

For example, a method has been described for the synthesis of block copolymers[196] by treating poly(propylene oxide) with 2,4-tolylene diisocyanate,



and subsequent polymerisation of ε-caprolactam in the presence of the resulting polymeric activator. It has been pointed out[196] that, apart from polyesters and polyethers, polythioethers, polyamides, and polycarbonates containing the following terminal functional groups can be used as the internal polymeric segment in the synthesis of block copolymers:

ε-caprolactam, ξ-oenantholactam, η-caprinolactam, ω-dodecylactam, and their *C*-substituted derivatives have been used as the lactam components.



According to another procedure[193], the terminal carboxy-groups of poly(ethylene glycol) are initially converted into acyl chloride groups by reaction with thionyl chloride in solution in xylene and then into acyl-lactam groups as a result of reaction with ε-caprolactam in the presence of pyridine:

The compound obtained is used as a macromolecular activator of the anionic polymerisation of ε-caprolactam. The block copolymer formed has antistatic properties which are improved compared with those of polycaproamide.

Jamashita et al.[194] used poly(tetramethylene glycol) with terminal chloroformate groups, obtained by treating the terminal hydroxy-groups with phosgene, as the polymeric activator of the anionic polymerisation of α-pyrrolidinone and ε-caprolactam. As polymerisation proceeds in the presence of the above polymeric activator, the authors observed an increase in the degree of conversion of the lactam and an increase of the intrinsic viscosity of the block copolymer formed. A linear relation was observed between the logarithm of the intrinsic viscosity and the logarithm of the degree of conversion of the lactam, which indicates, according to the authors[194], the absence of a chain termination reaction. The comparatively low concentration of the polymeric activator (2–4%) indicates a fairly high efficiency of poly(tetramethylene glycol) bischloroformate as an activator of the polymerisation of lactams.

Lincoln[204] used the reaction of the terminal amino-groups of the mixed polyamide 6/66 with *N*,*N*′-acylbislactam in order to obtain a polymeric activator for the synthesis of a block polyamide:

Polystyrene with terminal *N*-acylpyrrolidinone groups[201], synthesised by the radical polymerisation of styrene using 4,4′-azobis(pyrrolidinono-4-cyanovalerate) as the initiator, proved to be an effective activator of the polymerisation of α-pyrrolidinone:

The linear increase of molecular weight with increasing degree of polymerisation of α-pyrrolidinone as well as the increase in the degree of conversion and of the intrinsic viscosity with time confirmed, according to the authors[201], the stepwise chain propagation and the absence of chain termination during polymerisation. The authors do not quote any information about the activation of the anionic polymerisation of the lactam involving the inner –C≡N groups of the macromolecular activator.

Korshak and coworkers [205,206] described the synthesis of block copolymers involving the interaction of an N,N'-acylbislactam with a diamine in an ϵ-caprolactam melt,

$$(n+1)\ \underset{\underset{|__|}{}}{\mathrm{CO{-}NCOC_6H_4CON{-}CO}} + n\ \mathrm{NH_2R'NH_2} \rightarrow$$

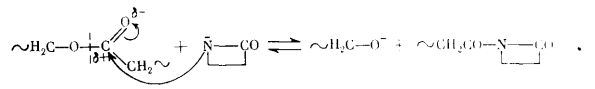
$$\rightarrow \underset{\underset{|__|}{}}{\mathrm{CO{-}NCOC_6H_4CO{-}}}\ [\mathrm{NHR'NHCOC_6H_4CO}]_n\ \underset{\underset{|__|}{}}{\mathrm{{-}N{-}CO}} + 2n\ \underset{\underset{|__|}{}}{\mathrm{NH{-}CO}},$$

with subsequent sodium-catalysed polymerisation of ϵ-caprolactam via the terminal acyl-lactam groups of the resulting polymeric activator. It was established that, with increase of the content of the polymeric activator in the reaction mixture, the degree of conversion of ϵ-caprolactam increases and the thickening time diminishes, which indicates an increase of the rate of polymerisation. When the ratio of the initial polymers is altered, block copolymers of the type A–B–A with different lengths of the segments are formed; this is also indicated by a change in the intrinsic viscosity and melting point of the resulting copolymers.

Very interesting and very promising studies have been made on the synthesis by anionic polymerisation of block copolymers of polybutadiene, containing terminal isocyanato-groups, with a lactam [197-199]. The presence of unsaturated double bonds in the butadiene segment,

$$\sim [\mathrm{CO(CH_2)_5\ NH}]_m\ \mathrm{{-}CONH{-}}\ [\mathrm{CH_2CH{=}CH{-}CH_2}]_n\ \mathrm{{-}NHCO{-}}\ [\mathrm{NH(CH_2)_5\ CO}]_m \sim$$

leads to further possibilities for the modification of the products. The authors [197] note the exceptionally high elasticity of the butadiene block copolymers even when the content of the ϵ-caprolactam units is up to 70–80%. It was shown that the plasticity of this polymer depends on the molecular weight of the polycaproamide segments. The high degree of conversion (~98% with respect to ϵ-caprolactam) shows that the macromolecular butadiene activator is highly effective. The impact strength, determined for hardened block copolymers with the above structure, increases with increasing content of the lactam units and increases sharply when the latter is more than 50%, which the authors [198] attribute to the higher impact strength of polycaproamide compared with the hardened polybutadiene. At the same time, the bending strength changes insignificantly with increasing fraction of polycaproamide in the block copolymer.



Thus the data presented concerning the use of macromolecular activators in the anionic polymerisation of lactams permit the following conclusions.

1. Prepolymers containing the $-O-$, $-COO-$, $-COCl$, $-CSCl$, $-SO_2Cl$, $-OCOCl$, $\rangle C{=}C{=}O$, $-N{=}C{=}O$, $-\underset{\underset{|__|}{}}{\mathrm{CON{-}CO}}$, etc. functional groups are effective activators of the anionic polymerisation of lactams.

2. The activating capacity of compounds of this kind is determined mainly by the nature of the functional group and not the length and nature of the macromolecular chain.

3. The properties of graft and block copolymers depend both on the activator : lactam ratio and on the nature of the macromolecular chain of the polymeric activator.

The anionic polymerisation of lactams can be activated not only by the functional groups at the ends of the macromolecules but also by the functional groups which are fragments of the main polymer chain. Thus it has been reported [207,208] that polyesters and polyethers can be used as activators of the anionic polymerisation of lactams. As a result of nucleophilic attack by the anion of the ester group, the heterobond is dissociated with chain transfer to the lactam molecule:

This case constitutes an example of chain transfer reactions with dissociation, which are common in the polymerisation of heterochain monomers [209]. As the interchain exchange reactions proceed, the block copolymers formed at the beginning of the process can be converted into a statistical polymer. For example, Korshak and Frunze [210] established that, when a mixture of homopolyamides is heated, a block copolymer is formed initially; the interchain exchange reactions gradually reduce the size of the blocks and the system attains a state of equilibrium characterised by the most probable distribution of the monomeric units in the copolymer.

It has been noted [206] that, when the anionic polymerisation of ϵ-caprolactam is carried out in the presence of polyhexamethyleneisophthalamide with terminal N-acyllactam groups at 140° and 180°C, the products are block copolymers whose intrinsic viscosities differ appreciably [η_{int} (140°) > η_{int} (180°)]. The authors explain the difference between the viscosity characteristics [206] by the fact that at 140°C the exchange reactions leading to interchain exchange and ultimately to the formation of block copolymers with a less regular structure proceed much more slowly than in the polymerisation at 180°C.

Taking into account the set of the possible exchange reactions in the anionic polymerisation of lactams in the presence of macromolecular activators, one must bear in mind that in practice one cannot obtain a "pure" block copolymer of the type A–B–A. In reality, under the influence of the interchain exchange, the system may contain, together with the block copolymer formed, also a graft copolymer and a mixture of homopolymers. The chemical structure of the products will be determined in each specific instance by the process conditions, i.e. by the nature of the macromolecular activators and the lactam, their proportions, temperature, reaction time, etc.

Analysis of Atmospheric Pollutants by Gas Chromatography

Yu.S.Drugov and V.G.Berezkin

Chromatographic methods for the analysis of atmospheric pollutants, including the principal stages of the determination, from the sampling procedure to the evaluation of the results of the analysis, have been examined. The difficulties and limitations frequently encountered in the examination of the separate stages of the analysis and the various methods have been analysed. The review is based on work published in the period 1965-1978. The bibliography contains 398 references.

I. INTRODUCTION

The contamination of the environment, particularly the atmosphere, which in many countries has become a serious international problem, is posing analytical chemistry important and complex problems in the analysis of many-component mixtures of various atmospheric pollutants, the components of which are present in trace concentrations. Practically the whole arsenal of physical and chemical methods available to analytical chemistry is now being used for the analysis of atmospheric pollutants [1]. Its high sensitivity and extremely high selectivity have made gas chromatography one of the basic methods of analysis in the chemistry of industrial hygiene and the chemistry of the atmosphere.

The importance of the problem of analysing the atmosphere is to a large extent responsible for the large number of publications on this subject, and the number is increasing continuously [2,3]. In 1968, a detailed review [4] analysed the achievements of gas chromatography during ten years of application in the chemistry of the atmosphere. A number of later reviews and monographs deal with the gas-chromatographic analysis of atmospheric pollutants [5,6] and the chromatographic determination of harmful substances in the air of industrial plants (industrial atmosphere). [7] The present review includes material published in the period from 1965 to 1978.

At the present time, the problem of separating complex mixtures of substances by gas chromatography often presents no special difficulties. The use of stationary phases of high selectivity (particularly in micro-packed capillary columns) and capillary columns with a separation efficiency of > 200000 theoretical plates makes it possible to separate and analyse complex mixtures of organic and inorganic compounds consisting of several hundred components. Another important advantage of this method is its extremely high sensitivity, which makes it possible to determine micro-concentrations of a substance at a level of 10^{-10}%†.

Nevertheless, the gas-chromatographic method also encounters certain difficulties in the analysis of micro-quantities of various toxic substances in air. Since the maximum permissible concentrations (MPC) for most toxic chemical compounds in the air of industrial plants is 0.01-0.001 mg m^{-3}, that is about 10^{-7}-10^{-8}%, the specimen of air for analysis, with a volume of 1-10 ml, should contain not more than 10^{-10}-10^{-12} g of the substance. This quantity lies at the limits of many chromatographic detectors used for the analysis of air [8]. The MPC of harmful substances in atmospheric air is lower by a factor of approximately 10. If in addition account is taken of the losses of the substance being analysed during sampling, the treatment of the sample and its introduction into the chromatograph, and the chromatographic separation, the problem of inadequate analytical sensitivity becomes particularly acute.

Another important problem is the qualitative analysis of many-component mixtures, since polluted air generally contains complex mixtures of chemical con pounds of different classes. The chromatographic analysis is also complicated considerably by rapid change in the composition of the air being analysed (particularly atmospheric air) under the influence of meteorological conditions and photochemical reactions taking place in the atmosphere between compounds present in the air, under the influence of solar radiation.

The gas-chromatographic analysis of micro-quantities of substances includes the following stages.

1. Sampling. Storage of the sample.
2. Concentrating the components.
3. Treatment of the sample and its introduction into the chromatograph.
4. Chromatographic separation of the components of the sample.
5. Detection, and also, at intervals,
   a) calibration of the chromatograph (detector);
   b) qualitative and quantitative analysis of micro-quantities of substances.

II. AIR SAMPLING PROCEDURE

Sampling (and the concentrating of micro-quantities of substances) presents one of the principal problems in the analysis of polluted air, because of the insufficient sensitivity of detectors and the existence of active sites, capable

†Here and subsequently, concentrations are given in wt.%.

of sorbing traces of material in the chromatographic apparatus (chromatograph connections, columns) and in the sorbents used. Concentrating the sample with micro-component concentrations at a level of 10^{-4}–10^{-5}% is often also carried out in work with highly sensitive ionisation detectors. In these cases it is usually sufficient to concentrate the components from one litre of the air being analysed. This technique is also used when it is impossible to carry out the direct analysis of the gaseous sample on capillary columns and in certain other cases.

Existing methods for sampling air can be divided into four groups: 1) sampling into various containers; 2) aspiration of the air through a solvent which retains the impurities; 3) absorption of harmful substances from the air by sorbents; and 4) freezing the impurities in a cooled trap on an inert packing or sorbent. The methods of the last three groups are techniques for concentration.

The simplest method is the direct introduction of the sample into the chromatograph. In this case the air is sampled with a glass or plastic syringe, and also into gas pipettes, steel or glass bottles, bags made of polymer film, and other containers. With this method, satisfactory results are obtained only in the analysis of gaseous samples containing traces of substances which are not too polar (light hydrocarbons, oxides of carbon, nitrous oxide, etc.). The accuracy of these determinations is low because in practice it is very difficult to take account of the losses of the substances being analysed, which in some cases (the analysis of reactive gases and vapours) may reach 40%[9]. Not only reactive compounds, but also hydrocarbons, are adsorbed on the walls of containers[4].

The sampling of components for analysis by absorption in a suitable solvent is also a method for the equilibrium concentrating of these compounds. In contrast to the case of sampling into containers, there is practically no limit to the range of substances that can be analysed by this method. In addition, the aspiration of the sample through a solvent makes possible the selective removal of substances of different classes from the air. Nevertheless, sampling into a solvent is not often used in chromatographic analysis, since it is not possible to achieve a very high sensitivity in the determination. This is because, despite the high degree of enrichment of the substances of the sample in the solution being analysed, only a small fraction of the absorbing liquid is taken for analysis (1–10 μl), that is 0.1–0.2% of the original volume of the solution, which should not be less than 3–5 ml. It is true that the sensitivity can be increased by repeating the concentration procedure, for example by evaporating the solution after sampling. This introduces an additional error into the determination, however, due to the volatility of the dissolved compounds of the sample. To avoid possible errors in the analysis of trace quantities, it is also necessary to take account of the volatility of the solvent itself and the rate of aspiration of the air through the absorber. To increase the sensitivity it may be more promising to extract the substances dissolved in the absorbing liquid by a much smaller volume of a selective solvent, that is by a repeated concentration. This is because the extracting agents used are solvents for which the distribution coefficient of the trace component is much greater than that of the main component[10].

A method particularly widely used in the gas-chromatographic analysis of atmospheric pollutants is frontal non-equilibrium concentration, based on the complete absorption of heavy impurities by sorbents with a highly developed surface. The substances being analysed are collected in traps (columns) filled with a small quantity of sorbent (silica gel, active carbon, polymeric sorbents)[4,11]. These are then desorbed and separated in a chromatographic column. The calculation of the minimum length of the trap, that is the length in which all the heavy trace components being analysed are completely retained, has been described in a monograph[10]; the equations given make it possible to formulate the principal requirements to be satisfied by the parameters of the concentration process and to carry out different versions of the analysis. An advantage of the frontal method of concentration is that it is possible to absorb large quantities of trace components quantitatively from the air (high degree of enrichment). In addition, sampling is usually carried out at the temperature of the surrounding medium (rarely with cooling). Moisture does not interfere in the determination for most sorbents (active carbon, graphitised carbon black, Porapak-S), since these sorbents are hydrophobic. By concentrating the substances in the sample on adsorbents, it is possible to achieve a very high sensitivity of the determination; it is often not necessary to pass large volumes of air through the trap, particularly when a sensitive detector is used. In this case the trap acts as a sampler rather than a concentrator.

A disadvantage of the frontal method of concentrating trace quantities is the difficulty of desorbing the substances absorbed by the trap, particularly when the trap is heated (that is in thermal desorption). A high desorption temperature for the trace components may lead to various undesirable side reactions, for example in the determination of unstable compounds. It is often therefore preferable to use displacement (extraction) of the trace components by a suitable solvent[10].

An adsorbent used particularly frequently in the frontal concentration of trace components is active carbon, which at a temperature from −60°C to +20°C can be used successfully for sampling and concentrating pollutants in atmospheric[4] and industrial[12] air. It should be noted that a concentrator containing active carbon has a very high adsorption capacity and retains micro-components strongly, making their thermal desorption difficult. Moreover, carbon reacts with various sulphur-containing compounds, and to trap effectively substances with a low molecular weight (ethylene, methylene chloride), extensive cooling of the trap is required[4]. Nevertheless, according to data obtained by American workers, the best method for the chromatographic determination of micro-quantities of organic substances in air involves the passage of large quantities of the contaminated air (about 10 litres) through active carbon[13] with subsequent desorption of the sorbed trace components by carbon disulphide and analysis of the extract obtained[14]. The efficiency of the adsorption of most organic substances on active carbon is almost 100%, and is not influenced by the volume of the sample nor the rate of sampling. The efficiency of the desorption of organic substances from carbon using carbon disulphide is on the average greater than 90%[15] (according to the data of the National Institute for Occupational Safety and Health (USA)[16] it varies for different substances in the range 81–100%).

The trapping of micro-components from air in a column containing silica gel at ordinary or more particularly at low temperatures is very effective. Silica gel is widely used to concentrate light and heavy hydrocarbons[4], and also organic substances of other classes and inorganic substances[17]. An unsatisfactory feature of silica gel is its highly hydrophilic nature and the incomplete trapping of light hydrocarbons (up to C_3). Thus ethylene is not completely sorbed on silica gel even when the trap is cooled to

−78°C.[4] In this case it is necessary to use more effective sorbents, for example molecular sieves, which are also among the best adsorbents for carbon dioxide[18]. The selectivity of zeolites with respect to various classes of compound and individual substances makes it possible to use them for the directed control and identification of micro-components[10]. A serious disadvantage of these adsorbents is the difficulty of desorbing the trace components, particularly heavy components.

Thermal graphitised carbon black, treated with hydrogen at a high temperature, is also used to concentrate trace components. At low temperatures this non-specific adsorbent makes it possible to trap micro-quantities of organic and inorganic substances, including reactive compounds, from the surrounding air[9].

To extract readily volatile organic substances from air, use is also made of carbon molecular sieves, consisting of highly pure porous carbon, obtained by the thermal decomposition of polyvinylidene chloride[11]. The high adsorption capacity (specific surface approximately 1000 m^2/g), ease of desorption of trace components, and high thermal stability (the adsorbent is stable up to 400°C) make carbon sieves (Carbopacks) valuable materials for filling sampling adsorption tubes. In addition, Carbopacks are extremely hydrophobic.

Other materials which do not absorb moisture include polymeric sorbents, which together with active carbon are most frequently employed to concentrate harmful substances from air in gas-chromatographic analysis[19]. Porous polymeric sorbents are fairly stable to heat, have a high adsorption capacity, and make it possible to sample air at a high rate; the nature of the polymer influences the selectivity of the absorption of micro-components belonging to different classes. Recently, a new highly effective sorbent, "Tenax GC", has been used to concentrate traces of toxic substances from air. This is a polymer of 2,6-diphenyl-*p*-phenylene oxide, which is now often preferred to other adsorbents[20], is less polar than Porapak-S and Chromosorbs, has a very high thermal stability, and is characterised by a non-specific type of adsorption; this is important for the desorption of high-boiling organic compounds. Tenax is used at temperatures up to 400°C; it does not react with most organic substances, and the efficiency of the adsorption and desorption of micro-quantities of organic compounds of different classes is greater than 90%. Another advantage of this polymer, which is used for the analysis of the most varied trace components in air, is the possibility of high-speed sampling (a sample can be taken in 10–20 s)[21] and the high adsorption capacity for compounds of different molecular weight.

Good results in the chromatographic analysis of air have been obtained using sampling devices filled with hydrophobic packing or surface-modified adsorbents or modified (for example by polyethylene) solid carriers[22], which have been used to analyse substances with different boiling points, including polyaromatic hydrocarbons.

One method for concentrating micro-components from air on sorbents involves the removal of a sample on to a moving sorbent (a so-called fluidised bed). This method ensures more uniform distribution of the substances being analysed throughout the volume of the sorbent and also a high rate of sampling (up to 16 litre min^{-1}).[10] The method is a version of the equilibrium concentrating method.

The methods for the absorption of trace components in a concentrating trap, described above, are based on the complete absorption of heavy trace components. A fundamentally new method was proposed by Novak and coworkers[23]. The gas sample was passed through a small concentrator column containing a suitable stationary phase at the temperature of the surrounding medium, until "breakthrough" of the trace components being analysed. Under these conditions, the concentration of heavy trace components in the sorbent along the entire length of the column is in equilibrium with their concentration in the original mixture. In the frontal method of concentration, only part of the layer of sorbent is treated, whereas in the equilibrium concentrating of trace components, the entire volume of sorbent in the trap is used, so that the total quantity of trace components absorbed in the concentrator is greater in this method. From the analytical viewpoint, the equilibrium concentrating method has the following advantages: 1) it is not necessary to measure accurately the volume of gas passed through the trap; it is necessary only to use an excess of gas and to know accurately the temperature of the concentrator; 2) the method makes it possible to increase selectively the sensitivity of the determination of trace components and to avoid the sorption of components which interfere in the determination, by selecting a suitable filler; 3) it is possible to "equalise" the quantities of individual components in the trap, since the distribution coefficients increase in proportion to the increase in molecular weight and the decrease in vapour pressure. The unsatisfactory features of this method include the need to keep the trap and sorbent at a constant temperature, and the possibly incomplete thermal desorption of the specimen.

A method has been proposed[24] for the gas-chromatographic analysis of atmospheric pollutants by saturating a volatile liquid with the air being studied until the equilibrium distribution of the trace components being determined between the two phases (gas–liquid) is achieved, followed by the chromatographic determination of the equilibrium concentration of trace components in the liquid. This method has the following advantages over the equilibrium concentrating of micro-components in non-volatile liquids with subsequent thermal desorption: it does not require a knowledge of the exact quantity of absorbing liquid, it allows repeated analysis from one sample of the concentrator, and it uses volatile solvents of low molecular weight. In some cases it is appropriate to use a non-volatile liquid as solvent.

The chromatographic analysis is sometimes preceded by a concentration based on the condensation (freezing) of trace components. After sampling, the trap is heated, and the trace components are displaced into the chromatographic column by a stream of carrier gas. To increase the efficiency of the condensation of the trace components, it is necessary to increase the cooled surface area of the trap. This can be achieved by increasing the length of the concentrating tube or by filling it with metal or glass spheres or a column sorbent or adsorbent. Since subsequent thermal desorption of the sample is necessary, thermally stable liquids are used as stationary phases for these sorbents[25]. If extensive cooling of the trap is used, micro-quantities of hydrocarbons in air at a level of 10^{-8}% can be determined using a flame ionisation detector[26]. At the temperature of liquid nitrogen, the stationary phase acts not as a solvent but as an absorbent with a low specific surface. The liquid phase is sometimes applied directly to the walls of the concentrator tube, and the impurities concentrated on it are desorbed by heating and collected again in a trap containing molecular sieves, with cooling by liquid nitrogen[27]. This two-stage concentration makes it possible to determine very low concentrations of trace components in air, for example in the study of various biological substrates. The original method provides for direct sampling into the chromatographic

column, the initial section of which is cooled to −78°C.[28] Here, the three stages of the chromatographic analysis of the trace components (sampling, concentration, and introduction of the sample into the chromatographic column) are replaced by a single operation.

A serious disadvantage of concentration methods involving extensive cooling of the concentrator trap is the condensation of water in the traps, leading to a sharp decrease in the adsorption capacity of the sorbent. Thus in the concentration of trace components, a column containing a reagent for the selective absorption of water vapour is placed in front of the trap. The selection of a drying agent is made difficult by the fact that it must retain only water vapour and readily allow the passage of the other components of the mixture being analysed[10]. Heated calcium chloride and magnesium perchlorate are often used to dry specimens of air for analysis[29]. It must be remembered, that Anhydrone irreversibly absorbs nitro-compounds, ethers, nitriles, and unsaturated hydrocarbons. Anhydrous potassium carbonate is a universal and readily accessible drying agent for organic compounds. Hydrocarbons, aldehydes, ketones, alcohols, esters, and many other organic compounds pass practically unchanged through absorbing columns containing potassium carbonate[30].

The temperature of the cooling mixture must be 150–180 K lower than the boiling points of the compounds being trapped from the air. If the temperature is too low, however, aerosols which are not held in the trap may be formed. Thus liquid nitrogen is suitable as a cooling agent only to trap the vapours of compounds which boil at temperatures not exceeding 100°C.[10]

The removal of aerosols and solid particles from air has its own specific features, associated with the fact that they are not absorbed by the usual sorbents. The sampling of aerosols, which represent the form in which most high-boiling hydrocarbons are present in air, and also solid particles (dust, soot) is carried out on fine-fibre filters of glass, plastic, or ceramic[31]. The compounds of the sample collected on the filter are usually extracted in a Soxhlet apparatus, and the resulting solution analysed. Specimens of solid particles carrying various chemical compounds on their surface in the adsorbed state are treated similarly. Aerosols of metals and various inorganic compounds (oxides, salts) are collected on filters of glass fibre or on highly-dispersed fibrous filters of polymeric materials (AFA-V-10 polyvinyl chloride filters).

An important contribution to the theory and development of methods for the analysis of micro-components‡ has been made by the work of Soviet scientists. The methods of chromatography without a carrier gas, many of which were first proposed and developed by Zhukhovitskii and coworkers[32], and which are also called high-concentration gas chromatography, make it possible, under isothermal conditions, to obtain a concentrated zone of both light and heavy trace components at the column outlet. The use of chromatography without a carrier gas, proposed by Zhukhovitskii and Turkel'taub[33], makes it possible to improve and simplify many methods for the analysis of trace components. The method of vacancy chromatography[34] is of considerable importance for the determination of trace components in air and other gases. A high degree of enrichment of the sample in the micro-components being analysed can be achieved by a thermal dynamic method of concentration[35] based on the use of a heater with a negative temperature gradient, moving at intervals along the chromatographic column; the principal component of the mixture being analysed is used as carrier gas. Under the influence of the thermal field, the trace components, which are sorbed more effectively than the principal component, are concentrated, move along the column, and are eluted from it at intervals. The trace component zones become narrower, and sharp separation of the zones takes place. These studies have made it possible to design several forms of chromatograph specially for the analysis of micro-components; these are now produced regularly by Soviet industry, in particular the "Luch" chromatograph, which uses enrichment of the micro-components for analysis on previously evacuated columns[36].

An interesting development of the method of chemical concentration was proposed by Sakharov and coworkers[37], who increased the sensitivity by chemical concentration of the micro-components being analysed, by means of a series of successive chemical reactions.

Since the analysis of micro-components exhibits a whole series of characteristic features, and the determination of trace quantities of harmful substances in air encounters various difficulties, these questions must be examined in more detail. Even in its present form, chromatography represents a method for determining traces (10^{-1}–10^{-7}%) and micro-quantities (below 10^{-7}%) of substances, that is it deals with specimens in the region of 10^{-8} g. At the same time, in some cases it is necessary to detect the compounds being analysed in quantities of 10^{-15} g. In quantitative analysis, the range of concentrations extends from 99.9999% to 10^{-10}%, and in the near future it may be necessary to work at even lower concentrations[5].

The limit of detection of the compounds being analysed is determined by a number of restrictions, namely: 1) non-representative removal of an average sample; 2) the inclusion of new components (contaminants) in the mixture being analysed, at different stages of the analysis (from the sampling device to detection) from foreign sources, and by consequent reactions of the components being analysed; 3) loss of material by selective adsorption during the analysis, and also by chemical reaction; and 4) a decrease in the maximum concentration of a substance during separation.

The problems of the removal of a representative sample are general for all analytical methods and are not examined in the present review. Selective sorption must be examined in more detail. This restriction is associated with the removal of the sample, and a number of factors—temperature, the polarity of the surface and the substances in the sample, their concentration, the degree of turbulence of the flow, and the ratio of the volume to the surface—all influence the results of the analysis. It is particularly difficult to determine traces of non-polar substances present in polar compounds, and also traces of polar substances present in non-polar compounds. The determination of traces of substances at concentrations lower than 3×10^{-6}% depends on the sorptive activity of the surface of the sampling device, which may lead to systematic errors. In this concentration range, therefore, the sampling should be dynamic[5]. In the analysis of micro-components, it is necessary to use special sampling methods, preferably of the continuous type, and special materials for the construction of the containers and connecting tubes; the roughness coefficient of the surface should be close to unity[5,38].

‡ The theory of the analysis and chromatographic separation of micro-components is not discussed in the present work, since it has been examined in detail in a number of papers and in a monograph[10].

Kaiser[5,39] lists the following difficulties in the analysis of trace quantities.

1. The number of individual chemical compounds which may be present in small quantities is extremely large. At concentrations in the region of 10^{-4}%, in addition to the principal component (for example with air) with a concentration of 99%, the maximum possible number of components present in trace quantities is 10000, and in many cases only several hundred can be detected individually. At concentrations in the region of 10^{-7}%, in addition to a principal component at a concentration of 99.9%, the possible number of components present in trace quantities reaches 10^6. All this complicates considerably the analysis and particularly the individual identification of micro-quantities of harmful substances present in air, after their chromatographic separation.

2. The chemical reactivity of a number of components present in trace quantities is extremely high. Many facts indicate that some substances present in concentrations of $\sim 10^{-7}$% cannot be concentrated to 10^{-4}%, since they tend to decompose at these concentrations. This introduces a considerable restriction on the possibility of concentrating micro-quantities of various substances from air.

3. The concentration of stable substances present in a sample in trace quantities may be so low, and the concentration of reactive unstable substances so high, that many attempts to manipulate the sample will systematically lead to a false result.

These difficulties in the analysis of micro-quantities of harmful substances in air cannot always be overcome, but there is now a fairly large number of chromatographic methods which make it possible to analyse atmospheric pollutants with a relative error of not more than 15–20%.

III. DETECTORS. CALIBRATION

Although more than fifty detectors of different types are now used in gas-chromatographic analysis, very few of these have found extensive application for the analysis of atmospheric pollutants. This is due chiefly to the inadequate sensitivity of many detectors, which makes it impossible to carry out the direct determination of ultra-small quantities of substances in air samples. The detailed characteristics and applications of chromatographic detectors for the analysis of micro-components have been described in monographs[40,41] and in a large number of reviews devoted to detectors of different types[42,43] and problems of specific detection[44].

1. Universal Detectors

Of the gas-chromatographic detectors known at present, the flame ionisation detector (FID) is most frequently used in atmospheric and industrial chemistry; the FID is an almost ideal detector for the analysis of micro-quantities of hydrocarbons and most organic compounds. It makes it possible to analyse hydrocarbons at a concentration in air of $\sim 10^{-7}$–10^{-8}%, and when combined with preliminary concentration of the sample, even from small volumes of air, the sensitivity of the determination is increased by an order of magnitude[4]. The FID, which was previously regarded as insensitive to most inorganic compounds[40], also reacts to the presence, in the sample being analysed, of oxygen, nitric oxide, nitrous oxide[45,46], ammonia, phosphine, other oxides of nitrogen and cyanogen[47], oxides of carbon[48], and perfluoroalkanes[49]; it can also be used to determine low concentrations in air of sulphur dioxide, hydrogen sulphide, carbon disulphide, and carbonyl sulphide, mixed with thiols[50]. For example, it is convenient to use the flame ionisation detector, the sensitivity of which for carbon disulphide depends on the rate of flow of hydrogen and the carrier gas, the flame temperature, and other factors, for determining carbon disulphide vapour at concentrations ≤ 0.01%. In this concentration range, the magnitude of the FID signal is directly proportional to the concentration; the formation of ions apparently takes place via the formation, from carbon disulphide, of a small number of $CH^{\cdot}$ radicals, followed by the ionisation reaction $CH^{\cdot} + O = CHO^{+} + e$, characteristic of the operation of the FID.[40,51] By using perfluoromethane (Freon 116) as carrier gas, it is possible to detect sulphur dioxide and carbon dioxide, and also nitrogen and inert gases[52]. The use of ammonia as carrier gas has made it possible to increase considerably the sensitivity of the FID towards chlorinated hydrocarbons[53].

An even more universal detector than the FID is the argon ionisation detector, used for the analysis of many organic and inorganic compounds[40]. The sensitivity of the argon detector towards inorganic compounds of sulphur lies in the range 10^{-6}–10^{-3}%;[54] for phosphine the value is $\sim 10^{-4}$%.[55] The threshold sensitivity of this detector for oxygen, nitrogen, hydrogen, methane, oxides of nitrogen and carbon, and sulphur dioxide is $\sim 10^{-5}$%,[40] although for organic compounds it lies at the sensitivity level of the FID.

Recently, micro-components in air have been analysed using a pyroelectric katharometer, the sensitivity of which is 500 times that of an ordinary thermistor katharometer[50].

2. Selective Detectors

The analysis of atmospheric pollutants is made particularly effective by using selective highly sensitive detectors--electron capture (ECD), thermo-ionic (TID), flame photometric (FPD), and coulometric (COULD) detectors—which make it possible to carry out the qualitative and quantitative analysis of micro-concentrations of pollutants in complex many-component mixtures of substances of different classes. Comparison of the chromatograms obtained using universal detectors (reacting to all components) and selective detectors (reacting to molecules with definite hetero-atoms and functional groups) provides a reliable means of identifying trace components in complex mixtures in atmospheric and industrial air. This method makes it possible, against a background of the hydrocarbons most frequently encountered in polluted air, to determine halogens (ECD), sulphur (FPD), phosphorus (TID), etc. Combinations of FID and ECD, FID and FPD, and FID and COULD are particularly effective. The mass-spectral detector[40] has a unique selectivity.

The most sensitive detector in gas chromatography (see Table) is the electron capture detector[57], which, in spite of its short linear range, is widely used to determine halogens, sulphur-, nitrogen-, and halogen-containing organic compounds, and also metal aerosols (as chelate or organometallic compounds) in air[58,59]. This is one of the few detectors which can be used to determine nitrogen dioxide[60], inorganic compounds of sulphur[61], and other reactive substances by the direct method at concentrations of $\sim 10^{-7}$–10^{-4}%.[62] The ECD can be used to detect micro-quantities of polyaromatic hydrocarbons[63]; in the determination of meteorological tracers, for example sulphur hexafluoride, in the atmosphere, the sensitivity of the analysis reaches the phenomenal value of 2×10^{-10}%.[64]

The very high sensitivity of the ECD towards compounds of the halogens (which increases with increased number of halogen atoms in the molecule), and in particular to pesticides[65], has made this detector irreplaceable in the analysis of residual quantities of pesticides in the environment.

Sensitivity and selectivity of the detectors most frequently used for the analysis of pollutants in air.

Detector	Selectivity*							Threshold sensitivity, wt.%	Refs.
	N	S	Hal	O	P	hydrocarbons	OMC		
FID	–	–	–	–	–	–	–	10^{-8}	40, 41
Mass spectrometer	–	–	–	–	–	–	–	10^{-8}	40
ECD	+	+	+	+	+	PAH	+	10^{-9}	58, 63
TID	+	–	+	–	+	–	–	$5\cdot10^{-9}$	63, 74
FPD	–	+	+	–	+	–	+	10^{-8}	71, 72
COULD	+	+	+	–	+	–	–	10^{-7}	76
Detector with microwave radiation	–	+	+	–	+	+	+	10^{-8}	63, 80
Spectrofluorimetric detector	–	–	–	–	–	AH PAH	–	10^{-5}	40, 63

*Symbols: PAH = polyaromatic hydrocarbons; AH = aromatic hydrocarbons; OMC = organometallic compounds. The "plus" symbol indicates the class of compound to which the given detector is most sensitive.

The FPD is also frequently used for this purpose. The FPD has a high selectivity and is used for the analysis of such atmospheric pollutants as sulphur-, phosphorus-, nitrogen-, and halogen-derivatives of hydrocarbons, oxides of nitrogen and sulphur, hydrogen fluoride, nitrogen fluorides, carbon disulphide, and metals (as chelate compounds)[40,63,66]. The FPD has been used to determine nanogram quantities of the halogens and alkyl halides[67,68] and 10^{-1}–10^{-8}% of volatile compounds of sulphur and phosphorus[60,70], and a combination of an FPD and an FID makes it possible to analyse separately, in atmospheric air, micro-quantities of sulphur-, chlorine-, phosphorus-, and nitrogen-containing compounds[71]. The chief characteristic of the FPD and its use for the analysis of volatile compounds of sulphur in air have been described[72]. This detector makes it possible to determine, in polluted air, ~ 10^{-7}% of sulphur dioxide, hydrogen sulphide, carbon disulphide, carbon oxide sulphide, sulphides, and thiols[73].

Ultra-small quantities of substances containing phosphorus, nitrogen, and halogens can be detected using the TID, the threshold sensitivity of which is 2×10^{-6}% for chlorine, 10^{-8}% for nitrogen, and 5×10^{-9}% for phosphorus[40,74]. Thus the TID, together with the ECD, is used for the analysis of residual quantities of pesticides, and also to determine toxic organic compounds of nitrogen and chlorine in air[41,75].

The COULD has a high sensitivity towards compounds of sulphur, nitrogen, the halogens, and phosphorus[63]. It has been used to determine micro-quantities of the halogens, sulphur dioxide, and hydrogen sulphide (10^{-5}%) in air[76]. The COULD, like other selective detectors (ECD, FPD, TID), has an extremely low sensitivity towards hydrocarbons (lower by 3–5 orders of magnitude than that for heteroatoms).

Among the other detectors used to determine traces of harmful substances in air, the helium ionisation detector has a high sensitivity. It makes it possible to analyse the permanent gases, various light compounds of sulphur, and light hydrocarbons (~ 10^{-7}%)[77], and also to determine low concentrations of chlorine and Freons in air[78].

In the analysis of air, increasing use is being made of sensitive spectral detectors, the selectivity of which may vary over a wide range; for example, the emission spectrometer[79], a detector using microwave radiation[80], and a spectrofluorimetric detector, selective towards aromatic compounds[63]. A very valuable detector for the gas-chromatographic analysis of micro-components is the mass spectrometer, the sensitivity of which is comparable to that of the FID.[40] A combination of gas chromatography and mass spectrometry makes it possible to determine very low concentrations of toxic substances in air, and this method is now preferred to all other methods for identifying traces of a substance leaving a chromatographic column[81].

3. Preparation of Standard Mixtures and Calibration

The magnitude of the signal of differential detectors depends to a considerable extent on the nature of the compounds being analysed. Thus to carry out accurate quantitative determinations it is necessary to know the individual sensitivity of the detecting assembly with respect to the substances being analysed. For the calibration, that is for the determination of the quantitative relationship between the instrument signal and the absolute concentration of a component, it is necessary to have mixtures of the compounds being analysed with known concentrations, that is standard mixtures. The basic principles, methods, and characteristic features of the calibration of chromatographic detectors has been examined in detail[40,41,43] and are well known.

Static methods for preparing these mixtures are simple and most convenient for gaseous and volatile substances. The simplest involves the use of gas-measuring devices of known volume, glass bottles, and other containers, into which an accurately known quantity of the substance or mixture of substances being analysed is introduced[82,83]. Static methods of calibration are characterised by a large number of possible sources of error, and are therefore less reliable than dynamic methods; the chief disadvantage of static methods of preparing standard mixtures is the adsorption of micro-components on the walls of the containers (in some cases the losses may reach 50%[10]).

The dynamic method of calibration, which does not have these disadvantages, is used much more frequently in analysis. The simplest version of this method involves the dilution (sometimes in several stages) of pure cylinder gases, which are not always available, however. Here it is necessary to have a special measuring apparatus which makes it possible to control the gas flow rate very accurately[84]. The National Bureau of Standards (USA) has developed an apparatus for creating micro-concentrations of hydrogen fluoride, arsine, and phosgene by dilution[85]. The method makes it possible to obtain mixtures with a concentration of substances in the range 0.5–5 times the MPC. The method of exponential dilution[86], previously proposed by Lovelock[10], makes it possible to decrease considerably adsorption on the walls of the container and to prepare very low concentrations of several substances simultaneously. For the production of ultra-low concentrations in a stream or in a closed volume, a method based on the electrochemical preparation of the components of

the mixture being produced[87] is of interest. A significant advantage of this method is the absence of parts subject to friction and the ease of control of the rate of liberation of the gas being calibrated, by changing the current strength through the electrolyte.

The method of preparing standard mixtures of micro-quantities of different substances, based on the diffusion of the gases or vapours of liquids into the stream of diluent gas (carrier gas), is most widely used. The diffusion may take place through a tube, a porous surface (glass or ceramic), or a polymer film; in diffusion methods, sorption on the walls of the vessels is not significant. The use of diffusion cells makes it possible to calculate the concentration of the mixture, but the accuracy of the dosage and the reproducibility of the method are not always satisfactory[88].

The ability of micro-components to diffuse through the walls of plastic tubing has aroused considerable interest among analytical chemists[89]. It has been found that the stationary rate of diffusion of gases through the walls of tubes of ethylene and propylene Fluoroplasts at a constant temperature is practically constant, depending to slight extent on the composition and pressure of the gas. The rate of diffusion (and hence the concentration of micro-components obtained) is determined from the decrease in the weight of the tube containing the liquefied gas. The method of preparing standard mixtures of micro-concentrations of different substances based on this phenomenon has been widely used. The permeability of polymer tubes to different substances has been studied[89,90]. Diffusion through Teflon has been used to prepare standard mixtures of hydrogen sulphide, carbon disulphide, hydrogen fluoride, chlorine, ammonia, phosgene, propane, and methanethiol in air[91,92]. The method of preparing the filling the diffusion tubes has been described[93]. Diffusion through a Teflon tube may be constant for several years, and the total error of this dosage method does not exceed 1–2%.[94] The preparation of mixtures of moist air containing oxides of carbon, sulphur, nitrogen, ammonia, chlorine, hydrogen chloride, and other gases has been described[95]. The construction of an apparatus for the accurately controlled dilution of a gas specimen using semi-permeable polymer membranes has been discussed[96]. For this purpose, use has also been made of silicone rubber, which passes the vapours of organic substances at a rate directly proportional to the surface area of the tube and inversely proportional to its wall thickness[97].

A simple method for preparing micro-concentrations of chlorine and nitrogen dioxide involves the saturation, by these gases, of BAU active carbon, from which the gases can be desorbed to give concentrations of the gases at the level of the MPC, which remain constant for a prolonged period[98]. Various experimental problems in the preparation of standard mixtures and the calibration of chromatographs have been discussed in various papers[99,100] and a monograph[13]. An interesting review of methods for preparing standard mixtures at ultramicro-concentrations has been published[101]. The theory of the principal methods for calibrating instruments for gas analysis (in particular chromatographs) has been described in detail[102].

IV. CHARACTERISTIC FEATURES OF THE QUALITATIVE AND QUANTITATIVE ANALYSIS OF MICRO-QUANTITIES OF HARMFUL SUBSTANCES IN AIR

The principal methods for identifying micro-concentrations of harmful substances in complex mixtures in polluted air, used in conjunction with gas chromatography, have been examined in detail[63]. The most promising method for the qualitative analysis of micro-components in complex mixtures of organic and inorganic compounds of different classes is undoubtedly the combination of gas-chromatographic separation with mass-spectral analysis of the individual components of the sample, leaving the chromatographic column (GC-MS). This method of identification gives the most reliable results and is widely used in the analysis of atmospheric air and the air in living quarters and in industrial plants (gas liberation from polymers, rubber, plastics, etc.). After sampling and preliminary treatment, the sample is introduced into the gas chromatograph–mass spectrometer system[103], and the results of the analysis are processed on a computer[104]. The method is expensive and complex, but is being used on an increasing scale for the control of pollutants in the environment, particularly in those cases where the polluted air contains many-component mixtures of toxic substances.

Simpler methods are now being used for the same purposes, and these methods, taken together, may give more or less identical information on the composition of complex mixtures of chemical substances. One such method is the chromatographic-distribution method of identifying volatile organic compounds[105]. This method makes it possible to carry out the qualitative and quantitative analysis of organic substances (dissolved in an absorbing liquid) from the relative distribution coefficients in a liquid–liquid system (K_{rel}). The value of K_{rel} is determined by gas chromatography from the results of the analysis of aliquot portions of both liquid phases.

Various methods for the qualitative analysis of micro-components after chromatographic separation of the compounds in the sample have been described[63,106]. For this purpose it is also possible to use purely chromatographic methods, identifying the substances in the sample from their retention characteristics[107–109] and from their logarithmic relationships[63,110] or by reaction gas chromatography[63,111–113] and various other methods of analysis[114].

Sometimes, the components leaving a chromatographic column are identified using colour reactions for individual functional groups in organic compounds[63], but their sensitivity (0.1–1.0 μg)[115] is often insufficient (in analysis on capillary columns and in various other cases when small samples are being analysed). The infrared spectrum of a substance provides a reliable method for its identification. The successful use of this method to characterise individual substances after chromatographic separation is difficult, however, in the case of micro-components, and is fairly infrequently encountered in the analysis of air, due to the difficulty of accumulating a sufficient quantity of substance (20–30 mg) to obtain infrared spectra[63]. A spectrometer can also be used directly as a gas-chromatographic detector, but this requires a special analytical technique (spectrometer connected to the chromatograph, special cells, etc.)[116].

The successful identification of micro-quantities of harmful substances in complex mixtures in polluted air depends largely on the completeness of the separation of the compounds being analysed in the sample. Thus the chromatographic separation of toxic substances in air samples is carried out using capillary packed columns containing selective liquid phases[117] or highly efficient capillary columns[118]. The characteristic features of the identification and quantitative analysis of micro-components in air have been examined[10,119,120].

It has been shown[121] that the analysis of various aromatic hydrocarbons at a concentration of 10^{-7}% from one litre of air can be carried out with an accuracy of ±25%.

The accuracy of the analysis depends on the complexity of the system used for sampling, concentrating, preparation of the sample for chromatographic separation, and the chosen method of calibration. The use of even a moderately complex concentrating system may in itself introduce an additional source of errors in all analytical operations[4]. To increase the accuracy of the chromatographic analysis of atmospheric pollutants, it is necessary to use special vapour–gas mixtures as standards, and also to measure the rate of flow of air by means of additional flow-meters in the dosage systems[99,101]. The methods of calculation used in chromatography and the question of the accuracy of chromatographic analysis have been discussed[122,123].

V. ANALYSIS OF INORGANIC SUBSTANCES

The principal inorganic atmospheric pollutants are the oxides of carbon, nitrogen, and sulphur, hydrogen sulphide, and the halogens, the main sources of which are industrial emission and automobile exhaust. In addition, atmospheric dust contains highly toxic oxides and aerosols of metals (lead, mercury, beryllium, etc.). The compositions of inorganic industrial poisons are determined by the specific features of the production process (inorganic synthesis, metallurgy, textile production, etc.). Various problems of the chromatographic analysis of micro-quantities of harmful inorganic substances in air have been discussed[4,124].

1. Halogens and Their Compounds

The determination in air of micro-concentrations of the halogens and their derivatives, which exhibit an appreciable toxicity, involves familiar difficulties, associated chiefly with the high reactivity of these substances: they react with the material of the traps, the chromatographic packing, the connecting tubes of the chromatographs, and the detectors used. This can be partly avoided by using apparatus constructed from corrosion-resistant materials and by using inert sorbents and stationary phases stable towards reactive compounds. Nevertheless, an unavoidable feature of the analysis of traces of corrosive and reactive substances is the prolonged conditioning of the chromatographic apparatus and sorbents in contact with the gases being analysed[9]. All these problems in the chromatographic analysis of air have been discussed in detail[9,124–127].

The gas-chromatographic determination in air of the extremely reactive fluorine and most of its compounds is carried out using completely inert sorbents and liquid phases (chlorofluorohydrocarbons and polymers based on them), and the parts of the chromatographic apparatus (columns, connecting tubes, detectors) are made of Teflon and pure nickel and its alloys[124]. The methods of sampling air contaminated by fluorine-containing inorganic compounds have been examined[128], but there is very little published information on the gas-chromatographic determination of fluorine in air, and this generally relates to the analysis of not fluorine, but its derivatives, for example triethylfluorosilane[129]. The very reactive chlorine trifluoride, which is liberated from liquid oxidants in the transport of rocket fuel, has been determined (at a concentration of 5×10^{-6}%) on a chromatograph with an ECD on a packing containing a methylsilicone oil after separation from air and halogens[130]. Analyses of this kind cannot be carried out on columns with halogen-containing stationary liquid phases, since the ECD is very sensitive to halogens.

The analysis of chlorine and hydrogen chloride does not require such rigorous conditions. These substances are separated on ordinary stationary phases[124], but particular care is necessary with the very unstable chlorine dioxide, particularly during its concentration[9]. The quantitative determination of the MPC of chlorine and nitrogen dioxide in the presence of other reactive gases has been described[131].

The conditions for the gas-chromatographic determination of various reactive gases in air have been examined in detail[132]. It was established that by using an ECD it is possible to analyse 10^{-4}–10^{-5}% of chlorine and oxides of sulphur and nitrogen with a relative error of ~ 10%, although for nitrogen dioxide the error may reach 50%.

The chromatographic analysis of phosgene presents no particular difficulty, and the use of an ECD makes it possible to analyse this gas in mixtures with chlorinated hydrocarbons in concentrations of ~ 10^{-6}–10^{-7}%[133]. The high sensitivity of the ECD makes it possible to analyse air for ultramicroconcentrations of sulphur hexafluoride and various other tracers used to study the propagation of air currents in the atmosphere and various pollutants in the troposphere (lower atmosphere)[64].

2. Compounds of Nitrogen

Among many methods for the analysis of oxides of nitrogen[134,135], their gas-chromatographic determination in air has recently been widely used[136], but at present this method is not preferred, because the chromatographic analysis of micro-quantities of oxides of nitrogen, particularly nitrogen dioxide, encounters a whole series of difficulties, associated with the high reactivity of these compounds. For the analysis of micro-concentrations of nitrogen dioxide, it is best to use glass columns and inert stationary phases based on chlorofluorohydrocarbons[137]. However, prolonged conditioning of the chromatographic packing in the presence of oxides of nitrogen makes it possible to analyse these and other reactive gases on ordinary stationary phases, for example diethyl phthalate[131]. Various chromatographic columns and detectors used for this purpose have been discussed[138]. The detection of nitrogen dioxide by a katharometer after preliminary concentration of the sample makes it possible to determine ~ 10^{-4}% of this gas in air[131]. A similar result is obtained in the direct determination of oxides of nitrogen using an ECD[139].

In view of the difficulties of the direct analysis of micro-quantities of nitrogen dioxide, the methods of reaction gas chromatography have been increasingly used in recent years for this purpose. By using an ECD, it is possible to determine with a high sensitivity the products of the reaction of oxides of nitrogen with phosphines or phosphites[140], styrene, or xylenes[141]. The conversion of nitrogen dioxide into nitrobenzene and the determination of the latter (10^{-12} g) using an ECD has been described[142].

The analysis of oxides of nitrogen in the atmosphere is further complicated by the fact that, under the influence of sunlight, they react with hydrocarbons, forming in the smog an even more reactive mixture of ozone, peroxyacetyl nitrate, and peroxybenzoyl nitrate. Methods for sampling air and for the chromatographic analysis of

oxides of nitrogen in the atmosphere in the presence of oxides of sulphur and carbon, oxidants, and hydrocarbons have been described[143,144].

Equal difficulties are encountered in the chromatographic analysis of nitric oxide, which is usually present in air mixed with other oxides of nitrogen[140]. The accuracy of the analysis can be improved by the quantitative removal of nitrogen dioxide in a special column using 2,2',2''-nitrilotri(ethanol) on a diatomite carrier[145]; to increase the sensitivity, the products of the reaction of nitric oxide with sodium butoxide are detected using an FID.[146]

The determination of nitrous oxide in atmospheric air presents no difficulties, and is generally carried out by gas-adsorption chromatography[147]. An interesting feature is that with increase in temperature from 20°C to 400°C the sensitivity of the ECD towards nitrous oxide increases by a factor of 1000. This phenomenon can be used to monitor low concentrations of nitrous oxide in the atmosphere[147].

The electron-capture detector makes it possible to determine 10^{-7}% of nitrates and nitrites in air and in biological media after conversion to nitrobenzene[148]. The direct chromatographic analysis of ammonia, particularly in the presence of moisture, is complicated by the spreading of the peak corresponding to this substance on most available packings[149]. The determination of ammonia in cigarette smoke has been described[150]; ammonia has been detected together with other gases in the products of the combustion of plastics[151].

Similar mixtures of inorganic gases, also containing cyanide vapours, are encountered in industrial air contaminated by the products of the combustion of polyurethanes[152]. Micro-quantities of hydrogen cyanide and cyanogen (~ 10^{-4}%) have been determined in air using an FID after the separation of hydrogen cyanide from other gases on a column containing Carbopacks on Teflon[153]. A method has been described for removing cyanide vapours on silica gel with subsequent extraction of the sample by methanol and chromatographic analysis of the resulting solution at room temperature on a column containing adiponitrile on celite[154]. Traces of cyanogen chloride in air have been determined using an ECD[155].

3. Compounds of Sulphur and Phosphorus

Inorganic compounds of sulphur are sampled and concentrated using cooled traps containing column packings[156] or concentration columns containing 13X molecular sieves[157] or active carbon[158] as adsorbents. In the last case, the sample is extracted from the column using benzene, and analysed on a chromatograph with a flame photometric detector.

In the analysis of compounds of sulphur, glass or Teflon columns are used[159], and Porapak-S is successfully used as sorbent for the chromatographic separation. Columns containing different packings, previously conditioned by the gases being analysed, are also used. The best solid carriers are Chromosorb W and porous polymeric sorbents, on which various liquid phases (chiefly polar phases) are deposited[160]. In the opinion of some authors[161], the separation of organic compounds of sulphur, hydrogen sulphide, sulphur dioxide, and carbonyl sulphide present in air in very low concentrations is best carried out using chromatographic columns containing Carbopacks, treated with a solution of phosphoric acid and nitrylsilicone XE-60.

Gas-chromatographic methods for determining micro-quantities of carbon disulphide and carbon oxide sulphide[158] and hydrogen sulphide[162], and the analysis of complex mixtures of inorganic compounds of sulphur in the atmosphere[163], in the neighbourhood of a cellulose and paper plant[164], in the effluent gases from plants producing starch[165], and in sulphuric acid manufacture[166] have been described.

Cryogenic gas chromatography has recently been used for the analysis of atmospheric pollutants. Traces of the oxides of nitrogen, carbon, and sulphur, hydrogen sulphide, carbonyl sulphide, and light hydrocarbons are much more effectively separated on ordinary chromatographic packing at low temperatures[167].

Elemental phosphorus in air is determined by trapping it in an absorber containing xylene and analysing an aliquot portion of the solution on a chromatograph with an FPD[168]. Phosphine can be determined in air at a concentration of 10^{-7}% using ionisation detectors[169].

4. Permanent Gases

The permanent gases and other low-boiling gases are generally analysed by gas-adsorption chromatography, since the solubility of these gases in the liquids used as stationary phases in gas-liquid chromatography is usually too low. Most work on the chromatography of the permanent gases has been devoted to the determination of the oxides of carbon, liberated into the atmosphere in various processes of fuel combustion and in forest fires.

The chromatographic separation of micro-quantities of the permanent gases is usually carried out using active carbon, molecular sieves, and porous polymers as adsorbents[124]. For the analysis of mixtures of substances having a wide range of boiling points (permanent and inert gases and hydrocarbons), 2–3 columns with different adsorbents are used[170].

In recent years, several detectors have been described, which make it possible to determine with a high sensitivity (10^{-4}–10^{-5}%) the oxides of carbon and other permanent gases in the atmosphere and in industrial air. These include discharge detectors[171], ultrasonic detectors[172], and the pyroelectric katharometer[173]. The last detector can be used to detect reliably 5×10^{-5} vol.% of carbon monoxide with a relative error of not more than 5%. A high sensitivity in the determination of CO can also be achieved using a detector of low sensitivity. In this case the carbon monoxide present in a sample of several litres of air is concentrated by extensive cooling on a column containing CaA zeolite[174]. By concentrating the CO in stages, it is possible to determine less than 10^{-6}% of carbon monoxide[175]. Nevertheless, the analysis of micro-concentrations of carbon monoxide (and sometimes also carbon dioxide) is most frequently carried out by catalytic hydrogenation of CO to methane with subsequent detection of the CH_4 on an FID.[176] The sensitivity of this method is ~ 10^{-5}%; an unsatisfactory feature is the low accuracy and the time taken for the conversion.

The chromatographic determination of micro-quantities of carbon dioxide is carried out using columns containing silica gel and other adsorbents[177]. In addition to the analysis of atmospheric air[178], gas chromatography is used to determine CO,[179] CO and CH_4,[180] and CO and light hydrocarbons[181] in respirator gases, and also to analyse air in sealed isolated compartments[182] and mines[183].

Gas chromatography can also be used to determine traces of ozone, separated from air and chlorine on silica gel at low temperatures, and detected using an ECD ($\sim 5 \times 10^{-3}\%$) [184] §.

5. Metal Aerosols

The ability of various metals to form volatile complex compounds with organic ligands, particularly chelate compounds [185], has made it possible to use gas chromatography to determine the aerosols of various toxic metals and their compounds in air.

Only a few minutes are required for the chromatographic analysis of picogram quantities of aluminium and chromium as their chelate compounds with trifluoroacetylacetone (TFA) [186]. The methods of sampling and the conditions for the separation and chromatographic analysis of highly toxic aerosols of metallic beryllium and its compounds have been described [187]. The air being analysed was passed through a filter, the aerosols retained were ashed with the filter and dissolved, and a solution of TFA in benzene was added. An aliquot portion of the benzene solution of the resulting $Be(TFA)_2$ was analysed on a chromatograph using an ECD, which makes it possible to determine metal chelate compounds with a very high sensitivity (10^{-10} g aluminium, 10^{-12} g chromium, and 10^{-13} g beryllium) [188].

VI. ANALYSIS OF ORGANIC SUBSTANCES

1. Readily Volatile Hydrocarbons

Methods for the gas-chromatographic analysis of micro-quantities of hydrocarbons in air have been fairly well developed and described in detail [4,189,190]. The substances present in a sample of polluted air are usually concentrated on a suitable adsorbent (silica gel, active carbon, polymeric sorbents) at the temperature of the surrounding medium (or with cooling), or trapped in a concentrator containing an inert packing at low temperatures, and the separation and analysis are carried out using various sorbents and a flame ionisation detector. For the overall determination of hydrocarbons and other organic substances in air [191], the sample being analysed is introduced directly into the FID. For the separate determination of the light hydrocarbons (C_1–C_4), gas-adsorption chromatography is used, with active carbon, silica gel [192], molecular sieves [193], or Porapak-S [194] as adsorbents. Micro-quantities of heavier hydrocarbons (beginning from $\sim C_5$–C_6) are analysed by gas-liquid chromatography, and several dozen liquids of different polarity are used as stationary phases.

Gas chromatography can be successfully used to analyse samples of polluted air of complex composition containing, in addition to hydrocarbons, their derivatives containing atoms of oxygen, nitrogen, sulphur, and halogens. Mixtures of industrial poisons of this kind are liberated into the air of industrial plants in the preparation, processing, and storage of polymers and technical compositions based on them, and also in the pyrolysis of these materials under different conditions [195,196]. A combination of chromatographic columns with stationary phases of different polarity has made it possible to separate and identify the components of the gases liberated in the vulcanisation of rubber [197] and in rubber mixing [198], and the combination of gas chromatography and mass spectrometry has given detailed information on the composition of the volatile products polluting air when various rubbers are heated [199].

The possibilities provided by gas chromatography in the study of toxic products in atmospheric and industrial air have been extended considerably by the use of highly efficient capillary columns. Approximately 100 paraffinic, naphthenic, and aromatic hydrocarbons have been determined in the air of industrial plants containing white-spirit vapour. The analysis was carried out on a chromatograph with a 70-metre capillary column containing squalane at 100°C [200-202]. A mixture of alkylbenzenes liberated into the air by plants producing polystyrene has been studied similarly [203]. Complex mixtures of hydrocarbons and their derivatives, polluting the air in the production of rubber footwear, have been separated on capillary columns and identified by various physicochemical methods [204]. The use of temperature programming on capillary columns containing silicones has made it possible to separate and identify up to 200 C_3–C_{12} hydrocarbons present in the gases emitted from automobile and diesel engines [205]. The absolute quantity of soot in treated automobile gases has also been determined by gas chromatography after trapping the soot by means of a sitall (glass ceramic) filter and pyrolysis of the sample [206], and the highly toxic tetra-ethyl-lead has been determined in air at a concentration of 1 mg m^{-3} using an ECD [207].

Particularly valuable information on the composition of atmospheric pollutants is given by the combination of gas chromatography and mass spectrometry. This method has been used to determine the concentration of organic pollutants in industrial and city air [208,209]. The sample of air being analysed was passed through a drying agent and a cooled trap containing Tenax GC [210] or Chromosorb W, impregnated with a silicone [211]; the concentrated components were displaced from the trap by heating, into a capillary column connected to the mass spectrometer.

2. Vapours and Aerosols of Hydrocarbons with a Low Volatility

The chromatographic analysis of hydrocarbons with a high molecular weight encounters certain difficulties associated with the sampling, separation, and detection of high-boiling compounds. Organic pollutants of high molecular weight in the form of aerosols, and also adsorbed on dust particles suspended in air, are trapped by mechanical or electrostatic filters and fractionated by extraction or thin-layer chromatography. Methods for isolating organic substances from aerosols and dust, and apparatus and procedures for the analysis of atmospheric pollutants of this kind have been described [212,213].

More than 100 organic substances (C_6–C_{20}) have been identified in city air after passing the sample through a cigarette filter of active carbon or through a column containing graphitised carbon black, with subsequent extraction of the sorbed compounds by carbon disulphide and chromatographic analysis of the substances liberated on a capillary column with a silicone liquid phase [214]. The components of these complex mixtures are identified by the usual chromatographic–mass-spectrometric method [214,215].

Gas chromatography has been used increasingly in recent years to solve the important problem of determining the concentration in air of polycyclic aromatic hydrocarbons (PAH), many of which are carcinogenic. The PAH

§ See also Ref. 340.

present in air, which are usually adsorbed on dust particles, are concentrated on active carbon[216] or collected on a glass fibre filter[217]; they are then extracted by benzene, cyclohexane, or nitromethane, and subsequently analysed by gas chromatography. A simple apparatus for the effective collection of samples of this kind, consisting of a condenser coil containing Tenax GC, has been described[218]. Micro-concentrations of PAH are now successfully separated using modified sorbents. A short column containing celite-545, the surface of which is covered by linear polyethylene, with temperature programming from 70°C to 290°C, can be used to separate 16 polyaromatic hydrocarbons[219], and even to separate such pairs as phenanthrene and anthracene, chrysene and benzanthracene, and perylene and 3,4-benzpyrene. Equally effective results were obtained using a column containing graphitised carbon black[220], and also carbon black impregnated with a small quantity of a polyphenyl ester[221]. This packing makes it possible to separate 3,4- and 1,2-benzpyrenes in 30 min, and anthracene and phenanthrene in 2–3 min (at 320°C).

The combination of gas-chromatographic separation with spectrofluorimetric detection has a high selectivity in the analysis of PAH[222]. The fluorimetric detector, the sensitivity of which with respect to fluorene is not less than 5 ng, can be used to detect selectively even PAH peaks which overlap on the chromatograms[223]. An even greater increase in the selectivity of this analysis can be achieved by preliminary separation of the PAH from the air sample by thin-layer chromatography[224]. Approximately 40 new PAH have been identified in air after separating an extract of the sample by liquid chromatography on a column containing silica gel, with subsequent gas-chromatographic analysis on a capillary column using a mass spectrometer[225]. This method has been used particularly frequently in recent years, and the polyaromatic compounds have been identified by a combination of gas chromatography, mass spectrometry, nuclear magnetic resonance, and computer calculations[226].

Progress in the gas-chromatographic analysis of polynuclear hydrocarbons in recent years has been discussed[227], and it has been pointed out that the extraction of the PAH sample from glass fibre filters, carried out in a Soxhlet apparatus, takes a long time and has a low reproducibility, and liquid-phase extraction using ultrasonics, or the even more effective gas-phase extraction, have been recommended for this purpose.

3. Oxygen-containing Organic Compounds

One of the most toxic atmospheric pollutants is peroxyacetyl nitrate (PAN), which is formed together with other compounds in the photolysis of automobile exhaust gases or as a result of atmospheric photochemical reactions involving hydrocarbons and oxides of nitrogen. Reactive PAN and alkyl nitrates are analysed using a glass or Teflon column with a packing of polyethylene glycol on Chromosorb W, and an ECD, which selectively detects PAN in mixtures with hydrocarbons[228,229]. The same methods are used to analyse toxic nitroalkenes[230], peroxypropionyl nitrate, and peroxybenzoyl nitrate[231].

Micro-quantities of polar aldehydes, ketones, and alcohols have been separated from hydrocarbons using a sectional chromatographic column containing OP-7 detergent and the highly polar cyanoethoxypropane, which are also present in the packing of the enriching column[232]. The determination of aldehydes and ketones in air by gas chromatography has been described[233,234]. In the analysis of alcohols and esters, a liquid absorber containing an alcohol or n-paraffinic hydrocarbons, or a column containing active carbon or silica gel, are used as concentrators[235]. The use of water for the selective extraction of C_1–C_4 alcohols adsorbed on carbon makes it possible to separate them from other compounds in the sample[236]. Chromatographic methods have been developed for the analysis of phenols in air; the phenols are separated on capillary and packed columns[237,238]. For the separate determination and identification of carboxylic acids, the air is passed through a glass fibre filter impregnated with alkali, or through a column containing silica gel; alternatively, the acids are absorbed by a solution of sodium hydroxide[239]. Capillary columns containing squalane and XE-60 cyanosilicone have been used to determine the composition of a complex mixture of oxygen-containing volatile substances (aldehydes, alcohols, carboxylic acids), contaminating air as a result of the decomposition of resin[240].

4. Organic Compounds of Sulphur and Phosphorus. Pesticides

Gas-chromatographic methods for determining volatile organic and inorganic compounds of sulphur using different detectors and different packing have been reviewed[241]. The sulphur compounds are trapped from the air in concentration tubes containing silica gel, active carbon, or Tenax GC[242,243]. Micro-quantities of organic compounds of sulphur are generally separated using the same packing as in the analysis of hydrocarbons, and the preferred detector is the FPD, which has a high sensitivity and selectivity to volatile compounds of sulphur[244]. Gas chromatography has been used to analyse sulphur-containing odourants and to determine other pollutants with a strong odour in air[245], and also for the analysis of traces of the highly toxic dimethyl sulphate[246].

The chromatographic analysis of organic compounds of phosphorus has been reviewed[247]. Gas chromatography is now the most sensitive and most convenient method for analysing the environment for pesticides, most of which are organic compounds of phosphorus and chlorine[248]. Most organic pesticides are fairly volatile, so that they can be separated in the vapour phase at temperatures up to 250°C. The methods of air sampling and the quantitative chromatographic analysis of pesticides have been discussed[249,250]. Micro-quantities of pesticides are analysed on glass columns (to avoid the decomposition of complex halogen-containing molecules) containing different packing, usually with silicone stationary phases[251,252]; glass capillary columns combined with an ECD are also used[253]. After enrichment of the sample, the sensitivity of the determination of pesticides using an ECD may reach 1 ng m^{-3} air[251]. The TID is extremely selective and sensitive to phosphorus-containing pesticides, and is now being used successfully to determine these substances in air[254].

5. Halogen-containing Organic Compounds

Fluorinated hydrocarbons[255], chlorofluorohydrocarbons[256], and fluoro-organic acids[257] in air are determined by gas chromatography using an ECD. In addition, a large number of recently published papers describe the chromatographic analysis of chlorinated hydrocarbons, particularly the determination of the highly toxic vinyl

chloride. Methods for determining chlorinated hydrocarbons, proposed as standard methods, have been described[258]. Organic chlorine-containing compounds are most frequently concentrated in short columns containing active carbon[259], from which they are desorbed by heating or extracted by an organic solvent; silicones, hydrocarbons, and phthalates are generally used as stationary phases for the separation of these compounds.

Micro-quantities of halogenated hydrocarbons are usually detected using the COULD and ECD[260,261], and the latter is an almost ideal detector for the analysis of halogen-containing substances. It is practically insensitive to hydrocarbons, whereas its sensitivity towards various organic compounds of chlorine may reach 8.5×10^{-11}%.[262] At the same time, the FID is most frequently used for the analysis of vinyl chloride (one chlorine atom in the molecule)[263]. Samples of air contaminated by vinyl chloride are obtained using Tenax GC or other adsorbents, the best of which is active carbon. If carbon disulphide is used as extracting agent, the efficiency of the desorption of vinyl chloride from carbon is greater than 90%.[264]

Gas chromatography has been used to analyse chlorine-containing pesticides[265], complex mixtures of Freons[266], polychlorobiphenyls[267], and other chlorine-containing organic pollutants of atmospheric and industrial air[268].

6. Nitrogen-containing Organic Substances

1 mg m^{-3} of the isomers of nitrotoluene can be determined by passing 20 litres of air through an absorber containing ethanol[269]. The gas-chromatographic analysis of air contaminated by benzene, chlorobenzene, nitrobenzene[270], and volatile N-nitroso-compounds has been described[271]. Nitriles, to which the ECD and FID are equally sensitive, are determined using the second of these detectors, by means of which it has been possible to detect 5×10^{-5}% of acrylonitrile in 1 ml of sample[272,273]. Micro-concentrations of 2,4-toluenedi-isocyanate have been determined in air using an ECD[274]. The accuracy of the chromatographic determination of mono-, di-, and trimethylamines in air using the FID is not less than 15%, and the sensitivity of the analysis is ~ 0.2 mg m^{-3}.[275,276] Good results are obtained by concentrating and separating amines on columns containing Tenax GC[277]. The flame ionisation detector has also been used to determine micro-quantities of aniline[278], pyridine, picolines, lutidines, and other pyrimidine bases, which contaminate the air in the production of tar and pitch[279]. The analysis of complex mixtures of polycyclic quinones in the atmosphere has been described[280].

VII. SUMMARY

Methods for the gas-chromatographic analysis of pollutants in the environment are being intensively developed. Among recently published studies, the following are noteworthy.

Sources of atmospheric pollution have been discussed[284], and the problems of analysis in the control of the pollution of the environment have been reviewed[285]. A detailed review of methods for the analysis of polluted air has been published[286]. Special reviews have recently been devoted to the gas-chromatographic analysis of air[287-289].

The general principles and methods of sampling air have been reviewed[290,291], and the criteria for evaluating methods for trapping traces of harmful substances in air on solid sorbents have been discussed[292]; active carbon[293] or polymeric sorbents[294] are most frequently used for this purpose. A promising sorbent is polyurethane foam, which has been found to be an effective material in traps for concentrating traces of phthalates[295], pesticides[296,297], polychlorobiphenyls[297], and PAH[298]. Polysorbimide-1[299] and the new carbon-containing sorbents Carbochrome-5 and Ambersorb XE-340[299,300] have proved to be very effective sorbents for micro-quantities of various chemical substances. Different types of apparatus and filters for trapping solid particles and aerosols have been described[301-303]. Selective sorbents for carbon monoxide have been found. These include silver-containing[304,305] and copper-containing[305] zeolites.

The electron-capture micro-detector, used in work with glass capillary columns, is being increasingly employed in the analysis of air[306]. The principles of the detection of traces of harmful substances in air using the COULD[307], conductometric[308], ultrasonic[309], and piezo-electric[310] detectors, the pyroelectric katharometer[311], and photometric[312] and electrochemical[313] detectors have been further developed. The combination of gas-chromatographic separation with detecting systems such as atomic-absorption[314] and atomic-fluorescence[315] spectrometers appears extremely promising for the analysis of micro-quantities of metals. The semiconducting detector[316] has an exceptionally high sensitivity towards organic substances with a large number of carbon atoms. A promising detector for the analysis of many inorganic compounds is the aerosol detector[317], and the neon ionisation detector can be used to determine approximately 10^{-5} vol.% of carbon monoxide in air without preliminary concentration[318]. A whole series of new methods based on reaction gas chromatography have been proposed for increasing the sensitivity of detection, and have been used to analyse air for micro-quantities of hydrogen fluoride[319], halogen compounds[320], styrene[321], carboxylic acids[322], and bischloromethyl ether[323]. The general principles of the chemical concentration of trace components using reaction gas chromatography has been described[324].

New versions have been developed for various methods of preparing standard mixtures of substances for calibrating detectors[325-327]; permeable polymer membranes are used particularly frequently for this purpose[328,329]. New methods of preparing effective glass capillary columns[330] and methods of using capillary columns for the highly sensitive quantitative analysis of micro-components[331] have been described. Micro-quantities of harmful substances in complex mixtures in polluted air are most frequently identified by the GC-MS method[332,333]. Other systems successfully used for this purpose include the microwave helium detector[334], a combination of gas chromatography with infrared and NMR spectroscopy[335], and the identification of the components of complex mixtures of hydrocarbons using the retention indices[336].

Gas chromatography has been used to analyse air for micro-quantities of phosgene[337], oxides of nitrogen[338], hydrogen cyanide[339], ozone[340], inorganic compounds of sulphur[341,342], carbon monoxide[343,344], the permanent gases[345], organometallic compounds[346], and metals in the form of chelate compounds[347]. Two recently published detailed reviews deal with the gas-chromatographic determination of metals, including the volatile complexes of metals with organic ligands[348,349].

A large number of papers have dealt with the determination of traces of organic substances in air. Methods for the analysis of hydrocarbons and other organic compounds

in solid dust particles and aerosols have been described[350-356]. Complex mixtures of atmospheric pollutants liberated from polymers and elastomers have been analysed[357,358] and the determination of a large number of organic substances in town and country air by GC-MS has been described[299,300]. Automobile exhaust gases contaminating the atmosphere have been analysed[359]. The gas-chromatographic method for determining traces of PAH in air has been further developed[360-362]; steel and glass capillary columns have been used to separate these carcinogenic substances. The analysis of air for phthalates[363], formic acid[364], phenols[365], acetone[366], acrolein and isoprene[367], biphenyl[368], peroxyacetyl nitrate[369], and various solvents[370] and odourants[371] has been described.

Gas chromatography has been used successfully for the analysis of amines[372], nitro-compounds[373], and the carcinogenic nitrosamines[374,375]. Odourants containing organic and inorganic compounds of sulphur[376-378], toxic low-molecular-weight chlorohydrocarbons[379-382], and very low concentrations of the carcinogenic vinyl chloride[383-385] and trichloroethylene[386] have been analysed. The ECD has been successfully used to analyse air for traces of pesticides[387,388], polychlorobiphenyls[389], and bischloromethyl ether[390].

A large number of automatic gas analysers have recently been developed for the operational control of the state of the atmosphere (in cities, industrial centres, factories, etc.), and the use of these analysers has been reviewed[391]. Gas-chromatographic analysers have been specially produced for analysing air for traces of carbon monoxide[392] and reactive hydrocarbons[393], for the analysis of solvent vapours[394], the determination of vinyl chloride[395], and the control of the concentration of sulphur dioxide[396], pesticide vapours[397], and bischloromethyl ether[398] in the atmosphere.

The present problems in the chemistry of the atmosphere and industrial hygiene relate chiefly to the accurate and sensitive determination of the concentration, in the troposphere, of hydrogen sulphide, sulphur dioxide, compounds of the halogens, and various acidic gases, and the identification and determination of a whole series of substances which irritate the eyes and have unpleasant odours. Gas chromatography, and particularly chromatographic–mass-spectral analysis with computer processing of the results, can obviously be of considerable assistance in the study of the qualitative composition of even very complex mixtures in polluted air, consisting of several hundred chemical compounds, and also for the accurate quantitative estimation of the level of contamination of air.

In recent years there has been a marked increase in interest in the standardisation of analytical methods for the study of polluted air[3]. It is now urgently necessary to unify methods for the analysis of photochemical oxidants, oxides of nitrogen, sulphur, and carbon, and solid particles suspended in air. The need to develop standard gas-chromatographic methods for the analysis of hydrocarbons in the atmosphere has been justified[281].

Methods of this kind have also been developed for other organic compounds[3,16,282,283].

---o0o---

In conclusion it should be noted that gas chromatography has become the chief method for the analysis of polluted air, and it is now used to determine traces of practically all organic and many inorganic substances, and also metal aerosols and organometallic compounds entering the atmosphere. A whole series of problems remains unsolved in this field of the analysis of micro-components, however, associated with obtaining representative samples of the air, the concentrating of the trace components, the sensitive and specific detection of the substances being analysed against a background of interfering components, and also the reliable identification of trace components after chromatographic separation.

The solution of the problem of sampling air, which is essentially the problem of concentrating the trace components, depends to a large extent on the development of polymeric sorbents of the "Tenax" type, which make it possible to trap various chemical compounds effectively from contaminated air. On the other hand, a no less effective method involves the selective trapping of the trace components using reactive sorption columns placed in front of the trace component concentrator. This method of sampling appears more promising, since it facilitates considerably the subsequent identification of the substances being analysed and increases the speed of analysis. Methods of sampling (concentrating) trace components by bubbling the air through an active liquid also deserve attention.

Approximately ten selective and sensitive detectors (ECD, FPD, COULD, etc.) are used for the chromatographic analysis of trace components in air, but there is still no suitable detector for the selective detection of microquantities of inorganic substances (particularly carbon monoxide) against a background of the interfering organic trace components of the sample. The development of detectors selective towards the principal classes of atmospheric pollutant has made it necessary in some cases to detect only particular components (usually the most toxic) of the sample against a background of all other substances contaminating the air.

The most reliable information on the composition of complex mixtures of atmospheric pollutants is obtained by the GC-MS method, but the extensive application of this method is restricted by the high cost of the analyses. This has made it necessary to develop simpler methods for identifying trace components, based, for example, on the use of reaction gas chromatography or the chromatographic–distribution method of analysis.

Artificial Light-sensitive Enzymatic Systems as Chemical Amplifiers of Weak Light Signals†

I.V.Berezin and Karel Martinek

The chemical principles of the amplification of weak light signals, based on photochemical and coupled chemical reactions, are examined. Systems where the dark amplification process is a catalytic reaction involving enzymes are discussed in greatest detail. Artificial enzymatic systems in which the level of catalytic activity can be varied under the influence of light is subjected to a critical analysis.
The bibliography includes 130 references.

I. INTRODUCTION

The reception of light signals constitutes the basis of a whole series of most important practical processes (ranging from photography to photoelectron multipliers) as well as unique natural phenomena such as vision, photosynthesis, phototaxis, etc. Usually (both in practical applications by man and in living nature) the primary received light signal is fairly weak and for its effective detection and utilisation it must be subjected to preliminary amplification in the receiving system.

Amplifiers are devices which amplify the transmitted power (in the given case the received light signal) by means of the energy of an extraneous source. Depending on the nature of this source, all amplifiers of light signals can be divided into physical (employing physical amplification principles, which are utilised, for example, in electronic devices)[1] and chemical (using chemical amplification principles, i.e. principles based on photochemical and coupled chemical reactions). In this review we shall consider only chemical amplifiers, because in the literature devoted to a general consideration of this problem unduly little attention has been given to such amplifiers.

The operation of any light-sensitive chemical system must include two stages: the absorption of light and the chemical reaction induced thereby. The amplification factor of a light signal in such a system can be naturally defined as the ratio of the number of molecules reacting

† Certain general aspects of this problem were discussed in our recent communication: K. Martinek and I. V. Berezin, Photochem. Photobiol., 29, 637 (1979).

under the influence of light (or the number of molecules of the reaction products formed) to the number of absorbed light quanta: the greater this quantity, the greater the light sensitivity of the system, i.e. the smaller the number of quanta which it can detect in principle. However, in conformity with the Stark–Einstein photochemical equivalence law, the yield of the primary photochemical reaction cannot be greater than unity. In this case the absorbed light quantum cannot give rise to more than one molecule of a chemical substance, so that the problem of the detection of a small number of light quanta is therefore transformed into the problem of the detection of a small number of molecules, which is just as difficult. Only a system where the primary intrinsic photochemical process is coupled to a subsequent "dark" process can therefore have a high amplification factor (i.e. an effective quantum yield exceeding unity). Ultimately the efficiency of the amplification will depend mainly on the nature of this secondary (dark) process. We shall examine certain examples.

Classical chemical amplifiers of light signals are silver halides suspended in gelatin gels, which are very widely used for the production of photographic images[2,3]. After absorbing a light quantum, the silver halide decomposes, giving rise to silver atoms, which play the role of catalysts of the subsequent dark development process. Another example of the chemical amplification of light signals is provided by the well known chain reactions induced by light[4]. The absorbed light quantum generates free radicals in the system, which then propagate the chemical chain growth stages (dark process).

In principle, the nature of the dark process which follows the primary photochemical reaction can be also non-chemical[2,3,5] (for example, in the "bubble" method based on the photochemical decomposition of azo-compounds with subsequent thermal expansion of nitrogen bubbles in a polymer film). However, the sensitivity (and sometimes also the resolving power) of the latter systems is low. Systems with a light-induced chain reaction, where the chain termination stages inevitably lead to a decrease of the amplification factor, suffer from the same disadvantage. On the whole, after analysing these and other examples[2,3,5], we concluded that one should regard as optimum from the standpoint of sensitivity systems with a *catalytic* dark process, which functions in accordance with the following general mechanism: catalyst molecules are generated under the influence of light, whereupon (in the dark reaction) they catalyse the chemical transformation of a substance present in the system (insensitive to light); in principle, the "turnover number" of a single catalyst molecule is unlimited (if it is possible to avoid the "poisoning" of the catalyst) and the amplification factor can therefore be as large as is required.

The principal and unfortunately evidently insurmountable disadvantage of silver halide catalytic system is that the world resources of silver are now being exhausted[5]. This makes it necessary to seek other, non-silver light-sensitive catalytic systems. There is no review in the literature dealing with the possibility of using biological catalysts for this purpose, but we believe that enzymes in fact give rise to excellent prospects in this field. Our confidence is based on the fact that, firstly, enzymes have a catalytic activity exceeding by many orders of magnitude that of the usual chemical catalysts[6] and, secondly, owing to their unique macromolecular structure, their action can be regulated in very fine detail, i.e. one can alter sharply and adequately the catalytic activity (and other processes) under the influence of even slight changes in the external medium[7]. On this basis, we put forward, justified, and applied experimentally the principle of the applification of light signals with the aid of light-sensitive enzymatic systems[8–10].

II. THE IDEA OF A CHEMICAL AMPLIFIER OF WEAK LIGHT SIGNALS USING ENZYMES

In order to elucidate the essential feature of the proposed approach, we shall consider a system containing a catalytically inactive derivative of an enzyme E_{inact} (which, however, is capable of being converted into an active catalyst E under the influence of light) and a substrate S of the given enzyme. When such a system is illuminated with light at the appropriate wavelength, the photochemical [reaction (1)] and dark [reaction (2)] reactions begin to take place in it:

$$E_{inact} \xrightarrow{light} E, \quad (1)$$

$$E + S \rightarrow E + P. \quad (2)$$

If theenzymatic reaction (2) obeys the Michaelis-Menten equation and the substrate concentration is sufficiently high to "saturate" the enzyme (see our previous publication[8]), the effective quantum yield Φ of the product is defined by the following expression[10]:

$$\Phi = \varphi k_{cat} t, \quad (3)$$

where k_{cat} is the catalytic rate constant for the enzymatic reaction (2) determined from the maximum rate of reaction and equal to the turnover number of the enzyme per unit time, φ is the quantum yield of the primary reaction (1), and t is the time of the dark enzymatic reaction. For the specified value of k_{cat} and in the presence of an inexhaustible supply of the substrate, the effective quantum yield Φ in such a system can evidently be as high as one wishes, since it is determined exclusively by the time of the dark reaction.

In practice the amplification of the light signal takes place as follows: if reaction (2) results in a coloured product P, then the "response" to a single light quantum (which cannot be actually perceived by the eye) is a number of the molecules of the coloured substance sufficiently large to be readily perceived even by the naked eye.

Eqn. (3) describes theoretically the functioning of light-sensitive enzymatic systems. However, for their experimental application, it is necessary to obtain specific derivatives of enzymes capable of changing their activity under the influence of light. Naturally, in principle one can use for this purpose light-sensitive proteins which already exist in living nature, such as, for example, the visual enzyme rhodopsin[11]. However, from the practical point of view, this procedure is quite unacceptable, because natural light-sensitive systems have an exceptionally detailed and complex organisation and are extremely unstable when isolated from their natural environment[12]. Consequently, the problem arises of synthesising artificial light-sensitive enzymatic systems, which is in fact the subject of this review.

III. GENERAL PRINCIPLES OF THE CONSTRUCTION OF ARTIFICIAL LIGHT-SENSITIVE ENZYMATIC SYSTEMS

It is logical to employ a chemo-bionic approach to the creation of artificial light-sensitive enzymatic systems[13]. After analysing photoregulatory processes *in vivo*,

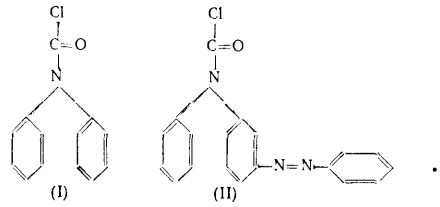
Erlanger[14] concluded that the vast majority of the latter are based on the same principle: small light-sensitive molecules function as effectors (inhibitors, activators) in relation to the biologically active macromolecules, for example, enzymes (which are themselves as a rule insensitive to light). On illumination, the effector molecule is photochemically modified; this results in a change of the nature and (or) degree of its interaction with the biomacromolecule and ultimately the biological activity of the system changes. If this principle is used as the basis for the creation of artificial light-sensitive systems, then the entire vast arsenal of modern photochemistry can be used for this purpose[15,16]. In other words, one must examine suitable light-sensitive low-molecular-weight substances and select enzymes which interact with them. This is an extremely fruitful but laborious procedure, since it involves the selection of a specific light-senstitive effector–enzyme pair and there are no rules for such selection.

One can follow another approach, namely one can induce by means of light a direct change in the reactivity of either the substrate or the enzyme. The medium of the enzymatic reaction (or the microenvironment of the enzyme) can also be altered by the action of light.

The artifical enzymatic systems described in the literature, in which the level of catalytic activity can be altered under the action of light using the above principles, are subjected to a critical analysis below. Naturally, as regards applied aspects of the problem, a chemical amplifier of weak signals can be based only on systems where the light *initiates* (generates) catalytic activity. In practice a system will be regarded as being of this kind if its activity increases by 3–4 and more orders of magnitude after illumination. In other words, in practice one can use only systems where the primary photochemical process [a reaction of type (1)] can be represented in the following general form:

$$\text{System (enzyme + substrate + low-molecular-weight effector + medium) virtually without catalytic activity} \xrightarrow{\text{light}} \text{System with a high level of catalytic activity} \qquad (1a)$$

In such systems light acts either directly on the components of the enzymatic reaction (by altering the chemical or sorption properties of the enzyme itself, or the substrate, or, finally, the low-molecular-weight effector) or on the components of the medium (by altering, for example, the pH of the solution or the microenvironment of the enzyme molecule).



If the enzymatic activity of the system changes only within the range of 1–2 orders of magnitude under the influence of illumination, then such action of light is more correctly referred to as regulating. Despite the fact that the difference between these two types of enzymatic systems is only quantitative, we shall nevertheless consider them separately, bearing in mind the practical importance of the former. However, one must take into account the fact that in future studies only a slight modification of the method available hitherto (for example the replacement of one enzyme by another) can in principle alter sharply the quantitative characteristics of a particular system. Consequently a system which nowadays exhibits only weak regulatory effects, tomorrow (after it has been slightly modified) it can "begin to operate at full strength".

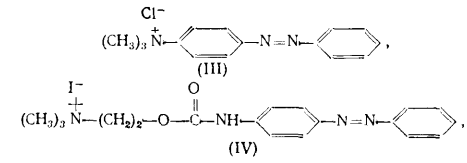
Fundamentally new possibilities for the regulation of catalytic activity have arisen from the use of immobilised enzymes (enzymes bound to a carrier)[17]. In this case sensitivity to an external stimulus can be "grafted" to the system via the carrier. This idea has already proved fruitful in the creation of sound-sensitive (mechano-sensitive) materials[18].

1. SYSTEMS WITH A LIGHT-SENSITIVE EFFECTOR

Regulation by Light of the Rates of Inactivation (or Reactivation) of Enzymes by their Interaction with Irreversible Photochromic Inhibitors

Diphenylcarbamoyl chloride (I) is a familiar irreversible inhibitor of α-chymotrypsin[19–21] and acetylcholinesterase[22]. Its photochromic azo-derivative, *N*-*p*-phenylazophenyl-*N*-phenylcarbamoyl chloride (II), can exist in the *cis*- and *trans*-configurations:

The equilibrium between these two forms can be displaced by illuminating (II) with light at a particular wavelength[13]:



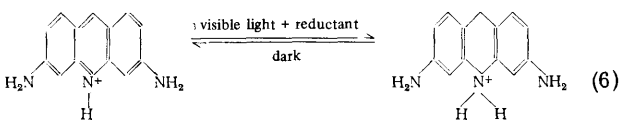
$$trans\text{-(II)} \underset{420\ nm}{\overset{320\ nm}{\rightleftharpoons}} cis\text{-(II)}\ . \qquad (4)$$

It was found[13] that *cis*-(II) inactivates chymotrypsin five times faster than *trans*-(II). Approximately the same differences between the rates of inactivation under the influence of the stereoisomers of (II) (as well as two other related azo-compounds) were noted also for acetylcholinesterase[23,24]. Thus, by illuminating the "enzyme + (II)" system with light having a greater or smaller wavelength, it is possible to alter the ratio of the inhibitor stereoisomers and thus regulate the rate of inactivation of the enzyme (and hence the catalytic activity of the system).

Chymotrypsin and acetylcholinesterase are inactivated under the influence of compounds of type (I) actually as a result of the carbamoylation of the active centre. The carbamoyl derivative of acetylcholinesterase can be reactivated by prolonged incubation at alkaline pH values, and for the *cis*- and *trans*-stereoisomers of inhibitor (II) slightly different rates of reactivation of the "inhibited" enzyme were found[23]. This made it possible to regulate with the aid of light also the rate of this stage of the enzyme–inhibitor interaction.

Regulation of Enzyme Activity by Light with the Aid of Light-sensitive Reversible Inhibitors

The *cis–trans* stereophotoisomerisation of azo-compounds has also been used[23,25] for the reversible regulation of the catalytic activity of acetylcholinesterase. *N*-*p*-Phenylazophenyltrimethylammonium chloride (III) and *N*-*p*-phenylazophenylcarbamoylcholineiodide (IV),



which are competitive inhibitors of this enzyme, exist in the *cis*- and *trans*-forms capable of photochemical interconversions, for example[25]:

$$\textit{trans}\text{-(IV)} \underset{\text{dark}}{\overset{\text{light (348 nm)}}{\rightleftharpoons}} \textit{cis}\text{-(IV)} \quad . \tag{5}$$

The inhibition constants for the *trans*- and *cis*-isomers of (IV) are 1.6 and 3.6 μmole litre^{-1} respectively[25]; the difference is due[26] to the specific structure of the active centre of acetylcholinesterase. Using the differences between the binding capacities of the stereoisomers in relation to the active centres, it is possible (by switching light on and off) to alter reversibly the degree of inhibition of the enzyme and hence the level of the catalytic activity of the system.

We used another photochemical reaction for the reversible regulation of the catalytic activity of α-chymotrypsin. Proflavin (3,6-diaminoacridine), which is a competitive inhibitor of this enzyme[27,28], is capable of being reduced photochemically under the action of visible light in the presence of an organic reductant with formation of 3,6-diaminoacridan: the latter is reoxidised in the dark to proflavin[29]:

(6)

We have shown[30] that, in the course of its photochemical reduction, the ability of proflavin to inhibit α-chymotrypsin disappears (probably as a result of the breakdown of the planar structure of the molecule because the $C_{(9)}$-atom becomes tetrahedral). Consequently, when the "α-chymotrypsin + proflavin + reductant (ascorbic acid)" system is illuminated, the level of its catalytic activity increases (because the inhibitor is inactivated), while in the dark it decreases again.

Regulation by Light of the Potential Difference across a Biological Membrane with the Aid of Photochromic Effectors

The potential difference across certain biomembranes, whose composition includes acetylcholinesterase, diminishes (the membrane depolarises) in the presence of agents interacting specifically with the enzyme (such as acetylcholine or carbamoylcholine)[31–33]. This fact has been used[34,35] for the creation of a system for the photoregulation of the membrane potential using both irreversible[13,23,24] and reversible[23,25] photochromic inhibitors of acetylcholinesterase: under the influence of light, it is possible to alter the ratio of the *cis*- and *trans*-isomers of the inhibitor and hence (bearing in mind their different reactivities in relation to the enzyme) the degree of inhibition of acetylcholinesterase. It was found[34,35] that the membrane potential of the electric organ of the ray can be regulated in this way.

Thus, in systems with light-sensitive effectors, examined above, it is indeed possible to regulate the level of catalytic activity within fairly wide limits. However, this is clearly insufficient for the creation of chemical amplifiers of weak signals. As already mentioned [see Eqn. (1*a*)], it is in fact necessary to *initiate* catalytic activity by the action of light; this can be achieved if the photochemical reaction results in the appearance in the system of an effector (for example, an activator or a cofactor) without which the enzyme is in principle incapable of catalysis.

Initiation by Light of the Catalytic Activity of Haem-containing Enzymes

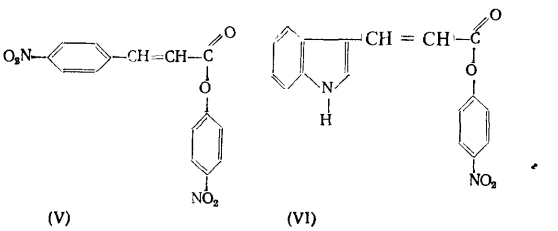
The active centre of the majority of haem-containing oxidation enzymes includes bivalent iron. For example, peroxidase is an enzyme whose globule contains, apart from the protein component, a prosthepic group (haemin), consisting of a complex of an iron ion and protoporphyrin. Neither apoperoxidase, which contains no haemin, nor haemin, nor the complex of apoperoxidase with protoporphyrin have any appreciable enzyme activity.

The principle of initiating activity by light in such systems has been developed in our laboratory[36]. One takes a mixture of apoperoxidase, protoporphyrin, and a complex iron salt [for example, potassium oxalatoferrate(III)], which does not interact with protoporphyrin; such a system should evidently have no catalytic activity. After illumination of the complex iron salt, the iron ion is liberated[37,38]:

$$\text{potassium oxalatoferrate(III)} \xrightarrow{\text{visible light}} Fe^{2+}, \tag{7}$$

and this is followed by complex formation processes:

$$\text{protoporphyrin} + Fe^{2+} \rightarrow \text{ferroprotoporphyrin} \xrightarrow{O_2} \text{haemin}, \tag{8}$$

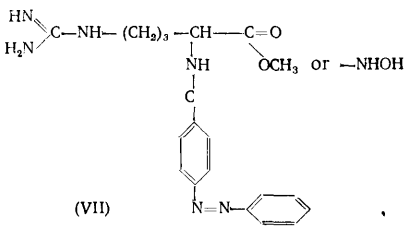


$$\text{apoenzyme} + \text{haemin} \rightarrow \text{peroxidase}. \tag{9}$$

Thus an active enzyme can be "constructed" as a result of the primary photochemical process (7) and the subsequent dark reactions (8) and (9).

2. SYSTEMS WITH A LIGHT-SENSITIVE SUBSTRATE (OR QUASI-SUBSTRATE)

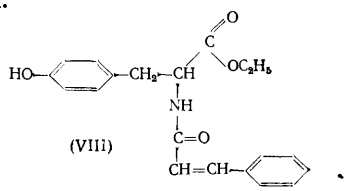
Regulation by Light of the Rates of Reaction of Enzymes with Synthetic Substrates Capable of Photoisomerisation



(a) The esters of β-arylacrylic acids can be regarded as structural analogues of specific α-chymotrypsin substrates[39]. The second-order rate constants for their hydrolysis by α-chymotrypsin are much higher for the *trans*-stereoisomers than for the *cis*-stereoisomers: by a factor of 5×10^3 for *p*-nitrophenyl esters of *p*-nitrocinnamic acid (V) [40] and by a factor of 10^3 for the *p*-nitrophenyl esters of indolylacrylic acid (VI) [41]:

(V) (VI)

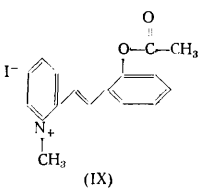
Consequently, by illuminating a mixture of the enzyme and the *cis*-isomer of the substrate, it is possible to accelerate the enzymatic process greatly[40].



(b) Amides and esters of *N*-α-benzoyl-L-arginine — classical low-molecular-weight substrates of trypsin[42–44]. The stereoisomers of their azo-derivatives (VII).

(VII)

The methyl ester and hydroxamide of *N*-**α**-*p*-phenylazophenyl-L-arginine differ severalfold in reactivity towards trypsin[45]. Under the influence of light at different wavelengths, the *cis*- and *trans*-stereoisomers of (VII) are interconverted. Consequently, with the aid of light, one can, as it were, "switch over" the rate of enzymatic reaction from one value to another[45].



(c) When the reaction involving the photostereoisomerisation with respect to the C = C bond was used, it was possible[46] to regulate with the aid of light the rate of the chymotrypsin hydrolysis of the ethyl ester of *N*-α-cinnamoyl-L-tyrosin:

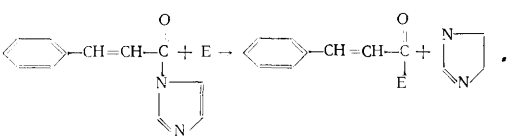
(VIII)

Compound (VIII) can be regarded as an analogue of the ethyl ester of *N*-acetyl-L-tyrosine, which is a classical specific substrate of α-chymotrypsin[39].

(d) The rates of hydrolysis of compounds of type (IX)

(IX)

catalysed by butyrylcholinesterase, differ severalfold for the *cis*-*trans*-stereoisomers[47]. Consequently, using the photostereoisomerisation of a substrate of type (IX), it is possible to regulate the rate of the enzymatic reaction. The authors[47] suggest that the rate-limiting stage in the enzymatic hydrolysis is the desorption of the product molecule (the corresponding alcohol) from the active centre. This hypothesis is extremely likely, because it is known that product molecules can be desorbed from enzyme macromolecules at a fairly low rate[48,49].



Reactions of Enzymes with Photoexcited Substrates

Molecules in photoexcited states differ sharply in their chemical properties from those in the ground state (it is therefore possible to investigate their reactions despite the extremely low steady-state concentration of the excited molecules)[59]. Consequently, in principle, one may expect that the reaction of the enzyme with the photoexcited substrate can have a different rate than that with the non-excited substrate. The foregoing may have a bearing on the surprising results obtained by Comorosan and coworkers[51–54], who showed that, when low-molecular-weight substrates of various enzymes are irradiated with low doses of ultraviolet light, long-lived excited states are formed and the rates of their reactions with enzymes can be several times higher than those observed with the non-excited substrates. This effect depends greatly on the irradiation conditions, but the mechanism of the phenomenon remains obscure.

Thus, with the aid of light-sensitive substrates it is also possible (as for light-sensitive effectors) not only to regulate the rate of the enzymatic reaction but actually to initiate the latter [this has been shown[40] in relation to compounds of type (V)]. However, the foregoing factors are insufficient for the creation of a chemical amplifier of weak signals— instead of initiating the reaction (by activating the substrate), the catalytic activity of the system must be stimulated. This can be achieved by employing "quasi-substrates", whose chemical reaction at the active centre proceeds via relatively unreactive (unstable) intermediate compounds. As a result of such "chemical modification of the active centre" by the quasi-substrate, the catalyst is, as it were, "poisoned". Using such stable and catalytically inactive "enzyme derivative" (modified by the quasi-substrate at the active centre), one can attempt to alter (increase) the enzyme reactivity under the influence of light and thereby regenerate the free active centre.

Initiation by Light of the Catalytic Activity of Enzymes with the Aid of Photochromic Quasi-substrates

(a) The possibility of initiating by light the catalytic activity of artificial enzymatic systems was demonstrated for the first time at Moscow University[8–10]. The principle of the effect is as follows. It is known[39] that acylation of the hydroxyl in the serine residues in the active centre of α-chymotrypsin (a protolytic enzyme) leads to complete inactivation of this biocatalyst. Deacylation of the resulting acylenzyme leads in its turn to the complete regeneration of the catalytic activity. Taking these factors into account, the active centre of α-chymotrypsin has been acylated[8,9] by *cis*-cinnamoylimidazole (the *trans*-stereoisomer of this reagent is a familiar titrant of α-chymotrypsin[55]):

(10)

(X)

The *cis*-cinnamoyl-α-chymotrypsin (X) formed in this process is an extremely stable acylenzyme: even at the pH optimum the deacylation rate constant is 4×10^{-4} min^{-1}, i.e. the half-deacylation time is more than 24 h. (By altering the pH away from the optimum, it is possible to increase this time still further). On illumination with ultraviolet light, the *trans*-stereoisomer is formed from the *cis*-acylenzyme, and is extremely rapidly deacylated (the half-reaction time is ~1 min). The observed difference between the reactivities of the *cis*- and *trans*-stereoisomers of the acylenzymes (by a factor of 2000) can be increased still further by introducing the nitro-group in the *para*-position of the aromatic ring in the cinnamoyl group. In this case the *trans*-acylenzyme is deacylated 2.5×10^4 times faster than the corresponding *cis*-acylenzyme[10]. The causes of the *trans*-specificity of α-chymotrypsin have been discussed[41,56]. The *cis*- and *trans*-cinnamoyl derivatives of another protolytic enzyme (trypsin) show a still greater difference in reactivity[57,58].

A chemical amplifier of weak light signals can be constructed in the following form using the systems described. We shall use, for example, *cis*-cinnamoylchymotrypsin, which is itself catalytically inactive (Fig. 1*a*) and is hardly deacylated under the experimental conditions[8,9]. If such a system is irradiated with ultraviolet light, the acylenzyme undergoes *cis-trans* photostereoisomerisation and the resulting *trans*-acylenzyme hydrolyses rapidly:

$$cis\text{-(X)} \xrightarrow{\text{light}} trans\text{-(X)} \xrightarrow{H_2O} \text{enzyme} + trans\text{-cinnamic acid.} \quad (11)$$

The kinetics of these processes can be followed on the oscillogram obtained in the flash-induced hydrolysis of *cis*-nitrocinnamoylchymotrypsin[59] (Fig. 2). Eqn. (11) shows that illumination results in the regeneration of catalytic activity (see Fig. 1*b*) and a coloured product, for example, will therefore begin to be formed in the presence of the substrate [Eqn. (2)]. The effect quantum yield Φ of the product **P** (the amplification factor for the light signal) in the system can be estimated by Eqn. (3) assuming that the quantum yield of the *cis-trans* stereoisomerisation is $\varphi = 0.3$ (at 313 nm) [56] and the catalytic constant for a specific substrate at the pH optimum for the activity of chymotrypsin is $k_{cat} \simeq 100\ s^{-1}$.[39] If the time of the dark reaction t is, for example, 1 h, then, according to Eqn. (3), $\Phi = 0.3 \times 200 \times 3600 \simeq 2 \times 10^5$, i.e. more than 10^5 product molecules are produced in the system during this period for one absorbed light quantum.

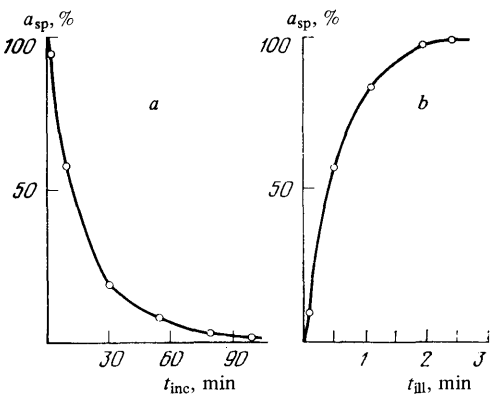


Figure 1. Variation of the specific catalytic activity (a_{sp}) of chymotrypsin incubated with *p*-nitrophenyl *cis*-4-nitrocinnamate (curve *a*; t_{inc} is the incubation time) and on subsequent illumination of the resulting acylenzyme—*cis*-4-nitrocinnamoylchymotrypsin (curve *b*; t_{ill} is the illumination time)[8,10].

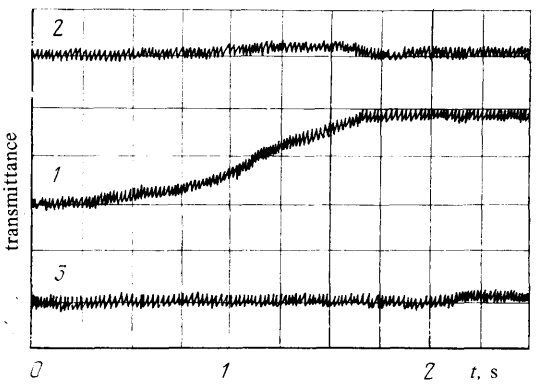
Thus it is seen that the systems described are extremely sensitive light detectors (see Kazanskaya's review[60]).

(b) Another principle has been formulated in studies[61,62] where a photochemical method was proposed for the investigation of the aminoacid environment of the active centre of the enzyme. For the reaction of α-chymotrypsin with *p*-nitrophenyl diazoacetate—an analogue of *p*-nitrophenyl acetate which is a classical non-specific substrate of proteases[63]—the product is a diazoacetylenzyme—an extremely stable acylenzyme without catalytic activity.

For example, diazoacetyl-α-chymotrypsin is hardly deacylated in the course of 48 h (at pH 6.5) [44], while acetyl-α-chymotrypsin is rapidly deacylated under these conditions. The difference is associated with the diminution, as a result of conjugation with the diazo-group, of the electrophilic properties of the carbonyl carbon atom in the substrate residue. On illumination of diazoacetyl-α-chymotrypsin with ultraviolet light, nitrogen is split off[61] from the diazoacetyl residue with formation of a carbene radical. This radical hydrolyses and the resulting hydroxyacetyl-α-chymotrypsin is rapidly deacylated with regeneration of enzyme activity:

$$\text{E}-\overset{\overset{O}{\|}}{C}-CH_2-\overset{+}{N}\equiv N \xrightarrow[H_2O]{\text{u.v.light}} \text{E}-\overset{\overset{O}{\|}}{C}-CH_2-OH + N_2 \rightarrow \text{E} + HOCH_2COOH \quad . \quad (12)$$



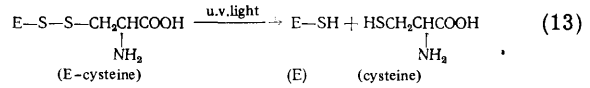


Figure 2. The oscillogram (curve *1*) of the change in the transmittance (320–360 nm) of a solution of *cis*-4-nitrocinnamoylchymotrypsin as a result of pulse irradiation (10^{-4} s) at time $t = 0$. Curves *2* and *3* correspond to 0 and 100% transmittance[59].

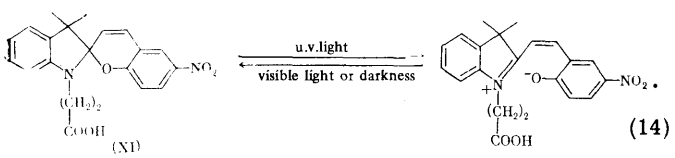
3. THE ACTION OF LIGHT ON THE ENZYME (INCLUDING A MODIFIED ENZYME)

Activation by Light of Catalytically Inactive Enzyme Derivatives (Modified at the Active Centre)

The principle of the approach is that the enzyme is modified initially with formation of a catalytically inactive derivative $E_{\mathbf{inact}}$ [see Eqn. (1)] and then the modifying agent (or its influence) is removed with the aid of light. A fairly convenient object for studies of this kind is the sulphydryl protolytic enzyme papain. The sulphydryl group of cysteine, which forms part of the active centre of the enzyme, plays the most important role in the catalytic function of papain[64]. However, the enzyme is usually in the inactive form, where the sulphydryl group of the active centre forms a mixed disulphide with an additional cysteine residue (papain–S–S-cysteine)[65,66]; for the catalytic activity to be shown by papain, the latter must be activated, for example, chemically (in this activation the S–S bond of the disulphide is cleaved).

In principle, disulphide bonds both in peptides and in proteins can be cleaved not only chemically but also photochemically[67-69]. This approach has been used[70] for the photochemical activation of papain: on illumination with ultraviolet light of a solution containing papain–S–S-cysteine, a catalytically active enzyme is formed:



(13)

This principle was developed further in our laboratory[71]. As a result of the oxidation of active papain catalysed by copper ions, a disulphide dimer of the enzyme, namely papain–S–S–papain, was obtained. On illumination of the dimer with ultraviolet light, the disulphide bond is cleaved with formation of two molecules of the catalytically active enzyme. The quantum yields of the photoactivation process are in both cases in the range 0.1–1.0.

Regulation by Light of the Catalytic Activity of Enzymes with the Aid of Photochromic Effectors Attached to the Protein Globule outside the Active Centre

When photochromic polymers are illuminated[72,73], one may expect a change in their structure. This effect has been observed experimentally[74-79]. In the above studies azo-dyes [for example compounds of type (II)–(IV)] were attached covalently or non-covalently to synthetic polymers or proteins. The *trans*-configuration of the dye is thermodynamically more stable but *trans–cis* stereoisomerisation takes place on illumination. It has been shown[74-76] that such photochemical reaction does indeed induce a considerable change in the polymer structure (revealed, for example, by a change in the viscosity of its solutions).

Enzyme macromolecules exhibit a biological activity which is extremely sensitive to the conformation of the protein globule[7]. From this point of view, it is of interest to modify the enzyme by photochromic reagents (but not at the active centre, in order to retain the catalytic activity) and to investigate the dependence of the activity of the biocatalyst on the light-regulated structure of the modifying agent. This idea has been realised experimentally[80]. A spiropyran (XI), widely used to produce photochromic polymers, served as the modifying agent for α-amylase[72,73]. On illumination with ultraviolet light, compound (XI) isomerises:

(14)

The isomerisation can be reversed by illumination with visible light or in the dark[15,81].

Namba and Suzuki[80] obtained the anhydride of compound (XI), which was then used to modify the amino-groups of α-amylase molecules. When the enzyme modified in this way is illuminated with ultraviolet light, its catalytic activity falls, while in the dark the enzyme is reactivated.

The mechanism of the regulation of systems described in this section is based on the fact that the molecular structure of the modifying agent changes under the influence of light. In principle, the mechanism of the regulation of the catalytic activity of the enzyme modified outside the active centre can also be different. The Change in the Conformational-Solvation state of the Enzyme Induced by Light. The protein molecules of enzymes contain a number of intrinsic chromophores (for example, aromatic aminoacid residues) capable of absorbing light effectively. In some cases such light absorption can activate the biocatalyst. Thus illumination of a solution of aldolase with ultraviolet light leads to a prolonged reversible increase of its enzymatic activity[82,83]. An analogous effect, but this time following the illumination of aldolase in the presence of a substrate, was observed by Volotovskii et al.[84], who proposed an interesting explanation of this effect: when light is absorbed by tryptophan residues, a radiationless dissipation of excitation energy in the form of heat can occur, in particular, in the enzyme–substrate complex, which can lead to the breakdown of the structure of water in the solvation shell of the macromolecule. This facilitates, in its turn, the allosteric conformational transition in the enzyme subunits, which leads to the formation of an aldolase conformation with an enhanced catalytic activity.

Other data[85,86] agree with this hypothesis. The difference between these results and those of the above studies[82-84] consists in the fact that the primary light acceptors were not the intrinsic chromophores of the protein but residues of diazotised *p*-aminobenzoic acid covalently attached to the sulphydryl groups of aldolase (in this case the protein absorbs visible light). Evidently such modification should not be reflected significantly in a change of the properties of the enzyme according to the mechanism of Volotovskii et al.[84] Indeed, when the modified aldolase is illuminated, its conformation changes (this can be followed from the change in the absorption spectra and the electrophoretic mobility)[86] and the kinetics of the cleavage of fructose-1,6-diphosphate catalysed by this enzyme are also altered[85]. Apparently the mechanism proposed[84] can be fairly general for different enzymes.

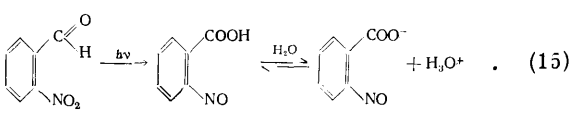
Another mechanism (one cannot rule out the possibility that it is to some extent similar to that already described) of the increase of the activity of enzymes under the influence of light may be proposed on the basis of Fröhlich's hypothesis[87,88], according to which biological objects, particularly proteins, can exist in long-lived excited states. In the case of enzymes the catalytic activity of these states may be different from that of the ground states; the transition from the ground to the excited state can be induced, for example, by light. An experimental study of this kind has been carried out[89], in which it has been shown that, when chymotrypsin is irradiated with a laser beam (457.9 nm), its activity increases appreciably. According to the authors[89], the picture outlined by Fröhlich actually obtains in this instance.

Photoinactivation of Enzymes

In principle, the familiar phenomenon of the photoinactivation of enzymes can be used to create light-sensitive enzymatic systems. The first study[90] devoted to this problem was published as early as 1879 and by now hundreds of such investigations have been made. We shall therefore merely refer to the most exhaustive reviews[91-97].

Inactivation under the influence of ultraviolet light is due to the photodegradation of the aminoacid residues of the protein globule (in the first place, tryptophan and cysteine residues). The photoinactivation quantum yield is in this case 0.001–0.1 and depends on the nature of the enzyme, its conformation, and the conditions in the medium. Certain flavin enzymes are inactivated under the influence of visible (blue) light. Here the cofactor (flavin

mononucleotide) plays the role of a sensitiser of the apoenzyme degradation process[98].



The so-called photodynamic effect, i.e. the photochemical oxidation of protein molecules sensitised by dyes, is also well known[99]. The mechanism of this effect consists in the transfer of molecular oxygen dissolved in water to the protein via the formation of an intermediate adduct of the triplet-excited dye molecule and oxygen. The photodynamic effect occurs when protein solutions are irradiated with visible light in the presence of various dyes (eosin, Methylene Blue, etc.); the enzyme photoinactivation quantum yields are usually in the range 0.001–0.1.[99]

4. THE CHANGE IN THE MEDIUM OF THE ENZYMATIC REACTION UNDER THE INFLUENCE OF LIGHT

The Light-Induced Jump in pH

Almost all enzymatic reactions are extremely sensitive to the pH of the solution: their rates decrease sharply when the pH deviates from the optimum value[6]. This factor led to the idea that the rates of enzymatic reactions can be regulated by a photoinduced change in the pH of the medium[100]. Photochemical reactions which lead to the formation of strong acids or bases have been described in the literature. We shall quote some examples of such reactions.

(a) When a solution of *o*-nitrobenzaldehyde is irradiated (436 nm), a phototautomerisation reaction takes place: *o*-nitrobenzaldehyde is converted into *o*-nitrobenzoic acid with a quantum yield $\varphi = 0.5$ (see Terenin[15], p.211):

(15)

When reaction (15) is carried out in aqueous solution, the resulting acid dissociates with formation of a hydronium ion, i.e. in this case illumination leads to a decrease of the pH of the medium.

(b) When complex transition metal (CO^{3+}, Cr^{3+}, etc.) ammines are irradiated with visible light, a photoaquation reaction takes place (with quantum yields of 0.01–1.0),[101,102] for example:

$$[CO(NH_3)_5Cl]^{2+} + H_2O \xrightarrow{h\nu} [Co(NH_3)_4(H_2O)Cl]^{2+} + NH_3 . \quad (16)$$

The ammonia formed as a result of reaction (16) reacts with water (i.e. with the reaction medium).

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-,$$

which leads to an increase in the alkalinity of the solution.

(c) Transition metal (Fe^{3+}, Co^{3+}) oxalates undergo a photochemical oxidation-reduction reaction with a quantum yield of approximately unity on illumination with visible light (this process constitutes the basis of the action of the oxalatoferrate (III) actinometer[37,38]), for example:

$$2Fe(C_2O_4)_3^{3-} \xrightarrow{h\nu} 2Fe(C_2O_4)_2^{2-} + C_2O_4^{2-} + 2CO_2. \quad (17)$$

The carbon dioxide formed in this process reacts with water:

$$CO_2 + H_2O \rightleftharpoons H_3O^+ + HCO_3^-,$$

which leads to an increase in the acidity of the medium.

Naturally the systems (a)–(c) enumerated above do not exhaust the photochemical reactions accompanied by a change in the pH of the medium.

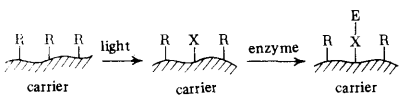
Consider an enzyme and a substrate at a pH such that the rate of the enzymatic reaction is negligibly small. We then add one of the above reagents, for example, *o*-nitrobenzaldehyde [Eqn. (15)] or chloropentamminecobalt [reaction (16)]. If such a system is now illuminated, the pH of the solution changes and if the change is directed towards the pH optimum for the enzyme activity, the rate of the enzymatic reaction increases.

The above principle[100] was tested in relation to photoinitiated reactions catalysed by α-chymotrypsin [using system (a)][46] and trypsin [system (b)].[103]

Photoregulation of the Rates of Enzymatic Reactions as a Result of the Change in the Microenvironment of the Enzyme under the Influence of Light

New possibilities for the regulation of the catalytic activity by light arose when the enzyme was incorporated in a polymer film (membrane) containing a photochromic effector. Such an effector can be either introduced mechanically into the polymer carrier or can be attached covalently.

(a) Chymotrypsin and azobenzene were incorporated mechanically in an octanol/water membrane stabilised with sodium stearate[104]. Azobenzene does not interact with the enzyme, but the change in its structure as a result of the *cis–trans* photostereoisomerisation induces structural changes also in the membrane, which influences the catalytic activity of chymotrypsin (apparently as a result of the effect of the microenvironment).



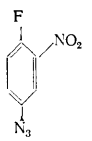
(b) An interesting idea for the photocontrol of enzymatic processes has been described in studies[105,106] where the amino-groups of collagen were modified by a photochromic compound [the anhydride of compound (XI)]. Films containing non-covalently incorporated enzymes—urease[105] or lactate dehydrogenase[106]— were then obtained from such collagen. When immobilised enzyme systems of this kind are illuminated, the structure of the modified polymer changes and hence also the microenvironment of the enzyme, which reduces the catalytic activity of the system. After the system has been kept in the dark, the photochemical reaction is reversed [in conformity with Eqn. (14)] and the activity of the enzymes rises to the initial level.

5. SYSTEMS WITH A CARRIER IN WHICH LIGHT INITIATES ENZYME IMMOBILISATION CENTRES

In virtually all the examples examined above (sub-sections 1–4) the presence of light sensitivity was indisolubly linked to a specific enzyme system. In other words, each mechanism whereby it was possible to "graft" light sensitivity artificially onto the system depends strongly either on the structure of the active centre, or on the nature of its interaction with low-molecular-weight ligands, or on the degree of its "response" both to changes in the structure of extremely remote regions of the protein globule and to changes in the reactivity of the medium, etc. Consequently the method developed for one enzyme cannot be automatically used in another system.

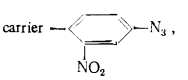
In order to overcome this disadvantage, we propose a fundamentally new, universal method based on the use of a carrier for the immobilisation of the enzyme. The basic

idea of this method is reflected in the following scheme:



(1b)

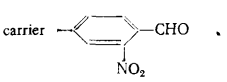
The functional groups R of the initial carrier do not interact with the enzyme. Under the influence of light, they are transformed chemically (R — X) with formation of functional groups X capable of interacting with the enzyme either chemically or via a sorption process. Thus the enzyme is attached to the regions of the carrier surface exposed to light, while it is absent from the non-illuminated sections. The attached enzyme can be made visible by treating the system with a substrate giving rise to coloured products as a result of the enzymatic reaction.



An evident advantage of this approach is that it is applicable to virtually any enzyme (because the molecules of all enzymes consist of the same aminoacid residues). Furthermore, methods for the immobilisation of enzymes on carriers have now been developed in extremely great detail[107-109]. We shall therefore indicate only photochemical methods whereby the ability to bind an enzyme can be "grafted" onto a carrier.

Photochemical Modification of the Functional Groups of the Carrier

(a) The immobilisation of aspartase with the aid of the photochemical Knowles reagent[112] [4-azido-1-fluoro-2-nitrobenzene (XII)] has been described[110,111]. This reagent was added to a carrier, namely to alkylamino-glass, in order to immobilise enzymes. As a result of the substitution of fluorine by the nucleophilic NH_2 groups of the carrier, compound (XIII) was formed:

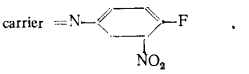


(XII)

(XIII)

which is capable of splitting off nitrogen under the influence of light with formation of an extremely reactive nitrene radical. If the illumination is carried out in the presence of an enzyme, then at the sites exposed to light the enzyme is bound covalently to the modified carrier (XIII) by interacting with the nitrene, the prospects for this approach in the photoimmobilisation of enzymes have been very fully described by Guire[111].

(b) Another method was proposed by ourselves[128]. In an optically transparent polymer carrier, containing *o*-nitrobenzaldehyde groups (XIV), the photochemical reaction (15) should proceed with formation of carboxy-groups:



(XIV)

The remaining aldehyde groups (in the non-illuminated regions) must be blocked by an amine and the existing carboxy-groups (at the illuminated sites) must be activated, for example, by carbodiimide and the enzyme must be grafted to them (by a standard method[107-109]).

Photochemical Addition to the Carrier of Functional Groups Capable of Interacting with Enzymes

The photochemical immobilisation of enzymes using the Knowles reagent (XII) can be achieved in two ways (see the discussion of this problem by Guire[111]): either by attaching (XII) to the carrier with the aid of a nucleophilic substitution reaction involving the aromatic ring (see above) or by illuminating a mixture of (XII) and a carrier without nucleophilic groups. In the latter case the reactive nitrene radical formed at the illuminated sites is attached covalently to the carrier with formation of compound (XV):

(XV)

If an enzyme solution is then added, the amino-groups of the protein react with the fluoronitrophenyl residue (nucleophilic substitution of fluorine) in compound (XV), which leads to covalent immobilisation of the biocatalyst. In order to increase the rate of the last reaction, the Knowles reagent can be replaced by its more reactive derivative[113], a whole series of which have been synthesised by Guire[114].

Photochemical Formation of a Carrier

We used the photogel-formation process for the photoimmobilisation of enzymes[115]. For example, the classical polyacrylamide gel for the immobilisation of enzymes[116] and other polyacrylate gels can be obtained by illuminating solutions of the corresponding monomers with visible light in the presence of the dye riboflavin[117] or by illuminating with ultraviolet light[118]. Thus, when a thin layer of a solution of monomers is deposited on a plate the illuminated, a gel, retained on the plate, is formed at the illuminated sites, at the non-illuminated sites the monomer solution can be readily washed off with water. The enzyme is retained in the carrier mechanically (when it is added beforehand to the polymerisation mixture)[118] or it can be "grafted" chemically after polymerisation to the gel already formed[115].

An important feature of the methods which we proposed[115] consists in the fact that the light-initiated radical polymerisation processes are characterised (by virtue of the chain mechanism) by high quantum yields, greatly exceeding unity. This implies that one light quantum can ensure, in principle, the immobilisation of more than one enzyme molecule. This leads to additional possibilities [apart from the coupled enzymatic reaction — see Eqn. (2)] for the amplification of the light signal.

IV. THE USE OF ARTIFICIAL LIGHT-SENSITIVE ENZYMATIC SYSTEMS IN PRACTICAL APPLICATIONS AND IN FUNDAMENTAL BIOCHEMICAL RESEARCH

Analysis of literature data combined with the new approaches which we proposed shows that catalytic activity in an enzyme system can be indeed "induced" by artificial means [via mechanisms (1a) or (1b)]. In conclusion we shall note the following three factors.

(1) There is no doubt that extremely effective amplifiers of weak light signals, including new non-silver photographic processes (see the relevant reviews[60,129,130]), will be created in the immediate future on the basis of artificial

light-sensitive enzymatic systems. The success of future research will depend on the following two characteristics of the enzymatic system employed: the amplification factor and the spectral sensitivity.

(a) As already mentioned above [see the discussion of Eqn. (3)], the effective quantum yield in light-sensitive enzyme systems is extremely high. Furthermore, there exist at least two ways of increasing it further.

In the first procedure the activation of the corresponding zymogen is used as the first of the dark reactions (2) (zymogens are catalytically inactive natural enzyme precursors capable of enzymatic activation). For example, trypsinogen has no enzyme activity, but is converted into an active enzyme under the influence of trypsin[119]. This process is autocatalytic: in principle, even one trypsin molecule can activate the entire available "store" of the zymogen. Consequently, trypsinogen is extremely sensitive to even very small concentrations of trypsin. Hence the idea of creating the following light-sensitive enzymatic system naturally arises: a catalytically inactive, but capable of being activated by light, trypsin derivative + trypsinogen + trypsin substrate. When such a system is illuminated, the active enzyme is formed from the inactive trypsin derivative and activates the zymogen, while the product of the activation process hydrolyses the substrate. Evidently in this case the trypsin formed under the influence of light as it were "multiplies" due to the activation of the zymogen, which leads to a transition from a linear dependence of the effective quantum yield on the dark reaction time [Eqn. (3)] to an exponential dependence[120] and this ensures increased primary light signal amplification factors; see also Refs. 57, 58, and 103 and a review[60].

In the second procedure the photochemical formation of the carrier ensures the possibility of immobilising more than one enzyme molecule with the aid of a single light quantum[115] (see Section III.5).

(b) As regards the second important characteristic of the light-sensitive enzymatic system, namely its spectral sensitivity, the latter can be altered by varying the molecular structure of light-sensitive low-molecular-weight components, i.e. the substrate (see, for example, Varfolomeev and coworkers[10,56]) or of the effector for the enzymatic reaction or, finally, of the enzyme modifying agent.

New possibilities arise from the use of sensitised photochemical reactions, because in this case it is sufficient to vary the molecular structure (and hence the spectral sensitivity) of the sensitiser. So far it has not been possible to find a sensitiser of photochemical reactions occurring directly in the active centre of the enzyme[121], which is apparently associated with the extremely complex organisation of the active centre, i.e. with different kinds of steric hindrance. The photopolymerisation process which results in the formation of a carrier for the subsequent immobilisation of enzymes is therefore extremely promising[115]. It is significant that photopolymerisation processes do not impose unduly drastic limitations on the structure of the sensitiser molecule[122].

(2) The approaches examined in the present review to the regulation under the influence of light of the rates of enzymatic reactions should find applications also in fundamental enzymological research. Particularly wide prospects arise in photochemical approaches when the latter are used to investigate the kinetics and mechanisms of reactions occurring in frozen or crystalline states (where, in particular, diffusion-dependent obstacles[123] interfere with the introduction of the required effectors or the substrate by a sufficiently rapid procedure).

We shall indicate two examples. Thus, the flash-induced change in the reactivity of the substrate (or the effector) can be used as a basis for a method whereby the kinetics of the rapid stages of the enzymatic process can be investigated[40,124]; the use of the flash-induced jump in pH merits particular attention in this connection (see Section III, 4).

Another example involves the use of reaction (11) for the investigation of the mechanism of enzymatic catalysis. Fig. 2 shows that the photostereoisomerisation of the substrate residue at the active centre of the acylenzyme proceeds almost instantaneously (there is a rapid increase of the optical density of the solution), but the subsequent chemical stage, namely the hydrolysis of the acylenzyme (a slow increase of the optical density), proceeds with an appreciable induction period. It may be that the observed induction period is due to the conformational-solvation rearrangements in the active centres ensuring the complementarity of the catalyst to the specific substrate produced under the influence of light (as a result of photostereoisomerisation). This explanation is consistent with the hypothesis[125–127] of the conformational (solvation) changes in the active centre, induced by the substrate, which are important for catalysis.

(3) Many of the enzyme systems examined in this review constitute extremely realistic models of more complex light-sensitive systems which function *in vivo*. Analysis of the simple models can therefore assist in a deeper understanding of the principles used by nature to regulate biological activity[14].

The Influence of the Solvent on the Rates of Chain Propagation and Termination Reactions in Radical Polymerisation

V.F.Gromov and P.M.Khomikovskii

The influence of the solvent on the rate of radical polymerisation and copolymerisation, observed and investigated in the last ten years and caused mainly by a change in the rate of the elementary chain propagation reaction, is discussed. The published data on the polymerisation and copolymerisation of a number of monomers in solvents of different types are surveyed. Attention is drawn to the fact that the greatest effects are observed for polar monomers, particularly for water-soluble monomers in an aqueous medium. The causes of the change in the overall rate of reaction, the constants k_p, and the copolymerisation constants for different monomers are examined.
The bibliography includes 104 references.

I. INTRODUCTION

Various aspects of solvent effects on the kinetics and mechanisms of chemical and particularly chain reactions have been investigated in many studies whose results have been surveyed[1-3]. However, the influence of the solvent on the rate of the chain propagation reaction in polymerisation proceeding via a radical mechanism has been scarcely discussed until recently. It has usually been assumed that the chain propagation and termination rate constants in the initial stages of homogeneous radical polymerisation are independent of the nature of the medium†. The influence of solvents on radical copolymerisation was tested experimentally as early as 1950s. It was established that, in the homogeneous copolymerisation of styrene and methyl methacrylate in benzene and acetonitrile (with dielectric constants of 2.28 and 38.8), the copolymerisation constants are similar. The same result was obtained for the copolymerisation of styrene and 2,5-dichlorostyrene in a number of solvents with markedly different dielectric constants[7]. Significant differences between the reactivities of reacting species as a function of the nature of the medium have been found only in the polymerisation and copolymerisation of certain polar, particularly ionising, monomers[8].

During the last 15–20 years, studies of the influence of the nature of the medium on homogeneous radical polymerisation and copolymerisation have developed extensively in various directions[8-23], including studies on the influence of the solvent on the kinetics and on the structure and properties of polymers. Appreciable effects have been observed in many instances. Furthermore, it has been found that inorganic complex-forming agents (coordination-unsaturated metal compounds) can alter significantly the rates of the elementary reactions and the molecular weights and structures of the polymers. This phenomenon was discovered and investigated in detail by a number of workers[24-27].

Thus the possibility arose of influencing appreciably the rate of chain propagation reactions under the conditions of radical polymerisation. In radical copolymerisation procedures were developed for the regulation and composition and distribution of units in the macromolecule and also of the structure of polymer chains. New ways for the regulation of the properties of the products were devised. Previously no such possibilities were available in radical polymerisation; it was assumed that, in contrast to ionic and ionic-coordination polymerisation, the constants k_p are determined solely by the nature of the monomer—namely by the reactivities of the monomers and the radicals, which are independent of the nature of the medium.

The influences of the solvent on the rates of chain propagation and termination reactions are different, in terms of the magnitude of the effect and frequently its mechanism, for weakly polar and polar monomers.

II. WEAKLY POLAR MONOMERS

Individual observations showing that the influence of solvents on the initial rate of homogeneous radical polymerisation cannot be reduced solely to their involvement in the initiation and chain transfer reactions, were published in several studies as early as the 1950s–1960s.[28-32] It was suggested that polymerisation in solutions involves the formation of complexes between the polymeric radicals and the monomer or solvent molecules. Thus, apart from the interaction with polymeric radicals via a chain transfer

† This review does not deal in detail with the widely known influence of the viscosity of this system on the rate constant for the termination of polymer chains (k_t), which is manifested most significantly at advanced stages of the process. At these stages an increase of the viscosity of the polymerisation system also induces a decrease of the chain propagation rate constant[4] (k_p). The influence of the viscosity of solvents on k_t at the beginning of the reaction has also been demonstrated. Little attention has been devoted to the above problems in the literature (see, for example, Bagdasar'yan[5] and Gladyshev and Popov[6]). The dependence of the rate of initiation on the viscosity of the medium has also been demonstrated[6].

mechanism, in the polymerisation of styrene in bromobenzene the molecules of the latter are probably involved in complex formation[31]. The extremely low rates of polymerisation of vinyl benzoate in bulk could be caused by the formation of a complex of the growing radical with the aromatic ring of the monomer[29]. The appreciable decrease of the rate of polymerisation of vinyl acetate in benzene could also be caused by the formation of a complex between the polymeric radicals and benzene molecules, which leads to the formation of species which are relatively inactive in the chain propagation reaction.

The influence of the nature of the solvent on the overall rate of radical polymerisation of styrene was probably first clearly established experimentally by Henrici Olive and Olive[11-13] A little later the constant k_p and k_t were determined for the polymerisation of methyl methacrylate in a number of solvents[16]. However, the influence of the medium on the rate of radical polymerisation of weakly polar monomers is low: the overall reaction rate changes at the most by a factor of 1.5–2.

The polymerisation of styrene has been investigated in a large number of organic substances of different classes (aromatic and carbonyl compounds, ethers, and alkyl halides) and the dependence of the overall rate of reaction on the nature of the solvent has been demonstrated[11-13]. The observed effect has been examined taking into account the intermolecular interaction between the polymer radicals and the monomer and solvent molecules.

Table 1. The influence of the "τ-ratio" in the polymerisation of styrene in solvents of different classes at 50°C.[13]

Solvent	τ_S/τ_M	Solvent	τ_S/τ_M
Mesitylene	1.62	Tetrahydropyrene	1.01
Methyl isobutyrate	1.53	Anisole	0.97
Dimethoxyethane	1.52	Bromobenzene	0.93
Ethyl acetate	1.44	Dimethylformamide	0.91
Ethylbenzene	1.28	Chloroform	0.90
Toluene	1.28	Pyridine	0.87
Butanone	1.22	Dioxan	0.87
Tetrahydrofuran	1.09	1,2-Dichloroethane	0.85
Benzene	1.04	Methylene chloride	0.83

The electron affinities of typical polymer radicals hardly differ from that characteristic of, for example, tetracyanoethylene and chloranil, which form charge-transfer complexes with the solvents usually employed in vinyl polymerisation. It is therefore assumed that donor–acceptor complexes of polymer radicals with both monomer and solvent molecules arise in polymerisation in solution. The concentration of complex species in the reaction system is proportional to the product of the monomer and solvent concentrations and to the lifetime of the corresponding complexes, which depends on the electronic structure of the species. The influence of the solvent on the rate of polymerisation can be expressed with the aid of a single parameter, namely the "τ-ratio"—the ratio of the lifetime of the donor–acceptor complex between the polymer radical and the solvent molecule (τ_S) to that of the complex between the polymer radical and the monomer molecule (τ_M). The values of the "τ-ratio" for 18 solvents of different classes have been determined from experimental data (Table 1).

The solvent is inert for $\tau_M = \tau_S$. If $\tau_M > \tau_S$, then the rate of polymerisation is higher than in an inert diluent; correspondingly, for $\tau_M < \tau_S$, it is lower. For polymerisation in bulk the "τ-ratio" is unity. Depending on the nature of the solvent, the "τ-ratio" and hence the overall rate of polymerisation of styrene vary at most by a factor of two.

The constants k_p and k_t for the polymerisation of styrene in several solvents have been determined[33] by the usual methods (k_p^2/k_t was obtained from the measured rate of polymerisation and the molecular weights of the polymers, and k_p/k_t was found by the rotating sector method). Table 2 shows that these quantities are somewhat smaller than in the polymerisation of styrene in bulk and decrease with increase of solvent concentration. It has been shown experimentally[33] that k_t is inversely proportional to the viscosity of the solution. The influence of the nature of the solvent on k_p has been explained by the formation of complexes of the growing radicals with the solvent. The stability and reactivity of these complexes determines the difference between the quantity k_p in solution and that of polymerisation in bulk.

Table 2. Photopolymerisation of styrene in solutions at 25°C in the presence of azobisisobutyronitrile[33].

Solvent	$\eta_{mixt.}$, cP	k_p, litre mole^{-1} s^{-1}	$10^{-7}k_t$, litre mole^{-1} s^{-1}
—	11.1	35±7	1.9±0.4
Bromobenzene (50%)	10.5	29±8	1.6±0.3
Bromobenzene (20%)	10.8	35±5	1.9±0.3
Diethyl malonate (20%)	12.1	29±7	1.5±0.4
Diethyl phthalate (50%)	26.1	20±5	0.8±0.2
Diethyl phthalate (20%)	15.2	23±8	1.1±0.2
Dinonyl phthalate (60%)	58.2	27±4	0.31±0.04

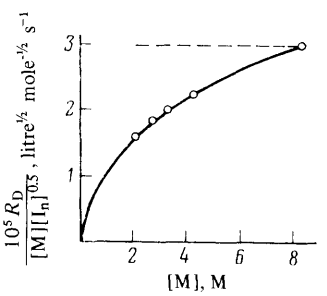

Figure 1. Dependence of the specific rate of polymerisation of styrene $R_p/[M][In]^{0.5}$ on the monomer concentration in the reaction mixture; $[In]/[M] = 0.71 \times 10^{-2}$; dashed line—ideal behaviour.

The influence of the solvent concentration in the reaction system on the overall rate of reaction has also been observed in the polymerisation of styrene in acetone under homogeneous conditions[34]. Here the rate of reaction (R_p) is proportional to the concentration of the initiator (In)

raised to a power of 0.45; however, the dependence of R_p on the monomer concentration differs sharply from linearity (Fig. 1). As in the studies of Henrici-Olive and Olive [11-13], the observed effect is explained by postulating the formation of a complex between the growing polymer radicals and acetone molecules. The formation of complexes between free radicals and various organic compounds has been established experimentally [35]. The stability constants of complexes of the t-butylmesitylnitroxy-radical with various organic substrates (monomers and solvents) as well as their free energies of formation have been determined by gas–liquid chromatography and spectrophotometry. It has been established that solvents forming the most stable complexes exert the greatest influence on k_p in the polymerisation of methyl methacrylate (Fig. 2). The formation of complexes between a stable radical (2,2,6,6-tetramethylpiperidinyl-1-oxy-radical) and methacrylate esters has also been established [36] by NMR and EPR.

The hypothesis put forward by Henrici-Olive and Olive [11-13] was confirmed in a study [16] of the photopolymerisation of methyl methacrylate in fluoro-, chloro-, and bromo-benzenes, anisole, and benzonitrile. The rate of polymerisation is somewhat higher in all these solvents than in benzene. Although all the values of k_p lie within the limits of the accuracy of the determination, nevertheless according to the authors [16] they increase steadily in the sequence benzene < fluorobenzene < chlorobenzene < anisole < bromobenzene < benzonitrile. The values of k_t vary in inverse proportion to the viscosity of the solvent.

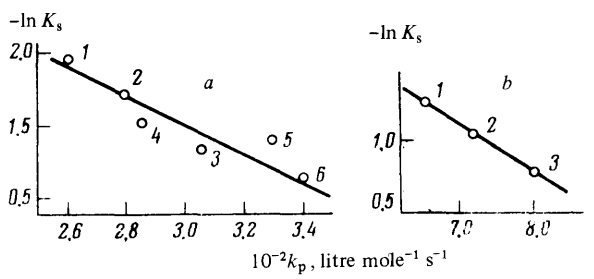

Figure 2. Dependence of k_p for the polymerisation of methyl methacrylate in different solvents at 25° (*a*) and 60°C (*b*) on the stability constants of the complexes of the t-butylmesitylnitroxy-radical with the solvents: *a*) [1) benzene; 2) chlorobenzene; 3) bromobenzene; 4) anisole; 5) benzonitrile; 6) methyl benzoate]; *b*) [1) 1-fluoronaphthalene; 2) 1-chloronaphthalene; 3) 1-bromonaphthalene].

The polymerisation of methyl methacrylate in solutions in halogeno-derivatives of benzene and naphthalene has been investigated in a series of studies [37-40]. The rate of polymerisation in monosubstituted aromatic hydrocarbons is higher than that in benzene and varies with the nature of the halogen in the sequence fluorobenzene < chlorobenzene < bromobenzene < iodobenzene, i.e. increases with decrease of the electronegativity of the substituent. Under identical conditions, the overall rate of reaction is 0.19 wt. % min^{-1} in benzene and 0.35 wt.% min^{-1} in iodobenzene. Dihalogenobenzenes increase the overall rate of polymerisation of methyl methacrylate to a somewhat greater extent than the monosubstituted derivatives and the 1,2-isomer is more effective than the 1,3- or 3,4-isomers. The nature of the substituent has the same influence in this case as for monosubstituted benzene derivatives. Di- and tetrabromobenzenes do not affect the rate of polymerisation.

It has been suggested [37-39] that the main cause of the influence of the solvent is a change in the rate of initiation. However, determination of the absolute rate constants for the elementary chain propagation and termination reactions as well as the rates of initiation in the polymerisation of methyl methacrylate in solution and halogenonaphthalenes [40] showed that the rate of initiation remains almost constant and the effect is due to a slight change in k_p and k_t. The constant k_t varies inversely with the viscosity of the solution; on the other hand, the variation of k_p is probably due to the formation of a complex with the solvent. As in the study of Bamford and Brumby [16], it was found that [37-40] the overall effect of the solvent on k_p is extremely small. On the basis of the results obtained in the polymerisation of methyl methacrylate in halogenated aromatic solvents in the presence of an inhibitor, it has been concluded [41] that the solvent affects mainly the constant k_t.

A slight increase of the overall rate of polymerisation, due to the increase of the ratio $k_p/k_t^{1/2}$, is also observed in the polymerisation of methyl methacrylate in aromatic solvents [42]. The rate of reaction increases in the sequence toluene < *p*-chlorotoluene < benzene < bromobenzene.

In the polymerisation of methyl methacrylate in ethereal solvents [43] a change in the overall rate of reaction as a function of the nature of the solvent is also observed. Here too, the change in k_t, associated with the different viscosities of the solution, exerts the main influence; however, the change in k_p, reaching 20–25%, also has some effect. Analogous results were obtained in the study of the polymerisation of benzyl methacrylate in ethereal solvents differing in viscosity [44] and also in the polymerisation of tetrahydrofurfuryl methacrylate [45] and phenyl methacrylate [46] in various media. The constant k_p for benzyl methacrylate increases somewhat with increasing viscosity of the solution (by 30–35%).

Table 3. Polymerisation of vinyl benzoate in different solvents at 30°C. [46]

Solvent	k_p, litre mole^{-1} s^{-1}	$10^{-8}k_t$, litre mole^{-1} s^{-1}
Anisole	106	2.53
Benzene	185	4.02
Fluorobenzene	245	5 22
Chlorobenzene	168	3.83
Ethyl benzoate	69	2.57
Benzonitrile	33	2.99
Ethyl acetate	267	4.51

Much greater effects are observed in the polymerisation of vinyl benzoate [46] in various aromatic solvents (Table 3). The change in the constant k_p in this system is probably due to the formation of π-complexes between solvent molecules and the growing radical, which leads to a significant alteration in the reactivity of the radicals. The constants k_t are inversely proportional to the viscosity of the reaction system.

The overall rate of homogeneous polymerisation of cyclohexyl and cyclododecyl acrylates increases in the following sequence of solvents: benzene < tetrahydrofuran < dioxan[47]. Thus at 60°C (azobisisobutyronitrile concentration 0.01 M, monomer concentration 0.8 M), the overall rates of polymerisation ($10^5 R_p$, mole litre^{-1} s^{-1}) of cyclododecyl acrylate are 15.1 in benzene, 21.3 in tetrahydrofuran, and 60.0 in dioxan. Under analogous conditions, the overall rates of polymerisation of cyclohexyl acrylate are 9.87, 11.6, and 22.1 respectively. The change in the overall rate of the process is caused, according to the authors[47], by the different degrees of polarisation of the carbonyl group in the acrylate monomer in the solvents investigated. It had been found earlier[48] that the polarisation of the carbonyl group ($\rangle C^+=O^-$) of methyl methacrylate increases the reactivity of this monomer in its copolymerisation with styrene. It has been established by infrared spectroscopy[47] that (the carbonyl groups of) cyclohexyl and cyclododecyl acrylates are polarised to a greater extent in solutions in dioxan and tetrahydrofuran than in benzene solutions. The change in the overall rate of polymerisation is therefore probably associated in this case with the change in k_p.

The influence of the solvent on the rate of polymerisation has also been demonstrated for the homogeneous polymerisation of vinyl chloride[49]. The ratio $k_p/k_t^{1/2}$ for the polymerisation is 0.68 in dichloroethane (50°C) and 0.19 in benzene.

III. POLAR MONOMERS

The influence of the nature of the medium has been found to be much greater in the polymerisation of vinyl polymers containing heteroatoms with a lone electron pair and capable of involvement in the formation of hydrogen bonds‡.

At the beginning of the 1960s it was already shown[50-53] that the rate of polymerisation of a number of monomers in bulk is related to the presence or absence of intermolecular hydrogen bonds in these substances. Thus the rates of polymerisation of the *o*-isomers of ethoxy- and methoxy-phenylmethacrylamides, ethoxy-phenylacrylamide, chlorophenylmethacrylamide, biphenylylmethacrylamide, and carboxyphenylmethacrylamide exceed the rates of polymerisation of the *m*- and particularly *p*-isomers. This is because the *o*-isomers of these compounds exist in the form of unassociated molecules, while the *m*- and *p*-isomers form associated species via hydrogen bonding. The presence of associated structures in the *m*- and *p*-compounds has been established[50-53] by infrared spectroscopy. One should note that in the case of tolylmethacrylamide, where all the isomers are capable of forming associated species via hydrogen bonding, the rates of polymerisation of the isomers do not differ from one another[51].

Presumably the addition of certain solvents, capable of dissociating intermolecular hydrogen bonds and thus preventing the association of monomer molecules, to the monomer present in the associated form leads to an alteration of the rate of its polymerisation.

A very appreciable influence of the solvent on the overall rate of polymerisation and the chain propagation rate constant has been established for acrylamide and methacrylamide[21,54]. The polymerisation was studied in water, dimethyl sulphoxide (DMSO), and tetrahydrofuran (THF) under the influence of azobisisobutyronitrile. In water and DMSO acrylamide polymerises under homogeneous conditions, while the polymerisation of acrylamide in THF and also that of methacrylamide in all the solvents investigated takes place heterogeneously. However, in all cases the reaction in dilute solutions takes place at the beginning of the process at a constant rate which is proportional to the monomer concentration and the square root of the initiator concentration. The overall rate of polymerisation of acrylamide and methacrylamide decreases significantly in the sequence water > DMSO > THF. The average molecular weights of the acrylamide polymers decrease in the same sequence. The ratio $k_p/k_t^{1/2}$ measured for acrylamide decreases to an even greater extent, since the rate of initiation varies in the opposite sequence. Thus at 40°C the ratio $k_p/k_t^{1/2}$ is 3.3 in water, 0.35 in DMSO, and only 0.05 in THF.

An appreciable increase of the overall rate of reaction and of the molecular weight of the polymer with increasing water content in the solvent has been observed in the polymerisation of acrylamide in water–methanol mixtures[55,56]. A similar influence of water has been observed also for the polymerisation of acrylamide in water–DMSO mixtures[57].

Table 4. Polymerisation of acrylamide in various solvents[22,54].

Solvent	$k_p/k_t^{1/2}$, litre$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$ (40°C)	E_p, kcal mole^{-1}	$10^{-7}A_p$, litre mole^{-1} s^{-1}	E_t, kcal mole^{-1}	$10^{-8}A_t$, litre mole^{-1} s^{-1}
Water (pH 7)	4.1	2.7	1.0	2.7	780

DMSO	0.32	5.4	3.0	0	2.5
Tetrahydrofuran	0.05				

The photopolymerisation of acrylamide (sensitised by azobisisobutyronitrile) has been studied in greater detail in water at pH 7 and 13, formamide, and DMSO[21,22,58]. The constants k_p and k_t and the corresponding activation energies were determined separately (Table 4). It was established that, compared with k_p for the polymerisation in water at pH 7, the constant k_p at 20°C is smaller by a factor of 2 in water at pH 13, by a factor of 12 in formamide, and by a factor of 35 in DMSO. The decrease of k_p is caused by the increased activation energy for this reaction: the pre-exponential factors are almost the same or change only slightly in the opposite sequence. The values of k_t, activation energies, and pre-exponential factors for this reaction (A_0) are the same in all the solvents investigated with the exception of water at pH 7. In the latter case higher values were obtained for E_0 and A_0. The

‡ The results of certain studies concerning the influence of the solvent on the radical polymerisation of polar monomers (acrylic acids, vinylpyridines, and *N*-vinylpyrrolidinone) and also on their copolymerisation with other vinyl monomers have been described in a recently published monograph[8] and are therefore not considered in detail in the present review.

latter quantity is higher than for other solvents by two orders of magnitude, so that ultimately k_t is somewhat higher despite the greater activation energy (2.7 kcal mole^{-1} compared with 0–1 kcal mole^{-1}).

The observed influence of the solvent on the kinetic parameters of the polymerisation process can probably be explained by the intermolecular interaction of the acrylamide molecules with one another (in the monomeric and polymeric forms) and also with solvent molecules. The different extents of this interaction are indicated by the heats of solution and polymerisation of acrylamide in certain solvents [22,59] (Table 5) and also by the results of cryoscopic measurements, which showed that the degree of association of acrylamide molecules is 1.30 in DMSO and 1.15 in formamide; in aqueous solution (at pH 7 and 13) acrylamide is almost non-associated. The heat of polymerisation of acrylamide also depends on the nature of the solvent. The polymerisation in aqueous solution has the highest heat, the latter being significantly smaller in organic media. The dependence of the heat of polarisation on the nature of the solvent shows that monomer molecules are associated to a greater extent than the polymer radicals and polymer molecules [59].

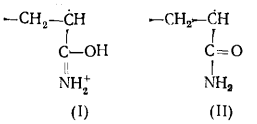

Table 5. Heats of solution and polymerisation of acrylamide and methacrylamide in various solvents [22,59].

Solvent	ΔH, kcal mole^{-1}			Solvent	ΔH, kcal mole^{-1}		
	of soln.	of polymerisation	of polymerisation		of soln.	of polymerisation	of polymerisation
	acrylamide		methacrylamide		acrylamide		methacrylamide
Water (pH 7)	−2.9	19.5	13.4	Chloroform	—	—	10.2
Water (pH 13)	−2.75	—	—	Acetone	—	16.9	9.4
Formaide	−2.5	—	—	Benzene	—	14.4	8.4
DMSO	−1.1	—	—	n-Hexane	—	13.8	—

Such intermolecular interaction makes the energy levels of the initial and final states in the polymer chain propagation reaction dependent on the nature of the solvent. For polymerisation in aqueous solutions the activation energy for the chain propagation reaction is therefore lowest and the heat of reaction highest. In formamide and DMSO, where the monomer molecules interact via hydrogen bonds, the activation energy for the propagation reaction is significantly higher, since it includes the energy necessary for the dissociation of the intermolecular hydrogen bonds.

Since the heat of polymerisation of methacrylamide in various solvents changes in the same way as for acrylamide [59], the decrease in the rate of polymerisation of this monomer in the sequence water > DMSO > THF is apparently due to the same causes.

The most intense solvation of acrylamide by solvent molecules is observed in aqueous solution. In the limiting case there is a possibility of a chemical reaction between acrylamide and the protons formed in the dissociation of water, because acrylamide has weakly basic properties. This reaction takes place with acrylamide radical to a greater extent, because the presence of an unpaired electron probably leads to an increase of the basicity of the radical compared with the neutral molecule, increasing thereby the equilibrium constant of the protonation reaction. The addition of a proton to the oxygen atom [60] of the acrylamide radical (I) and the consequent appearance of a positive charge at the nitrogen atom lead to the localisation of the unpaired electron and to an increase in the reactivity of the radical:

(I) (II)

In the non-protonated radical (II) there is a possibility of the conjugation of the unpaired electron with the C=O double bond; in radical (I) there is no such conjugation. The positive charge of the nitrogen atom draws the π electrons of the C=N double bond towards itself, which prevents the conjugation of the unpaired electron with this double bond.

The idea of the higher reactivity of the acrylamide radical in water as a result of the addition of a proton and of the involvement of this radical to some extent in the chain propagation and termination reactions is confirmed by the following experimental data: (1) the increase of the chain propagation and termination rate constants in the polymerisation of acrylamide in aqueous solution with decrease of the pH of the medium from 13 to 1 (Currie et al. [61]); (2) the increase of k_t for the reactions in water at pH 7 compared with the value of k_t for the polymerisation in water at pH 13, formamide, and DMSO. The activation energy for the termination of polymer chains in water at pH 7 is 1.7–2.7 kcal mole^{-1} higher than in other solvents. The difference is probably due to the energy expended on overcoming the repulsion of the charged polymer radicals.

The higher rates of chain propagation in the polymerisation of acrylamide in aqueous solution compared with the polymerisation in formamide and DMSO are caused both by more favourable solvation conditions in water and by a definite role of the hydrogen ion formed by the dissociation of water in interacting with the amide group of the growing chain. The two factors are interrelated and undoubtedly exert a parallel influence on the rate of polymerisation of acrylamide. The role of the second factor naturally increases with increase of the concentration of H^+.

The formation of insoluble polyacrylamide in neutral and particularly in acid concentrated aqueous solutions is associated with the presence of hydrogen ions and probably protonated acrylamide radicals (I). [62] This hypothesis is supported by the following facts: (1) polymerisation in alkaline concentrated aqueous solutions yields a fully soluble polymer; (2) the polymerisation of acrylamide in neutral and acid concentrated aqueous solutions in the presence of β,β',β'', nitrilotripropionamide, which is a stronger proton acceptor than acrylamide, is not accompanied by the cross-linking of the polymer chains; (3) in concentrated solutions in an aprotic solvent (DMSO) soluble polymers are formed at advanced stages of the reaction.

A fairly large number of studies [63–67] have been devoted to the investigation of the influence of the nature of the solvent on the polymerisation of acrylic and methacrylic acids§. Acrylic acid polymerises in bulk under the influence of γ-radiation at a very high rate with formation of

§The polymerisation of ionogenic monomers, particularly acrylic and methacrylic acids at different pH values as well as dioxan in the presence of complex-forming agents, has been examined in detail in a monograph [8].

high-molecular weight stereoregular polymers (with a molecular weight up to 3×10^7). The activation energy for this process in the temperature range from 20° to 70°C is only 2.7 kcal mole^{-1}. Solvents capable of forming hydrogen bonds with the monomer (water, methanol, acetic acid, and dioxan) do not alter significantly the rate of polymerisation of acrylic acid when they are added in an amount of 20–25%. None of these solvents (with the exception of water) influences the syndiotacticity of polyacrylic acid. On the other hand, small amounts of chloroform (5–10%) and hydrocarbon solvents (n-hexane and toluene) reduce appreciably the overall rate of polymerisation and the syndiotacticity of the polymer.

In order to account for these results, it has been suggested[63-67] that, apart from dimeric cyclic aggregates (characteristic of carboxylic acids), acrylic acid gives rise to a linear high-molecular weight aggregate structure, where the distribution of vinyl groups favours a very rapid chain propagation and the formation of a syndiotactic polymer. The addition of water, methanol, and dioxan leads to the binding of the linear acrylic acid aggregates to one another. In contrast to this, benzene, toluene, n-hexane, and chloroform disrupt the linear aggregates. Such changes in the structure of the aggregates of polymeric molecules in the solvents investigated are in fact responsible for the different kinetic characteristics of the polymerisation of acrylic acid in these solvents. The observed[65] sharp increase in the rate of polymerisation of acrylic acid in n-hexane when the temperature is raised from 20° to 40°C has also been explained by the equilibrium transition from cyclic dimers to linear associated species as the temperature is increased.

However, there is apparently no need to resort to ideas about the formation of high-molecular weight aggregates in acrylic acid solutions in order to account for the results obtained[63-67], particularly since according to some data[23,68], obtained by the cryoscopic method, acrylic acid exists in the form of individual molecules in water and formamide, while in solution in DMSO it is associated only to the extent of approximately 10%. It has been shown[69] that the reactivity of the dimerised acrylic acid is lower than that of the non-dimerised acid. The difference between rates of polymerisation of this monomer, observed in different solvents, can therefore be caused by the fact that acrylic acid in bulk exists in the form of dimers, which dissociate to some extent into individual molecules as a result of the formation of hydrogen bonds with solvent molecules in solutions in water and other polar solvents but are little altered in hydrocarbon media. In non-polar solvents, particularly in n-hexane, an increase of temperature favours the dissociation of the acid dimers, which leads to a marked temperature dependence of the rate of polymerisation in n-hexane.

In examining the results of the above studies[63-67], one must therefore take into account the phase state of the reaction system, which depends on the nature and amount of the solvent. Indeed, whereas in the polymerisation of acrylic acid in dilute solutions in water, methanol, and dioxan, the reaction proceeds in a homogeneous system, when acetic acid, toluene, n-hexane, and chloroform are used as solvents and also in polymerisation in bulk the resulting polymer is produced in the form of a new phase, which greatly complicates the kinetic picture of the process.

The influence of the nature of the solvent on the polymerisation of acrylic acid and its derivatives, (methacrylic and α-fluoroacrylic acids) has been investigated in greater detail in other investigations[23,68,70-72]. The homogeneous polymerisation has been studied in water, formamide, and DMSO. The overall rate of polymerisation is a maximum in water and diminishes on passing to formamide and then to DMSO. The reaction proceeds in all cases at a rate proportional to the concentration of the monomer and to the square root of the concentration of the initiator. The data in Table 6 show that the increase of the overall rate of the process is accompanied by the increase of k_p owing to the decrease of the activation energy for this reaction. At the same time the results indicate a significant difference in the behaviour of acrylic acid and its α-derivatives. Whereas in the polymerisation of acrylic acid a sharp dependence of the overall rate of reaction and of k_p on the nature of the solvent is observed, for methacrylic and particularly fluoroacrylic acids, the influence of the medium is much less. Thus k_p decreases by a factor of 50 on passing from water to DMSO for acrylic acid, by a factor of 25 for methacrylic acid, and only by a factor of 3 for fluoroacrylic acid.

Table 6. Parameters characterising the chain propagation and termination reactions in the polymerisation of acrylic (AA), fluoroacrylic (FAA), and methacrylic (MAA) acids in various solvents[71,72].

Monomer	k_p, litre mole^{-1} s^{-1} (20°C)	E_p, kcal mole^{-1}	$10^{-7}A_p$, litre mole^{-1} s^{-1}	$10^{-8}k_t$, litre mole^{-1} s^{-1} (20°C)	E_t, kcal mole^{-1}	$10^{-8}A_t$, litre mole^{-1} s^{-1}
			Water			
AA	27 200	3.1	0.60	1.8	0	1.8

FAA	850	5.2	0.66	0.49	0.4	1.0

It follows from cryoscopic data[68] that the observed influence of the solvent on the rate of the chain propagation reactions involving acrylic acids cannot be associated solely with the different degrees of association of the monomeric molecules in the solvents, as has been suggested for acrylamide[22]. Indeed, although acrylic acid is in fact partly dimerised in solution in DMSO, the concentration of dimers does not exceed 10%, so that their contribution cannot probably be decisive. Acrylic acid in aqueous solution and fluoroacrylic acid in solutions in water and in DMSO are present in the form of individual molecules.

As for acrylamide, the heats of solution and polymerisation of acrylic and fluoroacrylic acids vary with the nature of the medium (Table 7). However, the heats of solution of acrylic and fluoroacrylic acids in DMSO and formamide change in the same way for both monomers: the dissolution in water is accompanied by the absorption of heat; on passing to formamide and DMSO, the heat of solution increases. However, the heats of polymerisation of these monomers vary in different ways as a function of the nature of the solvent. Whereas the heat of polymerisation of acrylic acid in water is significantly greater than in DMSO

(18.5 and 14.1 kcal mole^{-1} respectively), the heat of polymerisation of fluoroacrylic acid in these solvents is virtually the same (~ 13 kcal mole^{-1}).

Table 7. Heats of solution and polymerisation of acrylic (AA) and fluoroacrylic (FAA) acids in various solvents[72].

Monomer	ΔH, kcal mole^{-1}		Monomer	ΔH, kcal mole^{-1}		Monomer	ΔH, kcal mole^{-1}	
	of soln.	of polymerisation		of soln.	of polymerisation		of soln.	of polymerisation
	Water			Formamide			DMSO	
AA	−0.2	18.5	AA	0.6	—	AA	3.0	14.1
FAA	−2.3	13.3	FAA	−1.1	—	FAA	0.3	13.0

The observed difference between the heats of polymerisation of acrylic acid in the solvents investigated can be due to the different conformational states of the polymer molecules in these media. Water is a better solvent for polyacrylic acid than DMSO. The polymer chain therefore exists in water in the form of looser coils than in DMSO, which promotes a more effective penetration of the solvent into the polymer coil in aqueous solution. This difference between the states of the polymer molecules in water and in DMSO leads to an appreciably higher energy of solvation of polyacrylic acid molecules in aqueous solution compared with the solution in DMSO which is the reason for the difference between the heats of polymerisation [because the solvation energies (heats of solvation) of the monomer and its saturated analogue are virtually the same[73,74]].

The greater density of the polymer coil of polyacrylic acid in DMSO compared with aqueous solutions leads to a lower rate of bimolecular polymer chain termination in DMSO compared with water (Table 6). The introduction of a fluorine atom into the polymer chain increases the rigidity of the chains, as a result of which the influence of the solvent on the conformational state of the macromolecules and hence also on the heat of polymerisation is much smaller for fluoroacrylic acid than for acrylic acid.

As for acrylamide[22], the decrease of the activation energy for chain propagation in the polymerisation of acrylic and fluoroacrylic acids is accompanied by an increase in the heat of polymerisation, i.e. the Polanyi–Semenov rule holds qualitatively. For isotypical reactions the following equality is valid[75]: $\Delta E = -\alpha\Delta(\Delta H)$, where $\alpha \simeq 0.25$ for the usual radical reactions. It follows from a comparison of the values of ΔH and E_p for the polymerisation of acrylic and fluoroacrylic acids in water that $\alpha = 0.26$. However, α for the polymerisation of acrylic and fluoroacrylic acids in DMSO exceeds 1.0. The value $\alpha > 1.0$ is also obtained on comparing the results for acrylic acid in water and in DMSO.

The failure of the Polanyi–Semenov rule can indicate a different nature of the reacting species in the solvents investigated. This is also suggested by data for the compensation effect observed in the polymerisation of acrylic acid in different solvents (see Table 6). The presence of the compensation effect in liquid-phase radical reactions can be due[2] to the specific interaction of the radicals with the medium (particularly the formation of π-complexes).

It has been suggested[11–13] that free radicals are capable of forming π-complexes with solvents exhibiting electron-donating properties. The formation of complexes of this kind has been shown[76] to lead to decreased unpaired electron density in the radical, which decreases the reactivity of the latter. The solvents employed[68,70–72] are electron donors under the conditions investigated, the electron-donating capacity increasing in the sequence water < formamide < DMSO. The complex between the polymer radical and the solvent is therefore most probably formed in solution in DMSO, which leads to the maximum reactivity of the polymer radical in this solvent. The probability of the radical forming of a complex with formamide and particularly with water is lower; consequently, the reactivity of the radical in these media diminishes to a smaller extent than in DMSO; this leads to the experimentally observed dependence of k_p on the nature of the solvent.

The formation of complexes between solvent molecules and polymer radicals should be reflected also in the energetics of the chain propagation reaction. In the transition state a complex between the radical and the solvent probably has to be decomposed in order to achieve the chain propagation reaction; this requires an additional energy, which is part of the activation energy for the chain propagation process. Since the formation of a radical–solvent complex takes place to the greatest extent in DMSO, the energy E_p for polymerisation should also be a maximum in this case.

The probability of the formation of complexes between the solvent and the polymer radical apparently decreases with decreased reactivity of the radical. In the polymerisation of methacrylic and especially fluoroacrylic acids, whose polymer radicals are less reactive than the radicals of polyacrylic acids, the influence of the nature of the medium is therefore less pronounced than for acrylic acid.

Thus the different effects of the nature of the solvent on the polymerisation of acrylic, methacrylic, and fluoroacrylic acids reduce the reactivity of the initially more reactive radical, formed from acrylic acid (the reactivity of this radical is characterised by the constant k_p in water, where the probability of the formation of a complex with the solvent is low), compared with the fluoroacrylic and methacrylic acid radicals in DMSO—a solvent capable of forming a complex with this radical.

Table 8. Polymerisation of methacrylic acid in various solvents at 10°C.[77]

Solvent	k_p, litre mole^{-1} s^{-1}	$10^{-7}k_t$, litre mole^{-1} s^{-1}
Methanol	517	3.7
Pyridine	527	2.3
Dimethylformamide	28	0.44

The polymerisation of methacrylic acid in different solvents has also been investigated by Shryver et al.[57] The reaction was carried out under the influence of azobisisobutyronitrile at 60°C. The authors showed that the addition of water to organic solvents (ethanol, ethanol–dioxan, and DMSO) increases significantly the overall rate of polymerisation and the molecular weight of the polymers. One should note particularly that the rate of reaction is almost independent of the dielectric constant of the reaction mixture and is determined by its water content. In this case the observed effect can probably be accounted for by the different degrees of complex formation between the polymer radicals and solvent molecules.

The polymerisation of methacrylic acid in methanol and pyridine is characterised by identical constant k_p and k_t (Table 8); in the polymerisation in dimethylformamide the above constants are significantly lower[77]. The observed change in the rate constants for the chain propagation and termination reactions has been attributed[77] to the polar effect, which changes as a function of the solvent. However, in this case the different degrees of association of the acid molecules in the solvents is also presumed to have a significant influence. Owing to the formation of hydrogen bonds between the acid and solvent molecules, in methanol and pyridine the degree of dimerisation of methacrylic acid is appreciably lower than in dimethylformamide, which is indicated by spectroscopic data[77]. The reactivity of dimerised methacrylic acid is lower, as with acrylic acid[68], than that of the non-dimerised acid.

A change in the degree of ionisation of the acid can also exert a definite influence on the polymerisation of acrylic acids in solvents of different polarity. Kabanov and coworkers[8] showed quite definitely that the reactivity of the ionised acid is much lower than that of the unionised acid.

Taking into account the different degrees of dimerisation and ionisation, it is possible to explain the results obtained in the polymerisation of butadiene-1-carboxylic acid in different electron-donating solvents[78]. The rate of polymerisation of this monomer under the influence of azobisisobutyronitrile increases in the sequence dimethylformamide < tetrahydrofuran < ethyl methyl ketone < acetonitrile < benzene.

Among the polar monomers for which the rate constants for the elementary chain propagation and termination reactions have been determined in different solvents, mention should be made also of *N*-vinylpyrrolidinone. It has been shown in an early study[79] that the rate of its radiation-induced polymerisation depends significantly on the nature of the solvent. The overall rate of reaction increases appreciably on passing from methanol to ethanol, isopropyl alcohol, and t-butyl alcohol. An even greater increase in the rate of the radiation-induced polymerisation was observed after the addition of water to methanol. Thus, following the addition of 25, 50, and 75% of water, the overall rate of reaction increased from 0.5–0.8 wt.% min^{-1} to 1.7, 3.5, and 5.75 wt.% min^{-1} respectively. Whereas the increase of the reaction rate in different alcohols can be accounted for by the increased rate of initiation owing to the change in the radiation-chemical yield of the initiation process (G_{in}), for aqueous methanol solutions the change in G_{in}, even if it is observed, cannot explain the sharp change in the overall rate of polymerisation.

Table 9. Polymerisation of *N*-vinylpyrrolidinone in various solvents at 26°C.[70]

Solvent	$k_p/k_t^{1/2}$, litre$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$	k_p, litre mole^{-1} s^{-1}
Tetrahydrofuran	0.08	400
Dichloroethane	0.08	400
Methanol	0.17	870
N-Vinylpyrrolidinone	0.15	1200
Water	1.40	>3500

In the study of the homogeneous polymerisation of *N*-vinylpyrrolidinone in different solvents it was established that the reaction under the influence of azobisisobutyronitrile can proceed in solution in methanol at a higher rate than in tetrahydrofuran or dichloroethane[80]. It follows from Table 9 that an increase of the overall rate of the process in methanol is almost fully due to the higher constant k_p. The change in k_p is in its turn related to the change in E_p: for virtually identical pre-exponential factors A_p (3.16×10^8 and 3.4×10^8 litre $mole^{-1}$ s^{-1} in methanol and tetrahydrofuran respectively), E_p for the polymerisation in methanol is smaller by 0.5 kcal $mole^{-1}$ than in tetrahydrofuran (7.6 and 8.1 kcal $mole^{-1}$ respectively).

The homogeneous polymerisation of *N*-vinylpyrrolidinone in bulk[81] and particularly in aqueous solution[70] is characterised by an even greater increase of the overall rate of the process (of the ratio $k_p/k_t^{1/2}$) than in methanol, compared with polymerisation in tetrahydrofuran and dichloroethane (Table 9). Here too, the change in the overall rate of polymerisation is accompanied by a change in k_p. In terms of their influence on k_p in the polymerisation of *N*-vinylpyrrolidinone the solvents can be arranged in the following sequence: tetrahydrofuran, dichloroethane < methanol < *N*-vinylpyrrolidinone < water. Evidently the increase in solvent polarity leads to an increase of k_p, which can be attributed to the influence of the solvent on the distribution of electron density in the pyrrolidinone ring and hence on the reactivity of the monomer and the radical formed from it. Neither can one rule out the influence of complex formation between the polymer radicals and the solvent, which varies as a function of the nature of the solvent.

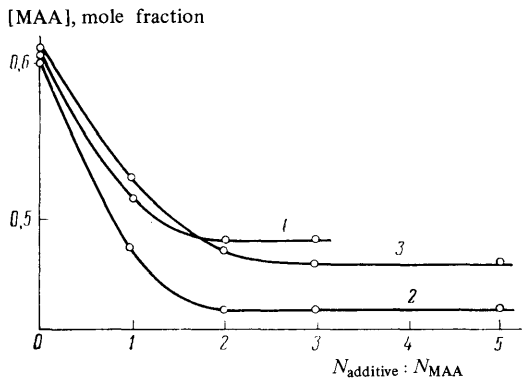
IV. COPOLYMERISATION

The different reactivities of the monomers in different solvents can lead to the variation of the rate of copolymerisation and the composition of the copolymers. The results of studies on the influence of the medium on copolymerisation involving acrylic and methacrylic acids as well as their amides are examined below, because the influence of the nature of the solvent on the reactivities of these monomers is most significant.

Many studies have been devoted to the copolymerisation of methacrylic and acrylic acids with certain vinyl monomers in solvents of different types. Both acrylic and methacrylic acids are known to exist in bulk phase as dimers, whose reactivity differs from that of the non-dimerised monomer molecules[69]. However, in many solvents the dimers decompose owing to the specific interactions between the acid and solvent molecules. In addition, one should bear in mind that the degree of ionisation of acid molecules can change with the polarity of the solvent, which should also be reflected in the reactivity of the acids. The composition of the copolymers of these acids with other monomers therefore usually depends on the nature of the solvent.

In the copolymerisation of methacrylic acid with methyl methacrylate or styrene the addition of dimethyl formamide or ethanol to the mixture of monomers reduces the content of the acid units in the copolymer[82] and dimethylformamide influences the composition of the copolymer to a much greater extent than does ethanol (Fig. 3). The decreased reactivity of methacrylic acid is caused by the formation of a complex with the solvent via –H...O–C hydrogen bonds, which is indicated by the appearance of a sharp maximum on the curve describing the variation of the viscosity of solutions of the acid in dimethylformamide or ethanol, as well as spectroscopic data. For mixtures of methyl methacrylate with dimethyl formamide, a linear

relation between the viscosity and mixture composition has been observed. The addition of water to the methyl methacrylate–methacrylic acid system also reduces the number of acid units in the copolymer[83].



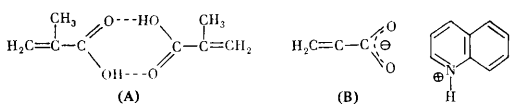


Figure 3. Variation of the content of methacrylic acid (MAA) in the copolymers formed in equimolar mixtures of methyl methacrylate (curves *1* and *2*) with methacrylic acid as the content of ethanol (curve *1*) and dimethylformamide (curve *2*) is increased and also in equimolar mixtures of styrene (curve *3*) with MAA as the content of dimethylformamide in the reaction mixture is increased.

The addition of Lewis bases (tetrahydrofuran, quinoline, pyridine, and DMSO) to the methacrylic acid–styrene system reduces the reactivity of methacrylic acid[84], pyridine and DMSO having the greatest effect. The reactivity of methacrylic acid decreases in their presence and the resulting copolymers are depleted in methacrylic acid compared with the copolymers synthesised in the absence of a solvent. It has been suggested[84] that in the presence of electron-donating solvents, for example quinoline, methacrylic acid can exist in two forms:

The reactivity of methacrylic acid in copolymerisation depends on the quantitative ratio between forms (A) and (B), which is determined in its turn by the nature of the solvent. The greater the amount of acid in form (B), the electropositive properties of the double bond of which are less marked than in (A), the lower the reactivity of the monomer in copolymerisation with styrene.

An appreciable variation of the constants for the copolymerisation of acrylic acid with styrene and methyl methacrylate as a function of the nature of the solvent has been observed[69,85,86]. Whereas for the reaction in bulk the constants for the copolymerisation of styrene with acrylic acid at 50°C are 0.25 (styrene) and 0.15 (acrylic acid), in solvents capable of forming hydrogen bonds with acrylic acid the relative reactivity of this monomer diminishes. In ethyl methyl ketone, dioxan, tetrahydrofuran, and dimethylformamide the copolymerisation constant is virtually invariant for the acid (0.13–0.15), but that for styrene changes from 0.70 (in ethyl methyl ketone) to 1.03 (in dimethylformamide), which indicates a decrease of the reactivity of acrylic acid. Analogous results were obtained for the copolymerisation of acrylic acid with methyl methacrylate[85,86]. A correlation has been established between the copolymerisation constants (for styrene and methyl methacrylate) and the stability constants of the complexes between acrylic acid and the solvent. One should note that the observed changes in the copolymerisation constants in the solvents investigated are not related to the different reactivities of the dissociated and undissociated acrylic acid, since a correspondence between the copolymerisation constants and the dielectric constants of the solvents has not been observed.

A more complete survey on studies of the influence of the medium on the copolymerisation of methacrylic and acrylic acids as well as vinylpyridines with other monomers, published up to 1973, has been carried out by Kabanov and Topchiev[8].

The different reactivities of the radicals formed from acrylic and fluoroacrylic acids in different solvents, established in a number of investigations[23,68,70-72], lead to a significant dependence of the rate of copolymerisation and the composition of the copolymers of these acids on the nature of the reaction medium[87]. Whereas in aqueous solution the addition of even small amounts of fluoroacrylic acid to acrylic acid entails a sharp decrease in the rate of the process, a different behaviour is observed in solution in DMSO (Fig. 4), where the rate of reaction passes through a small maximum as a function of the composition of the initial monomer mixture at low fluoroacrylic acid concentrations (20 mole%) and then gradually diminishes, reaching values characteristic of the rates of the separate polymerisation of acrylic and fluoroacrylic acids.

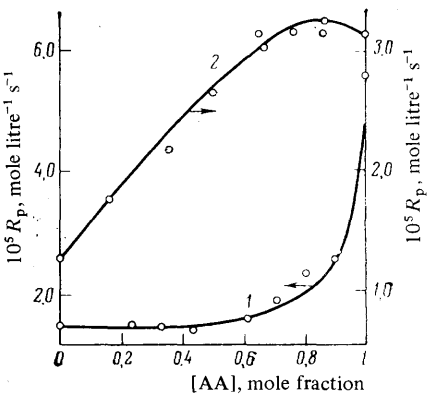

Figure 4. Dependence of the rate of copolymerisation of acrylic and α-fluoroacrylic acids on the composition of the mixture of monomers in copolymerisation in water (1) (initiator concentration 5×10^{-4} M) and in DMSO (2) (initiator concentration 4×10^{-3} M); $[M_1] + [M_2] = 1$ M.

The copolymerisation constants for the given pair of monomers are r_1(AC) = 0.5 and r_2 = 1.5 for copolymerisation in water, and r_1 = 0.5 and r_2 = 0.7 in DMSO. The rate constants for the addition of the radical to a "foreign" monomer (Table 10) have been calculated from the copolymerisation constants and rates of separate chain propagation[68]

(Table 10). These results show that, in the copolymerisation in water, the reactivities of the monomers and radicals differ strongly: the more reactive radical is that of acrylic acid and the more reactive monomer is fluoroacrylic acid. In polymerisation in DMSO the reactivities of the radicals and the monomers are similar. This is apparently associated with the formation of complexes between the polymer radicals and DMSO molecules, as suggested by Gal'perina et al.[72]

Table 10. The rate constants for chain propagation in the copolymerisation of acrylic (M_1) and fluoroacrylic (M_2) acids at 50°C.

Constant	Water	DMSO
r_1	0.5	0.5
r_2	1.5	0.7

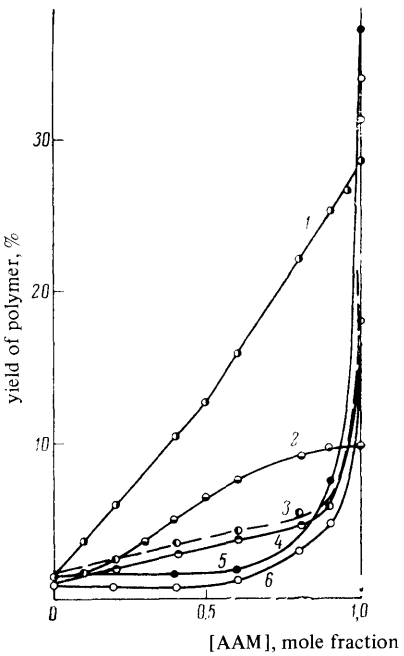

Figure 5. The influence of the composition of the initial mixture of monomers on the yield of copolymers of acrylamide and acrylonitrile in their radiation-induced copolymerisation in different solvents at 20°C; $[M_1] + [M_2] = 2.5$ M: 1) dioxan; 2) acetonitrile; 3) methanol; 4) dimethylformamide; 5) water; 6) acetic acid.

In the copolymerisation of methacrylic acid with acrylate and methacrylate esters (methyl acrylate, methyl methacrylate, and butyl methacrylate) in dioxan–water mixtures[88] an increase of the water content in the solvent leads to a decrease of the copolymerisation constant for the acid and an increase of that for the ester comonomer. The above data indicate a higher reactivity of the acid radical in water and are in good agreement with the ideas developed by Gal'perina et al.[72]

The formation of hydrogen bonds with the solvent also influences the reaction kinetics and the composition of the acrylamide–acrylonitrile copolymers[89]. In solutions in acetic acid, dimethylformamide, water, and methanol, i.e. solvents forming hydrogen bonds with acrylamide the addition of small amounts (up to 10%) of acrylonitrile to this monomer reduces the rate of the process significantly. In dioxan and acetonitrile the decrease of the rate of polymerisation following the addition of acrylonitrile is much smaller (Fig. 5). The greatest number of acrylamide units in the copolymer has been found in polymerisation in dioxan and acetonitrile. The copolymerisation constant for acrylamide depends little on the nature of the solvent (0.21–0.50), whereas for acrylonitrile the constant changes from 0.08–0.10 in acetonitrile and dioxan to 0.50 in acetic acid, 1.13 in methanol, and 1.9 in water and dimethylformamide. The observed effects are probably due to the different degrees of association of acrylamide molecules in the above solvents.

Table 11. Copolymerisation of acrylamide (M_1) with styrene in various solvents[90] ($\Delta\nu$, cm^{-1}, is the shift of the absorption bands).

Solvent	r_1	r_2	$\Delta\nu_{CO}$	$\Delta\nu_{NH^I}$	$\Delta\nu_{NH^{II}}$	$\Delta\nu_{NH,\,av}$
Benzene	12.5	0.25	1	15	10	12.5
o-Dichlorobenzene	12.5	0.25	3	5	5	5
Benzene–benzonitrile	4.4	1.5	8	46	45	45.5
Chloroform	—	—	13	47	55	51
Benzonitrile	2.4	1.35	12	70	55	62.5
Dioxan	1.38	1.27	10	205	170	187.5

*Gromov's data[21].

The copolymerisation of acrylamide with styrene in a large number of solvents of different types has been investigated[90]. The solvents selected were compounds which influence the acrylamide structure by the formation of hydrogen bonds, by dipole–dipole interaction, or by both factors. The change in the structure of acrylamide was inferred from the shift of the infrared absorption bands characterising the NH_2 or C=O groups. Thus the formation of hydrogen bonds between the monomer and the solvents as well as the polar interaction between them induce a change in the electron density around the double bond of acrylamide and hence alter its reactivity. The relatively low dipole moment as well as the inertness of styrene molecules with respect to the formation of hydrogen bonds entail a virtual constancy of the reactivity of this monomer as well as its radical in different solvents. The data presented in Table 11 show that the copolymerisation constant for acrylamide changes significantly in different solvents as $\Delta\nu_{NH}$ is altered. In solvents where neither dipole–dipole

interactions nor the formation of hydrogen bonds with acrylamide are observed (benzene, dichlorobenzene) the resulting copolymer is enriched in the acrylamide component. In those cases where the acrylamide molecules form strong hydrogen bonds with the solvent or are actively involved in a dipole–dipole interaction the copolymers are enriched in styrene.

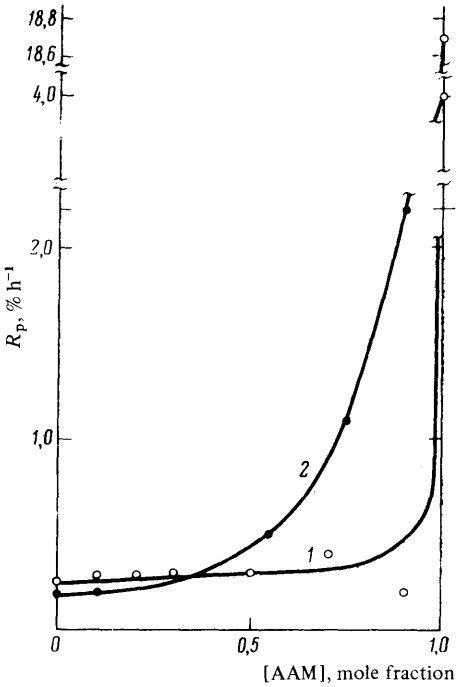

Figure 6. Dependence of the rate of copolymerisation of acrylamide with styrene on the composition of the initial mixture in DMSO (curve *1*) and THF (curve *2*); $[M_1]+[M_2] = 2.0 - 2.7$ M; initiator concentration $(5.3-6.5) \times 10^{-3}$ M; 40°C.

The nature of the solvent also influences the kinetics of the copolymerisation of acrylamide with styrene[22]. Fig. 6 shows that the addition of 10 mole % of styrene decreases the initial rate of reaction relative to the rate of the separate polymerisation of acrylamide, by a factor of approximately two in solution in tetrahydrofuran and by a factor of 50–60 in solution in DMSO. An even greater change in the rate of polymerisation is observed when the reaction is carried out in water. Thus the addition of even 0.01 mole % of styrene reduces the rate of reaction by a factor of 1.5–2.5, while the rate of polymerisation of a mixture of monomers containing 6 mole % of styrene is smaller by a factor of approximately 100 than the rate of homopolymerisation of acrylamide. The copolymers are in all cases enriched in styrene, the degree of enrichment being greater in DMSO and formamide than in tetrahydrofuran. The copolymer formed in water on copolymerisation of 94 mole % of acrylamide (AAM) and 6 mole % of styrene is virtually pure polystyrene. The copolymerisation constants for this pair of monomers are r_1(AAM) = 0.43 and $r_2 = 2.0$ in DMSO and $r_1 = 0.62$ and $r_2 = 1.1$ in tetrahydrofuran.

In conformity with the known characteristics of radical copolymerisation, the results obtained[22] indicate different reactivities of the acrylamide radical in the solvents investigated: the reactivity is highest in water and lowest in tetrahydrofuran, which agrees with the rates of separate polymerisation of acrylamide in the above solvents[54]. These results can be accounted for, as in Gal'perina's study[23], by the formation of complexes between the solvent and the polymer radical.

The different degrees of dimerisation of acrylamide and acrylic acid molecules as a result of hydrogen bonding with the solvent are responsible for the difference between the copolymerisation constants for the above monomers in water and acetone. r_1(AAM) = 1.38 and $r_2 = 0.36$ for the copolymerisation in acetone, while in aqueous solution $r_1 = 0.60$ and $r_2 = 0.43$.[91,92] These values indicate that the formation of hydrogen bonds between the monomeric molecules has a greater effect on the reactivity of acrylamide than on that of acrylic acid, since the transition from the associated form of acrylamide (in acetone) to the non-associated form (in water) is accompanied by a greater increase of the reactivity of the acrylamide radical compared with that of acrylic acid. Data[93] for the copolymerisation of acrylamide with acrylic and methacrylic acids in solvents of different polarity (dioxan, dioxan–ethylene glycol, and chloroform–ethanol), according to which an increase of solvent polarity entails a decrease of the copolymerisation constant for acrylamide, lead to the same conclusion.

Table 12. Copolymerisation of acrylamide and its derivatives (M_1) with styrene (St) and methyl methacrylate (MMA) in various solvents[95–99].

Solvent	St		MMA		Solvent	St		MMA	
	r_1	r_2	r_1	r_2		r_1	r_2	r_1	r_2
Acrylamide					**Dimethylacrylamide**				
Dioxan	1.38	1.27	2.45	2.55	Dioxan	0.44	1.28	0.51	2.04
Dioxan + ethanol (70:30 by volume)	0.59	1.13	0.82	2.53	Ethanol	0.42	1.33	0.42	2.30
Ethanol	0.30	1.44	0.44	2.60	Toluene	0.23	1.23	0.45	1.80
Diacetoneacrylamide					**Methacrylamide**				
Dioxan	0.47	1.85	0.50	1.80	Dioxan	1.29	1.46	1.27	1.55
Ethanol	0.30	1.80	0.31	2.00	Ethanol	0.54	1.27	0.43	1.68
Benzene	0.49	1.77	0.57	1.68					
Ethyl acetate	0.49	1.70	0.46	1.70					
					***N*-Methylacrylamide**				
					Dioxan	0.64	2.10	1.03	3.50
					Ethanol	0.20	2.20	0.28	3.30

These results conflict with data for the copolymerisation of acrylamide with methyl methacrylate published by Jacob et al.,[94] who showed that the addition of water to DMSO or chloroform increases significantly the content of acrylamide units in the copolymer and correspondingly the copolymerisation constant for acrylamide:

Solvent	DMSO	DMSO + H_2O (9:1)	Chloroform	Chloroform + 1% H_2O
