Advances in the Synthetic Chemistry of Macromolecular Compounds

V.V.Korshak and N.M.Kozyreva

The individual stages in the development of the synthetic chemistry of polymers are examined in their historical aspect. The present state of the chemistry of macromolecular compounds and the prospects for its development in the future are discussed and the types and characteristics of monomers used in polymerisation and polycondensation are considered. The entire wide variety of known polymeric macromolecules arising in various syntheses of polymers is demonstrated. Attention is drawn to the fundamentally important fact that all reactions involving the synthesis of macromolecular compounds lead to the formation of heterounit polymers, and the necessity to take into account the heterounit nature of polymers when problems of the dependence of their properties on their structure are considered is pointed out. Certain problems arising in modern technology and involving tasks soluble by synthetic methods are described and questions concerning the synthesis of polymers with specific properties are considered in relation to a number of examples. The present level of development of the syntheses of polymers by polymerisation and polycondensation methods and by the modification of existing polymers is described. The varieties of polymerisation and polycondensation processes and of the modification of existing polymers are examined (mainly in relation to new reactions, primarily those which lead to the formation of polymers of a new type). The increasing tendency towards the synthesis of polymers with specific properties, which is apparent at the present time, is emphasised.
The bibliography includes 122 references.

I. INTRODUCTION

The chemistry of macromolecular compounds is at the present time one of the most vigorously developing branches of chemistry. The rapid rate of its development can be accounted for by the fact that the synthetic chemistry of polymers ensures the growth of important branches of polymer technology involving the manufacture of plastics, synthetic rubber, synthetic fibres, and synthetic film-forming materials. The production of these materials plays in its turn an important role in the development of many of the most important branches of new engineering and modern industry: aviation, automobile, electro- and radio-technical, machine construction, building, etc. industries.

It may be assumed that the synthetic chemistry of polymers was initiated in 1833 [1] when Berzelius [2] formulated the concept of polymerisation, which has persisted, with some modification, to the present day. Gay-Lussac [3] obtained the first synthetic polymer—a polylactide based on lactic acid, and Braconnot [4] obtained cellulose nitrate, having achieved for the first time a polymer-analogue reaction. During the 145 years since then, the field of macromolecular compounds has been enriched by a large number of new synthetic methods and polymers of different structures. At the same time, theoretical ideas concerning the mechanism of the synthesis of polymers and the characteristics of their structure and properties have been developed. Studies of Staudinger, Carothers, Flory, Natta, and others have been very important in the formation of modern concepts concerning polymers. Russian and Soviet scientists made a significant contribution to the development of polymer chemistry. The studies by Butlerov, Lebedev, Favorskii, Shorygin, Kargin, Andrianov, Medvedev, Petrov, Korotkov, Ushakov, and others laid the foundations of polymer science and technology.

The first reports of the synthesis and investigation of macromolecular compounds described the results of random successes until the investigations of Butlerov, Kekulé, and Cooper led to the creation of the structural theory of organic chemistry [5]. The elegant edifice of polymer science was subsequently created on its basis. A huge army of investigators are now concerned with the synthesis, study, and applications of new polymers: 50% of organic chemists work directly or indirectly in the field of polymers, developing new methods for the synthesis of monomers, plasticisers, initiators, inhibitors, and other substances used in the synthesis and investigation of polymers. Many investigators are occupied with the synthesis and study of polymers and an even greater number of workers deal with the application of the results of these studies in industry, where polymers are manufactured, processed, and applied. To illustrate the wide scale of studies on the synthesis of polymers, one may say that during one year about 50 000 new polymers are now synthesised, i.e. more than 160 new polymers every day or one new polymer in each 3 min. [6] This has now led to the synthesis of hundreds of thousands of various polymers, but, despite this, the rate of synthesis increases continuously each year.

The explanation is that it is precisely in the field of synthesis of polymers that the efforts of investigators have been most effective both for the developments of the theoretical foundations of polymer science and for industry, enriching it in new polymeric materials. One is therefore fully justified in claiming that the synthetic chemistry of polymers constitutes a strategic component of the development of polymer science.

The industrial production of polymers is developing just as rapidly. The world production of polymers of all types has recently exceeded 64 million tons, approaching the scale of the manufacture of steel [7].

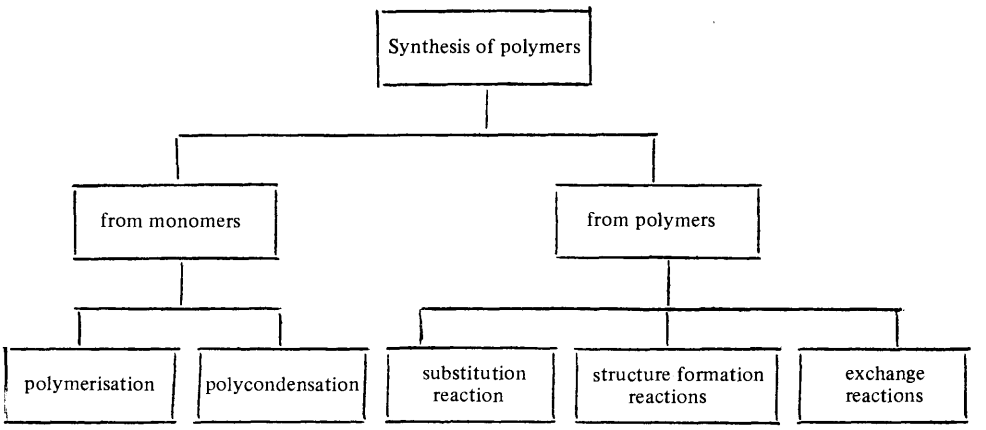

Figure 1. Scheme illustrating the fundamental ways of synthesising polymers.

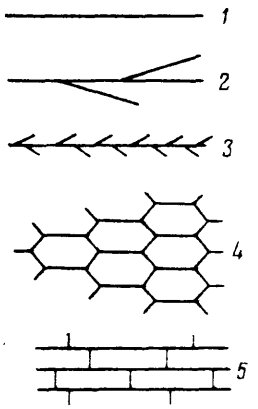

Figure 2. Shapes of macromolecules: 1) linear; 2) branched with a small number of long branches; 3) branched with a large number of short branches; 4) planar, parquet-like; 5) three-dimensional.

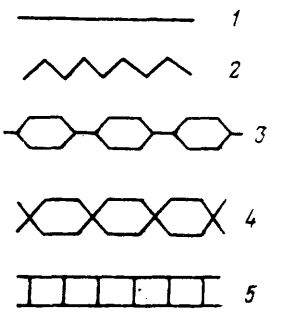
II. THE PRESENT STATE OF THE PROBLEM OF THE SYNTHESIS OF POLYMERS

Macromolecular compounds may be synthesised in several ways, as shown in Fig. 1. It is seen from the scheme that there are two types of synthesis of polymers: the first pathway involves the synthesis of polymers from low-molecular-weight substances by polymerisation and polycondensation and the second involves the modification of existing polymers by substitution, structure-formation, and exchange reactions.

We shall examine the present state of each of these types of synthesis in conformity with the above scheme. In the first place one should note that the advances in the synthesis of macromolecular compounds led to the formation of a wide variety of polymeric structures. As a result of the development of synthetic methods, it is now possible to obtain a wide variety of different forms of macromolecules, as shown in Fig. 2, where linear, planar, and three-dimensional forms of molecules known at the present time are illustrated. It is noteworthy that each of these forms also includes macromolecules of different types. Thus linear macromolecules may be of at least several types (Fig. 3). We see that the linear structure of the macromolecule is made up in different ways from units consisting of individual atoms or whole groups.



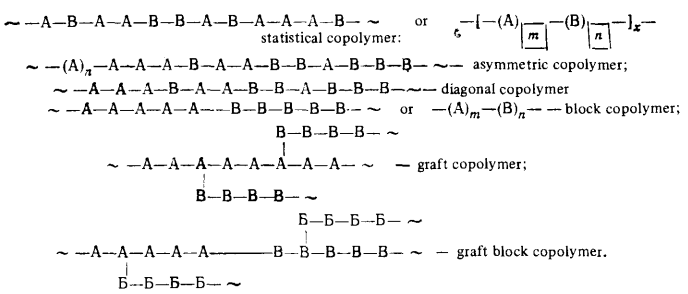


Figure 3. Forms of linear macromolecules: 1) straight ("carbene"); 2) zig-zag; 30 cyclochain; 4) cyclospiran; 5) ladder like.

There is also a wide variety of structures of macromolecular chains, particularly in different copolymers. Fig. 4 shows that the integral composition of the macromolecular chain varies along its length in various types of copolymers, starting from the usual statistical copolymers and extending via copolymers with macromolecular compositions varying along the chain (diagonal and asymmetric copolymers) to block and graft copolymers[8]. The structures of these copolymers can be represented by the

following formulae

The appearance of an increasing number of "hybrid" polymers, which are synthesised both by polymerisation and polycondensation or by the modification of existing polymers with the aid of polymerisation or polycondensation methods, should also be noted [6]. An example of "hybrid" polymers is provided by the hardening of unsaturated polyesters, which are obtained in the first stage by polycondensation, while in the second stage they copolymerise with styrene and other unsaturated monomers to form a three-dimensional copolymer [9]. Similarly, unsaturated polyamides, obtained by the polycondensation of fumaryl chloride with *N*-alkylated aromatic diamines, copolymerise with vinyl monomers to form copolymers with three-dimensional structures [10,11].

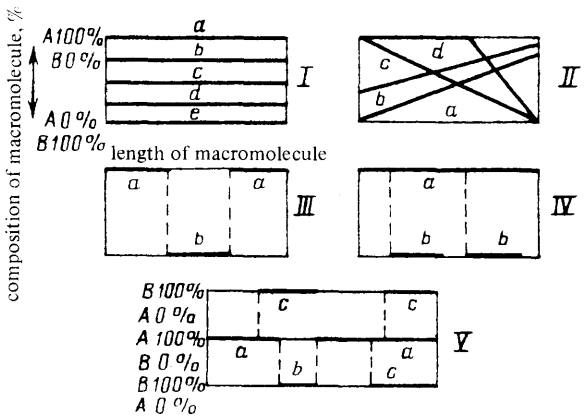

Figure 4. Variation of the integral composition along the length of the macromolecule in various copolymers: I) usual copolymers (*a*, *b*, *c*, *d*, *e*); II) variable-composition copolymers (*a*, *b*), diagonal copolymer (*c*), asymmetric copolymer (*d*); III) block copolymer [*a*) block consisting of A units; *b*) block consisting of B units]; IV) graft copolymer [*a*) main chain consisting of A units; *b*) grafted chains consisting of B units]; V) graft block copolymer [*a*) blocks consisting of A units; *b*) block consisting of B units; *c*) grafted chains consisting of B units].

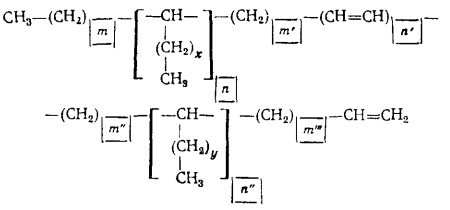
Certain polyamides are synthesised by the polycondensation of diamines with dicarboxylic acids, after which they are copolymerised with epoxy-compounds to form graft copolymers of the polyamide and epoxyalkanes [12]. Finally, block copolymers are synthesised by the reaction of poly(ethylene oxide), obtained by the polymerisation of epoxyethane, with poly(ethylene terephthalate) [13].

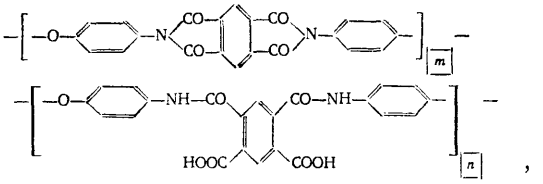
The wide variety of the structures of polymers, which is manifested particularly clearly in the case of copolymers, may be illustrated in relation to polypeptides. The exceptional complexity of the synthesis of polymers is associated, among other causes, also with the fact that in many instances there is a possibility of the formation of an unlimited number of isomers, since the 20 aminoacids encountered in natural proteins can form 10^{1200} macromolecules with different structures for a molecular weight of 100 000 (which corresponds to a polarisation coefficient of approximately 1000). In order to grasp the significance of this number, we may recall that the number of atoms of all the elements in the entire terrestial sphere is 10^{50}.

The enormous influence of the purity of the initial monomers on the course and result of the synthesis of polymers was established during research. The presence of impurities during polymerisation causes early chain termination, the branching of macromolecules, the formation of various unstable groups, and the formation of heterounit polymers as a result of these reactions. The presence of impurities in polycondensation also lowers the molecular weight of the polymers and leads to the formation of terminal groups of a different type, the branching of macromolecules, and other reactions leading to a heterochain polymer. Thus, since impurities as a rule are not inert in relation to the synthesis of polymers, they induce an uncontrollable modification resulting in the formation of heterounit polymers [14,15].

III. THE HETEROUNIT NATURE OF POLYMERS



The side reactions caused by the presence of various impurities as well as side reactions of all other types (for example, isomerisation, polymerisation, branching, etc.) alter the structure of part of the polymer units and lead to the formation of anomalous units, which produces heterounit polymers [16]. Fig. 5 presents examples of various reactions leading to the formation of anomalous units in the macromolecule and of heterounit polymers. Because of these causes, heterounit polymers having the general formula



where M is a normal unit and A an anomalous unit and m and n are coefficients indicating a statistical distribution of units, are formed in all syntheses of polymers by polymerisation and polycondensation methods [14-16]. Polymer modification processes (substitution, vulcanisation, and exchange reactions) also lead to the formation of heterounit polymers [15]. For this reason, a study of the formation of a heterounit macromolecule and of its microstructure is a most important task in polymer science, since only in this way can one solve the problem of the synthesis of polymers with a set of properties specified beforehand [15]. The establishment of exact relations between the structure and properties of polymers will be possible only when all the details of the structure of macromolecules and their mutual influence become known.

The enormous importance of the heterounit nature of polymers as a factor which influences significantly the entire set of their chemical and physical properties has been demonstrated in many instances [16]. This is particularly significant in view of the fact that heterounit polymers constitute at present the dominant form of polymeric

structures. For this reason, the formula of a real polymer should take into account its heterounit nature and the presence of anomalous units. Consequently the real formula of polymers such as polyethylene, expressing its heterounit nature, is as follows[17]:

It clearly differs markedly from the idealised formula $-[CH_2-CH_2]_X-$ usually employed. The heterounit polyimide, containing non-cyclised units, whose real formula is

constitutes yet another example.

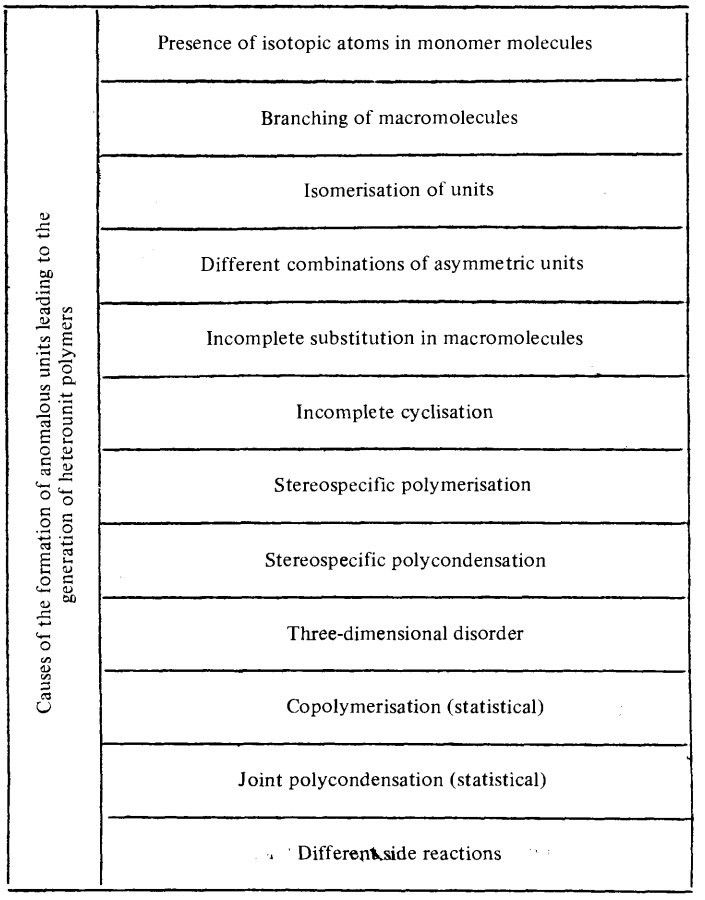


Figure 5. Causes of the formation of anomalous units leading to the generation of heterounit polymers.

In addition, the properties of polymers are influenced by the presence of the isotopes of hydrogen, carbon, and other polymer-forming elements. Thus it has been shown[18] that the replacement of hydrogen by deuterium in polyethylene alters appreciably physical characteristics such as density, melting point, glass point, yield point, and chemical properties. On this basis, it was concluded that the presence of isotopes in macromolecules leads to the formation of heterounit polymers, which affects the entire set of their physical and chemical properties. At the same time, account must be taken of the possibility of the simultaneous operation of the isotope effect and of the influence of the anomalous units arising as a result of branching, isomerisation, and other chemical reactions—these effects may coincide and enhance one another. The heterounit nature of polymers should be manifested particularly significantly in biopolymers, where one may expect very specific and very appreciable manifestations of the isotope effect. In fact, we know that, in structures such as proteins, nucleic acids, etc., very small structural changes influence significantly the biological functions. At the same time it is known that various isotopes are non-equivalent in their physiological properties. Thus, among the causes responsible for the heterounit nature of polymers, one must also point to the influence of the presence of stable isotopes in the molecules of the initial monomers and polymers.

IV. PROBLEMS OF THE SYNTHESIS OF POLYMERS WITH SPECIFIC PROPERTIES

Investigators working in the field of the synthesis of polymers are faced by complex tasks. These include tasks associated with the development of new and the improvement of existing methods for the synthesis of polymers in order to increase their yields and to improve the physicochemical characteristics of polymers and the articles made from them. At the same time problems concerning the application of methods of polymer chemistry to the synthesis of new polymers with the required set of properties, which are of practical interest and are essential for the execution of a particular task, are being solved. We shall consider certain examples of the synthesis of new polymers with specific properties.

The preparation of polymers with many practically important properties such as high heat resistance and thermal stability, non-combustibility, resistance to light, and specific electrophysical and other properties, constitutes an enormously important task[19-21]. An important branch of the synthesis of polymers involves the preparation of thermostable polymers capable of being used for a long time at high temperatures[19-22,23]. Many polymers have been synthesised for this purpose, including polyorganosiloxanes, particularly those with a ladder structure, and polyheteroarylenes, particularly polyimides, and similar structures[19,22,24,25]. Among these, polyamides based on pyromellitic anhydride and di-(4-aminophenyl) ether as well as polyoxadiazoles, polybenzimidazoles, and polybenzoxazoles proved to be particularly interesting. They are of practical interest as the starting materials for the manufacture of thermostable fibres and films. Studies on polymers for different electrotechnical purposes have been greatly developed: polymers for the manufacture of insulators, electrically conducting materials, semiconductors, polymers with photoelectric activity, etc. Many investigators have devoted much attention to the problem of the synthesis of polymeric

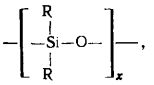
semiconductors and superconductors. Polymers with conjugated bonds of the polyvinylene, polyacetylene, polyphenylene, etc. type as well as polyheteroarylenes and their derivatives are obtained for this purpose [26].

The problem of the protection of the environment has faced synthetic chemists with the problem of the preparation of polymers capable of being decomposed after their utilisation, which is particularly important for packing materials. This problem is being solved in different ways, among which one of the most important is the synthesis of polymers capable of being decomposed by light. For this purpose, groups are introduced into the macromolecule increasing its sensitivity to light. On the other hand, practical problems necessitate the synthesis of noncombustible and self-extinguishing polymers, which is particularly important for the building industry and many branches of modern technology [27]. The preparation of composite and other materials with a high strength is likewise especially important [28-31]. The advantages of strengthened [reinforced?] compositions compared with traditional constructional materials are associated primarily with the possibility of a wide-scale variation of virtually all the properties of the material, which may be achieved by selecting the components and their proportions in the composition, the interaction conditions, the method of reinforcement, and other ways. Depending on the requirements which must be met by the composite materials, fibres and articles made from them, single-crystal fibres, films, hollow spheres, and other materials may be used as fillers [28].

High-strength, high-modular composite materials based on glass, boron, and carbon fibres and characterised by effective physicomechanical parameters are of special interest. The theoretical strength of steel and asbestos is 2000 and that of glass fibre is 1000 kgf mm^{-2}; on the other hand, the real strength is much lower and amounts to 250 kgf mm^{-2} for steel and 300 kgf mm^{-2} for asbestos. There is a theoretical possibility of increasing considerably the strength of articles made from polymeric materials; indeed, the strength of carbon fibres already reaches 300–400 kgf mm^{-2}. The problem of synthesising strong materials will evidently be solved also chemically, by synthesising polymers with rigid macromolecules. The ordered structure of polymers, achieved in different ways, will play a major role in this process.

Antifriction self-lubricating plastics (ASP plastics), which have found extensive applications in the construction of friction units (ball bearings, etc.) not requiring liquid lubricant, constitute a most interesting form of composite materials [31].

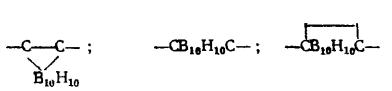
The problem of synthesising polymers for use in medicine with a wide variety of properties, such as thrombogenic properties, the ability to be dissipated in the organism, and conversely stability under the conditions of the living organism, pharmacological activity, etc., which are essential for the manufacture of artificial hearts, kidneys, livers, and other organs, is extremely urgent. The interesting problems of the synthesis of catalysts which are analogues of enzymes and of various biopolymer-like materials are also attracting the attention of investigators.



Increasing attention is being devoted to the problem of stereoregulation in the synthesis of polymers. In the field of polymerisation this involves the synthesis of stereoregular (isotactic, etc.) polymers, the synthesis of optically active polymers, the preparation of *cis*-1,4- and *trans*-1,4-polydienes, and the synthesis of stereoblock polymers. In the field of polycondensation examples of the regulation of the structure in the course of synthesis are provided by acceptor-catalytic polycondensation, the preparation of globular or fibrillar structures in polyarylates as a function of the conditions of synthesis, and the formation of right-handed or left-handed helices in polypeptides.

The study of copolymerisation and copolycondensation in order to obtain copolymers of practical value is being vigorously prosecuted [32]. Graft and block copolymerisation, which lead to new procedures for modifying polymers in a wide variety of ways, have developed greatly. Block copolymers, including polycondensation block copolymers, make it possible to obtain new types of elastomers, which do not require vulcanisation, as well as polymer systems suitable for the preparation of membranes capable of selective separation of gaseous mixtures.

Exceptionally important prospects have arisen in connection with the "chemical moulding" of polymers, which make it possible to obtain finished articles in the course of synthesis, for example, the manufacture of sheet poly(methyl methacrylate). Polyamides in the form of films or fibres can be obtained by interfacial polycondensation.



Anionic polymerisation of ϵ-caprolactam, which makes it possible to obtain poly-ϵ-caproamide in the form of finished articles of any shape which do not require mechanical working ("caprolite"), is of very great interest [33]. There is not doubt that the "chemical moulding" of polymers in the course of synthesis constitutes one of the most advanced procedures whereby one can eliminate the laborious processing steps usually employed when powdered polymers are used. In this case synthetic chemists merely copy nature, which learned a long time ago to synthesise silk, cotton, and other fibres from monomers, to form the skin of animals, blood vessels, etc.[17] There is no doubt that the polymer technology of the future will be largely based on chemical moulding processes.

The chemistry of organoelemental compounds, whose foundations were laid by A. N. Nesmeyanov, has itself become the foundation on which the edifice of the chemistry of organoelemental polymers grew [34]. K. A. Andrianov, who discovered the ability of silicon to form chains of alternating silicon and oxygen atoms, has played an outstanding role in the creation and development of the new field of the chemistry of polymers with inorganic main molecular chains. These polymers, having the structure

and known as polysiloxanes, have found an honourable place in polymer science and industry [35]. Despite the close relation between carbon and silicon, these polymers proved to constitute a completely unusual and very interesting group. Further studies showed that each element in the macromolecule makes its contribution to the set of properties of the polymer.

Polycarboranes are a very interesting group of polymers characterised by an unusual set of properties [36]. Together with various organic groups, their macromolecules contain *o*-, *m*-, or *p*-carborane rings:

Phosphorus-containing polymers, such as polyphosphazines having the structure [35]

$$-[N=P(R_2)]_x-$$

are also a promising group.

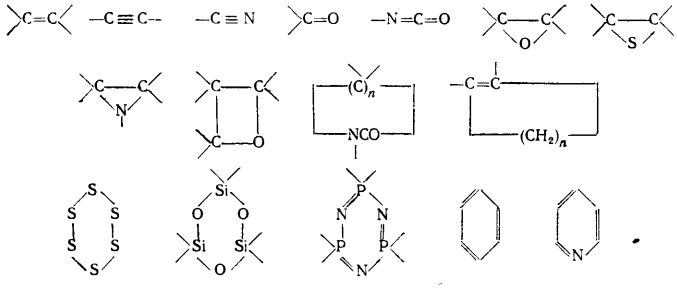
Table 3. Distribution of papers on the synthesis of new polymers.

Method	Proportion of papers devoted to the synthesis of new polymers in terms of methods of synthesis, %	Proportion of papers devoted to the synthesis of new polymers, % of total number of papers on given method of synthesis
Polymerisation	38.9	27.7
Polycondensation	49.3	66.6
Modification	11.8	20.0

The task of finding ways of synthesising a wide range of polymers, incorporating the entire wide variety of the elements in the Periodic System, is of great importance [35]. Thus the polymeric structures known at the present time include 59 elements in Mendeleev's Table, as shown in Table 1. [37]



We shall consider the importance of methods of synthesis of polymers such as polymerisation, polycondensation, and modification of existing polymers. Among the chemical papers published in 1974 in the journal "Vysokomolekulyarnye Soedineniya" (Macromolecular Compounds), 89.4% were devoted to the synthesis of polymers; their distribution with respect to methods of synthesis was as shown in Table 2. The proportion of the total number of chemical papers describing the synthesis of new polymers was 32.8%. Table 3 shows how these papers are distributed with respect to methods of synthesis.

These data permit the conclusion that at the present stage studies on polymerisation are devoted mainly to the improvement of polymerisation methods, to the search for more active catalysts, and to the determination of the optimum conditions for the synthesis of polymers which are already known. Polycondensation studies involve the synthesis of new polymers to a greater extent than the improvement of synthetic reactions. The research in the field of modification, like that in the field of polymerisation, is also mainly directed to the study of chemical reactions of polymers and the improvement of modification reactions. We shall next consider the state of affairs in each of these fields of the synthesis of polymers.

V. POLYMERISATION

In considering the syntheses of polymers, one should note that a characteristic feature of polymerisation is the presence of many structures of new monomers and of many new polymerisation processes.

The range of active functional groups used to prepare polymers has been greatly extended. The most important of these, used in polymerisation, are indicated below:

Polymerisation processes, occurring as reactions involving additions to double bonds and rings, are being vigorously investigated at the present time and considerable advances may be noted in this field.

Table 4 presents the polymerisation processes known at the present time and the dates of their discovery.

A characteristic feature of the modern period is the vigorous development of research into polymerisation processes. Together with the considerable progress in the development of classical methods such as radical, cationic, and anionic polymerisation of unsaturated compounds as well as the polymerisation of heterocycles, new polymerisation processes have been discovered and investigated in detail. Among these we shall mention in the first place ionic-coordination polymerisation, migration polymerisation, polycyclotrimerisation, polydisproportionation, Diels–Alder polymerisation, 1,3-dipolar polyaddition, etc. Ziegler's discovery [50] in 1950 of catalysts for the low-pressure polymerisation of ethylene initiated the period of rapid progress in the polymerisation of olefins and other monomers. In a series of brilliant investigations by Italian scientists, Natta [46] discovered a new pathway to the development of stereospecific polymerisation processes.

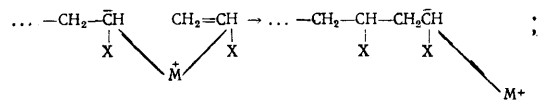
Stereospecific polymerisation has become the leading field in polymer synthesis, in which many scientists of all countries are engaged. These investigations led to the

industrial manufacture of many polyolefins: polyethylene, polypropylene, ethylene–propene copolymers, many higher polyolefins, poly(*cis*-1,4-polybutadiene) and poly-(*cis*-1,4-isoprene)—new types of synthetic rubbers which are complete substitutes of natural rubber, etc. As a result of studies by S.V.Lebedev, B.A.Dolgoplosk, A.A.Korotkov, and others, our country now occupies a leading place in the world as regards the technical quality and range of synthetic rubbers.

Table 4. Polymerisation processes.

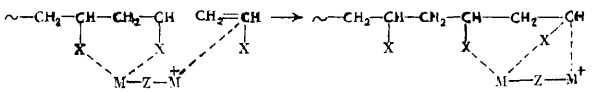
Reaction	Year of discovery	References
Radical polymerisation	1839	38
Cationic polymerisation	1873	39
Anionic polymerisation	1878	40
Diels–Alder polymerisation	1926	41
Migration polymerisation	1937	42
Hydrolytic polymerisation of heterocycles	1938	43
Cyclopolymerisation	1949	44
Dehydropolymerisation	1951	45
Stereospecific polymerisation	1955	46
Onium polymerisation	1961	47
1,3-Dipolar polyaddition	1963	48
Polycyclotrimerisation of acetylenic compounds	1965	49
Polydisproportionation	1967	52

Four mechanisms of chain propagation in ionic (cationic and anionic) polymerisation are now believed to be possible:



(1) polymerisation with participation of a free ion:

$$\ldots -CH_2-\overset{+}{C}HX + CH_2=CHX \rightarrow \ldots -CH_2-CHX-CH_2-\overset{+}{C}HX;$$

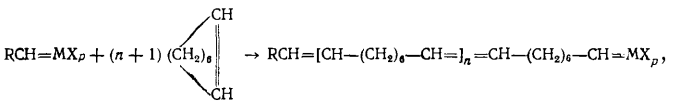


(2) polymerisation with an ion pair:

$$\ldots -CH_2-\overset{+}{C}H\ldots A^- + CH_2=CH \rightarrow \ldots -CH_2CH-CH_2\overset{+}{C}H \ldots A^-;$$

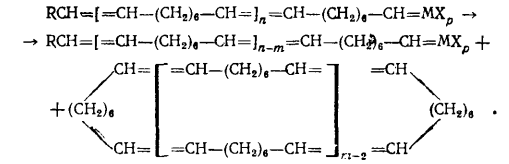
(3) two-centre coordination polymerisation:

(4) many-centre coordination polymerisation:



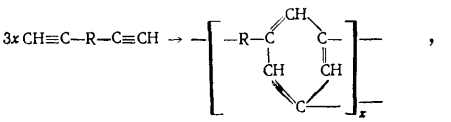
Stereoregulation is possible in each of these cases. However, in the first and second cases this possibility is realised only at low temperatures, while in the third and fourth cases the process is observed also at elevated temperatures. In the elementary chain propagation step of many-centre coordination polymerisation the polar groups of the monomer and the polar groups of the last two units of the growing chain form a complex with more than one active centre of the composite or associated catalyst, which limits the free rotation of the ends of the chains and the monomer molecules and ensures a definite disposition of the units in the elementary chain propagation step.

Isomerisation polymerisation accompanied by the isomerisation of the units has proved to be a very special case in the syntheses of polymers via both radical and particularly ionic polymerisation. This results in the formation of anomalous units and of heterochain polymers [16].

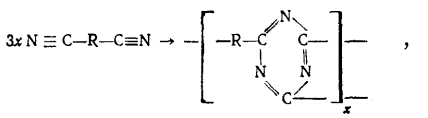


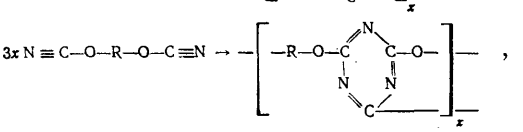
Studies on regular copolymerisation, leading to copolymers with a regular alternation of units, have been considerably developed [51]. The copolymers thus produced are frequently substances with an interesting set of properties.

A new field in polymerisation is polydisproportionation occurring in the presence of molybdenum- and tungsten-containing catalytic systems. Cyclic olefins such as cyclo-octadiene, cyclo-octene, norbornene, etc. are used as the initial monomers in this reaction [52,53].



The polydisproportionation reaction proceeds in accordance with the equation





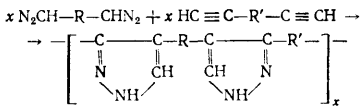
where M = Mo or W, and is accompanied by the formation of cyclic oligomers. A carbene is the intermediate active centre in this reaction, which proceeds as a chain process [54]. Cyclic oligomers are formed in this process as a result of the degradation of the active polymeric macromolecule via the reaction [55]

A new method for the synthesis of polymers with different structures, based on the cyclotrimerisation of multiple carbon–carbon and carbon–nitrogen bonds, has been developing vigorously recently. The polycyclotrimerisation of diacetylenes, dinitriles, dicyanates, and di-isocyanates, leading to the formation of benzene or triazine rings in accordance with the equations [56–58]

is particularly interesting. This reaction leads to a new way of synthesising polymers containing aromatic and heterocyclic groups in the macromolecules [59].

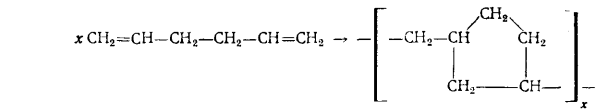
The polymerisation of aldehydes, ketones, and other carbonyl compounds has recently attracted the attention of investigators [60]. The polymerisation and copolymerisation of formaldehyde, which proceeds as a cationic process, namely

$$x\,CH_2O \rightarrow -[-CH_2-O-]_x- \quad ,$$



is being particularly vigorously investigated. Studies by N.S.Enikolopyan, who demonstrated the occurrence of an

unusual chain termination stage called "chain transfer with branching", have made a major contribution to the study of this process [61].



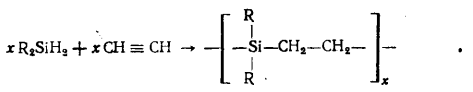
Polymers containing rings in the chain have been obtained with the aid of diene or Diels–Alder synthesis [62]. In this case it is necessary that the molecules of the initial monomer should contain a diene system and a dienophile, capable of reacting with one another under specified conditions via the mechanism

An unusual instance of polymerisation is the formation of polypyrazoles by the reaction of bisdiazo-compounds with diacetylenes via the 1,3-dipolar addition mechanism according to the equation [63]

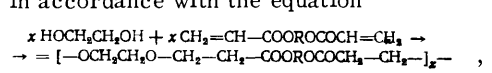
Cyclopolymerisation is a method of obtaining polymers containing cyclic groups in the macromolecular chain [44]:

It occurs in the polymerisation of various dienes containing separated double bonds. The reaction usually yields comparatively low-molecular-weight polymers.

Dehydropolymerisation is a reaction whereby a *p*-zylylene polymer has been obtained [45]. It occurs in the formation of *p*-xylylene and is described by the following equation:

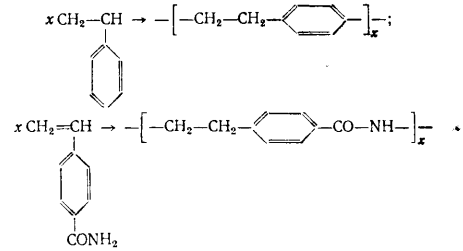


This process has also been carried out for a number of xylene analogues. The resulting biradicals are extremely reactive and readily copolymerise with other monomers.



Migration polymerisation is polymerisation involving the transfer (migration) of hydrogen atoms at each stage [64]. This process is sometimes referred to as polyaddition. The polymerisation of aldehydes via the Tishchenko reaction [65], the formation of polyacetals [66], the formation of polyamides from bisoxazolones and diamines [67], and the synthesis of important polymers such as polyurethanes and polyureas by the reaction of di-isocyanates with glycols and diamines [42] are of this type. The range of these processes has been increasingly expanded recently. As examples, we may mention the formation of polyurethanes

and the synthesis of organoelemental polymers containing silicon, germanium, and tin via hydride addition [68]:



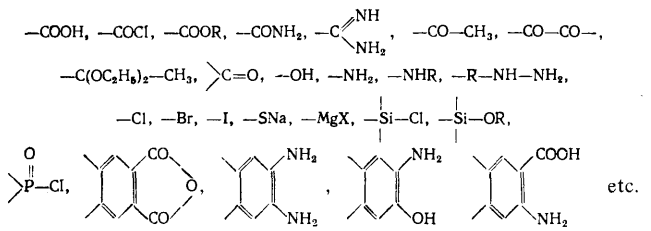
The formation of polymers via the addition of glycols or diamines to diacrylate or dimethacrylate esters, which proceeds in accordance with the equation [69]

is of the same type.

Many isomerisation polymerisation reactions also take place with migration of hydrogen [14]. Thus styrene and substituted styrenes can form polymers via the following mechanisms [70,71]:

The anionic polymerisation of propene is also accompanied by isomerisation and leads to the formation of polyethylene [72]:

Onium polymerisation has been investigated in relation to the reaction of γ-chloropyridine [47]:



Polymerisation processes may be initiated with the aid of energetic influences such as ionising radiation, explosive impact, high pressure, mechanical action, etc. [73–75] Ionising radiation has found practical application in the initiation of polymerisation [76]. An interesting case is the initiation by this procedure of solid-state polymerisation, particularly at low temperatures [74,75].

The study of solid-state polymerisation at low temperatures enabled Semenov [77] to devise the collective interaction theory. According to Semenov, solid-state polymerisation takes place very fast when a frozen monomer is irradiated, because, as a result of a particular orientation in the crystal, the ion or radical combines not with a single monomer molecule but with a chain of molecules at once, in the region where the crystal is ideal. Thus, owing to the favourable disposition of the molecules in the crystal, there exists a kind of "seed" for the formation of macromolecules (which is not the case in liquids) and this ensures a faster polymerisation.

The polymerisation of cyclic compounds has been acquiring increasing importance as a general method for the synthesis of macromolecular compounds. Many heterochain polymers containing oxygen, nitrogen, sulphur, metals and other elements as heteroatoms have been obtained in this way. Cyclic compounds polymerise via a typical polymerisation mechanism and the process can be achieved as a stepwise (hydrolytic) polymerisation and as a chain reaction (anionic polymerisation). It is now known that all cyclic systems with sufficiently polar or polarisable bonds are capable of polymerisation regardless of their size. The polymerisation of siloxane rings, widely used as a method of synthesis of polysiloxane rubbers and other polymers, is very important [78]. Polymerisation of cyclic systems by a very rapid method, involving the use of activators, is particularly promising [79]. The use of activators in the anionic polymerisation of ϵ-caprolactam is extremely effective: it makes it possible to carry out the process over a short period at comparatively low temperatures.

VI. POLYCONDENSATION

Processes of the polycondensation type have been extensively developed in connection with the synthesis of thermostable polymer and other polymeric compounds of different types. In the first place mention should be made of the large number of monomers, containing a wide variety of functional groups, which are used in polycondensation processes, for example:

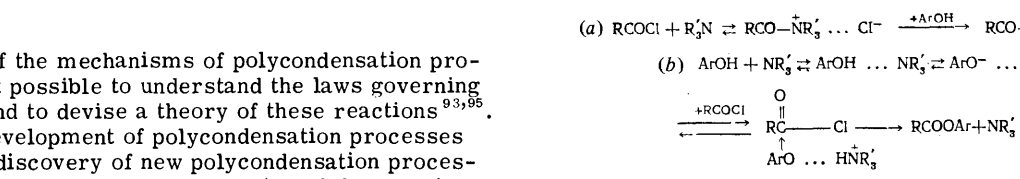
Polycondensation has been known for a long time as a general method for synthesis of polymers. It proceeds as a substitution reaction and is usually accompanied by the formation of a low-molecular-weight product [80]. Table 5 gives the dates of discovery of individual types of polycondensation.

Table 5. Polycondensation processes.

Reaction	Year of discovery	References
Equilibrium polyesterification	1833	3
Polyamidation	1862	81
Phenol-aldehyde polycondensation	1872	82
Polyazination	1889	83
Interfacial polycondensation	1898	84
Polyheterocyclisation	1908	85
Polycoordination	1953	86
Acceptor-catalytic polycondensation	1956	87
Polyrecombination	1957	88
Oxidative polycondensation	1960	89
Polycyclocondensation	1960	90
Stereospecific polycondensation	1970	91
Disproportionation polycondensation	1972	92

The study of the mechanisms of polycondensation processes made it possible to understand the laws governing their course and to devise a theory of these reactions [93,95]. The present development of polycondensation processes has led to the discovery of new polycondensation processes together with a deeper understanding of the reaction mechanism.

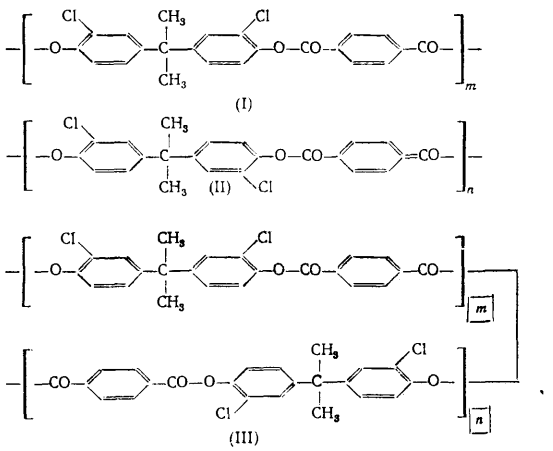
Depending on the structure of the starting materials and the way it is carried out, polycondensation can be achieved in two versions [94]: (1) equilibrium polycondensation; (2) non-equilibrium polycondensation. In equilibrium polycondensation the equilibrium constant of the reaction is in the range from 1 to 10^3, while in non-equilibrium polycondensation it exceeds 10^3 [93]. Equilibrium polycondensation proceeds as a rule at a low rate [95]. An example of this reaction is provided by the formation of polyamides from diamines and dicarboxylic acids in the melt.



Studies on equilibrium polycondensation during the period under consideration have been characterised by a deeper understanding of the fundamental characteristics of the processes and their wide-scale application in the synthesis of many new, mainly heterochain polymers (polyamides, polyesters, polyazines, coordination polymers, etc.). Equilibrium polycondensation is based on reversible elementary equilibrium reactions [95]. A new instance of equilibrium polycondensation is disproportionation polycondensation in accordance with the equation [92,96,97]

Together with equilibrium polycondensation, there are also polycondensation processes based on irreversible elementary reactions. Reactions of this type belong to the group combined under the general name "non-equilibrium polycondensation" [93]. There is a fairly large number of instances of non-equilibrium polycondensation. They include oxidative polycondensation reactions, polyrecombination, polycyclisation, as well as interfacial polycondensation, acceptor-catalytic polycondensation, and polycyclocondensation.

Non-equilibrium polycondensation is characterised by high equilibrium constants and as a rule a high rate [6,93]. An example of reactions of this type is provided by the formation of polyamides from diamines and dicarboxylic acid chlorides. There are many instances of non-equilibrium polycondensation where the reaction is comparatively slow. However, the polymers produced by the reaction are stable under its conditions and incapable of being hydrolysed or of undergoing degradative transformations, which is the reason for the irreversibility of the overall reaction. Dehydropolycondensation, polyrecombination, and polycyclisation, which were examined below, were examples of reactions of this kind.

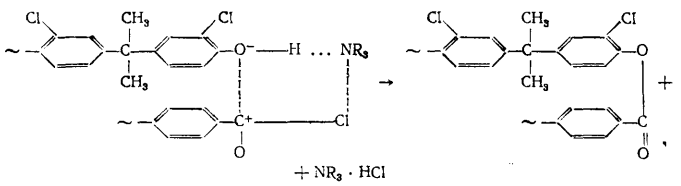


Polycondensation in solution, carried out at temperatures below 100°C, also referred to as low-temperature polycondensation, has recently attracted much attention by investigators and its various aspects are being vigorously developed. In the synthesis of polyesters from acid dihalides and diols in the presence of tertiary amines, it is referred to as acceptor-catalytic polycondensation [98]. In the synthesis of polyarylates the process proceeds via nucleophilic (a) or general base (b) catalysis in the following way:

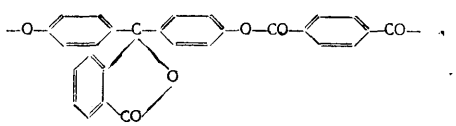
Apart from the activities of the starting materials, the formation of macromolecules is influenced by the nature of the solvent and the tertiary amine, particularly its ability to form complexes with the starting materials. The method permits a very fine control of the structure of the polymers obtained.

Conformationally-specific polycondensation has been achieved under the conditions of acceptor-catalytic polyesterification for the reaction of 3,3'-dichlorodian with terephthalic acid chloride [91]. The reaction results in the formation of macromolecular conformers whose structure is determined by the nature of the solvent and the tertiary

amine[99,100]. The formulae of polyarylates formed by this reaction are given below:



(I)



(II)

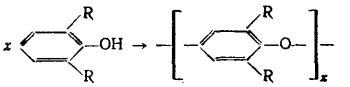
(III)

Here (I), (II), and (III) are *cis*-tactic, *trans*-tactic, and heterochain (atactic) polymers containing units of both conformations. The nature of the tertiary amine has a significant influence on the conformationally specific polycondensation, which is attributed to the formation of cyclic intermediate complexes[100]. In general base catalysis such a complex can be represented as follows:

The use of phenolphthalein and similar substances as starting materials in the reaction of an acid dichloride and a bisphenol leads to the formation of cardopolymers[101], a characteristic feature of which is that the carbon atom in the monomer residue is at the same time part of the polymer chain. The polyarylate formed from phenolphthalein and terephthalic acid is an example of such a cardo-polymer:

Oxidative polycondensation is being developed on an increasing scale as a general method for the synthesis of various polymers[102,103]. The application of this reaction to diacetylenic compounds of the type $HC\equiv C-R-C\equiv CH$ made it possible to obtain a large number of linear polymers having the general formula

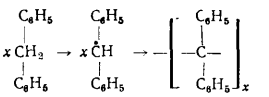
$$-[-C\equiv C-R-C\equiv C-]-_x,$$



containing triple bonds in the chain together with phenyl and other groups. "Carbene", which is a linear form of carbon, has been obtained in this way from acetylene[89]. It is formed in the oxidation of acetylene in the presence of copper salts via the reaction

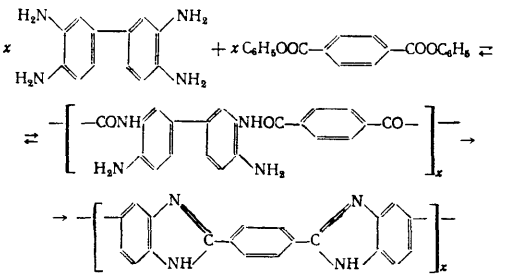
$$n\,HC\equiv CH \xrightarrow{Cu^{2+}} -[-C\equiv C-]_n- \quad .$$

A polyphenylene has been obtained by oxidative polycondensation from benzene[104]:



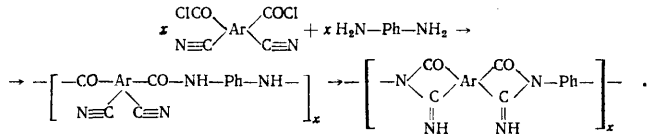
The oxidative polycondensation of 2,6-disubstituted phenols makes it possible to obtain polymeric phenyl ethers—poly(phenylene oxides):

This oxidative process takes place in the presence of catalysts (copper salts) and an oxidant[105].



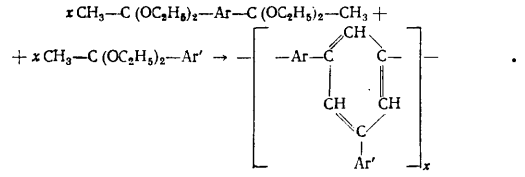
Increasing attention has been devoted recently in polymer chemistry to the problem of the synthesis of polymers with substances which are not monomers in the present sense of this term, i.e. do not contain double bonds, rings, or any other traditional functional groups. One of the ways of solving this problem is to employ a polyrecombination reaction, whereby saturated hydrocarbons and other substances incapable of polymerising in the usual way can be converted into polymers.

Polyrecombination involves the synthesis of polymers via the mechanism (when diphenylmethane is used as a starting material)[106]



The elementary processes in polyrecombination are the formation and recombination of free radicals. A characteristic feature of the monomers used in polyrecombination is the presence of hydrogen atoms, which are easily removed by free radicals. When the monomer contains two reactive hydrogen atoms, linear polymers are obtained and in the presence of three and more atoms the products are branched and three-dimensional polymers.

Polycyclisation is a new type of reaction leading to the formation of polymers having a cyclochain structure[107]. Although in terms of its mechanism the reaction is a polycondensation process, its mechanism is in fact extremely unusual. In the first stage this involves an ordinary equilibrium reaction leading to the formation of polyamides, polyesters, polyhydrazones, and similar compounds, depending on the structure of the starting materials. The characteristics of this stage do not in general differ from those known for analogous reactions. In the second stage, cyclisation proper takes place, i.e. the closure of the heterocycle characteristic of the given reaction. This stage constitutes non-equilibrium polycondensation, since the formation of stable rings is as a rule an irreversible process, which proceeds in the case of the synthesis of polybenzimidazoles by the Marvel method in accordance with the equation[108]



The polycyclisation reaction has been investigated nowadays in relation to the synthesis of polymers incorporating in their chains heterocycles such as thiazole, imidazole, pyrazole, triazole, oxadiazole, phthalimide, triazine, benzimidazole, benzoxazole, benzothiazole, etc.[109]

An interesting instance of polycyclisation is isomerisation polycyclisation, where the starting materials are aromatic acid dichlorides or diamines containing cyano-groups in the ring[110]. Under these conditions, the first stage involves non-equilibrium polycondensation, leading to the formation of polyamides. The latter then undergo cyclisation as a result of their addition to cyano-groups, as shown below:

Polycyclocondensation is a process involving the synthesis of polymers whose mechanism is close to that of polycyclotrimerisation[122]. Macromolecules are formed as a result of the formation of aromatic or heterocyclic units linking the molecular residues of various initial substances. As an example, one may quote the formation of polyphenylene from the diketal of *p*-diacetylbenzene and the ketal of acetophenone via the reaction

The polycondensation reactions considered above take place in the vast majority of cases as ionic processes which are extremely sensitive to the action of catalysts. The use of catalysts to accelerate the polycondensation reaction is therefore extremely effective[100].

VII. MODIFICATION OF POLYMERS

The reaction involving the modification of existing polymers has been developed on an increasing scale in the synthesis of polymers with a wide variety of structures. Whereas previously natural polymers (cellulose, starch, proteins) were subjected to modification processes, nowadays many synthetic polymers are used in this process. Table 6 presents examples and the dates of the first communications concerning the most important reactions of this type and shows that the modification reactions can be divided into three main groups: (1) chain substitution reactions; (2) structure formation reactions; (3) exchange reactions involving heterochain polymers.

Chain substitution reactions involving natural polymers (cellulose, starch, proteins, etc.) have been known for a long time and involve mainly the substitution of a hydrogen atom in a hydroxy- or amide group as well as hydrogen atoms linked to carbon in methylene or phenyl groups. These reactions have been investigated in relation to numerous examples and processes of this kind have been justified theoretically[116]. There are many side reactions as a result of which the polymers obtained are of the "heterounit" type[117]. The reactions of synthetic polymers involving the substitution of hydrogen atoms linked to carbon, halogen atoms, the sulpho-group, the phosphono-group, and alkyl-groups are of increasing importance. The introduction of polar groups such as the carboxy-, amino-, sulphonic, phosphonic, etc. substituents leads to the appearance of ion-exchange properties and is widely used in the synthesis of ion exchangers. Investigations of the grafting of carbochains and heterochain polymers on to cellulose have been greatly developed. Rogovin[118] showed that this makes it possible to modify extensively the properties of cotton and other cellulose materials. The structure of formation reactions discovered for natural polymers are being used on an increasing scale for synthetic polymers. Examples of this kind are provided by the radiation-induced vulcanisation of polyethylene and other polymers. As a result of these reactions, the structure of the macromolecules changes significantly.

Table 6. Modification processes.

Reaction	Year of discovery	Refs.
Nitration of cellulose	1833	4
Vulcanisation of rubber with sulphur	1839	111
Grafting via chain transfer	1933	112
Chlorination of poly(vinyl chloride)	1933	113
Polyester exchange reactions	1942	114
Sulphochlorination of polyethylene	1946	115

The exchange reactions of heterochain polymers constitute a specific means of synthesising copolymers by the interaction of two different polymers on heating or in the presence of catalysts. For example, a mixed polyamide is obtained from a mixture of two polyamides[119], a mixture of a polyamide and a polyester gives rise to a polyamido-ester[120], and a mixture of two polysulphides gives rise to the corresponding copolymer[121]. Polyacetals of the type of polyformaldehyde also form copolymers in the presence of catalysts[61].

In conclusion one should note that, as can be seen from the examples presented, in the field of the synthesis of polymers there has been a continuous and notable progress. New reactions leading to the synthesis of polymers are being discovered and investigated and the synthetic processes already known are being improved. Here one should note an increasing application of catalysis to polymerisation, polycondensation, and polymer modification reactions. As a result of this, science has become enriched in a large number of new polymers and many previously known polymers obtained by new improved methods have acquired a set of more valuable properties. A characteristic feature of the synthetic branch of the development of polymer chemistry is more detailed study of increasingly more complex chemical reactions, used in polymer synthesis, and the preparation of new extremely complex polymer structures, which characterises the growth of the chemical art in polymer synthesis and an extensive application of modern physical research techniques. Finally, one should note that a particularly characteristic feature of modern polymer synthesis is the endeavour to obtain polymers not only for constructional purposes, which has been characteristic of the earlier period of the development of polymer science, but to an

increasing degree to synthesise polymers with a specific set of chemical and physical properties. As an example, we may point to thermostable, non-combustible, semiconducting, electrically conducting, photoelectrically active, light sensitive, and biologically active polymers, polymers resembling biopolymers, polymeric catalysts, ion exchangers, complexones, and other polymers with a wide spectrum of specific properties.

Advances in Acceptor-catalytic Polyesterification

V.A.Vasnev and S.V.Vinogradova

Advances in the synthesis of polymers and copolymers by acceptor-catalytic polyesterification from dicarboxylic acid dichlorides and diols in the presence of tertiary amines are examined. The considerable possibilities of this method are demonstrated. It makes it possible to obtain polymers and copolymers of different composition and structure, including stereoregular polycondensation polymers of a new type—conformationally-regular polyarylates. The study of acceptor-catalytic polyesterification made it possible to establish experimentally the principal characteristics of the formation of polymers containing "head-to-tail" fragments and of copolymers under the conditions of non-equilibrium polycondensation and copolycondensation in a homogeneous system. The bibliography includes 128 references.

I. INTRODUCTION

As a method of synthesis of polymers, polycondensation was discovered in the past century. Many different polycondensation processes, based on particular substitution reactions, are now known. All these processes can be divided into two types: equilibrium (reversible) and non-equilibrium (irreversible) polycondensation[1].

Analysis and survey of a large number of experimental data made it possible to discover the fundamental features and general characteristics of equilibrium polycondensation[2]. In contrast to equilibrium polycondensation, which has been thoroughly investigated, non-equilibrium polycondensation had been scarcely studied by the 1960s[3]. However, at that time it had already been established that non-equilibrium polycondensation has many useful features, which promoted its subsequent rapid and wide-scale utilisation in laboratory and industrial practice. These features of non-equilibrium polycondensation include the absence of exchange and degradative reactions, high polymer chain propagation rate constants, and many others. Nevertheless many problems of non-equilibrium polycondensation, largely of a fundamental type, have until recently either not been considered at all or have been only slightly touched upon in a few publications. Such exceptionally important problems include those of the kinetics, mechanism, and fundamental characteristics of the formation of macromolecules of homogeneous and mixed polymers, including polymers with different three-dimensional microstructures and containing fragments of the "head-to-tail" type in the macromolecules[3].

Studies on the non-equilibrium polyesterification of dicarboxylic acid dihalides with diols in the presence of tertiary amines [see Eqn. (1)], known previously in the literature as "low-temperature polycondensation in solution"[3], were undertaken to solve these problems:

$$\begin{aligned} &\mathrm{HalOC{-}R'{-}COHal + HO{-}R''{-}OH + 2R_3N \rightarrow} \\ &\rightarrow \mathrm{-[-OC{-}R'{-}COO{-}R''{-}O-]_n- + 2R_3N \cdot HHal}\ , \end{aligned} \qquad (1)$$

The study of the mechanism of this reaction established that the tertiary amine plays the role of a reaction catalyst and not merely of a hydrogen halide acceptor. This justified the use of the term acceptor-catalytic polyesterification for this type of polyesterification[3,4].

In the first studies on the synthesis of polyesters by acceptor-catalytic polyesterification it was already shown that this variety of non-equilibrium polycondensation constitutes an extremely convenient method of obtaining polymers which are formed in solution at low temperatures, usually close to 20°C, the reaction terminating over a short period, as a rule within the limits of 30 min. The same factor makes acceptor-catalytic polyesterification a suitable model for the investigation of many fundamental problems associated with the characteristics of the formation of macromolecules under the conditions of non-equilibrium polycondensation.

II. SYNTHESIS OF POLYESTERS BY ACCEPTOR-CATALYTIC POLYESTERIFICATION

As a method of synthesis of polyesters (in the given case, polycarbonates), acceptor-catalytic polyesterification was used for the first time by Einhorn[5] as early as 1898. However, subsequently interest in this procedure lapsed for a long time. Only now, more than fifty years later, have chemists returned to acceptor-catalytic polyesterification[6]. During the 1950s, a vigorous development of acceptor-catalytic polyesterification began on the use of this method for the synthesis of polycarbonates from phosgene and bisphenols in pyridine or mixtures of pyridine and other organic solvents[7,8]. Many carbonates based on bisphenols of different structure have now been synthesised by acceptor-catalytic polyesterification[3,8-10].

In 1961 Sokolov and coworkers[11] synthesised polyarylates from oxalyl chloride or di(hydroxyphenyl)propane in the presence of pyridine. Morgan and coworkers[12,13] obtained polyarylates based on different dicarboxylic acid dichlorides and bisphenols by acceptor-catalytic polyesterification in the presence of tri-ethylamine. By 1965, only about ten papers had been published on the synthesis of polyesters from dicarboxylic acid dihalides and diols in the presence of tertiary amines[11-18]. This enabled Morgan[10] (p.329) to write in 1965, that, with the exception

of polycarbonates, low-temperature polyesterification "has been scarcely used for the synthesis... of polymers".

In recent years acceptor-catalytic polyesterification has begun to be used much more frequently for the synthesis of polyesters, in the first place polyarylates. The studies of Korshak and coworkers made a large contribution to the development of the synthetic possibilities of this method.

Korshak and coworkers[19,24] synthesised a large number of cardo-polyarylates [or 'cross-planar polyarylates' (Ed. of Translation)] based on 9,9-bis-(4-hydroxyphenyl)-10-anthrone and other bisphenols with cardo-groups by acceptor-catalytic polyesterification in the presence of triethylamine. Korshak and coworkers[25] synthesised by the same method cardo-polyarylates based on polycyclic bisphenols such as, for example, bis-(4-hydroxyphenyl)-2-norbornylidene. Morgan[26] reported the properties of many cardo-polyarylates, some of which could be obtained by acceptor-catalytic polyesterification in the presence of triethylamine.

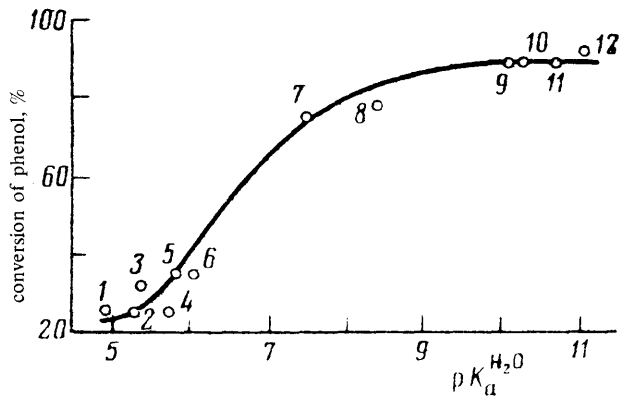

Figure 1. Dependence of the degree of conversion of phenol into phenyl benzoate on the basicity of tertiary amines. Molar ratios of phenol, methanol, tertiary amine, and benzoyl chloride 2.5 : 2.5 : 1 : 1, (dichloroethane, 25 °C)[68]; tertiary amines: 1) quinoline; 2) pyridine; 3) isoquinoline; 4) β-picoline; 5) quinaldine; 6) α-picoline; 7) γ-collidine; 8) triallylamine; 9) ethyldimethylamine; 10) cyclohexyldimethylamine; 11) triethylamine; 12) tributylamine.

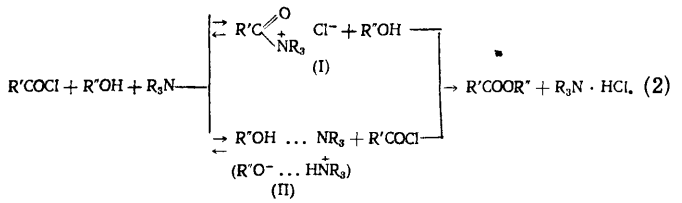
Numerous communications have been published during the last decade on the synthesis of many polyesters with a wide variety of structures from dicarboxylic acid dichlorides and diols in the presence of tertiary amines[27-36]. Among these, mention should be made of the work of Jedlinski and coworkers[30,31] on the synthesis of interesting, as regards practical applications, polyesters with naphthalene rings in the chain. Korshak and coworkers[33] were the first to obtain by acceptor-catalytic polyesterification polyesters based on bis-β-dicarbonyl compounds reacting in the enolic form.

Acceptor-catalytic polyesterification became very important as a method of synthesis of organoelemental polymers, particularly carborane-containing polyesters[37]. Thus Korshak and coworkers[37-46] were the first to obtain polyarylates with *o*- and *m*-carborane groups in the chain from the dichlorides of 1,2- or 1,7-bis-(4-carboxyphenyl)-carboranes and 1,2-bis-(4-hydroxyphenyl)carborane in the presence of triethylamine. They[37,47-50] used acceptor-catalytic polyesterification for the synthesis of carborane-containing polyesters and copolyesters from the dichlorides of *m*- or *p*-carboranedicarboxylic acids. Soluble and fusible polyester-chelates have also been obtained by acceptor-catalytic polyesterification[51]. Bisphenols, containing copper chelates, for example, bis(acetoacetatohydroquinone)copper, were used for this purpose in the reaction with the dichloride of diphenylphthalide-4,4'-dicarboxylic acid.

Thus studies in this field have now established the considerable synthetic possibilities of acceptor-catalytic polyesterification, whereby polyesters have been obtained with a wide variety of structures and possessing in many instances a set of interesting properties. It appears particularly promising to use this method for the synthesis of polymers which are extremely valuable in practice, namely polyarylates, including polycarbonates.

The problems of the synthesis of mixed polyesters, polyesters based on diols with an asymmetric distribution of hydroxy-groups ("head-to-tail"), and conformationally regular polyarylates by acceptor-catalytic polycondensation are examined in subsequent sections of this review.



III. THE KINETICS, MECHANISM, AND CHARACTERISTICS OF ACCEPTOR-CATALYTIC POLYESTERIFICATION

Acceptor-catalytic polyesterification is one of the first examples of non-equilibrium polycondensation whose kinetics, mechanism, and principal characteristics have been studied in detail. One of the important results of such research has been the conclusion that the tertiary amine plays a catalytic role in the given reaction. The importance of this conclusion becomes understandable if one takes into account the fact that in 1959 Conix[14] attributed to tertiary amines merely the function of acceptors of the hydrogen halide evolved. Ten years later, in 1969, Billmeyer and Eckard[52] still assumed that tertiary amines behave as acceptors of the acid in the polycondensation of dicarboxylic acid dichlorides with diols, "displacing the equilibrium towards the formation of polyesters".

By 1965 there was virtually no information in the literature about the kinetics of acceptor-catalytic esterification and polyesterification. Nevertheless in his monograph Morgan[10] admitted the possibility of three different reactions under the conditions of acceptor-catalytic polyesterification: the formation of a complex of the tertiary amine and the acid chloride (nucleophilic catalysis), the formation of a complex of the tertiary amine and the phenol (general base catalysis), and simple binding of hydrogen chloride. The majority of investigators concerned with the problems of acylation and polyacylation in the presence of tertiary amines gave preference to the first of the above pathways[8,53,54].

From 1969, Korshak and coworkers[55] began systematic studies on the mechanism of acceptor-catalytic esterification and polyesterification. They established by ^{35}Cl NQR and potentiometric measurements that the interaction of tertiary amines with carboxylic acid chlorides involves the formation of ionic complexes of the type of acylammonium salts (I) [see Eqn. (2)]. The equilibrium complex-formation constant is appreciably influenced by the steric

and resonance factors, while the basicity of the tertiary amine plays a secondary role[56,57]:

At the same time it was found by ^{1}H NMR and infrared spectroscopy that, under conditions close to those in acceptor-catalytic polyesterification, tertiary amines form hydrogen-bonded complexes (II) with phenols [see Eqn. (2)], whose stability increases with increasing acidity of the donor and basicity of the acceptor[58-60]. In many instances it was possible to isolate and investigate the equimolar complexes of bisphenols with trialkylamines[60-62].

Bearing in mind the virtual irreversibility of the reactions of carboxylic acid chlorides with phenols[63,64], the mechanism of acceptor-catalytic polyesterification can be represented on the basis of the results of studies of the initial stages of the reaction[55] by two catalytic fluxes: a nucleophilic flux [the formation of complex (I)] and the general base-catalytic flux [the formation of complex (II)]. The study of the esterification kinetics[65-67] and determination of the relative activities of the starting compounds by the competitive acylation method[68,69] established that, in the absence of steric hindrance at the reaction centre, an increase of the acidity of the hydroxylated compound and of the basicity of the tertiary amine creates conditions for reaction via the general base catalysis. Thus it was found for the competitive benzoylation of phenol and methanol that, in the presence of triethylamine, the degree of conversion of the more acid reagent (phenol) greatly exceeds that of the less acid reagent (methanol) (Fig. 1). This shows that the general base catalysis predominates under the given conditions over nucleophilic catalysis. On the other hand, if the competitive benzoylation is carried out in the presence of a less basic tertiary amine (pyridine), then methanol mainly reacts, i.e. nucleophilic catalysis predominates under these conditions[68].

The kinetic study showed that acceptor-catalytic esterification is of third order overall (of first order with respect to each reactant) and that the rate-limiting stage is the interaction of complex (I) with phenol or of complex (II) with the acid chloride[65-67]. It was found that the rate of benzoylation in the presence of triethylamine (in dioxan at 30°C) is greatly influenced by the acidity of phenols and the plot of the logarithm of the reaction rate constant against pK_a^{DMSO} for phenols (Fig. 2) consists of two linear sections with opposite slopes: $\lg k_3 = -0.40\ pK_a + 4.88$ ($r = 0.996$, $s = 0.05$) for phenols with $pK_a < 14$ and $\lg k_3 = 0.39\ pK_a + 5.99$ ($r = 0.973$, $s = 0.05$) for phenols with $pK_a > 14$. This permitted the conclusion that nucleophilic catalysis is possible when the following conditions are observed: (1) the tertiary amine is more basic than the leaving group in R'COX; (2) the R"–OH nucleophile attacking the acylammonium complex is more basic than the leaving ammonium ion[67]. In the system investigated the first condition is completely fulfilled, while the second apparently holds only for more basic phenols with $pK_a > 14$. For more acidic phenols ($pK_a < 14$), the second condition does not hold and the reaction proceeds via the general base catalysis pathway.

The study of the kinetics of the benzoylation of alcohols in the presence of tertiary amines in a non-polar medium led Bogatkov et al.[70] to the conclusion that, regardless of the formation of complex (I) or (II), the reaction proceeds in this case via a transition state with a five-coordinated carbon atom.

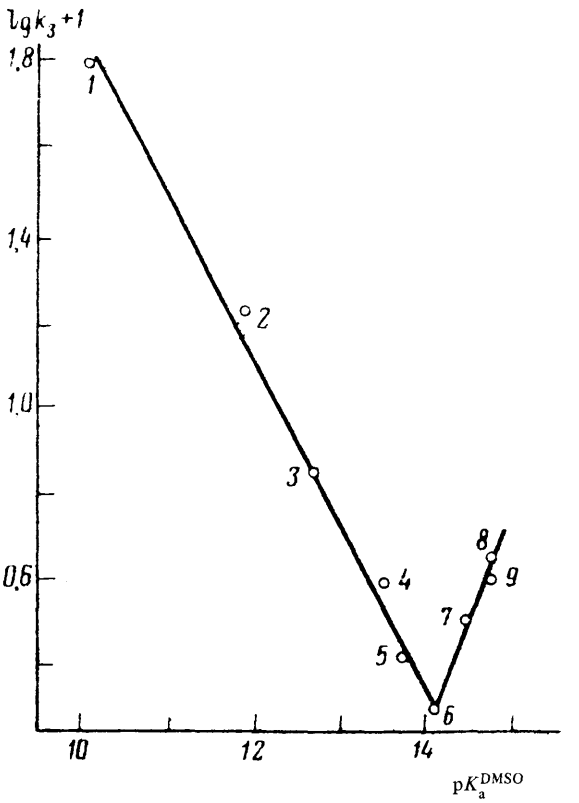


Figure 2. Dependence of the logarithm of the benzoylation rate constant on the acidity of phenols[67]; phenols: 1) *p*-nitrophenol; 2) *p*-acetylphenol; 3) *p*-chlorophenol; 4) *o*-hydroxyphenyl benzoate; 5) phenol; 6) *p*-t-butylphenol; 7) *p*-cresol; 8) *p*-methoxyphenol; 9) hydroquinone.

The solvent and reaction temperature have a marked influence on the rate of acceptor-catalytic esterification[71]. It has been found that an increase of the polarity of the solvent promotes an increase of the rate of reaction. A complex non-Arrhenius temperature dependence of the esterification rate constant (Fig. 3, curve *1*) has been established over a wide temperature range (from −30° to 80°C). The failure of the rate constant to obey the Arrhenius relation was attributed by the authors[71] to the fact that, in a complex reaction of this type, consisting of a series of consecutive stages [Eqn. (2)], temperature can have different effects on the rate of each individual stage. The resulting influence of temperature on the effective rate constant consists of these "partial" influences.

The results of the study of the kinetics and mechanism of acceptor-catalytic esterification enabled Korshak and coworkers to investigate at a qualitatively new level and to interpret the fundamental characteristics of acceptor-catalytic polyesterification as a characteristic example of non-equilibrium polycondensation[57,72]. Only a few aspects of this problem had been examined earlier[11,13,73,74]. In the analysis of the characteristics of acceptor-catalytic polyesterification and copolyesterification, data for the reactivities of diols and dicarboxylic acid dichlorides, first obtained in systematic studies of the above monomers by quantum-chemical[75,76], physical (potentiometry[77,78], ^{1}H NMR,[57,78] ^{35}Cl NQR [79,80]), and kinetic[80-83] methods, were used on a wide scale. It was established that the difference between the activities of the first and second functional groups of the monomer is determined by the distance between them, the structure of the bridge unit, and the structure of the attacking agent. Depending on the above factors, the activity of the second functional group of the monomer can decrease, remain unchanged, or after the first group has reacted, increase.

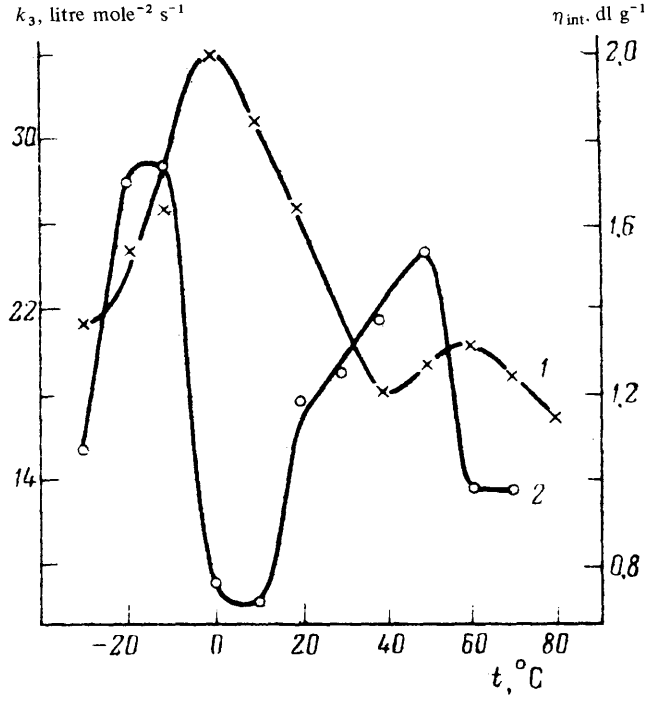

Figure 3. Dependence of the rate constant for the reaction of *o*-chlorophenol with *p*-chlorobenzoyl chloride (curve *1*) and of the intrinsic viscosity of the polyarylate obtained from 2,2-di-(3-chloro-4-hydroxyphenyl)propane and terephthalic acid dichloride (curve *2*) on the reaction temperature (toluene, triethylamine)[71].

Thus the results of the kinetic study of acceptor-catalytic esterification of terephthalic acid dichloride by phenols showed that the rate constants for the first and second COCl groups depend appreciably on the structure of the phenol (Table 1). Enhancement of the electron-accepting nature of the substituent in the phenol molecule increases the reactivity of the second COCl group of the acid dichloride, which actually begins to exceed that of the first COCl group when R = NO_2.[83] In the acceptor-catalytic esterification of di-(4-hydroxyphenyl) ether and 2,2-di-(4-hydroxyphenyl)propane by the chlorides of *p*-substituted benzoic acids, the ratios of the rate constants for the first and second OH groups have virtually the same value, which is independent of the structure of the acylating agent[83].

Table 1. Results of the kinetic study of the reaction of terephthalic acid dichloride with phenols (R–⟨⟩–OH) in the presence of triethylamine*[83].

R	k^1, litre^2 mole^{-2} s^{-1}	k^2, litre^2 mole^{-2} s^{-1}	$\varkappa = k^1/k^2$
CH_3	11.5±1.0	4.7±0.3	2.45
H	10.0±1.0	6.8±0.8	1.47
Cl	17±1	15±1	1.13
NO_2	48±2	62±3	0.77

* Here $\overline{k^1}$ and $\overline{k^2}$ are the rate constants for the reactions of phenols with the first and second COCl groups of the dichloride in dioxan at 30°C.

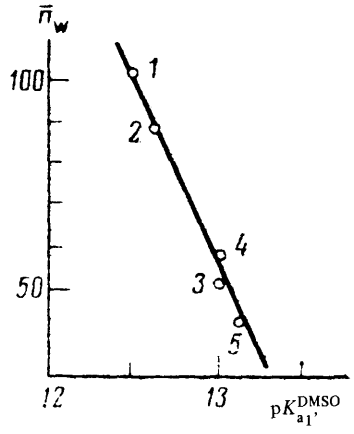

Figure 4. Dependence of the polymerisation coefficients of polyterephthalates $\bar{n}_W$ on the pK_{a_1} of bisphenols[88]; bisphenols: 1) 2,2-di-(3-chloro-4-hydroxyphenyl)propane; 2) 3,3-di-(4-hydroxyphenyl)phthalide; 3) di-(4-hydroxyphenyl)methylphenylmethane; 4) di-(4-hydroxyphenyl)-phenylmethane; 5) 9,9-di-(4-hydroxyphenyl)fluorene.

The study of acceptor-catalytic polyesterification showed that polyesters with the highest molecular weights are formed in high yields for an equimolar ratio of the acid dichloride and diol[57,84]. On the other hand, the optimum amount of tertiary amine is determined by the structure of the initial reactants. Thus, on passing from bisphenols to glycols and with decrease of the basicity of the tertiary

amine, the molar ratio of the acceptor-catalyst and the diol increases from 2 : 1 to 8 : 1.[4,57]

Comparison of the molecular weights of the polymers with the structures of the initial compounds established that, with increase of the acidity (activity) of the bisphenols[55,85,86] (Fig. 4) and the basicity of tertiary amines[87], the molecular weights of the polyarylates increase. The increase of the activity of the acid dichlorides also leads in most instances to an increase of the molecular weight of the polyarylates formed (Fig. 5); however, the increase of the activity of certain acid dichlorides is accompanied by a decrease of the molecular weight of the polymers[85,88].

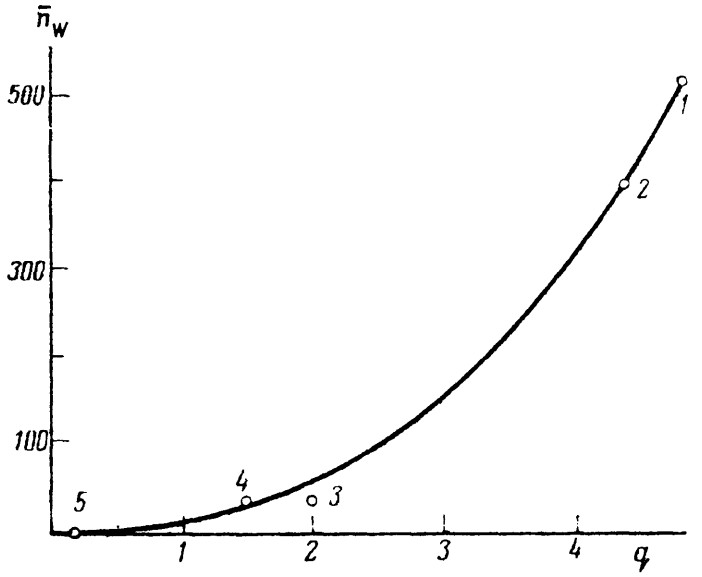

Figure 5. Dependence of the polymerisation coefficients of the polyarylates of 2,2-di-(3-chloro-4-hydroxyphenyl)-propane on the relative activity q of the acid dichloride[88]; dichlorides of different acids: 1) terephthalic; 2) isophthalic; 3) biphenyl-4,4'-dicarboxylic; 4) 1,1'-oxybisbenzene-4,4'-dicarboxylic; 5) tetrachloroterephthalic.

The study of the side reactions accompanying acceptor-catalytic polyesterification showed that the main chain-termination reactions under the conditions examined are hydrolysis and aminolysis of the acid halide groups[88,89], the contribution of these reactions increasing appreciably on passing from strongly basic (general base catalysis) to weakly basic (nucleophilic catalysis) tertiary amines[88]. Thus it has been found that in the presence of triethylamine the reactivity of diethylamine in the reaction with benzoyl chloride exceeds by several orders of magnitude the activity of phenol (Table 2). At the same time, the activity of water under analogous conditions is appreciably inferior to that of phenol. On passing to a less basic tertiary amine (pyridine), the reactivity of water increases and actually begins to exceed that of phenol (Table 2). In the presence of pyridine the role of the chain termination reaction due to the admixture of secondary amines also becomes more marked[88].

These results enabled Korshak and coworkers[88] to demonstrate experimentally for the first time that the molecular weights of the polymers obtained in non-equilibrium polycondensation depend on the ratio of the rates of chain propagation and termination. If an increase of the activity of the monomers (for example, the bisphenols) entails an increase of the contribution of the chain propagation reaction, then the molecular weight of the polymers increases. On the other hand, when an increase of the activity of the monomers (for example, acid dichlorides) is accompanied by an increase of the contribution of the chain termination reaction, the molecular weight of the polymers diminishes.

Table 2. The activities of HO- and NH_2-containing compounds relative to the activity of phenol in the reaction with benzoyl chloride in dichloroethane at 25 °C.[88]

RXH	$k_{RXH}/k_{C_6H_5OH}$ **	
	$N(C_2H_5)_3$	NC_5H_5
H_2O*	<0.1	3.4
CH_3OH	0.17	9.5
$C_6H_4NH_2$	3.0	<100
$(C_2H_5)_2NH$	>100	***

*Acylation carried out in dioxan.

**$k_{RXH}/k_{C_6H_5OH}$ is the ratio of the rate constants for the benzoylation of RXH and phenol.

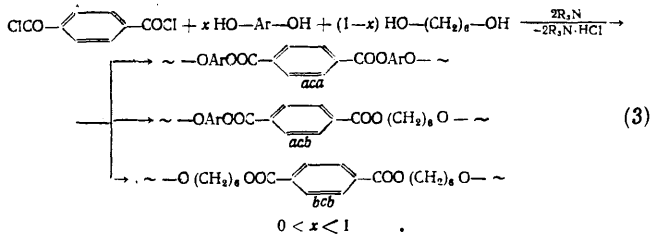
***Too high for determination by the method of competitive acylation.

On the basis of the theory of the heterounit structure of polymers developed by Korshak[90], one must suppose that the occurrence of certain types of reactions leads to the formation of heterounit polyesters. Thus, when acceptor-catalytic polyesterification is carried out in the presence of moisture, there is a possibility of the appearance of anhydride linkages in the macromolecules[33,89].

Interesting data were obtained in the study of the influence of reaction temperature on the results of acceptor-catalytic polyesterification[4,55,91-95]. It was found that, in the presence of highly reactive starting compounds in a homogeneous system, the dependence of the molecular weights of polyesters on the reaction temperature is represented by curves with two maxima (Fig. 3, curve 2). The results of kinetic studies suggested that this dependence is due to the presence of more than one extremum in the relation between the rate constant for the preparation of the polymer chain and the reaction temperature[71].

The study of the influence of the concentration of the initial compounds on the molecular weight of the polyester showed that, for a fairly high activity of the functional groups, the dependence of the molecular weights of the polymers on the concentration of the monomers is represented by a curve with a single maximum at 0.15–0.2 M.[4,91-95] The low activity of at least one of the initial compounds increases the optimum concentration of monomers to 1–2 M.[4]

The nature of the solvent has a major influence on the results of acceptor-catalytic polyesterification. Korshak and coworkers[94] showed that there is a tendency towards a decrease of the molecular weight of the polyester with



increasing dielectric constant of the medium. When acceptor-catalytic polyesterification is carried out in a metastable solution, the aggregation of macromolecules creates more favourable conditions for the formation of macromolecular compounds than in polyesterification in a thermodynamically stable solution with a similar dielectric constant[94]. Such aggregation of macromolecules apparently leads to a local increase of the concentration of the terminal groups of the polymer chains, which causes, on the one hand, an increase of the rate of propagation of macromolecules, and, on the other hand, diminishes the contribution of side reactions.

The precipitation of the polymer from solution under the conditions of acceptor-catalytic polyesterification does not in principle prevent further increase of its molecular weight, which takes place owing to the interaction of the terminal groups of the macromolecules with one another and with the initial compounds[94,96,97]. The optimum conditions for the synthesis of polyarylates in a heterogeneous system are a high solubility of the initial compounds in the reaction medium, an appreciable swellability of the polymer in a weakly polar medium, or a high polarity of the medium when the swellability of the polymer in the solvent is insignificant[97].

Acceptor-catalytic polyesterification in a heterogeneous system is of considerable practical interest, since the technological scheme of the synthesis of polymers is then significantly simplified.

IV. CHARACTERISTICS OF THE SYNTHESIS OF COPOLYMERS IN A HOMOGENEOUS SYSTEM

The successful discovery of the laws of formation of macromolecules under the conditions of non-equilibrium polycondensation depends in many respects on the extent to which the fundamental rules controlling the formation of fixed polymers have been found. The problems of the composition and structure of both polycondensation and polymerisation copolymers are especially important in this respect. Up to 1972, there were no experimental data for the influence of various factors on the composition and structure of copolymers obtained by non-equilibrium copolycondensation in a homogeneous system. In 1972 Korshak and coworkers[98,99] published for the first time experimental data concerning the rules governing the formation of the macromolecules of mixed polymers under the conditions of non-equilibrium copolycondensation in solution in relation to joint acceptor-catalytic polyesterification of a bisphenol and a glycol (comonomers) with terephthalic acid dichloride (the intermonomer).

(3)

The relative contents of the homo-(*aca*, *bcb*) and hetero-(*abc*) triads in the copolyesters were determined by high-resolution ^{1}H NMR.[98-104] The parameter K_M—the coefficient of the microheterogeneity of the copolymer—was calculated from the results[105,106]. $K_M = 0$ for a mixture of two homopolymers, $K_M = 1$ for statistical copolymers, and $K_M = 2$ for regularly alternating copolymers. Consequently the absolute values of the deviations of K_M from unity may make it possible to infer in quantitative terms the degree of order in the distribution of units, block copolymers being located in the region where $0 < K_M < 1$.

Interesting experimental data were obtained in the study of the structure of copolymers obtained when copolyesterification is carried out in solution by a single-stage method, in which the intermonomer and comonomer are in solution at the beginning of the reaction[98,101-104]. It was established that, regardless of the difference between the activities of the comonomers, copolymers are formed with a nearly statistical distribution of units (Table 3, Nos. 1 and 3). For low degrees of reaction, the composition of the copolymer is enriched in units containing the more active comonomer, but, as the copolyesterification reaction proceeds, the number of units becomes equal to the initial molar ratio of the comonomers[106]. Copolymers with a statistical distribution of units have been obtained also in two-stage copolycondensation, where the second comonomer was introduced into the reaction sphere only after the completion of the polycondensation of the intermonomer with the first comonomer, i.e. under conditions simulating an infinitely large difference between the activities of the comonomers (Table 3, Nos. 2 and 4).[100] It was shown that certain deviations from the statistical distribution of units in the macromolecules are caused by a change in the activity of the second COCl group of the intermonomer after the first COCl group has reacted (Table 1). These results demonstrated the erroneous nature of the view according to which statistical copolymers are difficult to obtain by non-equilibrium copolycondensation of comonomers with different activities[8,10,107].

Table 3. The structure of copolyterephthalates based on a bisphenol and hexamethylene glycol and obtained by joint acceptor-catalytic polyesterification in the presence of triethylamine (dichloroethane, 40°C).

No.	Bisphenol	Copolymerisation constant for comonomers q	Content of triads, mole fraction			K_M
			aca	*acb*	*bcb*	
1	2,2-di-(4-hydroxy-3-methylphenyl)propane*	5.3[103]	0.19	0.62	0.19	1.24
2	ditto**	∞	0.19	0.64	0.17	1.28
3	2,2-di-(3-chloro-4-hydroxyphenyl)-propane*	33[103]	0.22	0.56	0.22	1.12
4	ditto**	∞	0.25	0.54	0.21	1.09

*A solution of terephthalic acid dichloride (0.2 M), the bisphenol (0.1 M), and hexamethylene glycol (0.1 M) was treated with triethylamine (0.4 M) and the copolyesterification was continued for 1 h.[103]

**A solution of terephthalic acid dichloride (0.2 M) and the bisphenol (0.1 M) was treated with triethylamine (0.4 M). After 30 min, hexamethylene glycol (0.1 M) was introduced into the reaction mixture and the reaction was continued for 1 h.[100]

It was found that block copolymers can be obtained under the conditions of single- and two-stage acceptor-catalytic copolyesterification when the intermonomer is gradually introduced into the reaction zone (Table 4).[99-104]

In this case the length of the blocks increases with increasing difference between the activities of the comonomers and with decrease of the rate of entry of the intermonomer into the reaction zone. A convenient method for the synthesis of block copolymers is three-stage copolycondensation, where the acceptor-catalytic polyesterification of the intermonomer with each comonomer is carried out in different reaction volumes. The intermonomer in one reaction volume is introduced in an excess, while in the other it is present in a deficiency in relation to the monomer, the amounts being calculated so that the overall molar amounts of the functional groups of the intermonomer and the comonomers in the two reaction volumes are equal[103]; at the end of the reaction the first and second systems are combined. It was found that the smaller the deviation from equivalence in each system, the greater the length of the blocks in the block copolymers.

Table 4. The structure of copolyterephthalates based on a bisphenol and hexamethylene glycol, obtained by single-stage copolyesterification in the presence of triethylamine with gradual introduction of terephthalic acid chloride into the reaction solution (dichloroethane, 40°C).[99]

Bisphenol	q^{103}	Length of blocks		K_M
		n_{ac}	n_{bc}	
2,2-di-(4-hydroxy-3-methylphenyl)propane	5.3	4.4	4.4	0.46
9,9-di-(4-hydroxylphenyl)fluorene	12.6	5.6	5.6	0.36
2,2-di-(4-hydroxy-3-nitrophenyl)propane	31	8.2	8.5	0.24
2,2-di-(3-chloro-4-hydroxyphenyl)propane	33	9.2	9.2	0.22

By varying the above factors, it is possible to obtain block copolymers with different lengths of the blocks, regulating thereby the structure of the macromolecules of mixed polymers in the required way.

Experimental data for the influence of various factors on the composition and structure of copolymers were confirmed by the fundamental conclusions arising from the quantitative theory of non-equilibrium copolycondensation in a homogeneous system developed by Kuchanov[105, 106, 108]. A satisfactory quantitative correspondence between the experimental and theoretical data was established, the difference between them being within the limits of the experimental error (see, for example, Table 5). This shows that the conclusion reached from the results of the study of joint acceptor-catalytic polyesterification are of general validity and apply satisfactorily to the formation of the macromolecules of copolymers under the conditions of non-equilibrium copolycondensation in a homogeneous system.

Table 5. The values of K_M for copolyterephthalates synthesised by two-stage copolycondensation (dioxan, 40°C)*[83].

X in 2,2-di-(4-hydroxy-3-X-phenyl)propane	x***	K_M (expt.)	K_M (theor.)
CH_3	2.45	1.28	1.33
Cl	1.13	1.09	1.05
NO_2	0.77	0.93	0.91

* See second footnote to Table 3.
** See Table 1.

By surveying the experimental data, it was possible to formulate the fundamental characteristics of the formation of the macromolecules of mixed polymers under the conditions of non-equilibrium copolycondensation in a homogeneous system[98-104, 106].

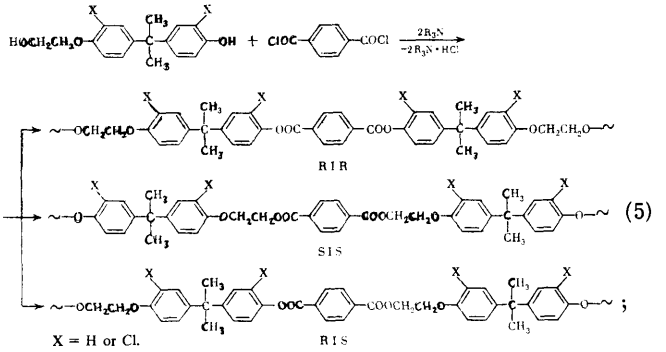
1. When the entire amount of the intermonomer is introduced at once into the reaction zone at the beginning of non-equilibrium copolycondensation, statistical copolymers are formed regardless of the difference between the activities of the comonomers. The use of a bifunctional compound with dependent functional groups as the intermonomer influences the structure of the copolymers: the decrease of the activity of the second functional group after the first has reacted leads to an increase of the fraction of regularly alternating fragments in the polymer chains; the increase of the activity of the second functional group of the intermonomer promotes an increase in the length of the blocks.

2. The introduction of comonomers into the reaction zone in stages is not a sufficient condition for the synthesis of copolymers with a block structure.

3. The synthesis of block copolymers by single-stage non-equilibrium copolycondensation in a homogeneous system requires that the activities of the comonomers should be different and that the rate of introduction of the intermonomer into the reaction zone should be smaller than the rate of its interaction with the more reactive comonomer.

V. CHARACTERISTICS OF THE SYNTHESIS OF POLYESTERS FROM DIOLS WITH AN ASYMMETRIC DISTRIBUTION OF HYDROXY-GROUPS

The non-equilibrium polycondensation of bifunctional compounds with an asymmetric distribution of functional groups (z–RS–z) gives rise to the problem of the determination of the structure of heterounit polymer chains, and to the possibility of additions of the "head-to-head" ("tail-to-tail") or "head-to-tail" type:



$$z\text{–RS–}z + y\text{–I–}y \rightarrow \begin{cases} \sim\text{–RS–I–RS–I–RS–I–}\sim + 2xy \\ \text{"head-to-tail"} \\ \sim\text{–RS–I–SR–I–RS–I–}\sim + 2xy \\ \text{"head-to-head", "tail-to-tail"} \end{cases} \quad (4)$$

Here z–RS–z and y–I–y are bifunctional monomers with asymmetric and symmetrical distributions of functional groups respectively. This type of problem arises in the polymerisation of asymmetric vinyl monomers, for example, monosubstituted ethylenes, in which heterounit macromolecules with "head-to-head" or "head-to-tail" distributions of units are also formed. This problem has been fairly well investigated in polymerisation and it was established that the "head-to-tail" addition occurs more frequently[109, 110].

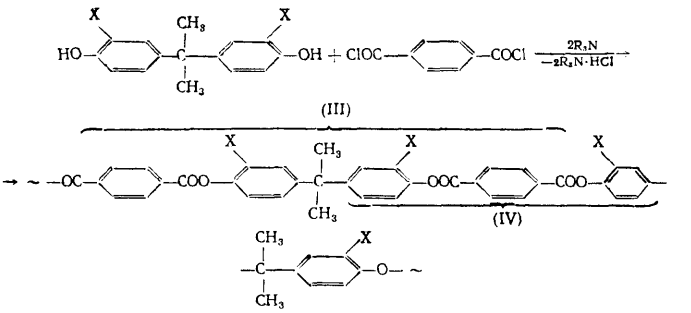
There have been a number of studies[111-116] in which the problem of the structure of polycondensation polymers based on the monomers shown in Eqn. (4) is discussed,

and the possibility of "head-to-head" or head-to-tail" additions is considered. The view is expressed in these studies that the different activities of the functional groups in z–RS–z is the decisive factor in the formation of monomers in which "head-to-head" additions predominate.

In 1974 Korshak et al.[117] published the first study where they established the structure of polymers based on monomers with an asymmetric distribution of functional groups, in relation to the acceptor-catalytic polyesterification of the β-hydroxyethyl ethers of bisphenols with terephthalic acid dichloride, and determined the fundamental principles of the formation of their macromolecular structure[117,118]:

(5)

The structure of the polyesters was studied by high-resolution ^{1}H NMR, based on the different chemical shifts of the phenylene protons in the terephthalic acid residue in homo-(RIR, SIS) and hetero-(RIS) triads corresponding to the "head-to-head" ("tail-to-tail") or "head-to-tail" addition respectively[117,118]. The coefficient of microheterogeneity K_M served as a quantitative characteristic of the regularity of the structure of the macromolecules. For regularly alternating polymers of the "head-to-head" and "tail-to-tail" type, $K_M = 0$, while for polymers involving "head-to-tail" additions, $K_M = 2$. $K_M = 1$ corresponds to a statistical distribution of units in macromolecules.

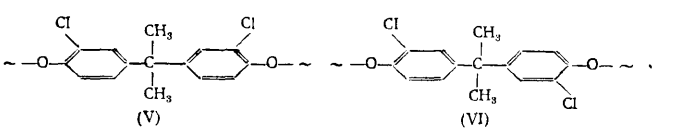


It was established that, when both initial monomers are in solution at the beginning of polycondensation, a polymer with a nearly statistical distribution of units is formed regardless of the difference between the activities of the hydroxy-groups ($K_M = 1.01–1.11$).[117,118] This result showed that, even a considerable difference between the reactivities of the phenolic and alcoholic groups, does not constitute a sufficient condition for preferential addition of the "head-to-head" type. The deviation of K_M from unity is apparently due to the fact that the activity of the second COCl group of terephthalic acid dichloride diminishes after the first COCl group has reacted[83], which leads to a predominance of the "head-to-tail" structures[117]. It has also been established that the formation of polymers with "head-to-head" ("tail-to-tail") structures, predominating under the conditions of non-equilibrium polycondensation, requires a gradual addition of a monomer with a symmetrical distribution of functional groups (terephthalic acid dichloride) to a solution of the monomer with an asymmetric distribution of functional groups (the diol). K_M depends on the rate of addition of the acid dichloride and on the difference between the activities of the OH groups of the diol[117,118].

Analysis[117], has shown that the kinetic mechanism of the above process (and hence its mathematical description) is the same as the mechanism described earlier in connection with calculations on copolycondensation[105,106,108,119]. The experimental and theoretical characteristics of the formation of the structures of the polymer chains based on monomers with a "head" and a 'tail" agree satisfactorily[117].

VI. SYNTHESIS OF CONFORMATIONALLY REGULAR POLYARYLATES

An interesting feature of acceptor-catalytic polyesterification is conformational specificity of this process, which makes it possible to obtain conformationally regular polymers whose conformational tacticity is established in the course of the reaction, and the macromolecules contain regular sequences of one or other (but fully defined) rotational isomer in the monomer residue[120,121].



The study of the kinetics, mechanism, and characteristics of acceptor-catalytic polyesterification and of the properties of the polymers obtained enabled Korshak et al.[122] to establish for the first time in 1970 that non-equilibrium polycondensation gives rise to considerable possibilities for the synthesis of stable stereoregular polycondensation polymers of a new type, whose macromolecules contain regular sequences of stable rotational isomers. Conformationally regular polyarylates of the above type were synthesised under the conditions of acceptor-catalytic polyesterification from *o,o'*-disubstituted, 2,2-di-(*p*-hydroxyphenyl)propane and terephthalic acid dichloride[57,123–126]:

(6)

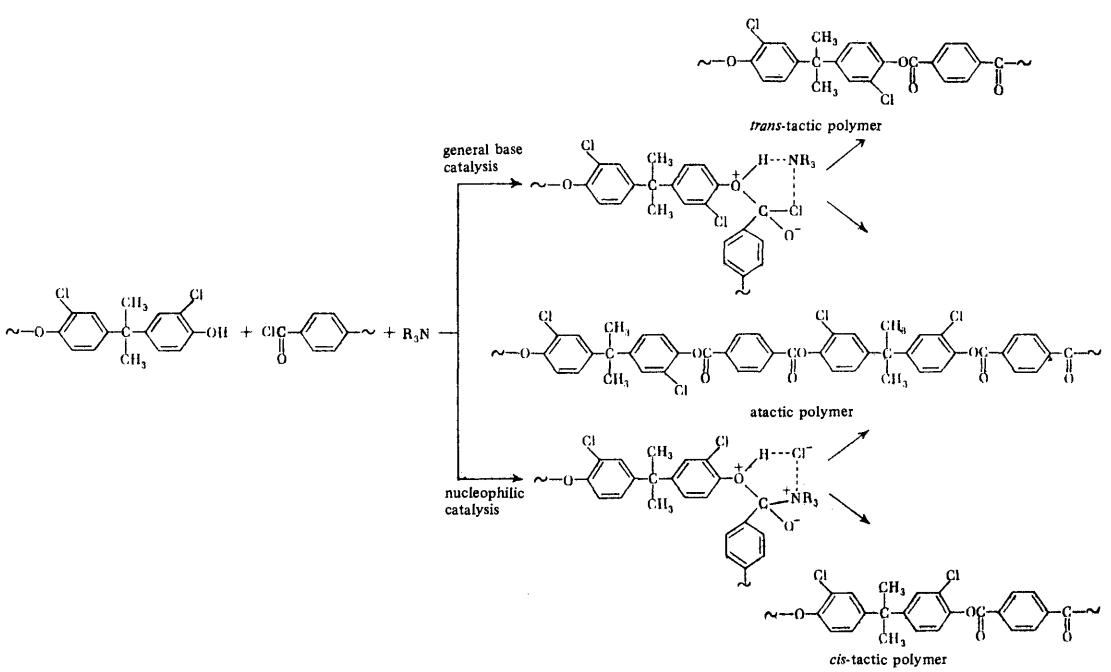
The fundamental novelty of the synthesis of conformationally-regular polymers under the conditions of acceptor-catalytic polyesterification is the fact that their regular three-dimensional microstructure is formed directly during the growth of macromolecules.

Conformational analysis by ^{35}Cl NQR of the polyterephthalates of 2,2-di-(3-chloro-4-hydroxyphenyl)propane (dichlorodian) as well as compounds (III) and (IV) (X = Cl), simulating the fragments of the polymer chain, showed that, depending on the conditions of synthesis, the macromolecules of the given polyarylate contain regular sequences of cisoid (V) or transoid (VI) rotational isomers of the bisphenol residue[57,124,125]:

It was established that the microstructure of conformationally regular polyarylates is influenced by the structure of the initial compounds (bisphenols, dicarboxylic acid dichlorides, and tertiary amines) and by the conditions of acceptor-catalytic polyesterification[121–127].

Comparison of the properties of polyterephthalates based on di-(3-chloro-4-hydroxyphenyl)alkanes with different bridge groups showed that the decrease of the barrier to rotation about the $C_{(1)}-C_{(2)}$ bonds, where $C_{(1)}$ and $C_{(2)}$ are respectively the carbon atoms of the bridge group and the benzene ring, in the sequence $C(CH_3)_2 > C(CH_3)(C_7H_{15}) > C(CH_3)_2 > CH_2$ promotes the formation of conformationally regular polyarylates, the high stereotacticity of which in the case of the methylene bridge is apparently caused not so much by the conformational specificity of acceptor-catalytic polyesterification as by the ready crystalisability of such polymers[125,127]. Thus, regardless of the conditions of synthesis, crystalline polyterephthalates of di-(3-chloro-4-hydroxyphenyl)-methane contain only one type of conformational isomer of the bisphenol residue.

The use of sterically hindered bisphenols [di-(5-chloro-2-hydroxyphenyl)alkanes] in acceptor-catalytic polyesterification made it possible to obtain conformationally regular polyarylates with a high degree of order in their structure[125,127]. It has been suggested that the considerable stereotacticity of these polymers is due to the energetic non-equivalence of different conformations in the bisphenol residue, which leads to the formation of macromolecules containing mainly one conformation of the bisphenol fragment.



A characteristic example of the conformational specificity of acceptor-catalytic polyesterification is the synthesis of conformationally regular dichlorodian polyarylates based on various dicarboxylic acid dichlorides[126] in the presence of various tertiary amines[57,125,126]. It was established that, depending on the nature of the tertiary amine (primarily depending on its basicity) and hence depending on the reaction mechanism (nucleophilic or general base catalysis)[57,66-68], macromolecules containing one or other type of rotational isomer are formed. In the presence of weakly basic heterocyclic tertiary amines (nucleophilic catalysis) polymers with *cis*-isomers (V) of the bisphenol fragment are formed, whereas in the presence of highly basic trialkylamines (general base catalysis) the products are polymers with *trans*-isomers (VI).[125] Korshak and coworkers[57,125] attribute the cause of this phenomenon to the different geometries of the transition complexes corresponding to the nucleophilic and general base catalysis, which promotes the formation of different rotational isomers in the bisphenol residue [see Eqn. (7)].

A significant factor is that, in the crystallisation of amorphous polyarylates by a secondary treatment, polymers containing only the *trans*-isomers (VI) in the macromolecules are formed, whereas under the conditions of acceptor-catalytic polyesterification polymers with both cisoid and transoid isomeric forms of the dichlorodian residue may be produced. The role of the acceptor-catalyst in the establishment of the conformational tacticity of polyarylates apparently consists in determining the relative contributions of the two catalytic processes competing in the reaction, which leads in its turn to the predominance in the polymer chains of one or other rotational isomer.

Korshak and coworkers[121-127] showed that the presence of regular sequences of isomeric forms in polyarylate macromolecules influences significantly their properties. In particular, an increase of the stereotacticity of the polymers increases the degree of their crystallinity and the softening temperature, and diminishes their solubility.

The study of the influence of the conditions of synthesis and subsequent treatment of conformationally regular polyarylates on their properties showed a fairly high stability, including their state in solution, of the conformations of the bisphenol residue in the polymer chains[27,121,123,124,128]. Under the influence of mechanical, thermal, and other influences, there is a possibility of the conversion of conformationally regular polymers into conformationally atactic polymers[57,121,123,124].

---o0o---

(7)

Thus the data presented in this review show that acceptor-catalytic polyesterification is of considerable interest as a method of synthesis of homogeneous and mixed polyesters with a definite macromolecular structure, including conformationally regular polyarylates.

Acceptor catalytic polyesterification has acquired particular importance as a model reaction for the investigation of the characteristics of the formation of the macromolecules of copolymers and polymers containing "head-to-tail" fragments under the conditions of non-equilibrium polycondensation in a homogeneous system. There are at present virtually no literature data concerning the characteristics of the formation of macromolecules of this type under the conditions of non-equilibrium polycondensation in a heterophase system. Studies on the characteristics of acceptor-catalytic polyesterification under heterophase conditions may play a definite role in the solution of this problem. The determination of the scope of the synthesis of configurationally regular polymers under the conditions of acceptor-catalytic polyesterification, or in other words, the synthesis by acceptor-catalytic polyesterification of stereoregular polymers (for example iso- or syndio-tactic polymers) from monomers consisting of a mixture of geometrical or optical isomers, is of considerable interest.

Some Structural and Chemical Aspects of Polycondensation

E.Turska, S.Boryniec, and W.Sulkowski

Data concerning the influence of the structure of asymmetric monomers and monomers with bulky substituents on the structure and physicochemical properties of polycondensation polymers are compiled and analysed. The influence of the chemical structure of the monomers on the course of copolycondensation and the microstructure of the resulting macromolecules is explained.
The bibliography includes 79 references.

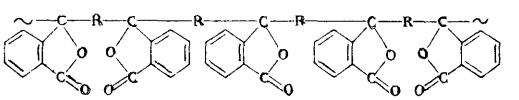
I. Introduction 28
II. The steric structure of polycondensation polymers 28
III. The composition and structure of polycondensation copolymers 30

I. INTRODUCTION

The problem of the influence of the chemical structure of monomers on the course of polycondensation processes involving the synthesis of macromolecules and the structure of the resulting polymers has long been the subject of vigorous thorough research. Nevertheless, despite the advances achieved and the considerable number of published studies, there are still phenomena and relations in this field of the chemistry of macromolecular compounds whose nature is not clear. This is quite understandable bearing in mind that the problems of the structural and chemical relations embraces a wide range of processes, phenomena, and objects.



In the analysis of the structural and chemical aspects of polycondensation, it is possible to isolate two fundamental problems: (1) the influence of the chemical structure of the monomers on the reactivity of the functional groups and on the course of polycondensation; (2) the influence of the chemical structure of the monomers on the structure of the resulting macromolecules, their ability to form ordered structures, and ultimately the properties of the polymers.

Copolycondensation processes are still more complex, since, apart from the factors indicated above, the influence of the reactivity of the monomers on the microstructure of the resulting macromolecules and the influence of the microstructure of the chains of copolymers on their ability to crystallise and other properties also play a significant role.

A complete description of the structural and chemical aspects of polycondensation involves such extensive data that in the present review we shall deal only with problems of polycondensation with participation of asymmetric monomers and monomers containing bulky substituents. Polymers with interesting structures, having a set of valuable physicochemical properties, have been obtained on the basis of these monomers. Part of the review is devoted to the problem of the influence of the reactivity of the functional groups of monomers on the course of joint polycondensation processes and the microstructure of polymer chains, which makes it possible to relate the physicochemical properties of polymers to the microstructure of their macromolecules.

II. THE STERIC STRUCTURE OF POLYCONDENSATION POLYMERS

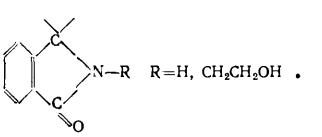
A characteristic feature of the majority of polymers obtained by polycondensation methods is the symmetrical structure of the monomers employed; the stereoregularity of the structure has therefore not been investigated for a long time. However, as in the synthesis of polymers by polymerisation methods, one can foresee the possibility of the synthesis of stereoregular polymers by polycondensation methods. The principal essential condition for this purpose is known to be the use of monomers capable of forming asymmetric units. Thus the employment of optically active monomers makes it possible to synthesise polymers with a sterically regular alternation of fragments. The use of monomers containing carbon atoms with two different and two identical substituents yields atactic polymers. The polyarylates obtained from phenolphthalein and different dicarboxylic acids are an example of polymers of this type[1-7]. The following schematic formula illustrates the structure of an atactic polyarylate of this kind:

According to Korshak and coworkers[8-16], when ring-substituted bisphenols are used, polymers having various crystallographic forms are produced under the conditions of acceptor-catalytic polyesterification, depending on the nature of the solvent and the tertiary amine. The polyarylate obtained from 2,2-di-(3-chloro-4-hydroxyphenyl)-propane and terephthalic acid in the presence of pyridine is crystalline and gives rise to narrow NQR signals. This was the first stereoregular polymer of this type obtained by polycondensation. The use of the dichlorides of isophthalic and 1,1'-oxybisbenzene-4,4'-dicarboxylic acid instead of the dichloride of terephthalic acid leads to a decreased degree of crystallinity of the polymers and a consequent improvement of their solubility. A general feature has been observed for all the acid dichlorides employed—the precipitation of the polymer from the reaction mixture (dioxan, dichloroethane, acetone, and nitrobenzene) during synthesis promotes the formation of

polyarylates with a high degree of crystallinity (stereoregularity) compared with the polymers which remain in solution. Korshak and coworkers established that a decrease of the distance between the carbonyl groups in the acid fragment has a favourable influence on the crystallisability of the polymers, which is apparently associated with the increased regularity of the macromolecular structure.

Korshak[1-4] postulates that polymers with a regular structure and without defects (anomalous fragments) in their macromolecules should have more close-packed chains, should crystallise more readily, and should possess more effective mechanical and physical properties than polymers with a non-regular structure. This is to some extent confirmed by data concerning the dependence of the melting points of the copolymers on the amount of the second monomer introduced into the copolymer. If the treatment is confined to a consideration of those copolymers which contain only small amounts of the second monomer, then the melting point is found to decrease with increasing content of the second monomer, i.e. the monomer which increases the number of anomalous fragments in the polymer chain.

Chemical defects in macromolecules are also an important factor determining the ability of polymers to crystallise. The greater the number of defects, the greater the irregularity of the macromolecules, and the smaller the capacity of the polymer for crystallisation, other conditions being equal.



The influence of the chemical structure of the initial monomers on the ability of polycondensation polymers to crystallise is manifested in many instances. This phenomenon can be illustrated in a particularly interesting manner in relation to cardo-polyarylates. A large number of cardo-polyarylates, containing cardo-groups such as the phthalide, phthalimidine, fluorene, anthrone, cyclohexane, norbornane, and other groups, have been synthesised by polycondensation[1-37]. Cardo-polyarylates are obtained by non-equilibrium polycondensation: low-temperature (acceptor-catalytic) polycondensation[1-19,23-30], high-temperature polycondensation in solution[6,7,19,31,32], and interfacial polycondensation[1-6,17-23]. In interfacial polycondensation account must be taken of the specific behaviour of cardo-monomers of the phenolphthalein type in aqueous alkaline media. However, Morgan[18] and Korshak and coworkers[20-23] established that conversion of phthalide derivatives into phthalimidine derivatives makes it possible to synthesise macromolecular polyarylates by interfacial polycondensation. The use by the authors of phthalimidine derivatives such as phenolphthalein imide and 2-β-hydroxyethyl-3,3-di-(4-hydroxyphenyl)phthalimidine, containing functional groups with appreciably different reactivities, leads to the formation by interfacial polycondensation of cardo-polymers with free >NH and NCH_2CH_2OH groups respectively, which permits their chemical modification. The joint polycondensation of the above bisphenols and the dichloride of isophthalic or terephthalic acid results in the formation of a cross-linked copolymer under certain conditions.

Acceptor-catalytic polycondensation has come to be widely used in recent years as a method for the synthesis of cardo-polyarylates[1-19,24-30]. Korshak and coworkers[10,11,25,30] obtained by this method phenolphthalein polyterephthalates. The synthesis was carried out in a medium (dichloroethane) in which the polymer is soluble and in a medium (acetone) from which the polymer is precipitated during synthesis. It was established that the nature of the solvent employed affects the molecular weight of the polymer, as low-temperature polyesterification in a metastable solution (a mixture of the solvent and precipitant) leads to the formation of polyarylates with a narrow molecular-weight distribution[12]. The yield and molecular weight of the polyarylate depend appreciably on the sequence in which the monomers are introduced[14,26].

Many cardo-polyarylates have been synthesised by the high-temperature polycondensation of dicarboxylic acid dichlorides and bisphenols in organic solvents. The study of the kinetics of the reaction of terephthalic acid dichloride with 9,9-di-(4-hydroxyphenyl)fluorene and certain bisphenols of the type of norbornane enabled Korshak and coworkers[31,32] to suggest an ionisation mechanism for this reaction. It was established that the polycondensation of phenolphthalein and dicarboxylic acid dichlorides in ditolylmethane leads to the formation of polymers which are precipitated from solution. The synthesis of such polyarylates in more polar chlorinated solvents or nitrobenzene takes place in solution, according to Korshak and coworkers[6,7], with formation of polymers having better physicomechanical properties. This phenomenon was explained by the fact that, in a medium dissolving the polymer, macromolecules having uncoiled rigid conformations and giving rise to a fibrillar structure are formed, whereas the polymer obtained in ditolylmethane gives rise to irregular globular structures. Thus in the synthesis of polymers with rigid macromolecular chains it is necessary to take into account the influence of the reaction medium on the formation of the corresponding conformations.

All the cardo-phenolphthalein polyarylates are amorphous non-crystallising polymers. Korshak and coworkers[2-5] suggest that their structure is analogous to that of atactic polymers. However, one must assume that under certain conditions it is possible to obtain a crystalline stereoregular phenolphthalein polyarylate. The possibility is indicated by the finding that the cardo-polyarylates formed by di-(4-hydroxyphenyl)fluorene and 9,9-di-(4-hydroxyphenyl)-10-anthrone with terephthalic acid crystallise and the conditions of their synthesis influence, according to Vinogradova et al.[33], not only the molecular weight of the polyarylates but also their structure.

Studies by Korshak and coworkers[22,23] showed that, by using an appropriate solvent, it is possible to synthesise a stereoregular crystalline cardo-polyarylate containing asymmetric groups. Thus, crystalline phthalimidine polyarylates containing NH groups have been synthesised. The formation of the crystalline structure of the polymer is probably associated with decreased solubility of the given polyarylate and increased rigidity of its macromolecules by hydrogen bonding between the phthalimidine groups and the electron-accepting groups of the macromolecules. This effect is manifested even more clearly in *N*-β-hydroxyethylphthalimidine:

During recent years much attention has been devoted to cardo-polyarylates containing carborane rings[34-37]. The carborane-containing polyarylates obtained by Korshak and coworkers are characterised by an increased thermal stability, a high degree of order in their structure, and other properties of practical interest.

Investigations have established that a mixed crystalline polyarylate may be obtained when even one of the monomers is capable of forming a crystalline homopolyarylate and this monomer is taken in a large excess [38].

The data presented show that the chemical structure of the monomers and particularly the presence of asymmetric bulky substituents influence significantly not only the course of the process but also the structure and properties of the polymers obtained.

III. THE COMPOSITION AND STRUCTURE OF POLYCONDENSATION COPOLYMERS

1. General Postulates

A significant change in the properties of polymeric materials obtained by polycondensation can be achieved by synthesising copolymers, i.e. by carrying out the joint polycondensation of a large number of monomers.

The physicochemical characteristics of copolymers are in many respects determined by their chemical composition by the inhomogeneity of their composition, and by the different chemical structures of the macromolecular chains. Without considering here the important factor of the average chemical composition, on which the properties of the copolymer depend significantly, one should note that the chemical inhomogeneity and the inhomogeneity of the structures of macromolecules are very important, although it is very difficult to control them in the course of the synthesis.

The inhomogeneity of chemical composition is associated with the presence in the copolymer macromolecules of different elementary units in different proportions. In polycondensation copolymers, which are the subject of the present review, an inhomogeneity of the composition is observed, but it is not as important as for polymerisation copolymers. The stepwise nature of the copolycondensation process and the occurrence of reactions between macromolecules promote an equalisation of the compositions of the individual macromolecules formed in the early stages of the process. Nevertheless the results of fractionation studies have shown that the chemical composition of polycondensation copolymers is inhomogeneous [39,40].

Another problem concerning the microstructure (microheterogeneity) of copolymer chains is associated with the different ways in which the corresponding units alternate along the macromolecular chain. Even copolymers with identical molecular weights and identical chemical compositions may differ appreciably in the distribution of units and their sequence. A quantitative estimate of the microheterogeneity of copolymers involves the measurement of the relative contents of the corresponding chain units having a definite chemical structure. Modern research methods make it possible to determine the sequence of only small fragments of the chain—with a length not exceeding 3–4 units. Analysis of the sequence of units throughout the macromolecule is based on the hypothesis that the processes responsible for the chain microstructure are entirely random. The experimental determination of the alternation (sequence) of units in copolymer chains is based on the measurement of a property of the polymer which depends on the number of units of definite types and on the order in which they are joined together. Depending on the nature of the copolymer investigated, such a property may be, for example, the absorption intensity at certain frequencies in the ultraviolet or infrared regions, the melting point, the glass point, and the presence of chemical functional groups characteristic of a given structure [41,42]. High-resolution NMR has acquired the greatest importance in recent years in the study of the microstructures of copolymers. The relative intensities of the signals of the corresponding nuclei make it possible in many instances to determine accurately the fraction of chemical groups characteristic of a particular type of alternation.

The properties of the copolymer depend strongly on the sequence of units in its macromolecules; this applies particularly to the extreme cases of the distribution of elementary units. If it is assumed that the copolymer is made up to two types of main units c_1 and c_2, their distribution may be as follows:

(a) a distribution characterised by the maximum number of linkages between the units c_1 and c_2. This sequence corresponds to a regularly alternating structure of the copolymer chain:

$$\sim -c_1-c_2-c_1-c_2-c_1-c_2-\sim;$$

(b) a distribution distinguished by the maximum number of linkages between units of one type. Such a sequence corresponds to a block structure of the copolymer chain:

$$\sim -c_1-c_1-c_1-c_1-c_2-c_2-c_2-c_2-\sim;$$

(c) chains with an intermediate distribution of units may manifest a tendency towards irregular alternation or to a block structure, or their structure may be completely disordered:

$$\sim c_1-c_1-c_2-c_1-c_2-c_2-c_2-c_1-c_1-c_2-\sim .$$

A copolymer with a completely disordered distribution of units is called a statistical copolymer.

The problem of the sequence of units in polycondensation copolymers has been the subject to theoretical considerations long before the development of experimental methods permitting the study of the microstructure of copolymers. A mathematical treatment of the problem was published as early as the 1950s by Case [43] and Beste [44]. In subsequent years the studies by Yamadera and Murano [45] and Kuchanov and coworkers [46,47] assumed a considerable importance.

A quantitative description of the microheterogeneity of polycondensation copolymers may be achieved in two ways. Like polymolecularity or the inhomogeneity of composition, microheterogeneity is described with the aid of the corresponding distribution function. The distribution functions for both types of units make it possible to describe exactly the nature and degree of order in the chemical structure of chains. A theoretical treatment of this problem has been described by Beste [44] and Kuchanov [48].

Another widely used method for the description of the microheterogeneity of copolycondensation products is based on a numerical characteristic of the degree of order in the structure of copolymer chains. The method of numerical estimation of the chemical structures of polycondensation copolymers from high-resolution NMR data, used by the majority of workers, was first introduced in the classical study of Yamadera and Murano [45]. They investigated the microheterogeneity of copolyesters obtained by the high-temperature copolycondensation of glycols with dimethyl dicarboxylates and also the nature of the changes in microheterogeneity owing to exchange reactions between poly(ethylene terephthalate) and poly(ethylene sebacate). Yamadera and Murano [45] developed a method for the estimation of the degree of

order in the chemical structure of copolymer chains in relation to the copolyester obtained by the latter reaction. For example, the chains of the copolymer obtained from ethylene glycol (G), dimethyl terephthalate (T), and dimethyl sebacate (S) may contain three types of diads — two homodiads T–G–T and S–G–S and one heterodiad T–G–S. The intermonomer G, which joins together the T and S comonomers in the chains, has different environments in the above diads, which induces the appearance of three different signals in the NMR spectra. The intensity of these signals enabled the authors to determine the mole fractions of the terephthalate x_T and the sebacate x_S:

$$x_T = \frac{S_{TGS}}{2} + S_{TGT}, \quad (1)$$

$$x_S = \frac{S_{TGS}}{2} + S_{SGS}, \quad (2)$$

where S_{TGT}, S_{SGS}, and S_{TGS} are the fractions of the above diads respectively.

The probability of the appearance in the copolymer chain of the T unit after the S unit is defined by the relation

$$P_{TS} = \frac{S_{TGS}}{2x_S}; \quad (3)$$

and the probability of the appearance of the S unit after the T unit is correspondingly

$$P_{TS} = \frac{S_{TGS}}{2x_T}. \quad (4)$$

According to Yamadera and Murano[45], the quantity characterising the microheterogeneity of the copolymer is the sum of the above probabilities. These workers denoted the above quantity by B and called it the degree of randomness. Kuchanov[46] called the same quantity the coefficient of microheterogeneity (K_M) and Slonim and coworkers[49] used the term "coefficient of non-regularity". For the example under discussion,

$$K_M = B = P_{ST} + P_{TS} = \frac{S_{TGS}}{S_{TGS} + 2S_{TGT}} + \frac{S_{TGS}}{S_{TGS} + 2S_{SGS}}. \quad (5)$$

When $K_M = 1$, the arrangement of the T and S units in the chains is disordered. If $K_M < 1$, there is tendency towards the formation of blocks. The quantity $K_M = 0$ corresponds to a mixture of homopolymers. When $K_M > 1$, the number of consecutively connected diads of the same type diminishes and the limiting case $K_M = 2$ corresponds to a regularly alternating copolymer. The number-average lengths of the sequences of T and S units are respectively

$$\bar{L}_{nT} = \frac{2x_T}{S_{TGS}} = \frac{1}{P_{TS}}. \quad (6)$$

$$\bar{L}_{nS} = \frac{2x_S}{S_{TGS}} = \frac{1}{P_{ST}}. \quad (7)$$

Consequently

$$K_M = \frac{1}{\bar{L}_{nT}} + \frac{1}{\bar{L}_{nS}}. \quad (8)$$

However, these equations are valid only when any macromolecule contains a fairly large number of units.

Experimental conclusions reached from the study of Yamadera and Murano[45] under consideration concern the microheterogeneity of the copolymers obtained by copolycondensation and exchange reactions. Since the values of K_M calculated from NMR data for the above copolymers are close to unity, the authors speak of a random distribution of units in the macromolecules obeying the Bernoulli statistics.

When the method proposed by Yamadera and Murano[45] is used, one must not forget that the coefficient of microheterogeneity K_M can serve only as a very approximate characteristic of the alternation of units in the copolymer chains and that its value does not in many instances yield an exact idea about the real macromolecular structure. An example illustrating the ambiguity of the description of the chain structure with the aid of the K_M coefficient has been given by Turska and Matlangiewicz[50]. According to the postulates of Yamadera and Murano, K_M close to unity indicates a random distribution of units in the copolymer chain. However, a value of K_M close to unity characterises, for example, a copolymer made up of units of two types, linked into dimeric sequences, i.e. the copolymer

$$\sim\!-c_1c_1c_2c_2c_1c_1c_2c_2c_1c_1c_2c_2-\!\sim$$

whose chain structure is entirely ordered. One can quote many similar examples. The use of a method which would permit the estimation of the distribution of units in longer chain fragments would make it possible to obtain more accurate data about the real structure of macromolecules.

Despite the ambiguity indicated above, the method of Yamadera and Murano is widely used by many workers investigating the microstructure of copolymers.

As already noted, Eqn. (8) is valid only for fairly long macromolecular chains. Since polycondensation products contain not unduly long chains, there is a risk that such simplification of the description can lead to appreciable inaccuracies. This problem has been considered by Slonim and coworkers[49], who proposed a modified method for the estimation of the microheterogeneity of chains of finite length. These workers consider a copolymer formed in the reaction between an intermonomer and two comonomers c_1 and c_2 which do not react with one another. The copolymer macromolecule can be represented schematically as follows:

$$R-(c_i)_p-(a-c_i)_n-a_q-R',$$

where R and R′ are the end groups, $i = 1$ or 2, p and $q = 0$ or 1 depending on the molar ratio of the monomers and the intermonomer, and n is the degree of polymerisation. Taking into account the above assumptions, the authors[49] derived a relation defining the coefficients K_M for the copolymer macromolecule:

$$K_M = \frac{1}{N-1}\left(\frac{N-\bar{L}_1}{\bar{L}_1} + \frac{N-\bar{L}_2}{\bar{L}_2}\right), \quad (9)$$

where $\bar{L}_1$ and $\bar{L}_2$ denote the average lengths of the block ac_1 and ac_2. For very long chains ($N \gg \bar{L}_n$), Eqn. (9) is converted into Eqn. (8).

The authors[49] used Eqn. (9) to estimate the microheterogeneity of the chains of the copolymer obtained from ethylene glycol (the intermonomer) and dicarboxylic acids — malonic and sebacic (the comonomers). According to the authors, a tendency is observed in the product towards the formation of block structures, as shown by the values of K_M, which lie in the range 0.78–0.89 for a series of experiments. It is of interest that both the

physicochemical parameters of the copolymers investigated required for the calculation of K_M (the composition and degree of polymerisation) have been determined by NMR.

Another method of characterising the microstructure of polycondensation of copolymers has been described in a theoretical study by Gritsenko[51]. The author analyses the nature of the distribution of units in copolymer chains for the simultaneous and consecutive introduction of the reactants into the reaction zone.

An important aspect of the problem of the microstructure of copolymer chains has been examined by Sawada[52,53], who defines the conditions which must be fulfilled in order that the synthesis of a polycondensation copolymer should lead to a product with a definite type of structure of macromolecular chains. Sawada characterises the degree of order in the structure of the copolymer with the aid of a parameter γ, which he introduced: $\gamma = -1$ corresponds to a block structure, $\gamma = 1$ corresponds to a regularly alternating structure, and $\gamma = 0$ corresponds to a copolymer with a statistical distribution of units in the macromolecular chains. Sawada's theory explains the statistical structure of the chains of copolymers obtained in the melt by the influence of the high process temperature. According to the author, under the conditions of low-temperature processes, there is a possibility of the formation of macromolecules with a more ordered structure.

However, the thermodynamic approach to the solution of the problem of the structure of copolymers developed by Sawada gives rise to certain objections. The author does not take into account in his treatment the dependence of the enthalpy ΔH on temperature. One can also assume that an experimental test of Sawada's theory will encounter major difficulties due to the complexity of the selection of the corresponding systems and the similarity of the temperature of low- and high-temperature copolycondensations.

The most extensive studies on the synthesis and chemical structure of polycondensation copolymers have been made in the course of many years by members of the Institute of Organoelemental Compounds of the USSR Academy of Sciences under the direction of Academician V.V. Korshak. He has made a major contribution both to the theory and practice of copolycondensation processes. Many conclusions which follow from the work of Korshak and coworkers concerning acceptor-catalytic copolycondensation can be extended also to other copolycondensation methods. Many of these studies embrace the problems of the synthesis of new polycondensation copolymers from various monomers. Another field of study is associated with the determination of the chemical structure of copolycondensation products. The influence of various factors, particularly factors such as the reactivity of the functional groups, the mode of introduction of the monomers into the reaction medium, etc., on the nature of distribution of units in the copolymers obtained by acceptor-catalytic copolycondensation has been investigated[54-56]. Together with theoretical studies, experimental investigations are being carried out at the Institute of Organoelemental Compounds on the microstructure of polycondensation copolymers by NMR.[54,57,58] The results of the theoretical and experimental research by Korshak and coworkers have been surveyed in recent years in a number of reviews[47,59,60].

In Poland studies on the synthesis and properties of polycondensation copolymers have been made by Jedlinski and coworkers[30,61,62]. The aromatic copolyesters containing bisnaphthol rings, which they obtained, are characterised, in particular, by a high thermal stability and are effective electrical insulators.

2. Kinetic Description of the Copolycondensation Process

In order to characterise the processes involving the synthesis of polycondensation copolymers, account must be taken of the fact that the copolycondensation process in all its varieties is a result of a superposition of two or more simultaneous or consecutive reactions between the functional groups. Consequently the difference between polycondensation and copolycondensation is entirely quantitative and the methods used to carry out the two processes are in principle identical. We shall therefore not consider the elements of theory and practice common to all polycondensation processes. Only certain characteristics of the kinetics of copolycondensation, associated with the simultaneous occurrence of reactions between functional groups having different reactivities, require separate consideration.

A homopolycondensation reaction can be described, after introducing certain simplifying assumptions, with the aid of simple formal kinetic equations. Taking into account these assumptions, the copolycondensation process can be regarded as a series of parallel (synchronous reactions) with participation of two or more functional groups and it can also be described by formal kinetic equations assuming that the rate of the process as a whole is determined by the rates of these reactions.

A simple example of copolycondensation is the reaction between the functional groups of three bifunctional monomers. The independent functional groups of one of the monomers are capable of reacting with the independent functional groups of the other two monomers, which are incapable of reacting under these conditions with one another. The first monomer is called the intermonomer; it binds identical or different copolymers into diads in the chains of the resulting copolymer. Having denoted the intermonomer by A and the comonomers by B and C, the structure of such a copolymer can be represented schematically as follows:

$$\cdots\text{—A—B—A—B—A—C—A—B—A—C—A—C—}\cdots$$

The copolymer is formed as a result of consecutive reactions of functional groups of type A with groups B and C, the reactions being governed by kinetic constants k_{AB} and k_{AC} respectively. If the irreversibility and second order of both reactions are assumed, the standard kinetic equations for the concentrations of the functional groups can yield relations between the compositions of the copolymer and the monomer mixture on the one hand, and the kinetic constants for the process and the initial concentrations of the monomers for different degrees of reaction, on the other[63,64]. In particular, the equation for the composition of a polycondensation copolymer becomes

$$\frac{dc_B}{dc_C} = \alpha\frac{c_B}{c_C}, \quad \alpha = \frac{k_{AB}}{k_{AC}}, \tag{10}$$

where c_B and c_C are the concentrations of the functional groups of the comonomers B and C.

The limitations of Eqn. (10) refer mainly to the limits of its applicability. Sokolov and Kurglova[65] believe that the composition equation is inapplicable to copolycondensation under homogeneous conditions in solution or in the melt. In order to attain fairly high molecular weights

of the copolymer under such conditions, not only an equimolar ratio of the reacting functional groups but also a high degree of reaction are necessary. However, when the degree of reaction is high, the composition of the copolymer becomes the same as that of the initial mixture of monomers regardless of the difference between the reactivities of their functional groups. The excess of functional groups of one type precludes, in its turn, a high molecular weight of the copolymer. According to the authors [65], Eqn. (10) can be used for copolycondensation processes at the boundary of two immiscible liquid phases, although it is known that classical kinetic equations cannot be used to describe processes occurring in heterogeneous systems.

Another limitation is associated with the identification of the monomer concentration in Eqn. (10) with the concentration of its functional groups. Evidently the concentrations of the functional groups do not change solely as a result of reactions between the monomer molecules. One should add that the equation has been obtained without taking into account the reversibility of the polycondensation reactions. The introduction of the rate constants for the reverse reactions into the kinetic equations would create significant difficulties in the calculations.

The copolycondensation process is known to be accompanied by side reactions, which can have a very significant influence on its course. The side reactions affect also the composition of the copolymer formed. In certain cases this influence may be determined exactly by an appropriate modification of the composition equation. An example of reactions in which the monomers B and C react with a compound D present in the system, apart from their reaction with the intermonomer A, is given in Sokolov's monograph [66].

One of the assumptions in the derivation of the composition equation is that the reactivities of all the functional groups are the same and do not change during the copolycondensation. However, systems in which the reactivity of a functional group depends on whether it is the first (monomer) or second (oligomer or polymer) to react are encountered much more frequently. Allowance for the different reactivities of the first and second functional groups requires, even in the simplest case, the use of a computer for the calculations.

Such calculations have been made by Sokolov and coworkers [67] for the copolycondensation of an intermonomer A with two comonomers B and C. In this process two reactions take place between the comonomers and the intermonomer and two reactions between the oligomers or polymers. The monomers and oligomers or polymers participate in the four reactions. Six kinetic equations for a process of this kind characterise the decrease in the concentrations of the individual functional groups during the reaction. The results show that the composition of the copolymer formed depends on the ratio of the reactivities of the functional groups of the monomers B and C and on the ratio of the reactivities of the first and second groups in each comonomer. The composition of the copolycondensation products is influenced significantly also by the degree of reaction. The difference between the reactivities of the first and second functional groups of the intermonomer does not affect the composition of the copolymer.

Kuchanov [46], who examined only low-temperature copolycondensation, reached similar conclusions. He believes that the rapid interchain reactions in high-temperature copolycondensation lead to a random, statistical distribution of units in the copolymer chains.

The term "copolycondensation" embraces all the processes involving the synthesis of polycondensation copolymers in which the reaction mechanism corresponds to one of the known polycondensation mechanisms and the chains of the macromolecules formed made up of two or more types of units. Even if one omits processes involving synthesis using trifunctional monomers (because they differ significantly) and the treatment is confined to the copolycondensation of bifunctional monomers, the range of the possible different versions is very wide.

The kinetic equations used to describe copolycondensation processes must contain formal expressions corresponding to a particular type of process. This requirement is valid even when different types of processes can be described by the same general kinetic relations.

The simplest copolycondensation which is most often encountered in laboratory practice is the copolycondensation of three monomers: the intermonomer A and the comonomers B and C. A correct kinetic analysis of even this not unduly complex system requires that one takes into account the mechanism of the reaction and the way it is carried out. The high-temperature copolycondensation of the above three monomers under homogeneous conditions is a kinetically simple case. However, even in this simple instance the use of formal kinetic equations requires many assumptions, the most important of which are as follows: 1) Flory's postulate that the reactivities of the terminal groups are the same and independent of the size of the macromolecule; 2) the postulate that the reacting system is homogeneous; 3) the postulate that the volume and mass of the system remain constant during the process; 4) the postulate that the reaction is irreversible under the given conditions; 5) the postulate that side reactions, primarily chain transfer reactions, do not occur under the conditions considered.

A critical consideration of each of the above postulates permits the following conclusions.

1. The hypothesis that the reactivities of the functional groups are the same is used very frequently and in principle yields a satisfactory approximation to real systems. However, it is valid also if there are no significant differences between the reactivities of the functional groups of the monomer molecules and the molecules of oligomers and polymers. The appearance of such a difference is largely caused by the structure of the monomer molecules. For example, it is known that the first OH group in ethylene glycol is more reactive than the second. After the substitution of the first group, the reactivity of ethylene glycol falls appreciably, which gives rise to significant differences in the employment of this monomer. On the other hand, bisphenols, for example, bisphenol A (dian) do not exhibit an appreciable difference between the reactivities of the first and second functional groups. The above hypothesis cannot therefore lead in all cases to a satisfactory approximation by the kinetic description to the real situation.

2. The postulate that the system is homogeneous is extremely indefinite, although it is used by all investigators of the kinetics of polycondensation in solution. In general this hypothesis is fulfilled only for a solution which constitutes a homogeneous system and must not contain a deposit (an insoluble monomer or the precipitated polymer). The evolution of a gaseous side product is as a rule neglected. However, bearing in mind that this not unduly accurate hypothesis is generally accepted for the description of homopolycondensation processes in solution

and yields a satisfactory agreement between theory and experiment, one can also adopt it for copolycondensation processes.

3. The postulate that the volume and mass remain constant throughout the process when a gaseous product is removed from the reaction system is likewise inaccurate. Despite this, many investigators employ this assumption, since the error caused by its inaccuracy is frequently small and may be disregarded. This hypothesis leads, however, to appreciable errors when a side product with a high molecular weight is removed from the process in the melt. For example, in the synthesis of the polyester from terephthalic acid dichloride and dian the relative error associated with the removal of hydrogen chloride is about 8% for the reaction in the melt. For the reaction in solution, the error diminishes by more than an order of magnitude. It can then be legitimately disregarded and one can assume with an adequate degree of approximation that the volume of the reaction mixture is constant for polycondensation in solution.

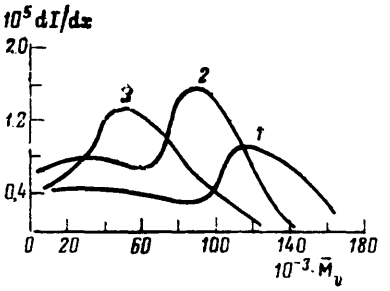


Figure 1. Differential MWD curves for a polycarbonate containing dian and inorganic compounds as admixtures: 1) specimen before heat treatment; 2) specimen heat-treated for 4 h at 260°C; 3) specimen heat-treated for 9 h at 260°C.

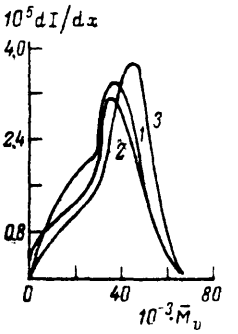

Figure 2. Differential MWD curves for a polycarbonate without admixtures: 1) specimen before heat treatment; 2) specimen heat-treated for 4 h at 260°C; 3) specimen heat-treated for 9 h at 260°C.

4. The postulate that the formation of the copolymer is a reversible reaction is in principle inapplicable to a process carried out under conditions where the equilibrium is not displaced by the constant removal of the side product from the reaction medium. However, if the equilibrium is effectively shifted towards the formation of the polymer, the above hypothesis can be adopted. One must take into account the fact that the efficiency of the displacement of the equilibrium in general diminishes with increasing degree of reaction. The hypothesis that the reaction is irreversible therefore yields an accurate description of the process for low degrees of the latter and is much less accurate for high degrees of reaction.

5. The hypothesis that there are no side reactions can also lead to major errors depending on the process conditions. Side reactions as a rule accompany polycondensation processes. However, according to literature data[60], one can select conditions such that side reactions virtually do not take place and may be disregarded. Nevertheless, this hypothesis cannot be adopted without an experimental test under the selected conditions. Presumably, under the conditions of high-temperature polycondensation in solution, the contribution of side reactions involving interchain exchange is small. Kinetics studies on the high-temperature polycondensation of dian chloroformate with dian in solution[68] showed that, under certain process conditions, chain transfer reactions may be disregarded, because their rate is too small to be measured under such conditions. These observations were confirmed subsequently in other systems. Studies on the dependence of the molecular weight distribution (MWD) of polycarbonates on the duration of their heat treatment showed in their turn that admixtures greatly influence the course of the process and the extent of side reactions[69]. In particular, it has been observed that chain transfer reactions occur in the presence of a very low content of impurities in the reaction mixture. In the absence of impurities, chain transfer reactions hardly take place. Figs. 1 and 2 show how the molecular weight distribution functions for polycarbonates, both contaminated and without impurities, vary after heat treatment. Evidently heat treatment influences appreciably only the MWD of the polycarbonate with impurities.

The above considerations suggest that, although the assumptions can lead in many cases to discrepancies between theoretical and experimental data, nevertheless there exist systems and polycondensation conditions for which they can be used without much error. Polycondensation and copolycondensation in solution under appropriate conditions may be classified as processes of this kind. This fact makes it possible to employ the fundamental equations of formal kinetics for the kinetic analysis of such processes.

We shall now consider the homogeneous high-temperature copolycondensation in solution of the intermonomer A with the comonomers B and C. Suppose that the composition of the initial monomeric mixture corresponds to equimolar proportions of the functional groups and that all the simplifying assumptions formulated above for the derivation of Eqn. (10) are valid. Using the normal kinetic equations, it is possible to derive expressions describing the time dependence of the concentrations of the individual types of functional groups[69]:

$$-\frac{dc_B}{dt}=\frac{k_{AB}c_C^0}{(c_B^0)^{1/\alpha}}c_B^{1/\alpha+1}+k_{AB}c_B^2, \qquad (11)$$

$$-\frac{dc_C}{dt} = \frac{k_{AC}c_B^0}{(c_C^0)^\alpha} c_C^{\alpha+1} + k_{AC}c_C^2, \quad (12)$$

where c_B^0 and c_C^0 are the initial concentrations of the functional groups B and C respectively. These equations can be numerically integrated on a computer for arbitrary values of the parameters. Knowing the values of c_B and c_C, it is easy to determine the degree of reaction p and the mole fractions of the bonds formed in the copolymer between the monomers A and B (x_{A-B}) and A and C (x_{A-C}):

$$p = \frac{c_B^0 + c_C^0 - c_B - c_C}{c_B^0 + c_C^0}, \quad x_{A-B} = 1 - x_{A-C} = \frac{c_B^0 - c_B}{c_B^0 + c_C^0 - c_B - c_C}, \quad (13)$$

and to obtain an equation for the kinetic curve for the process:

$$\frac{dp}{dt} = (1-p)(k_{AB}c_B + k_{AC}c_C). \quad (14)$$

3. Experimental Study of High-Temperature Polycondensation

Eqns. (11) and (12) show that the complex relation between the concentrations of the functional groups and the reaction time is evidence for the complexity of the copolycondensation processes. The concentrations of the functional groups c_B and c_C are influenced during copolycondensation by the relative reactivities of both groups in their reactions with the groups of the intermonomer and also by the initial composition of the reaction mixture. The determination of c_B and c_C as well as k_{AB} and k_{AC} (Table 1) by kinetic investigation of the corresponding polycondensation processes permits the calculation by Eqn. (14) of the theoretical $dp/dt = f(p)$ curve. Comparison of the theoretical curve and the experimental curves for the monomer A–terephthalic acid dichloride, monomer B–dian, and monomer C–tetrachlorodian [70] systems established that Eqn. (14) constitutes a satisfactory approximation for the description of the kinetics of the copolycondensation process (Fig. 3).

Table 1. The rate constants k and activation energies E for the polycondensation of terephthaloyl chloride with bisphenols in solution in α-chloronaphthalene.

Biphenol	10^3k, litre mole^{-1} s^{-1}				E, kcal mole^{-1}
	180° C	190° C	200° C	220° C	
Dian	1.19	1.78	2.78	4.40	15.3
Dimethyldian	0.49	0.85	1.29	4.10	23.6
Tetramethyldian	0.14	0.17	0.35	1.09	19.2
Tetrachlorodian	0.10	0.15	0.34	0.86	23.9
Dinitrodian	0.08	0.15	0.25	0.68	23.7

The applicability of Eqn. (14) to other systems has been demonstrated in a study of the kinetics of the copolycondensation of terephthalic acid dichloride (A) with dian (B) and phenolphthalein (C) in solution [71]. The polycondensation rate constants k_{AB} and k_{AC} were determined at 220°C in α-chloronaphthalene as 52.4×10^{-4} and 27.0×10^{-4} litre mole^{-1} s^{-1} and graphical relations between the degree of reaction and reaction time were constructed. As an example, Fig. 4 presents one of such graphs. Evidently the experimental points fit satisfactorily on the theoretical curve. Analogous relations, plotted for the copolycondensation of terephthalic acid dichloride with dian and tetrachlorodian also revealed a satisfactory agreement between the experimental and theoretical data.

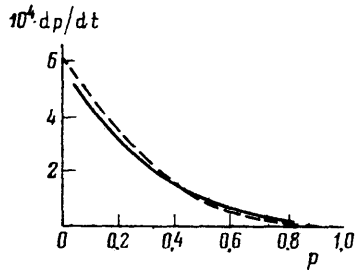

Figure 3. Dependence of dp/dt on the degree (p) of copolycondensation; continuous line—experimental curve; dashed line—theoretical curve.

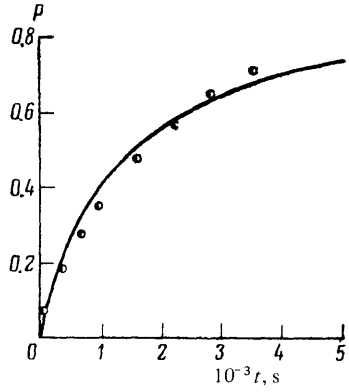

Figure 4. Dependence of the degree of reaction in α-chloronaphthalene at 220°C on the duration (t) of the copolycondensation of terephthalic acid dichloride (c_A^0 = 0.2 M) with dian (c_B^0 = 0.08 M) and phenolphthalein (c_C^0 = 0.12 M). Continuous line—theoretical curve; circles—experimental data.

The undoubted applicability of Eqn. (4) to the description of the degrees of certain high-temperature copolycondensation reactions in solution permitted its extension to an arbitrary number of comonomers (B, C, D,..., N) [73]:

$$\frac{dp}{dt} = (1-p)(k_{AB}c_B + k_{AC}c_C + k_{AD}c_D + \cdots + k_{AN}c_N). \quad (15)$$

The concentrations of the functional groups of the reacting comonomers are linked by the relation

$$\frac{c_B^0}{c_B} = \left(\frac{c_C^0}{c_C}\right)^{k_{AB}/k_{AC}}, \quad \frac{c_C^0}{c_C} = \left(\frac{c_D^0}{c_D}\right)^{k_{AC}/k_{AD}}, \ldots \quad (16)$$

Eqns. (15) and (16) were solved numerically for the copolycondensation of terephthalic acid dichloride (A) with dian (B), tetrachlorodian (C), and phenolphthalein (D) in α-chloronaphthalene at 220°C. Fig. 5 presents the dependence of the degree of copolycondensation and the concentration of the functional groups B, C, and D which failed to react on the reaction time. The most active groups are exhausted at the beginning of the processes and those with a lower reactivity at later stages. The variation of the fractions of functional groups which have not reacted with copolycondensation time can be conveniently represented graphically for the given system of monomers in an equilateral triangle. The vertices of the triangle correspond to 100% contents of the functional groups. As the copolycondensation proceeds, the fraction of less reactive groups in the reaction mixture increases (Fig. 6).

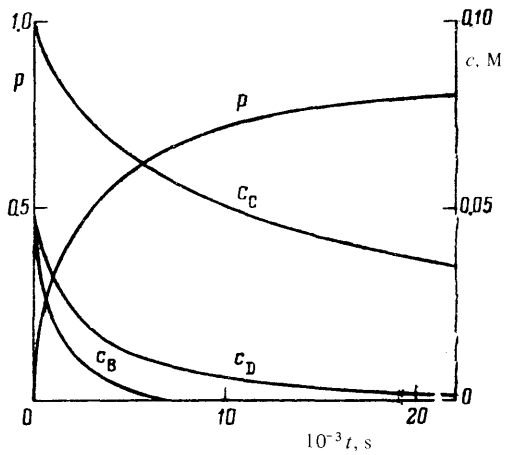

Figure 5. Dependence of the concentrations of the functional groups which have failed to react and the degree of reaction on the duration of the copolycondensation of terephthalic acid dichloride (A) with dian (B), tetrachlorodian (C), and phenolphthalein (D) at 220°C in α-naphthalene [calculated from Eqn. (16)].

It is seen from the above considerations that the nature of the variation of the chemical composition of the copolymer formed may be foreseen and its composition calculated with the aid of Eqn. (16). The composition of the copolymer obtained from terephthalic acid dichloride, dian, and tetrachlorodian has been determined experimentally and it has been established that, under the conditions of high-temperature copolycondensation in solution in α-chloronaphthalene at 220°C, the ratio of the monomers in the reaction mixture varies with reaction time [74]. Thus the study of samples of the reaction mixture by thin-layer chromatography showed that the more reactive dian virtually disappears after only 20 min of copolycondensation, while the less reactive tetrachlorodian can still be detected 80 min after the start of the reaction.

The compositions of the copolymers obtained from terephthalic acid dichloride, phenolphthalein, and dichlorodian were determined by elemental analysis.

Fig. 7 illustrates the dependence of the content of dichlorodian in the copolymers on the duration of copolycondensation. It is readily seen that, in conformity with theoretical considerations, the composition of the copolymer varies as the reaction proceeds. This phenomenon is undoubtedly associated with the different reactivities of the functional groups of the comonomers.

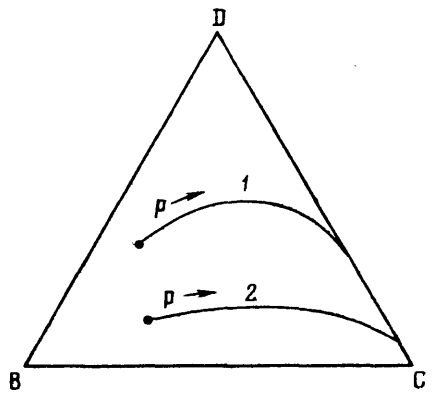

Figure 6. The mole fractions of the functional groups which failed to react in the copolycondensation of terephthalic acid dichloride (A) with dian (B), tetrachlorodian (C), and phenolphthalein (D) at 220°C in solution in α-chloronaphthalene. Curves *1* and *2* correspond to different initial conditions.

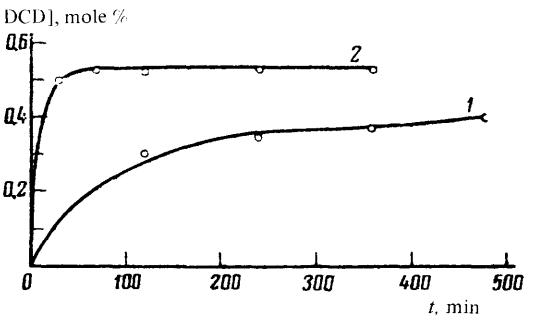

Figure 7. Dependence of the content of dichlorodian (DCD) in the 0.5 : 0.5 : 1 copolymer of dichlorodian, phenolphthalein, and terephthalic acid dichloride on the reaction time; reaction temperature (°C): 1) 180; 2) 242 (isokinetic temperature).

Data indicating the inhomogeneity of the compositions of the copolyesters synthesised from terephthalic acid dichloride, bisnaphthol, and dian were obtained by fractionation and by plotting integral and differential MWD curves for the copolymers. According to theoretical studies [75,76], fractionation of copolymers does not yield an exact characteristic of either the inhomogeneity of the

macromolecules with respect to size or of the inhomogeneity of their chemical composition. However, it follows from these studies that it is possible to select a system in which fractionation is based solely on the molecular weight of the macromolecules. Fractionation in the system where the result obtained is influenced by another parameter (chemical composition) nevertheless does not permit the elimination of the influence of the first parameter. Thus, although it is impossible to determine the distribution function with respect to composition by fractional precipitation, one can observe the chemical inhomogeneity of copolymers if different results are obtained in different systems. It has been found that the solvent (chloroform + ethanol)–precipitant (ethylene glycol) system is relatively insensitive to the chemical composition of the copolymer investigated. This factor enables us to obtain fractions with virtually identical compositions and to plot MWD curves having the shape typical of polycondensation polymers. The same samples, fractionated in a solvent (tetrachloroethane + phenol)–precipitant (n-heptane) system, give rise to fractions differing in chemical composition, and the MWD curves differ appreciably from those obtained previously.

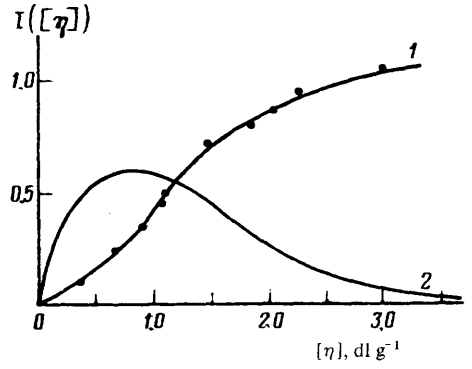

Figure 8. Isokinetic (curve *1*) and differential (curve *2*) MWD curves for the copolyarylate of terephthalic acid dichloride, dian, and bisnaphthol obtained by fractionation in the chloroform + ethanol (5 : 1 by weight)–ethylene glycol system at 25°C.

Figs. 8 and 9 also illustrate MWD curves for both systems, whose comparison leads to the conclusion that the polycondensation copolymers are chemically inhomogeneous.

Thus the experimental data suggest that, when there are differences between the reactivities of the comonomers, the more reactive comonomer is comparatively rapidly exhausted, while the gradual disappearance of the less reactive monomer continues up to high degrees of reaction.

We believe that the consecutive introduction of comonomers into the reaction should be reflected in the microstructure of the macromolecules of the copolycondensate. Similarly, if the reactivities of the two comonomers are the same or almost the same and the composition of the copolymer remains constant regardless of the degree of reaction, the microstructure of the macromolecules must be affected.

Consequently a new problem arises—that of the selection of a system in which both comonomers would have the same activity. It can be solved theoretically fairly readily. It is known[77,78] that the temperature dependence of the reactivity of the terminal groups during high-temperature condensation obeys the Arrhenius equation. If a polycondensation reaction between functional groups A and B take place in the system, then the temperature dependence of the reaction rate constant is

$$\ln k_{AB} = D_{AB} - \frac{E_{AB}}{RT}, \qquad (17)$$

or, for a reaction between functional groups A and C:

$$\ln k_{AC} = D_{AC} - \frac{E_{AC}}{RT}, \qquad (18)$$

where D_{AB}, D_{AC}, E_{AB}, and E_{AC} are constants characteristic of the corresponding polycondensation reactions, T is the temperature (K), and R the gas constant.

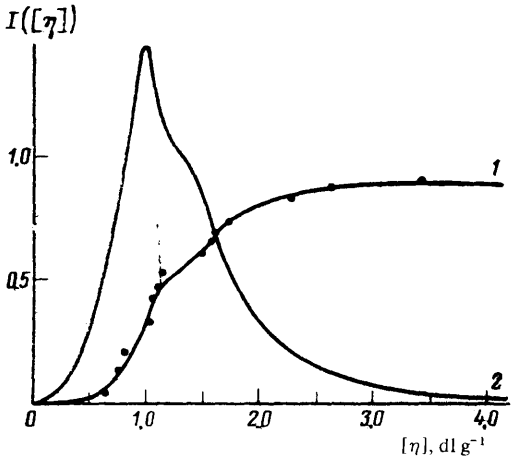

Figure 9. Integral (curve *1*) and differential (curve *2*) MWD curves for the copolyarylate of terephthalic acid dichloride, dian, and bisnaphthol obtained by fractionation in the phenol + tetrachloroethane (1 : 3 by weight)–*n*-heptane system at 25°C.

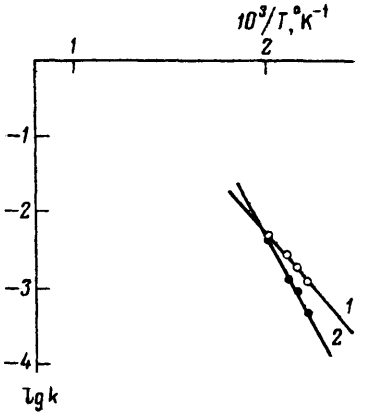
The reactivities of the comonomers B and C in their reaction with the intermonomer A are equal, whereupon $k_{AB} = k_{AC}$. This happens at a temperature which is called the isokinetic temperature (T_{is}):

$$T_{is} = \frac{E_{AC} - E_{AB}}{R(D_{AC} - D_{AB})}. \qquad (19)$$

At any instant during the copolycondensation process, carried out at the isokinetic temperature, the concentrations of the functional groups of the two comonomers B and C which have not reacted are proportional to the initial concentrations c^0_B and c^0_C. The probabilities of the reaction of both functional groups at any instant are therefore identical and equal to the mole fractions of the given comonomers in the mixture of monomers; consequently, the structures of macromolecular chains formed at the isokinetic temperature should be statistical.

However, the existence of the isokinetic temperature does not alone imply that reaction can be carried out at this temperature. For high-temperature copolycondensation in solution, the range of temperatures suitable for reaction is only a few tens of degrees. On the one hand, this range is restricted by the low rates of both reactions at low temperatures and, on the other, by the thermal instability of the monomers in the solvent above 200°C. However, Turska et al.[79] found that there exist monomer systems whose isokinetic temperature is in the range accessible to study. They determined T_{is} graphically using the Arrhenius coordinates $\lg k = f(1/T)$. The point of intersection of the experimental straight lines corresponds on the abscissa axis to a quantity which is the reciprocal of the isokinetic temperature (Fig. 10). Table 2 lists the isokinetic temperatures found by Turska and coworkers.



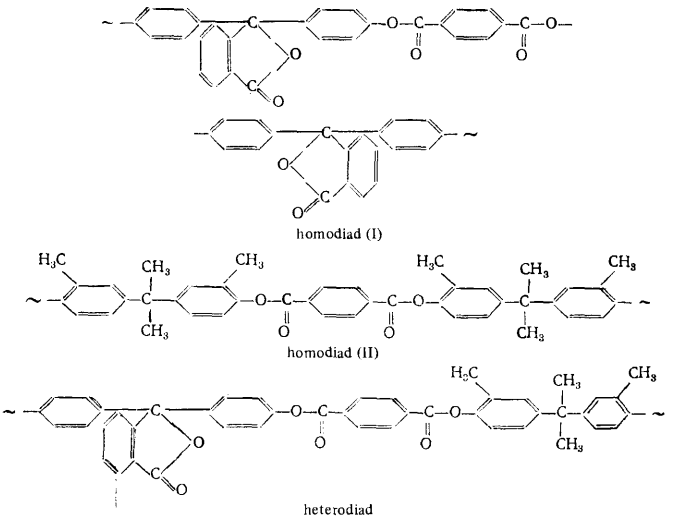


Figure 10. Graphical determination of the isokinetic temperatures for dian (line *1*) and dimethyldian (line *2*) in the reaction with terephthalic acid dichloride in α-chloronaphthalene.

Table 2. The isokinetic temperatures for the copolycondensation of the comonomer systems investigated (the intermonomer is terephthalic acid dichloride).

Comonomers		T_{is}, °C
B	C	
Dian	Phenolphthalein	155
Dian	Dimethyldian	229
Dian	Tetramethyldian	341
Dian	Dinitrodian	366
Dian	Dichlorodian	355
Dian	Tetrachlorodian	340
Phenolphthalein	Dimethyldian	200
Phenolphthalein	Dinitrodian	307
Phenolphthalein	Dichlorodian	242
Phenolphthalein	Tetramethyldian	280
Phenolphthalein	Tetrachlorodian	287

As an example, we shall consider one such system, consisting of terephthalic acid dichloride (the intermonomer A), dimethyldian, and phenolphthalein (the comonomers B and C). It was established by thin-layer chromatography, infrared spectroscopy, and elemental analysis of the reaction products that, when the process is carried out at T_{is} = 200°C, the composition of the copolymer hardly changes with the degree of reaction. The microstructure of the copolymer was studied by high-resolution ^{1}H NMR, whereby the contents of the homo- and hetero-diads in the macromolecules were determined:

Preliminary studies showed that the signal of the phenylene protons of the terephthalic acid residue in the ^{1}H NMR spectra of the polyesters investigated is a singlet (δ = 8.4 p.p.m.). In order to resolve this signal into individual components due to homo- and hetero-diads, tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-3,5-dioneeuropium [Eu(fod)$_3$] was used as an additive. Fig. 11 shows that, in the presence of Eu(fod)$_3$, it is possible to distinguish clearly signals in the ^{1}H NMR spectrum corresponding to the chemical shifts of the phenylene protons of the intermonomer in the homo- and hetero-diads.

The constancy of the composition of the copolycondensate synthesised at the isokinetic temperature, observed by other methods, was confirmed by ^{1}H NMR. Use was made for this purpose of Eqn. (5) quoted above. The values of K_M determined by ^{1}H NMR for copolymers synthesised at the isokinetic temperature (with a high accuracy) proved to be unity, which corresponds to a statistical distribution of units in their macromolecules. This result confirms the validity of our theoretical considerations.

The problem of the nature of the copolycondensation process at temperatures fairly different from the isokinetic temperature is no less interesting. For the above system of monomers, a study was made of the composition and structure of the copolymers obtained at 180° and 220°C, i.e. at temperatures above and below T_{is}. At a temperature different from T_{is} the reactivities of the comonomers are different and, when, for example, $k_{AB} > k_{AC}$, the monomer B reacts faster and the macromolecules of the oligomers and polymers in which it predominates are formed faster and in greater amounts. The concentration of the functional groups of the comonomer B decreases very rapidly almost up to complete exhaustion, after which new molecules are formed in which the comonomer C predominates or molecules where chains containing mainly the less active comonomer C join onto the chains

already formed and begin to grow. Depending on the degree of reaction for which the process is terminated, copolymers are obtained with different degrees of structural inhomogeneity, but there is always a tendency towards a block structure. One may expect the formation in the macromolecule of internal blocks of the more reactive comonomer, while the ends of the chains should contain primarily the less reactive comonomer. For very high degrees of reaction, the interactions between the macromolecules should lead to the formation of multiblock copolymers with different internal blocks, but always with the less reactive comonomers at the ends of the chain.

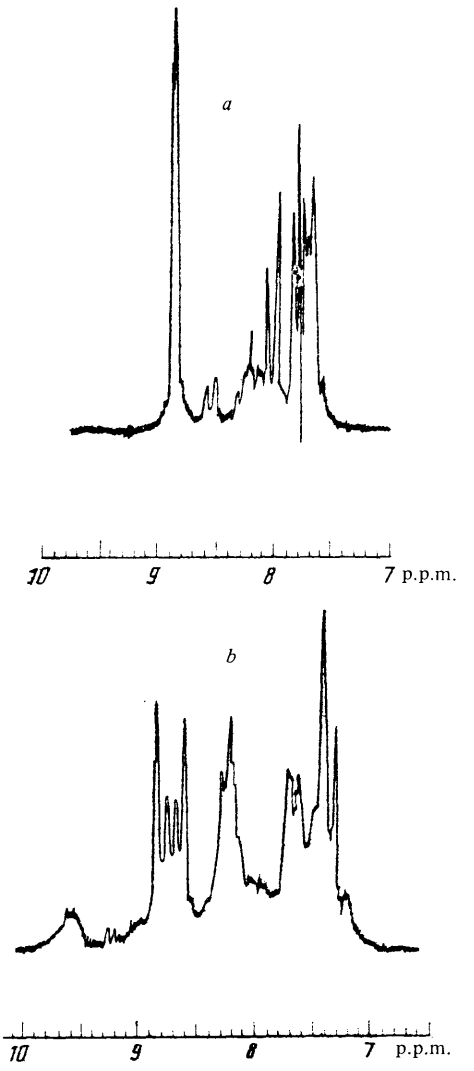

Figure 11. ^{1}H NMR spectrum of the copolyester of terephthalic acid dichloride, dian, and phenolphthalein: *a*) without Eu(fod)$_3$; *b*) with added Eu(fod)$_3$.

In order to confirm the validity of this reasoning, the composition of the copolymer was determined in the course of the reaction. In conformity with earlier considerations, above the isokinetic temperature (220°C) the more reactive comonomer proved to be dimethyldian, which disappeared faster from the reaction mixture, while phenolphthalein, the less reactive comonomer failed to react for a long time. Below the isokinetic temperature (180°C), phenolphthalein proved to be more reactive and dimethyldian failed to react for a long time. The study of the microstructure of the copolymers by ^{1}H NMR using Eu(fod)$_3$ showed that the coefficient of microheterogeneity of the copolymers is $K_M = 0.87$ in both cases.

The difference between the numerical values of K_M for the copolymers obtained at the isokinetic or another temperature indicates a difference between the microstructures of their molecules. The values of the parameter K_M show that copolymers with a completely random statistical chain structure are formed at the isokinetic temperature, while at a non-isokinetic temperature there is a tendency towards the formation of block structures. One should take into account the fact that, for high degrees of reaction, the synthesis of copolymers at isokinetic and non-isokinetic temperatures should lead to the formation of products of the same compositions but with a different structure of macromolecular chains.

oOo

The present review of studies in the field of copolycondensation permits the conclusion that there is as yet no generally recognised equation giving a complete description of the observed phenomena. One should also note that no attempts have been made at an experimental confirmation of the results of the majority of very interesting theoretical studies. Although one should bear in mind that a satisfactory agreement between experiment and theory does not alone demonstrate the validity of the theory, nevertheless the assumptions made in the development of the theory can then be regarded as admissable.

The reason for the discrepancies between different workers' views is apparently the lack of justification of the attempts to describe extremely varied copolycondensation processes in terms of a single theory. It may be that hypotheses which are correct for one group of processes are inadmissible for another. The introduction of limitations as regards the applicability of the theoretical ideas which have been developed should reduce to a large extent the discrepancies in this field. Studies dealing with definite groups of processes hardly involve contradictions under these conditions and in addition permit more general conclusions in many instances. These may include the demonstration of a significant influence of temperature on high-temperature copolycondensation in solution, where even a slight change of temperature in the region of T_{is} may alter the macromolecular structure. Consequently, instead of being a purely kinetic parameter, temperature becomes a parameter which influences the composition and structure of copolymers. Presumably this conclusion is valid also for other groups of copolycondensation processes.

Block Copolymers of the Polycondensation Type

P.M.Valetskii and I.P.Storozhuk

A new class of block copolymers. namely block copolymers of the polycondensation type, is considered. A general indication of the methods of synthesis and structures of such block copolymers is given and the available information about different examples of block copolymers of the polycondensation type is surveyed.
The bibliography includes 174 references.

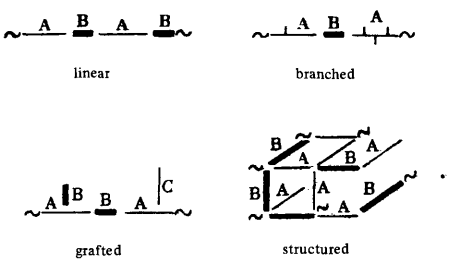
IV. Two-type block copolymers 49
V. Three- and multi-type block copolymers 58



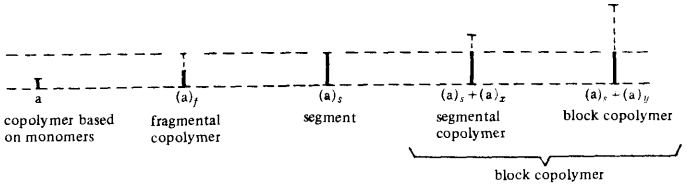
I. INTRODUCTION

The majority of the block copolymers known at this present time have been obtained by polymerisation methods [1-6], but in recent years an increasing number of studies have been devoted to block copolymers synthesised with the aid of polycondensation processes [7,8].

A separate examination of block copolymers of the polycondensation type merits attention for a number of reasons. 1. Virtually any homopolymer, of either polymerisation or polycondensation type, may be used as the corresponding oligomer with terminal functional groups in polycondensation reactions leading to the formation of block copolymers. The synthesis by polymerisation methods of oligomers having terminal functional groups capable of condensation is much simpler and technologically more effective than the synthesis by polycondensation methods of oligomers having terminal functional groups capable of polymerisation. Thus the synthesis of oligomers of the first type leads to considerable possibilities, realisable in practice, for the synthesis of block copolymers containing simultaneously polymer blocks of the polymerisation and polycondensation types. 2. In contrast to block copolymers of the polymerisation type, block copolymers of the polycondensation type can contain blocks of a wide variety of different kinds: aliphatic and aromatic, flexible and rigid, hydrophilic and hydrophobic, unsaturated and saturated, organic and inorganic, etc. 3. In most instances block copolymers of the polycondensation type are multiblock copolymers with a controllable length of blocks, whereas block copolymers of the polymerisation type are mainly two- and three-block copolymers with a poorly controllable length of blocks. The transition to the multiblock structure of block copolymers in which microphase separation occurs is accompanied by the formation of a more perfect physical network owing to the formation of a large number of domains consisting of highly fusible blocks, their more uniform distribution throughout the bulk of the polymer, and the involvement of the same macromolecule in the construction of a large number of domains. The controllable length of blocks permits the development of a stable technological manufacturing process for block copolymers. 4. Finally, perhaps the most significant factor is the successful development, to a large extent owing to the studies by V.V.Korshak and his school, of the theory of irreversible (non-equilibrium) polycondensation [9], which laid extensive foundations for the synthesis of block polymers of the polycondensation type. This refers primarily to acceptor-catalytic polycondensation, the mild conditions for the occurrence of which permit the synthesis of block copolymers with virtually complete suppression of the exchange processes and also lead to the possibility of the formation of block copolymers directly from the monomers [10,11].

II. METHODS OF SYNTHESIS AND STRUCTURE OF BLOCK COPOLYMERS OF THE POLYCONDENSATION TYPE

Block copolymers of the polycondensation type include block copolymers the last stage in the formation of which is a polycondensation reaction. Such copolymers can be linear, branched, grafted (graft block copolymers), and structured:



Linear block copolymers, to the consideration of which the present review is devoted, have been most thoroughly investigated at the present time.

Linear block copolymers are copolymers whose macromolecules consist of alternating blocks of homopolymers or statistical copolymers differing in composition or structure [12]. The concept of the "block" implies a relatively long sequence of elementary units of the polymer, whose length is equal to or greater than the length of the macromolecular segment which is a statistical element of the hypothetical polymer chain adequately simulating the physical properties of the macromolecule [13]. For this reason, terms such as "segmented (segmental) copolymers" and "block copolymers" are used simultaneously in the literature. The first term is frequently applied to segmented polyurethanes [12-15], where the molecular weights of the blocks do not exceed several thousand.

These are short-block copolymers, so that the number of blocks in their macromolecules is considerable. The second term, "block copolymers", is more applicable to long-block copolymers. The molecular weights of the constituent blocks in such copolymers can range from several to tens of thousands. The number of blocks in the macromolecules of polymers of this kind may vary from two (the minimum value for block copolymers) to several tens. Evidently, when the lengths of the blocks in the copolymer are similar to the length of the geometrical segment of the macromolecule, the terms "segmental copolymer" and "block copolymer" become synonymous.

Copolymers containing sequences of elementary units whose length is less than that of the geometrical segment of the macromolecule cannot be regarded as block copolymers; they can be called fragmental copolymers. These copolymers are formed when bifunctional fragmental compounds, consisting of more than one repeating elementary unit and whose chain length is less than that of the segment, are used. The introduction of such a compound into the copolymer macromolecule is equivalent to the introduction into the latter of a chain fragment of another polymer. However, in contrast to blocks, the fragments impart to the new polymer an insignificant proportion of the properties characteristic of their high-molecular-weight homologue.

Bearing in mind the foregoing considerations, the hierarchy of linear copolymers can be represented as follows as a function of the length of the sequences of elementary units incorporated in the macromolecule:

Here a is the elementary unit and f, s, x, and y are the numbers of elementary units ($f < s$ and $x \leqslant y$).

Taking into account the fact that the block length should not be smaller than the length of the segment, the structure of block copolymers can be described by terms such as segment-monomeric, segment-fragmental, segment(1)–segment(2)-al, etc. copolymers (Table 1). These names enumerate initially the polymeric segments with structures (1), (2), etc. in the copolymer macromolecule and indicate the nature of the chain-lengthening agent (if one is used), whereby the segments are chemically combined in the macromolecule.

We shall examine the definitions of certain characteristics of the block copolymers presented in Table 1. A component is a block of a homopolymer or a copolymer having a definite composition and structure incorporated in the block copolymer. "Componentality" is the number of blocks of different composition and structure constituting the macromolecules of the block copolymer. One-component block copolymers contain blocks of a single chemical kind connected via the residues of the chain-lengthening agent; the molecules of two-component block copolymers include blocks with two different structures, which may differ by the presence of other substituents or by the steric structure of the chain, etc. The type composition of a block copolymer (it can be a one-type, two-type, three-type, and multitype copolymer) is a quantity equal to the number of types of macromolecular compounds incorporated in the form of chemically combined oligomeric analogues (blocks) in the macromolecule of the block copolymer. "Blockability" is the total number of blocks of any kind in the macromolecule of the block copolymer. The minimum number of blocks which can be observed in long-block copolymers is two and the maximum number is determined by the length of the constituent blocks and the length of the macromolecule of the block copolymer itself and can amount to several tens. In terms of the regularity of the alternation of blocks along the macrochain, block copolymers of the polycondensation type can be divided into regularly alternating and irregularly alternating. This characteristic of block copolymers refers to their fine structure (microstructure) and its determination, particularly for irregularly alternating block copolymers, is as yet difficult.

Table 1. Characteristics of block copolymers.

Structure of copolymer	No. of components ('componentality')	No. of blocks ('blockality')	No. of types	Regularity in alternation of blocks
Segment-monomeric	1	two-, three-, and multi-block	1	regularly and irregularly alternating
Segment-fragmental	1	two-, three-, and multi-block	1	ditto
Segment-fragment-monomeric	1	three- and multi-block	1	ditto
Segment (1)-segment(2)-al	2	two-, three-, and multi-block	1 and 2	regularly alternating
Segment(1)-segment(2)-monomeric	2	two-, three- and multi-block	1 and 2	regularly and irregularly alternating
Segment(1)-segment(2)-fragmental	2	two-, three-, and multi-block	1 and 2	ditto
Segment(1)-segment(2)-segment(3)-al	3	three- and multi-block	1,2 and 3	ditto
Segment(1)-segment(2)-segment(3)-monomeric, etc.	3 (multi-component)	three- and multi-block > 3 (multiblock)	1,2 and 3 ⩾ 1	ditto

The chemical structure of polymers can be treated at two different levels: at the levels of the macrostructure and the microstructure. The macrostructure of the polymer is characterised by parameters of the following kind:

I. The chemical structure of the elementary unit of the polymer (idealised formula which does not reflect all the characteristics of the polymer chain structure).

II. The average chemical (elemental) composition of the polymer.

III. The average molecular weight of the polymer. The knowledge of the macrostructure of the polymer is usually sufficient to achieve a comparative characterisation of different polymers, but the macrostructure cannot explain the whole series of features of the physical and chemical properties of high-molecular-weight compounds. In such instances a more detailed study of polymers, yielding information about their microstructure, is necessary.

The concept of the microstructure of the polymer is much more profound than the concept of its macrostructure and includes a much greater number of parameters characterising the structure of the polymeric compound [16-20]; these parameters are listed below:

I. The chemical structures of the main and "anomalous" [18,19] elementary units in the chain (the heterounit property of polymers), terminal blocks, units, and terminal functional groups.

II. Chemical inhomogeneity:

1. Inhomogeneity with respect to molecular weight.

2. Inhomogeneity with respect to chemical composition (compositions inhomogeneity).

3. Inhomogeneity with respect to chemical structure [18, 19]: (a) inhomogeneity with respect to the degree of branching (number of branching points, chemical structure, and length of branches); (b) inhomogeneity in the "head-to-head" and "head-to-tail" combinations of units; (c) inhomogeneity as regards the presence of isomeric units; (d) inhomogeneity with respect to microtacticity (owing to the differences in the configurations of the asymmetric carbon atoms making up the macromolecular chain); (e) inhomogeneity of macromolecules induced by the presence of anomalous units owing to incomplete trimerisation, incomplete formation of the carbo- or hetero-cycle in the polycyclisation or polycyclocondensation reaction, copolymerisation and copolycondensation, and chemical reactions of the units in the macromolecules.

4. Inhomogeneity with respect to the chemical nature of the terminal blocks, units, and functional groups.

III. Inhomogeneity in the distribution of the main and anomalous units and sections of different chemical compositional structure in the macrochain.

One should note that, whereas the method for the determination of the macrostructure of the polymer has now been thoroughly developed and presents no difficulty, the determination of its microstructure is difficult even for simple polymeric systems. This problem becomes still more complex on passing from homopolymers to copolymers and block copolymers [17,20].

Nevertheless, even without experimental data for the microstructure of block copolymers of the polycondensation type, one can assume that these block copolymers will exhibit an appreciable inhomogeneity, i.e. a difference between the macromolecules of the same specimen of the block copolymer.

We shall now consider in a general form certain kinds of block copolymers of the polycondensation type and methods for their synthesis.

A. ONE-COMPONENT BLOCK COPOLYMERS OF THE POLYCONDENSATION TYPE

One-component block copolymers are at the same time one-type block copolymers and can have a two-, three-, and multi-block structure (Table 1). One-component two-block copolymers can be obtained by the interaction of an excess of the oligomer having terminal functional groups f with a monomeric or fragmental chain lengthening agent (cl):

$$2\ \mathrm{f{-}A{-}f} + \mathrm{f'{-}cl{-}f'} \rightarrow \mathrm{f{-}A{-}cl{-}A{-}f}\ . \qquad (1)$$

One-component three-block copolymers can also be obtained from the same initial compounds as two-block copolymers, but in this case two stages are required; the low-molecular-weight compound can behave under these conditions as a functional group substituting agent (fgs) (monomeric or fragmental) in the oligomer rather than a chain lengthening agent:

$$\mathrm{f{-}A{-}f} + 2\mathrm{f'{-}fgs{-}f'} \xrightarrow{(a)} \mathrm{f'{-}fgs{-}A{-}fgs{-}f'}\ ;$$
$$\mathrm{f'{-}fgs{-}A{-}fgs{-}f'} + 2\mathrm{f{-}A{-}f} \xrightarrow{(b)} \mathrm{f{-}A{-}fgs{-}A{-}fgs{-}A{-}f}\ . \qquad (2)$$

Thus the functional group substituting agent is a low-molecular-weight compound used to substitute one set of functional groups in oligomers and polymers by another, whereby block copolymers having a specified structure can be synthesised. Functional group substituting agents can be divided into those whose residues are incorporated in the macromolecule of the block copolymer (monomeric and fragmental substituting agents) and substituting agents which are not incorporated in the macromolecule of the block copolymer (H_2O, $POCl_3$, etc.).

One-component multiblock copolymers are formed when equimolar amounts of a bifunctional oligomer react with a single chain lengthening agent:

$$n\,\mathrm{f{-}A{-}f} + n\,\mathrm{f'{-}cl{-}f'} \rightarrow \mathrm{f{-}[{-}A{-}cl{-}]_n{-}f'} \qquad (3)$$

or simultaneously with several chain lengthening agents of different chemical types. In the latter case one may speak of a regular or irregular alternation of lengthening agents of different kinds along the macrochain of the block copolymer.

Before the synthesis of a multiblock block copolymer, the initial oligomers may be subjected to interaction with a rigorously stoichiometric or an excess amount of functional group substituting agents in order to replace functional groups inactive with respect to the chosen chain lengthening agent by active groups:

$$n\,\mathrm{f''{-}A{-}f''} + 2n\,\mathrm{f{-}fgs{-}f} \xrightarrow{(a)} n\,\mathrm{f{-}fgs{-}A{-}fgs{-}f}\ ; \qquad (4)$$
$$n\,\mathrm{f{-}fgs{-}A{-}fgs{-}f} + n\,\mathrm{f'{-}cl{-}f'} \xrightarrow{(b)} \mathrm{f{-}[{-}fgs{-}A{-}fgs{-}cl{-}]_n{-}f'}\ .$$

Among one-component multiblock block copolymers, one can distinguish block copolymers with constant block lengths:

$$\sim\!\!\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\mathrm{cl}\overset{A}{\text{—}}\sim$$

and variable block lengths (varied, for example, by one of several chain lengthening agents, which do not yield an anomalous unit on combination of two oligomers):

$$\sim\!\!\overset{A}{\text{—}}\mathrm{cl}_2\overset{A(A+A+A)}{\text{———}}\mathrm{cl}_3\overset{A}{\text{—}}\mathrm{cl}_3\overset{A(A+A)}{\text{———}}\mathrm{cl}_2\overset{A}{\text{—}}\sim\ .$$

All the polymers containing anomalous units in their macromolecules can be regarded as the latter variety of block copolymers.

B. TWO-COMPONENT BLOCK COPOLYMERS OF THE POLYCONDENSATION TYPE

Since most attention is being devoted nowadays to the synthesis and the study of the properties of block copolymers of this kind, we shall consider them in greater detail. Two-component two-block copolymers of type A–B may be obtained by the interaction of two polymers, each containing at the ends of its macrochains one functional group capable of polycondensation, and by the interaction of a stoichiometric amount of a chain lengthening agent with an equimolar amount of two polymers whose molecules each contain one functional group at the end of the chain:

$$\mathrm{A{-}f} + \mathrm{f'{-}cl{-}f'} + \mathrm{f{-}B} \rightarrow \mathrm{A{-}cl{-}B}\ . \qquad (5)$$

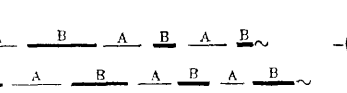
The polymers A–f and f–B, which differ in their composition or structure, may belong either to polymers of one type (a polyether, a polyamide, etc.) or to two different types of polymers (a polycarbonate and a polyorganosiloxane, a polyester and a polyether, etc.).

Two-component three-block block copolymers with A–B–A and B–A–B block sequences can be obtained by the interaction of a bifunctional oligomer B or A with an excess of the oligomer A or B respectively:

$$\geqslant 2f-A-f+f'-B-f' \rightarrow f-A-B-A-f \quad . \qquad (6)$$

If one of the initial oligomers contains only one functional group at the end of the chain, the synthesis of the three-block copolymer is simplified:

$$2\,A-f+f'-B-f' \rightarrow A-B-A \quad . \qquad (7)$$



Two-component multiblock copolymers of the polycondensation type may be regularly alternating or irregularly alternating (regular and irregular).

1. Regularly Alternating Block Copolymers

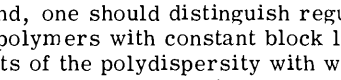
Regularly alternating block copolymers are multiblock copolymers with a regular alternation of blocks of different kinds along the macrochain. Among the block copolymers of this kind, one should distinguish regularly alternating block copolymers with constant block lengths (within the limits of the polydispersity with which the initial oligomers having the specified molecular weight have been obtained):

and regularly alternating block copolymers with varying block lengths (one or both):

In view of the different types of behaviour under certain conditions of blocks of the same kind but different lengths, the block copolymers $-(-AB-)_n-$, $-(-A'B-)_n-$, $-(-AB'-)_n-$, and $-(-A'B'-)_n-$ will apparently exhibit different properties.

Regularly alternating two-component multiblock copolymers can be obtained in one stage when the initial oligomers have terminal functional groups of different types which interact with one another:

$$3n\,f-A-f+3n\,f'-B-f' \rightarrow f'-B-(-A-B-)_n-f'+$$
$$+f-(-A-B-)_n-A-f+f'-B-(-A-B-)_{n-2}-A-f \quad . \qquad (8)$$



On the other hand, if the initial oligomers have terminal functional groups of the same type which do not interact with one another, regularly alternating block copolymers are formed in two stages and it is necessary to use a functional group substituting agent. Compared with the previous case, a wider spectrum of different block copolymer macromolecules is formed, the copolymers differing from one another in the nature of the terminal blocks, units, and functional groups:

$$10n\,f-A-f+20n\,f'-fgs-f' \xrightarrow{(a)} 10n\,f'-fgs-A-fgs-f' \xrightarrow{(b)}$$
$$\xrightarrow{+10n\,f-B-f} f-B-(-fgs-A-fgs-B-)_n-f+$$
$$+f-(-A-fgs-B-fgs-)_n-A-f+f-B-(-fgs-A-fgs-B-)_{n-2}-$$
$$-fgs-A-f+f'-fgs-B-(-fgs-A-fgs-B-)_n-f+$$
$$+f'-fgs-B-(-fgs-A-fgs-B-)_n-fgs-f'+ \qquad (9)$$
$$+f'-fgs-(-A-fgs-B-fgs-)_n-A-f+$$
$$+f'-fgs-(-A-fgs-B-fgs-)_n-A-fgs-f'+$$
$$+f'-fgs-B-(-fgs-A-fgs-B-)_{n-2}-fgs-A-f+$$
$$+f-B-(-fgs-A-fgs-B-)_{n-1}-fgs-A-fgs-f'+$$
$$+f'-fgs-B-(-fgs-A-fgs-B-)_{n-2}-fgs-A-f$$

Thus the macromolecules of two-component regularly alternating multiblock copolymers of the polycondensation type differ from one another by the molecular weight of both the macromolecules themselves and their constituent blocks, by their chemical composition and structure, by the inhomogeneity in the distribution of the main and anomalous units along the chain (blocks and the macromolecules), and by the nature of the terminal blocks, units, and functional groups.

2. Irregularly Alternating Block Copolymers

Irregularly alternating block copolymers are multiblock copolymers with an irregular alternation of blocks of different kinds. Among block copolymers of this type, one should distinguish irregularly alternating block copolymers with constant block lengths (within the limits of the polydispersity with which the original oligomers having a specified molecular weight have been obtained):

and irregularly alternating block copolymers with varying (for example on increasing the length of block B without the appearance of an anomalous unit) lengths of the blocks (one or both):

(The subscripts $\underline{n}$ and $\underline{m}$ denote an irregular distribution of blocks A and B along the macrochain.)

Many methods for the synthesis of irregularly alternating two-component block copolymers have now been described; an even greater number appear to be possible in view of the prospects arising from the very principle of the synthesis of these block copolymers. We may formulate these methods of synthesis in an abbreviated form (each component is an individual substance):

ol + m + cl,	ol-1 + ol-2,
ol + m-cl,	ol-1 + ol-2 + cl,
ol + cm + cm-cl,	cm-1 + cm-2,
ol + cm-fgs + cm-cl,	

where ol is a bifunctional oligomer, m a monomer (a substance capable of homopolycondensation), m-cl a substance behaving simultaneously as a monomer and a chain lengthening agent, cm a comonomer (a substance incapable of homopolycondensation), cm-cl a substance behaving as a comonomer and a chain lengthening agent (for example, a diol in the synthesis of polyurethanes), and cm-fgs a substance behaving simultaneously as a monomer and a functional group substituting agent (for example, di-isocyanate in one of the methods for the synthesis of polyurethanes).

We shall now consider block copolymers obtained by two of the most frequently used methods for the synthesis of irregular block copolymers.

(a) Irregular (ol-1 + ol-2 + cl) two-component multiblock copolymers. Such block copolymers are formed when the initial oligomers with

terminal groups of the same type which do not interact with one another are combined into a common macrochain in a single stage with the aid of a chain lengthening agent:

$$\begin{aligned} &zn\,f{-}A{-}f + zm\,f{-}B{-}f + z(n+m)\,f'{-}cl\ {-}f' \rightarrow \\ &\rightarrow f{-}A{-}cl\ {-}\{{-}[{-}A{-}cl\ {-}]_{\underline{n}}{-}[{-}B{-}cl\ {-}]_{\underline{m}}{-}\}_z{-}A{-}f + \\ &+ f'{-}cl\ {-}A{-}cl\ {-}\{{-}[{-}A{-}cl{-}]_{\underline{n}}{-}[{-}B{-}cl{-}]_{\underline{m}}{-}\}_z{-}A{-}cl{-}f' + \\ &+ f'{-}cl\ {-}A{-}cl\ {-}\{{-}[{-}A{-}cl\ {-}]_{\underline{n}}{-}[{-}B{-}cl\ {-}]_{\underline{m}}{-}\}_z{-}A{-}f + \text{etc.} \end{aligned} \quad (10)$$

In all, there is a possibility of ten combinations of terminal blocks, units, and functional groups:

A ~ A; cl–A ~ A–cl; cl–A ~ A;
B ~ B; cl–A ~ B–cl; cl–B ~ B;
A ~ B; cl–A ~ B–cl; cl–A ~ B; A ~ B–cl.

The macromolecules of irregular (ol-1 + ol-2 + cl) two-component multiblock copolymers of the polycondensation type differ from one another by the molecular weights of both the macromolecules themselves and their constituent blocks, by the chemical composition (determined mainly by the molecular weight and numbers of blocks of different kinds) and chemical structure, by the inhomogeneity in the distribution of the main and anomalous units along the chain (blocks and macromolecules), by the inhomogeneity in the distribution of blocks of different chemical composition or structure along the macrochain, and by the nature of terminal blocks, units, and functional groups [Eqn.(10)].

The examples quoted show that the chain lengthening agent is a low-molecular-weight compound (monomeric or fragmental) which is capable of reacting with oligomers or low-molecular-weight polymers having terminal functional groups and thereby lengthening the polymer chain. Furthermore, compounds which interact simultaneously with the initial oligomer and with the low-molecular-weight compound, intended for the synthesis of a non-oligomeric block, also behave as chain lengthening agents. Depending on the chemical structure of the initial oligomer, the chain lengthening agent can be of the same kind (its residue is present in the oligomer chain) or "alien" in relation to the oligomer (the oligomer does not contain residues of this kind). If the chain lengthening agent is used to synthesise at least one of the initial oligomers, then the molecular weight of blocks of different chemical composition or structure is related not only to the numbers of blocks A or B in a single macrochain but also to their length, which may differ from the length of the initial oligomers (an irregularly alternating block copolymer with varying block lengths). If the chain lengthening agent is of an "alien" type, then the overall molecular weight of blocks of the same kind will be determined by their number in the macromolecule.

The number of blocks A and B in the macrochain is a statistical quantity and depends on the length of the entire macrochain, on the conditions for the synthesis of the block copolymer, on the relative reactivities of the terminal functional groups of the oligomers, and on the nature of the chain lengthening agent. Precisely in the case of a homogeneous chain lengthening agent the number of the corresponding (related) blocks, for example A, may be greatly reduced owing to the increase in their length without the appearance of heterounits. In the case of an "alien" chain lengthening agent, each block of the macrochain, including blocks of the same nature, is separated from others by an anomalous unit. In this situation the number of blocks A or B in a single macrochain is therefore determined by the number of oligomers f–A–f or f–B–f used to form the macrochain.

(b) Irregular (ol + cm + cm-cl) two-component multiblock copolymers. Such block copolymers are formed in a single stage from the initial oligomer, for example, f–B–f, and the monomer f–A–f or f″–A–f″ with the same functional groups as in the oligomer or others which are also capable of reacting with a chain lengthening agent:

$$\begin{aligned} &zn\,f{-}a{-}f + zm\,f{-}B{-}f + z(n+m)\,f'{-}cl{-}f' \rightarrow \\ &\rightarrow f{-}\{{-}[{-}a{-}cl{-}]_{\underline{n}}{-}[{-}B{-}cl{-}]_{\underline{m}}{-}\}_z{-}a{-}f + \\ &+ f'{-}cl\ {-}\{{-}[{-}a{-}cl{-}]_{\underline{n}}{-}[{-}B{-}cl{-}]_{\underline{m}}{-}\}_z{-}a{-}cl\ {-}f' + \\ &+ f{-}\{{-}[{-}a{-}cl{-}]_{\underline{n}}{-}[{-}B{-}cl\ {-}]_{\underline{m}}{-}\}_z{-}a{-}cl{-}f' + \text{etc.}; \end{aligned} \quad (11)$$

In all, there is a possibility of 21 combinations of terminal blocks, units, and functional groups.

In this case [Eqn.(11)] the molecular weight of blocks A = $-(-a-cl-)_n-$ in individual macromolecules is determined not only by the number of these blocks but also by their length. Variations in the length of blocks A in irregular (ol + cm + cm-cl) block copolymers may be more numerous than in the case of irregular (ol-1 + ol-2 + cl) block copolymers.

The considerations described in relation to two-component block copolymers show that the determination of the complete microstructure of block copolymers of the polycondensation type constitutes an extremely complex and important problem, which still awaits solution. In the present stage the determination of the microstructure of polymers is frequently limited to the determination of the molecular weight distribution and the distribution with respect to chemical composition.

C. THREE-COMPONENT BLOCK COPOLYMERS OF THE POLYCONDENSATION TYPE

It is possible to distinguish the following kinds of such block copolymers:

1. Three-component three-block copolymers in which the distribution of blocks of different chemical kinds along the macrochain is of the type A–B–C, A–C–B, or B–A–C.

2. Three-component multiblock copolymers. These block copolymers can be regularly alternating, $-[-A-B-C-]_z-$, $-[-A-C-B-]_z-$, and $-[-B-A-C]_z-$, or irregularly alternating, $-\{-[A-]_n--[-B-]_m--[-C-]_p--\}_z-$, etc. with constant or variable block lengths.

The properties of three-component block copolymers can be greatly influenced by the distribution of different blocks along the copolymer macrochain. Depending on the chemical nature of the constituent blocks and the required structure of the final polymeric product, three-component multiblock copolymers can be synthesised in one or two stages from mono- or bi-functional oligomers and may require the use of different chain lengthening agents and functional group substituting agents. Two-, three-, and multi-block seeds with terminal functional groups can also be used as the initial compounds.

D. MULTICOMPONENT BLOCK COPOLYMERS OF THE POLYCONDENSATION TYPE

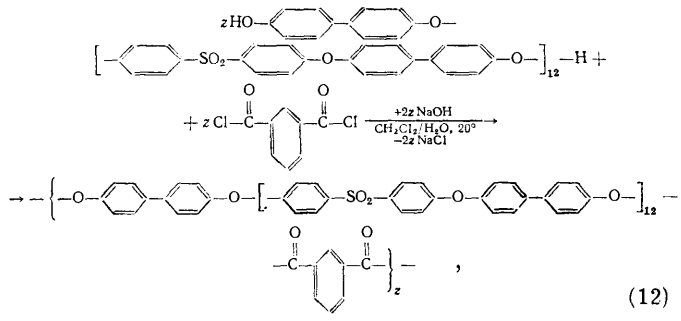
It is possible to distinguish the following kinds of such block copolymers:

1. Multicomponent block copolymers in which the number of blocks in the chain is equal to the number of

components or slightly exceeds it, for example, four-component four-block A–B–C–D copolymers, five-component six-block A–B–C–D–E–A copolymers, etc. These block copolymers can have a large number of analogues differing from one another by the distribution of blocks of different chemical types along the macrochain.

2. Multicomponent multiblock copolymers which can be regularly alternating with constant or variable block lengths, $-[-A-B-C-D-E-]_z-$, etc., or irregularly alternating with constant or variable block lengths, namely $-\{-[-A-]_{\underline{n}}-[-B-]_{\underline{m}}-[-C-]_{\underline{p}}-[-D-]_q-\}_z-$, etc.

III. ONE-TYPE BLOCK COPOLYMERS



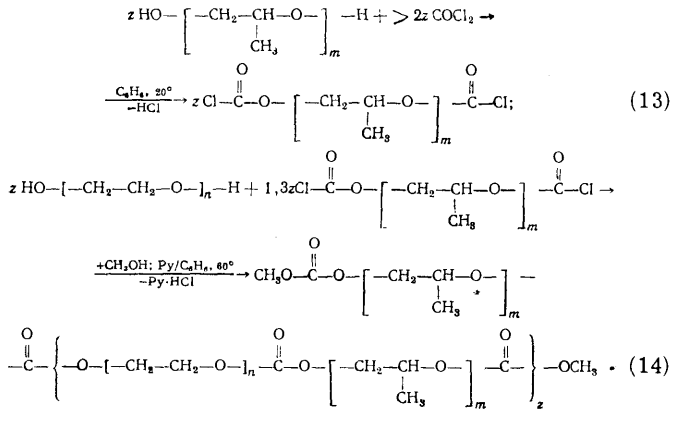
One-type block copolymers of the polycondensation type are copolymers consisting of polymer blocks of the same type which have identical or different compositions. Such block copolymers can be synthesised for the following purposes: (a) to increase the molecular weight of low-molecular-weight polymers having one or two terminal functional groups; (b) to obtain polymers with a uniform distribution of functional groups along the chain; (c) to modify the properties of the polymer by means of residues of the chain lengthening agent (monomeric or fragmental); (d) to modify the properties of the polymer by introducing into its macromolecules blocks of a polymer-analogue differing in its properties.

The increase in the molecular weight of polymers with the aid of a chain lengthening agent may be important in many instances, since many processes yielded only low-molecular-weight polymers are known. In particular, the molecular weight of poly(phenylene oxide) based on 2,6-dimethylphenol may be increased by a factor of two when its sodium salt interacts with di-(4-chlorophenyl) sulphone[23]. The two-block copolymer formed as a result made it possible to obtain stable relatively flexible films.

The low molecular weight of polymers with a system of conjugated multiple bonds greatly impairs their physicomechanical properties and reduces the possibility of obtaining polymeric materials on their basis. The lengthening of the molecules of such low-molecular-weight polymers by means of chain lengthening agents, for example, the poly-Schiff base derived from *p*-phenylenediamine and benzil using a di-isocyanate or a dicarboxylic acid[24], lead, according to Eqn.(1), to the formation of multiblock copolymers with improved physicomechanical properties and effective semiconducting properties.

Block copolymers obtained from oligomers and trifunctional chain lengthening agents (two groups out of three being of the same kind) may be of interest as polymers capable of forming structures with a specified density of the chemical network and also as initial polymers for the synthesis of graft copolymers having a specified frequency of branching points.

The modification of the properties of polymers by the introduction of the residues of a monomeric or fragmental chain lengthening agent, for example, by the interaction of bifunctional oligomers with a chain lengthening agent [Eqn.(1)], is attractive in view of its simplicity: for any bifunctional oligomer intended for subsequent synthesis of two-type block copolymers, it is possible to select a whole series of readily available chain lengthening agents. For example, dihydroxyoligo(arylene sulphone oxides) can react with aromatic[25] and aliphatic[26] dicarboxylic acid dichlorides:



(12)

and with aromatic disulphonyl chlorides[25]. The block copolymers obtained exhibit a high thermal and hydrolytic stability and have useful mechanical and dielectric properties. Segmental-monomeric block copolymers with improved mechanical properties have been obtained from low-molecular-weight polycarbonates having terminal chloroformate groups and diamines, for example, piperazine[27]. Modified polyquinazolinones with improved thermal properties and ready solubility in many solvents have been obtained by the interaction of oligoquinazolinones with terminal amino-groups and pyromellitic dianhydride[28].

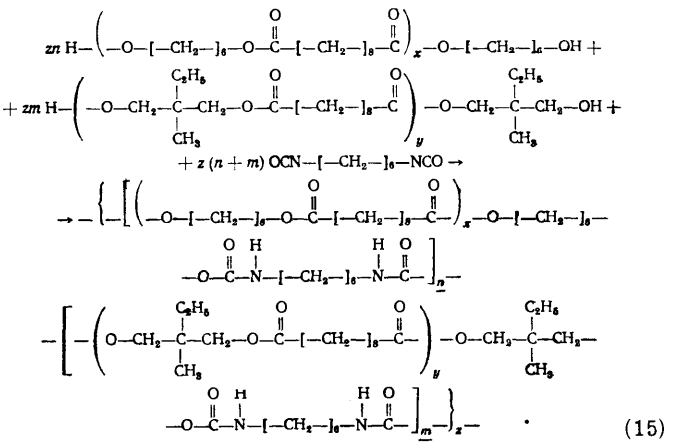
In all the examples quoted above one-component block copolymers were described, but the synthesis of two-component one-type block copolymers for which one may expect interesting combinations of the properties of polymer-analogues are of no less interest.

1. Polyether–Polyether Block Copolymers

Regularly alternating multiblock poly(ethylene oxide)-poly(propylene oxide) block copolymers have been obtained[29], in conformity with Eqn.(4), by the condensation of α,ω-dihydroxypoly(ethylene oxide) with poly(propylene oxide) α,ω-bischloroformate. The chloroformate derivative of α,ω-dihydroxypoly(propylene oxide) was obtained with the aid of phosgene, which behaves in this instance as a functional group substituting agent:

(13)

(14)



In the resulting block copolymers the crystalline lamellar phase consists of poly(ethylene oxide) blocks and the amorphous phase is made up of poly(propylene oxide) blocks. According to dilatometric data, the degree of

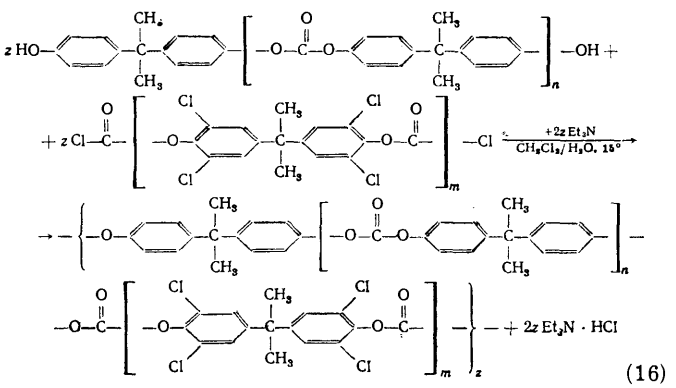
crystallinity of multiblock copolymers is lower by 60% than the degree of crystallinity of the corresponding three-block copolymers. The crystallinity of the specimens increased when the latter were annealed; the melting points of the block copolymers ranged from 37° to 56°C depending on composition [29].

Irregular (ol + m-Cl) multiblock poly(2,6-dimethylphenylene oxide)-poly(2,6-diphenylene oxide) block copolymers have been obtained by the dehydropolycondensation of 2,6-dimethylphenyl in the presence of oligo-(2,6-diphenylphenylene oxide) [30]. Oxidation of a mixture of 2,6-dimethylphenol with 2,6-diphenylphenol leads to the formation of a statistical copolymer; oxidation of 2,6-diphenylphenol in the presence of poly-(2,6-dimethylphenylene oxide) prepared beforehand leads to a mixture of part of the initial polymer and of the newly formed statistical copolymer as a result of exchange processes occurring in the course of dehydropolycondensation. Depending on the method of isolation of the block copolymer from the reaction mixture, the oligo-(2,6-dimethylphenylene oxide) blocks can constitute the amorphous or crystalline phase. The oligo-(2,6-dimethylphenylene oxide) blocks in the isolated copolymer always constitute the amorphous phase, but they crystallise on heating, while oligo(2,6-diphenyl oxide) blocks become amorphous. The block copolymers synthesised are inhomogeneous with respect to chemical composition: on heating their solutions in *m*-xylene, macromolecules enriched in oligo-(2,6-diphenylphenylene oxide) blocks are precipitated.

2. Polyester–Polyester Block Copolymers

There are numerous examples of the synthesis of two-component block copolymers the constituent block of which consists of polyesters. In particular, the reaction of a mixture of two hydroxylated or carboxylated low-molecular-weight aliphatic [poly(ethylene sebacate), poly-(ethylene succinate), poly(ethylene adipate) and poly-(propylene adipate) [31], poly(butylene saccinate) and poly(butylene sebacate) [32], poly(hexamethylene sebacate) and poly-(2-ethyl-2-methyl-1,3-propylene sebacate) [33] or aromatic and aliphatic [poly(ethylene terephthalate) and poly(ethylene succinate) poly(ethylene adipate), etc. [34]] polyesters with di-isocyanates yielded irregular (ol-1 + ol-2 + cl) block polymers:

(15)



Multiblock poly(hexamethylene sebacate)–poly(2-ethyl-2-methyl-1,3-propylene sebacate) block copolymers [see Eqn.(15)] contain blocks consisting of isomeric polymers having identical chemical compositions but different chemical structures: the first polymer is highly crystalline with $T_m = -70°C$, while the second is entirely amorphous; its $T_g = -69°C$. [33] These block copolymers contain crystalline and amorphous phases and, as the content of crystallising oligo-(hexamethylene sebacate) blocks in the block copolymer increases, i.e. as the number of these blocks in the macrochain diminishes, the degree of crystallinity of the block copolymers increases. It has been suggested that [35] this is associated with the marked dependence of the crystallinity of the blocks on their molecular weight, i.e. on the fact that an isolated block as it were recovers its initial length, whereupon its ability to crystallise and undergo aggregation with other crystallising blocks of the same type becomes more marked. Dielectric relaxation studies on specimens have shown that β-relaxation processes in block copolymers depend on their composition and are associated with the relaxation of the polymethylene chain fragments [36].

Irregular (ol + cm + cm-cl) polyester–polyester block copolymers have been obtained from oligo(butylene adipate) with terminal hydroxy-groups, butylene glycol, and dimethyl terephthalate [37]. These block copolymers manifest the properties of thermoelastoplastic materials.

Regularly alternating poly(decamethylene terephthalate)–poly(decamethylene isophthalate) block copolymers have been obtained by the reaction of previously formed oligomers, one of which contained hydroxy-groups and the other contained acid chloride functional groups [38]. The same method has been used to synthesis other similar block copolymers.

3. Polycarbonate–Polycarbonate Block Copolymers

A typical method for the synthesis of these block copolymers involves the interaction of two reaction solutions containing oligocarbonates with hydroxy- or chloroformyl terminal functional groups synthesised by interfacial polycondensation from various bisphenols [29]

(16)

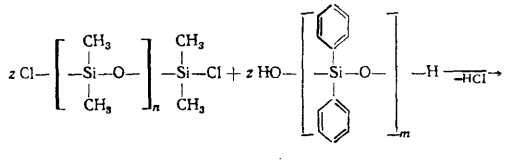
The thermalstabilities of polycarbonate–polycarbonate block copolymers are superior to those of statistical copolymers having an analogous composition. Some of them have been recommended as a base for photographic materials.

Polycarbonate–polycarbonate block copolymers can also be obtained by other synthetic procedures, for example, by the introduction of measured amounts of starting materials into the reaction medium, by the interaction of a mixture of an oligocarbonate prepared beforehand and a bisphenol with phosgene to give irregular (ol + cm + cm-cl) block copolymers, etc.

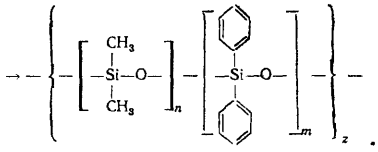
4. Polysulphide–Polysulphide Block Copolymers

Irregular (ol-1 + ol-2) aliphatic multiblock polysulphide–polysulphide block copolymers can be obtained by oxidising a mixture of two or more liquid (M.W. = 4000 to 8000) oligosulphides of various structure having terminal mercapto-groups[40]. Such block copolymers possess unique physicomechanical properties at low temperatures.

5. Polyamide–Polyamide Block Copolymers



Polyamide–polyamide block copolymers of the polycondensation type can be obtained by a number of procedures, particularly by the polycondensation in the melt of a mixture of primary and secondary aliphatic–aromatic diamines, having appreciably different reactivities, with aliphatic dicarboxylic acids[41]. These crystallising irregular (cm-1 + cm-2 + cm-3) block copolymers consist of two phases and have two melting points.



Irregular (ol-1 + ol-2 + cl) block copolymers have been obtained by the interaction of two diamino-oligoamides of different structure with di-isocyanates[42]. Two-component block copolymers with a regular alternation of polyamide blocks have been obtained by the interaction of diamino- and dichloroformyl-oligoamides synthesised from *trans*-2,5-dimethylpiperazine and the dichlorides of dicarboxylic acids such as terephthalic, isophthalic, and sebacic acids[43,44] and from *p*-diaminobiphenyl or *trans*-2,5-dimethylpiperazine and terephthalic or adipic acid dichloride[45,46].

6. Polyorganosiloxane–Polyorganosiloxane Block Copolymers

Block copolymers consisting of polyorganosiloxane blocks can be obtained in different ways; in particular, multiblock regularly alternating polydimethylsiloxane–polydiphenylsiloxane block copolymers of the polycondensation type have been obtained by the interaction of "living" block copolymers of the polymerisation type with a chain lengthening agent[47]. The initial four-block copolymer B–A–A–B was obtained by the polymerisation of hexamethylcyclotrisiloxane in the presence of an initiator (a complex of the dilithium salt of 1,1,3,3-tetraphenyldisiloxanediol with hexamethylphosphoramide) with subsequent addition and polymerisation of hexaphenylcyclotrisiloxane. When structured polydimethylsiloxane–polydiphenylsiloxane block copolymers are compared, the best properties are exhibited by multiblock copolymers. Both types of block copolymers have analogous morphologies, but the rate of formation of domains is higher for the multiblock copolymer. The continuous amorphous phase consists of polydimethylsiloxane and the dispersed phase consists of crystalline polydiphenylsiloxane domains[48].

Regularly alternating block copolymers can be obtained also by the heterofunctional condensation of oligosiloxanes, for example by the reaction of α,ω-dichloropolydimethylsiloxane with α,ω-dihydroxypolydiphenylsiloxane[49]:

(17)

They can also be synthesised by the reaction of polydiorganosiloxanediols with siloxane oligomers having terminal acetoxy-groups[50], alkoxy-groups, or hydrogen atoms.

Irregular (ol-1 + ol-2) polyorganosiloxane–polyorganosiloxane block copolymers can be obtained by the reaction (in the presence of catalysts) of two oligo-organosiloxanediols[49] or a mixture of two oligodiols and a silanol[51]. Readily structured irregular (ol + m-1-cl + m-2-cl) block copolymers can be obtained from oligo-organosiloxanediol, trichlorophenylsilane, and dichloromethylphenylsilane[52].

IV. TWO-TYPE BLOCK COPOLYMERS

Two-type block copolymers consist of polymer blocks belonging to two different types. Such block copolymers constitute the vast majority among block copolymers of the polycondensation type known hitherto. Two-type block copolymers may be synthesised for the following purposes: (a) for imparting elasticity to rigid-chain polymers; (b) for increasing the strength characteristics of elastomers; (c) for imparting hydrophilic properties to polymers; (d) for increasing the permeability of polymers to gases and the selectivity of their permeability; (e) for reducing the viscosity of melts of rigid-chain polymers; (f) for imparting antistatic properties to polymers; (g) for increasing the chemical stability of polymers; (h) for synthesising polymers capable of being degraded biologically, etc.

In order to achieve these aims, blocks of different polymers, having a wide variety of physicochemical properties, are combined in a single macromolecule. At the same time, whatever the properties of the constituent blocks of the block copolymers, they can be divided into (a) blocks with enhanced chain mobility (flexible blocks with a low thermal stability) and (b) blocks with a reduced chain mobility (rigid blocks with a high thermal stability). All two-type block copolymers can therefore be divided into the following groups:

A. Elastoplastic block copolymers (copolymers containing blocks with appreciably different thermal stabilities).

B. Thermoplastic block copolymers (copolymers containing blocks with relatively similar high thermal stabilities).

C. Elastomeric block copolymers (copolymers containing blocks with relatively similar low thermal stabilities).

A general list of block copolymers belonging to a particular group is presented in Table 2.

A. ELASTOPLASTIC BLOCK COPOLYMERS

1. Block Copolymers Containing Blocks Comprising Aliphatic Polyethers

Aliphatic polyethers are elastic crystallisable polymers. The presence of polar groups and the high flexibility of the macromolecules ensure a high solubility of the polymers in organic solvents. Poly(ethylene oxide) exhibits a

unique solubility in water. Some of the first block copolymers based on aliphatic polyethers were segmented polyurethanes incorporating polyurethane and polyurea block copolymers[1].

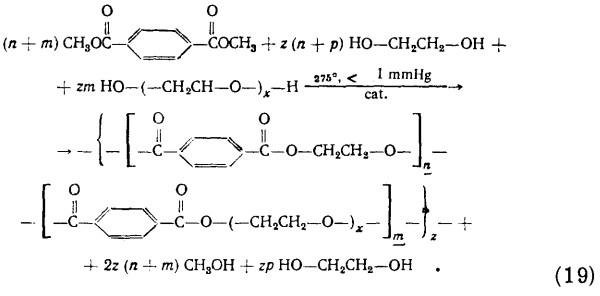
*Block copolymers manufactured on an industrial scale.
**Block copolymers manufactured in the form of experimental batches.

(a) Polyurethane–poly(alkylene oxide) block copolymers. Polyurethane–poly(alkylene oxide) block copolymers, which are some of the first block copolymers of the polycondensation type[53], consist of rigid polyurethane blocks (T_g† or T_m‡ in the range 100–250°C), obtained from a di-isocyanate and a low-molecular-weight glycol, and flexible poly(alkylene oxide) blocks ($T_g < 0$°C). Regularly alternating block copolymers are formed when equimolar amounts of oligo(urethane di-isocyanate) and oligo(alkene oxide)diol, obtained beforehand, are made to react. Irregular (ol + cm + cm-cl) copolymers are formed when all the starting materials are mixed simultaneously: the oligodiol, the low-molecular-weight glycol, and the di-isocyanate. However, irregular (ol + cm-fgs + cm-cl) urethane block copolymers, which are synthesised by a two-stage procedure, are nowadays of greatest importance, for example:

(18)

Oligoethers such as oligo(propylene oxide), oligo(tetramethylene oxide) etc. are used as the initial oligodiols with a molecular weight of 1000–3000 in the synthesis of polyurethane–poly(alkylene oxide) block copolymers; the initial di-isocyanates are methylenedi-(4-phenyl) di-isocyanate, tolylene di-isocyanate, 1,6-hexamethylene di-isocyanate, etc., and the initial low-molecular-weight glycols usually employed are 1,2-ethylene glycol, 1,4-tetramethylene glycol, etc.

Polyurethane–poly(alkylene oxide) block copolymers are microheterogeneous two-phase systems in which rigid oligourethane blocks, segregated into a separate phase owing to the incompatibility of the blocks, form 30–100 Å domains, greatly strengthened by strong intermolecular hydrogen bonds. Owing to the presence of a strong physical network, polyurethane block copolymers are very strong and hard and possess a high resistance to tearing and wear[14-17,54-57].



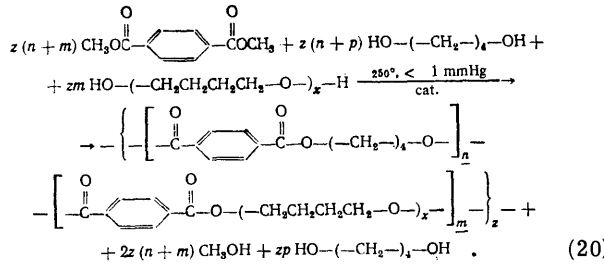
(b) Polyurea–poly(alkylene oxide) block copolymers. The principal difference between the synthesis of polyurethane–poly(alkylene oxide) and polyurea–poly(alkylene oxide) block copolymers involves the

† Glass point.

‡ Melting point.

use of diamines instead of glycols in the latter case. Owing to the presence of an excess of di-isocyanate [Eqn. (18)], the growth of rigid oligourea blocks is accompanied by the formation of a certain amount of biuret cross-links[55,56]. In contrast to polyurethane block copolymers, polyurea block copolymers are less stable in the melt but are harder. More detailed information about the synthesis and properties of polyurethane–poly(alkylene oxide) and polyurea–poly(alkylene oxide) block copolymers may be found in a number of reviews[14-17,54-57].

(c) Polyester–poly(alkylene oxide) block copolymers. Aliphaticaromatic or aromatic polyesters constitute the rigid blocks in block copolymers having this structure. Block copolymers containing rigid blocks of crystallising poly(ethylene terephthalate) (T_m = 265 °C) and flexible poly(ethylene oxide) blocks (T_m = 65 °C, T_g = −55 °C) as well as segmented polyurethanes were some of the first block copolymers of the polycondensation type synthesised[58-60]. Modification of poly(ethylene terephthalate) by replacing part of the ethylene glycol by oligo(ethylene oxide)diol with a molecular weight of 1000–6000 was undertaken in order to impart hydrophilic properties, an improved capacity for dyeing, and increased elasticity to poly(ethylene terephthalate) fibres. Irregular (ol + cm + cm-cl) poly(ethylene terephthalate)–poly(ethylene oxide) block copolymers, usually containing 20–30 wt.% of flexible blocks, are synthesised in the melt in the presence of a catalyst:



(19)

The disperse phase in the block copolymer is crystalline poly(ethylene terephthalate) and the continuous phase consists of amorphous poly(ethylene oxide) [oligo(ethylene oxide) blocks with a molecular weight of 1000–3000 remain amorphous, but, with increase of molecular weight to 6000, they may crystallise]. The poly(ethylene terephthalate) may be modified further by replacing part of the dimethyl terephthalate by dimethyl isophthalate[61] or by synthesising poly(ethylene terephthalate)–poly(tetramethylene oxide) block copolymers[62].

By analogy with poly(ethylene terephthalate)–poly(ethylene oxide) copolymers, it has been possible to synthesise in recent years poly(propylene terephthalate–poly(propylene oxide),[63] poly(tetramethylene terephthalate)–poly(propylene oxide),[64] poly(tetramethylene terephthalate)–poly(ethylene oxide),[65] poly(hexamethylene terephthalate)–poly(ethylene oxide),[66] and poly(alkylene terephthalate)–poly(tetramethylene oxide)[67] block copolymers. Among polymers of this type, the greatest interest attaches to poly(tetramethylene terephthalate)–poly(tetramethylene oxide) block copolymers, which are manufactured under the name Hytrel by the Du Pont Company.

Irregular (ol + cm + cm-ol) poly(tetramethylene terephthalate)–poly(tetramethylene oxide) block copolymers, initially intended for the synthesis of strong and elastic fibres[68], are synthesised in the melt in the presence of catalysts for equilibrium transesterification[69-71]:

(20)

The molecular weight of the initial oligo(tetramethylene oxide) (M.W. = 1000–4000) is usually 1000 and its content in the polymer is usually 30–70 wt.%.[70] In this composition range the block copolymer has in fact the most effective physicomechanical properties[70-82].

Owing to the presence of the crystalline phase, the block copolymers are insoluble in the majority of organic solvents. The rigid blocks in poly(tetramethylene terephthalate)–poly(tetramethylene oxide) copolymers crystallise very rapidly, so that there is no need for annealing articles made from this material, which cannot be said, for example, of poly(ethylene terephthalate)–poly(ethylene oxide) block copolymers, where the rate of crystallisation of rigid blocks is much lower[72]. The block copolymer containing 67% of the flexible blocks has T_m = 176 °C and T_g = −78 °C, the stress corresponding to 300% elongation is 110 kgf cm^{-2}, the tensile strength is 400 kgf cm^{-2}, and the relative elongation on rupture is 800%.

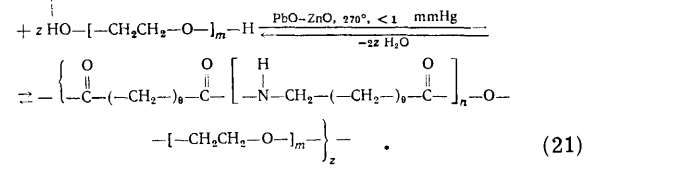
The block copolymers possess an unusual two-phase structure and consist of continuous (and not discrete) and interacting crystalline (in the form of lamellae) and amorphous domains[73].

Industrial brands of the Hytrel polymer contain a small amount of tetramethylene isophthalate units[70,82] and, depending on composition, have a tensile strength of 350 to 450 kgf cm^{-2} and a relative elongation on rupture of 500–600%. The block copolymers possess useful rheological properties and their melts have low viscosities and high stabilities and can be processed by rotational casting, casting under pressure, etc.[83] They are also distinguished by a high chemical stability, resistance to repeated deformation, and resistance to tearing, wear, and creep.

Irregular (ol + cm + cm-cl) block copolymers containing rigid aromatic polyester blocks (polyarylates) and flexible poly(ethylene oxide) or poly(propylene oxide) blocks have been obtained by high-temperature polycondensation in solution by the interaction of a mixture of a bisphenol, terephthalic acid dichloride, and oligo(alkylene oxide) diols[84,85]. The block copolymers exhibited high thermal stability and a solubility in organic solvents higher than that of polyarylates, but the increase in their elasticity was insignificant. At the same time regularly alternating, polyarylate–poly(ethylene oxide) block copolymers, obtained under the conditions of low-temperature polycondensation in solution from oligo(ethylene oxide) bischloroformate (M.W. = 1000–2000) and oligoarylate diol based on 2,2-di(4-hydroxyphenyl)propane and terephthalic acid dichloride, exhibit a high strength (100 to 350 kgf cm^{-2}) and a high relative elongation on rupture (700–400%) respectively. There are polyarylate and poly(alkylene oxide) crystalline and amorphous phases

respectively in these polymers and on extension the specimens are strengthened[86].

Regularly alternating polyarylate–poly(ethylene oxide) block copolymers containing blocks of amorphous polyarylate based on phenolphthalein and terephthalic acid dichloride (1000–5000) and poly(ethylene oxide) blocks (400–20 000) have been obtained under the conditions of acceptor-catalytic polycondensation from dihydroxyoligoarylates and dihydroxyoligo(ethylene oxides)[87]. Terephthalic acid dichloride and not phosgene[86] was used as the functional group substituting agent. When the molecular weights of the oligo(ethylene oxide) blocks are low, these block copolymers are amorphous, but, with increased molecular weight of the flexible blocks (2000 to 20 000), they become segregated in a separate phase and crystallise. The block copolymers exhibit a high strength (200–1000 kgf cm^{-2}) and a large relative elongation on rupture (800–100%).



(d) Polycarbonate–poly(alkylene oxide) block copolymers. Regularly alternating block copolymers containing rigid oligocarbonate blocks based on 2,2-di-(4-hydroxyphenyl)propane and phosgene and flexible blocks of poly(ethylene oxide) or poly(tetramethylene oxide) are formed under the conditions of interfacial polycondensation from an oligocarbonate diol (2000 to 4700) obtained beforehand and an oligo(alkylene oxide) (1000–3000) with terminal chloroformate groups[88,89]. These block copolymers have fairly effective mechanical properties. Their strength is 100–150 kgf cm^{-2} and their relative elongation on rupture is >200%. The rate of crystallisation of oligocarbonate blocks in the copolymers is much higher than the rate of crystallisation of homopolycarbonate. There is a poly(alkylene oxide) amorphous phase in the block copolymers, but, when the molecular weight of the flexible blocks reaches 3000, a second crystalline phase is observed.

Irregular (ol + cm + cm-cl) polycarbonate–poly(alkylene oxide) block copolymers have been obtained by low-temperature polycondensation in solution from a mixture of oligo(alkylene oxide) diol [poly(ethylene oxide), poly(propylene oxide), and poly(tetramethylene oxide)], 2,2-di-(4-hydroxyphenyl)propane, and phosgene[90]. Block copolymers containing approximately 50 wt.% of oligo(ethylene oxide) blocks (4000–6000) have effective mechanical properties: an ultimate strength of 500 kgf cm^{-2} and a relative elongation on rupture of 600%. Block copolymers containing amorphous oligocarbonate blocks based on bisphenols with bulky bridge groups have been synthesised by the same method[91]. It is suggested[91] that the bulky norbornene rings in the rigid blocks constitute the nodes of a physical network which reduces the mobility of the macromolecules and imparts to the block copolymers the properties of thermoelastoplastic materials.

(e) Poly(arylene sulphone oxide)–poly(alkylene oxide) block copolymers. Regularly alternating poly(arylene sulphone oxide)–poly(ethylene oxide) block copolymers have been obtained[92] in accordance with Eqn.(21) from oligo(arylene sulphone oxide) diols (2400, 4600, and 9100) based on 2,2-di-(4-hydroxyphenyl)-propane and di-(4-chlorophenyl) sulphone and oligo(ethylene oxides) (400, 1000, 3000, and 15 000) with terminal acid chloride groups. Block copolymers with short flexible blocks (400–3000) consist of a single phase and have effective mechanical properties. For example, the copolymer containing 58 wt.% of rigid blocks with M.W. = 4600 and 42 wt.% of flexible blocks with M.W. = 3000 has an ultimate strength of 280 kgf cm^{-2} and a relative elongation on rupture of 460%. However, block copolymers with long (M.W. = 15 000) oligo(ethylene oxide) blocks have been found to contain a crystalline phase of the latter and such polymers have low values of the parameters characterising the mechanical properties; for example, the ultimate strength of a copolymer with rigid blocks having M.W. = 4600 and flexible blocks having M.W. = 15 000 is 180 kgf cm^{-2} and the relative elongation on rupture is 5%. Depending on composition, poly(arylene sulphone oxide)–poly(ethylene oxide) block copolymers swell in water by 1–120% and have effective antistatic properties.

Regularly alternating poly(arylene sulphone oxide)–poly(tetramethylene oxide) block copolymers obtained from oligo(arylene sulphone oxide) diols and oligo(tetramethylene oxides) with terminal chloroformate groups have been described[93].

(f) Polyamide–poly(alkylene oxide) block copolymers. Regularly alternating block copolymers with aliphatic polyamide blocks (usually polyamide 6 or polyamide 6,6) and poly(alkylene oxide) blocks are formed when oligo(alkylene oxides), in which the terminal hydroxy-groups have been substituted (in one or several stages) by isocyanate[94] or amino-groups[95], interact with oligoamines having terminal amino- or carboxy-groups. A dehydration reaction has been used recently to synthesise regularly alternating polyamide(11)–poly(ethylene oxide) block copolymers[96,97]:

(21)

The initial oligomers are incompatible, so that the reaction proceeds initially in a heterogeneous medium. The heterogeneity of the melt disappears if 10 wt.% of the finished block copolymer is added to the mixture of oligomers before the reaction[97]. The block copolymers can be used as thermoelastoplastic materials or as elastic fibres.

In order to reduce T_g and to improve the capacity of aromatic polyamides for being processed, multiblock irregular (ol + cm-fgs + cm-cl), irregular (ol + fgs + cm-fgs + cm-cl), and three-block polymetaphenyleneisophthalamide–poly(ethylene oxide) block copolymers have been synthesised[98]. They consist of two phases: the poly(ethylene oxide) phase (molecular weight of blocks 1000–6000) is dispersed in the continuous polyamide phase[99,100]. The rheological and physicomechanical properties of the copolymers have not been published as yet.

(g) Polystyrene–poly(alkylene oxide) block copolymers. Multiblock regularly alternating polystyrene–poly(ethylene oxide) block copolymers have been obtained by increasing the chain lengths of three-block poly(ethylene oxide)–polystyrene–poly(ethylene oxide) copolymers of the polymerisation type having terminal hydroxy-groups with phosgene or a dicarboxylic acid dichloride[101]. Another method of synthesis of the block copolymers consists in the interaction of an oligostyrene di-isocyanate (2000–6000) with an oligo(ethylene oxide)diol (400–6000).[102] The block copolymers exhibit

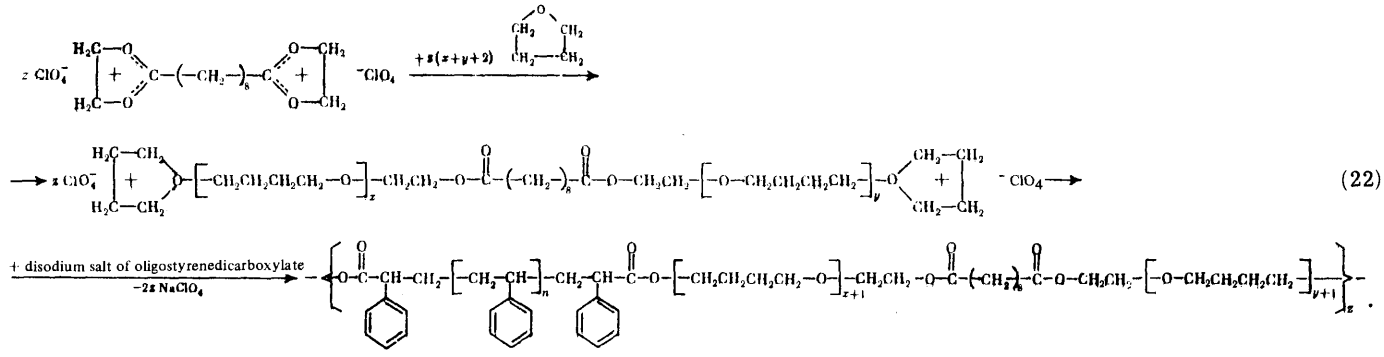
an enhanced capacity (compared with polystyrene) for absorbing atmospheric moisture, which increases with increasing content of hydrophilic blocks. Polystyrene–poly(ethylene oxide) copolymers are amorphous, but, during isothermal annealing, the segregation of oligo(ethylene oxide) blocks in a separate phase initiated by crystallisation is observed. The maximum rate of crystallisation has been noted for blocks with M.W. = 6000: they form twofold and threefold structures incorporated in crystalline domains [103]. The block copolymers containing flexible blocks with M.W. = 2000 do not crystallise. The short blocks in such copolymers act as plasticisers, lowering the temperature of the α-transitions of the polystyrene blocks [104].

Regularly alternating polystyrene–poly(ethylene oxide) block copolymers can also be obtained by converting a "living" oligostyrene with terminal carbanionic groups under the influence of an excess of phosgene into a bischloroformate with its subsequent polycondensation with an oligo(ethylene oxide) diol [105].

Two-block and three-block polystyrene–poly(tetramethylene oxide) block copolymers have been obtained by the reaction of a "living" oligo(tetramethylene oxide) cation or dication and a "living" oligostyrene anion [106]. Multiblock regularly alternating polystyrene–poly(tetramethylene oxide) block copolymers are formed in the interaction of an oligo(tetramethylene oxide) dication and an oligo-styrene dicarboxylate, used instead of the oligostyrene dianion, because the latter is involved in side reactions [107] [Eqn.(22)]. Block copolymers having an analogous structure have been obtained by the interaction of oligostyrene [108] or oligo-α-methylstyrene [109] dianions with an oligo(tetramethylene oxide) dication obtained with the aid of the $AgPF_6$–alkyl bromide initiator. It is suggested that the reaction between "living" polymeric dianions and dications is accompanied by the elimination of a tetrahydrofuran molecule.

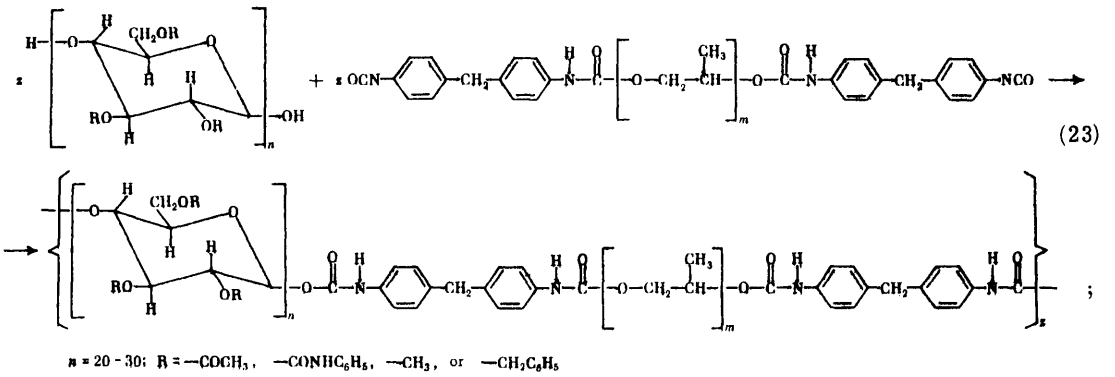
(h) Cellulose–poly(alkylene oxide) block copolymers. Regularly alternating cellulose–poly(alkylene oxide) block copolymers have been obtained by the reaction of substituted, for example, acetylated, cellulose oligomers having terminal hydroxy-groups with oligo(alkylene oxides) having terminal isocyanate groups [110–112] [Eqn. (23)]. Acetylation of cellulose makes it possible to carry out its oligomerisation and at the same time increase its resistance to biodegradation. If the block copolymers synthesised are subjected to deacetylation, the result is the formation of cellulose–poly(propylene oxide) block copolymers capable of undergoing enzymatic hydrolysis. Biodegradation of the block copolymers takes place under these conditions many times faster than the degradation of cellulose [111,112].

The introduction of oligomeric cellulose blocks and other polymers capable of biodegradation (starch, casein, gelatin, etc.) into the macromolecules of the polymers used to prepare mass consumption articles is of considerable interest in view of the problem of the protection of the environment. It appears that the synthesis of block copolymers capable of biodegradation and having acceptable physicomechanical properties may become one of the approaches to the solution of this problem.



2. Block Copolymers Containing Aliphatic Polyester Blocks

Aliphatic polyesters are elastic crystallisable polymers with low melting and glass points. In this sense they are important for the synthesis of block copolymers of the polycondensation type, although their properties are inferior to those of polyethers.



(a) Polyurethane–polyester block copolymers. These block copolymers consist of rigid polyurethane blocks, obtained from a di-isocyanate and a low-molecular weight glycol, and flexible polyester blocks with M.W. = 1000–3000. Oligo(ethylene adipate), oligo(ethylene sebacate), oligo(tetramethylene adipate), etc. are usually employed as the initial oligoesters with terminal hydroxy-groups. Among polyurethane–polyester block copolymers, irregular (ol + cm-fgs + cm-cl) copolymers [Eqn.(18)] have acquired the greatest practical importance. In contrast to the analogous polyurethane–polyether block copolymers, segmented polyurethanes based on aliphatic polyesters exhibit a much lower hydrolytic stability [54–56].

(b) Polyurea–polyester block copolymers. These block copolymers are synthesised in accordance with the same principle as polyurethane–polyester block copolymers. The difference is that, instead of a low-molecular-weight glycol [Eqn.(18)], a diamine is used [54–56].

(c) Polycarbonate–polyester block copolymers. Regularly alternating polycarbonate–poly(ethylene adipate) block copolymers have been obtained by the reaction of oligo(ethylene adipate) bischloroformate with oligocarbonatediol [88]. Irregular (ol + cm + cm-cl) block copolymers have been obtained by the reaction of a mixture of oligocarbonatediol based on 2,2-di-(4-hydroxyphenyl)propane and an oligocaprolactonediol with phosgene [113].

(22)

(23)

n = 20 - 30; R = —COCH$_3$, —CONHC$_6$H$_5$, —CH$_3$, or —CH$_2$C$_6$H$_5$

These block copolymers have the properties of thermoelastoplastic materials. Annealing of the specimens appreciably accelerates the crystallisation of the polycarbonate domains uniformly distributed in the amorphous polyester phase.

A series of other irregular polycarbonate–polycaprolactone block copolymers containing polycarbonate blocks based on 2,2,4,4-tetramethylcyclobutanediol [114] and various bisphenols [115] have also been described.

(d) Polyamide–polyester block copolymers. Regularly alternating polyamide(12)–poly(ethylene adipate) block copolymers have been obtained in the melt from aliphatic oligoamides with terminal carboxy-groups and oligo(ethylene adipates) with terminal hydroxy-groups [116]. The block copolymers exhibit a high strength and elasticity. The structure of the copolymers is appreciably influenced by exchange side processes.

Block copolymers consisting of rigid aromatic polyamide blocks and flexible polycaprolactone blocks have been obtained by the reaction of an oligocaprolactone having terminal isocyanate groups and an oligoamide having terminal amino-groups [117].

3. Block Copolymers Containing Diene Polymer Blocks

Polydienes (polybutadiene, polyisoprene, polypiperylene, polychloroprene, etc.) are elastic polymers capable of crystallisation only at very low temperatures. Owing to the high mobility of their macromolecules, polydienes have low glass points; for example $T_g = -108°C$ for *cis*-1,4-polybutadiene. The possibilities for the synthesis of block copolymers containing flexible polydiene blocks have greatly increased recently in connection with the development of the industrial manufacture of living "rubbers" [118].

(a) Polyurethane–polydiene and polyurea–polydiene block copolymers. Among segmented polyurethanes, block copolymers consisting of rigid oligourethane or oligourea blocks and flexible oligodiene blocks (polybutadiene, polyisoprene, copolymers of butadiene with acrylonitrile and isoprene, etc.) have been acquiring increasing importance recently. These block copolymers have the properties of thermoelastoplastic materials and exhibit a high hydrolytic stability [55,56,61].

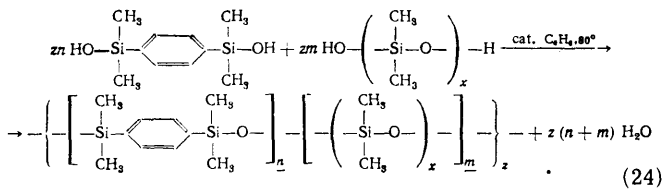
(b) Polyamide–polydiene block copolymers. Irregular (ol-1 + ol-2 + cl) poly-ϵ-caprolactam–polybutadiene block copolymers have been synthesised [119]; oligo-ϵ-caprolactam with terminal amino-groups, oligobutadienediol, and 4,4′-diphenylmethane di-isocyanate were used as the initial compounds.

(c) Polyimide–polydiene block copolymers. Irregular (ol + cm + cm-cl) multiblock polyimide–polybutadiene block copolymers have been obtained from an oligobutadiene having terminal amino-groups, *m*-phenylenediamine, and the dianhydride of benzophenonetetracarboxylic acid [120].

4. Block Copolymers Containing Aliphatic Polysulphides

Aliphatic polysulphides (thiokols) are elastic polymers capable of crystallising on extension; the glass points of polysulphide rubbers are in the range from −20° to −60°C. Both polydisulphides and polytetrasulphides are special purpose rubbers characterised by high resistance to swelling in solvents, fuels, and oils, resistance to ozone and sunlight, and reduced permeability to moisture and gases.

(a) Polyurethane–polysulphide block copolymers. Block copolymers consisting of rigid oligourethane and flexible aliphatic oligosulphide blocks are obtained using oligosulphidedithiols, di-isocyanates, and glycols as the initial compounds. Polyurethane–polysulphide block copolymers have lower values of T_g compared with polyurethane–polyester block copolymers and exhibit a satisfactory radiation stability [121].



(b) Polyimidothioether–polysulphide block copolymers. Irregular (ol + cm-fgs + cm-cl) polyimidothioether–polysulphide block copolymers have been obtained from an oligosulphidedithiol, bismaleimide, and hydrogen sulphide [122]. These block copolymers exhibit the properties of thermoelastoplastic materials and are insoluble in organic solvents. A great obstacle to the processing of block copolymers via the melt is the low thermal stability of the polysulphide blocks, whose degradation begins at 200°C.

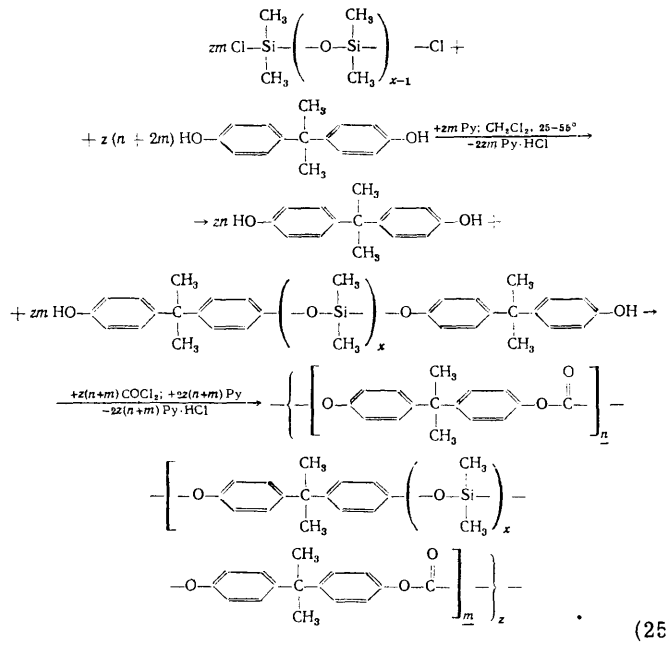
5. Block Copolymers Containing Polyorganosiloxane Blocks

(a) Polyurethane–polyorganosiloxane and polyurea–polyorganosiloxane block copolymers. Segmented polyurethanes containing flexible polyorganosiloxane blocks exhibit an enhanced thermal stability compared with polyurethanes based on oligoethers,

have effective low-temperature properties, and exhibit a high resistance to tearing[54].

(b) Polytetramethylsilphenylenesiloxane–polydimethylsiloxane block copolymers. Irregular (ol + m-cm) polytetramethyl-*para*-silphenylenesiloxane–polydimethylsiloxane block copolymers have been obtained in the presence of non-equilibrating catalysts from oligodimethylsiloxanediol and tetramethyl-*para*-silphenylenesiloxane[123]:

(24)



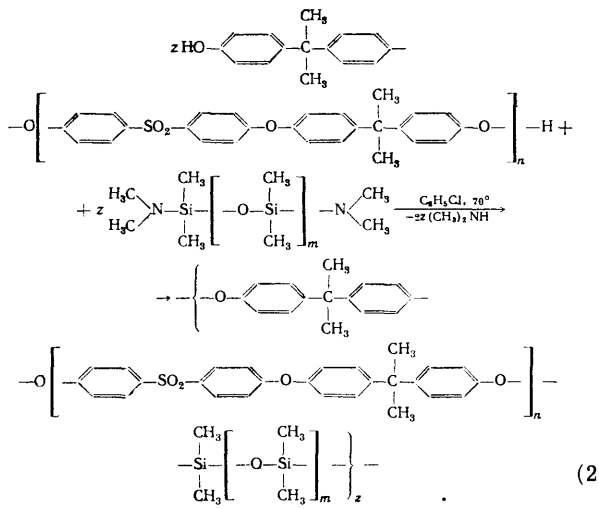
The block copolymers obtained comprise two phases: the continuous phase consists of amorphous polydimethylsiloxane blocks and the disperse phase is made up of crystalline domains of polytetramethyl-*para*-silphenylenesiloxane blocks which melt in the temperature range from 25° to 139°C, depending on the composition of the copolymers[124]. The block copolymers manifest the properties of thermoelastoplastic materials, have a strength of 70 to 200 kgf cm^{-2}, and a relative elongation on rupture of 500–960%.[125]

(c) Polystyrene–polydimethylsiloxane block copolymers. Regularly alternating polystyrene–polydimethylsiloxane block copolymers of the type $-(A-B-A-)_n$ have been obtained by the interaction of "living" polydimethylsiloxane–polystyrene–polydimethylsiloxane block copolymers of the polymerisation type with chain elongating agents such as diacetoxydiphenylsilane, dialkyldichlorosilanes, or dichloromethyltrifluoropropylsilane[126,127]. These block copolymers constitute a two-phase system comprising a continuous polydimethylsiloxane phase with $T_g = -120$°C and a disperse polystyrene phase with $T_g = 50$°C. The polymers have the properties of thermoelastoplastic materials, possess effective dielectric properties, and exhibit a high permeability to gases[128].

Regularly alternating block copolymers of the type $-(-A-B-)_n-$ have been obtained by the dehydropolycondensation of polydimethylsiloxane–polystyrene–polydimethylsiloxane A–B–A block copolymers having terminal hydroxy-groups in the presence of a catalyst[129].

(d) Poly-α-methylstyrene–polydimethylsiloxane block copolymers. Regularly alternating poly-α-methylstyrene–polydimethylsiloxane block copolymers of the type $-(-A-B-)_n-$ have been obtained by the polycondensation of oligo-α-methylstyrenediols and oligodimethylsiloxanes having terminal dimethylamino-groups in chlorinated aromatic solvents at 120° to 180°C.[130] The low reactivity of the hydroxy-groups in the aliphatic terminal units of oligo-α-methylstyrenediols may be increased with the aid of carbon dioxide, which catalyses the reaction. The block copolymers consist of two phases and have the properties of thermoelastoplastic materials. The replacement of polystyrene blocks by poly-α-methylstyrene blocks ($T_g = 170$°C) made it possible to extent the temperature range where the block copolymers are useful from between −100°C and +50°C to between −100°C and +130°C.

(e) Polycarbonate–polydimethylsiloxane block copolymers. Irregular (ol + cm-fgs + cm) polycarbonate–polydimethylsiloxane block copolymers have been obtained by treating with phosgene a mixture of 2,2-di-(4-hydroxyphenyl)propane and an oligodimethylsiloxane having terminal phenolic groups[131–133]:



(25)

The block copolymers consist of two phases and manifest the properties of thermoelastoplastic materials. With increase in the content of rigid oligocarbonate blocks from 35 to 85%, the ultimate strength rises from 70 to 420 kgf cm^{-2} and the relative elongation on rupture falls from 800 to 100%.[133] The glass point of the continuous polydimethylsiloxane phase depends little on the length of the flexible blocks and is in the region of −110°C; on the other hand, T_g for the polycarbonate domains depends markedly on the length of the rigid blocks, varying from 60°C for blocks with five elementary units in the chain to 140°C for blocks with 46 repeating units. Crystallisation of the polycarbonate domains is observed when the block copolymer films are kept in ethyl methyl ketone or its vapour[134]. The solvent greatly influences the morphology of the block copolymer films obtained by casting from solutions[133]. The thermal stability of the block copolymers is somewhat inferior to that of homopolycarbonate[135]. Polycarbonate–polydimethylsiloxanes have useful dielectric properties[136] and a high permeability to gases[137]. Membranes based on them are used in apparatus designed for the enrichment of air in oxygen and for the oxygenation of blood. The block copolymers can be employed as coatings and adhesives[131].

Regularly alternating[138] and irregular (ol + cm-fgs + cm) polycarbonate–polydimethylsiloxane block copolymers based on cardobisphenols[139] and 2,2,4,4-tetramethylcyclobutane-1,3-diol[140] have also been obtained.

(f) Poly(arylene sulphone oxide)–polydimethylsiloxane block copolymers. Regularly alternating poly(arylene sulphone oxide)–polydimethylsiloxane block copolymers have been obtained by the interaction of equimolar amounts of an oligo(arylene

sulphone oxide)diol and an oligodimethylsiloxane having terminal dimethylamino-groups [141,142]:

(26)

Such block copolymers consist of two phases and exhibit the properties of thermoelastoplastic materials. The glass point of the polydimethylsiloxane phase is −120°C and that of the poly(arylene sulphone oxide) phase is +160°C, the ultimate strength of block copolymers containing 50–70 wt.% of the organosilicon phase is 100–180 kgf cm^{-2} and the relative elongation is 500–350%.[142] The block copolymers are resistant to hydrolysis, have a high thermal stability[142] and useful dielectric properties, and exhibit a high permeability to gases[143]. Poly(arylene sulphone oxide)–polydimethylsiloxane block copolymers can be used as film materials, as thermoelastoplastic substances with a wide range of working temperatures (from −120° to +160°C),[142] and as additives to poly(arylene sulphone oxides) (which increase their impact strength)[144].

(g) Poly(phenylene oxide)–polydimethylsiloxane block copolymers. Three-block poly(phenylene oxide)–polydimethylsiloxane block copolymers of the type A–B–A have been obtained by the reaction of an oligo(phenylene oxide) having a terminal hydroxy-group and an oligodimethylsiloxane having terminal isopropylamino-groups[145]. The block copolymers may be used as electrically insulating and thermally shrinkable films.

(h) Polyester–polydimethylsiloxane block copolymers. Regularly alternating poly(hexamethylene sebacate)–polydimethylsiloxane block copolymers have been obtained by the reaction of oligo(hexamethylene sebacate)diols and oligodimethylsiloxanes having terminal dimethylamino-[146] or chloro-groups[147]. The block copolymers consist of two phases. The rigid phase with T_m = 57°C is highly crystalline and consists of spherulites.

Regularly alternating block copolymers containing rigid blocks based on 2,2-di-(4-hydroxyphenyl)propane and isophthalic or terephthalic acid dichloride consist of two phases and exhibit the properties of thermoelastoplastic materials. The glass points of the flexible and rigid phases are −125°C and between +120°C and +135°C respectively and the melting point of the rigid phase is 295 and 260°C for the copolymers obtained from the dichlorides of terephthalic and isophthalic acids respectively[148].

Regularly alternating block copolymers containing amorphous blocks based on bisphenols and phthalic acid dichlorides have also been synthesised. Polyarylate–polydimethylsiloxane block copolymers are made up of two phases and exhibit the properties of thermoelastoplastic materials[149–151]. A high degree of segregation of the rigid and flexible blocks is observed in the block copolymers; the domains of the polyarylate phase have a diameter of approximately 160 Å. Polyarylate–polydimethylsiloxanes have high hydrolytic[152] and thermal[153] stabilities, effective electrically insulating properties, and a high permeability to gases. The properties of the resulting films are greatly influenced by the solvent[154].

(i) Polyamide–polydimethylsiloxane and polyimide–polydimethylsiloxane block copolymers. Regularly alternating polyamide–polydimethylsiloxane block copolymers have been obtained by the reaction of oligoamidediols based on α-amino-acids and oligodimethylsiloxanes having terminal dimethylamino-groups[155] and by the reaction of oligo-*meta*-phenyleneisophthalamides having terminal amino-groups and oligodimethylsiloxanes having terminal acid chloride groups[98]. The synthesis of regular (ol + fgs + cm-fgs + cm-cl) poly-*meta*-phenyleneisophthalamide–polydimethylsiloxane block copolymers has been described[98].

Regularly alternating polyimide–polydimethylsiloxane block copolymers have been synthesised by the reaction of oligoimides having terminal anhydride groups and oligodimethylsiloxanes having terminal aminoalkyl groups[156].

B. THERMOPLASTIC BLOCK COPOLYMERS

Thermoplastic block copolymers consist of thermoplastic polymer blocks.

1. Block Copolymers Containing Polycarbonate Blocks

(a) Polycarbonate–polyurethane block copolymers. Irregular (ol + cm + cm-cl) polycarbonate–polyurethane block copolymers have been obtained by the reaction with phosgene of a mixture of an aromatic oligourethanediol and 2,2-di-(4,4-hydroxyphenyl)propane or by the reaction of a mixture of an aromatic oligourethane bischloroformate and phosgene with 2,2-di-(4-hydroxyphenyl)propane[157].

Articles made from modified polycarbonates (for example, the base used for photographic film and recording tape) exhibit a high stability as regards size but, owing to the presence of aromatic polyurethane blocks, their thermal stability is reduced.

(b) Polycarbonate–polystyrene block copolymers. Regularly alternating polycarbonate–polystyrene block copolymers have been obtained by the interaction of oligostyrene bischloroformates with oligocarbonatediols[88].

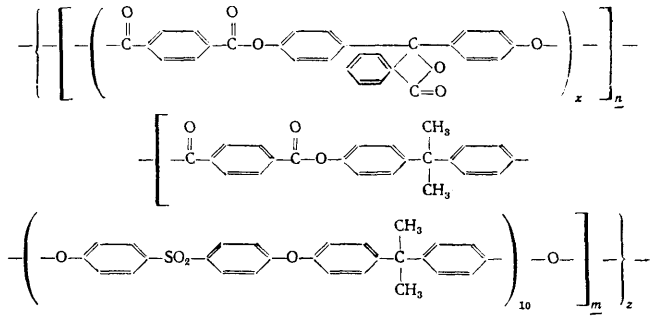
Irregular (ol + cm + cm-cl) block copolymers have been synthesised by the reaction of a mixture of an oligostyrenediol [obtained by treating a "living" oligostyrene with phosgene and then with an excess of 2,2-di-(4-hydroxyphenyl)propane] and 2,2-di-(4-hydroxyphenyl)propane with phosgene[158]. Oligostyrenediols having molecular weights of 2900, 4100, and 9300 have been used to synthesise block copolymers. It was found that at 250°C the melts of the block copolymers have lower viscosities than that of the homopolycarbonate. The decrease of the viscosity

of the melt depends to a greater extent on the content of oligostyrene blocks (19, 22, and 29 wt.%) in the block copolymer than on their molecular weight.

(c) Polycarbonate–poly(phenylene oxide) block copolymers. Three-block polycarbonate–poly-(2,6-dimethylphenylene oxide) block copolymers of the type A–B–A having effective physicomechanical properties have been obtained by the reaction of an oligo-(phenylene oxide) having a terminal hydroxy-group with an oligocarbonate bischloroformate [159].

(d) Polycarbonate–polyester block copolymers. Irregular (ol + cm + cm-cl) polycarbonate–poly(ethylene terephthalate) block copolymers with satisfactory physicomechanical properties have been obtained in the melt from a mixture of oligo(ethylene terephthalate)diol, 2,2-di-(4-hydroxy-phenyl)propane, and diphenyl carbonate [160].

2. Block Copolymers Containing Poly(arylene sulphone oxide) Blocks



(a) Poly(arylene sulphone oxide)–polycarbonate block copolymers. Irregular (ol + cm + cm-cl), irregular (ol-1 + ol-2 + cl), and regularly alternating poly(arylene sulphone oxide)–polycarbonate block copolymers have been synthesised in three different ways [161]. The initial compounds were oligo(arylene sulphone oxide)diols based on 2,2-di-(4-hydroxyphenyl)-propane and di-(4-chlorophenyl) sulphone with molecular weights from 5000 to 26 000, oligocarbonatediols or oligo-carbonate bischloroformates based on 2,2-di-(4-hydroxy-phenyl)propane and phosgene with molecular weights from 5000 to 22 000, di-(4-hydroxyphenyl)propane, and phosgene. The resulting block copolymers of all three types and any composition were single-phase, despite the fact that the mixtures of the corresponding homopolymers and also the mixtures of the oligomers were heterophase. It has been suggested [162] that the formation of a second phase in the system can begin when oligomers with molecular weights greater than 22 000–26 000 are used. The glass points of the single-phase block copolymers depend on their composition and vary from 175° to 184°C. Furthermore, T_g depends also on the method of synthesis of the block copolymer; in particular, among irregular (ol + cm + cm-cl) and irregular (ol-1 + ol-2 + cl) block copolymers of the same composition, the irregular (ol-1 + ol-2 + cl) copolymer has a higher T_g. [161] Exposure of the specimens to acetone leads to the selective crystallisation of the oligocarbonate blocks, whereupon a single value of T_g and a single melting point T_m of the crystallites (T_m = 235°C) are observed.

(b) Poly(arylene sulphone oxide)–polystyrene block copolymers. Irregular (ol-1 + ol-2 + cl) poly(arylene sulphone oxide)–polystyrene block copolymers have been synthesised by the reaction of a mixture of oligo(arylene sulphone oxide)diol based on 2,2-di-(4-hydroxyphenyl)propane and di-(4-chlorophenyl)-sulphone and an oligostyrenediol with phosgene (Noshay and McGrath [8], p. 312). The block copolymers synthesised from oligomers with a molecular weight less than 4000 are single-phase, but if the molecular weight of the oligomer is greater than 4000, the block copolymers consist of two phases.

(c) Poly(arylene sulphone oxide)–poly-(phenylene oxide) block copolymers. Three-block poly(arylene sulphone oxide)–poly(phenylene oxide) block copolymers of the type A–B–A, suitable for the manufacture of cast articles and films, have been synthesised from oligo(phenylene oxides) having a terminal hydroxy-group and oligo(arylene sulphone oxides) having terminal acid chloride, chloroformate, or isocyanate groups [163].

(d) Poly(arylene sulphone oxide)–polyester block copolymers. Irregular (ol + cm + cm-cl) poly(arylene sulphone oxide)–poly(butylene terephthalate) block copolymers have been obtained by the reaction in boiling trichlorobenzene of an oligo(arylene sulphone oxide), having terminal acid chloride groups, and terephthalic acid dichloride with butylene glycol (Noshay and McGrath [8], p. 324). The glass point of the mixed amorphous phase in the block copolymers is 139°C and the melting point of the crystalline polyester phase is 200°C.

Poly(arylene sulphone oxides)–polyarylate block copolymers have been obtained in three different ways: (a) from pre-synthesised heterofunctional oligo(arylene sulphone oxides) and oligoarylates; (b) from homofunctional oligomers and the corresponding chain lengthening agents; (c) by introducing oligo(arylene sulphone oxides) into a mixture of initial low-molecular-weight compounds [164]:

where x is 10 for regularly alternating block copolymers, a multiple of 10 for irregular (ol-1 + ol-2 + cl) block copolymers, and ≥1 for irregular (ol + cm + cm-cl) block copolymers. Poly(arylene sulphone oxide)–polyarylate block copolymers consist of a single phase, while mixtures of the corresponding homopolymers and oligomers are heterophase. For low contents of oligo(arylene sulphone oxide) blocks in irregular (ol + cm + cm-cl) block copolymers, Young's modulus of elasticity, the ultimate tensile strength, and the relative elongation increase. This effect is very similar to the "antiplasticisation" effect observed for rigid-chain polymers plasticised by low-molecular-weight plasticisers.

It is especially interesting that the viscosity of melts of poly(arylene sulphone oxide)–polyarylate block copolymers varies non-additively with respect to the change in composition. A characteristic feature is a minimum in the viscosity of the melt for a relatively low content of oligo-(arylene sulphone oxide) blocks in the copolymers. The rheological characteristics of block copolymers of this composition are close to those of poly(arylene sulphone oxide) [165].

3. Block Copolymers Containing Polystyrene Blocks

Polystyrene–polycarbonate and polystyrene–poly(arylene sulphone oxide) block copolymers were described above.

(a) Polystyrene–polyester block copolymers. Irregular (ol + cm + cm-cl) polystyrene–poly(ethylene terephthalate) block copolymers have been obtained at 280°C in the presence of a catalyst from a mixture of an oligostyrenediol, ethylene glycol, and dimethyl terephthalate. The block copolymers consist of two phases; with increased content of crystallising polyester blocks in the copolymers, a uniform increase of the melting point and density of the block copolymers is observed [166].

(b) Polystyrene–polyamide block copolymers. Irregular (ol + m-cl) polystyrene–polyamide 6 and polystyrene–polyamide 6,6 block copolymers have been obtained by the interaction in the melt of a diammonium adipate salt derivative of oligostyrene (obtained by the interaction of oligostyrenediamine with adipic acid) with ϵ-aminocaproic acid or hexamethylene adipate (HA salt) respectively [166]. The block copolymers consist of an amorphous polystyrene phase and a crystalline polyamide phase. With increase of the content of crystallising blocks in the copolymers, a uniform increase of the melting point and density of the block copolymers is observed.

4. Block Copolymers Containing Polyether Blocks

Poly(phenylene oxide)–polycarbonate and poly(phenylene oxide)–poly(arylene sulphone oxide) block copolymers were described above.

Apart from these block copolymers, copolymers consisting of blocks of sulphonated polyethers, for example, those based on 2,2-di-(4-hydroxyphenyl)propane and 1,4-dichlorobutane, and polyester blocks, for example blocks based on ethylene glycol and dimethyl terephthalate, are known [167]. Irregular (ol + cm + cm-cl) polyether–polyester block copolymers have been obtained by the interaction of a mixture of a sulphonated polyetherdiol and glycol with dimethyl terephthalate. These block copolymers may be used as additives which increase the affinity of polyether [polyester?] fibres for basic dyes.

5. Block Copolymers Containing Polyester Blocks

Polyester–polycarbonate, polyester–poly(arylene sulphone oxide), polyester–polystyrene, and polyester–polyether block copolymers were described above.

Regularly alternating copolymers consisting of poly(ethylene terephthalate) and polyamide 6 [168] or polyamide 6,10 [169] blocks are also known. The block copolymers are obtained by the interaction of oligoamidedicarboxylic acids with oligoesterdiols [168] or by the reaction of oligoamidediamines with oligoesterdiacylchlorides [169].

C. ELASTOMERIC BLOCK COPOLYMERS

Elastomeric block copolymers consist of flexible rubberlike polymer blocks. A limited number of such block copolymers are known at the present time.

1. Polydimethylsiloxane–Poly(alkylene oxide) Block Copolymers

Linear polydimethylsiloxane–poly(alkylene oxide) block copolymers are formed when oligo(alkylene oxide)-diols interact with oligodimethylsiloxanes having acetoxy-, [170] dialkylamino-, [171] or isocyanate [172] end groups. These block copolymers are widely used as stabilisers ("silicone" surfactants) of polyurethane foams and also for the treatment of textile fibres (Allport and Janes [7], p. 342).

2. Polydimethylsiloxane–Polyester Block Copolymers

Irregular (ol + cm + cm-cl) polydimethylsiloxane–poly(butylene sebacate) block copolymers have been obtained from an oligodimethylsiloxane having terminal chloro-groups, butylene glycol, and sebacic acid dichloride; they may be used as loosening and levelling agents in electrophotographic compositions [173].

V. THREE- AND MULTI-TYPE BLOCK COPOLYMERS

Three-type block copolymers consist of polymer blocks of three different types [polyethers (polyesters?), polyorganosiloxanes, polydienes, polycarbonates, polyamides, etc.].

Very limited information is available at present about block copolymers of this kind; for example, the synthesis of five-block three-type polystyrene (A)–polybutadiene (B)–polyurea (C) block copolymers of the type A–B–C–B–A has been described [174], but no syntheses of multitype block copolymers have been published. In the future the synthesis of three- and multi-type block copolymers of the polycondensation type will undoubtedly be important in the manufacture of polymeric materials with a specified set of properties.

Ladder Polyheteroarylenes—Progress and Problems

A.L.Rusanov

Survey of the present state of the chemistry of these polymers and examination of their resistance to various types of degradation show that a ladder structure does not guarantee great stability, although a high degree of structural perfection and highly stable heterocycles confer significantly improved heat resistance, thermal stability, non-flammability, radiation resistance, etc. relative to traditional heteroarylenes. The principal methods for synthesising ladder polyheteroarylenes of high degrees of cyclisation are considered, various modes of practical application are examined, and their prospects are noted. A list of 260 references is included.

I. INTRODUCTION

The development of several modern technologies—primarily aviation, rocket manufacture, electrical engineering, electronics, etc.—made it necessary to produce polymeric materials with operating temperatures around 300°C. Solution of this problem largely involved the elaboration of novel thermostable polymers. For this reason many investigations were undertaken in the USSR and abroad from the mid-1950s with the aim of creating new thermostable macromolecular compounds[1]. These investigations led to a considerable number of heterorganic[1-9] and aromatic carbon-chain polymers[1,3,4,6-19] possessing a combination of valuable properties, but the greatest development occurred in the chemistry of aromatic polymers containing different heterocycles in the main chains—so called polyheteroarylenes[1,3,4,6-16,20-40].

The most widely used polyheteroarylenes have been polyimides[1,4,6-10,20,22,41,42] and polyazoles[1,4,6-10,21-32,40,43-47], whose development and introduction into industry solved the problem of producing polymeric materials capable of prolonged operation at temperatures up to 300°C. However, these polyheteroarylenes and materials made from them do not meet the constantly increasing demands, in particular for operation at temperatures above 300°C. During the mid-1960s, therefore, the development was undertaken of polyheteroarylenes that would surpass known heterocyclic polymers in a combination of properties, primarily in heat resistance and thermal stability. This problem could in principle be solved in several ways.

(1) Replacement of heterocyclic fragments in macromolecules of polyheteroarylenes by more thermostable heterocycles—an approach suggested by the preferential degradation of polyheteroarylenes at the heterocyclic fragments[48-56]—required a detailed study of the comparative thermal stability of individual heterocyclic systems[57-59] and the development of methods for synthesising polyheteroarylenes containing heterocycles of maximum thermal stability. This approach has now been followed quite successfully, although by no means all syntheses of highly thermostable aromatic heterocycles can be readily and successfully extended to polyheteroarylenes of high molecular weight.

(2) Polyheteroarylenes can be synthesised containing hetero-organic groups—e.g. organoboron[60,61] and organosilicon[62,63] groups.

(3) The production of polyheteroarylenes having a completely or partly ladder structure is the most promising approach, although quite controversial from various points of view. Ladder polymers—also termed "strip"[1], "double-chain", "ordered linear-spatial", and "non-randomly cross-linked"[64] polymers—attracted the close attention of investigators after the publication by Tessler[65,66] of results indicating that such polymers should be considerably more resistant to various types of degradation than are ordinary, "single-chain" polymers. The "period of enthusiasm" following his publications (1966-1970) saw the preparation of a considerable number of different classes of polyheteroarylenes, having a complete or partial ladder structure as a consequence of the introduction into the main chains of highly fused aromatic heterocycles[67-77]. Since in several cases such polymers differed little in thermal stability from the traditional polyheteroarylenes, interest in the ladder polymers diminished appreciably, and the "enthusiasm" was followed by a "period of scepticism", although research has continued on individual classes of ladder polymers.

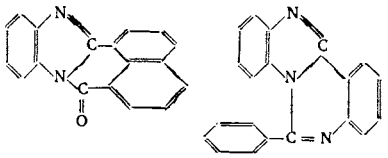
Current views on ladder polyheteroarylenes can be summarised in the following statements: (i) partial and complete ladder structures can be expected to be more resistant than traditional polyheteroarylenes to various types of degradation; (ii) at the present time this potential advantage has not been realised; and (iii) the comparatively poor stability of known ladder polyheteroarylenes is due to the low degrees of cyclisation characterising all ladder polyheteroarylenes. All these statements are true within certain limits, but absolute acceptance of any of them will lead to erroneous conclusions, in particular to an unduly pessimistic assessment of ladder polyheteroarylenes.

An attempt has now been made at an objective survey of the present state of the chemistry of these polymers and their prospects.

II. RESISTANCE TO VARIOUS TYPES OF DEGRADATION—PRECONDITIONS AND REALITY

According to Tessler[65,66] great stability towards degradation of polymers having a complete or partial

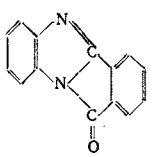
ladder structure, in comparison with single-chain macromolecules, is a consequence of the following considerations. Any reaction involving rupture of the macromolecular chains of single-chain polymers will lead to a decrease in molecular mass of the latter and hence a decrease in their strength characteristics. Double-chain (ladder) polymers can undergo rupture of any one bond without decrease in molecular mass and impairment of strength properties. Moreover, random rupture of several bonds may also be unaccompanied by decrease in molecular mass, and only two "concerted" chain breakages, occurring at strictly defined sites, will lead to fracture of the macromolecule into two fragments with all its consequences.



The above arguments were supported by quantitative results obtained by using the Monte Carlo method to analyse randomly occurring degradation processes in ladder and single-chain polymers [65,66]. The calculation was based on several postulates: (i) all bonds in the polymer were equally strong and equally accessible independently of their positions in macromolecules of different chain lengths; (ii) all polymer chains had the same length; and (iii) rates of degradation were proportional to the number of unbroken bonds in the polymer.

The calculations indicate that, for a given number of bonds ruptured in the macromolecules, completely laddered polymers undergo considerably smaller decreases in molecular mass than do single-chain polymers: in particular, the molecular mass of the former remains almost constant when the number of bonds broken would lead to an 80% decrease in single-chain polymers. Partly laddered structures occupy an intermediate position. In developing these principles Tessler [66] calculated rates of loss in weight of polymers of ladder and single-chain structure with increase in the number of bonds destroyed, and showed that in the initial stages of degradation ladder polymers undergo considerably smaller weight losses than do single-chain macromolecules.

Tessler's scheme is undoubtedly extremely empirical, since it disregards several factors—tending either to hinder or to promote degradation—among which the following may be mentioned. (i) Positive changes in entropy accompanying degradation are larger with ladder than with single-chain polymers, which facilitates such processes. (ii) The energetics of degradative processes may change after the first bond rupture, and in particular the possibility of autocatalytic degradation is ignored [78]. (iii) Ladder polymers are more rigid than single-chain structures. Flexibility of completely ladder polymers can result only from microdeformations of the macromolecular lattice (i.e. deformations of valence angles and bonds) during its thermal vibrations [79,80]; the great rigidity of ladder polymers hinders the development of concerted movements of the segments—even at very high temperatures—which significantly retards the start of degradative processes [81,82]. (iv) Development of the "cage effect" [83,84] involves retention in the vicinity of the radicals formed after rupture of any bond, which can thus readily recombine after the excess of energy has been dissipated: the construction of ladder polymers from aromatic systems leads after rupture to more ready restoration of the original structure [64,72].



The empiricism of Tessler's scheme is still more evident when we pass from abstract double-chain systems to actual polymers. In particular, one of the principal postulates underlying the scheme—the equal strength of all bonds—is in effect impossible in polyheteroarylenes. Violation of this postulate, of course, nullifies a random character for degradation, and results in its preferential occurrence at the weakest bonds [1,3]. Thus a double-chain structure does not yet guarantee enhanced thermal stability in comparison with single-chain polymers, so that improved thermal characteristics in relation to traditional polyheteroarylenes cannot be expected from all ladder polyheteroarylenes, but only from those from which weak bonds are definitely absent.

Quantum-chemical calculations on several model compounds of ladder polyheteroarylenes and study of their degradation [85-88] have convincingly demonstrated significant differences in stability to thermal and thermohydrolytic degradation between models of different types of ladder polyheteroarylenes. In particular, 1,2-1',8'-naphthoylenebenzimidazole (I) and 2-phenylbenzimidazolo-[1,2-*c*]quinazoline (II)

(I) (II)

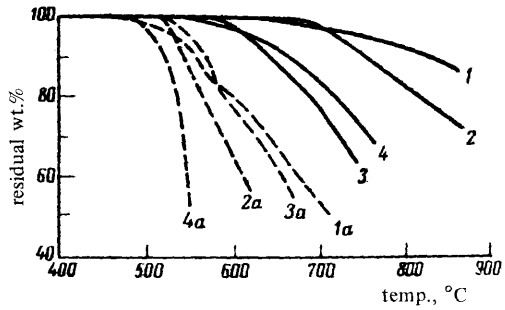
undergo degradation at temperatures 75 deg above that at which degradation of 1,2-benzoylenebenzimidazole (III)

(III)

begins [86,87]. Still more significant differences have been observed in the degradation of the polymers modelled by the above compounds and of other ladder polyheteroarylenes [88]. These differences are so considerable (up to 100–150 deg) that it is evidently inappropriate to speak of the thermal stability of ladder polyheteroarylenes as a whole.

Analysis of published results—extremely contradictory and frequently not comparable—nevertheless indicates that in several cases ladder polyheteroarylenes appreciably surpass traditional heterocyclic polymers in thermal stability. Thus ladder polyquinoxalines obtained by Stille et al. [89-91] begin to decompose, according to dynamic thermogravimetric analysis, in air at 550°C, but in an inert atmosphere at 700°C (Fig. 1). Polynaphthoylenebenzimidazoles exhibit high thermal stability [82,92-99], in full agreement with quantum-chemical calculations and results of a study of the degradation of model compounds [85-88]: under conditions of dynamic thermogravimetric analysis polymers of this type begin to decompose in air at 550°C, but after isothermal aging in air at 316°C for 500 h they retain 60–90% of the initial weight depending on structure [100] (Fig. 2). Polybenzimidazoloquinazolines possess still greater thermal stability, appreciably surpassing polynaphthoylenebenzimidazoles under conditions of isothermal thermogravimetric analysis [101] (Fig. 3). Under conditions of dynamic thermogravimetric analysis polybenzobispyrimidobenzimidazoles occupy an intermediate position between ordinary polyheteroarylenes and graphite [102] (Fig. 4), but under isothermal conditions they undergo no appreciable loss in weight on prolonged heating in air at 400°C. All the polyheteroarylenes examined are characterised not only by highly stable model compounds but also by high degrees of cyclisation. Thus polynaphthoylenebenzimidazoles are nearly 100% cyclised [92,100,103,104],

while polybenzimidazoloquinazolines and polybenzobispyrimidobenzimidazoles are 95% cyclised[105].



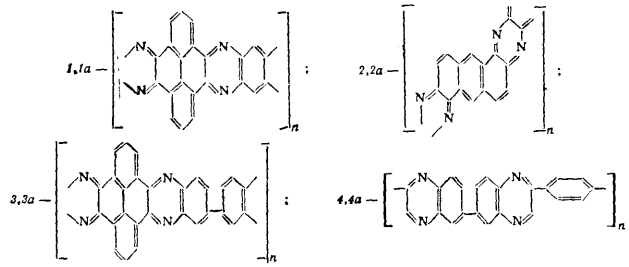


Figure 1. Dynamic thermogravimetric analysis curves (ΔT = 5 deg min^{-1}) in: 1)–4) an inert atmosphere; 1*a*)–4*a*) air for the polyquinoxalines:

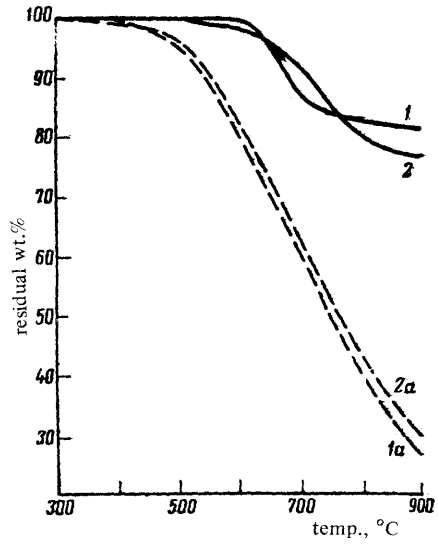
Apart from ladder polyheteroarylenes possessing exceptionally high thermal stability several polymers of the same type are known whose thermal characteristics either do not surpass or are inferior to those of traditional polyheteroarylenes[106]. Some authors explain the low thermal stability of such ladder polymers either by the presence of readily decomposed groups[107] or by low thermal stability of the heterocycles forming the macromolecular double chain[108,109]. In the majority of cases, however, investigators are inclined to attribute inadequate thermal characteristics to structural defects[92,93,106,110,111], etc. to the heterounit character of the polyheteroarylenes[112–115]. This explanation is used especially frequently to interpret the unsatisfactory thermal stability of polybenzoylenebenzimidazoles, better known as "pyrrones"[92, 93,106,110–117]. The degree of cyclisation of pyrrones is indeed low (≤ 70%), which is confirmed both by experimental results[92,118,119] and by logical computations based on the complicated progress of a model reaction yielding together with the required 1,2-benzoylenebenzimidazole a wide range of products[76,77,120–123], as well as by the difficulties of solid-phase cyclisation in rigid polymer chains[93,124].

The heterounit character of pyrrones is responsible for their low thermal stability and leads in particular to the lower resistance of these polymers to degradation in comparison with the corresponding model compounds[116,117]. However, one deduction that may be made from this premise, formulated as "production of a polybenzoylenebenzimidazole of 100% (or simply a high degree of) cyclisation should yield a polymer of very high thermal stability", seems unsound, since compounds modelling pyrrones are characterised by comparatively low stability under conditions of thermal and thermohydrolytic degradation[85–88], in good agreement with earlier results[125–132] and with the high electrophilic reactivity of bis-1,2-benzoylenebenzimidazoles[133–135]. A similar principle applies also to other classes of ladder polyheteroarylenes having low degrees of cyclisation.



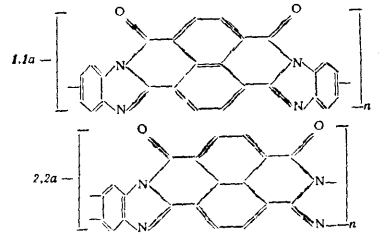


Figure 2. Dynamic thermogravimetric analysis curves (ΔT = 5 deg min^{-1}) in: 1), 2) air; 1*a*), 2*a*) an inert atmosphere for the polynaphthoylenebenzimidazoles

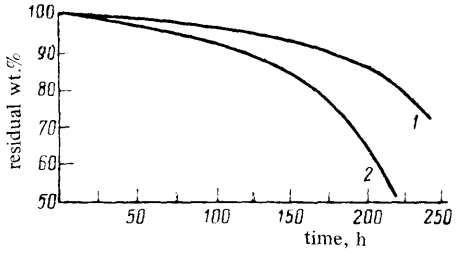
The heterounit character of ladder polyheteroarylenes is in principle closely connected with the stability of the heterocycles towards thermohydrolytic degradation and the action of various reagents, since the least stable heterocycles readily undergo all kinds of secondary reactions, tending to intensify the heterounit character of the polymers.

The high thermal stability of several of the above ladder polyheteroarylenes—polyquinoxalines, polynaphthoylenebenzimidazoles, polybenzimidazoloquinazolines, and polybenzobispyrimidobenzimidazoles—is apparent not only in higher temperatures at which they start to lose weight than for traditional polyheteroarylenes but also higher coking values, which in turn are closely related to the enhanced flame resistance of the polymers[136]. Ladder polymers possess considerably higher flame resistance

than traditional polyheteroarylenes: their oxygen indices exceed 0.6, in comparison with 0.3–0.45 for the latter.

Isolated experimental results indicate that ladder systems have a higher ablation resistance than traditional polyheteroarylenes. Polynaphthoylenebenzimidazoles[137,138] and polynaphthoylene-1,2,4-triazoles[139] possess especially high ablation resistance. Some workers[140–142] have noted considerable superiority of ladder polyheteroarylenes, in particular polyaroylenebenzimidazoles, in radiation resistance.



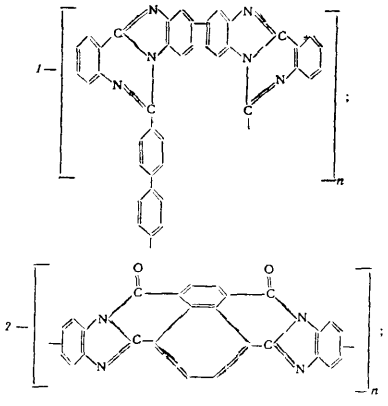


Figure 3. Isothermal thermogravimetric analysis curves in air at 361°C for: 1) polybenzimidazoloquinazolines; 2) polynaphthoylenebenzimidazoles:

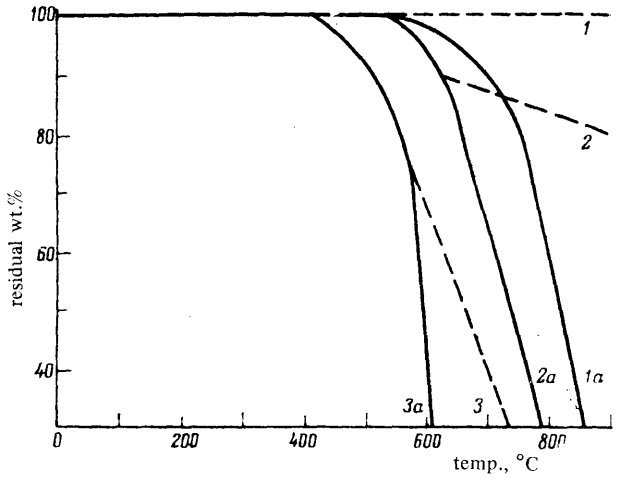
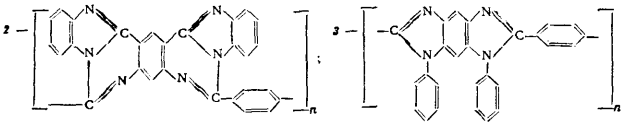
Ladder systems are indisputably superior to the usual polyheteroarylenes in heat resistance. As a consequence of the great rigidity of polyheteroarylenes having a completely ladder structure their softening points are usually higher than the temperatures at which they begin to degrade. Even saturation by "hinge" groups of the main chains in partly ladder polyheteroarylenes rarely lowers their softening points below 400°C.

Significant advantages of ladder polyheteroarylenes have been found also in studying the working ranges of polynaphthoylenebenzimidazoles, polynaphthoylene-1,2,4-triazoles, polybenzimidazoloquinazolines, etc. Comparison with the corresponding ranges for traditional heterocyclic polymers[143] indicates the considerable superiority of ladder systems both in temperature and in strength parameters: ladder polyheteroarylenes are intermediate between ordinary polyheteroarylenes and sodium or potassium silicate glasses (Fig. 5).

Even the above far from complete analysis shows convincingly the considerable superiority of several ladder polyheteroarylenes over traditional heterocyclic systems in thermal stability and in heat, flame, radiation, and ablation resistance. Such superiority is due to highly stable heterocyclic groups in the macromolecules and also to close approach by the actual polymers to their ideal structures. The former factor is governed by the chemical structure of the polymers, whereas the latter largely depends on the method of synthesis of the polyheteroarylene.





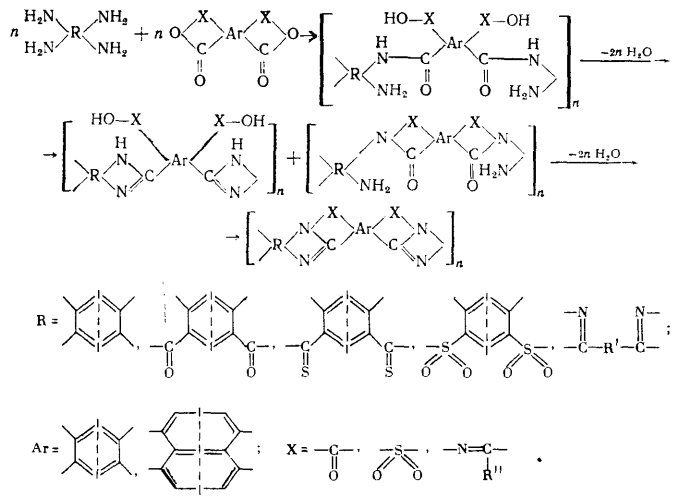


Figure 4. Dynamic thermogravimetric curves (ΔT = 5 deg min^{-1}) in: 1)–3) an inert atmosphere; 1*a*)–3*a*) air for: 1) graphite; 2) polybenzobispyrimidobenzimidazoles; 3) poly-*N*-phenylbenzimidazoles:

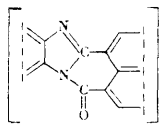


III. PRINCIPAL METHODS OF SYNTHESIS

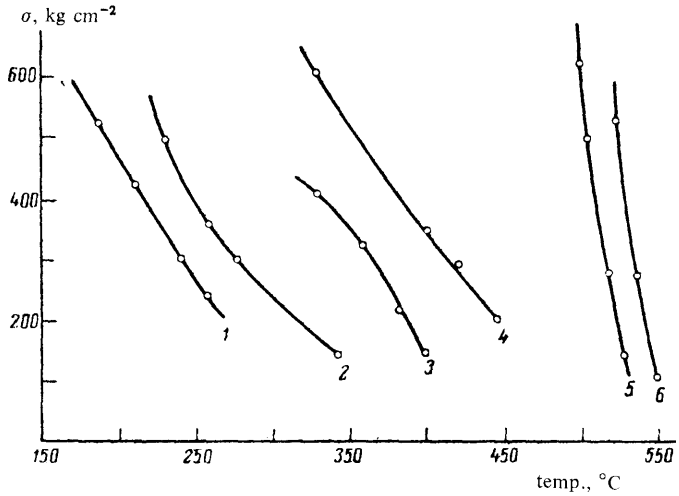
Most ladder polyheteroarylenes are obtained by multifunctional polycondensation, primarily by condensation polyheterocyclisation[72]. The synthetic reactions involved in this form of the process can be divided into three main groups[76]: (1) three-stage reactions of aromatic tetracarboxylic acids, their derivatives or analogues, with tetrafunctional nucleophilic reagents containing four amino-groups in the form of amine, amide, hydrazide, and other fragments[76]; (2) two-stage reactions of aromatic dicarboxylic acids or their derivatives with aromatic diamines containing in *ortho*-positions aromatic heterocycles with labile hydrogen atoms; and (3) two-stage homo- or co-polyheterocyclisations of tetrafunctional monomers containing the functional groups in pairs with *ortho*, *α*, or *peri* mutual orientation.

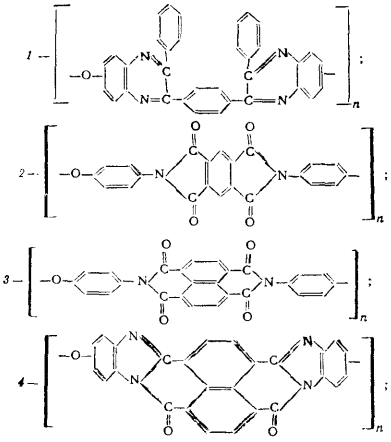
(1) The three-stage process is a logical continuation and development [76] of two-stage polyheterocyclisation yielding polyimides, which can be represented by the formalised and generalised scheme

Little has changed in this field since a recent detailed review of this process [76], and fundamental investigations confirming the earlier tendency [76] have been made on the synthesis and technology of polynaphthoylenebenzimidazoles of general formula

obtained by the polycyclocondensation of bis-*o*-phenylenediamines with bis-(naphthalic dianhydrides). Among these a noteworthy development is a method for synthesising polynaphthoylenebenzimidazoles of high molecular weight with high degrees of cyclisation by high-temperature catalytic polycyclocondensation in an organic solvent [144], which enables the polymers to be obtained as finely divided powders. Novel polynaphthoylenebenzimidazoles soluble in phenolic solvents have been obtained from bis-3,4-diaminophenylhexafluoropropane. [145] In addition, polynaphthoylenebenzimidazoles can be obtained from dianhydrides other than naphthalene-1,4,5,8-tetracarboxylic, namely, 4,4′-dinaphthalic anhydride [146] and 8,8′-biquinolyl-4,4′,5,5′-tetracarboxylic dianhydride [147]. Besides this synthetic work research has been aimed at improving traditional methods for obtaining polynaphthoylenebenzimidazoles in acidic solvents, by developing the method of synthesis without waste in Lewis acids [148] and by supercooling under special conditions to obtain polymers of large surface area [149]. Most probably pure and applied research on the manufacture of polynaphthoylenebenzimidazoles will remain in the near future the main lines of development of the three-stage method for the synthesis of ladder polyheteroarylenes.

(2) The first of the above two-stage processes was developed by Korshak and his coworkers [150,151] in the search for optimum methods of synthesising polybenzimidazoloquinazolines and poly-1,2,4-triazoloquinazolines, for which the three-stage method does not give satisfactory results [76]. The two-stage method [150,151] is a logical development of the general synthesis of polybenzazoles [44-46] based on the two-stage reaction of aromatic dicarboxylic acids or their derivatives with aromatic diamines containing simple substituents such as hydroxy, mercapto, amino, phenylamino, etc. *ortho* to the amino-groups. The first stage involves formation of aromatic polyamides containing these substituents *ortho* to the amide links. In the second stage these *ortho*-substituents react with the amide groups to form benzazole heterocycles.





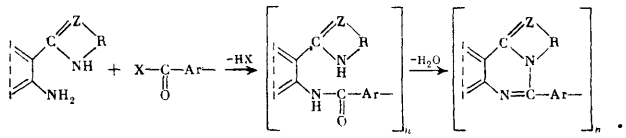


Figure 5. Working ranges of traditional polyheteroarylenes, ladder polyheteroarylenes, and glasses:

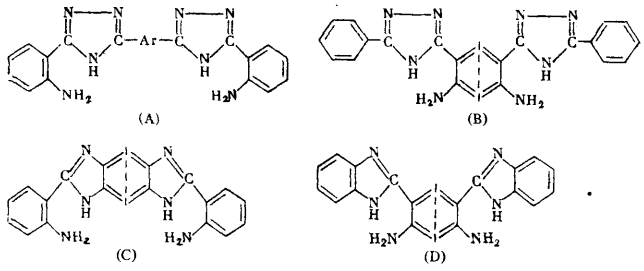
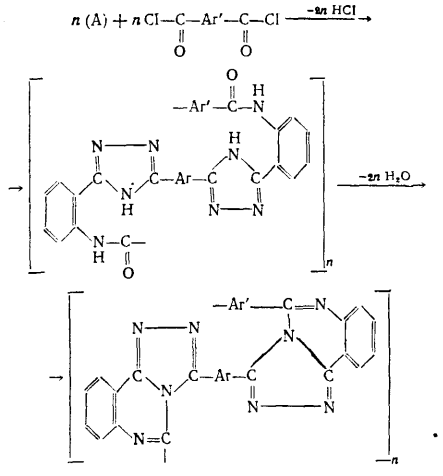
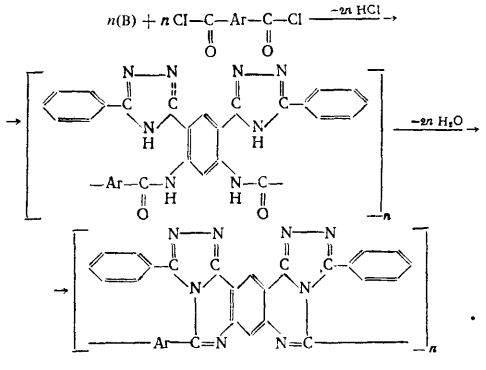


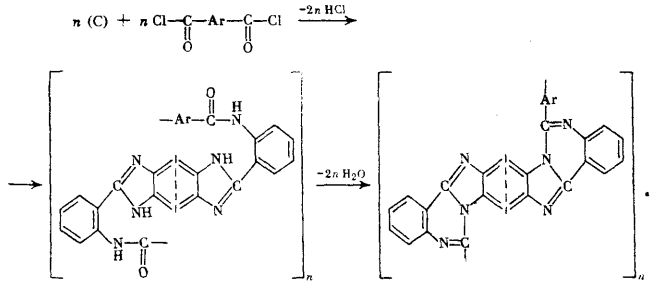
5) sodium silicate glass; 6) potassium silicate glass.



When diamines containing aromatic heterocycles in *ortho*-positions are used as monomers, the reactions follow a similar course, except that highly fused aromatic heterocycles are formed as a result of polycyclodehydration, and yield a partly ladder structure in the polyheteroarylenes obtained:



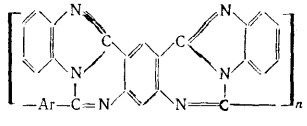
Among heterocycles that could potentially be used as *ortho*-substituents in the aromatic diamines the most widely used have been benzimidazole and 1,2,4-triazole rings:



All four types of diamines have been used to obtain polyheteroarylenes of partly ladder structure. Diamines of type (A), bis-5-*o*-aminophenyl-1,2,4-triazol-3-ylarylenes, have given poly-1,2,4-triazoloquinazolines.[152-157] The most widely used synthesis of these polymers has been based on the two-stage method of mild interaction of the diamines with aromatic acid dichlorides in hexamethylphosphoramide followed by thermal cyclodehydration of the resulting poly-*o*-acylaminophenyltriazoles:

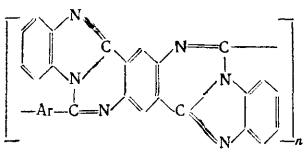
Under analogous conditions diamines of type (B), 4,6-di-(5-phenyl-1,2,4-triazol-3-yl)-1,3-phenylenediamines, have been treated with aromatic acid dichlorides to yield polybenzobistriazoloquinazolines of partly ladder structure[102,158,159]:

The same method of synthesis has been used to obtain partly ladder polyheteroarylenes from diamines of types (C) and (D). The action of acid dichlorides on 2,2'-di-*o*-aminophenylimidazolobenzimidazoles has given polybenzimidazoloquinazolines[150,151,160-166]:



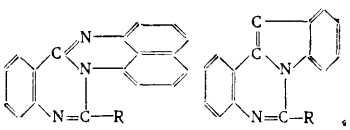
When diamines of type (D) are used as initial compounds, polybenzimidazoloquinazolines[160,167] and polybenzobispyrimidobenzimidazoles[102,158-160,168,169] are obtained.

Single-stage processes—polycyclocondensation in the melt with the use of diphenyl dicarboxylates[101,166,179,171] and high-temperature polycyclocondensation in polyphosphoric acid—can also be employed to obtain the above polymer systems. With triphenyl tricarboxylates as monomers "cross-linked" polybenzimidazoloquinazolines are obtained[101,171,172].

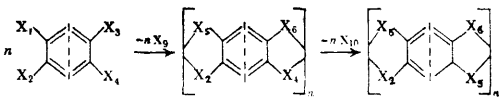


All the polyheteroarylenes obtained by the present method are closely similar in properties, both in the prepolymer stages and in the final stages. Depending on the specific structure of the prepolymers—copolyamidobenzimidazoles and copolyamido-1,2,4-triazoles, as well as polyamides containing *o*-benzimidazolyl and *o*-triazolyl substituents—they exhibit either limited solubility or complete insolubility in bipolar aprotic solvents. These polymers are characterised by comparatively low molecular weights (up to 30 000), probably because of the relatively weak nucleophilic character of the initial diamines containing bulky shielding substituents *ortho* to the amino-groups. The required partly ladder polymers are soluble only in strong acids such as sulphuric, trifluoroacetic, polyphosphoric, etc. These systems possess high heat resistance and thermal stability: under conditions of dynamic thermogravimetric analysis in air many of these polymers undergo no loss in weight right up to 500°C.

The greatest thermal stability is shown by polybenzobispyrimidobenzimidazoles

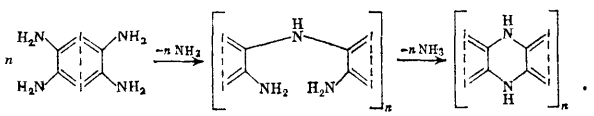


which are formed by the action of aromatic acid dichlorides on 4,6-bisbenzimidazol-2'-yl-1,3-phenylenediamine. The high thermal stability of these systems is probably due not only to stability of the heterocycles and high degrees of cyclisation of the polymers but also to absence of isomerism in the heterocycle, which according to Marvel[173] should influence favourably the thermal properties of polymers. For comparison we note that ladder polyheteroarylenes obtained by the three-stage method[76] contain a large quantity of structural isomers even in the ideal completely cyclised structures. Perhaps the thermal stability of polybenzobispyrimidobenzimidazoles



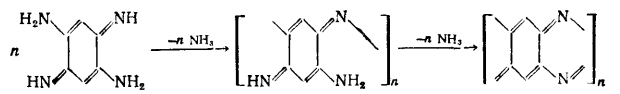
can be further enhanced by passing to more regular structures [173], e.g.

Diamines containing perimidine, indole, pyrrole, and other groups *ortho* to the amino-groups can also be used as monomers. This is supported by published results on the formation of the model compounds [174,175]



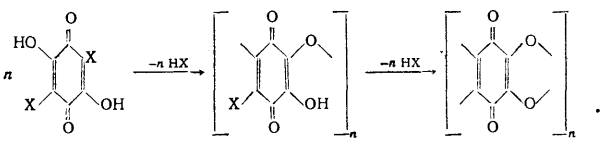
(3) The second of the above two-stage methods is the most widely used for the synthesis of partly or completely ladder polyheteroarylenes containing aromatic or hydroaromatic six-membered heterocycles. The general scheme of homocondensation can be written

where X_1–X_4 are the same or different functional groups, which differ from the groups X_5–X_8 by the molecules of the condensation by-products X_9 and X_{10}.



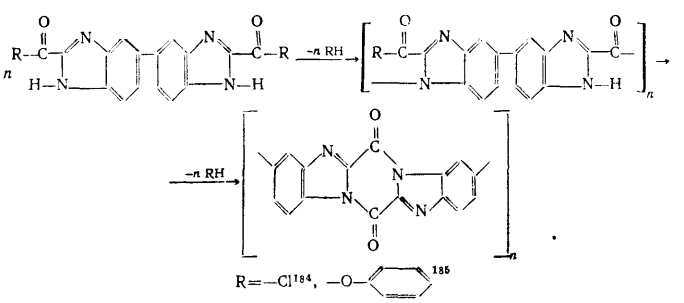
The simplest reactions of this type, in which $X_1 = X_2 = X_3 = X_4$, involve the homocondensation of bis-*o*-phenylenediamines [176–178] in polyphosphoric acid at 250–350°C:

The reaction products are polydihydrophenazines, which can undergo partial oxidation of quinoxaline fragments. The polymers obtained possess high thermal stability (that from bis-3,4-diaminophenyl ether loses only 14% of its initial weight when heated in nitrogen to 900°C). However, their thermo-oxidative stability is considerably lower (owing to the presence of the NH groups); they have limited solubility in sulphuric and methanesulphonic acids, and poor viscosity characteristics (specific viscosity 0.2–0.4 dl g^{-1}).



Polymers of closely similar structure have been synthesised by the homocondensation of 6,7-diaminoquinoxaline-2,3-diol in polyphosphoric acid [179]. The presence of imino-groups in the resulting polyquinoxalinodihydrophenazines is responsible for their relatively low resistance to thermal oxidation in comparison with the above polydihydrophenazines. An attempt at a fundamental improvement in the solubility and stability of the polymers by replacing hydrogen atoms in the dihydrophenazine rings with phenyl groups by using bis-*N*-phenyl-*o*-phenylenediamines as monomers did not yield the desired poly-*NN'*-diphenyldihydrophenazines [180].

A rather more successful attempt to use the homocondensation of tetrafunctional monomers to produce completely aromatic ladder polyheteroarylenes was made with 2,5-diamino-1,4-benzoquinonedi-imide in polyphosphoric acid [181]:

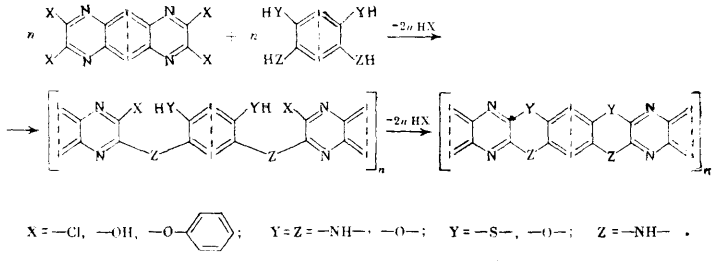


The resulting polymers have high thermal stability: weight losses associated with the start of degradation are observed at 450–480°C, while the most thermostable specimens lose 5% and 19% at 600 and 900°C respectively. Nevertheless, the products of homocondensation have only limited solubility in sulphuric acid and exhibit very poor viscosity characteristics (specific viscosity not exceeding 0.05 dl g^{-1}).

Other derivatives of *p*-benzoquinone have attracted the attention of research workers. In particular, Berlin et al. [182,183] accomplished the homocondensation of chloro- and bromo-anilic acids to polyquinonedioxins:

The synthesis of polyquinonedioxins in the melt [182] and in biphenyl, dimethylformamide, and *N*-methylpyrrolid-2-one [183] gives intensely coloured products of low molecular weight, characterised by sparing solubility and poor thermal stability. Thus these polymers lose up to 50% of their initial weight when heated in an inert atmosphere to 400°C for a few hours.

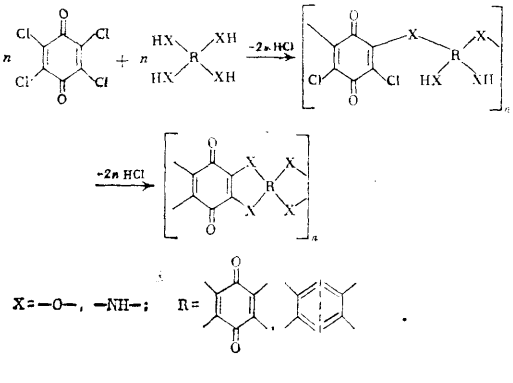
The homocondensation of derivatives of 5,5'-bibenzimidazolyl-2,2'-dicarboxylic acid [184,185] differs somewhat from the above reactions:



The mobile hydrogen atom of the benzimidazole ring acts as a functional group involved in polyheterocyclisation. Homocondensation of the acid dichloride was effected in thionyl chloride [184], and that of the diphenyl ester in the melt or in thiolan *S*-dioxide [185]. The resulting polybisbenzimidazopyrazinediones are partly soluble in sulphuric and methanesulphonic acids, have $[\eta] = 0.15$–0.62 dl g^{-1}, and according to thermogravimetric data begin to decompose in an inert atmosphere and in air at 465 and at 350–400°C respectively.

Inspection of the above results indicates that most ladder polyheteroarylenes obtained by the homocondensation of tetrafunctional monomers possess comparatively low molecular weights, limited solubility, and comparatively low (especially under conditions of thermal oxidation) temperatures at which degradation begins, which in combination present considerable difficulties to the use of

these polymers as foundations for thermostable materials. Another noteworthy feature is the limited range of tetrafunctional monomers used in homocondensation processes.

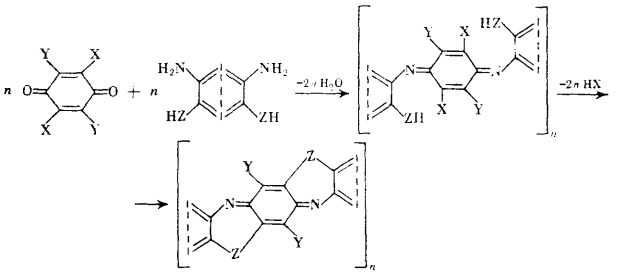


A considerably wider range of monomers can be used in the polycyclocondensation of two different tetrafunctional monomers. Marvel et al.[178,186-196] have made a comprehensive investigation of the reactions of tetrasubstituted bisquinoxalines and tetra-aza-anthracenes containing activated halogen, hydroxyl, and phenoxyl groups with bis-*o*-phenylenediamines, bis-*o*-aminophenols, bis-*o*-aminothiols, and tetraphenols. These processes can be represented by the general scheme

X = —Cl, —OH, —O—⟨benzene⟩; Y = Z = —NH—, —O—; Y = —S—, —O—; Z = —NH— .

The polymers can be synthesised in the melt or by high-temperature polycyclocondensation in an organic solvent of high boiling point or in polyphosphoric acid. They contain alternating quinoxaline and dihydrophenazine, oxazine, thiazine, and dioxin rings. They possess comparatively high thermal stability (dynamic thermogravimetric analysis indicates that their degradation begins at 450–550°C), but relatively low molecular weights and limited solubility, which presents considerable difficulties when they are processed into articles.

Although various groups can be used as functions in tetrasubstituted bisquinoxalines and tetra-aza-anthracenes, tetrachloro-derivatives have been most commonly employed, in which the chlorine atoms are highly reactive. Such derivatives have found the widest use also in another group of monomers—derivatives of *p*-benzoquinone—from which ladder polyheteroarylenes are obtained[197,198]. The general scheme of reaction of these compounds with tetrafunctional monomers can be represented

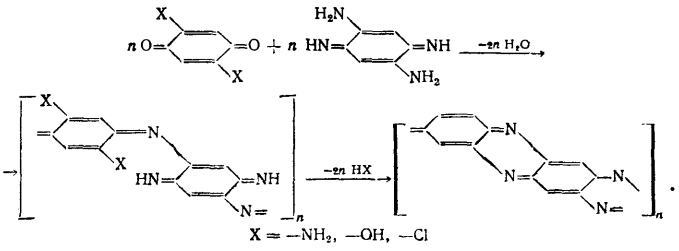


X = —O—, —NH—; R = ⟨quinone⟩ .

Polymers analogous in structure to products of the homocondensation of chloro- and bromo-anilic acids are obtained by reaction between chloranil and tetrahydroxy-*p*-benzoquinone[197]. The resulting polyquinonedioxins are intensely coloured substances of comparatively low molecular weight, identical in properties with products of the homocondensation of chloro- and bromo-anilic acids.

Polymers very similar in properties to polyquinonedioxins are obtained by the action of chloranilic acid or chloranil on bis-*o*-phenylenediamines[198].

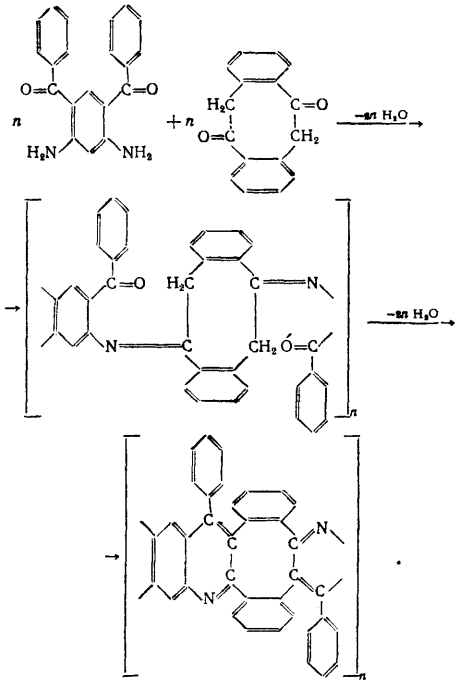
In the above syntheses of ladder polyheteroarylenes the carbonyl groups of *p*-benzoquinone are not involved in polycyclocondensation but remain in the final macromolecular structures. A somewhat different approach was made by Stille and by Marvel[108,109,181,199-202], who achieved the polycyclocondensation of *p*-benzoquinone derivatives with various monomers in which the carbonyl groups of the former were involved in ring formation:



X = —OH, —O.CO.CH$_3$, —NH$_2$, —Cl; Y = —H, —Cl; Z = —O—, —NH—, —S— .

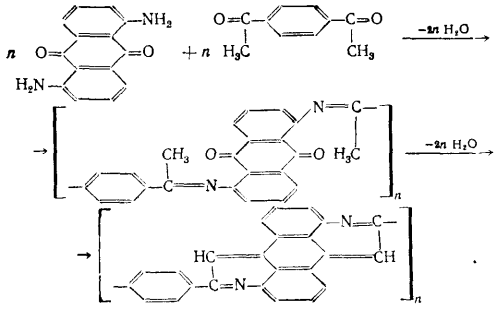
Thus polyphenoxazines of high molecular weight were obtained by reaction of bis-*o*-aminophenols with 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone and with its diacetate[108,109]. The chief defects of these polymers are limited solubility in organic solvents and low thermal stability (in nitrogen a loss in weight was observed at 250–275°C), the latter due, as already noted, to the low thermal stability of the phenoxazine ring[108,109].

Polymers of great interest with respect to thermal stability have been obtained by the reaction of 2,5-dihydroxy-, 2,5-dichloro-, and 2,5-diamino-1,4-benzoquinones with bis-*o*-phenylenediamines[199-201]. In the case of the diol polycyclocondensation was accomplished in dimethylacetamide, hexamethylphosphoramide, and polyphosphoric acid; the polymers obtained in hexamethylphosphoramide were completely soluble in this solvent and possessed an intrinsic viscosity of 0.60–1.40 dl g^{-1}. Polydihydrophenazines obtained in dimethylacetamide and polyphosphoric acid are 50% and 30% soluble in hexamethylphosphoramide, and possess intrinsic viscosities of 0.57 and 1.45 dl g^{-1} respectively. The polymers begin to decompose in air and in nitrogen at 525 and 535°C respectively.



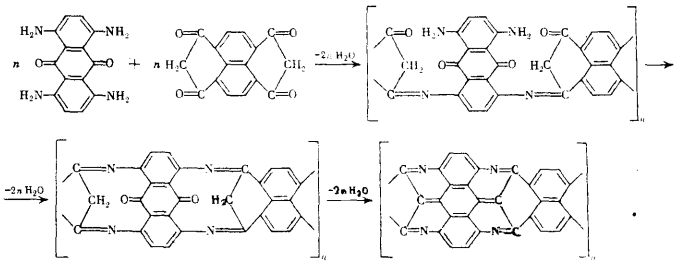
Analogous polymers have been obtained with 2,5-diamino- and 2,5-dichloro-1,4-benzoquinones[199-201]. Marvel et al.[202] obtained a polytriphenodithiazine from the reaction of 2,5-dichloro-1,4-benzoquinone with the dihydrochloride of 4,4′-diaminobiphenyl-3,3′-dithiol. Continuing the reaction in dimethylacetamide at 150°C for 24 h gave a polymer of low molecular weight having a specific viscosity of 0.12 dl g^{-1}, soluble only in sulphuric acid. The same process in polyphosphoric acid gave a polymer that was partly soluble in sulphuric acid (specific viscosity 0.54 dl g^{-1}). Dynamic thermogravimetric analysis in helium indicates that the polymer loses 3% of its initial weight at 500°C.

Polymers of completely ladder structure have been obtained by the reaction of 2,5-diamino-, 2,5-dihydroxy-, and 2,5-dichloro-1,4-benzoquinones with 2,5-diamino-1,4-benzoquinonedi-imide in polyphosphoric acid[181]:

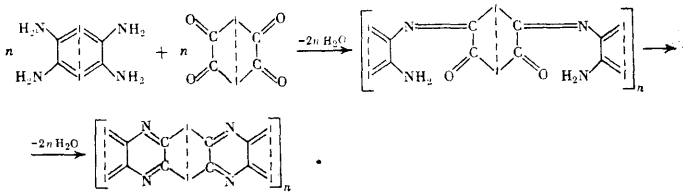


Dynamic thermogravimetric analysis in nitrogen showed that the resulting polyphenazines possess comparatively high thermal stability, comparable with that of products of the homocondensation of 2,5-diamino-1,4-benzoquinone-di-imide. The ladder polyphenazines have the defects of poor solubility (they are only partly soluble in sulphuric acid) and comparatively low viscosity characteristics (specific viscosity ≤ 0.2 dl g^{-1}).

Extending the Friedländer and related processes to the synthesis of macromolecular compounds is of considerable interest for the production of novel polyheteroarylenes of partly and completely ladder structure[203-205]. In particular, Stille et al.[204] have obtained a polymer of ladder structure from 4,6-dibenzoyl-1,3-phenylenediamine and a cyclic bisketomethylene compound—dibenzo[*a*,*e*]-cyclo-octene-5,11(6*H*, 12*H*)-dione:



A process related to the Friedländer reaction has been used[206] to obtain a partly ladder polybenzodiquinoline from 1,5-diaminoanthraquinone and a series of diacetylated aromatic compounds. Most interesting results are obtained with *p*-diacetylbenzene[206]:

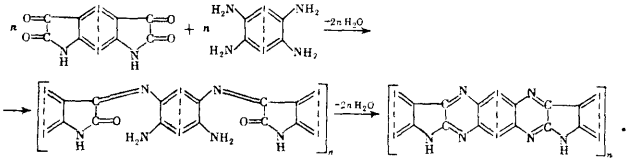


The first stage, effected in the melt at 240°C for 30 min, gives a polymeric Schiff base soluble in sulphuric and methanesulphonic acids, having a specific viscosity of 0.46 dl g^{-1}. The second stage occurs when the polymer is heated in polyphosphoric acid at 150°C for 5 h. Dynamic thermogravimetric analysis indicates that the resulting polybenzodiquinoline begins to decompose in air at 440°C, but in nitrogen it loses only 10% of its initial weight at 900°C.

Further development of this line of attack led to the synthesis of a graphite-like polymer[207-209] from 1,4,5,8-tetra-aminoanthraquinone and 1,2,3,6,7,8-hexahydropyrene-1,3,6,8-tetraone. It would be more correct to regard this not as a two-stage polycyclocondensation of two tetrafunctional monomers but as a three-stage polycyclocondensation of two hexafunctional compounds:

Interaction of the initial compounds in polyphosphoric acid at 170°C for 20 h gave a polymeric Schiff base soluble in sulphuric acid, with specific viscosity 2.7 dl g^{-1}. Subsequent vacuum treatment at 340°C for 2–5 days yielded the required highly condensed system. Isothermal thermogravimetric analysis in circulating air indicated appreciable weight losses even at 300°C, probably largely owing to the low degree of cyclisation of the system. An interesting feature of the polymer is its high electrical conductivity of 2×10^{-4} ohm^{-1} cm^{-1}.[210]

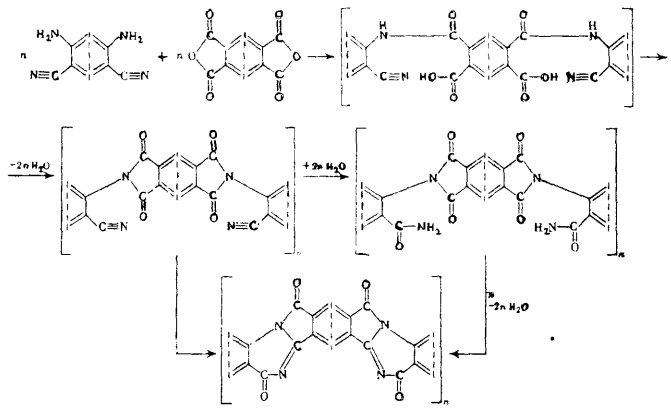
Examination of the literature indicates that the reaction most often used in the synthesis of ladder polyheteroarylenes is the condensation of amino and carbonyl groups. The same reaction forms the basis of the synthesis of ladder polyquinoxalines[89-91,107,204,211]:



Using 3,3,6,6-tetramethylcyclohexane-1,2,4,5-tetraone as tetracarbonyl compound, Stille et al.[107] obtained polyquinoxalines of comparatively low thermal stability resulting from the ease of decomposition of the isopropylidene groups. In air the polymers began to break down at 200–290°C depending on their structure, but in an inert atmosphere at 400°C.

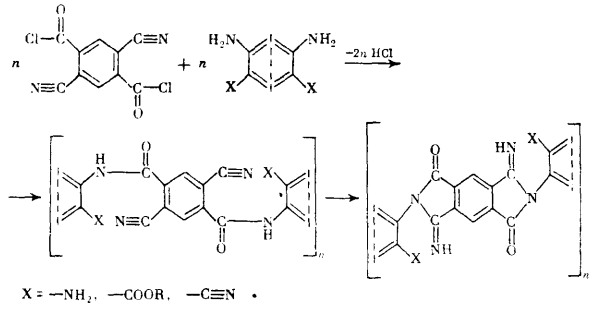
Completely aromatic ladder polyquinoxalines were obtained by the use of pyrene-1,2,6,7-tetraone and anthracene-1,2,6,7-tetraone as initial tetracarbonyl compounds, and of benzene-1,2,4,5-tetra-amine, naphthalene-1,2,5,6-tetra-amine, 1,2,5,6-tetra-aminoanthraquinone, and dibenzo-*p*-dioxin-2,3,6,7-tetra-amine as the initial bis-*o*-phenylenediamines[89-91].

Thus the reaction of benzenetetra-amine with pyrene- and anthracene-1,2,6,7-tetraones in hexamethylphosphoramide at 180°C for 120 h gave completely aromatic polyheteroarylenes, which would have been more correctly termed not polyquinoxalines but polytetra-aza-anthracenes[89]. These polymers did not dissolve in cold hexamethylphosphoramide, but were completely soluble in dichlorotetrafluoroacetone hydrate. The specific viscosities of the polymers reached 2.1 dl g^{-1}, corresponding to molecular weights of 7000–15 000. Still higher molecular weights were obtained by synthesising the polymers in polyphosphoric acid: the above polytetra-aza-anthracenes had specific viscosities up to 3.6 dl g^{-1}. Such polymers are characterised by *syn–anti* isomerism in the macromolecular chains, which enhances their solubility and processability into articles.



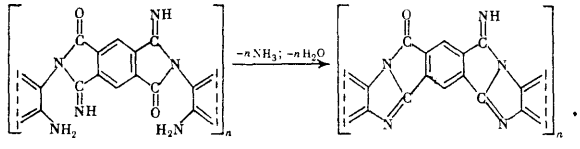
Several of the polymers possess film-forming properties. Dynamic thermogravimetric analysis indicates that the start of their degradation in air lies in the same temperature range as for linear polyquinoxalines (~550°C), but in an inert atmosphere the ladder systems exhibit considerably greater stability, beginning to decompose in the region of 700°C.

Bi-isatyls have also been used as tetraoxo-monomers: they react with bis-*o*-phenylenediamines to form polyindoloquinoxalines[212-219]:

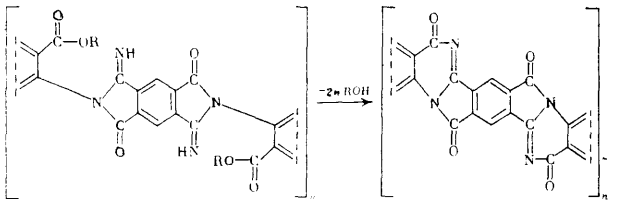


The synthesis of these polymers, like that of ladder polyquinoxalines, proceeds most smoothly in polyphosphoric acid, when the products are completely soluble in sulphuric and methanesulphonic acids with intrinsic viscosities up to 1 dl g^{-1}.[217-219] Dynamic thermogravimetric analysis indicates that these polymers begin to decompose at 460 and at 700°C in air and in nitrogen respectively[217-219].

All the aoove processes involve condensation polyheterocyclisation: i.e. they are accompanied by the evolution of volatile products of low molecular weight, which makes it difficult to obtain massive articles free from defects (pores, cracks, etc.). As a consequence, isomerisation cyclisation, which does not involve the formation of volatile products, is of considerable interest for the production of ladder polyheteroarylenes, as of heterocyclic polymers as a whole[220-224]. Ladder polyheteroarylenes have been most commonly synthesised from prepolymers containing nitrile groups, although by no means all the processes considered below involve purely isomerisation polycyclisation. Thus reaction between tetracarboxylic dianhydrides and bis-*o*-amino-nitriles forms poly-*o*-carboxy-*o'*-cyano-amides, cyclodehydration of which yields polyimides containing *o*-nitrile substituents; cyclisation of these polyimides in turn leads to poly-isoindoloquinazolinediones[225-227]:

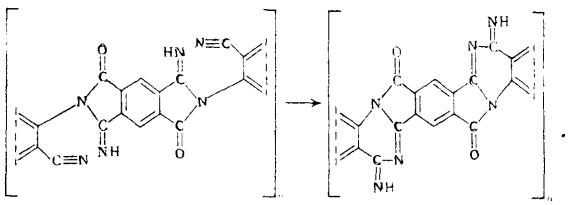


Several ladder polyheteroarylenes are obtained by thermal cyclisations of *ortho*-substituted poly-imino-imides[228]:



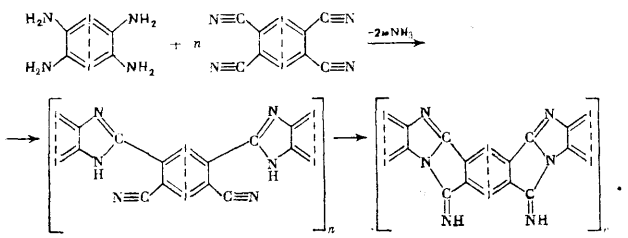
X = —NH_2, —COOR, —C≡N .

In some cases only intermediate *ortho*-substituted poly-iminoimides are formed by the isomerisation mechanism, and the concluding stage is accompanied by the evolution of simple products. Thus the reaction of hydrochlorides of aromatic tetra-amines with 2,5-dicyanoterephthaloyl chloride gives rise to poly-*o*-amino-*o'*-cyano-amides, heat-treatment of which at 150°C is accompanied by isomerisation cyclisation giving poly-*o*-amino-imino-imides. Heating these polymers at 250–350°C leads to the formation of polybenzoylenebenzimidazoles and their imino-analogues with the liberation of water or ammonia[229]:



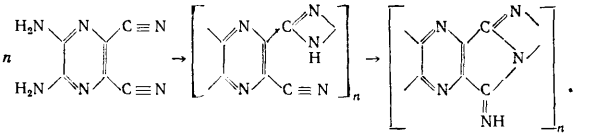
The resulting polymers are soluble in sulphuric acid, possess specific viscosities of ~0.5 dl g^{-1}, and according to thermogravimetric analysis lose 5% of their initial weight in air at 400°C. The comparatively low thermal stability is not surprising in view of the great activity of the 1,2-benzoylenebenzimidazole ring[76], also containing an exocyclic imino-group, which is undoubtedly the "weak spot" in these systems.

The action of 2,5-dicyanoterephthaloyl chloride on bisaniline-*o*-carboxylic acids or their methyl esters forms polyamides containing nitrile and carboxyl or methoxycarbonyl *ortho*-substituents. Isomerisation cyclisation of these systems at 130–150°C results in poly-iminoimides containing *o*-carboxyl or *o*-methoxycarbonyl groups and undergoing at 200–250°C cyclocondensation with the liberation of water or methanol and formation of polyisoindoloquinazolinediones [230]:

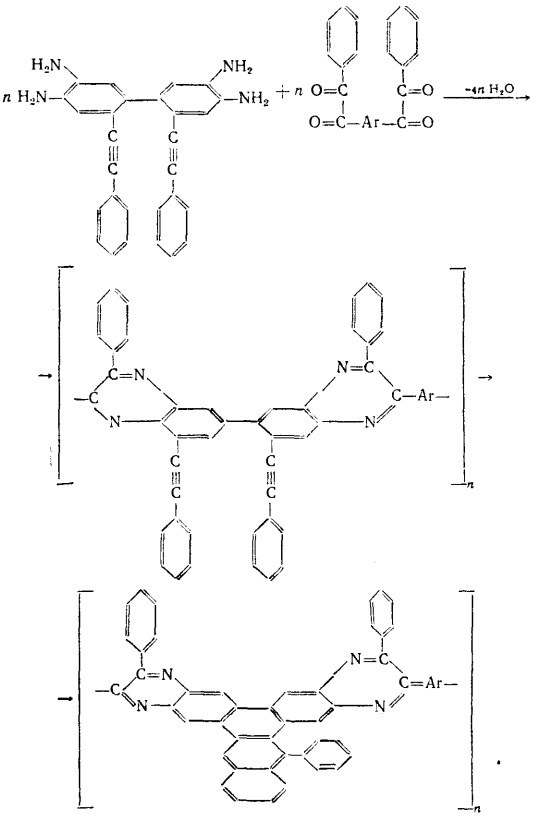


The resulting polymers are soluble only in sulphuric acid, possess specific viscosities up to 0.8 dl g^{-1}, and begin to undergo extensive degradation at 500°C.

Polyheteroarylenes of partly or completely ladder structure, which undergo cyclisation solely by an isomerisation mechansim, are obtained by reaction between 2,5-dicyanoterephthaloyl chloride and bis-*o*-aminonitriles followed by heat-treatment of the resulting poly-*oo'*-dicyano-amides with the temperature raised step by step to 300°C [231,232]:



The poly-*oo'*-dicyano-amides formed in the first stage are readily soluble in polar organic solvents and possess sufficiently high molecular weights to form strong and flexible films. The final polyiminoisoindoloquinazolinediones begin to decompose at 400–450°C according to thermogravimetric data. Since the second stage of isomerisation cyclisation does not involve the separation of simple products, the resulting polymers can be processed into monolithic articles of considerable thickness or used as binders for glassfibre-reinforced plastics and for adhesives.



Polybenzimidazoles containing *ortho*-nitrile substituents can also undergo isomerisation cyclisation [233,234]. Thus the condensation of equimolecular quantities of tetranitriles with bis-*o*-phenylenediamines in boiling 2-methoxyethanol containing sodium 2-methoxyethoxide gives insoluble black polymers [233]:

Thermogravimetric analysis indicates that the polymer formed from biphenyl-3,3'-4,4'-tetra-amine and the tetranitrile of pyromellitic acid is the most thermostable, losing 10% of its weight respectively at 500 and 700°C in air and in argon. Still better thermal characteristics are attributed to the product of the homocondensation of 2,3-diamino-5,6-dicyanopyrazine [234]

Isomerisation cyclisation can be applied also to polymers containing ethynyl side-chains. A typical example of such intramolecular processes is the formation of condensed systems by the heat-treatment of polyphenylquinoxalines obtained from 6,6'-diphenylethynyl-biphenyl-3,3',4,4'-tetra-amine and various tetraones [235-238]:

The resulting phenylated polyanthrabisquinoxalines have high glass points combined with high degradation temperatures (respectively > 360 and ~450°C).

On the whole ladder polyheteroarylenes obtained by isomerisation cyclisation do not possess especially good thermal characteristics, but the advantages of the cyclisation process open up wide prospects before isomerisation cyclisation.

IV. PRACTICAL APPLICATION—ACHIEVEMENTS AND PROSPECTS

The most considerable achievement in the practical application of ladder polyheteroarylenes is the development of polynaphthoylenebenzimidazole fibres, obtained

by spinning sulphuric-acid solutions of these polymers[239-245]. After being stretched 80–120% at 525–600°C these fibres possess at room temperature a tensile strength of 5 g denier^{-1} and an extension at break of 5%. In air the fibres retain 55–60% of their strength after 1 min at 660°C and after 30 h at 360°C; they resist the action of moisture and ultraviolet radiation[243]. At the present day they are the most thermostable among organic fibres. Not only fibres but also thermostable films[246], composition materials[247-249], and several other materials have been obtained from polynaphthoylenebenzimidazoles.

Polybenzimidazoloquinazolines can form the basis for carbon plastics that retain good strength characteristics (bending strength 1080 kg cm^{-2}) at temperatures around 370°C,[101,170-172] and also for adhesives which maintain a high strength after being aged in air at 400°C.[250]

Ladder polyquinoxalines have been used as binders for glassfibre-reinforced plastics[252], but only fragmentary attention has been paid to the properties of these materials. Practical utilisation of ladder polyheteroarylenes—even the most heat-resistant and thermostable—is governed primarily by their poor processability into articles: the great rigidity of these ladder polymers is responsible for their high softening points, which often lie even above the temperatures at which decomposition begins. The same factor also causes the limited solubility of ladder polyheteroarylenes, most of which are soluble only in strong acids. Several approaches are now envisaged towards overcoming the poor processability of ladder polyheteroarylenes.

Among purely synthetic approaches an important place will probably be occupied by the above trend to diminish the rigidity of the macromolecules[145-147,254] by using new monomers containing single carbon–carbon bonds or "hinge" groups. However, this requires the development of novel monomers and careful selection of the most readily available among them. In this connection it seems more promising to prepare copolymers and make polymer mixtures[255]. In particular, considerable interest attaches to the production of random and block copolymers containing fragments of ladder polyheteroarylenes and no less thermostable polymers that appreciably surpass the former in processability, among which polyphenylquinoxalines present the greatest interest[256-258]. On the other hand, such production of copolymers of polyphenylquinoxalines and ladder polyheteroarylenes can be regarded as a method of enhancing the thermal stability of the former, an urgent problem in the chemistry of polyphenylquinoxalines[256-258]. Mixtures of traditional polymers with ladder polyheteroarylenes are still more promising, provided, of course, that the components show good compatibility. Small additions of ladder polyheteroarylenes to traditional polymers may lead to stabilisation[259] and "alloying"[260] of the latter, whereas the introduction of considerable quantities of ladder polyheteroarylenes can probably raise the temperature of prolonged operation of the polymeric materials to 300–350°C. The search for optimum forms of such mixtures of polymers is an extremely promising approach, since it may lead to relatively cheap thermostable polymeric materials.

V. CONCLUSION

The present survey enables us to assess the present situation in the chemistry of ladder polyheteroarylenes. Greater resistance to various types of degradation can be expected from partly and completely ladder polyheteroarylenes than from traditional polyheteroarylenes, provided that the heterocycles in the main chains are very stable and the polymers as highly cyclised. At the present time this potential advantage of ladder polyheteroarylenes has been realised only with a comparatively small number of systems—ladder polyquinoxalines, polynaphthoylenebenzimidazoles, polybenzimidazoloquinazolines, polybenzobispyrimidobenzimidazoles, and a few others—which meet both requirements formulated above.

A low degree of cyclisation is not adherent in all ladder polyheteroarylenes: high degrees can be achieved in such systems, but careful choice both of the reactions themselves and of the reaction conditions is necessary. The latter requirement is quite understandable, for the synthesis of ladder polyheteroarylenes (especially the three-stage process[76]) may involve the formation of various intermediate structures and lead to a wide range of end-products. As a consequence, processes that in the chemistry of individual (model) compounds give maximum yields of the required systems are to be preferred. There is no doubt that more careful selection of the processes involved in synthesis of ladder systems and careful selection of reaction conditions can lead to the appearance of novel polymers possessing enhanced stability to various types of degradation.

Synthesis of Polymers by Polycyclotrimerisation

V.A.Sergeev, V.K.Shitikov, and V.A.Pankratov

Research on the synthesis and properties of cross-linked polymers obtained by a promising new method—polycyclotrimerisation of monomers containing acetylenic and multiple carbon-nitrogen bonds—is surveyed with attention concentrated mainly on recent studies of the laws governing the reaction, elucidation of the influence of the heterounit character of cross-linked systems on their properties, and the development of methods for effecting highly selective polycyclotrimerisation with the aim of diminishing the "defectiveness" of the polymers and obtaining molecularly regular networks. Characteristics of polycyclotrimerisation of monomers having various functional groups (C:CH, C:N, N:C:O, O.C:N, NH.C:N, NR.C:N) are identified, and the influence of the structure of the initial monomers on the properties of the resulting cross-linked polymers is examined. A list of 159 references is included.

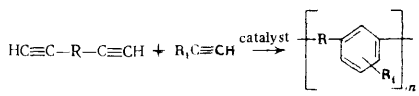
I. INTRODUCTION

Progress in the chemistry of macromolecular compounds results not only from the introduction of increasing numbers of novel monomers into known polymerisation reactions but also from the application and development of new synthetic methods. Investigations devoted to the latter occupy an important place in the work of Korshak and his pupils: for example, Korshak and Kolesnikov[1] discovered transarylation, and Korshak and Sosin[2] polyrecombination. Recently Korshak and his coworkers have been actively studying polycyclotrimerisation, a new reaction in polymer chemistry[3-7]. This process permits the synthesis of cross-linked polymers of regular chemical structure containing segments of definite size between cross-links, and six-membered carbocyclic and heterocyclic rings at the branch points: i.e. cross-linked polymers can be obtained of a qualitatively new standard in comparison with hitherto known synthetic methods for such systems.

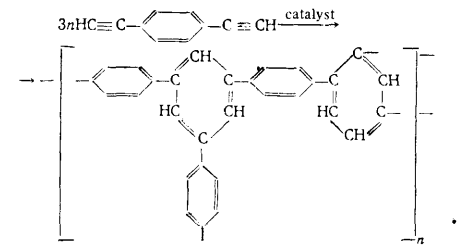


The present Review surveys the polycyclotrimerisation of monomers containing triple carbon-carbon and multiple carbon-nitrogen bonds— the two main types used for such synethses of cross-linked polymers.

II. POLYCYCLOTRIMERISATION OF ACETYLENIC COMPOUNDS

The new synthetic method is based on the cyclotrimerisation of various acetylenic compounds, a reaction known in organic chemistry[3]. When diacetylenic compounds or mixtures of diacetylenic with monoacetylenic compounds are used, the formation of polymers can be represented by the general schemes[8]

(1)

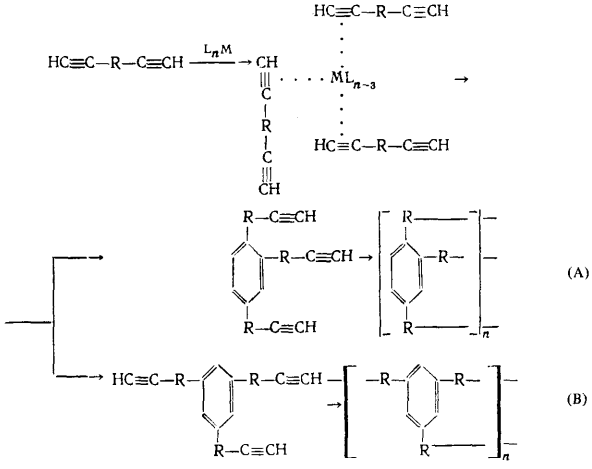


(2)

Polymer formation can thus be regarded as polycyclotrimerisation (1) or copolycyclotrimerisation (2). Such reactions had not previously been studied systematically with the aim of obtaining polymers. However, a considerable body of results have already been published on various cases of the polycyclotrimerisation of acetylenic compounds, which we can summarise in the light of the formation of polymeric products as a whole.

Conversion of acetylene into benzene, naphthalene, and other aromatic compounds at high temperatures (above 600°C) was first achieved by Berthelot[9] as early as 1866. Zelinskii[10] obtained high yields of aromatic hydrocarbons by passing acetylene over activated charcoal at 600–650°C. Studies were made[11-15] of the influence on the aromatisation of acetylenes of diverse catalysts–activated charcoal, kaolin, coke, alumina, quartz, china, pumice, brick, and also metals such as aluminium, iron, nickel, cobalt, etc.

The catalytic cyclotrimerisation of acetylenes was discovered by Reppe et al.[16,17] in 1940; it enabled high yields of products of diverse structure to be obtained under comparatively mild conditions. At the present time it is a process of great practical interest. The broad groups of catalytic systems used for the cyclotrimerisation of acetylenes comprise various complex organometallic catalysts, based e.g. on hydrides[18,19], salts[20-22], and π-complexes of metals[23,24], complexes of zerovalent metals[25], metal-oxide catalysts[26], and others[27].

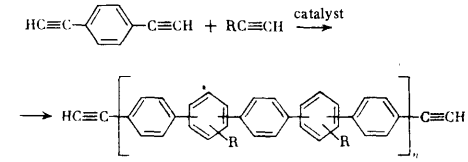


Korshak et al.[28] were the first to develop the new method for obtaining polymers of polyphenylene type from *p*-diethynylbenzene, whose polycyclotrimerisation can be represented by the scheme

The new aromatic rings formed are substituted at positions 1,2, 4 and 1,3, 5.[29,30] The proportions of the trisubstituted aromatic isomers depend on the nature of the catalytic system (mainly a metal) and on the reaction conditions.

Kinetic investigation of the polycyclotrimerisation of *p*-diethynylbenzene in the presence of trialkyl-phosphite cobalt complexes of general formula $[(AlkO)_3P]_nCoHal$ (where $n = 3$ or 4) has established[31] that the degree of conversion of the initial monomer depends not only on its initial concentration and that of the catalyst but also on the nature of the organic solvent and the duration of heating. Almost complete (97%) conversion of *p*-diethynylbenzene into a polymer can be achieved by selecting appropriate conditions by trial and error. The kinetic order with respect to *p*-diethynylbenzene is approximately first, with a rate constant of 0.01183 s^{-1}. Polycyclotrimerisation on the above catalytic complex forms strongly branched polymers containing mainly unsymmetrically trisubstituted benzene rings. This was demonstrated by nuclear magnetic resonance data for soluble specimens obtained in the initial stages at low degrees of conversion[31].

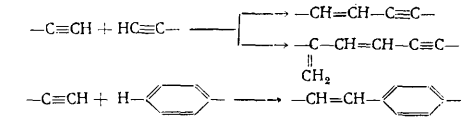
The reactions involved in the catalytic polycyclotrimerisation of diacetylenes can be represented by the general scheme[20,31]



where L_nM is a catalytic complex of a metal M and a ligand L. The reaction mechanism may involve other intermediate stages, but the slowest stage is probably interaction of the intermediate complex with the third acetylenic group[20,31].

Polymers of polyphenylene type based on *p*-diethynylbenzene are yellow-brown powders. The maximum molecular weight of the soluble polyphenylenes reaches 2600. However, the reaction mixture may also contain a large quantity of alcohol-soluble oligophenylenes of molecular weight $\geqslant 350$ together with insoluble and infusible polyphenylenes, which are amorphous to X-rays, in contrast to the crystalline poly-*p*-phenylenes obtained by the oxidative dehydropolycondensation of benzene[32]. The infusible amorphous polyphenylenes from *p*-diethynylbenzene do not dissolve when heated in chlorosulphuric and concentrated sulphuric acids, an indication of their cross-linked structure. The comparatively high yield of lower oligomers at 86% conversion is attributed to relatively low reactivity of the macromolecular products (in comparison with the monomer), which may be due to steric inhibition of cyclotrimerisation in the highly branched polymer[33].

Soluble polyphenylenes are formed from *p*-diethynylbenzene in the presence of titanium tetrachloride and diethylaluminium chloride or of a nickel(II) catalyst up to 88.5% conversion of the monomer[33]. The number-average molecular weights of the polymers measured osmometrically increase slowly with conversion of the monomer, but remain fairly low (up to 1460). Complete transformation of the reaction product into a high polymer occurs at ~90% conversion, close to the point of gel formation, which corresponds to a content of 8 mass % of ethynyl groups in the polymer. The properties of the soluble oligophenylenes based on *p*-diethynylbenzene depend largely on their content of unchanged ethynyl groups, whose presence is due to the incompleteness of polycyclotrimerisation. When such oligophenylenes are heated, the ethynyl groups are involved in polymerisation and the formation of three-dimensional structures.

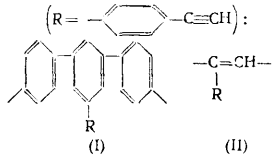


Thus the polycyclotrimerisation of *p*-diethynylbenzene yields either strongly cross-linked polyphenylenes or branched oligophenylenes of relatively low molecular weight. In order to obtain soluble oligophenylenes of higher molecular weight one active position in the newly formed benzene ring was blocked during chain growth. This was achieved by using as initial monomers various mixtures of aromatic and aliphatic mono- and di-ethynyl derivatives, whose copolycyclotrimerisation can be represented by the general scheme

where R = Ar, Alk, $CH_2:CH$, etc.

The copolycyclotrimerisation of *p*-diethynylbenzene and phenylacetylene has been studied[34] in the presence of $[(C_2H_5O)_3P]_4CoBr$ as catalyst. However, when the process was conducted under conditions similar to those for the polycyclotrimerisation of the diyne, even when the initial mixture contained three moles of phenylacetylene per mole of the diyne, insoluble polyphenylenes were formed in yields up to 16%. Kinetic investigation established[34] that the rate of conversion of *p*-diethynylbenzene exceeded considerably that of phenylacetylene under the same conditions.

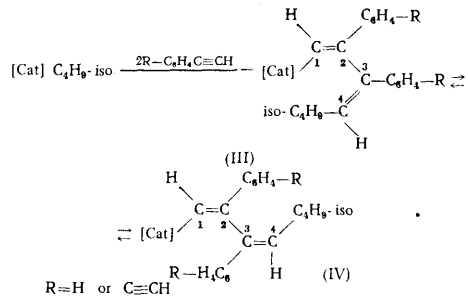
The polyphenylenes obtained by the polycyclotrimerisation of a mixture of *p*-diethynylbenzene and phenylacetylene were oily or solid products, whose properties were directly dependent on the reaction conditions, primarily on the molecular proportion of phenylacetylene and the initial concentrations of the acetylenes. Soluble and insoluble polyphenylenes were obtained; the infrared spectra indicated that those of greater molecular mass had lower contents of ethynyl groups relative to the aromatic portion of the polymer molecule. The maximum molecular weight of the soluble polyphenylenes was 4800. When soluble polyphenylenes containing terminal ethynyl groups were heated, they set with the formation of infusible and insoluble products, in which the process of structure formation could be represented[35]



A catalytic system of the Ziegler–Natta type, comprising a trialkylaluminium and titanium(IV) chloride, is most often used for the copolycyclotrimerisation of *p*-diethynylbenzene and phenylacetylene. Such a system in which the alkyl was isobutyl was employed[36] because the trimerisation of phenylacetylene in the presence of such a catalyst gave 1,3,5-triphenylbenzene in almost theoretical yield. In order to obtain soluble polyphenylenes of more regular

structure by the preferential formation of 1,3,5-substituted benzene rings, therefore, the copolycyclotrimerisation of *p*-diethynylbenzene with various quantities of phenylacetylene was conducted in solution (in heptane) at room temperature. Polymers that were completely soluble in benzene, toluene, and other organic solvents were obtained only when the molecular ratio of phenylacetylene exceeded unity[36]. Yet copolycyclotrimerisation of the components in benzene solution in the presence of the above catalyst at 60°C gave soluble and insoluble products, with the yield of insoluble polymers and the molecular weights of the soluble oligophenylenes (1170–5300) almost independent of the initial proportions of the monomers (within the range 1 : 2, 1 : 1, and 2 : 1).[37]

Infrared spectral data and kinetic investigation by gas-liquid chromatography of copolycyclotrimerisation indicated that, with the catalyst ratio Al/Ti = 0.5 at 60°C, the rate of conversion of phenylacetylene and *p*-diethynylbenzene changed as the reaction progressed. The ratio of the numbers of diyne and monoyne molecules that have reacted after 8 h at the same total concentration but different molecular concentrations of the monomers, together with the composition of the soluble copolymers determined from the intensity of the 710-cm^{-1} band characteristic of a monosubstituted benzene ring, shows that only at a molar ratio of diyne to monoyne of 2 : 1 is predominant formation of structural units of the above types (A) and (B) possible[37].



Investigation of the kinetics of the addition of ozone and the composition of the decomposition products from the ozonides indicated[37] structural non-uniformity of the soluble copolymers independently of the initial ratio of the monomers. The products of ozonolysis included benzoic and terephthalic acids. Thus the complicated mechanism of the copolycyclotrimerisation of *p*-diethynylbenzene and phenylacetylene may result in copolymers containing not only phenylene segments but also anomalous units, including polyene segments. The study[38] of the influence of such anomalous units on certain properties of the copolymers formed from various ratios of the monomers in the presence of the tri-isobutylaluminium—titanium(IV) chloride catalytic system in benzene solution at 60°C revealed that increase in the proportion of the diyne in the initial mixture increased the content of triple bonds and polyene segments in the soluble oligomers. This may be due to the presence in the copolymer of the structures (I) and (II).

(I) (II)

since terephthalic acid was detected in the products of ozonolysis, whereas different acids were present in the degradation products from insoluble fractions of copolymers and homopolymers.

The formation of linear (polyene) and aromatic structures in the polymers involves cleavage of a triple bond[39], a cyclic trimer being formed by detachment of a linear trimer from a catalytic centre with ring closure[40]. This process depends not only on the nature of the acetylenic compounds and the catalytic system but also on the conditions of polycyclotrimerisation. With *trans*-cleavage of the triple bond, for example, linear polyenes are formed owing to the impossibility of *trans–cis* isomerisation with respect to the resulting double bond; with *cis*-cleavage of the triple bond, *cis-s*-cisoid (III) and *cis-s*-transoid (IV) conformations can be formed, responsible for the formation of cyclic and linear fragments respectively:

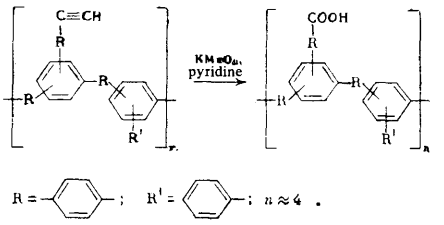
Cyclotrimerisation predominates in the case of phenylacetylene (R = H), which indicates *cis*-cleavage of the triple bond and free rotation about the $C_{(2)} - C_{(3)}$ single bond. In copolymers with *p*-diethynylbenzene (R = C⋮CH) rotation about this single bond is hindered owing to the formation of branched and cross-linked structures, which increases the probability of polyenisation. These ideas find experimental support: increasing the diyne content in the mixture impedes polycyclotrimerisation and creates conditions for the formation of polyene structures, the quantity of which is determined from the quantity of ozone added per unit weight of the copolymer.

Investigations of the structural direction of copolymerisation of these monomers on the $AlR_3-(TiCl_4)_n$ catalytic system (R = C_2H_5 or iso-C_4H_9) have also revealed[41,42] that polycyclotrimerisation is not the only process of macromolecular chain growth.

In order to formulate optimum conditions for polycyclotrimerisation to high degrees of conversion of the initial acetylenic compounds into fusible and soluble polyphenylenes of practical interest the copolycyclotrimerisation of mono- and di-acetylenic compounds was studied[43,44] in the presence of the catalytic systems

$$[(C_2H_5O)_3P]_4CoBr;\quad NiCl_2\cdot 2P(C_6H_5)_3\cdot 2NaBH_4;$$

$$Ni(CO)_2\cdot[P(OC_6H_5)_3]_2\ ;\quad Al\ (iso\text{-}C_4H_9)_3—[TiCl_4]_n.$$



This involved preliminary preparation of complexes of the catalytic systems—the triethyl-phosphite complex of cobalt and the mixed organometallic catalyst based on triphenylphosphine, nickel chloride, and sodium tetrahydroborate—with *p*-diethynylbenzene and phenylacetylene followed by examination of their structure. In the presence of the first catalytic system above the rate of polycyclotrimerisation could be controlled by the introduction of electron-donor additives such as tertiary amines into the reaction mass or of electrophilic substituents, e.g. chlorine, bromine, etc., into the aromatic ring of the phenylacetylene. Copolycyclotrimerisation is strongly activated by electron-donor additives: the rate increases sharply, the induction period disappears, and the range of simultaneous conversion of the initial monomer mixture is enlarged.

High yields (~70%) of copolymers are obtained by copolycyclotrimerisation in the presence of the catalytic system $NiCl_2.2(C_6H_5)_3P.2NaBH_4$ under comparatively mild conditions with high rates of conversion of the initial monomers. The yield of soluble products increases considerably with increase in the phenylacetylene content of the initial mixture, and completely soluble oligophenylenes free from terminal ethynyl groups are formed when its molecular ratio to *p*-diethynylbenzene is 4 : 1. Use of a *p*-halogenophenylacetylene in copolycyclotrimerisation

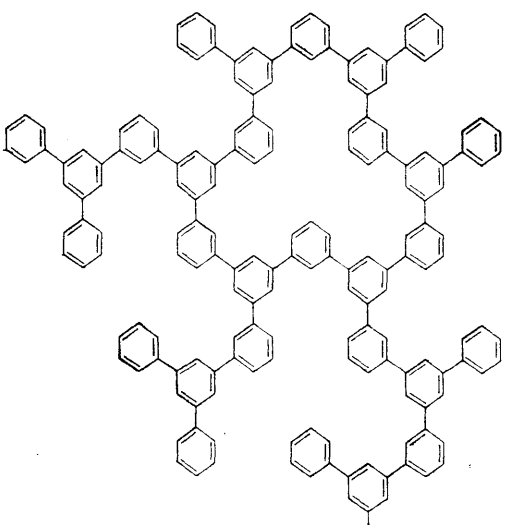
enabled[43,44] the relative activities of acetylenic monomers in the reaction to be assessed and in most cases highly halogenated soluble copolymers to be synthesised.

Thus it follows from the above results that the nature of the catalytic complexes has a significant influence on the conditions of polycyclotrimerisation, on the relative reactivities of mono- and di-yne, and on the structure and properties of the resulting copolymer.

A method of oxidising toluene-soluble oligophenylenes obtained in the presence of a Ziegler–Natta type of catalyst (iso-$C_4H_9)_3Al-(TiCl_4)_n$, a mixed organometallic catalyst $NiCl_2.2(C_6H_5)_3P.2NaBG_4$, and also $(C_8H_7O_2)_2Ni.(C_6H_5)_3P$ and $[(C_2H_5O)_3P]_4CoBr$ has been devised[45,46] in order to make a comparative assessment of the efficiency and ascertain the influence of different catalytic systems on copolycyclotrimerisation, as well as to establish the structure of the polymeric products. Since multiple (double and triple) carbon–carbon bonds are readily oxidised in the presence of chromic and nitric acids or potassium permanganate, and their rupture produces organic acids or ketones[47–49], oxidation of the oligophenylenes followed the scheme

The oxidation products were pale grey powders soluble in pyridine, dioxan, dimethylformamide, and oxolan.

Properties of oxidised oligophenylenes[47–49].



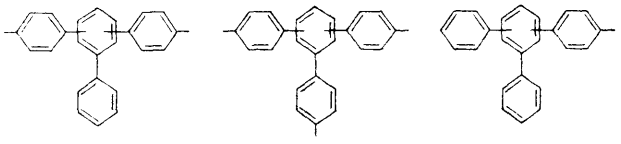
Catalytic system	Acid value, mg KOH g^{-1}	M.p., °C	Yield, %
Al (iso-$C_4H_9)_3$—$[TiCl_4]_n$	63.0	207–213	60.0
Al (iso-$C_4H_9)_3$—$[TiCl_4]_n$	75.5	250–260	60.6
$NiCl_2 \cdot 2P(C_6H_5)_3 \cdot 2NaBH_4$	71.5	130–139	34.2
Ni $(C_8H_7O_2)_2 \cdot P(C_6H_5)_3$	71.2	275–279	21.0
$[(C_2H_5O)_3P]_4CoBr$	80.0	178–193	23.6

The Table shows that the acid values and the melting points of the oxidised products depend on the conditions of formation and the structure of the initial oligophenylenes. Thus oligophenylene obtained in the presence of the sodium tetrahydroborate catalyst melted at 130–139°C after oxidation, whereas the corresponding temperatures obtained with a Ziegler–Natta type of catalyst were 250–260°C. The highest yield of oxidised product was found for a *p*-diethynylbenzene-phenylacetylene oligophenylene obtained in the presence of the Ziegler–Natta type of catalyst. From the molecular weights of the methyl ester of this copolymer (1800) and the content of methoxy-groups (6.3%) it follows that the macromolecule of the oxidised oligophenylene contains ~4 carboxy-groups. Alcohol-soluble lower oxidation products were isolated by precipitates in water; they had molecular weights of 300–450, acid values 100 to 160, and melting points 120–160°C depending on the structure of the initial oligophenylenes.

Decarboxylation of the oligophenylenecarboxylic acids at 400°C gave high yields of products having molecular weights close to those of the initial oligophenylenes (before oxidation) and with an elementary composition close to that calculated theoretically for oligophenylenes free from groups and bonds other than aromatic rings. Furthermore, acid values and infrared spectra indicated that the products contained no carboxy-groups and were almost devoid of multiple bonds, since the iodine values were close to zero. Since the initial oligophenylene, the methyl oligophenylenecarboxylate, and the product of decarboxylation of the oligophenylenecarboxylic acid had molecular weights of the same order, it was concluded[47–49] that the higher the yield of oxidised product (oligophenylenecarboxylic acid) the greater the extent of copolycyclotrimerisation of *p*-diethynylbenzene and phenylacetylene, the dominant process in the presence of the Ziegler–Natta catalyst (iso-$C_4H_9)_3Al-(TiCl_4)_n$.

Synthesis of soluble branched polyphenylenes of high molecular weight by polycyclotrimerisation of a mixture of *m*-diethynylbenzene and phenylacetylene in chlorobenzene solution was accomplished[50] in the presence of a Fischer catalyst, the active principles of which are complexes $TiCl_2.(AlCl_3)_n$, where $n = 1$ or 2. Examination of the effect of the molecular ratio of the initial monomers on the properties of the products revealed that soluble polyphenylenes were obtained with up to 50% excesses of the diyne. The yield of methanol-insoluble fractions was 88%; gas chromatography revealed neither of the initial monomers in the lower fractions. The resulting polyphenylenes were cream-coloured powders soluble in chlorinated hydrocarbons and cyclic ethers. They softened at ~320°C and had number-average molecular weights up to 70 000 (measured osmometrically in chlorobenzene solution at 30°C). The ultraviolet and infrared spectra of the polymers contained absorption bands characteristic of mono-, di-, and trisubstituted aromatic rings, but none indicating terminal ethynyl groups.

Thus the resulting polymers probably had a branched structure with macrocyclic polyphenylene fragments in the chain



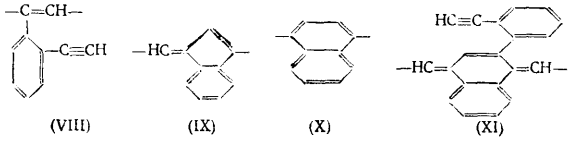
The formation of macrorings within a polymer molecule explains also the appearance of soluble polyphenylenes of high molecular weight when excess of *m*-diethynylbenzene is present (up to 1.5 moles per mole of phenylacetylene).

Soluble copolymers have been obtained[51] by heating an equimolecular mixture of phenylacetylene with a 9 : 1 mixture of *m*- and *p*-diethynylbenzenes in the presence of a catalyst $Ni(CO)_2.2(C_6H_5)_3P$ in benzene. Infrared bands characteristic of triple bonds ⋮CH and C⋮C (3300 and 2100 cm^{-1} respectively) were absent, but the appearance of an absorption band in the region of 965 cm^{-1}, typical of terminal *trans*-disubstituted double bonds, was regarded as attributable only to linear telomerisation of acetylenic compounds[52]. Solid cross-linked products separated when solutions of the copolymers were allowed to stand in the air.

Copolymers readily soluble in aromatic solvents have been obtained[51] by the copolycyclotrimerisation of the above diethynylbenzene mixture with phenylacetylene or *m*-ethynyltoluene in the presence of a $(C_2H_5)_2AlCl-(TiCl_4)_n$ catalyst (with Al : Ti = 3 : 1), which converts[53] phenylacetylene into a high (up to 80%) yield of triphenylbenzene with only slight quantities of linear products. Infrared and ^1H and ^{13}C nuclear magnetic resonance data indicate that the copolymers contain predominantly aromatic groups with very minute quantities of double and triple bonds. The reactions of these triple bonds are not those typical of terminal acetylenic compounds, since attempts to increase the molecular weight of the products by oxidative dehydropolycondensation were unsuccessful. Comparison of the n.m.r. absorption areas due to aromatic and aliphatic protons in the diethynylbenzene–*m*-ethynyltoluene copolymer indicated a ratio of mono- to di-functional initial compounds of 1.2–1.0.

Polycyclotrimerisation of diethynylbenzene with phenylacetylene or *m*-ethynyltoluene gave high yields of soluble copolymers having molecular masses of 10 000–50 000 and softening points of 200–300°C depending on the reaction conditions. Gel-permeation chromatography established that the degree of polydispersity and the molecular mass of the copolymers were almost unaffected by the initial catalyst concentration (over a fivefold range)[51]. The good solubility of the copolymers in organic solvents, the low viscosity of their solutions ($[\eta]$ = 0.089–0.288), and also the very great brittleness of films based on them (independently of molecular mass) provide convincing evidence of the branched structure of the copolymers. Furthermore, the value $\alpha \approx 0.5$ in the Mark–Houwink equation $[\eta] = KM_\omega^{\alpha}$ found experimentally also confirms a branched structure.

Because the effect of the catalyst is relatively non-specific the three possible aromatic groupings



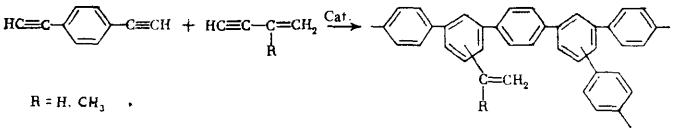
(V) (VI) (VII)

may be formed during cyclotrimerisation[51]. Group (V) arises from the interaction of one monofunctional and two difunctional molecules, and results in a linear polymer. Actually, however, groups (VI) and (VII) may also be formed, and give rise respectively to branched polymers and chain termination. Each of the groupings may in turn contain 1,2, 4- and 1,3,5-substituted aromatic rings. Two mathematical models have been suggested for theoretical calculation of the probability of formation of a particular structure at various stages of polycyclotrimerisation, and these establish foundations for conducting the process under optimum conditions and obtaining polyphenylenes having specified properties[51].

Furthermore, the statistics of branching processes based on the cascade theory has been applied[54] to the polycyclotrimerisation of *p*-diethynylbenzene and its copolycyclotrimerisation with phenylacetylene on the hypothesis of equal and constant reactivity of the ethynyl groups, with the aim of determining the degree of conversion at the point of gel formation and the mean molecular weights under random reaction conditions. The statistical estimations for the diyne indicated that the gelation point is determined by the condition $\alpha_{cr} = 0.5$: i.e. the critical degree of conversion of ethynyl groups is in this case 0.5, as for the random polycondensation of a trifunctional polymer. The values of α_{cr} calculated for the copolycyclotrimerisation increased from 0.5 to 1 with increase in the proportion of phenylacetylene in the initial mixture from 0 to 2 moles per mole of *p*-diethynylbenzene.

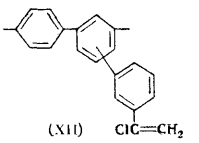
The possibility of controlling polycyclotrimerisation at the gel point, at which formation of a three-dimensional network begins, has been confirmed experimentally[54], and the reactivity of the ethynyl groups is shown to diminish during the reaction, probably owing to slow diffusion or steric hindrance. In discussing the properties of the resulting polyphenylenes, however, the authors unfortunately do not consider such an effect of polyenisation processes, which in some measure govern the formation of polymer molecules and their properties.

Study of the polymerisation of *o*-diethynylbenzene in the presence of various catalysts has established[55], that, in contrast to the behaviour of the *para*- and *meta*-isomers, 30–50% of the second ethynyl groups are not involved in coordination polymerisation in the presence of the catalytic systems $R_nAlCl_{3-n}-(TiCl_4)_n$ and $R_nAlCl_{3-n}.(C_5H_7O_2)_3Ti$ (where n = 1,2, or 3), 70% of these groups remain uninvolved in radical polymerisation in the presence of azoisobutyronitrile, and only one ethynyl group in the *o*-diethynylbenzene molecule reacts in cationic polymerisation in the presence of titanium tetrachloride. From these results it is assumed that polymers containing groupings of the types



(VIII) (IX) (X) (XI)

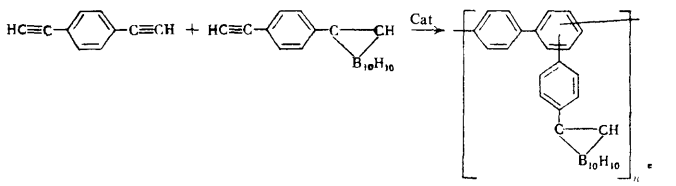
may be formed from the *ortho*-isomer. Methyleneindane and naphthalene cyclic structures can be formed only in the presence of catalysts for coordination or radical polymerisation. However, a study of molecular models indicates[55] that formation of the six-membered cyclic structures (X) and (XI) is sterically more probable than the successive arrangement of five-membered structures (IX) in a chain, although formation of the latter is not excluded by the mechanism.



Reports have appeared[56–60] on the synthesis of branched oligophenylenes from *p*-diethynylbenzene and butadiyne or certain other monoacetylenes by polycyclotrimerisation in the presence of $(iso\text{-}C_4H_9)_3Al-(TiCl_4)_n$ (Al : Ti = 3 : 1). Polycyclotrimerisation of butadiyne or its mixture with phenylacetylene[57] gives branched oligophenylenes readily processed by hot moulding into infusible and insoluble polymeric materials distinguished by high thermal stability. This method of obtaining polyphenylenes is of definite practical interest, since butadiyne, in contrast to *p*-diethynylbenzene, is a by-product in the production of acetylene by the pyrolysis of hydrocarbon raw materials. Copolycyclotrimerisation of *p*-diethynylbenzene with hex-1-yne gives copolymers whose content of triple bonds diminishes with

increase in the proportion of the latter monomer[59]. Oligophenylenes containing free double bonds have been obtained[56] by partial or complete substitution of an alkenylacetylene—butenyne or 2-methylbutenyne—for phenylacetylene in its reaction with *p*-diethynylbenzene:

Increase in the quantity of unsaturated groups in such oligophenylenes increases their tendency to set, and plastometric tests reveal no deformation changes in hardened *p*-diethynylbenzene–2-methylbutenyne specimens even at 400°C and above, which indicates the high density of cross-linking and the enhanced thermal stability of such specimens.



Oligophenylenes containing chlorovinyl groups

(XII)

have been obtained[60] from a mixture of *p*-diethynylbenzene, phenylacetylene, and *m*-ethynyl-1-chlorovinylbenzene. These groups not only increase the unsaturation of the resulting oligophenylenes but also confer on the polyphenylenes greater thermal stability than in the absence of this third monomer. Phenylacetylene is found to be more active than the chlorovinylethynylbenzene in polycyclotrimerisation.

Results of the model reaction of *p*-*o*'-dicarbadodecaboranylphenylacetylene in the presence of $(iso\text{-}C_4H_9)_3Al-(TiCl_4)_n$ and $NiCl_2.2(C_6H_5)_3P.2NaBH_4$, with the separation of *tris*-*p*-*o*'-dicarbaboranylphenylbenzene, suggested[58] that copolycyclotrimerisation of the former compound with *p*-diethynylbenzene could follow the scheme

Equimolecular proportions of the initial monomers gave a 75% yield of completely soluble copolymers having a boron content of 19%. They were amorphous yellow powders having M_n = 3350. With the aim of controlling the boron content in copolymers of *p*-diethynylbenzene, phenylacetylene, and *p*-*o*'-dicarbaboranylphenylacetylene in the molecular proportions 1 : 1 : 0.5 a 73% yield of a mixed copolymer having a boron content of 12% was obtained. Formation of an insoluble fraction in 20% yield was due to some inhibition of copolycyclotrimerisation of the components[58]. Thermogravimetric analysis under dynamic and isothermal conditions indicated that copolymers containing carbaboranes were highly resistant to thermal oxidation in air[58].

Polymers containing 1,2,4-substituted aromatic rings are obtained[61] by the polycyclotrimerisation of diethynyldiphenylsilane or its mixture with phenylacetylene in heptane solution in the presence of $(iso\text{-}C_4H_9)_3Al-(TiCl_4)_n$. Such polymers have smaller elastic moduli than have polyphenylenes obtained from *p*-diethynylbenzene. This is attributed to greater elasticity of the "hinge" bond in the silicon-containing polymer.

In conclusion it must be noted that a distinguishing feature of the polycyclotrimerisation of acetylenic compounds is the formation mainly of trisubstituted aromatic rings in the polymer structure[3]. The rigidity of a polymer molecule increases with the content of aromatic groups, while the polymer as a whole is characterised by high heat resistance and thermal stability[4,5]. Therefore polyphenylenes obtained by the copolycyclotrimerisation of diynes with monoynes are of definite practical interest, since they can readily be processed by the usual methods of chemical forming into articles that withstand high temperatures for a long time[30,36,51].

III. POLYCYCLOTRIMERISATION OF MONOMERS WITH MULTIPLE CARBON–NITROGEN BONDS

The polycyclotrimerisation of several compounds containing multiple carbon–nitrogen bonds was already known in the nineteenth century, but most research in this field has been undertaken during recent years. At the present time a number of cyanogen compounds—such as hydrocyanic acid, cyanogen chloride, cyanamide, acetone cyanohydrin, β-hydroxypropionitrile, acrylonitrile, etc.—are large-tonnage industrial products. Several 1,3,5-triazines (cyanuryl chloride, cyanuric acid, melamine, and their derivatives), obtained by the cyclotrimerisation and cyclocondensation of appropriate compounds, are also produced industrially on a large scale.

Research on the polycyclotrimerisation of monomers containing multiple carbon-nitrogen bonds has been widely developed only during the past decade in connection with the need for highly heat-resistant and thermostable polymers and composition materials for various branches of modern technology, especially for air and space travel. As already noted above, this method has several advantages over well known syntheses of thermostable polymers and is distinguished by the simplicity of its technical organisation, the availability of the starting materials, the absence of separation of secondary products, etc. A considerable number of publications have now appeared on the cyclotrimerisation and polycyclotrimerisation of monomers containing multiple carbon-nitrogen bonds, the synthesis and the properties of the polymers, the laws of their formation, etc.

We do not intend to discuss in detail all aspects of the problem, since several reviews have already been published in this field during recent years[3,4,7,62–66]. We shall consider recent studies of the polycyclotrimerisation of monomers with cleavage of multiple carbon–nitrogen bonds, e.g. in aliphatic, aromatic, and hetero-organic nitriles, cyanates, cyanamides, etc. Attention will be paid mainly to work on the mechanism, kinetics, and thermodynamics of polycyclotrimerisation, gel formation, the molecular weight characteristics of the polymers, the influence of the structure of the monomers on the properties of the polymers, and specific features of this synthesis of cross-linked polymers.

During recent years Korshak[7,67] has developed the concept of the heterounit character of polymers consequent on several secondary processes accompanying the main polymerisation reaction. Such structural "defectiveness" of a particular polymer leads in most cases to diminished heat resistance, thermal stability, physicomechanical indices, etc. For example, the polycyclotrimerisation of isocyanates, nitriles, and other monomers is accompanied by many secondary reactions (chain polymerisation,

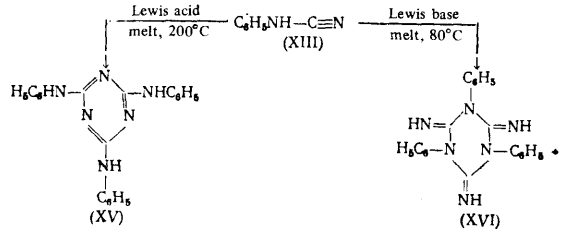
dimerisation, etc.)[3,4,7,67–79]. The production of polymers of almost perfect structure is therefore an urgent problem, whose solution will improve considerably many characteristics of the polymers and may lead to materials having qualitatively novel properties.

Recent papers by Korshak and his coworkers have shown that cyanates and cyanamides are potentially the most promising and convenient compounds for studying this new field in polymer chemistry[62,64,65]. These monomers are more reactive than nitriles, which makes them convenient for investigating the laws of polycyclotrimerisation. The cyclotrimerisation of cyanates and cyanamides, in contrast to that of isocyanates, is uncomplicated by dimerisation, carbodi-imidisation, or linear polymerisation, and these compounds are considerably less subject to hydrolysis of functional groups and are stable on storage. Furthermore, cyanates and cyanamides are non-toxic, and are less volatile than isocyanates [64,65]. They can be prepared simply, in high yields from readily available starting materials[64,66]. Their great synthetic possibilities have permitted the establishment of various systematic series of initial monomers and oligomers, detailed study of the influence of their structure on the properties of the resulting polymers, and formulation of principles governing the directed synthesis of networks having specified properties[62,64,65].

1. Laws of Polycyclotrimerisation

Research on the kinetics and mechanism of the cyclotrimerisation of nitriles has been discussed in detail in several reviews[3,4,62–65], and therefore will not be considered here.

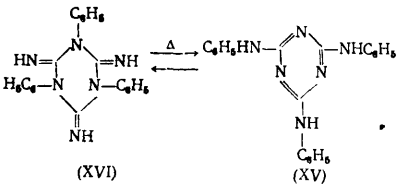
A series of papers of Korshak et al. [3,4,80–90] has been devoted to a detailed investigation of the kinetics and the mechanism of the cyclotrimerisation and polycyclotrimerisation of aryl cyanates. Since the polycyclotrimerisation of arylene dicyanates yields insoluble, infusible, highly cross-linked polymers, it is more convenient to use monofunctional cyanic esters for investigation of kinetics, heat of reaction, and also the effect of the structure of cyanic esters on reactivity. The cyclotrimerisation of phenyl cyanate into triphenyl cyanurate — a reaction that models the formation of a polymer by polycyclotrimerisation and is not complicated by such processes as gel formation, etc. — was studied first. The reaction was conducted in ditolylmethane solution in the presence of chromium acetylacetonate $(acac)_3Cr$, one of the most active catalysts for this process. The rate of cyclotrimerisation was measured by means of a double calorimeter from the quantity of heat evolved in a certain time. The reaction was found to be autocatalytic[81–90]. The heat of cyclotrimerisation of phenyl cyanate is -27.9 ± 1.4 kcal mole^{-1}. The energy of stabilisation of the 1,3,5-triazine ring has also been estimated (as 26 kcal mole^{-1}); this ring is stabilised both by delocalisation of electrons with formation of a system analogous to the π system of the benzene ring and also by partial polarisation of a cyclic nitrogen–carbon bond[81].



The kinetics of the conversion of various substituted aryl cyanates have been studied and the enthalpies measured to ascertain the effect of the structure of cyanic esters on their reactivity and the heat of cyclotrimerisation[89]. The nature of substituents has a significant influence on the rate. Thus electron-donor substituents (*p*-methoxyl, *p*-methyl) lower the rate of cyclotrimerisation, whereas electron-accepting substituents (*p*-chloro) increase it in comparison with that of unsubstituted phenyl cyanate. The maximum rate, the time of its achievement, and the heat of reaction are linear functions of the σ constants of the substituents[89].

Direct calorimetry has been used[83–86,88,90], under conditions analogous to those of the model reactions, to make a more thorough kinetic study and measure the heat of the polycyclotrimerisation of di-2-*p*-cyanatophenylpropane. The kinetic features are mainly the same as in the cyclotrimerisation of phenyl cyanates. The mean heat of polycyclotrimerisation of the dicyanate is $\Delta H = -56.8$ kcal mole^{-1}, i.e. 28.4 kcal mole^{-1} per N:C.O group. The close agreement between this value and the above heat of cyclotrimerisation of phenyl cyanate (−27.9) confirms the great selectivity of the polycyclotrimerisation of arylene dicyanates[83,84].

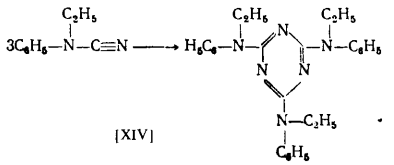
The rate of polycyclotrimerisation of di-2-*p*-cyanatophenylpropane, the heat of reaction, and also the effective activation energy depend on the nature of the solvent[88]. The solvents used can be arranged in the sequence ditolylmethane > nitrobenzene > anisole > diglyme in which the rate falls. Both physical and specific solvation of the arylene dicyanate by solvent molecules are responsible for the decreased rate and heat of polycyclotrimerisation[88]. Bonetskaya et al. [83,85,86] have found that the presence of water in the system has an appreciable effect on the rate. Gas–liquid chromatography reveals traces of pentane-2,4-dione after the reaction mass has been thermostatted at 140°C. The reaction velocity is increased by the addition of water, but diminished by that of the pentanedione. These results suggest[86,90] that an active form of the catalyst is formed by the action of water, and is present in equilibrium with the main form.



The kinetic features of the polycyclotrimerisation of arylene dicyanates established in the above studies reduce essentially to the following points. The process has a clearly defined autocatalytic character. Independently of the concentrations of catalyst and monomer, the maximum rate is observed at a definite extent of conversion (~40%) of the dicyanate. The maximum rate is proportional to the square root of the product of the concentrations of the catalyst and water, and varies linearly with the concentration of the arylene dicyanate. Addition of small quantities of pentane-2,4-dione in addition to the chromium acetylacetonate catalyst decreases the maximum rate, while the time of achievement of this maximum is sharply increased. In the absence of a catalyst additions of the final reaction products (triphenyl cyanurate or a polymer) do not catalyse the reaction[81,83–86,90].

Korshak et al. have made a series of studies[91–97] of the polycyclotrimerisation of cyanamides, another type of hetero-substituted nitriles. Phenylcyanamide (XIII) and *N*-ethylphenylcyanamide (XIV) were first chosen as model compounds. Either normal triphenylmelamine (XV) or triphenylisomelamine (XVI) could be formed depending on the conditions of cyclotrimerisation[91,92,94]:

Thus the cyclotrimerisation of (XIII) in the melt under mild conditions (20–80°C) gives (XVI), whereas at 200°C



the main product is (XV). Hydrolysis of the isomeric products (XVI) and (XV) gave high yields respectively of triphenyl isocyanurate and cyanuric acid[91,92,94]. Study of the effect of temperature on the isomers showed that structure (XV) remains unchanged until it decomposes (above 400°C), whereas (XVI) isomerises into (XV) at temperatures above its melting point (185°C)[91,94]:

(XVI) (XV)

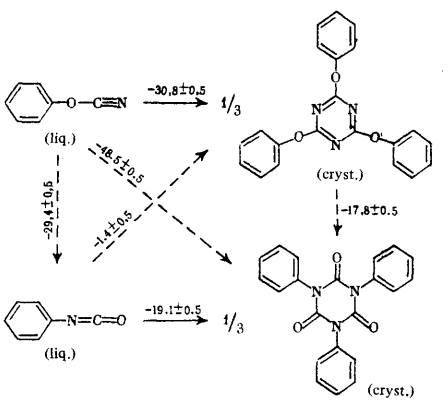
Isomerisation of (XVI) into (XV) takes place at considerably lower temperatures in solution. The normal melamine structure is more stable than the isomelamine structure at high temperatures, so that it is of greater interest for the development of thermostable polymers[91]. Korshak et al.[91,92,95,96] have investigated the action of various catalysts with the aim of directing the cyclotrimerisation of *N*-monosubstituted cyanamides to give a definite isomeric structure. They find that the formation of triphenylmelamine (XV) is favoured by catalysts such as Lewis acids (metal chlorides), but that of triphenylisomelamine (XVI) by Lewis bases.

To ascertain the effect of a substituent in the cyanamide group on the reactivity of an arylcyanamide and on the structure of the products the same workers have studied[93,94,96,97] the cyclotrimerisation of *N*-ethylphenylcyanamide (XIV)

[XIV]

The presence of the aliphatic substituent α to the nitrile group diminishes the reactivity of the cyanamide group, so that the process occurs only in the presence of such catalysts as Lewis acids. A substituted melamine of normal structure is formed: the iso-structure was not detected among the reaction products[94]. The above features of *N*-mono- and *NN*-di-substituted cyanamides and of the products of their cyclotrimerisation must be taken into account in preparing polymers from cyanamides and examining their properties.

Korshak et al.[93,94] have studied the polycyclotrimerisation of primary and secondary *N*-substituted biscyanamides. The highly reactive di-*p*-cyanamidophenylmethane begins to polymerise below its melting point of 162°C. Heating at 100°C for 2 h leads to 43% conversion. The rate of polycyclotrimerisation increases sharply at temperatures above the melting point, and at 180°C, for example, conversion reaches 87% after 30 min. As in the case of the model compound phenylcyanamide, two isomeric polymelamine structures can be formed depending on the temperature of polycyclotrimerisation of the biscyanamide: at 100 and 140°C, i.e. at temperatures below the melting point of di-*p*-cyanamidophenylmethane, the process results in formation of a polymer predominantly of isomelamine structure; at 180°C and above, i.e. above the melting point of the monomer, the main product is a polymer having the normal melamine structure[94].



Di-*p*-*N*-methyl(and ethyl)cyanamidophenylmethane have been used as examples for kinetic study of the polycyclotrimerisation of secondary *N*-substituted cyanamides. As with the model compound (*N*-ethyl-*N*-phenylcyanamide) the presence of aliphatic substituents α to the nitrile group diminishes the reactivity of the cyanamide group in comparison with primary *N*-substituted cyanamides. Such compounds undergo polycyclotrimerisation in the presence of cationic catalysts such as Lewis acids, but hardly at all in the absence of catalysts under the same temperature conditions. An isomelamine structure was not detected[94] among the products of the polycyclotrimerisation of secondary *N*-substituted biscyanamides.

2. Thermodynamic Parameters of Cyclotrimerisation and Polycyclotrimerisation

Study of the thermodynamic parameters helps to elucidate the conditions under which polycyclotrimerisation is possible and is reversible, and will give information on the temperature range of thermodynamic stability, structural features of the resulting polymers, the relative stability of isomeric compounds, the possibility of their isomerisation, and other important aspects of the process.

Thermodynamic characteristics of the polycyclotrimerisation of dicyanates have been studied in greatest detail on di-2-*p*-cyanatophenylpropane[98]. Measurements have been made on the temperature dependence of the heat capacity of the polymer and of the initial dicyanate, as well as the enthalpies of combustion of these compounds. Calculations of enthalpy, entropy, and Gibbs free energy have been made for polycyclotrimerisation of the dicyanate into a regularly cross-linked amorphous polymer. Within the limits of experimental error the enthalpy of polymerisation $-\Delta H_{pol}$ found at 420 K coincides with the value determined by direct calorimetry (respectively 53.2 and 56.8 kcal mole^{-1}), which yet again confirms the unidirectional character of the polycyclotrimerisation of arylene dicyanates[98].

Great interest attaches to comparative estimates of the thermodynamic parameters of the cyclotrimerisation and polycyclotrimerisation of isomeric esters of cyanic acid—cyanates and isocyanates — into corresponding isomeric derivatives of cyanuric acid[99]. Because of the complexity of the investigation of cross-linked systems and the occurrence of numerous secondary processes accompanying the polycyclotrimerisation of di-isocyanates it is more convenient to examine model compounds (phenyl cyanate and isocyanate) and their trimers (triphenyl cyanurate and isocyanurate). Enthalpies of combustion of these compounds have been determined[99], and enthalpies calculated for cyclotrimerisation

and the hypothetical reactions indicated by the broken

arrows. Here the arrows indicate the directions of exothermic reactions and the numerals thereon their enthalpies (in kcal mole^{-1}) for the given physical states. Inspection of the values for the hypothetical isomerisations shows that the iso-form is considerably more stable than the normal form in both monomers and trimers. The validity of this conclusion, based on calculated values, is confirmed by published information on the isomerisation of aliphatic cyanates and alkyl cyanurates into high yields of the corresponding isocyanates and alkyl isocyanurates[64,73,100]. Despite the greater thermodynamic stability of the iso-form of the initial compounds and trimers, however, aromatic cyanates and cyanurates do not isomerise, and conditions have not yet been found which would permit such reactions[64,73,100].

A comparative thermodynamic study has been made not only on model compounds but also on di-isocyanates isomeric with arylene dicyanates[99]. The enthalpy of polycyclotrimerisation of di-*p*-isocyanatophenylmethane (-24 kcal mole^{-1}) was rather more than half the value for the dicyanate. The decrease in entropy accompanying polymerisation both of the dicyanate and of the di-isocyanate is ~36 e.u., exceeding by about 30% the value of linear polymerisation. This is a feature of polycyclotrimerisation resulting in the formation of regularly cross-linked polymers[99].

For the polycyclotrimerisation of di-2-cyanatophenylpropane over the range 100–420 K both ΔH_{pol}^0 and ΔS_{pol}^0 are negative[98]. The upper temperature limit to polymerisation of this dicyanate is 1480 K, much higher than the temperatures at which thermal decomposition of monomer and polymer begins. (Below 1480 K there is no thermodynamic hindrance to conversion of monomer into polymer, but above this temperature formation of the polymer is impossible). The absolute values of the Gibbs free energy show that the polycyclotrimerisation equilibrium for dicyanate and di-isocyanate ($-\Delta G_{pol}^0$ respectively 40.3 and 19.1 kcal mole^{-1}) is almost completely displaced towards formation of the polymer[98,99].

3. Gel Formation and Molecular Weight Characteristics in Polycyclotrimerisation

The investigation of gel formation and molecular-weight characteristics is a key to understanding the formation of three-dimensional structures. Knowledge of these processes will in turn enable the direction of the reaction to be controlled both in the initial stage of oligomerisation and following the gel point, and also polymers to be produced having a definite topological structure and thus their physicochemical and thermal properties to be influenced. Polycyclotrimerisation is a fundamentally new method for synthesising three-dimensional polymers, which enables networks of regular chemical structure to be built with segments of strictly specified size M_c between cross-links. Such systems are ideal models for experimental investigation of gel formation.

Korshak et al.[101–103] have used aromatic dicyanates and the isomeric di-isocyanates to make a detailed investigation of the influence on gel formation of such factors as method of synthesis, nature of solvent, catalyst, and monomer, and also monomer and catalyst concentrations. Di-2-*p*-cyanatophenylpropane and di-*p*-isocyanatophenylmethane were used as initial monomers. The gel point and the dependence of yield of gel on degree of conversion are governed by the method of synthesis and the solvent employed. The type of catalyst affects these parameters only in certain solvents[101].

The influence of monomer concentration on the character of gel formation depends on the nature of the solvent. With decrease in concentration in a "good" solvent (nitrobenzene, chlorobenzene) the conversion at the gel point increases, whereas in a "bad" solvent (ditolylmethane) the dependence is "anomalous", i.e. the conversion at the gel point diminishes[101].

No appreciable effect of temperature on gel formation was observed. On polycyclotrimerisation in the mass of either of the above monomers the main parameters of gel formation were unaffected by nature or concentration of the catalyst[102].

The close agreement of several of the main rules of gel formation in the polycyclotrimerisation of dicyanates and of di-isocyanates, i.e. of different classes of monomers, together with investigation of the molecular weight characteristics during the reaction up to the gel point and the sol fraction after this point, has enabled general ideas to be formulated on the construction of a topological gel structure in this method of synthesising cross-linked polymers[102,103]. Comparison of the experimental results [102] with the theory of gel formation developed for polycyclotrimerisation reveals close agreement in several cases. Differences existing between calculated and experimental values are explained by the fact that the theory ignores the macrocyclisation resulting from the considerable branching of the macromolecules[102,103].

Traditional methods of synthesising cross-linked polymers from monomers, oligomers, or polyfunctional polymers are complicated by such factors as differences in reactivity between functional groups not leading to branching, a difficultly controllable distribution among molecular weights and types of functionality for initial oligomers and polymers, and many others. All this makes it difficult to synthesise cross-linked polymers having a chemically regular structure. Polycyclotrimerisation eliminates most of these disadvantages and enables polymers to be obtained that are regularly cross-linked at a molecular level. In this method of synthesis the entry of each functional group into reaction is accompanied by branching of the macromolecule, except for the "loss" of functional groups on macrocyclisation.

The detailed investigation of gel formation and molecular weight characteristics made by Korshak and his coworkers[101–103] has shown that macrocyclisation can be controlled by varying the reaction conditions. This in turn affects the topological structure of the resulting polymers. The possibility of acting at a higher (than molecular) level of structural organisation of the networks opens up great prospects for controlling the physical properties of cross-linked polymers by changing their topology.

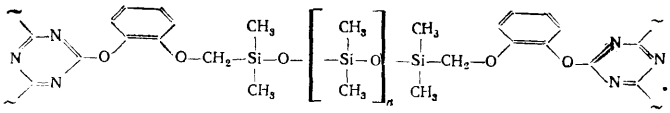
4. Structure and Properties of Polymers obtained by Polycyclotrimerisation

The main types of monomers that have been widely investigated in polycyclotrimerisation are isocyanates, nitriles, cyanates, and cyanamides. Many papers have been published on the cyclotrimerisation and polycyclotrimerisation of isocyanates, and the results have been summarised in several exhaustive reviews[3,4,68–75,77–79]. Discussion of the polycyclotrimerisation of monomers of this type lies outside the scope of the present Review; we note merely that several interesting studies have recently appeared on

the mechanism of the cyclotrimerisation of isocyanates[104,105]. However, polycyclotrimerisation of isocyanates with formation of cross-linked structures has been little studied, and published views on its mechanism are often contradictory[3,4,68–75,77–79,106–111].

Most of the information on polymers based on isocyanates comes from the patent literature, from which in most cases it is difficult to assess the structure of the polymers or the presence of secondary structures. Among the known groups of compounds that form cyclotrimers isocyanates are most likely to undergo various secondary reactions—dimerisation, carbodi-imidisation, linear polymerisation, chain termination by hydrolysis of isocyanato-groups, etc.—accompanying cyclotrimerisation. The occurrence of these numerous secondary processes, which are extremely difficult to eliminate, is the main hindrance to investigation of the polycyclotrimerisation of isocyanates and a correct interpretation of the results in relation to the reaction mechanism and the structure of the resulting cross-linked polymers.

Nitriles are usually unreactive in comparison with isocyanates, and their polycyclotrimerisation requires severe conditions (high temperatures, pressures, catalyst contents, etc.), which hinders their processing into articles. A considerable content of catalysts (usually highly active compounds) in the cross-linked polymer also affects adversely the thermal stability and other properties of materials obtained from such polymers[3,4,7,62,63,65]. Furthermore, the cyclotrimerisation of nitriles may be accompanied by several secondary processes—linear polymerisation of cyano-groups with formation of azomethine structures, chain termination by various reactions of nitrile groups in the presence of a high content of catalytic systems, formation of cyclic products by aliphatic nitriles, etc.—especially under severe conditions. The presence in such polymers of various "defect" structures makes difficult the formation of a chemically regular network, which in turn diminishes their thermal and physicochemical characteristics[3,4,7,62,63,65]. In the Reviewers' opinion necessary conditions for overcoming these disadvanatages of the synthesis of cross-linked polymers by the polycyclotrimerisation of nitriles are— the discovery of highly active catalysts for polycyclotrimerisation, development of convenient and cheap methods for obtaining the initial monomers, and also synthesis of nitriles containing electron-accepting groups to strengthen polarisation of the N⋮C bonds.



Korshak and his coworkers[3,4,62,64,65,80–99,101–103] have shown that, in contrast to isocyanates and nitriles, cyanates and cyanamides undergo highly selective polycyclotrimerisation under certain conditions with almost quantitative conversion of functional groups. The resulting polycyanurates and polymelamines are highly cross-linked heterochain polymers with 1,3, 5-triazine rings as branch points separated by segments of aromatic and heterorganic diols, glycols, and diamines[80–99,101–103,112–152]. Such polymers, especially those having highly cross-linked aromatic structures, were not known previously. In contrast to randomly cross-linked systems, polymers having a chemically regular network should exhibit a qualitative change in several properties of cross-linked polymers. Thus polycyanurates surpass in heat resistance and thermal stability the similarly constructed polyisocyanurates obtained from di-isocyanates, although the study of model compounds shows that the isocyanurate ring is thermally more stable than the cyanurate ring[73,74,113,118,120]. The presence of numerous "defect" structures—urea groups, linear structures, dimers, etc.—probably has a considerable influence on the thermal stability of polymers obtained by the cyclotrimerisation of di-isocyanates. In contrast to all known highly cross-linked aromatic polymers block polycyanurate specimens have abnormally high specific impact resistance (up to 30 kgf cm^{-1} cm^{-2}) and are distinguished by good physicochemical indices both at room temperature and at high temperatures[112,113,122].

In order to ascertain the causes of the unusual mechanical properties of polycyanurates electron microscopy has been used to monitor the formation of a supermolecular structure at various stages of synthesis[123]. The product of the early stages of polycyclotrimerisation has a globular structure, and then aggregation of the globules is observed, leading in the final stage (on 98% conversion of cyanato-groups) to fibrillar organisations. Parallel with the investigation of the super molecular structure of polycyanurates a study was made of the relaxation properties of the solid networks formed at various stages of conversion of the cyanato-groups of the initial monomer (di-2-*p*-cyanatophenylpropane). With increase in the degree of conversion the relaxation curves first moved to higher stresses, but after ~90% conversion of the monomer they then began to move into the region of lower stresses. The results indicate that, as the polycyclotrimerisation of arylene dicyanates progresses, and hence the network becomes more regular, the character of the supermolecular structure changes from the simplest globular form to fibrillar structures, which in turn leads to a regular variation in the mechanical properties of the cross-linked systems, to diminished brittleness and enhanced elasticity[123]. Perhaps obtaining in the usual thermosetting systems a regular network free from defects might also yield polymeric materials of enhanced elasticity and impact resistance.

Another interesting feature of, regular highly cross-linked polymers obtained by the polycyclotrimerisation of monomers containing multiple carbon-nitrogen bonds is their ability to crystallise. Although crystalline cross-linked polymers had been known[153–158], they contained as segments M_S between cross-links flexible aliphatic and siloxane fragments with $M_S \geqslant 2000$, and their crystalline structure was completely analogous to that of the initial oligomers. Korshak et al.[124] have been the first to obtain highly cross-linked rigid-chain polymers (for a polycyanurate based on *p*-phenylene dicyanate $M_S = 108$) of completely different structure from that of the original crystalline monomer. A tendency to crystallise has been observed in several polycyanurates and polymelamines obtained from various aromatic dicyanates and biscyanamides[93,94,112,113]. The ability of polycyanurates to crystallise, like many other usual properties of these polymers, is a consequence of their regular structure resulting from highly selective cyclotrimerisation of the cyanato-groups in the initial monomers and almost complete quantitative polycyclotrimerisation of the dicyanates.

In order to assess the density of packing of macromolecules in cross-linked polymers and establish the influence of the chemical structure of the initial monomers Korshak et al.[122] have been the first to calculate packing coefficients for such systems. Values for cross-linked polymers of diverse structure are found to lie within the narrow limits 0.673–0.698, close to the mean value 0.681 for linear polymers[159]. An exception is provided by polycyanurates containing dimethylsiloxane segments of various lengths

between junction points of the network

These polymers have abnormally low packing coefficients K, which decrease as M_S increases, from 0.651 to 0.587 with increase in n from 0 to 100.[131,152] Special determination on these systems showed zero porosity, so that these abnormally low packing coefficients can be attributed to loose packing of the macromolecules of the organosilicon polycyanurates[131,152].

Control of the chemical nature and length of the network segments has permitted monitoring of the influence of these parameters on the properties of cross-linked polymers obtained by the polycyclotrimerisation of monomers containing multiple carbon–nitrogen bonds, which in turn has led to directed improvement of the heat resistance, thermal stability, and physicomechanical indices of polymeric materials.

Besides aromatic polycyanurates and polymelamines, polymers of this type have been synthesised from organofluorine, organoboron, and organosilicon monomers. The presence of perfluorinated segments between cross-links in the structure of polycyanurates leads to glass points from −40 to +350°C.[116,134] Such polymers can be used as thermostable films, adhesives, and elastomers possessing improved flame resistance[134].

Polymers containing carbaborane fragments possess several unique properties, among which the most interesting is the high carbon residue at high temperatures (up to 1000°C), often with retention of definite strength properties[115,135,137,141,142,149]. Korshak, Andrianov, et al. have prepared organosilicon polycyanurates[127-131,145-147,152], which have glass points from −120 to +180°C depending on the length of the siloxane chain between the cross-links. These polymers possess high thermal stability with a wide temperature range of the hyperelastic state, from −120 to +340°C, i.e. up to the temperatures at which they begin to degrade[145-147,152].

The influence of the length of network segments on the properties of polycyanurates and polymelamines has been investigated also on the products of the polycyclotrimerisation of oligoarylates, oligo(arylene sulphones), and oligoamides with terminal cyanato- or cyanamido-groups[64,65].

A method based on the statistical theory of hyperelasticity has been used to examine the main parameters of the network structure of polymers obtained from oligodicyanates[131,152]. It involves measuring the stress relaxation at constant deformation on uniaxial extension of the polycyanurate films. The experimental number-average molecular masses and concentrations of active chains in unit volume of the cross-linked polymers are similar in magnitude to those calculated theoretically, which is evidence of selectivity of polycyclotrimerisation and quantitative conversion of the cyanato-groups of the oligodicyanates[131,152].

The size of the cross-linked segment influences also several other physicomechanical indices of the polycyanurates. Thus polymers containing dimethylsiloxane segments show a sharp increase in tensile strength and higher elastic moduli with increase in the frequency of cross-linking[131,152]. Enhancement of tensile, bending, and compressive strengths with increase in network frequency has been found also with polycyanurates containing aromatic oligoester segments[152].

In addition to the wide modification of properties of polycyanurates and polymelamines by the use of particular initial dicyanates and biscyanamides, several studies have shown that physicomechanical and thermal properties can be varied by synthesising copolymers of dicyanates and biscyanamides with monocyanates, nitriles, cyanamides, isocyanates, and acid anhydrides[64,65,94,117,125,126,133,134,138,151,152].

The very promising outlook for polycyclotrimerisation as a method for synthesising cross-linked systems having a regular chemical structure has been demonstrated by the combined study by Korshak and his collarborators[80-99, 101-103,112-152] of the synthesis of monomers and polymers and the physical properties of cross-linked systems obtained from monomers containing multiple carbon-nitrogen bonds. Thus several polycyanurates formed from aromatic and hetero-organic dicyanates possess high physicochemical indices, considerably surpassing in this respect most known highly cross-linked rigid-chain polymers[64,112,113,122]. The majority of cross-linked polymers obtained are characterised by high heat resistance and thermal stability: they begin to lose mass at about 400°C or above; and highly cross-linked systems do not soften right up to their decomposition temperature[64,65,93,94,112,113,119,122].

From the above account it may be concluded that polymers based on cyanates and cyanamides are of great practical interest. All the reagents required to prepare the initial monomers (phenolic diols, diamines, cyanogen chloride, triethylamine, acetone) are multitonnage industrial products. The monomers are obtained at temperatures of 0–20°C by technically simple processes. The yields of cyanates and cyanamides are close to theoretical. The products possess great stability, can be stored at room temperature for a long time, and are nontoxic. Their processing into goods via an oligomerisation stage is accomplished by gradually heating the initial monomers, does not require special equipment, and can be undertaken directly at the site at which the goods are obtained from the polymers[64,65]. Materials based on polycyanurates and polymelamines (adhesives, coatings, filled plastics, insulating compounds, etc.) possess excellent physicochemical properties and thermal stability[64,65,93,94,112,113,122,132-152].

Advances in the Production of Thermostable Antifrication Plastics

I.A.Gribova and O.V.Vinogradova

Methods of producing self-lubricating antifriction plastics are examined. Filling with a solid lubricant a polymeric binder that does not possess a low coefficient of friction when unfilled is a promising development. The principal physicochemical requirements to be met by a polymer to be used as a binder are formulated. Possible chemical changes undergone by the polymeric binder and the filler during friction are discussed. Published information on the effect of the chemical nature of the polymeric binder on the properties of antifriction materials is summarised. The Review concludes with 211 references.

IV. Properties of thermostable antifriction plastics 100

I. INTRODUCTION

Many polymeric antifriction materials are known that can be used in friction units. Polymeric materials are far more effective in their antifriction properties than are antifriction alloys[1-6], graphitic and oil-filled bronzes[7]. Polymeric antifriction materials are distinguished by the ease of production of articles, low specific gravity, good antifriction properties, and the possibility of modifying the properties of the polymers by simple technical operations. They can be applied to friction units in various ways—by coating a metal surface with a thin layer of the polymer, making parts from blocks of the polymer with and without fillers, or impregnating a porous metal base with the polymer[8].

Materials possessing antifriction properties now face increasingly severe demands—high heat resistance and thermal stability, vibration strength, radiation resistance, good machinability. They should ensure the functioning of friction units under extreme conditions—high and low temperatures (from +500 to −200°C), corrosive media, high vacua, great speeds, and high unit loads. The use of liquid lubricants under these conditions is ineffective.

The attention of investigators has therefore been attracted to multicomponent materials, in which the functions of structural material and lubricant are combined. The production of such materials having specified properties is an extremely complicated task. Account must be taken of the nature of the polymeric binder, the properties, composition, and quantity of fillers added, and also the chemical and physicochemical processes involved in interaction between polymer and fillers[9-15].

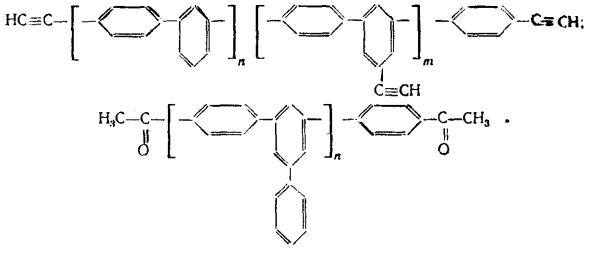
Numerous investigations have been made on the friction of solids, including polymeric antifriction materials, which have been summarised in monographs[16-28], proceedings of conferences[29-31], reviews[32-36], and individual papers[37-42]. However, this research has been concerned with problems of the mechanics, technology, and physical chemistry of filled systems. Considerably less attention has been paid to chemical aspects of the production of antifriction plastics.

The present Review examines the influence of the chemical nature of the polymeric binder on the properties of antifriction materials, and also on the chemical and physicochemical changes undergone by the components during friction.

II. PRODUCTION OF THERMOSTABLE SELF-LUBRICATING ANTIFRICTION PLASTICS

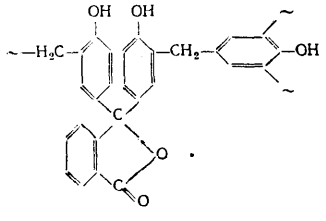
Self-lubricating antifriction plastics can be obtained in two fundamentally different ways. A method widely discussed in the literature is to produce materials based on polytetrafluoroethylene[21,43-52], Thiokols[53,54], and other polymers possessing good lubricating properties and low coefficients of friction (~0.1). In this case the lubricating principle is the polymer itself, while the introduction of fillers merely improves its physicomechanical properties—by enhancing thermal conductivity, wear resistance, hardness, strength, and heat resistance, and by diminishing cold flow.

The second method is to obtain materials based on polymers having a comparatively high coefficient of friction (0.1–0.5). Such polymers include polyhydrocarbons, halogenated polyhydrocarbons, polyamides, polyesters, polyurethanes, phenolic resins, etc. Solid or liquid lubricants are generally included in the composition of such polymers for use in dry friction units. This process was made possible by research on highly filled polymers undertaken during 1949–1950 by Rebinder and his school[55,56]. This second method is most promising, since it opens up wide opportunities of purposeful searching for binders among a large number of known and new polymers.



In order to solve the problem of producing the heat-resistant and thermostable self-lubricating antifriction plastics required by modern technology a broad research programme on filled antifriction polymer systems has been followed under the direction of V. V. Korshak in the Institute of Hetero-organic Compounds of the USSR Academy of Sciences. These investigations included study of the influence of the chemical structure of the polymers, their physical structure, and also the chemical nature of the filler and the strength of polymer–filler bonding on the properties of the antifriction plastics, study of the behaviour of filled systems during friction at high temperatures, as well as aspects of structure formation and the synthesis of network polymers in the presence of fillers under processing conditions, and study of the properties and the stabilisation of filled polymers.

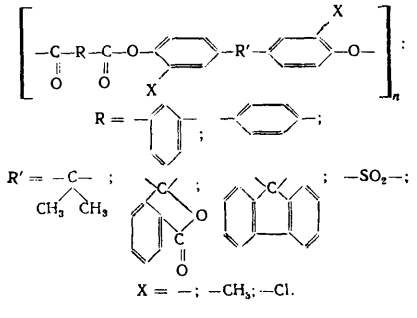
Advances made in the synthesis of thermostable polymers, establishment of the relation between the chemical



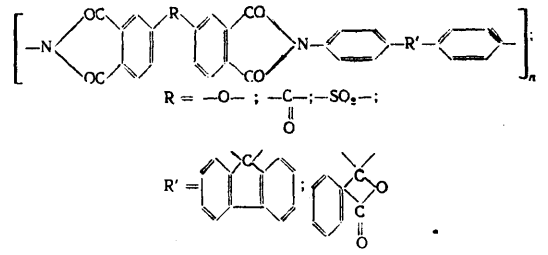
structure of polymers and their properties, and the hetero-unit character of polymers have offered wide opportunities for the production of antifriction plastics[57–59]. Both thermoplastic and thermosetting polymers of diverse chemical structure have been used as binders in the development of self-lubricating antifriction plastics. Choice has concentrated mainly on members (see List) of new classes of thermostable rigid-chain organic and hetero-organic polymers containing rings in the chain, bulky side-groups, hetero-groups, cross-links (such polymers include polyphenylenes, phenolphthalein–phenol–formaldehyde polymers, polyarylates, polyimides, polybenzimidazoles, polybenzoxazoles, polyphenylquinoxalines, polyoxadiazoles, polycyanates, etc., as well as polymers containing boron, silicon, phosphorus, or sulphur). Korshak and his coworkers[60–67] have used these polymers to develop new thermostable antifriction materials possessing several valuable properties.

A. Carbon-chain Polymers

1. Polyphenylenes[65,88,91]

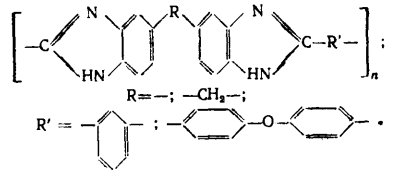


2. Phenolphthalein–phenol–formaldehyde polymers[66,70,82,91]

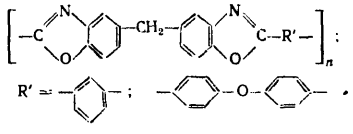


B. Heterochain Polymers

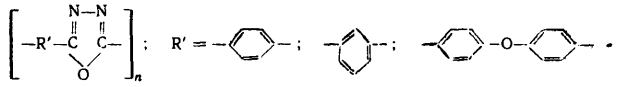
1. Polyarylates[71,72,81,82,91]



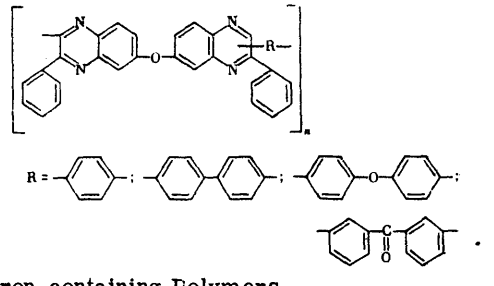
C. Heterocyclochain Polymers



1. Polyimides[71,74,82]

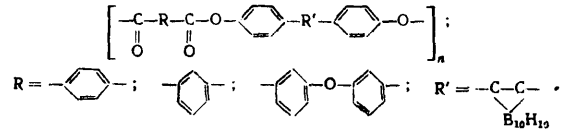


2. Polybenzimidazoles[73]

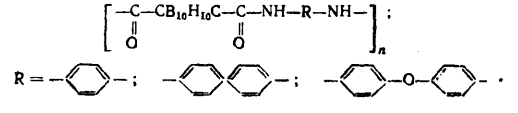


3. Polybenzoxazoles[91]

4. Polyoxadiazoles[60]

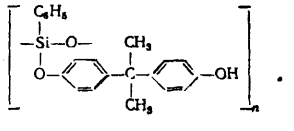


5. Polyphenylquinoxalines[74,79,87,90]

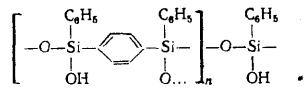


D. Boron-containing Polymers

1. Polyarylates[68,75,93–96]

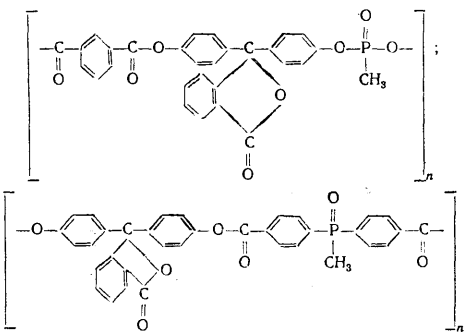


2. Polyamides[68,75,93–96]



E. Silicon-containing Polymers

1. Polymer B-1[63]



2. Polyphenylenephenylsiloxane[76,91]

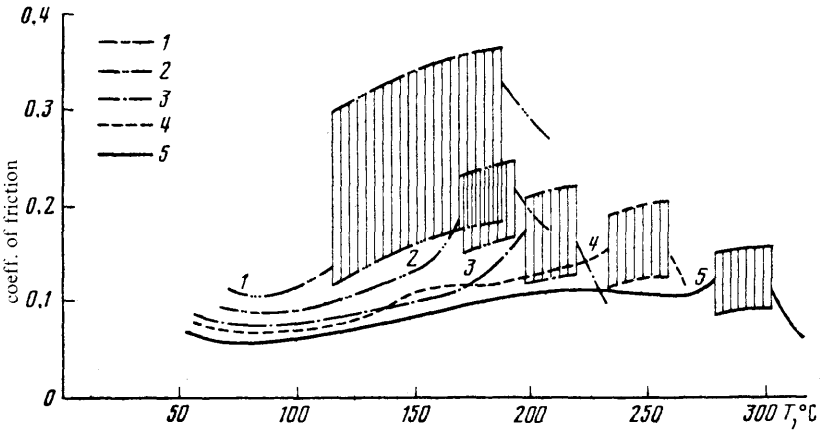
F. Phosphorus-containing Polymers

1. Polyesters[78,81,91]

Substantial attention was paid to the behaviour of filled polymer systems during friction at high temperatures and to revealing the role of the polymeric binder, since under these conditions the system undergoes considerable changes in physicomechanical and antifriction properties[80–86]. Studying the thermal friction properties of several thermostable polymers—polyarylates, polyimides, a phenolphthalein-phenol–formaldehyde polymer—filled with molybdenum disulphide, Korshak et al. have shown[81,82,91] that all the filled polymers have a common type of temperature dependence of the coefficient of friction characterised by several friction zones— respectively of minimum coefficient, increasing coefficient, unstable friction, and decreasing coefficient[82] (Figs. 1 and 2)— rapid growth in the coefficient being observed considerably below the glass point of the polymers.

Investigation over a wide temperature range of the relaxation and thermal cohesive properties of self-lubricating antifriction plastics based on polyarylates and polyimides has shown[82] that the temperature limits of variation in these properties coincide with the temperature boundaries of the friction zones. Analysis of the behaviour in thermal friction tests of many filled systems based on polymers of diverse chemical structure, study over a wide temperature range of the relaxation and thermal cohesive properties of the polymers, and determinations of molecular mass and intrinsic viscosity before and after tests under various conditions suggested to Korshak et al.[82] that the temperature variation of the coefficient of friction is governed largely by the structure and properties of the polymeric binder. On the basis of their results they formulated the main physicochemical requirements to be met by polymers used as binders in the development of thermostable antifriction plastics—high heat resistance, thermal stability, and resistance to thermal oxidation, and absence from the chemical and physical structure of such polymers of mobile fragments capable of passing into a labile state at temperatures below the limit of their heat resistance— which are largely satisfied by polymers whose chains contain rings, bulky side-groups, hetero-groups, polar bonds.

In the development of thermostable self-lubricating materials based on thermoplastic polymers close attention has been paid to the influence of the chemical structure of



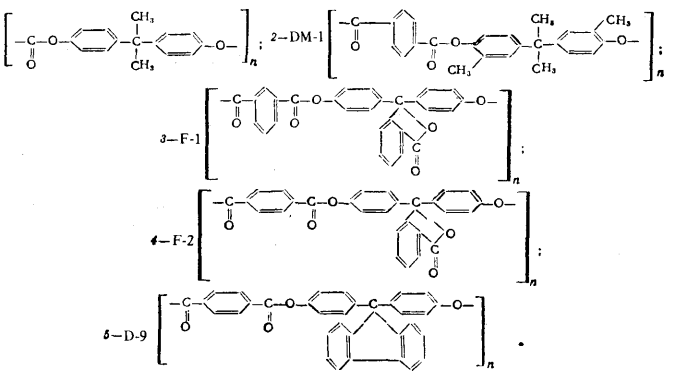


Figure 1. Thermal friction properties of self-lubricating antifriction plastics based on polyarylates of diverse chemical structure: *1*) Diflon.

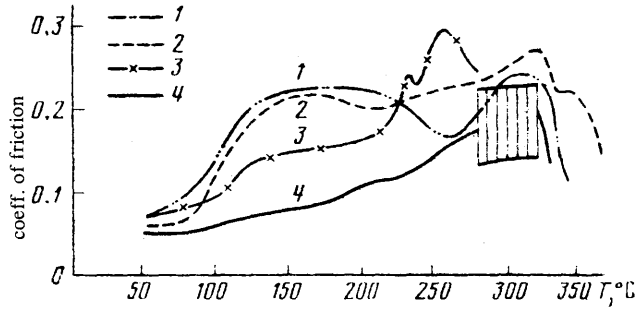
the monomer unit on the thermal friction properties of the filled systems. With polyarylates of diverse chemical structure as example Korshak et al. [81] have shown that the presence of card [large, planar] groups such as phthalide and fluorene tends to extend the temperature limits of the zone of stable and low coefficient of friction (Fig. 1). Isomerism between dicarboxylic acids (isophthalic and terephthalic acids were used) displaces the "seizing" zone by 30–50 deg to higher temperatures on passing from the *meta*- to the *para*-isomer. Intensifying interchain interaction in the polyarylate macromolecule by introducing polar substituents (chloro) into the aromatic ring system of a diol increases the coefficient of friction of the materials throughout the temperature range. The results indicate that the temperature limits of effective application of self-lubricating antifriction plastics are extended with increase in the rigidity of the polyarylate macromolecules due to increase in the number of aromatic rings, to the presence of card groups[81].

A factor tending to diminish the mobility of the polymer chains is the presence of fused ring systems (benzoxazole, benzimidazole, pyromellitimide) in the monomer unit, which leads to a considerable increase in the heat resistance of polymers. In such polymers the heat resistance usually surpasses the thermal stability, so that in most cases they do not melt, which hinders their processing[58]. In several cases introduction into the chain of mobile units — "hinge" heteroatoms (oxygen, sulphur) bulky substituents, or such hetero-groups as carbonyl and sulphonyl — yields polymers possessing quite high heat resistance while capable of softening below the decomposition point. Fig. 2 illustrates results of thermal friction tests on self-lubricating antifriction plastics based on polyimides containing such "hinge" hetero-groups and -atoms. Comparison of Fig. 1 and 2 shows that such plastics posses higher coefficients of friction than those based on polyarylates, owing to the strong intermolecular interaction of the polymer chains[81,82,91]. The chemical nature of the "hinge" hetero-atom or -group in the monomer unit in the polyimide has a significant influence on the thermal friction properties. Thus the introduction of oxygen atoms into diamine and dianhydride components, by conferring enhanced flexibility on the polymer chain, increases the coefficient of friction and narrows the temperature limits of the zone of minimum coefficient. Increasing the rigidity of the polyimide chain by introducing bridging hetero-groups (carbonyl and sulphonyl) into the dianhydride component or bulky substituents into the diamine component increases the hardness of the material, lowers the coefficient of friction, and extends the temperature limits of the friction zones.

The mobility of the chains can be diminished also by the formation of cross-linked structures. The possibility has been investigated of forming network polymer structures from oligomers (reactophenes, acephenes, phenol-formaldehyde oligomers)[65,66,70,88], from polymers (polyphenylquinoxalines, polyimides)[82,89–91] in the presence of fillers. Korshak et al.[66,82] have shown for a self-lubricating antifriction plastic based on a phenolphthalein–phenol–formaldehyde polymer (FF-40) that the coefficient of friction increases, while wear diminishes, with increase in the degree of hardening of the polymer. The start of the increase in the coefficient at moderate temperatures (~80°C) and within a narrow temperature range (80–90°C) was attributed[66] to the peculiar structure of phenol–formaldehyde polymers, to the presence in the three-dimensional network of two types of junctions — chemical (stable) and physical (labile), formed by hydrogen bonds.



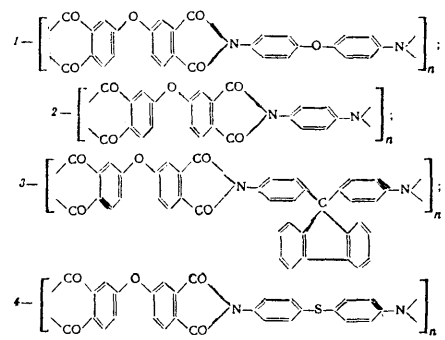


Figure 2. Thermal friction properties of self-lubricating antifriction plastics based on polyimides of diverse chemical structure:

Antifriction plastics based on a slightly hardened polymer exhibit unstable friction and an increase in the coefficient in the temperature range in which the material softens with increase in the thermal cohesive strength. Increase in the degree of hardening of a phenolphthalein–phenol–formaldehyde polymer is accompanied by increase in the viscosity of frictional contact in the zone of incipient softening. However, the cohesive bonding strength is still quite low, so that friction in this zone is stable in character[66].

The use of polymers capable of forming cross-lined structures during processing offers wide opportunities for obtaining new thermostable self-lubricating antifriction plastics with good physicomechanical properties. The possibility of forming a cross-linked structure by means of agents containing reactive groups (terephthalaldehyde, pyromellitonitrile, etc.) has been examined on polyphenylquinoxalines, which are cyclochain polymers; "self-cross-linking" polyphenylquinoxalines, which contain reactive carbonyl groups, have also been used for this purpose[89–91]. Materials based on cross-linked polymers possess a stable coefficient of friction and greater wear resistance at high temperatures.

Considerable attention has been paid to the effect of the chemical nature of the monomer unit in hetero-organic polymers on the antifriction properties[66]. Use of these polymers as binders is not only of theoretical but also of practical interest, since many of them possess high heat resistance and thermal stability, as well as several spe-

cific properties, i.e. incombustibility, radiation resistance, water repellency. The properties of the self-lubricating antifriction plastics are determined not only by the nature of the heteroatom but also by the conditions of formation of the filled system and the chemical structure of the monomer unit[81].

The use as binders of polymers containing carborane groups, which have a considerable effect on the behaviour of the polymers at high temperatures, is of great interest for the production of thermostable self-lubricating antifriction plastics[92–94]. Examination of polyamides and polyesters containing 1,2-, 1,7-, and 1,12-dicarbadodecaborane groups has shown[93–96] that at 400–500°C these polymers form "secondary" structures (pyropolycarboranes), which are thermostable, undeformable, cross-linked polymeric products. The structure and the properties of pyropolycarboranes depend on the method of synthesis, the isomerism of the carborane ring system, and its position in the monomer unit. The strongest tendency to form thermostable, undeformable pyropolycarboranes is exhibited by a polyamide containing 1,7-dicarborane and a polyester containing 1,2-dicarborane in the diol part of the macromolecule. Two types of filled antifriction materials—(*a*) thermoplastic, showing high wear resistance and thermal stability during friction (up to 350°C), and (*b*) cross-linked, undeformable and capable of operating under conditions of dry friction at 350–400°C— can be based on carborane-containing polymers. Korshak et al.[68,75] have used carborane-containing polyamides and polyesters with fillers to obtain new heat-resistant thermostable self-lubricating antifriction plastics that can be employed in dry friction units in the absence of a liquid lubricant up to 400°C. The decrease in the coefficient of friction at 300 to 400°C is largely due to the ability of carborane-containing polymers to evolve hydrogen at these temperatures[91].

Polymers containing silicon, phosphorus, or sulphur have been used to produce self-lubricating antifriction plastics[63,76,81]. Phosphorus-containing polymers and monomers possess the interesting property that filled systems can be stabilised and modified, which permits considerable extension of the temperature limits of application of the materials.

Great attention has been paid to establishing the relation between the chemical structure of a polymer and the wear resistance of filled systems based on it. Results obtained by Korshak et al.[81] show that the production of thermostable wear-resistant materials is a complicated problem, which cannot be solved merely by using more thermostable binders and fillers, since increasing the rigidity of the polymer chain leads to a considerable increase in the viscosity of the melt and raises the processing temperature right up to incipient thermal degradation of the polymer.

The physical structure of rigid-chain polymers, formed either during synthesis or on subsequent heat-treatment, has a significant influence on thermal friction properties. Korshak et al.[97] have examined polyarylates of different supermolecular structure filled with molybdenum disulphide, and have shown that, because of the greater elasticity and lower hardness of a polymer having a fibrillar structure, the coefficient of friction is higher for such specimens than in the case of a globular structure, throughout the temperature range. The depression of the operating temperature limits under friction conditions for a self-lubricating antifriction plastic based on a polyarylate having a fibrillar structure is due to the greater temperature sensitivity of the more complicated fibrillar supermolecular structures.

Investigation of the influence of supermolecular structure on thermal friction properties when poly-*m*-phenyleneisophthalamide (Phenylone) was used as binder[98] led to the development of novel antifriction plastics based on self-reinforcing polymers having the same chemical structure but differing in type of supermolecular structure, which resulted in an optimum combination of frictional and strength properties[72].

Belyi et al.[99–101] made widespread use of a tribometric method to study the influence of supermolecular structures on the friction of polymers and also to investigate self-lubricating compositions comprising polymers and dry lubricants. These studies make it possible to assess the mechanism of the friction of self-lubricating materials, and the influence of the components, their nature, dispersity, and physicomechanical properties on the frictional behaviour of a composition material.

Thus both the chemical structure of monomer unit and macromolecular chain and the physical structure of the polymers influence significantly the thermal friction properties of filled systems. At the same time the filler also has an important role in determining the structure and the properties of the systems: it should ensure not only good lubricating properties but also adequate strength of the materials[84,86,97,102,103]. The structure and the properties of a filled system depend on both the nature and the quantity of a filler. All materials of various degrees of filling can be divided into two groups with respect to their lubricating power[71,103]: the first comprises self-lubricating antifriction plastics containing at most 15–30% of polymer, which possess a low coefficient of friction (0.04–0.12) and high wear resistance; the second group of specimens, containing >15–30% of polymeric binder, is characterised by an unsteady régime in the case of dry friction and a high coefficient. The boundary of "self-lubricating power" depends on the chemical structure of the binder, and is displaced towards higher polymer contents with increase in the rigidity of the macromolecular chain. Within the limits of "self-lubricating power" all materials possess high wear resistance.

Table 1. Variation of molecular-mass characteristics of polyarylate F-1 during friction of self-lubricating antifriction plastics[138] (conditions of frictional contact: p = 2 kgf cm^{-2} and v = 2 m s^{-1}).

Medium	T, °C	F-1-MoS_2		F-1-MoS_2-Cu	
		M*	$[\eta]$ in C_2HCl_3	M	$[\eta]$ in C_2HCl_3
Argon	~50	14000 (44000)**	0.160 (0.284)**	34500 (27100)	0.356 (0.317)
Argon	120	17500	0.185	28500	0.295
Air	~50	23600 (44000)	0.165 (0.284)	29500 (24600)	0.300 (0.265)
Air	120	24000	0.40	66900	0.265

*Molecular masses M determined from the scattering of light.

**Initial values given in parentheses.

The fillers or solid lubricants[104] used have been molybdenum disulphide[105,106], graphite[107], tungsten disulphide[108], fluorinated graphite[109], metal sulphides[110], boron nitride[111], oxides of lead, molybdenum, cobalt, zinc, tin, copper, and

other metals, fluorides of metals, and other solid materials[112].

In the creation of multicomponent self-lubricating antifriction plastics account must be taken of the complicated chemical and physicochemical processes occurring in the polymeric binder, the fillers, and also the boundary layers in the contact zone between binder and fillers on formation of the filled system. The mechanical characteristics of filled polymers largely depend on the adhesion at the polymer–filler boundary[9,10,15,29,113,114]. The interfacial interaction has a special character[98], apparent in the orientation of thin polymer films along the faces of the filler crystals (molybdenum disulphide). These films are assumed to effect cohesion between the filler crystals. In some cases a film may be several micrometres thick even with a high filler content. The filler may have either a plasticising or a strengthening effect depending on its chemical nature and its content[83].

III. CHEMICAL REACTIONS OF POLYMERIC BINDER AND OF FILLER DURING FRICTION

Modern self-lubricating antifriction plastics are essentially filled multicomponent polymer systems in which solid lubricants are accompanied by various powdered fillers— metal powders, powdered coke, quartz, titanium dioxide, etc. — and also fibrous fillers (cellulosic, asbestos, etc.). During operation both individual components and the antifriction system as a whole undergo chemical and physicochemical changes. The operating temperature limits in friction units are determined both by the chemical structure of the polymeric binder, its heat-resistance and thermal stability, and by the nature of the filler, its dispersity, particle shape, activity towards the polymer, proportions of components, and several other factors[102].

The creation of new wear-resistant thermostable self-lubricating antifriction plastics is impossible without a detailed study of the behaviour of the initial components and the filled systems at high temperatures as well as during friction. Relatively little work has been done on the chemical and physicochemical changes occurring in filled polymer systems during friction at high temperatures: greater attention has been paid to the behaviour of pure polymers during friction.

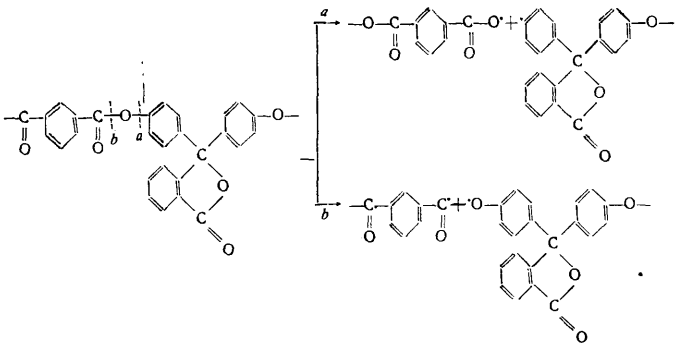
Study of the mechanism of frictional transfer during contact between a polymer and another polymer, a metal, or another material is of both scientific and practical importance[19,33,34]. During friction between a metal and a polymer the latter is transferred to the metal surface, on which it forms a monolayer[115]. Under heavy-duty conditions metal is transferred to the polymer[116,117]. Sviridenok et al.[118] have used an adhesion–deformation mechanism of frictional interaction of solids[16,25] as a basis for the investigation of transfer between polymers differing in adhesive power and cohesive strength, such as polytetrafluoroethylene, polyethylene, poly(methyl methacrylate), polyhexanamide, and poly(ethylene terephthalate). Adhesive power was assessed from the critical surface tension, which established three characteristic types of contact—non-polar–non-polar (polytetrafluoroethylene–polyethylene), non-polar–polar (polytetrafluoroethylene–poly(ethylene terephthalate), polyhexanamide), and polar–polar (poly(methyl methacrylate)–polyhexanamide). Infrared spectroscopy shows[118] that transfer takes place from a less polar to a more polar polymer, and is accompanied by breakdown of the initial material. At the same time changes occur in the surface layer of the other material. The nature of the interacting materials also has a significant influence on transfer. Thus, when a highly polar polyhexanamide film is used together with polytetrafluoroethylene, a strong, continuous layer of the latter 1 μm thick is formed on the film surface. Increase in the duration of contact and in the loading result in amorphisation of the material owing to breakdown of macromolecules in the surface layer. It is assumed that highly reactive radicals of the type CH_2. .C'H.NH.CO are formed during friction. Other workers have also noted the possibility of the occurrence of free-radical reactions in the course of frictional interaction[116,117].

In the region of contact, processes affecting the properties of the surface layers of the rubbing bodies take place under the influence of friction. In the case of a metal–polymer pair this applies both to the polymer and to the metal. At the site of contact an extremely thin third body is formed, with properties determined by the frictional conditions[23]. Its formation is due to coating of the harder body with a thin layer of the softer material, adsorption of a polar lubricant on the surface, formation of stable chemical compounds, etc.

The deformation and thermal processes accompanying the friction of polymers tend to promote tribochemical phenomena[119,120], complicated multistage processes involving activation of the rubbing surfaces by mechanical deformation (i.e. actually the supply and absorption of mechanical energy) and various physicochemical processes occurring under the influence of mechanical activation, which favour the conversion of mechanical into chemical energy[121]. Mechanochemical reactions occur in stages[117,121–124], involving changes of a morphological, supermolecular character (mechanical disaggregation) followed by changes at a molecular level (mechanical degradation), and such degradation leads to chemical reactions[125–127] determined by the polymer structure. Processes occurring under the influence of mechanochemical factors have been studied in polyamides[128–130], phenol–formaldehyde polymers[129], polyethylene[131–136], poly(ethylene sulphide)[132,133], polyformaldehyde[134], poly(ethylene oxide)[133,137], polystyrene[134–136], and poly(methyl methacrylate)[134–136].

Study of the behaviour of filled polymer systems during friction, especially at high temperatures, has established an interconnection between thermochemical and tribochemical reactions in the polymeric binder and in the filler system[138–142]. The friction of filled self-lubricating antifriction plastics entails formation of surface films of the antifriction material both on the surface of the specimen and on the steel counterbody, between which rubbing then occurs[82,138,139]. The character of the films depends on the conditions of frictional contact. X-Ray diffraction and local X-ray spectroscopy have established[139] that the surface films on the counterbody correspond in chemical composition with the antifriction material. Korshak et al.[139] have examined the behaviour during friction of a self-lubricating antifriction plastic based on a polyarylate, and have shown that the polymeric binder undergoes considerable chemical changes depending both on the conditions of frictional contact (atmosphere, temperature) and on the nature of the fillers. Table 1 shows that the friction in argon of an antifriction plastic comprising F-1 polyarylate (based on isophthalic acid and phenolphthalein) and molybdenum disulphide as filler entails a decrease in the molecular mass of the polymer and a proportionate decrease in the intrinsic viscosity (in comparison with the initial values), which indicates the occurrence of degradative processes in the polymeric binder. In an oxidising environment (friction in air) cross-linking degradative pro-

cesses occur in the polymer, leading to some branching of the macromolecular chains.



Linear wear on friction is less in argon than in air (Table 2), owing to oxidation of molybdenum disulphide in the latter with impairment of its lubricating properties, as well as mechanical degradation in the polymeric binder. Raising the temperature at the frictional contact intensifies mechanical degradation and diminishes wear resistance of a self-lubricating antifriction plastic comprising F-1 polyarylate and molybdenum disulphide. The presence of copper powder changes the character of the mechanical degradation processes on friction both in argon and in air. When the temperature at the frictional contact is 50° C, cross-linking degradative processes occur in the polyarylate leading to branching and some increase in length of the polymer chain. The wear resistance of the ternary system is greater in argon than in air. Raising the temperature to 120° C intensifies mechanical degradation on friction in air, owing to formation of a partly cross-linked structure. As a consequence the wear resistance of the antifriction material diminishes.

Table 2. Wear resistance of self-lubricating antifriction plastics based on polyarylate F-1 and various fillers[138].

Medium	T, °C	Linear wear, $10^9 I$*	
		F-1-MoS_2	F-1-MoS_2-Cu
Air	50	2.0	1.05
Air	120	3.8	2.2
Argon	50	1.5	0.5
Argon	120	2.7	1.2

*Ratio of height of layer worn away to friction path during surface friction.

Tribochemical reactions in a polyarylate filled with molybdenum disulphide are assumed to occur in argon according to the scheme[139–141]

Increase in the degree of branching of the polymer followed by cross-linking of the macromolecules may occur also as a consequence of cleavage of the lactone ring.

An antifriction filler undergoes considerable changes during the rubbing process, apparent in variation in particle size, some decrease in thermal stability, and chemical interaction with the contacting surfaces and accompanying fillers, which has a significant influence on the lubricating properties of the plastic systems[140]. Thus X-ray diffraction at room temperature has revealed the presence of ferrous sulphide in the surface film formed on the steel counterbody during friction of the F-1–MoS_2 system[139]. When copper is present, however, ferrous sulphide is not detected, owing to the greater strength in this case according to the physicochemical characteristics) of polymer–filler bonding. Infrared spectroscopy, X-ray diffraction, and dynamic thermogravimetric analysis have shown that compounds in which interstitial copper atoms are present in the molybdenum disulphide lattice are formed during friction in the range 110–180° C, with a consequent increase in the coefficient of friction[138,139].

Table 3. Composition of surface films formed on steel during friction of ASP self-lubricating antifriction plastic[138,139] (test conditions: p = 2 kgf cm^{-2} and v = 2 m s^{-1}).

ASP	T, °C	Time, h	Crystallite, Å	Product
F-1-MoS_2	50	2	335	FeS
	120	10	335	FeS
	200	10	430	MoO_2
F-1-MoS_2-Cu	50	2	103	—
	120	2	61	—
	200	10	47	MoO_2, CuS

Raising the temperature at the rubbing contact to 200° C produces a sharp change in the character of the thermal friction curves. Diffractograms of the surface film obtained during friction (Table 3) showed the formation of new tribochemical reaction products. The surface film formed from the F-1-MoS_2 antifriction plastic contained molybdenum dioxide, an oxidation product of the disulphide. Its formation was confirmed by electron diffraction of the film[139]. The presence of copper in the system has a more marked effect on the friction curves at temperatures above 200° C. Tribochemical processes occur more vigorously in the surface films, which contain not only molybdenum dioxide but also small quantities of copper(I) sulphide[138,139].

Thus the composition and the nature of the filler have a significant influence on the formation of surface films when antifriction plastics are subjected to rubbing, and also on the tribochemical reactions occurring both in the polymer binder and in the system of fillers.

IV. PROPERTIES OF THERMOSTABLE ANTIFRICTION PLASTICS

The present Section is a brief survey of the properties and fields of application of a few groups of antifriction materials based on thermostable polymers.

1. Self-lubricating Antifriction Plastics based on Phenol–Formaldehyde Resins

Pheno-formaldehyde resins are widely used as binders in the production of antifriction plastics[66,69,70,143–151]. These polymers find widespread application in industry by

virtue of a combination of valuable properties, primarily thermal stability, heat resistance, and wear resistance[152,153].

Phenoplasts—phenol–formaldehyde resins—are most commonly used with various fillers— such as glass fibre, cotton-wool[154], cotton waste[155], pressboard[156], asbestos fibres[157], etc.— in the manufacture of parts of friction units. Good lubricating properties are conferred on phenoplasts by introducing various solid lubricants, such as molybdenum disulphide, graphite, boron nitride, and polytetrafluoroethylene[158–161]. Another common material for friction units is textolite (resin-impregnated fabric laminate), of which ball-bearing cages and parts for electric motors, pumps, and motor vehicles are made. Textolite is used in friction units with a lubricant. Introduction into textolite of molybdenum disulphide, titanium dioxide, graphite, or selenides or tellurides or their mixtures enables the working capacity of a friction unit to be increased without application of an additional lubricant[162].

Among disadvantages of phenol–formaldehyde resins we must include brittleness and instability towards vibrational overloads; those of reinforced materials based on this thermosetting plastic are low heat conductivity, absorption of several liquids, and high coefficient of thermal expansion.

2. Self-lubricating Antifriction Plastics based on Polyamides

Among heterochain macromolecular compounds the best known as antifriction materials are polyamides[163–167]. These are widely used in mechanical engineering for the production of pinions, bearings[168–170], and cages, as well as various wear-resistant parts[171].

The coefficient of friction of polyamides and their wear resistance depend on the load and the sliding rate[172]. Study of the dry friction of polymers having various chemical structures showed[172] that the coefficient for low-pressure polyethylene increases with rise in temperature less sharply than for polyamides, but for polytetrafluoroethylene it decreases. The type of variation in the case of polyamides was attributed[172] to their structure: the presence of polar groups and hydrogen bonds produces a marked increase in energy of molecular cohesion, which intensifies intermolecular interaction and that between the surfaces during friction, the latter increasing with rise in temperature owing to rupture of the interchain hydrogen bonds of the polyamides. A considerable increase in the coefficient of friction is observed at some "critical" load characteristic of each polymer. With this change in the coefficient with load the polyamide sticks on the steel surface and the intensity of abrasion diminishes. Thus a sharp increase in the coefficient of friction of capron to ~0.9 at a sliding rate of ~1 m s^{-1} coincides with the appearance of adhesion of the polyamide on the steel.

The application of polyamides in pure form as structural materials in friction units is restricted by their strongly hygroscopic character, low heat conductivity (0.25–1.0% of those of metals), large coefficient of linear expansion (9.8×10^{-5}), low hardness, dimensional instability, and moderate load capacity at low temperatures[173,174]. Such defects of polyamides are eliminated by the introduction of various fillers, such as graphite[175,176], molybdenum disulphide[165,176,177], boron nitride, metal powders, fibrous fillers[178], and polytetrafluoroethylene[175,176]. Fillers enhance the rigidity and the compressive strength of polyamides, lower the water absorption and the coefficient of linear expansion, and improve considerably the frictional properties.

Thus the introduction of polyethylene into antifriction compositions based on polyhexanamide helps to separate steel and polyamide surfaces undergoing active molecular interaction and to create under heavy-duty régimes conditions for transition from external to internal friction, ensuring prolonged functioning of the dry friction unit with such operation[179].

An important defect of antifriction plastics based on polyamides is their relatively low heat resistance. The operating temperature range for polyamides is 80–140°C. With rise in temperature the antifriction properties deteriorate continuously. Capron and its compositions can be used[163] in friction units at surface temperatures not exceeding 100°C, P-68 polyamide up to 130°C, and AK-7 mixed polyamide up to 140°C.

3. Self-lubricating Antifriction Plastics based on Polyimides

Among cyclochain polymers polyimides are the most widely used as antifriction materials[71,72,74,180–193]. Aromatic polyimides have very high thermal and thermo-oxidative stability. They can be used at temperatures from −150 to +370°C. Polyimide materials surpass all known plastics in wear resistance, which permits their use in unlubricated bearings. Polyimides are highly resistant to radiation, sunlight, and solvents. Their low volatility in a vacuum makes them promising antifriction materials for use in friction units operating in space. Polyimides filled with graphite or molybdenum disulphide are used for the manufacture of ball-bearing cages[181,189,191,192,194].

Investigation of the influence of moisture on the antifriction properties of a polyimide–steel system shows[195] that entry even of a minute quantity of water is accompanied by a sharp increase in the coefficient of friction and in wear. The variation in the antifriction properties of polyimides and compositions based on them is due to the occurrence of mechanochemical processes at the rubbing surface under the influence of the medium.

4. Self-lubricating Antifriction Plastics based on Epoxy-polymers

Epoxy-polymers are finding increasing application as binders for antifriction materials[196–204]. Bearings based on epoxides are usually employed at temperatures from −50 to +230°C, but under large mechanical loads the upper limiting operating temperature is only 155°C.[153] The fillers generally used in epoxide antifriction materials are graphite, molybdenum disulphide, metal powders and oxides, quartz sand, and also fibrous fillers. An epoxy-plastic filled with graphite or molybdenum disulphide[204] possesses high compressive strength, a low coefficient of friction (0.08–0.09), and heat resistance up to 200°C.

To improve the physicomechanical properties, heat resistance, and lubricating properties epoxy-resins are used in compositions with polyarylates[205], phenol–formaldehyde[206,207] and silicone[200,208] resins, polysulphides[209], or rubbers[210]. A special advantage of materials prepared from epoxy-resins is their ability to harden at room temperature and serve as an antifriction liner.

5. "ASP Plastics"

The scientific principles of the production of thermostable antifriction materials developed by Korshak et al. have enabled several new antifriction plastics to be obtained, among which we must note the "ASP plastics"[211] of various brands (AMAN, TESAN, ESTERAN, VILAN, etc.). These are multicomponent filled systems, in which the binders are polymers possessing a combination of necessary properties— thermal stability, resistance to heat, radiation, and chemical attack, and technical suitability for processing. In their combination of properties the ASP plastics considerably excel known dry friction materials— plastics based on polytetrafluoroethylene and fillers (Table 4).[211]

Table 4. Temperature ranges of application of lubricating materials.

Lubricant	T, °C
Liquid lubricants	−60÷+150
Lubricating greases	up to +180
Polytetrafluoroethylene lubricant	up to +220
ASP plastic	−100÷+300

A distinguishing feature of ASP plastics is their low coefficient of friction and its constancy with variation in temperature. The dependence of the coefficient on the rate of slippage and on the pressure is governed by the ambient temperature. Up to 100°C the permissible loads on these plastics in bearing contact are 100–150 kgf cm^{-2}. The ASP plastics are resistant to benzene, oils, and vibration, are unaffected by moisture, and can be stored for long periods.

The principal use of ASP plastics is as self-lubricating retainers in antifriction bearings, and also as linears in friction bearings. Several standard sizes of ball-bearings with ASP plastic retainers have been designed in the Soviet Union, and introduced into the national economy. The use of such plastics at high temperatures is especially promising. Thus ball-bearings with ASP plastic cages remain in a working state at 250°C after 1000 h operation. These plastics can be used in bearing contact units in which high rates (up to 16 000 rev/min) or high loadings (up to 150–200 kgf cm^{-2}) are required with small rates of displacement of the shaft, and also in cases in which translational motion must be realised after prolonged stationary contact[211]. It is possible to make also ASP plastics pinions bearing a low load, which may ensure high rates of rotation of the shaft.

The superiority of ASP plastics is especially noticeable when they are used in friction units in which other lubricating materials cannot be applied because of high temperatures, radiation effects, or other conditions.

* * *

Thus the above survey makes clear how complicated is the problem of designing antifriction plastics. However, several relations have already been established between the chemical structure of thermostable polymers and the frictional properties of filled polymer systems. This offers wide opportunities for obtaining new materials with specified properties by controlled variation of the chemical structure of the polymer binder.

Information

The Ninth International Symposium on the Reactivity of Solids will be held between the 1st and 6th September, 1980, in Krakow (Poland). The symposium is devoted to problems of the mechanisms of reactions in the solid phase. The following questions will be discussed:

1. Defects and transport in solids.
2. Chemical condensation of vapours.
3. The role of the properties of the surface in the reactivity of solids.
4. The formation and transformations of non-crystalline solids.
5. New aspects of phase transformations—the formation of hybrid crystals, non-diffusional transformations, superstructure ordering, etc.
6. The role of solid phase reactions in the development of new technological processes.

A second circular will be sent in 1979.

The "Nauka" Publishing House is Preparing for Publication a Collection of Articles "Sorbtsiya i Khromatografiya" (Sorption and Chromatography), 20 Sheets, Price 3 Roubles

The book covers various sorption phenomena, surface chemistry, the properties of sorbents, sorption dynamics, and extractive processes. The theoretical articles deal with the phenomenology of sorption processes and thermodynamics; quantum-mechanical calculations on catalyst–adsorbate systems as well as other problems necessary for the understanding of the state of research in the field of sorption are described.

The book is intended for physical chemists working in various fields as well as lecturers and postgraduates at higher educational establishments.

ORDERS SHOULD BE SENT TO ONE OF THE ADDRESSES OF THE "KNIGA–POCHTOI" "AKADEMKNIGA" WAREHOUSES LISTED BELOW:

The Carbon-Nitrogen Triad Prototropic Tautomerism

B.A.Shainyan and A.N.Mirskova

Data on the imine-enamine and related types of tautomerism are surveyed and different approaches to problems of the tautomerism of enamides, which play a major role in biological processes, are examined.
The bibliography includes 98 references.

V.	Certain approaches to the problem of the enamide-*N*-acylimine tautomerism	112

I. INTRODUCTION

Systematic studies on the carbon–nitrogen triad prototropic tautomerism have been carried out for little more than ten years. As a result of the development of spectroscopic techniques, particularly NMR spectroscopy, quantitative data have been obtained during this period concerning the influence of internal and external factors on the position of the equilibrium

(1)

The major role of unstable tautomeric *N*-acylimino-forms as reactive intermediates has been demonstrated and many reactions have been examined from the standpoint of the involvement of both tautomeric forms. The tautomeric equilibrium constants and the energies of the tautomers have been obtained by kinetic and computational methods.

There has been a considerable growth of interest in the last five years in the study of the enamide–*N*-acylimine tautomerism in connection with research on α-carboxy-enamides (*N*-acyldehydroamino-acids), since it has been observed that such structures are present in natural peptides. A direct relation between the enamide–*N*-acylimine tautomerism

(2)

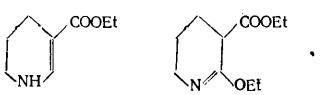
and the reactions occurring in living organisms (the synthesis and hydrolysis of peptides, the racemisation of natural amino-acids, the metabolism of antibiotics, etc.) has been demonstrated. Methods for the synthesis of penicillins substituted by functional groups at $C_{(6)}$ have been developed on the basis of the formation of reactive intermediate *N*-acylimines.

Bearing in mind the great importance of these studies and the lack of a complete review devoted to the enamine–imine tautomerism, we surveyed the literature published

up to October, 1976, in order to draw attention to this interesting and hitherto little studied field of organic chemistry. Of the earlier publications, we may mention Layer's review[1] of imines in which reactions confirming the possibility of the transformation of imines into enamines are surveyed; there have been no direct observations of the tautomeric equilibrium by physical methods at that time[1].

II. THE IMINE–ENAMINE TAUTOMERISM

Equilibrium (1) has been studied quantitatively mainly for imine–enamine systems and to a lesser extent for iminoesters and hydrazines; there have been only isolated studies on enamines with N-functional group substituents. We shall therefore consider below a quantitative assessment of equilibrium (1) for simple systems and then certain approaches to problems of the tautomerism of enamines with N-functional group substituents.



1. The Influence of Substituents in the α-Position

It has been noted in a number of studies that various alkyl substituents in the α-position have a weak influence on the equilibrium position. On passing to aliphatic-aromatic and then to aromatic substituents, the equilibrium usually shifts towards the enamine[2-4], which shows that an α-substituent capable of non-polar conjugation promotes the formation of the enamine (see also Bourbon et al.[5]). However, an approximately 1 : 1 ratio of the two forms for R = CH_3, $CH_2C_6H_5$, and C_6H_5 has been found[6] for the equilibrium

$$C_6H_5-CH=\underset{\displaystyle R}{\underset{|}{C}}-NH_2 \rightleftarrows C_6H_5-CH_2-\underset{\displaystyle R}{\underset{|}{C}}=NH \quad . \qquad (3)$$

The influence of α-substituents is manifested more clearly on passing to α-alkoxyenamines.[7,8]

The introduction of an OR group instead of the hydrocarbon residue into the enamine $C_6H_5CH=C(R)-NH_2$ wholly displaces the equilibrium towards the iminoform[7]; the compound exists as the iminoester $C_6H_5CH_2C(=NH)OR$. The same has been found[8] for the tetrahydronicotinate ester, which exists as the enamine, while its α-ethoxy-derivative exists in the imino-form:

The introduction of a thio-group in the α-position also leads to a high content of the imino-form (up to 70%) [9] (the imino-form is usually absent in the presence of strong electron acceptors in the β-position[4]). When the α-substituents were varied in the system

$$C_6H_5NH-\underset{\displaystyle SR}{\underset{|}{C}}=C(COOEt)_2 \overset{K}{\rightleftarrows} C_6H_5-N=\underset{\displaystyle SR}{\underset{|}{C}}-CH(COOEt)_2 \quad , \qquad (4)$$

a correlation was observed[9] between $\lg K$, on the one hand, and the σ^* constants and the basicity of the enamines on the other: $\lg K = 0.614 - 0.24\sigma^*_R$; $\lg K = -2.992 + 0.34pK_a$. The first expression indicates a very weak dependence of K on the nature of the residue R, which leads to the conclusion that the nature of the atom linked directly to the carbon atom in the α-position has a decisive influence on equilibrium (1).

2. The Influence of Substituents in the β-Position

Substituents attached to the tautomeric centres (i.e. to the β-carbon atom and the nitrogen atom) have a greater influence than substituents at the central atom of the tautomeric system (the α-carbon atom). This is clearly seen from a comparison of the data of Bourbon et al.[5] and Ahlbrecht and Fischer[10]. Thus the content of the enamine form varies from 50 to 67% for α-substituted compounds $CH_3-CH=CRNH_2$ (R = 2-, 3-, or 4-pyridyl), while the variation for the β-substituted analogues is within the wider range from 33 to 100%.[10]

The influence of substituents in the β-position such as NO_2, CN, CO, etc.[4] is such that the imine form is absent. The replacement of the methylgroup in the β-position by the phenyl group also causes a sharp shift of the equilibrium towards the enamine[4,6].

The dependence of equilibrium (1) on the nature of the substituents in the β-position has been studied in detail for a series of enamines $RC_6H_4C(CH_3)=CHNHAr$.[11,12] It was shown that electron-donating substituents shift the equilibrium towards the imine, the shift depending on the solvent: it is greater in polar nitrobenzene than in non-polar bromobenzene.

The introduction of a strong electron-accepting group (R^1 = CN) in the β-position of the iminoesters $R^1CH_2C.(=NR)OR^2$ leads to the appearance of the enamine form, while for R^1 = Ar the compound consists of the pure imine[7].

The increase of the bulk of the R^1_2N group in the enediamines $R^1_2NCH=C(C_6H_5)NHR$ leads to a sharp increase of the content of the enamine and, when R^1_2N = 2,6-dimethylpiperidino, the imine is not detected at all, whereas for $R^1_2N = N(CH_3)_2$ the fraction of the imine is 91%.[13]

3. The Influence of Substituents at the Nitrogen Atom

Analysis of the influence of substituents at the nitrogen atom on equilibrium (1) is of greatest interest, because it makes it possible to build a logical "bridge" from the imine–enamine systems which have been fairly thoroughly investigated to the enamide–N-acylimine system which have been little studied but are extremely important.

The study of the equilibrium (5)

$$R-CH=CR^1-NHC_6H_4-X \rightleftarrows R-CH_2CR^1=N-C_6H_4-X \qquad (5)$$

showed[4] that electron-donating substituents X in the benzene ring shift the equilibrium towards the imine form. The sensitivity to this influence increases in polar solvents (DMSO > pyridine > CCl_4).

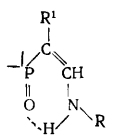
An analogous relation for N-aryl-substituted tautomeric systems has been found also in a number of other studies[12,14-16]. N-Alkyl substituents shift equilibrium (1) towards the imine form compared with aromatic substituents[11,14,15]. This permits a conclusion important for subsequent exposition: the conjugation of the lone electron pair of the nitrogen atom with the substituent displaces equilibrium (1) towards the enamine tautomeric form.

A qualitatively analogous picture has been obtained for equilibrium (6)[2]:

$$(CH_3)_2CH-\underset{\displaystyle R}{\underset{|}{C}}=NR^1 \rightleftarrows (CH_3)_2C=\underset{\displaystyle R}{\underset{|}{C}}-NHR^1 \quad . \qquad (6)$$

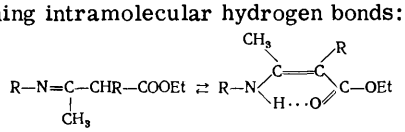
The authors[2] analysed the relation between the equilibrium position and the π charge on the nitrogen atom in the imine form. A satisfactory correlation has been

observed between the imine content and the π charge on nitrogen: the greater the π charge, the smaller the imine content in the equilibrium mixture.



An attempt has been made[3] to find a relation between the content of the enamine and its pK_a. A parallel variation of these quantities has been observed qualitatively although no correlation could be found. Nevertheless, one may conclude that the greater the mobility of the proton in the amino-group the greater the shift of the equilibrium towards the enamine. Since any tautomeric prototropic equilibrium is always displaced towards the less acid form, one may reach an important and unexpected conclusion on the basis of the results of Savignac et al.[3]: the CH acidity of the imine increases to a greater extent than the NH acidity of the enamine as the electron-accepting properties of the substituents at the nitrogen atom are enhanced.

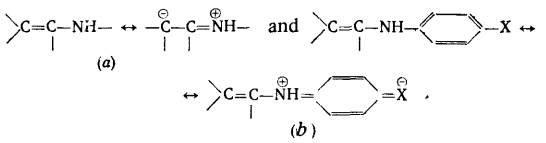
Apart from the electronic effects one should also note the influence of steric factors on the position of equilibrium (1). An increase of the bulk of the substituent R in the enediamines $R^1_2N-CH=C(C_6H_5)-NHR$ leads to an increase of the content of the enamine[13].



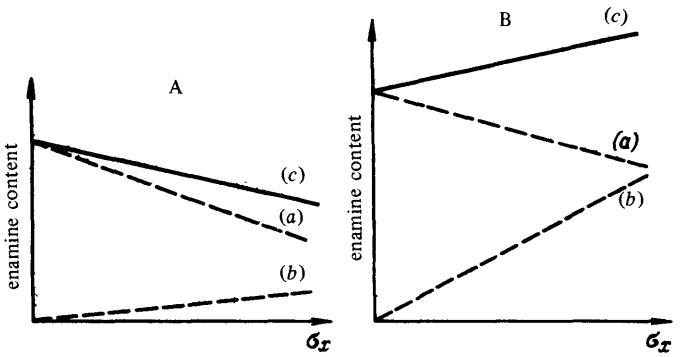
In contrast to the above data, the introduction of aromatic substituents at a nitrogen atom instead of aliphatic substituents in β-phosphorylated enamines

$>P(=O)CR^1=CHNHR$ shifts the equilibrium towards the

imine form; in the R = Ar series electron-accepting substituents in the ring displaces the equilibrium in the same direction[17-19]. Unfortunately the authors do not explain this contradiction between their data and literature results, although they do note a feature of the structure of enamines—the presence of an intramolecular hydrogen bond (IAHB):

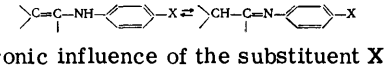


Yakimovich and coworkers[20,21] investigated other systems containing intramolecular hydrogen bonds:



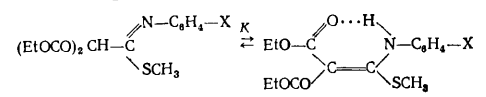
(7)

and also found a situation which is the opposite of that for enamines without such bonds. The authors explained this finding by the fact that the equilibrium position for simple imine–enamine systems[2,4,11-14] is determined by the stability of the enamine form, while in the presence of an IAHB[17-21] it is determined by the stability of the imine form, because the benzene ring in the enamine is not conjugated with nitrogen for steric reasons. The conjugation of the lone electron pair of the nitrogen with the benzene ring is easier than the conjugation of the C=N bond, so that in the absence of an IAHB the electron-accepting substituents stabilise the enamine form to a greater extent than the imine form and displace the equilibrium towards it. In the presence of an IAHB the conjugation in the enamine vanishes and electron acceptors stabilise only the imine, shifting the equilibrium in its direction.



We believe that the simplest and convincing explanation of the unusual behaviour of systems containing electron-accepting groups (C=O, P=O, etc.) in the β-position has been given by Walter and Meyer[22], who considered two mechanisms of the stabilisation of the enamine:

Electron-accepting substituents in the benzene ring promote stabilisation via mechanism (*b*) and act against stabilisation via mechanism (*a*). In the presence of strong electron-accepting groups in the β-position, where the mechanism (*a*) should play an important role, electron-accepting substituents at the nitrogen atom therefore decrease the stability of the enamine and displace the equilibrium towards the imine, which has in fact been observed for such systems[17-21]. This is illustrated graphically in the Figure. The straight line (*c*), which summarises the influence of the substituent at the nitrogen atom on both stabilisation mechanisms [(*a*) and (*b*)], has a negative slope for strong electron-accepting substituents in the β-position. As their electron-accepting properties are weakened, the contribution to stabilisation via mechanism (*b*) increases and the slope of line (*c*) diminishes. This is consistent with the results of other studies[2,4,11,12,14-16].



Dependence of the position of the equilibrium

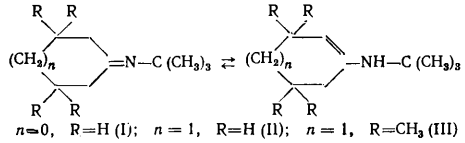
on the electronic influence of the substituent X [22]: A) in the presence of strong electron-accepting substituents in the β-position; B) in the absence of such substituents.

To confirm their conclusions, Walter and Meyer investigated[9] the equilibrium

(8)

and found the following correlation with a negative slope ρ

ρ : $\lg K = 0.534 - 0.61\sigma_X$ ($r = 0.994$; $s_0 = 0.03$).



4. The Influence of the Solvent

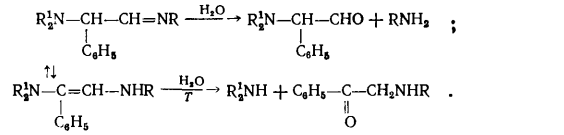
Two tautomeric forms $C_6H_5-CH(CH_3)-N=C(CH_3)-CH_2COOEt$ and $C_6H_5-CH(CH_3)-NH-C(CH_3)=CHCOOEt$, which form an equilibrium mixture after standing for a

time, were isolated separately in one of the early studies[23]. Equilibrium is established faster in non-polar solvents than in polar solvents. Compared with methanol, pyridine displaces the equilibrium towards the enamine, while acetic acid displaces it towards the imine, which has been explained[23] by the greater basicity of the imine form.

A shift of equilibrium towards the enamine has been observed in many instances in polar solvents: in nitrobenzene relative to bromobenzene[11] and in DMSO relative to benzene [10] or carbon tetrachloride.[24] Ahlbrecht[25] showed that the content of the enamine $CH_3NHC(C_6H_4NO_2) = CHC_6H_4NO_2$ in the tautomeric mixture increases in the following sequence of solvents: $CHCl_3 < C_6H_6 < CH_3NO_2 < CH_3CN <$ acetone $<$ pyridine $<$ DMSO. Evidently a single monotonically varying characteristic cannot be isolated in the above series; this is understandable, because the equilibrium position is influenced both by the solvent polarity and by the ability of the solvent to form hydrogen bonds, as well as other types of specific solvation. Studies on iminoesters showed[7,26,27] that DMSO displaces the tautomeric equilibrium towards the enamine relative to nitrobenzene or dimethylformamide (DMF). The imine–enamine equilibrium constant for the imines $RCH_2CR^1{=}NR^2$ increases on passing from carbon tetrachloride to pyridine and then to DMSO.[4] In other cases the equilibrium also shifts towards the enamine in polar solvents (DMSO, nitrobenzene) relative to non-polar solvents ($CDCl_3$, CCl_4).[6] An attempt to investigate the influence of the solvent was also undertaken by Savignac et al.[3], but, since the imine form greatly predominates in the mixture (up to 95%) and the solvent has only an insignificant influence, the results are difficult to interpret unambiguously.

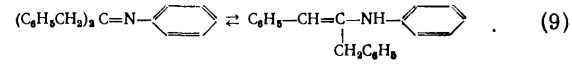
The series of solvents corresponding to an increasing content of the enediamine $C_4H_9NH-C(C_6H_5){=}CH-N(CH_3)_2$ in the equilibrium mixture is somewhat different[13]: $C_6D_6 < CDCl_3 <$ DMSO $<$ pyridine. The influnece of solvents on the equilibrium position has been studied for the cyclic five- and six-membered imines (I)–(III) [28]:

$n=0$, R=H (I); $n=1$, R=H (II); $n=1$, R=CH_3 (III) .



The following series of solvents which cause a shift of the equilibrium to the right has been found for (III): $CD_3OD < CDCl_3 < CH_2Cl_2 < CD_3NO_2 < CD_3CN < C_6H_5NO_2 < CCl_4 < C_6D_6 <$ pure substance $<$ acetone $<$ dioxan $<$ pyridine $<$ DMF $<$ DMSO $<$ cyclohexane. The series is fairly heterogeneous but it is nevertheless possible to distinguish two main tendencies in it: an increase of polarity and of the ability to accept a proton with formation of an intermolecular hydrogen bond (IRHB) from left to right (cyclohexane deviates from this relation). For compounds (I) and (II), the series of solvents investigated are shorter but the qualitative relation is the same.

Hence the ability of the solvent to form intermolecular hydrogen bonds as a rule stabilises the enamine form. The only exception is enamines with an electron-accepting group (C=O or P=O) in the β-position, which gives rise to an IAHB.[17-19]. In these cases solvents forming intermolecular hydrogen bonds disrupt the stable six-membered ring with an IAHB and destabilise the enamine. Thus the compounds $(iso\text{-}C_3H_7O)_2P(=O)CH{=}CH-NHR$ which exist as enamines in carbon tetrachloride, are converted into the corresponding imines in tributyl phosphate[17-19]. Similarly the following series of solvents, increasing the content of the imine form, has been found for equilibria (4) and (8): $CCl_4 \leqslant CDCl_3 \leqslant C_6D_6 < C_6D_5NO_2 < CD_3OD <$ DMSO $<$ pyridine $< CD_3NO_2 \simeq$ acetone.



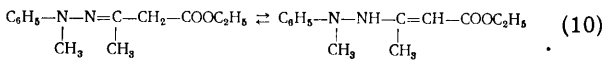
5. The Influence of Temperature

This problem has been studied less than others, although in the investigation of tautomeric equilibria it is very important, since information about the process energetics, the stabilities of individual forms, the entropies of transition of one form into another, etc. can be obtained from the temperature dependence.

The content of the enediamine $C_4H_9NH-C(C_6H_5){=}CH-N(CH_3)_2$ increases from 21% at -25° to 65% at 36°C.[13] This yields the difference between the energies of the tautomeric forms (not calculated by the authors) as $\Delta E = 5$ kcal mole^{-1}, the imine form having a lower energy in this instance. The results of physicochemical analysis have also been confirmed by chemical transformations[13]: hydrolysis to the aldehyde and the amine proceeds in the cold, while on heating the substance is converted into the aminoketone via the following mechanism:

Töke and coworkers[26,27] studied the influence of temperature on the position of the tautomeric equilibrium for iminoesters in DMF and DMSO. $\Delta E = 2.8$ kcal mole^{-1} in DMF and $\Delta E = 4.2$ kcal mole^{-1} in DMSO may be calculated from the data which they obtained. In this case the enamine form is energetically more favourable. An increase of the imine content with increasing temperature was also noted by Ahlbrecht[25]. The following equilibrium in DMSO has been studied over a wide temperature range[24]:

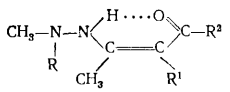
(9)



The energy difference (not calculated by the authors) is small (2.3 kcal mole^{-1}), the enamine having a smaller energy than in other studies[25-27]. The temperature dependence of equilibrium (4) has been studied for $R = CH_2C_6H_5$ in $CDBr_3$ and $C_6D_5NO_2$.[29] The parameters $\Delta H^\circ = 3.59$ kcal mole^{-1} and $\Delta S^\circ = 9.35$ cal mole^{-1} K^{-1} in $CDBr_3$ and $\Delta H^\circ = 2.60$ kcal mole^{-1} and $\Delta S^\circ = 6.87$ cal mole^{-1} K^{-1} in $C_6D_5NO_2$ were found; the relative stabilities of the tautomeric forms are analogous to those observed in other studies[24-27].

The influence of paramagnetic additives on the position of the tautomeric equilibrium studied in relation to cyclohexanone imines should also be mentioned[30]. The addition of the europium complex $Eu(fod)_3$ shifts the equilibrium towards the imine, which indicates a greater basicity of the imine form (cf. Potapov et al.[23]). Analysis of the literature data for the tautomerism of simple imine–enamine systems permits certain general conclusions. In the absence of conjugation with an electron-accepting substituent the imine form is more stable. Conjugation with an electron-accepting substituent in any position stabilises the enamine. Solvents forming intermolecular hydrogen bonds displace the equilibrium towards the enamine, apart from the instances where the enamines contain an IAHB; in such systems the solvent has the opposite influence. In the absence of conjugation with electron-accepting groups the imine–enamine equilibrium

constant increases with temperature, while in the presence of such conjugation it diminishes. Finally, the conversion of one tautomeric form into another involves an intermolecular proton transfer, because the intramolecular process is forbidden by the Woodward–Hoffmann orbital symmetry rules[8].



III. THE HYDRAZONE–ENEHYDRAZINE TAUTOMERISM

We shall consider briefly, in addition to the foregoing, the tautomerism of *N*-aminoimines (hydrazones), discovered by Ahlbrecht[31] in relation to the equilibrium

(10)

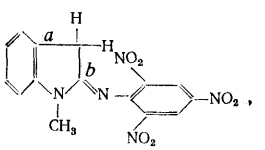
It has been shown for the compounds $(CH_3)_2NNH-CR^1=CR^2COOEt$ [32] that the conjugation of the group R^1 with the double bond increases the content of the hydrazone (in contrast to simple enamines[2,3,5]). The influence of β-substituents in enehydrazines is the same as in the enamines, i.e. electron-accepting substituents stabilise the enehydrazine. The influence of steric interactions of the substituents R^1 and R^2 in the strained planar structure

has been emphasised[33].

The results of a study[34] where it was shown in relation to the compound $R^1N(CH_3)NHC(CH_3)=CHCOR$ that an enhancement of the electron-accepting properties of the COR residue shifts the equilibrium towards the enehydrazine agree with the data for the influence of β-substituents. A study of the temperature dependence of the tautomeric equilibrium constant for the phenylhydrazone of acetoacetic ester[35] showed that the enehydrazine form is energetically more favourable (as should in fact be the case in the presence of an electron-accepting group in the β-position). The energy difference between the tautomeric forms, which is 2.5 kcal mole^{-1} in C_6D_5Br and 4 kcal mole^{-1} in DMSO, can be calculated from the temperature dependence of the composition of the tautomeric equilibrium mixture. In contrast to these data (as for the imine–enamine systems), in the absence of an electron-accepting group in the β-position, the hydrazone[36] or semicarbazone[37] form is energetically more favourable according to the results of quantum-chemical calculations (the Hückel method).

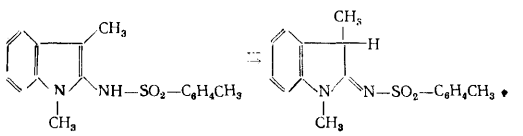
The shift to the enehydrazine form in DMSO compared with C_6H_5Br is consistent with data for the influence of the solvent (see Section II).[35] Overall, in the absence of electron-accepting substituents, hydrazones are more stable than the tautomeric enehydrazines, the difference in stability being greater than in an imine–enamine system[20,21,32].

IV. THE TAUTOMERISM OF CERTAIN ENAMINES WITH *N*-FUNCTIONAL GROUP SUBSTITUENTS



Few studies have been made on the tautomerism of the enamines $\diagdown\!\!\diagup C=C-NH-X$, where X = COR, SO_2, COOR, or another electron-accepting group. One of the first investigations demonstrated the occurrence of tautomerism in *N*-alkoxycarbonylimines[38]. The authors investigated vinylcarbamates $R-CH=CR^1-NH-COOEt$ by infrared spectroscopy and discovered a tautomeric equilibrium involving "iminourethanes" $R-CH_2-CR^1=N-COOEt$ [$R,R^1=(CH_2)_4$(a); $R,R^1=(CH_2)_5$(b); $R=H$, $R^1=C_6H_5$(c)]. The content of the enamide is 67–71% for compound (a), 60–68% for (b), and 31% for (c).

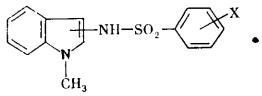
Despite this promising start to studies on the tautomerism of *N*-acylated imine–enamine systems, these data are not very trustworthy. Thus it has been shown[5] that the enamine $CH_3-CH=C(C_6H_5)NH_2$, unsubstituted at the nitrogen atom and having a structure similar to the enamine (*c*), exists in the enamine form to the extent of 92%, although the introduction of the electron-accepting group COOEt at the nitrogen atom should greatly displace the equilibrium towards the enamine, which follows from the analysis of all the available literature data and general considerations. Studies have been made recently[28] also on cyclic enamines analogous to compounds (a) and (b) with a t-butyl group at the nitrogen atom. Even in this instance the content of the enamine reaches 50%, so that it is altogether unlikely that the replacement of the electron-donating t-butyl group by the electron-accepting COOEt group gives rise to a very slight shift of the equilibrium towards the enamine form.



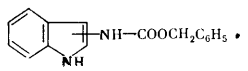
As will be shown below, the available literature data show on the whole that enamines with *N*-functional group substituents exist in the enamine and not the imine form, i.e. when groups of the type C=O, SO_2, and other electron-accepting substituents are present at the nitrogen atom, the enamine form is much more stable than the imine form.

For example, it has been shown[39] that nitriles, which do not have an α-hydrogen atom, combine with triethylsilane, giving rise to aldimines $R-CH=N-Si(C_2H_5)_3$ ($R = t\text{-}C_4H_9$ or C_6H_5). In the presence of an α-hydrogen atom aldimines rearrange almost wholly to the enamines $RR^1C=CHNHSi(C_2H_5)_3$.[40] When $R = R^1 = C_4H_9$, for example, the content of the imine form is only 4.

Interesting studies on indole derivatives have been made by Bailey and coworkers[41,42]. The imine structure has been found for *N*-methyl-2-(*N*-picrylamino)indole in the crystalline state[41]:



This was done in a fairly unusual way—by X-ray diffraction analysis involving a comparison of the bond lengths *a* and *b*; they are virtually the same (1.52 ± 0.005 Å). On the other hand, in solutions, this compound exists as an enamine (in different solvents). The same workers investigated also 1,3-dimethyl-2-tosylaminoindole, which exists in equilibrium with tosylimine[42]:



As for imine–enamine systems, in $CDCl_3$ this equilibrium is displaced towards the imine, while in DMSO it is displaced towards the enesulphamide.

The analogous 2- and 3-substituted indoles have been investigated[43,44]:

It was shown that the 3-substituted indole exists solely in the enesulphamide form, while the 2-substituted indole exists predominantly in the imine form. The equilibrium was found to be displaced towards the sulphonylimine when electron-accepting substituents X are introduced into the benzene ring. The sensitivity to this influence is small and independent of the solvent. In pure DMSO the content of the enesulphamide is higher than in the mixture of DMSO and 15% $CDCl_3$. *N*-Acyl-derivatives have been synthesised for comparison[43]:

Regardless of the position of the substituent, these compounds exist solely as the enamides. The difference in the behaviour of 2- and 3-substituted enesulphamide isomers can be explained by the fact that the lone electron pair of the nitrogen atom in the α-position with respect to the sulphamide group in the 2-substituted isomer stabilises the sulphonylimine form; such stabilisation is impossible for the 3-substituted isomer. The above explanation has been confirmed by data[45] demonstrating the existence of the compound $R_2NC(CH_3)=NSO_2Ar$ (R_2N = morpholino) only in the form of the sulphonylimine.

α-Thio-substituted enamides have been studied in detail in a series of investigations by Walter and coworkers[46-48]. In contrast to the oxygen analogues iso-C_3H_7-$C(OCH_3)$=N-COR,[49] *N*-acyliminothioesters are in equilibrium with the enamides:

This is apparently due to the greater electron-donating capacity of the lone electron pair of the oxygen atom compared with that of the sulphur atom. The dependence of the equilibrium position on the nature of the groups R, R^1, and R^2 and on the solvent has been studied and the kinetics of the tautomerisation reaction have been investigated by ^{1}H NMR. The reaction was found to be of first order. Analysis of the authors' data leads to the following main conclusions: the change from R = CH_3 to R = C_6H_5 causes a very marked displacement of the equilibrium towards the *N*-acylimine form; electron-donating substituents in the β-position also stabilise the *N*-acylimine; DMSO in most cases causes a complete displacement of the equilibrium towards the enamide form relative to $CDCl_3$.

A further enhancement of the electron-donating properties of the α-substituent leads to a complete displacement of the equilibrium towards the *N*-acylimine. Thus acyliminodithioesters $C_6H_{11}CH_2C(SSR^1)$=NCOR exist entirely in the *N*-acylimine form[47]. The replacement of the cyclohexyl residue in the β-position by the phenyl group leads to the stabilisation of the enamine as a result of the conjugation of the double bond with the aromatic ring and the compound is the enamide $C_6H_5CH=C(SSR^1)NHCOR$. The replacement of the acyl group COR in this compound by the SO_2CH_3 residue leads to its complete conversion into the sulphonylimine $C_6H_5CH_2C(SSR)=NSO_2CH_3$ [47] (in agreement with the results of the study of Harmon and coworkers[43,44] on the relative stabilities of the enamide and enesulphamide systems). A weakening of the electron-donating capacity of the thio-group in the α-position destabilises the *N*-acylimine group and the ketene *S*,*N*-acylals are not converted into the tautomeric *S*,*N*-diacyliminothioesters[48]:

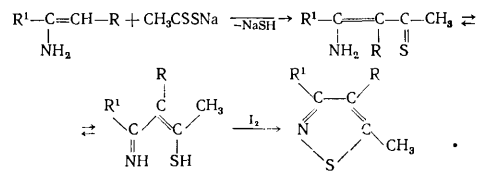
Thus one may conclude that the presence in the α-position of substituents exhibiting an appreciable +*C* effect (for example, OR, SR, and NR_2) is a necessary (but not sufficient!) condition for the appearance of the imine tautomers of enamides or enesulphamides.

V. CERTAIN APPROACHES TO THE PROBLEM OF THE ENAMIDE–*N*-ACYLIMINE TAUTOMERISM

As shown in the previous section, there have been rather few direct studies on enamide–*N*-acylimine tautomeric mixtures. On the other hand, this important problem is directly related to research fields such as transformations of antibiotics, the hydrolysis of peptides, transformations of optically active aminoacids, etc. In contrast to the enamine–imine tautomerism, the enamide–*N*-acylimine equilibrium is in most instances pseudomeric, i.e. is wholly displaced towards the enamide form. This hinders a direct study of the enamide–*N*-acylimine equilibrium and, on the other hand, justifies indirect approaches involving the acylation of tautomeric imine–enamine mixtures, the study of the reactivity of enamides, etc., which will be considered below.

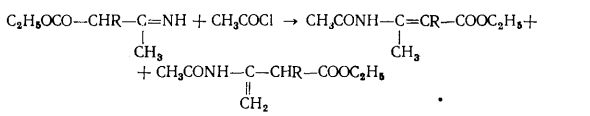
The first major study on vinylcarbamates and vinylureas was published by Sato[50] as early as 1961. The study of the infrared spectra under different conditions led to the conclusion that vinylcarbamates unsubstituted in the α-position do not isomerise to *N*-acylimine, while α-substituted derivatives do isomerise. Such isomerisation of vinylureas proceeds even with the unsubstituted compounds and takes place very readily with α-substituted derivatives. A deficiency of Sato's study is that only infrared spectroscopy was used to demonstrate the structure; this method is not suitable, because the assignment of the bands in the range 1640–1700 cm^{-1} to the C=O, C=N, and C=C groups is fairly difficult for enamide–*N*-acylimine tautomeric systems and one is hardly justified in reaching any quantitative conclusions.

Ultraviolet spectroscopy has been used to study divinylurea $[(C_6H_5)_2C=CH-NH]_2CO$.[51] This compound has a maximum at 318 nm in the ultraviolet spectrum. When one of the nitrogen atoms is methylated, a 40 nm hyspochromic shift is observed, while methylation of both atoms entails a 51 nm hypsochromic shift, which the authors explain by the impossibility in the latter case of tautomerism of two types:



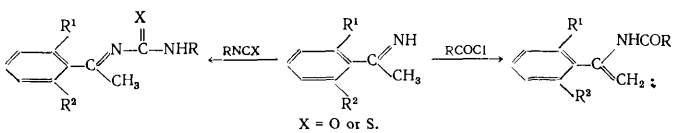
Analogous conclusions were also reached by the authors in the next investigation[52].

Here a small digression is necessary and the problem of the amide–imidol tautomerism as a possible alternative to the enamide–*N*-acylimine tautomerism must be touched upon. For saturated amides, such tautomerism is indeed sometimes observed if the imidol group is stabilised by substituent effects[53]. However, in the absence of such structural features calculation[54] indicates a much higher energy of the imidol form (by 15–20 kcal $mole^{-1}$), which



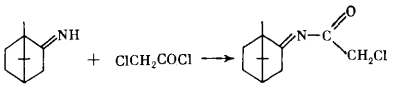
makes it possible to disregard it. So far there have been no comparative calculations of the energies of the *N*-acylimine and imidol forms and our recent calculation[55] for the tautomers $CHCl_2-CH=N-COCH_3$ and $CCl_2=CH-N=C(OH)-CH_3$ showed that the *N*-acylimine form is energetically more favourable than the imidol form to the extent of 16 kcal mole^{-1}.

Goszczynski and Zielinski[56] investigated the acid hydrolysis of *N*-styrylacetamides $CH_3-CO-NH-CR=CR^1-Ar$; it has been shown by infrared spectroscopy that in the protonated form these compounds are *N*-acylimine tautomers $CH_3-CO-NH=CR-CHR^1-Ar$. A similar fact was noted also in an earlier study of the oxidation of imine–enamine systems[57], where it was shown that, when salts are formed, both imines and enamines give rise to imine salts†.

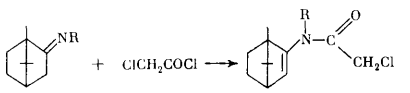


The problem of the enamide–*N*-acylimine tautomerism has also been studied by investigating the acylation of imine–enamine tautomeric mixtures. Such studies were published ten years ago, that of Crenshaw et al.[58] on the thioacetylation of enamines being one of the first. By oxidising with iodine the product of the interaction of CH_3CSSNa with the enamine, the authors were able to isolate an isothiazole, which is formed via the following mechanism according to their view:

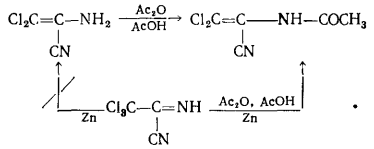
When cyclohexanone and isobutyral imines are acylated by acyl chlorides, isocyanates, and isothiocyanates,[59] the products are the tautomeric enamides or enethioamides and not *N*-acylimines. When the $H_2NCR=CR^1R^2 \rightleftharpoons HN=CRCHR^1R^2$ tautomeric mixture is acylated, only the enamide is again formed[6]. Attempts have likewise been made to obtain *N*-acylimines by acylating imines. For aliphatic imines, such an attempt was unsuccessful—the authors[60] obtained the two isomeric enamides:



The reactions of acetophenone imines with isocyanates or isothiocyanates yielded *N*-acylimines, while those with acyl chlorides gave enamides[61]:

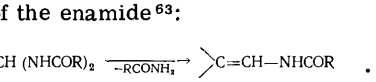


X = O or S.



The yield of the *N*-acylimine increases with increasing branching of the substituents R^1 and R^2. *N*-Acylimines are formed more readily by reaction with isocyanate than by reaction with isothiocyanate. Thus, for $R^1 = R^2 = CH_3$, treatment with RNCS yielded the enamide, while treatment with RNCO gave rise to the *N*-acylimine. The *N*-acylimine was also obtained by reaction with chloroacetyl chloride[61]:

The stability of the *N*-acylimine is in this case apparently related to the greater stability of the exocyclic double bond, although in principle the double bond can be converted into a ring[61]:

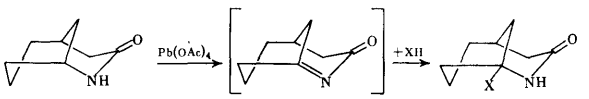


The following transformations have been described in connection with a study of chloral derivatives[62]:

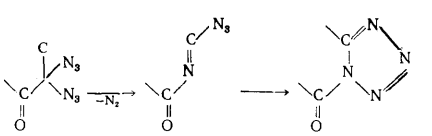
Evidently, both the enamine and imine give rise to β,β-dichloro-α-cyanovinylacetamide.

Thus *N*-acylation of enamines always results in the formation of enamides, while *N*-acylation of imines sometimes gives rise to *N*-acylimines, although the tautomeric enamides are again more frequently produced.

The greater stability of the enamide form compared with the *N*-acylimine form may be inferred also from the results of the elimination of amides from alkylidenebisamides.[63,64] If there is a hydrogen atom in the β-position relative to the amido-group, the elimination proceeds with formation of the enamide[63]:

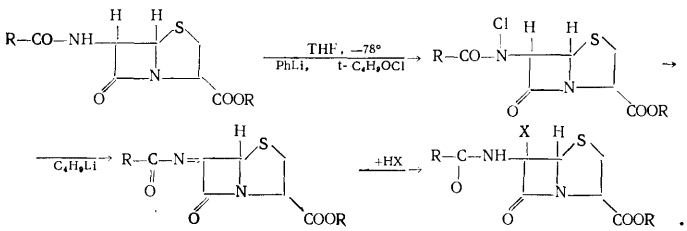


If such a hydrogen atom is absent, the elimination process proceeds under more severe conditions and *N*-acylimines are formed[64]:

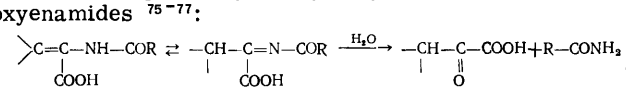


Studies which demonstrated the formation of an unstable tautomeric *N*-acylimine form as the reactive intermediate belong to another series of investigations associated with the problem of the enamide–*N*-acylimine tautomerism. Almost all studies in this group have been carried out in the last five years.

For example, the oxidation of a bicyclic lactam proceeds via the *N*-acylimine[65]; the intermediate *N*-acylimine readily combines with nucleophiles:



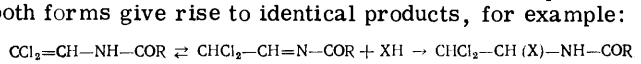
Many photochemical reactions of amides[66] and azidoketones[67,68] involve the formation of intermediate *N*-acylimines. The *N*-acylimines formed in the reaction can readily combine with alcohols[66], can be isolated in a free state[68], or, as in the case of diazidoketones, are converted into tetrazoles[67]:



†However, one should bear in mind that the same cation is obtained on *N*-protonation of the *N*-acylimine form and on *C*-protonation of the enamide, so that in this sense the problem of the tautomerism of the initial compounds remains open.

The formation of *N*-acylimines from saturated amides was demonstrated in studies [69,70] where an amide containing a hydrogen atom in the α-position was acted upon by t-butyl hypochloride and an alcohol was then made to add to the *N*-acylimine formed on dehydrochlorination. Using this method, Firestone and Christensen [71] introduced various functional groups in the $C_{(6)}$ position in penicillin:

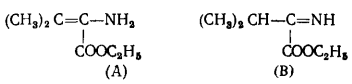
It may be that a study of such reactions will assist a deeper understanding of the metabolism in the living cells of penicillin-based preparations.



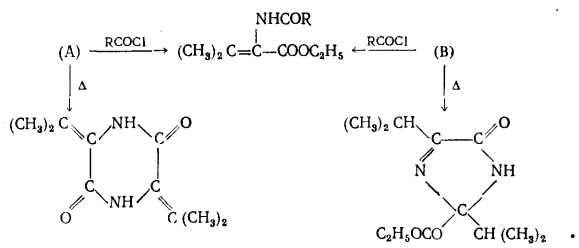
According to the results of Morin and coworkers [72-74], the thermal and catalytic expansion of five-membered O- and S-containing lactams proceeds via the *N*-acylimine form. The formation of the intermediate *N*-acylimine form is accompanied by the hydrolysis of various α-carboxyenamides [75-77]:

The bond between nitrogen and the vinyl group is also broken in the alkaline hydrolysis of β,β-dichlorovinylamides [78]: consequently, the reaction proceeds via the *N*-acylimine form (since the nitrogen–carbonyl bond is broken in the usual hydrolysis of amides):

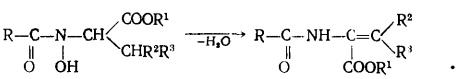
In those cases where the enamide and *N*-acylimine forms lead to different products, it is not difficult to establish the involvement of the *N*-acylimine tautomeric form in the reaction. The situation is more complex when both forms give rise to identical products, for example:



The occurrence of tautomerism in β,β-dichlorovinylamides or their derivatives has been suggested in a number of studies [78-81], but nucleophilic addition to β,β-dichlorovinylamides has been studied quantitatively only recently [82-84]. That the reaction proceeds via the *N*-acylimine form is indicated by data concerning the influence of the catalyst concentration and substituents on the rate of reaction, the presence of the kinetic isotope effect, the reactions with model secondary enamides, etc. The study of the kinetics of the addition of alcohols to *N*-acylimines using the reactions of alcohols with *N*-acylchloral imines, [85] as well as quantum-chemical calculations for individual tautomeric forms and the corresponding common anions [55] made it possible to estimate the tautomeric equilibrium constants (5.7×10^{-4}), the energy difference between the two forms (5 kcal mole^{-1}), and the influence of substituents on the equilibrium position. Electron-donating substituents tend to shift the equilibrium towards the *N*-acylimine form, which agrees well with data for simple imine–enamine systems without a hydrogen bond [4,12,14-16].

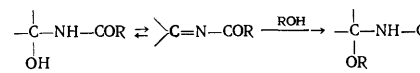


Shin and coworkers [86-90] studied α,β-unsaturated acids and their esters involved in the equilibrium

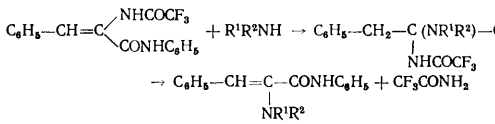


It is of interest that there is no such equilibrium for the analogue unsubstituted at the nitrogen atom—both forms exist individually:

The compounds (A) and (B) give rise to a single enamide on acylation (cf. Refs. 6 and 59) and to different condensation products on heating:

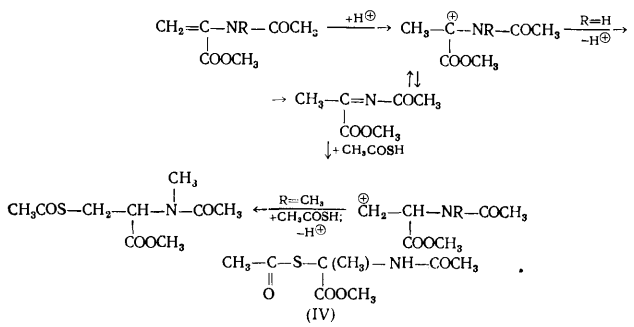


The same workers [87-90] found that, instead of the expected *N*-acylimines, their more stable tautomers (enamides) are formed on dehydration of *N*-substituted α-carboxy-*N*-hydroxyamides:



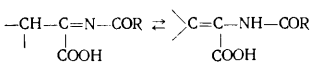
Isomerisation proceeds more readily for $R^2 = H$ than for $R^2 = OCH_3$. [90] This agrees with the general postulate that any electron-accepting influence stabilises the enamine.

Nucleophilic substitution in the α-position of an *N*-substituted enamide also proceeds, according to Meyers and Shaw [91], via the *N*-acylimine (elimination–addition):



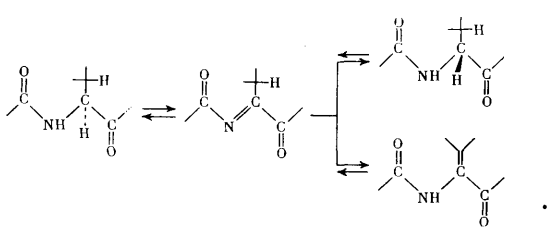
The reactions of a series of α-substituted enamides $C_6H_5CH{=}C(CONHR)NH{-}COR^1$ with mercaptans, amines, and hydrazines were studied recently [92]. The addition proceeds in accordance with the Markovnikov rule; in the case of amines and hydrazine, the reaction continues further:

For hydrazine, the hydrazone form $C_6H_5{-}CH_2{-}C(CONHC_6H_5){=}N{-}NH_2$ is more stable. The formation of the transamination product as a result of addition–elimination has been demonstrated by the absence of reaction for saturated analogues. The authors believe [92] that the addition takes place at the C=N bond of the *N*-acylimine tautomer, because they claim that the addition to the C=C bond of the enamine should proceed contrary to the Markovnikov rule because of the polarisation of the C=C bond under the influence of the carbonyl group. However, the *N*-acylimine form cannot be detected by spectroscopic methods [92].



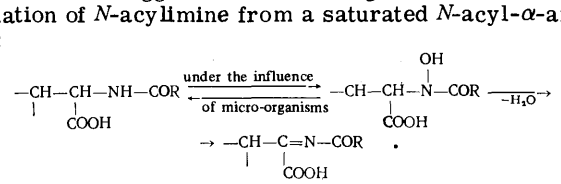
The literature data on *N*-acylimines as the reactive intermediates in the reactions of α-carboxylated enamides have been surveyed to some extent in a brief report [93], which also describes a study of the interaction of α-methoxycarbonyl-enamides with thioacetic acid. The mode of

addition is different for compounds with an NH group and for the *N*-methylated compound. The authors[93] suggest the following reaction mechanism:



The exchange of the thioacetate group in compound (IV) for the OCH_3 group as well as the reduction of (IV) to $CH_3OCS-CH(CH_3)-NH-COCH_3$ apparently proceed similarly[93].

Studies in which the problem of the enamide–*N*-acylimine tautomerism is considered in relation to the structures of antibiotics, peptides, and optically active aminoacids are of very great interest. Bycroft[94] noted the great importance of the following processes in living organisms:



(11)

In particular, Bycroft explains the presence of racemates of aminoacid derivatives in organisms. Since the peptides in living cells are made up of L-aminoacids, D-aminoacids are apparently formed via reversible oxidation-reduction involving *N*-acylimine:

As shown in the scheme above, it may be that the intermediate *N*-acylimine is converted into an enamide. The mechanism illustrated in the above scheme is confirmed by the absence of the D-configuration from the *N*-methylaminoacids, which frequently form part of antibiotics, and by the presence in many peptides of α,β-unsaturated *N*-acyl-α-aminoacids, formed as the tautomers of *N*-acylimines. The above scheme also explains the α-epimerisation rule: if the aminoacid contains more than one chiral centre, the configuration is inverted only at the α-carbon atom. Only one point remains obscure in this scheme—namely why an oxidation–reduction equilibrium occurs at all and what reagents cause it to be established.

Some light has been thrown on this problem by studies[95,96] whose authors suggested the following mechanism for the formation of *N*-acylimine from a saturated *N*-acyl-α-aminoacid:

α-Aminoacids, *N*-acyl-α-aminoacids, and their derivatives $>CHC(COOR)=NR$ and $>C=C(COOR)NHCOR$ have been obtained[96] by a method analogous to that in Refs. 68 to 70. It is seen that here too acylation of imines gives rise to the tautomeric enamides.

Recently there has been a particular growth of interest in α-carboxyenamides (*N*-acyldehydroaminoacids) when it has become clear that they are the starting compounds in the synthesis of peptides[97] and in addition are components of natural peptides[98]. The overall mechanism of the reactions of *N*-acylaminoacids in organisms is as follows[95]: initially biological *N*-hydroxylation and dehydration lead to the *N*-acylimine; in the presence of proton-containing nucleophiles they then rapidly add to the C=N bond, while in the absence of such bonds *N*-acylimines rapidly rearrange to α-carboxylenamides. The addition of peptide residues to the latter also apparently proceeds via the *N*-acylimine form, because the mode of addition is inconsistent with the polarisation of the double bond under the influence of the carboxy-group.

Investigation of Isotope Effects with the Aid of Kinetic and Catalytic Polarographic Currents

A. Čalusaru

Two types of chemical reactions, used to investigate isotope effects, are considered: reactions preceding the electrochemical stage proper and reactions accompanying this stage. The results of studies on the dehydration of formaldehyde are presented as examples of reactions of the first type and those on the oxidation of titanium(III) to titanium(IV) by hydroxylamine and the decomposition of hydrogen peroxide by catalase are presented as reactions of the second type. The results of a polarographic determination of the rate constants for reactions involving isotopic molecules, on the basis of which it is possible to determine the isotope effect for the corresponding reaction, are described together with the results of the determination of the equilibrium constants with the aid of both classical polarography and oscillographic polarography with rapid potential scanning. The equilibrium constants of the acid dissociation and dehydration reactions involving formaldehyde were determined and were employed to determine the corresponding thermodynamic isotope effects. It is shown that a direct isotope effect obtains in the acid dissociation reaction and the inverse effect obtains in the dehydration reaction.
The possibility of using the results of the study of isotope substitution in relation to catalytic currents in the cobalt-sodium nitrohydroxylaminate-cysteine sytem in an ammonia buffer for the determination of the isotopic composition of water is demonstrated. It is concluded that the polarographic method has many possibilities for the inverstigation of both kinetic and thermodynamic isotope effects and the isotope effects of the solvent.

I. INTRODUCTION

The polarographic method makes it possible to determine the rate constant for any chemical reaction, provided that it is coupled with a charge transfer process. Taking into account the sequences in relation to the electrode process, it is possible to distinguish the following coupled reactions: reactions preceding and accompanying catalysis and subsequent reactions. A theoretical analysis has been carried out for all three cases and the tabulated values of special functions make it possible to calculate the corresponding rate constants from experimental data for kinetic waves (a general literature review may be found in the book by Heyrovský and Kuta[1]). If the polarographic method is used to investigate a chemical reaction involving isotopic molecules, atoms, or ions, it is possible to determine the rate constant for the reaction corresponding to the given isotopic species; furthermore, the kinetic isotope effect may be determined from the ratio of the observed rate constants.

The first study devoted to the use of polarographic kinetic currents for the determination of isotope effects was published by the present author in 1965.[2] The decomposition of hydrogen (deuterium) peroxide by catalase in the course of the reduction of oxygen at a mercury dropping electrode was investigated. Later kinetic waves were also used to study certain chemical reactions involving isotopic molecules in light and heavy water[3-5].

Polarographic currents of another type, namely catalytic currents associated with the discharge of hydrogen ions[6-11], were used to study certain special isotope effects[12,13]. Although in this case it is impossible to determine the reaction rate constants from the experimental data, nevertheless the observed isotope effects may be referred to kinetic phenomena, particularly in connection with protonation–deprotonation reactions. In this instance the isotope effect is expressed by the ratio of the numbers of hydrogen and deuterium ions participating in the protonation–deprotonation reaction[12].

This review presents the results obtained in the study of certain typical chemical reactions with participation of isotopic molecules. The classification unsually employed in polarographic studies is adhered to in the description of the results.

II. KINETIC CURRENTS

In order to determine isotope effects, studies were made of only two types of chemical reactions: reactions preceding charge transfer and reactions accompanying this process. However, the number of reactions investigated is very limited in precisely these two instances. The difficulties encountered in the synthesis or deuteriation of large and complex organic molecules may be regarded as the main cause of this situation.

1. PRECEDING REACTIONS

In the determination of isotope effects, we chose only the dehydration of formaldehyde as the preceding reaction[4]:

$$X_2C(OX)_2 \underset{k'}{\overset{k}{\rightleftarrows}} X_2C{=}O + X_2O, \qquad (1)$$

where X is the protium (H) or deuterium (D) and k and k' are the rate constants for the forward and reverse reactions. This process is most characteristic of preceding reactions and makes it possible to determine both thermodynamic and kinetic isotope effects. Among the components of reaction (1), only the aldehydic form X_2CO is

reducing, because the hydrated form [methylene glycol $X_2C(OX)_2$] is not a depolariser. In conformity with Eqn. (1), the dehydration reaction therefore precedes the electrochemical reduction of the aldehyde.

In the first study on the polarographic reduction of formaldehyde, Jahoda[14] found that formaldehyde is reduced to methanol via a two-electron process. This result was confirmed by other investigators[15-18].

The overall electrode reaction may be described as follows:

$$\underbrace{X_2C(OX)_2 \underset{k'}{\overset{k}{\rightleftarrows}} X_2CO}_{\text{chemical stage}} \underbrace{\overset{+2e}{\rightarrow} X_3COX}_{\text{electrochemical stage}} \quad . \qquad (2)$$

The chemical stage may undergo acid–base catalysis and for higher values of pX (pX > 13) account must be taken of the dissociation of the hydrated form. The study of reaction (2) requires the use of certain deuteriated substances. Clearly the most important factor is the preparation of $D_2C(OD)_2$; this substance has been synthesised[4] by the acid catalysis of the exchange of hydrogen bound to the carbon atom. For acid catalysis, solid paraformaldehyde was dissolved in 53% D_2SO_4. A concentrated solution of deuteroformaldehyde was obtained by distillation with dissolution of gaseous formaldehyde in 99.5% D_2O. This solution was redistilled and finally a solution with an overall formaldehyde concentration of 1 M was obtained. NaOD solutions were prepared by the reaction of metallic sodium with heavy water. Deuteriated boric acid D_3BO_3 was synthesised by dissolving boron trioxide in heavy water. The concentration of protons was determined by NMR and proved to be fairly low compared with that in the heavy water usually employed (99.5% D_2O).

(a) Thermodynamic Isotope Effects

In order to determine the rate constant for the chemical reaction preceding the electrode stage proper, it is necessary to know the equilibrium constant for the reaction[1]. As a result of the kinetic effect described by Eqn. (2), it is impossible to determine by classical polarography the equilibrium concentrations of the non-hydrated form of formaldehyde. It is therefore necessary to eliminate the contribution of the chemical reaction itself to the overall current. This problem was solved for the usual non-deuterated formaldehyde by Valenta[19], who used a single-cycle oscillographic polarographic method with a very high rate of change of potential. Using the same procedure, the present author and his coworkers[4] studied systems incorporating both protium and deuterium. i–E curves are presented in Fig. 1 for protium (*a*) and deuterium (*b*); evidently, for a rate of change of potential $s = 4$ V s^{-1} in light water, there is no maximum in the current, while in heavy water there is a small peak, indicating a contribution of diffusion to the reduction of non-hydrated formaldehyde. At a higher rate of change of potential, the diffusional current increases in both light and heavy water. It was found unexpectedly that the diffusion-controlled current in heavy water is reached for lower rates of change of potential than in light water. For very high rates of change of potential ($s = 320$ V s^{-1}, Fig. 1*c*), the maximum currents correspond to the analytical concentration of the free aldehyde form, since the kinetic component has been fully eliminated. Knowing the equilibrium concentration of formaldehyde, it is possible to calculate the equilibrium constant for its dehydration in both light and heavy water.

The concentration of the non-hydrated form in the bulk of the solution can be found from the results obtained by the single-cycle oscillographic polarographic method, treating the height of the diffusion-controlled current peak as a function of $s^{1/2}$ (Fig. 2). For low values of s, the variation of the current is of the kinetic type and the difference between the currents corresponding to systems with light and heavy water is small, while for high rates of change of potential, the difference becomes considerable; as we predicted, the currents are greater in heavy water than in normal water.

The corresponding concentrations of the free aldehydic form can be calculated from the slopes of the straight lines illustrated in Fig. 2. The calculation is possible if it is assumed that the reduction reaction has a

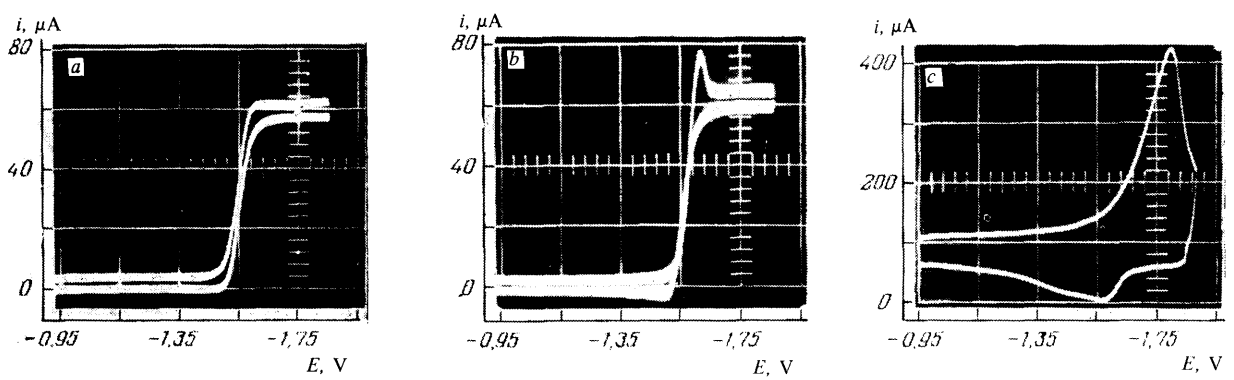

Figure 1. Oscillographic i – E curves for the reduction of formaldehyde at rates of change of potential of 4 V s^{-1} (*a* and *b*) and 320 V s^{-1} (*c*); initial potential −0.95 V; anode–saturated calomel electrode; triangular pulse. Solution: 0.03 M borax and 1.3 M KCl: *a*) 0.217 M H_2CO in H_2O; *b*) and *c*) 0.555 M D_2CO in D_2O. Characteristics of the capillary: $m = 0.227$ mg s^{-1}; $t_1 = 48$ s for $h = 46$ cm (m is the flow rate and t_1 is the drop time).

two-electron mechanism and the following equation derived by Delahay[20] is used:

$$i_p = 3.03 \cdot 10^5 n (\alpha n_\alpha)^{1/2} A D_b^{1/2} c_b s^{1/2},$$

where i_p is the peak current (A), n the number of electrons involved in the overall reaction, n_α the number of electrons involved in the rate-determining stage, α the transfer coefficient, A the drop area (cm^2), D_b the diffusion coefficient of the electrochemically active form ($cm^2\ s^{-1}$), c_b the concentration (mole cm^{-3}), and s the rate of change of potential ($V\ s^{-1}$). The slope, i.e. $\tan\varphi$, can be found from the data in Fig. 2:

$$\tan\varphi = \Delta i_p / \Delta s^{1/2},$$

so that the concentration of the non-hydrated form is

$$c_{b,X_2O} = (\tan\varphi)_X / 3.03 \cdot 10^5 n (\alpha n_\alpha)^{1/2} A D_b^{1/2}. \quad (3)$$

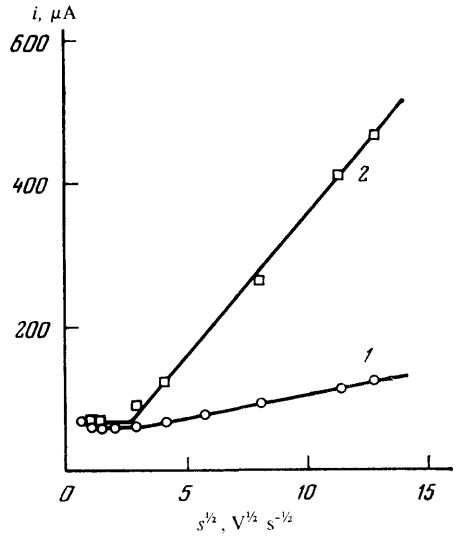

Figure 2. Dependence of the current peak on the rate of change of potential s. Solution: 0.03 M borax and 1.3 M KCl: 1) 0.217 M H_2CO in H_2O; 2) 0.555 M D_2CO in D_2O.

We obtain the following values from Fig. 2: $(\tan\varphi)_H = 6.3 \times 10^{-6}$ and $(\tan\varphi)_D = 41.3 \times 10^{-6}$. Other numerical values are as follows: $n = 2$; $\alpha = 1.48$;[19] $n_\alpha = 1$; $D_{b,H_2O} = 1.22 \times 10^{-5}$ $cm^2\ s^{-1}$;[16] $D_{b,D_2O} = 1.09 \times 10^{-5}$ $cm^2\ s^{-1}$;[21] $A = 2.67 \times 10^{-2}$ cm^2 for the flow rate $m = 0.227$ mg s^{-1} and the drop time $t = 20$ s. On substituting these values in Eqn. (3), we obtain the formaldehyde concentrations $c_{b,H_2O} = 0.94 \times 10^{-1}$ M and $c_{b,D_2O} = 6.4 \times 10^{-4}$ M. The analytical concentrations are $c_{b,t,H_2O} = 0.217$ M and $c_{b,t,D_2O} = 0.555$ M. The equilibrium constants for the dehydration reactions then assume the following values: $K_{h,H_2O} = 4.33 \times 10^{-4}$ and $K_{h,D_2O} = 1.15 \times 10^{-3}$.

The thermodynamic isotope effect can be obtained from the ratio of these two constants:

$$K_{h,H_2O}/K_{h,D_2O} = 0.376\ .$$

Evidently this is in fact an inverse isotope effect, which shows that formaldehyde is more solvated in heavy water than in light water.

This result may be interpreted taking into account the difference between the energies of the chemical bonds of the isotopic molecules. The overall energy of the molecule can be expressed as the sum of the following quantities:

$$E = E_\nu + E_{R,e} + E_{R,i} + E_{Tr} + E_{R,\nu} + E_{El} + E_k,$$

where the subscripts denote vibrations (ν), external rotations (R, e), internal rotation, namely the vibration of a molecule bound to another molecule (R, i), translation (Tr), rotational-vibrational interaction (R, ν), electron shell (El), and atomic nucleus (k).

Analysis of atomic and molecular spectra permitted the conclusion that the difference between the electronic energies of protium and deuterium cannot be responsible for the isotope effect, which exceeds 0.5%. Consequently molecular vibrations may be regarded as the only possible cause of isotope effects[22]. Isotopic molecules have the same chemical formula but, owing to the difference between their masses, their vibration frequencies and "zero-point" energies also differ. A molecule containing a heavy isotope has a "zero-point" energy smaller than the molecule containing the light isotope. Clearly the energy required for the dissociation of each isotopic molecule is different and the difference depends both on the enthalpy and entropy of reaction.

In the formaldehyde dehydration reaction the chemical bond between oxygen and hydrogen is of greatest importance. In water and formaldehyde these bonds are different. In water each molecule has three vibration frequencies, while in formaldehyde their number is greater ($n > 3$). In a water molecule the frequencies ν_i are higher than in a formaldehyde molecule[23]. The zero-point energy is given by the formula

$$E^0 = \sum_{i=1}^{n} \frac{1}{2} h\nu_i.$$

It follows from experimental dehydration constants that

$$E^0(H_2O) - E^0[H_2C(OH)_2] > E^0(D_2O) - E^0[D_2C(OD)_2]$$

or

$$E^0[H_2C(OH)_2] - E^0[D_2C(OD)_2] < E^0(H_2O) - E^0(D_2O) = 3.55 \text{ kcal mole}^{-1}, \text{ (Ref. 21)},$$

Eqn. (4) agrees well with the rule known from isotope chemistry, which states that the heavy isotope enters preferentially the chemical compound in which it is bound more strongly. This rule is applied on the hypothesis that the molecules are in their lowest vibrational energy level and that the entropy change is insignificant.

The hydrogen isotope effect at room temperature depends mainly on the type of chemical bond. The separation fractors, defined as $(D/H)_{compound}/(D/H)_{water}$, are close for compounds with similar bond types. For alcohols, the separation factor depends on the given molecule: whereas for methanol the separation factor is 1.0, for ethanol it is 1.1. In this connection, mention should be made of an important postulate, namely that the greatest isotope effect is noted when the isotopes are considered in compounds where they form a strong chemical bond with a free monatomic element.

We have already noted that, for high pX values, the degree of dissociation of hydrated formaldehyde molecules becomes considerable:

$$X_2C(OX)_2 \rightleftarrows X_2C(OX)O^- + X^+ \quad . \qquad (5)$$

It is possible to calculate the dissociation constant for this reaction, which occurs at high pX values, using the kinetic currents determined by the classical polarographic method.

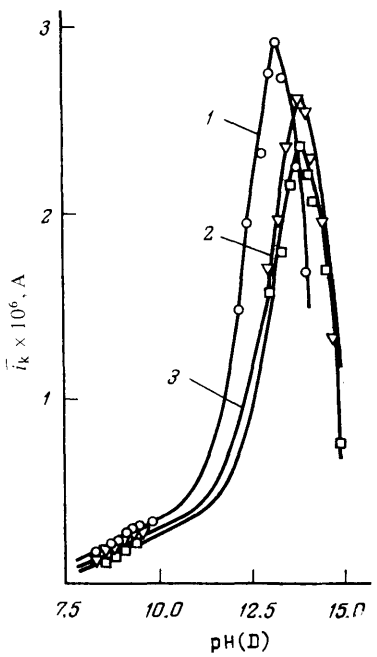

Figure 3. Average limiting current $\bar{i}_k$ as a function of pH(D) for the polarographic reduction of formaldehyde (4×10^{-3} M): 1) H_2CO in H_2O; 2) H_2CO in D_2O; 3) D_2CO in D_2O. A borate buffer was used in the pH range 7.5–10.0 and sodium hydroxide was used in the pH range 10.0–15.0; temperature 20°C.

Fig. 3 [4] illustrates the height of the kinetic waves $\bar{i}_k$ as a function of pH(D) for the reduction of formaldehyde in an alkaline medium. Evidently, in contrast to diffusion currents, kinetic currents are smaller in heavy water than in light water for H_2CO and smaller still for D_2CO. The validity of this result was tested by adding in succession increasing amounts of heavy water at a constant H_2CO concentration and at pH close to the value corresponding to the maximum kinetic current (Fig. 4). Extrapolation of the curve to 100% D_2O agrees, within the limits of experimental error, with the corresponding maximum value on curve 2 in Fig. 3.

In order to determine the dissociation constant K_a for reaction (5), we used the formula derived by Vesely and Brdička[16]:

$$K_a = \frac{[X^+]_M^{1/2}}{[X^+]_M^{1/2} + 2a} ,$$

where $[X^+]_M$ is the H^+ or D^+ concentration for maximum $\bar{i}_k$ (Fig. 3) and a is a constant[16] defined by the formula

$$a = \frac{\bar{i}_k}{(\bar{i}_d)_{b,aq} - \bar{i}_k} [X^+]^{1/2} .$$

Here $(\bar{i}_d)_{b,aq}$ is the diffusion current corresponding to the overall constant concentration of the undissociated form $X_2C(OX)_2$. In the region of low pX values, where the degree of acid dissociation of formaldehyde is very low, the diffusion current corresponds to the analytical concentration of formaldehyde and may be calculated by the Ilkovič equation. Ultimately the following values were obtained[4]: $K_a = 2.5 \times 10^{-14}$ ($pK_a = 13.6$) for H_2CO in H_2O and $K_a = 10^{-14}$ ($pK_a = 14$) for H_2CO and D_2CO in D_2O. The thermodynamic isotope effect is defined as the ratio of these equilibrium constants:

$$K_a(H_2O)/K_a(D_2O) = 2.5 \quad . \qquad (6)$$

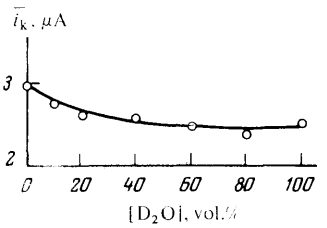

Figure 4. Influence of the content of D_2O on the kinetic current for the reduction of 4×10^{-3} M H_2CO in 0.15 M sodium hydroxide solution (which corresponds to the current maximum in Fig. 3).

In contrast to the dehydration reaction, in the dissociation of formaldehyde the isotope effect is direct, as expected. This result can be accounted for on the basis of the difference between the ionic products of light and heavy water: $pK_{H_2O} = 14.167$ at 20°C [24] and $pK_{D_2O} = 14.963$ at 20°C (calculated from the value of pK obtained by Abel et al.[25] at 25°C). In general the acid dissociation constants of OH, NH, SH, and CH in D_2O are smaller than in H_2O.[26] For weak acids, it has been found experimentally that the ratio K_H/K_D is in the range from 2.5 to 3.9. This agrees well with the value obtained using Eqn. (6) for X_2COXO^-.

(b) Kinetic Isotope Effects

On the basis of data obtained by classical polarography, it is also possible to determine the product of the equilibrium constant K_{h,X_2O} and the dehydration rate constant k_{i,X_2O}. K_{h,X_2O} was defined above and the corresponding rate constant may be found from the formula derived by Weber and Koutecký[27]:

$$\frac{\bar{i}_k}{\bar{i}_d} = \frac{0.886\,(K_h k_i t_1)^{1/2}}{1 + 0.886\,(K_h k_i t_1)^{1/2}} ,$$

where t_1 is the drop time and $\bar{i}_d$ the calculated current determined by diffusion and corresponding to the analytical concentration of undissociated formaldehyde.

The overall rate constant is the sum of the partial rate constants for the dehydration of formaldehyde with participation of water, hydrogen ions, hydroxide ions, and acid (A) and alkaline (B) components:

$$k = k_{X_2O} + k_{X^+}[X^+] + k_{OX^-}[OX]^- + \sum k_{XA}[XA] + \sum k_B[B],$$

In a weakly alkaline borate buffer it is possible to neglect the contribution of the ions X^+ and acid components, and the rate constant is then obtained from a simpler formula:

$$k = k_{X_2O} + k_{X_2BO_3^-}[X_2BO_3^-] + k_{OX^-}[OX^-].$$

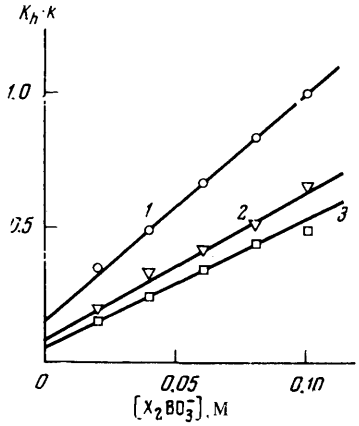

Figure 5. Variation of $K_h k$ with borate concentration. Formaldehyde concentration 4×10^{-3} M: 1) H_2CO in H_2O; 2) H_2CO in D_2O; 3) D_2CO in D_2O; temperature 20°C.

This expression shows that the dependence of $K_h k$ on $[X_2BO_3^-]$ is linear {[the term $k_{OX^-}[OX^-]$ can also be neglected (Fig. 5)]}. The products $K_h k_{X_2O}$ and $K_h k_{X_2BO_3^-}$ can be determined from the intercept made by the straight line on the ordinate axis and from its slope respectively. Their values at 20°C are listed below:

Solution	$10^4 \cdot K_h \cdot k_{X_2O}$, s^{-1}	$10^4 \cdot K_h \cdot k_{X_2BO_3^-}$, litre mole^{-1} s^{-1}	$K_h \cdot k_{OH^-}$, litre mole^{-1} s^{-1}
H_2CO in H_2O	15	8.5	0.279
H_2CO in D_2O	8	5.5	0.6666
D_2CO in D_2O	5.5	4.8	0.496

The corresponding rate constants calculated using the equilibrium constants for the dehydration reaction, determined previously, are:

X	$10^3 \cdot k_{X_2O}$, s^{-1}	$k_{X_2BO_3^-}$, litre mole^{-1} s^{-1}	$10^{-3} \cdot k_{OX^-}$, litre mole^{-1} s^{-1}
H	3.46	1.69	6.44
D	0.478	0.417	4.31

The kinetic isotope effect k_H/k_D assumes the following values at 20°C:

k_i	k_{X_2O}	$k_{X_2BO_3^-}$	k_{OX^-}
k_H/k_D	7.25	4.7	1.5

The maximum theoretically possible kinetic isotope effect for hydrogen isotopes at 25°C is 18,[28] but the experimental values proved to be smaller by a factor of 3. The results can be explained taking into account both the electrode reaction and the reaction medium. Among the three rate constants quoted above, that which corresponds to the solvent (k_{X_2O}) is determined by its nature. In the dehydration of formaldehyde the solvent behaves both as a catalyst and a reactant. A greater isotope effect is therefore to be expected for the rate constant k_{X_2O}, as has been confirmed experimentally. The OH or OD bonds are dissociated in the hydration–dehydration reaction. The maximum theoretical value of k_H/k_D expected for this process at 25°C is 10.6. In practice this value may be largely compensated by other isotope effects. For the given reaction and the constant k_{X_2O} under consideration, the main isotope effect is determined by the transfer of a hydrogen atom and a hydroxy-group from the bound state to water. In order to examine the process more completely, account must also be taken of the changes in the vibration frequency of the system, the anharmonicity of the phenomenon, and the liberation of liquid water molecules.

The isotope effect corresponding to the catalytic constant $k_{X_2BO_3^-}$ probably depends on the dissociation constant of boric acid in light and heavy water. There are no literature data for this constant in heavy water. The relatively high isotope effect is determined by the transfer of a hydrogen ion between the water molecule and the species undergoing reduction, i.e. the process constituting the stage which determines the rate of the entire reaction. This result may be compared with the isotope effect[4,5] in the alkaline catalysis of the ionisation of acetylacetonate[29].

For the constant k_{OX^-}, the isotope effect is determined by the dissociation and hence the strength of the alkali which catalyses the dehydration of formaldehyde. Fig. 3 shows that pD > pH for this process. The relatively small isotope effect in this instance can be accounted for by the two-step mechanism of this reaction. If there is no bond dissociation in the first step, which determines the rate of the entire reaction, and the system undergoes only a slight change, then only a secondary isotope effect of the overall reaction may be noted[30]. A more modern explanation of this mechanism was given by Westheimer[31], who believes that the high asymmetry of the transition state in this reaction, where the proton transfer is the rate-determining step, reduces the isotope effect to a mass coefficient, i.e. $k_H/k_D = 1.4$.

Evidently other chemical reactions preceding the electrode reaction proper can be investigated similarly. Among the substances containing a hydrated aldehyde group and behaving similarly to formaldehyde, mention may be made of the following: pyridine-2-aldehyde, pyridine-3-aldehyde, pyridine-4-aldehyde, glyoxalic acid, pyruvic acid, etc. All these substances have already been investigated in normal water[1]. There also exists a group of substances belonging to the same class, which have not been investigated quantitatively: acetaldehyde, propionaldehyde, glycolaldehyde, alloxan, tetroses, halogenoaldehydes, phthalic aldehyde, and mesoxalic, phenylpyruvic, trimethylpyruvic, and phenylglyoxalic acids.

Another preceding chemical reaction involves the recombination of anions with hydrogen ions. Phenylglyoxalic acid is reducible, while boric acid is non-reducible. The dissociation reactions of complex compounds, among which those of cadmium complexes with nitrilotriacetic acid have been most thoroughly investigated, are analogous. Monosaccharides (particularly aldoses) constitute an important class of organic substances which give rise to kinetic waves. In the study of the isotope effects in all the above instances the greatest

difficulty is the synthesis of the corresponding isotopic molecules.

2. REACTIONS ACCOMPANYING ELECTRON TRANSFER

In contrast to preceding reactions, which the rate constants for the reactions accompanying electron transfer are determined, there is no need to know the equilibrium constants. This facilitates significantly the experiment and classical polarographic data are sufficient for the calculation of the rate constant. In order to determine the kinetic isotope effects, the following reactions have been studied: the oxidation of titanium(III) to titanium(IV) by normal and deuteriated hydroxylamine; similar reactions involving the oxidation of iron(II) to iron(III) and of chromium(II) to chromium(III); decomposition of hydrogen and deuterium peroxide by catalase.

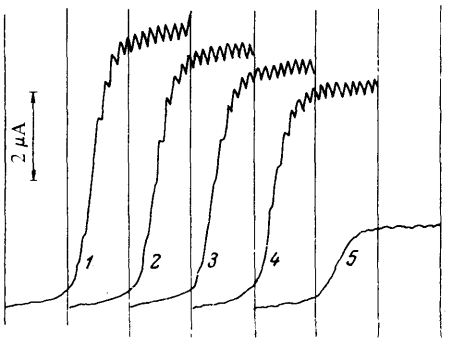

Figure 6. The influence of the concentration of heavy water on the titanium reduction wave in the presence of hydroxylamine; 10^{-3} M $TiCl_4$; 0.2 M $H_2C_2O_4$; 0.0855 M NH_2OHHCl; $[D_2O]$ in 10 ml of solution (ml): 1) 0; 2) 2; 3) 4; 4) 5.8; 5) without hydroxylamine; $t_1 = 3.8$ s; initial potential 0 V; scan along abscissa axis 200 mV; anode–saturated calomel electrode; temperature 24.5°C.

(a) Oxidation of Titanium(III) by Hydroxylamine[3]

In the presence of hydroxylamine the change in the limiting current accompanying the reduction of titanium(IV) to titanium(III) has a kinetic mechanism[32] and is due to the chemical oxidation of titanium(III) by hydroxylamine. The kinetics of this reaction were first studied polarographically by Blažek and Koryta[32]. The rate constant determined by the authors is $k_{25\,°C} = 42.1 \pm 1.5$ litre mole^{-1} s^{-1} and the activation energy is E_H 7.9 kcal mole^{-1}. Delahay et al.[33], who studied this reaction by the chronopotentiometric method, found that the rate constant is $k_{30\,°C} = 30$ litre mole^{-1} s^{-1}. Saveant and Vianello[34] obtained by the same method $k = 42.0 \pm 1.7$ litre mole^{-1} s^{-1}. Using an improved chronopotentiometric method, other investigators[35] found $k_{27\,°C} = 32.0 \pm 2$ litre mole^{-1} s^{-1}. Lingane and Christie[36] used a two-cycle chronopotentiometric method and found $k_{25\,°C} = 43.4 \pm 1.1$ litre mole^{-1} s^{-1} and the activation energy $E_H = 17.3$ kcal mole^{-1}.

In the study of the isotope effect in the above reactions all the substances were deuteriated in the following way: $TiCl_4$ was dissolved in D_2O and deuteriated oxalic acid was then added to the solution. The acid and hydroxylamine were deuteriated by isotope exchange in three successive recrystallisations from 99.9% D_2O. As the heavy water gradually substitutes normal water, the height of the kinetic wave decreases appreciably (Fig. 6). Fig. 7 shows that the dependence of the ratio i_l/i_d on the amount of D_2O is linear (i_l is the limiting current of titanium in the presence of hydroxylamine and i_d is the diffusion current in the absence of hydroxylamine). The kinetic current increases with hydroxylamine concentration and with the ratio i_l/i_d (Fig. 8). It follows from the data in Fig. 8 that, at the same hydroxylamine concentration, the current ratio is always smaller in the deuterium system than in the hydrogen system, but the overall form of the curves is the same in the two systems.

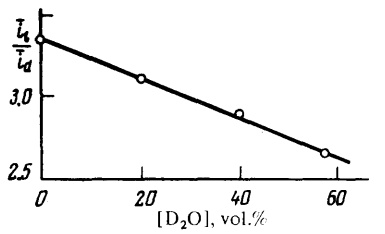

Figure 7. Influence of the concentration of deuterium on the current ratio at 24.5°C.

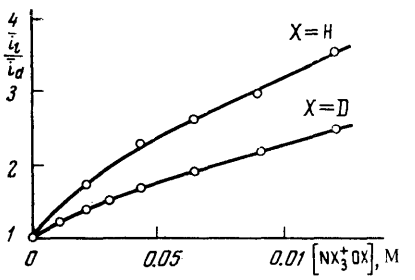

Figure 8. Dependence of the current ratio on hydroxylamine concentration at 23°C.

The kinetic current is determined by the rate of reaction, which explains the rapid increase of its limiting value with increase of temperature. The extent of this change depends on the activation energy, which can be calculated with the aid of the familiar Arrhenius equation:

$$\lg k = -0.43E/RT + \text{const.}$$

Fig. 9 presents plots of $\lg k$ against $1/T$ for the oxidation of titanium(III) to titanium(IV) by hydroxylamine in the hydrogen and deuterium systems. The following activation energies were obtained from the slopes of these straight lines: $E_H = 16.7$ kcal mole^{-1} and $E_D = 17.6$ kcal mole^{-1}; these values are comparable to those published

by Lingane and Christie[36]. It is noteworthy that the activation energies for the hydrogen and deuterium systems are very close, which can be used to elucidate the reaction mechanism.

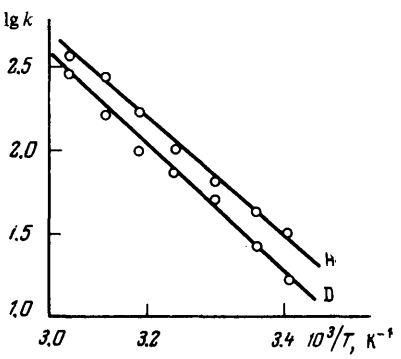

Figure 9. Dependence of $\lg k$ on $1/T$ for the oxidation of titanium(III) by hydroxylamine in the hydrogen and deuterium systems.

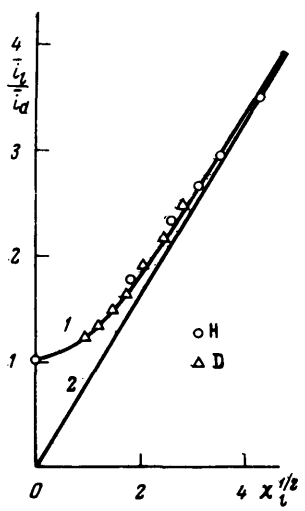

Figure 10. Variation of the ratio $\bar{i}_l/\bar{i}_d$ with $\chi_l^{1/2}$ (curve *1*) and the asymptotic solution (curve *2*); $t_1 = 3.8$ s; $k^H = 41.3 \pm 1.5$ litre mole^{-1} s^{-1}; $k^D = 18.2 \pm 0.8$ litre mole^{-1} s^{-1}; temperature 23 °C.

The following reactions are involved in the given process:

$$Ti^{IV} + e \rightarrow Ti^{III} \text{ (electrochemical stage)}, \quad (7)$$

$$Ti^{III} + NX_3^+OX \rightarrow Ti^{IV} + X_2O + \dot{N}X_2 \text{ (chemical stage)}. \quad (8)$$

The current corresponding to reaction (7) increases owing to reaction (8), which determines the kinetic nature of the limiting current. Since the measurements are made in the presence of an excess of hydroxylamine, reaction (8) is pseudounimolecular and Koutecký's method of calculation[37] may be used to determine the rate constants for the chemical reactions accompanying the electrode process. The calculation shows that the ratio i_l/i_d is a function of χ_l defined by the equation

$$\chi_l = k_X [NX_3^+OX] t_l.$$

The dependence of the ratio i_l/i_d on $\chi_l^{1/2}$ is illustrated in Fig. 10; the experimental data[3] for the oxidation of titanium(III) to titanium(IV) by normal and deuteriated hydroxylamine were used. The calculation yielded the following rate constants at 23 °C: $k_H = 41.3 \pm 1.5$ litre mole^{-1} s^{-1} and $k_D = 18.2 \pm 0.8$ litre mole^{-1} s^{-1}. The kinetic isotope effect is

$$k_H/k_D = 41.3/18.2 = 2.26.$$

The isotope effect in the activation energy for reaction (8), found from the experimental values already indicated, is

$$E_H/E_D = 16.7/17.6 = 0.946.$$

On the basis of the Arrhenius equation in the form

$$k_X = A_X \exp(-E_X/RT)$$

it is possible to determine three isotope effects: in the rate constant, in the activation energy, and in the frequency factor A_X. The first two isotope effects can be calculated from the experimental values of k_X and E_X. The isotope effect associated with the frequency factor A_X can be obtained from the formula

$$\frac{A_H}{A_D} = \frac{k_H}{k_D} \frac{\exp(-E_D/RT)}{\exp(-E_H/RT)} = 1.95.$$

Its value shows that the difference between the rate constants for the reactions of isotopic molecules depends little on the difference between their activation energies. At the same time it is seen that the lower collision frequency in the presence of the heavy isotope leads to a decrease of the rate constant.

The isotope effects in the oxidation of iron(II) to iron(III) and of chromium(II) to chromium(III) by hydroxylamine[5] were determined by the same methods as for the oxidation of titanium(III) to titanium(IV).[3] The reaction medium consisted of an alkaline solution of triethanolamine, which forms complexes with iron and chromium. The test substances were deuteriated as in the case of titanium[3]. Triethanolamine was recrystallised several times from heavy water (clearly only the mobile hydrogen was deuteriated).

The following values were obtained for the oxidation of iron(II): $k_H = 205 \pm 25$ and $k_D = 151 \pm 25$ litre mole^{-1} s^{-1}. Hence the kinetic isotope effect is $k_H/k_D = 205/151 = 1.36$; the activation energies are $E_H = 14.15$ and $E_D = 15.55$ kcal mole^{-1} and the corresponding isotope effect is $E_H/E_D = 14.15/15.55 = 0.909$. This value does not compensate the isotope effect in the rate constant. If the isotope effect in the frequency factor is calculated from the Arrhenius equation, we obtain $A_H/A_D = 1.35$.

The situation is the same in the oxidation of chromium(II) to chromium(III) by hydroxylamine. The observed values are $k_H = 274 \pm 29$ litre mole^{-1} s^{-1} and $k_D = 168 \pm 17$ litre mole^{-1} s^{-1}, $E_D = 12.4$ kcal mole^{-1}, $E_H = 9.74$ kcal mole^{-1}, and the corresponding isotope effects are $k_H/k_D = 274/168 = 163$, $E_H/E_D = 9.74/12.4 = 0.78$, and $A_H/A_D = 1.62$. Hence it follows that the collision frequency plays a decisive role in the kinetic isotope effects for reactions of this type.

(b) Decomposition of Hydrogen Peroxide by a Catalase

In the study of isotope effects the decomposition of hydrogen peroxide by catalase was also examined as a reaction accompanying the electrode process. Polarographic investigation of haemoproteins[38,39] showed that these substances react with the hydrogen peroxide formed in the cathodic reduction of oxygen. One group of haemoproteins reacts with hydrogen peroxide and the resulting compounds can be reduced at potentials intermediate between those of the oxygen and hydrogen peroxide waves. The following haemoproteins belong to this group: haemin[39], haemoglobin, and cytochrome[28]. Catalase differs from haemoproteins by its behaviour[38], because it decomposes hydrogen peroxide. In this process the height of the first oxygen wave increases, while that of the hydrogen peroxide wave diminishes and ultimately the two waves merge into one.

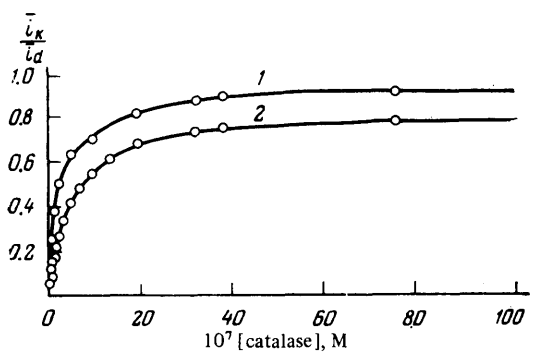

Figure 11. Dependence of the ratio $\bar{i}_k/\bar{i}_d$ on the catalase concentration in Sorensen phosphate buffers in H_2O (curve *1*) and D_2O (curve *2*); pH = pD = 7.2; t_1 = 2.56 s.

Koutecký et al.[40] determined polarographically the rate constants for the decomposition of hydrogen peroxide by catalase. The theoretical interpretation was based on the hypothesis that catalase decomposes into two components the hydrogen peroxide formed during the reduction of molecular oxygen: water and oxygen[2,40]:

$$O_2 + 2X^+ + 2e \rightarrow X_2O_2 \xrightarrow{\text{catalase}} X_2O + \frac{1}{2}O_2 \quad .$$

The study of this reaction in heavy water requires the deuteriation of the test substances[2]. The authors synthesised the deuteriated compounds in the following way. Deuterophosphoric acid was obtained by dissolving P_2O_5 in heavy water and NaOD was synthesised from metallic sodium and heavy water. Since it is clearly impossible to obtain fully deuteriated catalase, we recrystallised catalase twice from a buffer with deuteriated phosphate. In this procedure only the mobile hydrogen was deuteriated. The dependence of the ratio i_k/i_d on the catalase concentration in the range from zero to 1.05×10^{-5} M is illustrated in Fig. 11. Evidently curves having a similar overall shape are obtained in both systems, although the process is slower in D_2O.

The displacement of the second oxygen wave until it coincides with the first wave in the presence of catalase can be accounted for by two causes[41]: the decomposition of hydrogen peroxide by catalase results in the formation of molecular oxygen, which is reduced in the region of the first wave; the hydrogen peroxide formed reacts on the electrode surface with catalase and the resulting compound is then reduced at the electrode, also in the region of the first wave. Koutecký et al.[40] believe that the first mechanism is more probable, since a better agreement can be obtained in this way between the polarographic and oscillographic polarographic methods.

According to this mechanism, the kinetic current $\bar{i}_k$ is determined by the rate of formation of oxygen during the catalytic decomposition of hydrogen peroxide and deuterium peroxide. If the rate constant for the bimolecular decomposition of the peroxides by catalase is denoted by k_X, one can write

$$-\frac{d[X_2O_2]}{dt} = k_X\,[\text{cat}]\,[X_2O_2]_0,$$

and the rate of formation of oxygen is then expressed in the form

$$\frac{d[O_2]}{dt} = \frac{1}{2}k_X\,[\text{cat}]\,[X_2O_2]_0 \,.$$

The rate constant may be calculated from the formula[40]

$$\frac{i_l}{i_d} = 1 + \frac{\chi_l}{7.42 + 1.25\chi_l}, \qquad (9)$$

where

$$\bar{i}_l = \bar{i}_d + \bar{i}_k \text{ and } \chi_l = k_X\,[\text{cat}]\,t_1 \,.$$

The rate constant is then given by

$$k_X = \frac{7.42}{t_1\,[\text{cat}]} \cdot \frac{\bar{i}_k}{(\bar{i}_d - 1.25\bar{i}_k)} \,.$$

Fig. 12 illustrates the dependence of the ratio $\bar{i}_k/\bar{i}_d$ on χ_l. The average rate constants found are[2] $k_H = 1.72\times10^7$ litre mole^{-1} s^{-1} and $k_D = 5.29\times10^6$ litre mole^{-1} s^{-1}. There is good agreement between our value of k_H and that found by Koutecký et al.[40]

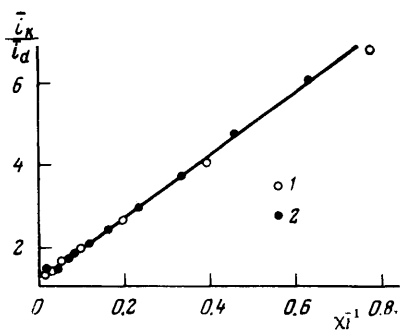

Figure 12. Variation of the ratio $\bar{i}_k/\bar{i}_d$ with χ_l^{-1}; continuous line—calculation by Eqn. (9). The abscissae of the experimental points were calculated from the following values: 1) H_2O_2, $k^H = 1.72\times10^7$ litre mole^{-1} s^{-1}; 2) D_2O_2, $k^D = 5.29\times10^6$ litre mole^{-1} s^{-1}; t_1 = 2.56 s.

Finally the ratio of these constants $k_H/k_D = 1.72\times10^7/0.529\times10^7 = 3.25$ characterises the kinetic isotope effect in the decomposition of hydrogen peroxide by catalase.

III. CATALYTIC CURRENTS

Although the catalytic discharge of hydrogen ions is a very important electrochemical process, the explanation of its mechanism remained for a long time unsatisfactory. The cobalt–nitrohydroxylaminate anion system was the first in which the formation of a cobalt–dinitrohydroxylamine complex, undergoing discharge [oxidation?] and having catalytic properties, was investigated[41]. On the basis of the model of such a dischargeable catalytic complex, mathematical equations were derived for the catalytic waves and a very satisfactory agreement was obtained between the calculated and experimental values[42]. The equations for the catalytic waves in the cobalt–cycloserine system[7,8] were derived on the assumption that the active principle in the catalytic discharge of hydrogen ions is a cobalt complex with a zero charge. In the mechanisms with and without discharge account was taken only of the number of neutralisable protons in a single molecule of the catalyst-complex. Thus the catalytic current depends on the catalyst concentration at the given potential and on the catalytic activity, expressed in terms of the number of protons discharged by a single molecule. This mechanism proved to be useful for the prediction of conditions under which it is possible to obtain the catalytic double wave characteristic of proteins. The equation for the catalytic nth degree wave[6–8,42] suggests that, when the same solution contains two complexes with different catalytic properties, a double catalytic wave will be recorded. The theory was tested experimentally for solutions containing cobalt(III), sodium nitrohydroxylaminate, the cysteine in an ammonia buffer[43].

It is well known that, for substances exhibiting catalytic properties in the presence of cobalt (giving rise to the so called Brdička waves), the height of the hydrogen wave is independent of pressure, in contrast to the nitrohydroxylaminate ion. This behaviour is characteristic of kinetic waves, i.e. waves determined by the chemical reactions accompanying the electron transfer process. However, the study of the cobalt–cycloserine system[7,8] showed that the independence of the overall catalytic hydrogen wave of pressure is due to the superposition of two catalytic hydrogen waves of different types: of the type of the "pre-sodium" wave and the wave determined by diffusion induced by the discharge of hydrogen ions under the influence of the cobalt–cycloserine complex. The resolution of the complex wave into the above components can be achieved at very low cobalt concentrations. At high cobalt concentrations the decrease of the first wave as the height of the mercury column is varied is compensated by the increase of the second. Ultimately the resulting overall hydrogen wave is independent of pressure. Clearly such independence is not evidence for the kinetic nature of the polarographic waves of the Brdička type. Any mechanisms in which such complex waves are assumed to be of the kinetic type must therefore be completely excluded from the interpretation of the Brdička type hydrogen ion discharge process.

Another important type of the catalytic discharge of hydrogen ions was discovered recently[9–11] in acetate buffer solutions containing nickel and selenocysteine[9,10] or normal cysteine[11] as the catalyst in weakly acid or neutral media. Such discharge of hydrogen proceeds in the region of the catalytic pre-wave with a half-wave potential of approximately –1.14 V relative to the saturated calomel electrode (sat.c.e.).[9] It was shown[9] that in this case catalysis is due to the uncharged partly protonated form of the nickel complex of selenocysteine or cysteine.

If the half-wave potential is adopted as a criterion in the classification of the hydrogen ion discharge processes at a mercury dropping electrode, the following waves may be indicated: (1) the catalytic hydrogen pre-wave at –1.14 V;[9] (2) the normal hydrogen wave at –1.67 V;[1,9] (3) the Brdička hydrogen wave between –1.67 and –1.70 V;[6,11] (4) the catalytic pre-sodium hydrogen wave at –190 V (sat.c.e.);[6] (5) secondary discharge of hydrogen ions beginning at –2.63 V (relative to a stationary mercury electrode in 10^{-3} M KCl, after the subtraction of the ohmic potential drop[44]). Thus the discharge of hydrogen ions at a mercury dropping electrode is a fairly complex process.

Since the catalytic discharge of hydrogen ions involves protonation–deprotonation reactions and more or less protonated catalyst molecules in a free or bound form, it follows that the catalytic hydrogen waves should be influenced by the substitution of hydrogen ions by deuterium ions. On the other hand, as shown in the first part of this review, the dissociation constants of normal and heavy water differ. Despite the complexity of the processes occurring in the catalytic discharge of hydrogen, it is possible to characterise the overall isotope effect (I) by the ratio of the numbers of protons (N_H) and deuterons (N_D) discharged by one molecule of the catalytic complex[12]:

$$I = N_H/N_D;$$

N_H and N_D can be calculated from the formulae for the catalytic waves[8,42].

When a non-dischargeable complex or a complex with a zero charge is taken into account in the mechanism of the catalytic discharge of hydrogen ions, the equation for the waves assumes the following form[8]:

$$\bar{i}_t = \frac{\bar{i}_{d,\mathrm{Co(II)}}}{1+\exp[(\varepsilon-\varepsilon_{1/2,\mathrm{Co(II)}})\,\alpha_l n_l F/RT]} + \frac{\bar{i}_{l,\mathrm{H(0)}}}{1+\exp[(\varepsilon-\varepsilon_{1/2,\mathrm{H(0)}})\,\alpha_3 n_3 F/RT]} + \frac{\bar{i}_{l,pv}}{1+\exp[(\varepsilon-\varepsilon_{1/2,pv})\,\alpha_4 n_4 F/RT]} + \bar{i}_{el}\,, \tag{10}$$

where $\bar{i}_t$ is the overall average current, $\bar{i}_{d,\mathrm{Co(II)}}$ the Co(II) diffusion current, ϵ the electrode potential, $\epsilon_{1/2,\mathrm{Co(II)}}$ the experimental half-wave potential of the cobalt wave, α_l the effective transfer coefficient, n_l the valence of the electrode reaction, F the Faraday, and T the absolute temperature; $\bar{i}_{l,\mathrm{H(0)}}$ has the value stated above, but refers to the uncharged zero-valent cobalt complex catalysing the discharge of hydrogen ions. The subscript pv refers to the catalytic pre-sodium wave and $\bar{i}_{el}$ is the current corresponding to the discharge of the ions of the indifferent electrolyte.

The quantity N_X can be calculated from $il,\mathrm{H(0)}$ by Eqn. (10), provided that the concentration of the uncharged complex on the electrode surface is known.

When the complex undergoing discharge is involved in the mechanism of the catalysis of the discharge of hydrogen ions, the equation for the wave can be written in the following form[2,4,6,8]:

$$\bar{i}_t = \frac{\bar{i}_{l,\mathrm{Co}}}{1+\exp[(\varepsilon-\varepsilon_{1/2,\mathrm{Co}})\,\alpha_l n_l F/RT]} + \frac{\bar{i}_{l,k}}{1+\exp[(\varepsilon-\varepsilon_{1/2,k})\,\alpha_2 n_2 F/RT]} + 1 - \frac{1}{1+\exp[(\varepsilon-\varepsilon_{1/2,k})\,\alpha_2 n_2 F/RT]} \cdot \frac{N\,(\bar{i}_{l,k}/n_2)}{1+\exp[(\varepsilon-\varepsilon_{1/2,c})\,\alpha_3 n_3 F/RT]} + \frac{i_{l,pv}}{1+\exp[(\varepsilon-\varepsilon_{1/2,pv})\,\alpha_4 n_4 F/RT]} + X\cdot c\cdot\exp[-(\varepsilon-\varepsilon_{1/2,el})\,\alpha_{el} n_{el}\cdot F/RT]\,.$$

In this equation the subscripts k and 2 correspond to the complex being reduced and c and 3 correspond to the wave associated with the discharge of hydrogen ions by

the catalytic complex; X is the constant of the Ilkovič equation and c is the concentration of the indifferent electrolyte. In practice only the third term of Eqn. (11) need be taken into account in the calculation of N_X. This type of calculation has been carried out for hydrogen[42] and deuterium[12] and for cobalt–cysteine solutions in an ammonia buffer.

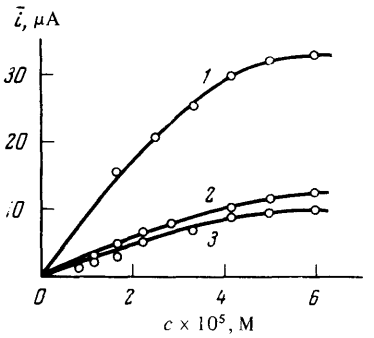

Figure 13. Variation of the height of the catalytic wave with cysteine concentration; 10^{-3} M $CoCl_2$; 10^{-1} M NX_4Cl–NX_4OX: 1) X = H; 2) and 3) X = D; 1) in the presence of 0.01% of gelatin; 3) in the presence of deuteriated gelatin.

A marked isotope effect was shown in the cobalt–cysteine system for waves corresponding to the catalytic discharge of hydrogen ions. As in previous instances, deuteriated compounds are necessary for the investigation of the isotope effect. ND_4OD was synthesised by the reaction

$$Mg_3N_2 + 8D_2O = 2ND_4OD + 3Mg(OD)_2.$$

ND_3 was then separated from $Mg(OD)_2$ by a partition and by bubbling with gases. DCl was synthesised by the reaction

$$SiCl_4 + 4D_2O = 4DCl + Si(OD)_4.$$

$DCl.D_2O$ was separated from $Si(OD)_4$ by the distillation of an azeotropic mixture. (Both ND_4OD and DCl are also available commercially.) The substance ND_4Cl was obtained either by the reaction of ND_4OD with DCl or by isotope exchange between N–H and D_2O with repeated recrystallisations. The mobile hydrogen in gelatin was deuteriated by repeated dissolution in D_2O and evaporation. Cysteine for the deuterium system was recrystallised three times from solution in D_2O.

Waves corresponding to the catalytic discharge of deuterium ions can be obtained with the aid of these deuteriated compounds and compared with the corresponding hydrogen waves. Fig. 13 illustrates the experimental variation of the current maximum on the catalytic waves as a function of cysteine concentration. The currents are much smaller in the D_2O system. $N_H = 740$ and $N_D = 238$ were calculated from the experimental data. Hence

$$I = N_H/N_D = 740/238 = 3.2.$$

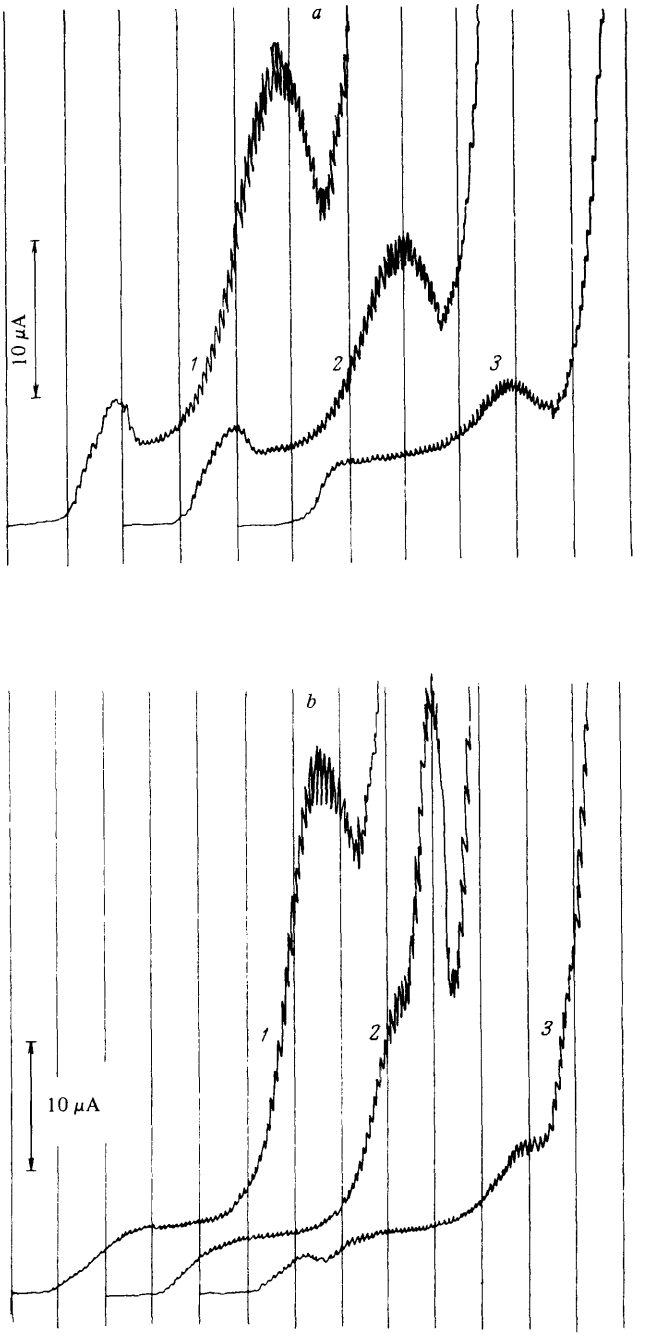

Figure 14. The catalytic isotope effect in the presence of 10^{-3} M Co^{2+} (*a*) and Ni^{2+} (*b*); 5×10^{-5} M (*a*) and 3×10^{-4} M (*b*) cysteine solutions; 0.1 M NX_4Cl; 0.1 M NX_4OX (X = H or D); initial potential −0.8 V (*a*) and −0.4 V (*b*); scan along the abscissa axis 200 mV; anode–saturated calomel electrode; deuterium content (vol.%): 1) 0; 2) 60; 3) 100.

The isotope effect is even greater in solutions containing cobalt or nickel (Fig. 14) in the absence of gelatin. A polarographic determination of the D_2O content in

enriched systems has been suggested as an application of this very intense isotope effect[13]. Calibration plots for the cobalt system are illustrated in Fig. 15*a* and that for the nickel system in Fig. 15*b*. A straight line is obtained when the maximum catalytic current is plotted against the deuterium content. The accuracy of the analytical determinations is equal to the accuracy of the polarographic method (1–3%). An advantage of the method is the simplicity of the procedure and apparatus.

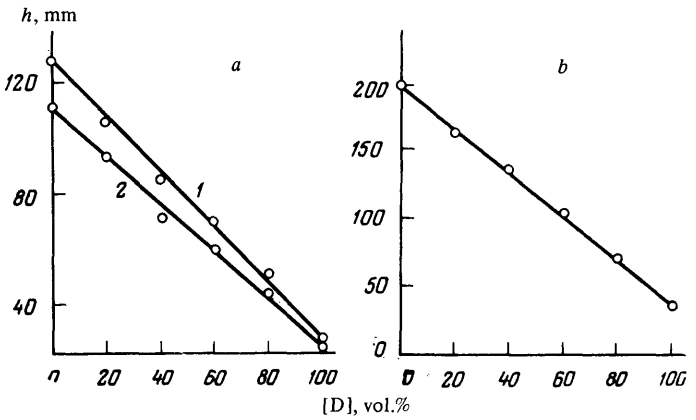

Figure 15. Variation of the height of the catalytic wave (*h*) with the deuterium content in the presence of cobalt (*a*) and nickel (*b*). Solutions the same as Fig. 14: 1*a*) first recording; 2*a*) second recording.

The study of isotope substitution in relation to catalytic currents constitutes an important procedure for the determination of the mechanism of this main type of polarographic currents. The intense isotope effect demonstrates the fundamental role of protonation–deprotonation processes and the importance of this stage, which determines the rate of the overall reaction. Isotope substitution also demonstrates the importance of hydrogen catalysis when other criteria are unsuitable for the determination of the nature of the polarographic wave.

---o0o---

In conclusion one must emphasise that, despite the complexity of the phenomenon under consideration, the study of the isotope effect with the aid of kinetic and catalytic waves gives rise to much scope for the understanding of the mechanisms of many reactions and at the same time demonstrates the advantages and possibilities of the polarographic method in this field.

Structural Rearrangements in Carbaboranes and Related Compounds

V.I.Stanko, V.A.Brattsev, and S.P.Knyazev

The rearrangements of polyhedral boron compounds are described systematically and classified. The fundamental characteristics of various types of rearrangements are examined and the relation between them and the electronic structure and symmetry of the molecules is established.
The bibliography includes 191 references.

I. INTRODUCTION

Rearrangements of atoms and of the molecular skeleton are characteristic of polyhedral boron compounds, particularly carbaboranes. They can take place under both thermal and chemical influences. This review presents a systematic arrangement of studies in this field in order to discover the relation between the chemical properties and the electronic structures of molecules and to establish on this basis the general characteristics of the rearrangement of polyhedral boron compounds†. Data published up to 1978 are used in the review.

From the entire multiplicity of the rearrangements of cyclic and open-chain polyhedral molecules and ions, it is possible to isolate two main groups: (a) rearrangements in which the initial and final molecules (ions) have structures based on the same polyhedron; (b) rearrangement involving a change in the type of polyhedron. The rearrangement of the first type (thermal rearrangements) are characterised by the fact that they are caused by thermal excitation and proceed without a change in the number of electrons between the initial and final systems. The rearrangements initiated by electromagnetic radiation, for example, ultraviolet light, and chemically initiated thermal rearrangements also take place without a change in the type of polynedron. Rearrangements of the second type are characterised by a change in the total number of electrons in the atoms of the skeleton. Depending on whether the rearrangement takes place owing to an increase of the number of electrons in the system or their decrease, it is possible to distinguish reductive and oxidative rearrangements respectively. Reductive rearrangements involve the opening of the polyhedral molecule following the appearance of additional external σ bonds. On the other hand, oxidative rearrangements lead to the closure of the polyhedral molecule or ion.

When the mechanisms of thermally initiated (i.e. without the involvement of chemical reagents) rearrangements of polyhedral compounds are considered, different versions of the so-called *dsd* mechanism (diamond–square–diamond) are most widely used (Fig. 1). This mechanism was proposed by Lipscomb, who used it to account for the rearrangement of virtually all closed polyhedral systems[3]. The second mechanism discussed in the literature is based on the hypothesis that different fragments of the polyhedral molecule can rotate in both the ground and transition states[4-7]. The third type of possible mechanisms, involving *closo*-compounds, is based on the hypothesis that the molecule is opened in the transition state to give a fragment of the next polyhedron and is then reclosed but in a different direction[5,8], while in the case of *nido*-compounds the polyhedral molecule is closed with subsequent opening[9-12]. The lack of adequate experimental data on this problem permits in most cases only a theoretical consideration of various mechanisms of the thermal rearrangements. We believe that the limitations due to the symmetry of the occupied and vacant boundary molecular orbitals can serve as a criterion for the selection of the most probable pathways in the rearrangements (see Section III).

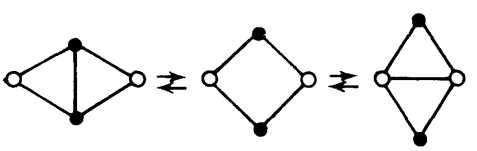

Figure 1. Model of the *dsd* (*diamond-square-diamond*) mechanism.

The rule governing the relation between the type of structure, the class of compound, and the number of electrons binding the skeleton of an n-atomic molecule, which was discovered by Wade, plays an important role in determining the direction of the reductive and oxidative rearrangements: the $n + 1$, $n + 2$, and $n + 3$ electron pairs characterise the *closo*-, *nido*-, and *arachno*-structures. The addition of two electrons to a closed n-atomic polyhedral molecule should lead to its opening with formation

† This review constitutes a stage in the systematic analysis of studies in the chemistry of carbaboranes and other polyhedral boron compounds (this is a development of our previous communications[1,2]).

of the *nido*-structure of a fragment of the next $(n + 1)$-atomic polyhedron; the addition of the next electron pair gives rise to the *arachno*-structure of an n-atomic fragment of the $(n + 2)$-atomic polyhedron, etc.[13] Taking into account the importance of the above features of the chemistry of polyhedral boron compounds, we shall refer to them as the *"Wade rule"*.

As will be shown below (see Sections II and III), a change in the number of electrons and in the general case in the number of orbitals occupied by electrons in the transition stage constitutes the driving force also of a number of thermal rearrangements, including those of closed polyhedral systems. On the other hand, reductive rearrangements are associated with the accommodation of additional electrons in the lowest unoccupied molecular orbitals (LUMO), while oxidative rearrangements involve the removal of electrons from the highest occupied molecular orbitals (HOMO) of the initial molecule. The rearrangement proper proceeds as a spontaneous process or as a process with a low activation energy and in the latter case constitutes in essence a thermal process. Using a particular classification one must therefore bear in mind the limits of its applicability. Although the proposed classification is partly conventional, particularly when the individual stages of the rearrangements are considered, we nevertheless believe that it is useful when the process as a whole is considered.

II. GENERAL CHARACTERISTICS OF THE REARRANGEMENTS OF POLYHEDRAL BORON COMPOUNDS

In many chemical reactions of carbaboranes and other polyhedral boron compounds the decisive role of the characteristic features of the chemical bonds involving the atoms in these compounds is manifested. Analysis of literature data on the structures and reactivities of polyhedral boron compounds enabled us to isolate the following most significant features which determine the feasibility, direction, and mechanism of the rearrangements.

1. The presence of a reactive dynamic electronic system linking the atoms of the molecular skeleton, in the absence of a σ skeleton characteristic of classical carbon compounds.
2. The dependence of the configurational stability of polyhedral molecules on the symmetry of the boundary HOMO and LUMO and the energy gap between them and the consequent relation between the type of the resulting structure of the polyhedral molecule and the number of electrons binding the molecular skeleton (Wade's rule).
3. The reactions of polyhedral compounds with electrophiles involving HOMO and the reactions with nucleophiles involving LUMO.
4. The equal participation of boron and carbon atoms as well as other hetero-atoms in the electronic structure of the skeleton of the polyhedral molecule and the consequent appearance of an excess charge on the heteroatoms (for example, a positive charge on the carbon atoms in carbaboranes) and polarisation of the entire electronic system binding the atoms of the skeleton.

1. THE CHEMICAL BOND IN POLYHEDRAL BORON COMPOUNDS

Two main approaches have now been developed, permitting a description of the valence and electronic structures of the molecules of polyhedral boron compounds: the topological approach[14-17] and quantum-chemical calculations based mainly on the molecular orbital method in various approximations[14,18-29].

The topological approach is based on the idea that a strong two-electron bond may be formed between three atoms, i.e. a three-centre bond[30]. This concept was introduced because polyhedral systems cannot be described solely in terms of two-centre bonds, since in these compounds each boron atom supplies only two electrons for three atomic orbitals involved in the formation of the bonds of the skeleton. In order to describe the polyhedral molecule within the framework of the topological approach, equations are derived for electron balance, charge balance, orbital balance, and hydrogen atom balance. Their solution yields the number of three-centre and two-centre bonds characterising the given system. Next, using a series of topological limitations, topologically allowed valance structures are selected from all the possible combinations. Bearing in mind that formally 2/3 of the electronic charge corresponds to each atom on formation of a closed three-centre bond, a single charge corresponds to each atom on formation of a two-centre bond, etc., the method makes it possible to assess, together with the possible valence structures, also the charge distribution among the atoms of the polyhedral molecule. The topological approach is used to describe the chemical reactions of polyhedral compounds[31,32] and rearrangements[32,33] too. However, we believe that in the given instance the formalism of this method does not permit an understanding of the essential features of the transformations taking place and it is necessary to impose additional boundary conditions on the possible directions and mechanisms of the chemical reactions (see below).

The quantum-chemical calculations for the description of the electronic structures of polyhedral compounds are based on the molecular orbital method, which, being the most general procedure for the description of the chemical bond, makes it possible to obtain quantitative parameters characterising the given molecule. The molecular orbital method is used for the calculations on the ground states, for the determination of the possible directions of the reactions in particular rearrangements, and for the estimation of the stabilities of the intermediate compounds[10,34,35] (for example, in the rearrangement of 1,2-$C_2B_4H_6$ to the 1,6-isomer[36]).

Using the criteria governing the localisation of molecular orbitals proposed in the literature[37-40], Lipscomb and coworkers determined the localised valence structures of many boron hydrides and carbaboranes[23,24,28,29,41-44]. The valence structures obtained by the localisation of molecular orbitals agree on the whole with the topologically allowed structures when one considers in the latter case the set of possible structures taking into account the symmetry of the molecule. The majority of the molecules for which calculations have been made within the framework of the localisation criteria contain atoms whose bonds have minimal electron populations. The concept of a *fractional* three-centre bond was therefore introduced[41] and in the general case the concept of a fractional bond[28]. In order to represent the extent to which the bond is fractional (its population), together with valence bonds represented by continuous lines the following conventional representations have been introduced:

dashed line with an arrow	(·····→)	0.15 - 0.25 e;
continuous arrow	(——→)	0.25 - 0.35 e;
dashed line	(·····)	0.35 - 0.5 e;
continuous line	(——)	0.5 e.

Bonds with populations $< 0.15\ e$ are excluded from consideration[28]. Fig. 2 presents as an example the localised valence structures of 2,4-$C_2B_5H_7$,[24,41,43] 2,3-$C_2B_4H_8$,[24,41,44] $C_2B_7H_{13}$, 7,8-$C_2B_9H_{12}^-$, and $C_2B_{10}H_{13}^-$.[28] The hypothesis that fractional bonds are formed by localised molecular orbitals can apparently be also interpreted from the standpoint of delocalised three- and two-centre bonds, and they can be considered as delocalised (multicentre) bonds.

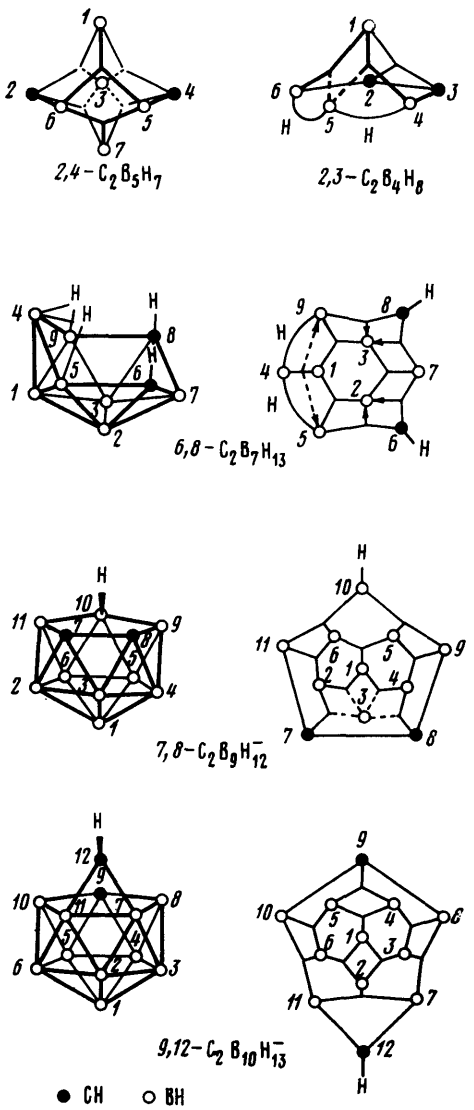

Figure 2. The valence structures of certain carbaboranes.

Since each valence line originating from an atom is usually associated with an atomic orbital, the notation used for fractional bonds requires some explanation. In this instance the "valence line" does not designate a localised atomic orbital but represents the direction of highest electron density in space. For localised two- and three-centre bonds, these concepts are identical. Within the framework of the valence bond method, fractional three-centre bonds can be described by resonance structures (Fig. 3).[41] The ideas concerning rapid electronic exchange processes and the combinatorial treatment of electron transfer in "electron deficient" polyhedral molecules have features in common with these concepts[45].

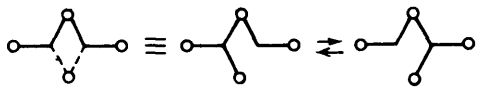

Figure 3. Representation of fractional three-centre bonds in terms of the valence bond method.

In polyhedral boron compounds localised two-centre bonds in general need not be normal σ bonds, since, owing to the geometrical characteristics of the molecular structure, they may not have axial symmetry, whereupon, like π bonds or "banana" type bonds, they should possess increased energy. This should in turn facilitate reactions with electrophiles involving such bonds and should lead to the formation of a three-centre bond (Fig. 4*a*).[2]

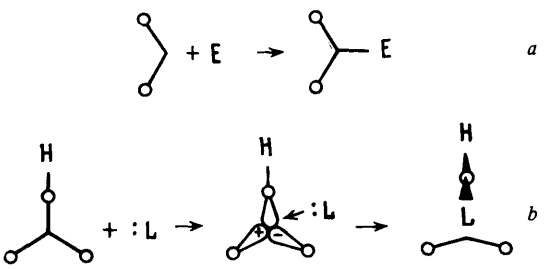

Figure 4. Models of the interaction of valence fragments of polyhedral boron compounds: *a*) formation of a two-centre bond with electrophiles; *b*) formation of a three-centre bond with nucleophiles.

Bonds of the second type, localised three-centre bonds, are characterised by three localised molecular orbitals, one of which is bonding and has low energy and the other two are antibonding. Depending on the symmetry and nature of the atoms forming the bond, one of the antibonding orbitals may have a very low position and its energy may approach that of a non-bonding level. Hence follows the high reactivity of the three-centre bond in relation to nucleophiles and reductants (Fig. 4*b*).[2]

Bonds of the third type in polyhedral compounds, delocalised (many-centre) bonds, are in general characterised by the presence of a high-energy HOMO and a low-energy LUMO. This should be manifested by a tendency of these bonds to undergo both electrophilic and nucleophilic reactions.

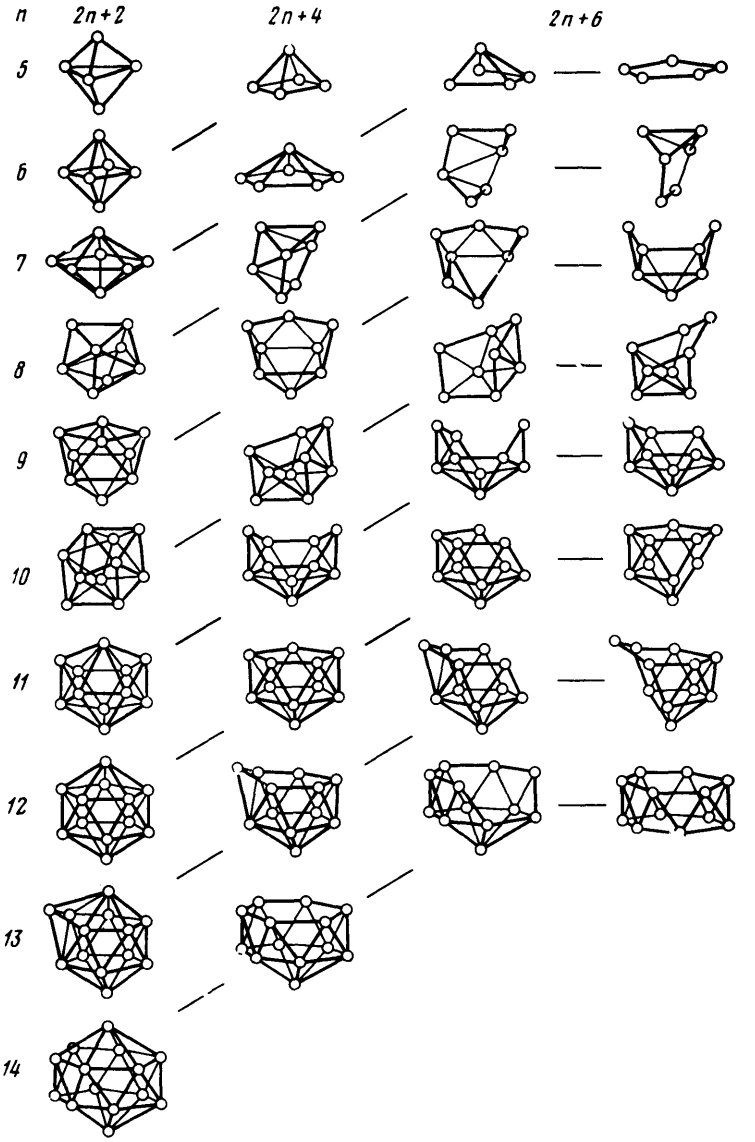

Figure 5. Relation between the type of structure of polyhedral boron compounds and their electronic structure (illustration of the Wade rule).

Thus chemical bonding in polyhedral boron compounds is characterised by a system of highly reactive two-, three-, and many-centre bonds. On the other hand, in the compounds under consideration there is no additional electronic system strongly binding the atoms of the molecular skeleton, in contrast to classical organic, particularly aromatic compounds where there exists, in terms of the σ–π approximation, a relatively inactive σ-skeleton imparting stability to the molecule in many reactions, in addition to the active π-electron system. Structural rearrangements of the molecular skeleton can therefore occur in polyhedral boron compounds during chemical reactions and thermal or electronic (under the influence of radiation) excitation.

2. RELATION BETWEEN THE NUMBER OF ELECTRONS AND THE STRUCTURE OF POLYHEDRAL COMPOUNDS

The direction of the rearrangements and the nature of the compounds formed are determined by the electronic structure of the polyhedral molecules and ions. Wade's rule, which establishes the relation between the number of electrons (or the number of electron pairs) participating in the binding of the atoms in the molecular skeleton and the type of structure, plays an important role in the understanding of the reductive and oxidative rearrangements of carbaboranes and other polyhedral boron compounds [13]. Rudolph and Pretzer [46] examined this relation in detail and confirmed by molecular orbital calculation the validity of

this rule: in particular they found that, when $n = 5$ for a system of $2n + 2 = 12$ electrons, there is a potential energy minimum corresponding to the *closo*-structure—a trigonal bipyramid, for a system with a $2n + 4 = 14$ electrons the minimum corresponds to the *nido*-structure—a tetragonal pyramid, and for a system with $2n + 6 = 16$ electrons, the minimum corresponds to the *arachno*-structure—a pentagonal fragment of a pentagonal bipyramid (Fig. 5). The authors[46] give an excellent illustration of this rule for the structural relation governing various polyhedral compounds[47]. This scheme (see Fig. 5) was supplemented by the present authors by the structures of closed polyhedra with 13 and 14 vertices and their fragments as well as certain alternative structures of *arachno*-compounds corresponding to the structures of borane and carbaborane ligands in transition metal complexes and, when $n = 9$, to the structure of the *arachno*-carbaborane $C_2B_7H_{13}$ (the first column in Fig. 5). This scheme does not include certain derivatives of boron hydrides and metalloboranes where bonds are formally formed by $2n$ electrons, for example in B_4Cl_4 (tetrahedron)[48-50], B_8Cl_8 (square antiprism)[51-54], B_9Cl_8H or $(\eta^5\text{-}C_5H_5)_3Co_3B_4H_4$, $(\eta^5\text{-}C_5H_5)_4Co_4B_4H_4$,[56] and $(\eta^5\text{-}C_5H_5)_3Co_3B_5H_5$.[57] As a possible structure of the above metalloboranes, Miller and Grimes[56] and Hall et al.[57] proposed $n - 1$ *closo*-polyhedra, where the "superfluous" BH or $Co(\eta^5\text{-}C_5H_5)$ structural unit is located above one of the triangular faces.

Among polyhedral boron compounds, there are examples of compounds which do not formally fit within the framework of the relations noted by Wade. We shall consider for example, the *arachno*-carbaboranes $C_2B_7H_{13}$[58,59] and $C_2B_8H_{14}$.[60,61] In these compounds the number of electrons binding the atoms of the molecular skeleton is the same as in the *closo*-carbaboranes $C_2B_7H_9$ and $C_2B_8H_{10}$ respectively. However, in the latter all the $3n$ atomic orbitals are involved in the construction of the molecular orbitals of the skeleton, while in *arachno*-carbaboranes only $3n - 2$ orbitals are involved, since two atomic orbitals, one from each carbon atom, form the C–H σ bond and for this reason there are two CH_2 structural units. Similarly in the series of the *nido*-carbaboranes $C_2B_7H_{11}$ has the BH_2 structural unit[62], i.e. $3n - 1$ atomic orbitals participate in the formation of the bonds of the skeleton; although the number of electrons binding the atoms of the skeleton is $2n + 2$, i.e. corresponds to the *closo*-structure, the compound is a *nido*-carbaborane and has an open structure.

Thus, when Wade's rule is applied to molecules in the ground state, account must be taken not only of the number of electrons binding the atoms in the skeleton but also of the total number of electrons in the $3n$-atomic orbitals of the n-atomic polyhedral molecule‡. In the more general case, including the excited states of the molecule, it is necessary to consider the number of occupied molecular orbitals made up of $3n$-atomic orbitals and not the number of electrons: the $n + 1$, $n + 2$, and $n + 3$ occupied orbitals will characterise the *closo*-, *nido*-, and *arachno*-structures respectively.

‡ $3n$ atomic orbitals are considered, and not the total number $4n$, because one orbital of each atom is involved in the formation of an outer σ bond and does not affect the nature of the structure.

3. REARRANGEMENTS INITIATED BY ELECTROPHILES AND NUCLEOPHILES

A graphical representation of localised two- and three-centre bonds can be conveniently employed for a clear description of reactions of polyhedral boron compounds with electrophiles and nucleophiles[2]. As already mentioned, chemical reactions with electrophiles E can proceed via two-centre or many-centre bonds (Figs. 4*a* and 6). In the latter case the reaction should lead to the localisation of the electron pair and the formation of either a three-centre bond BEB or a two-centre bond B–E or C–E with the electrophile. The reaction via a two-centre bond involves the intermediate formation of a three-centre bond BEB[2]. The strength of the latter is determined by the nature of the electrophile, the possibility of additional stabilisation as a result of the overlap of the electrophile orbitals, not involved in the formation of the bond, with the orbitals of the molecular skeleton, and finally, the symmetry of the three-centre bond[63,64]. Three-centre bonds BHB are quite stable. BEB bonds, where E = SiR_3, GeR_3, etc, are less stable and isomerise on heating in such a way that the electrophile moves to the terminal position relative to the boron atom (a B–E σ bond is formed), although the corresponding compounds with a bridge position of the electrophile E may be isolated and characterised, for example, μ-Me_3Si-2,3-$C_2B_4H_7$.[65-68] When E = Alk, compounds with a bridging alkyl group, for example μ-Alk-7,9-$C_2B_9H_{11}^-$ are stable only below 0°C, isomerising at room temperature to 10-Alk-7,9-$C_2B_9H_{11}^-$ in a few minutes[63,64]. Analogous compounds with an asymmetric alkyl bridge group, for example, in the 7,8-isomer (μ-Alk-7,8-$C_2B_9H_{11}^-$) are unstable even at low temperatures if they are formed at all.[12,69]

If the boron atoms forming a three-centre bond with the electrophile are non-equivalent, the BEB bond should be polarised in the direction ensuring the compensation of this non-equivalence. As a result of this, the three-centre bond is cleaved in such a way that the electrophile appears at the boron atom with the higher positive charge (in the initial state) (Fig. 6*a*). The directing effect in the rearrangement of the three-centre bond is static and to some extent resembles that in the directing effect in addition to the double bond in olefins.

There are several pathways leading to the transformation of a compound with a bridge group (Fig. 6). Pathways *b* and *c* (Fig. 6)§, leading to the formation of substitution products, were discussed in our earlier communication[2]. Pathways *d*, *e*, and *f* correspond to the oxidation of the system, i.e. to the closure of the polyhedron in the case of *nido*-compounds. Pathway *g* involves a rearrangement of the system, consisting in the migration of the boron atom with the substituent to the site of the missing vertex of the polyhedron with formation of a new isomer of the *nido*-carbaborane. As a result, the substituent passes to the terminal position and the hydrogen atom, previously in the terminal position, migrates to the bridge position. This mode of reaction was observed in the interaction of dicarbollide ions $C_2B_9H_{11}^{2-}$ with alkyl halides[12,63]. The driving force of this rearrangement is apparently electron transfer from the bonding orbital of the skeleton (B–Alk–B) to the B–Alkσ bond, oriented axially, i.e. involves in

§ Pathway *b* is in principle unlikely, since it requires the abstraction of a hydride hydrogen atom in the form of a proton.

essence the oxidation of the system and, in conformity with the Wade rule, the closure of the molecule into an octadecahedron. There are two σ-linked groups at the migrating boron atom in the transition state and stabilisation takes place as a result of further migration of the atom and the supply of electrons from the B–H σ bond to the bonding BHB orbital of the molecular skeleton. The molecule is then again opened and a fragment of an icosahedron with an equatorial orientation of the substituent is formed (Fig. 7).[12] The transition state in the given rearrangement can be stabilised, in principle, also as a result of the ejection of H^- or E^- (Alk^-) (Figs. 6*d*, 6*e*, and 6*f*) and in this instance the structure of the closed polyhedron is fixed (see also Section V, subsection 2).

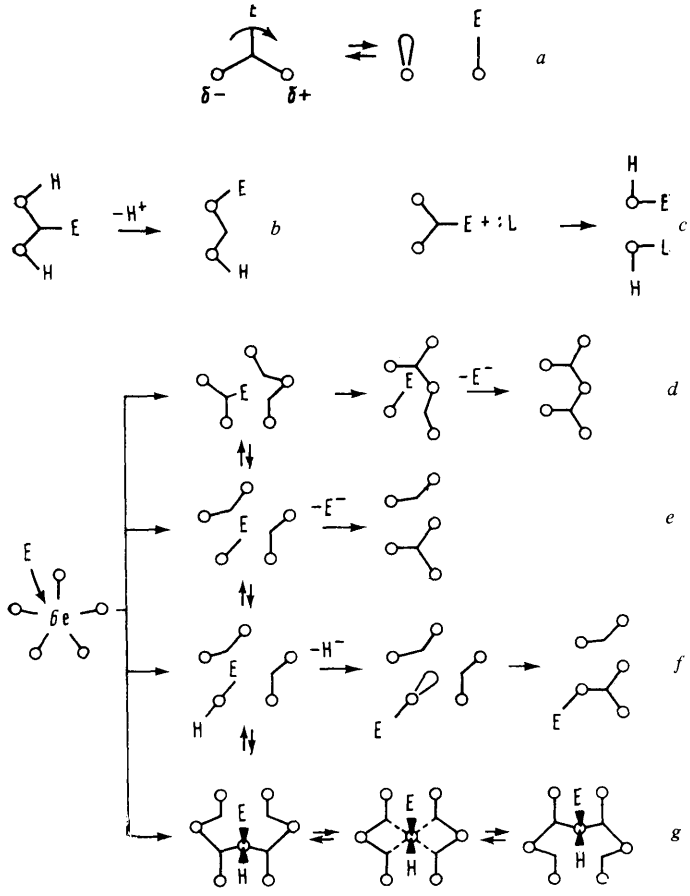

Figure 6. Possible rearrangements of bonds in systems with three- and many-centre bonds on interaction of two- and many-centre (five-centre) bonds with electrophiles.

The interaction of carbaboranes and other polyhedral compounds of boron with nucleophiles L and the reductants among them should proceed, as mentioned above, via three-centre and many-centre bonds having in the general case the lowest vacant orbitals. The attack by the nucleophile is on the three-centre bond and leads to its dissociation in such a way that L is oriented axially and H equatorially relative to the open face produced (Fig. 4*b*)¶. The stabilisation of the system requires the supply of electrons to orbitals linking the atoms of the molecular skeleton. This condition is fulfilled either on ejection of a proton from the boron atom forming a bond with the nucleophile and the involvement of the liberated electron pair in the binding of the atoms of the skeleton or after a rearrangement similar to that discussed above for the reaction of dicarbollide ions with alkyl halides. As a result electrons of the B–H σ bond (L) are used for the binding of the atoms of the skeleton, i.e. a BHB bridge bond is formed.

The characteristics found for the rearrangements initiated by electrophiles and nucleophiles show that, like the oxidative and reductive rearrangements, they proceed with a change in the number of electrons and in the general case in the number of orbitals binding the atoms of the skeleton of the molecule or ion in the transition state. We suggest that the thermal rearrangements of closed polyhedral systems can also proceed via a transition state in which the number of orbitals occupied by electrons changes (increases). As will be shown below, this is equivalent to the supply of additional electrons to the vacant orbitals. Thus, in the course of such thermal rearrangements, one may expect the opening of the *closo*-structure to the *nido*-structure due to electron transfer to a vacant orbital closest as regards energy and subsequent reclosure of the polyhedron, but in another direction. The foregoing permits the conclusion that an essential condition for the above rearrangements is a change in the number of occupied molecular orbitals during the reaction.

III. QUANTUM-CHEMICAL CRITERIA OF THE REARRANGEMENTS

The quantum-chemical approach is the most general and promising when the rearrangements of polyhedral molecules are considered. The possibility of determining the potential energy surface for a given system enables one to characterise unambiguously and quantitatively all possible molecular transformations. The difficulty of calculations of this kind in practice suggests that it might be useful to determine semiquantitative or even qualitative but objective criteria characterising a given rearrangement. The prediction of the relative configurational stability, direction, and mechanism of the rearrangements can be based in many instances on the first- and second-order Jahn–Teller effects[70]. The first-order Jahn–Teller effect arises under the following conditions: when a molecule with a given symmetry has a degenerate electronic state, the corresponding configuration of atoms in the polyhedral molecule is unstable and the structure changes in such a way that the degeneracy is removed[71]. Rearrangements of the skeleton can be both static and dynamic, i.e. the degeneracy may be removed by the vibrational motions of the molecule. The second-order Jahn–Teller effect is manifested when there is no degeneracy in the ground state but the boundary molecular orbitals have similar energies[70]. In this case the symmetry

¶When the nucleophile approaches from the other side of the bond (from the side opposite to the direction of the corresponding atomic orbital), L and H have the opposite orientations: equatorial for L and axial for H.

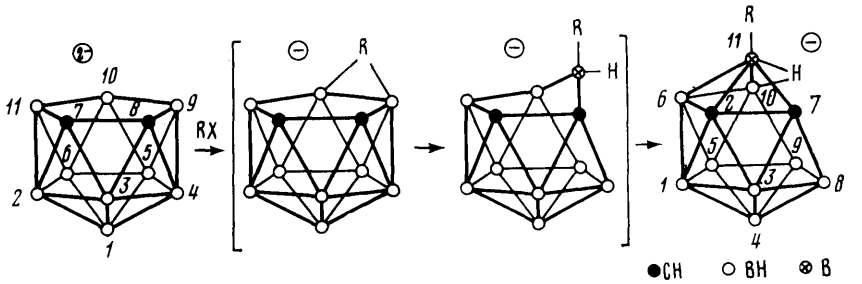

Figure 7. The proposed mechanism for the rearrangement of 7,8-dicarba-*nido*-undecaborate to the 2,7-isomer during the reaction of the dicarbollide ion with alkyl halides.

of the HOMO and LUMO and the energy gap between them determines the possibility of the rearrangement (makes it symmetry-allowed) and its ease in the particular direction.

It has been shown[72-74] that the energy change in the system following a small shift along a normal coordinate Q can be represented as follows:

$$E_0 - E_0' = \Delta E_0 = Q\left\langle \Psi_0 \left| \frac{\partial V}{\partial Q} \right| \Psi_0 \right\rangle + \frac{1}{2} Q^2 \left\langle \Psi_0 \left| \frac{\partial^2 V}{\partial Q^2} \right| \Psi_0 \right\rangle + Q^2 \sum_k \frac{\left[\left\langle \Psi_0 \left| \frac{\partial V}{\partial Q} \right| \Psi_k \right\rangle\right]^2}{E_0 - E_k}; \quad (1)$$

having assumed that the first term of the series characterising symmetrical shifts is zero, i.e. by considering only shifts which alter the initial molecular symmetry, the following expression was obtained[74]:

$$\Delta E_0 = \frac{1}{2} Q^2 \left\langle \Psi_0 \left| \frac{\partial^2 V}{\partial Q^2} \right| \Psi_0 \right\rangle + Q^2 \sum_k \frac{\left[\left\langle \Psi_0 \left| \frac{\partial V}{\partial Q} \right| \Psi_k \right\rangle\right]^2}{E_0 - E_k} = f_{00} Q^2 + f_{0k} Q^2, \quad (2)$$

where Ψ_0 and Ψ_k are the wave functions of the ground degenerate state with the energy E_0 and of the excited state with the energy E_k and V is the potential energy of the system corresponding to the nucleus–nucleus and nucleus–electrons interactions.

For any Q, we have $f_{00} > 0$, since it characterises the energy change averaged with respect to the initial optimised electron distribution. On the other hand, $f_{0k} < 0$, since $E_0 - E_k < 0$. Thus the stability of the given molecular configuration in relation to the rearrangement along the coordinate Q is determined by the relative values of f_{00} and f_{0k}:

(1) $f_{00} \gg f_{0k}$, $\Delta E_0 \gg 0$—system with the given symmetry is stable;

(2) $f_{00} \sim f_{0k}$, $\Delta E_0 \sim 0$—a rearrangement with a low activation energy is possible;

(3) $f_{00} \ll f_{0k}$, $\Delta E_0 \ll 0$—system is unstable and rearranges spontaneously to a system with another symmetry[74].

In a qualitative consideration of rearrangements it is not necessary to consider all the excited states and the treatment may be restricted to the one-electron transition between occupied and unoccupied boundary orbitals. These transitions can be observed experimentally in the ultraviolet and visible spectra. The smaller the energy gap and the closer the HOMO and LUMO levels, the greater the ease of the rearrangement. The initial configuration is regarded as unstable if the energy gap is < 4 eV.[74]

The choice of the possible direction of the rearrangements is restricted to the condition where the integral $\langle \Psi_0 | \partial V/\partial Q | \Psi_k \rangle$, which is included in the expression for f_{0k}, is not equal to zero. For this purpose, the representations of the given coordinate Q should be included in the products of the representations of the boundary molecular orbitals, and in the more general case of the orbital ψ_i, occupied in Ψ_0, and the orbital ψ_j, populated in Ψ_k.[74]

The Jahn–Teller effects can have important stereochemical manifestations in the chemistry of polyhedral boron compounds and can be used both for the explanation of the existing empirical rules, for example the Wade rule, and for the prediction of the possible mechanisms of the rearrangements of the skeleton of a polyhedral molecule[63].

It is possible to distinguish the following most characteristic manifestations of these effects.

1. The thermodynamic and kinetic stabilities of polyhedral boron compounds in relation to thermal rearrangements are determined by the energy gap ΔE between the boundary molecular orbitals, which, as already mentioned, may be estimated from spectroscopic data. For example, in the case of icosahedral carbaboranes(12) ΔE is large, which follows from the absence of absorption in the visible and ultraviolet spectra up to 200 nm, i.e. $\Delta E > 6$ eV, and the rearrangements of $C_2B_{10}H_{12}$ are observed only at temperatures of approximately 500°C and above. On the other hand, the spectra of the monoanions $C_2B_{10}H_{13}^-$ show absorption bands with a maximum at $\lambda = 260$ nm[75] and $\Delta E = 4.8$ eV; as a result of this, the rearrangements in the monoanions occur even at 100°C.[76,77] The dianions $C_2B_{10}H_{12}^{2-}$ derived from 1,2- and 1,7-$C_2B_{10}H_{12}$ absorb at $\lambda = 300$ nm, and those derived from 1,12-$C_2B_{10}H_{12}$ absorb at 335 nm,[75] to which correspond $\Delta E = 4.1$ and 3.7 eV respectively, and the rearrangements proceed readily at room temperature. The possible direction and type of the resulting isomers are then determined by other factors, including the symmetry of the boundary molecular orbitals.

When the mechanisms of thermal rearrangements are considered, it is striking that deformations which do not alter the initial molecular symmetry should be excluded from consideration. Otherwise, the first term of the expansion, which is positive by definition, must be again taken into account in Eqn. (1). Furthermore, the representation of a fully symmetrical deformation can be included only in the product of the deformations of boundary orbitals with identical symmetry. Thus fully symmetrical deformations will increase greatly the energy of the system. For example, in the rearrangements of icosahedral

carbaboranes $C_2B_{10}H_{12}$ the mechanisms involving a cubo-octahedral transition state appear unlikely on symmetry grounds, since the corresponding normal vibrations of a molecule with C_{2v} symmetry are fully symmetrical (see also Section V, subsection 2).

2. Any change in the number of orbitals occupied by electrons should lead to the destabilisation of the molecules or ions having a given symmetry. Indeed the atoms of the skeleton tend to assume a configuration such that all the electrons occupy bonding orbitals and the energy gap ΔE between the boundary orbitals is a maximum. For example, although the addition of electrons reduces the energy of the system on the whole, it destabilises the molecule or ion with the given symmetry relative to the zero non-bonding level, since the electrons are accommodated in antibonding molecular orbitals. The ease of rearrangements leading to a change in the initial symmetry and the accommodation of additional electrons at a bonding level is determined by the low value of ΔE between the antibonding orbital being filled and the nearest unfilled orbital and the occurrence of normal vibrational displacements with a suitable symmetry. In the borane anions $B_nH_n^{2-}$ ($n = 5,6,7,8,10,12$), the LUMO are degenerate[14,18], so that the rearrangements arising on increasing the number of electrons and the formation of $B_nH_n^{4-}$ may be caused by the first-order Jahn–Teller effect[46]. On passing the corresponding carbaboranes, for example, the $C_2B_nH_{n+2}$ series, the symmetry of the polyhedral molecule decreases, for example, from I_h in $B_{12}H_{12}^{2-}$ to C_{2v} in 1,2- and 1,7-$C_2B_{10}H_{12}$ or D_{5d} in 1,12-$C_2B_{10}H_{12}$. This should be accompanied by the splitting of the corresponding degenerate levels. However, the splitting is apparently not very great and the addition of electrons to carbaboranes and heteroboranes is also accompanied by a change in the initial structure owing to the second-order Jahn–Teller effect†. Here one should note that the degeneracy of the ground state is not in the general case a sufficient condition for the rearrangements (static deformations), as has been suggested, for example, by Rudolph and Pretzer[46] and Pearson[74]. In most cases the electronic degeneracy is converted into a vibronic degeneracy as a result of dynamic processes (see Bersuker[78], chapter VI). However, owing to the specific features of the reactions with nucleophiles and reductants via three-centre or many-centre bonds in polyhedral boron compounds, the addition of electrons should lead to the opening of the closed polyhedral molecule with formation of a tetragonal, pentagonal, or hexagonal face[2] (see also Sections II and IV).

3. The excitation of an electron to a vacant orbital is equivalent in terms of its stereochemical consequences to the addition of one or two electrons to the same orbital, and the symmetry of the molecule in the excited state should therefore be the same as that of the molecule which has combined with one or two electrons[79]. Thus, on excitation of electrons, there is a possibility of easy rearrangements of the atoms of the skeleton and the consequent formation of, for example, positional isomers depending on the positions of the substituents and heteroatoms in the polyhedral molecule. When the stereochemical results of the excitation or addition of electrons to a polyhedral molecule are compared, account must be taken of the lifetime of the excited state of the molecule. If the latter is short, the system may not attain the optimum configuration and the structure of the excited molecule may differ from that which has combined with the electrons.

4. The change in the symmetry of the polyhedral molecule or ion when the number of occupied orbitals is altered is determined by the symmetry of the possible soft deformations, i.e. the deformations of the boundary molecular orbitals. After the rearrangement, a molecule (ion), characterised by the correspondence of the number of occupied bonding orbitals with the number of electrons and by the maximum energy gap, is formed.

5. The decrease of molecular symmetry, i.e. the symmetry of the molecular orbitals, after the introduction of polar substituents at the atoms of the skeleton of the polyhedral molecule should lead, as already mentioned, to the splitting of the molecular orbital energy levels. Consequently, in the general case there is a possibility of the mutual approach of the HOMO and LUMO levels. In conformity with the second-order Jahn–Teller effect, this is manifested by the facilitation of the rearrangements of the corresponding molecules and by an increase of their reactivity. For example, the introduction of polar substituents in 1,5-$C_2B_3H_5$ destabilises the molecule to such an extent that the compounds prove to be unstable at room temperature[80].

The fundamental principles and rules of both thermal and reductive and oxidative rearrangements follow from the data discussed above: the Wade rule for rearrangements induced by a change in the number of electrons in the system, and the change in the number of molecular orbitals, binding the atoms of the molecular skeleton and occupied by electrons in the ground and transition states, for a series of thermal rearrangements.

IV. REDUCTIVE AND OXIDATIVE REARRANGEMENTS

According to the Wade rule, any change in the number of electrons without the alteration of the given set of molecular orbitals in conformity with the Jahn–Teller effects, should be accompanied by the destabilisation of the initial configuration and a change in the symmetry of the skeleton of the molecule or ion. When electrons are added, the molecule tends to undergo a rearrangement to achieve an increase in the number of bonding orbitals, and when electrons are removed, it tends to undergo a rearrangement involving a corresponding decrease. The Wade rule fully satisfies these requirements. For example, the addition of two electrons to an n-atomic polyhedral molecule with a *closo*-structure, i.e. having $n + 1$ electron pairs and the corresponding number of bonding orbitals, should lead to a *nido*-structure of the n-atomic fragment of an $(n + 1)$-atomic closed polyhedron having $n + 2$ pairs of bonding electrons distributed in $n + 2$ bonding orbitals.

1. REDUCTIVE REARRANGEMENTS

(a) The Addition of Electrons

The three-centre bonds between carbon and boron atoms in *closo*-carboaranes are the most polarised and therefore have the lowest unoccupied molecular orbitals. This determines the course of the reactions with nucleophiles, including reductants, formally at the boron atoms adjoining carbon atoms. The opening of a *closo*-structure to give a *nido*-structure after the addition of two electrons with formation of a pentagonal or hexagonal face may be

† If the LUMO remain degenerate in the given compounds, the rearrangement is again determined by the first-order Jahn–Teller effect.

accounted for by the rearrangement of the three-centre bonds to two-centre bonds in accordance with the schemes illustrated in Fig. 8.[2] The reduction is usually carried out with metallic sodium in liquid ammonia or tetrahydrofuran (THF). In the latter case electron-transferring agents, for example, naphthalene, are frequently used to achieve the addition of two electrons[81,82]. Electrochemical reduction of polyhedral molecules has also been described[83-87].

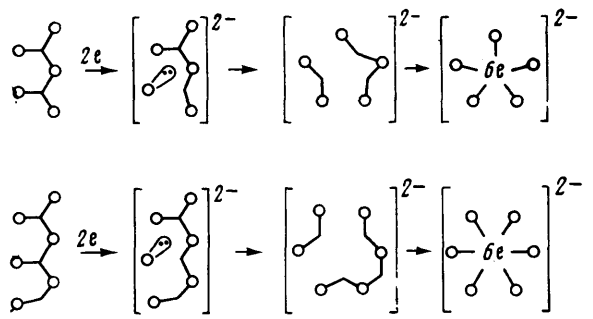

Figure 8. Models of the interaction of possible fragments of polyhedral molecules with reducing agents.

The complexity of the study of reactions involving the addition of electrons to polyhedral molecules consists in the fact that, owing to the one-electron multistage mechanism of this process, radical-anions are formed at an intermediate stage and this determines in many instances the course of cross-linking and disproportionation reactions. Furthermore, the dianions formed may not be individual species and may consist of sets of dynamic structures. Thus the energy barriers between different $C_2B_3H_5^{2-}$ isomers are very low and easy rearrangements of the atoms of the skeleton are therefore possible[10]. The interaction of the dianions with electrophiles is accompanied by the fixation of the open structure and it is possible to isolate individual compounds. Protonation of the dianions leads to the corresponding monoanions and uncharged *nido*-carbaboranes. Depending on the nature of the binding of the proton, the open face retains its structure completely on formation of the BHB bridge bond or partly contracts on formation of B–H or C–H bonds[2]. The above features are illustrated by the examples described below.

$1,2\text{-}C_2B_8H_{10}$. The addition of two electrons to $1,2\text{-}C_2B_8H_{10}$ gives rise to a dianion whose protonation gave the *nido*-carbaborane $5,6\text{-}C_2B_8H_{12}$ (Fig. 9) in 30% yield[88]. The reduction of *nido*-$5,6\text{-}C_2B_8H_{12}$ with sodium amalgam in ethanol leads, in conformity with the Wade rule, to the *arachno*-carbaborane $6,9\text{-}C_2B_8H_{14}$ in 26% yield. The formation of the 6,9-isomer in this reaction can be explained by the migration of the $C_{(6)}$ atom (Fig. 9).[61]

$C_2B_{10}H_{12}$. The dianions of all the carbaborane(12) isomers and many of their *C*- and *B*-derivatives have now been investigated. The results of the early theoretical calculations suggested that the addition of electrons to $C_2B_{10}H_{12}$ may not be accompanied by a significant change in the icosahedral structure[14,34]. It was therefore postulated that the opening of the icosahedral molecule does not occur in the stage involving the addition of electrons to the molecule, but during the protonation of the dianions formed[14]. However, experimental ^{11}B NMR, infrared spectroscopic, and ultraviolet spectroscopic data indicate a significant change in the icosahedral structure of $C_2B_{10}H_{12}$ molecules when electrons are added to them. The ^{11}B NMR spectra of the dianions derived from *o*-, *m*- and *p*-$C_2B_{10}H_{12}$ and their various derivatives, recorded at 32.1 MHz by a double resonance technique, are characterised by a set of broad lines over a wide frequency range and differ fundamentally from the spectra of the initial carbaboranes(12)[75,89]. The *nido*-structure of $C_2B_{10}H_{12}^{2-}$ is also indicated by the infrared spectra of the dianions in THF solution where there are two signals in the range 2400–2600 cm^{-1} due to the stretching vibrations of two types of B–H bonds, apparently located in the open face and in the closed part of the polyhedron. The ultraviolet spectra of the dianions $C_2B_{10}H_{12}^{2-}$ derived from 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$ contain absorption bands with maxima at 298 ± 10, 295 ± 10, and 335 nm respectively. This distinguishes them from the initial icosahedral carbaboranes, which do not absorb in the visible and ultraviolet (up to 200 nm) spectra[75].

On the basis of these data, we suggest that the dianions $C_2B_{10}H_{12}^{2-}$ have a structure of the molecular skeleton similar to that of the corresponding carbaborane ligands in transition metal complexes (Fig. 10) and are characterised by rapid dynamic rearrangements of the molecular skeleton[75,89].

The chemical properties of the dianions derived from 1,2- and $1,7\text{-}C_2B_{10}H_{12}$ indicate specific differences between their structures. Thus protonation of these dianions under identical conditions gives rise to mixtures differing in the ratio of the isomeric monoanions[75,89]. Oxidation of the complexes of the corresponding dianions by cobalt(III) also leads to neutral carbaboranes(12) with different yields and different mixture compositions[89,90]. The nature of the

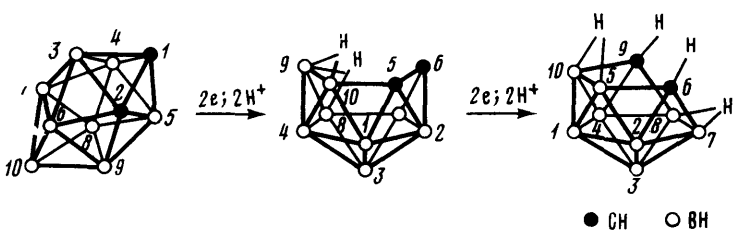

Figure 9. The opening of *closo*-$1,2\text{-}C_2B_8H_{10}$ to give *nido*-$5,6\text{-}C_2B_8H_{12}$ and *arachno*-$6,9\text{-}C_2B_8H_{14}$ on reduction and subsequent protonation.

structural differences between the dianions cannot be determined exactly by experimental methods. Presumably they are associated with the different positions of carbon atoms in the open face: for example, 1,2-$C_2B_{10}H_{12}$ and 1,7-$C_2B_{10}H_{12}$ give rise to the dianions 7,9-$C_2B_{10}H_{12}^{2-}$ and 7,10-$C_2B_{10}H_{12}^{2-}$ respectively. The structure in which only one carbon atom is on the open face has been suggested for the dianion derived from 1,12-$C_2B_{10}H_{12}$ (Fig. 10).[11]

It is noteworthy that the dianions obtained from 1,2- and 1,7-$C_2B_{10}H_{12}$ have similar spectroscopic characteristics. Furthermore, oxidation of these dianions leads to the same product—1,2-$C_2B_{10}H_{12}$. Some workers used these data as the basis for the hypothesis that the dianions from 1,2- and 1,7-$C_2B_{10}H_{12}$ are identical[77,83,91,92]. However, the foregoing considerations, the non-characteristic nature of the spectroscopic characteristics examined, and the possibility of the formation of *o*-carbaborane(12) on closure of the fragment of a 13-vertex polyhedron with an arbitrary distribution of carbon atoms in the open face[11,75] led us to the conclusion that this view is erroneous.

(b) Electrochemical Reduction

$C_2B_9H_{11}$. The electrochemical reduction of *closo*-2,3-$(CH_3)_2$-2,3-$C_2B_9H_9$ and its *B*-hydroxy- and *B*-alkoxy-derivatives proceeds in stages. The first stage leads to the formation of radical-anions. For 2,3-$(CH_3)_2$-$C_2B_9H_9$ and its *B*-hydroxy-derivatives, this process is electrochemically irreversible, which is attributed to the possibility of the occurrence of a chemical reaction or a change in the carbaborane molecule. For B-alkoxy-derivatives of carbaborane(11), the addition of two electrons in stages is observed, the first stage being reversible. The radical-anions formed are stable in this case. Analogous stable radical-anions are formed when the corresponding carbaboranes are acted upon by sodium in THF. Both electrochemical and chemical (Na in THF) addition of an electron to the radical-anions leads to the formation of derivatives of 7,9-$C_2B_9H_{11}^{2-}$ dianions[87].

$C_2B_{10}H_{12}$. In contrast to the multistage reduction of $C_2B_9H_{11}$ derivatives discussed above, a single two-electron wave is observed in the electrochemical reduction of icosahedral *o*-carbaboranes[83-86].

(c) Transition Metal Complexes of the Dianions

The fixation of the structure of the dianion and the overall stabilisation of the carbaborane ligand take place also when transition metal complexes are formed. The addition of electrons from sodium to polyhedral molecules with a *closo*-structure and subsequent treatment with transition metal salts and $C_5H_5^-Na^+$ constitute one of the main methods for the synthesis of metallocarbaboranes, metalloheteroboranes, and metalloboranes (the polyhedral expansion method[81,82,93-97]). The method involving the direct insertion of a transition metal atom in the polyhedral molecule without preliminary reduction of the latter[98-102] is in essence analogous to the polyhedral expansion method, since in this case electrons are also transferred to the polyhedral molecule, but this time from the transition metal atom‡ and the reduction and complex formation stages are thus combined. Since the number of atoms constituting the molecular skeleton changes in these reactions (increases), we shall describe only the fundamental principles without considering in detail all the available literature data concerning the synthesis of metal-containing molecules and ions (see the relevant reviews[103-106]). The rearrangements of polyhedral molecules in polyhedral expansion reactions are fully consistent with the Wade rule, i.e. complexes having the structure of the next polyhedron are formed as a result. The metal atom then occupies the vertex with the highest coordination number. As a result of the addition of electrons, the initial polyhedral molecule rearranges and becomes a ligand in the complex. The structure of the ligand corresponds to the structure of a fragment of the next polyhedron (the Wade rule) and in carbaborane ligands the carbon atoms are located in the open face. This reflects the mode of addition of electrons

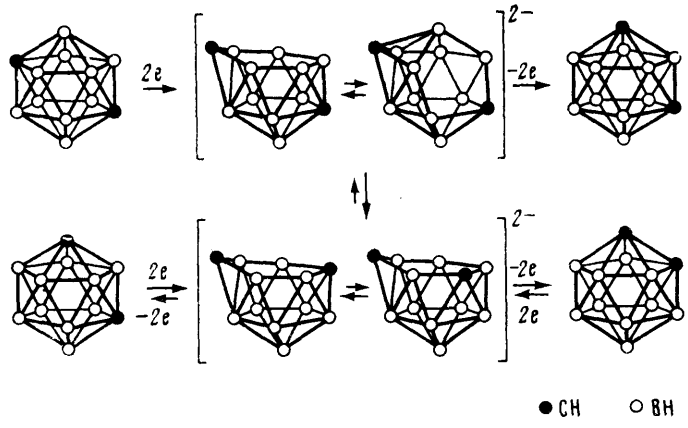

Figure 10. The possible modes of opening of icosahedral carbaboranes following the addition of electrons and rearrangement of the resulting dianions.

‡ For example, the following transition metal complexes are used as reagents: $Fe(CO)_5$, $(C_5H_5)Co(CO)_2$, $(C_2H_4)Ni(PPh_3)_2$, (*trans*-stilbene)$Pt(PMe_3)_2$, etc.

and the stability of the corresponding dianions in which the carbon atoms are in the open face.

Successive application of the polyhedral expansion method yielded metallocarbaboranes containing two and three transition metal atoms, i.e. formally the initial n-atomic molecule with a *closo*-structure, which ultimately combines with three pairs of electrons, is converted into an n-atomic fragment of the $(n + 3)$-atomic polyhedron and the sites of the three missing vertices are occupied by the transition metal atoms (Fig. 11*a*). The hitherto unknown structures of polyhedra with 13 and 14 vertices were also obtained by the polyhedral expansion reaction of the icosahedral carbaborane (Figs. 11*b* and 11*c* [95]).

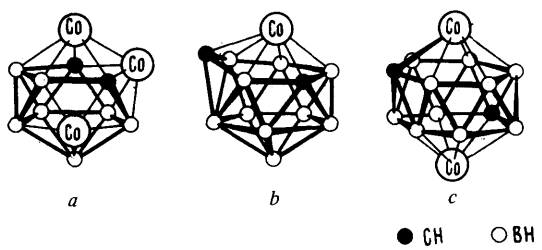

Figure 11. The structures of metallocarbaboranes obtained by the polyhedral expansion method: *a*) 1,2,8,3,6-(η^5-C_5H_5)$_3$$Co_3C_2B_7H_9$; *b*) 1,2,4-($\eta^5$-$C_5H_5$)$CoC_2B_{10}H_{12}$; *c*) 1,14,2,10-($\eta^5$-$C_5H_5$)$_2$$Co_2C_2B_{10}H_{12}$ (suggested structure of one of the isomers). The ligands C_5H_5 are not shown in the Figure.

By reducing the carbaboranes $Me_4C_4B_8H_8$ with $NaC_{10}H_8$ and subsequent treatment with NaC_5H_5 and $FeCl_2$, Grimes and coworkers [97] obtained several (η^5-C_5H_5)$_2$$Fe_2Me_4C_4B_8H_8$ isomers. X-Ray diffraction analysis established that two out of the four isomers isolated have the structure of 14-vertex fragments of 15-vertex closed polyhedra with an open tetragonal or pentagonal face [the *nido*-structure of a $(2n + 4)$-electron polyhedron] (Fig. 12). Nevertheless, the authors [97] believe that 14 atoms of the molecular skeleton are linked by 30 electrons, i.e. belong to the type of $(2n + 2)$-electron polyhedra, which should have a *closo*-structure according to the Wade rule.

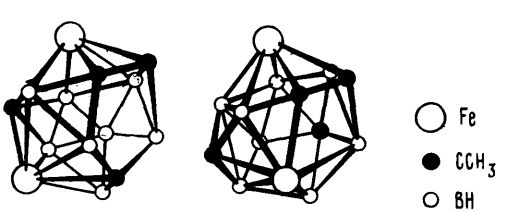

Figure 12. The structures of 15-vertex *nido*-metallocarbaboranes. The ligands C_5H_5 are not shown in the Figure.

Hawthorne and coworkers [107] examined the problem of the application of the Wade rule to metallocarbaboranes. Taking into account the tendency of the transition metal atom to complete its outer electron shell, i.e. to have 18 electrons in the latter, and also the fact that six ligand electrons participate in the coordination of the ligand to the transition metal, the "magic numbers" determining the type of structure and class of metallocarbaboranes were also derived. For complexes with a single transition metal atom and a single carbaborane ligand, $2n + 14$ electrons characterise *closo*-compounds and $2n + 16$ electrons characterise *nido*-compounds. For the metal : ligand = 1 : 2 ratio, the corresponding numbers are $2n + 12$ for a *closo*-structure, $2n + 14$ for *closo*- and *nido*-structures, and $2n + 16$ for a *nido*-structure. For the ratio 2 : 1, a polyhedral *closo*-molecule is characterised by $2n + 26$ electrons [107].

In his study of the structure of transition metal complexes with dicarbollide ions, Wegner [108] noted that the molecules have an icosahedral structure for metals with a $d^5 - d^7$ electronic configuration and a significantly distorted (open) structure for $d^8 - d^9$ metals. The transition from a d^6 configuration to d^7, d^8, and d^9 configurations is equivalent to the addition of one, two, and three electrons respectively. Thus the opening of an icosahedral *closo*-structure takes place directly in the reduction of the polyhedral system and not in the protonation stage [108].

(d) The Addition of Nucleophiles

Reductive rearrangements (opening) of closed polyhedral molecules as a result of the addition of nucleophiles should include, as already noted, several stages apart from the addition of electrons (see also the footnote in Section II, subsection 3): the ejection of a proton from the boron atom with which the nucleophile has formed a bond, and reorientation of the resulting atomic orbital with an electron pair; another more probable reaction pathway involves a rearrangement of the polyhedral molecule and the supply of electrons from the B–H bond to the orbitals of the skeleton as a result of the formation of a BHB bridge bond. If the compound formed is unstable, for example, because the carbon atoms are not located in the open face, stabilisation may be achieved due to further rearrangements (see Section V, subsection II).

$C_2B_4H_6$. The addition of nucleophiles, for example, Me_3N, Me_3P, or H^-, to *closo*-1,6-$C_2B_4H_6$ leads to the opening of the molecule and the formation of *nido*-5-Me_3N-2,4-$C_2B_4H_6$, 5-Me_3P-2,4-$C_2B_4H_6$, and 2,4-$C_2B_4H_7^-$ respectively (Fig. 13*a*). [109-111]

$C_2B_9H_{11}$. The interaction of 2,3-$C_2B_9H_{11}$ with a wide range of nucleophiles L proceeds with formation of 10-L-7,9-$C_2B_9H_{11}^-$ [112-114] (Fig. 13*b*). The suggested formation of 3-L-7,9-$C_2B_9H_{11}^-$ was disproved [115,116].

The opening of closed polyhedral metallocarbaboranes on treatment with nucleophiles has been observed in many instances [117-119].

2. OXIDATIVE REARRANGEMENTS

The oxidative rearrangements of *nido*-carbaboranes may be described in terms of schemes which are the opposite of those for the addition of electrons. The oxidant E interacts with the highest occupied two-centre or delocalised five- or six-centre orbital and a two-centre B–E or C–E bond or a three-centre BEB bond is formed. The opening of the latter and the formation of a B–E or C–E bond lead

to partial closure of the *nido*-structure. Electron transfer to the oxidant completes the closure of the structure (Figs. 6*d*, 6*e*, and 6*f*). Evidently the mode of oxidative rearrangements is determined by the direction of electrophilic attack and may not take place along the same coordinate as the reverse process involving the opening of the structure under the influence of a reductant or a nucleophile.

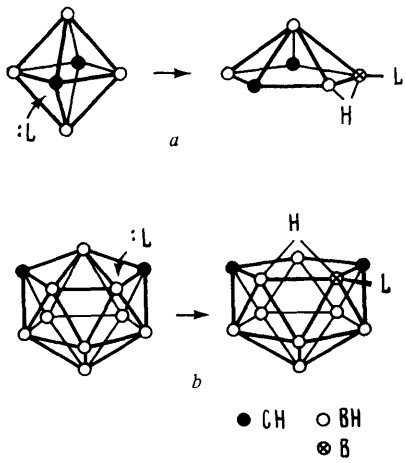

Figure 13. The opening of *closo*-carbaboranes on interaction with nucleophiles: *a*) 1,6-$C_2B_4H_6$; *b*) 2,3-$C_2B_9H_{11}$.

Many transformations of neutral *nido*-carbaboranes into *closo*-carbaboranes on pyrolysis may be classified as oxidative rearrangements. Such a reaction is used in the synthesis of all the lower and medium carbaboranes $C_2B_nH_{n+2}$:

$$C_2B_9H_{13} \xrightarrow{-H_2} C_2B_9H_{11}\ ^{58,\,120},$$
$$C_2B_8H_{12} \xrightarrow{-H_2} C_2B_8H_{10}\ ^{62,\,88,\,121-120},$$
$$C_2B_7H_{13} \xrightarrow{-H_2} C_2B_7H_9\ (+\ C_2B_6H_8 + C_2B_8H_{10})\ ^{58,\,124},$$
$$C_2B_4H_8 \xrightarrow{-H_2} C_2B_4H_6\ (+\ C_2B_3H_5 + C_2B_5H_7)\ ^{125-127}.$$

Owing to the radical mechanism of the pyrolysis, reactions involving the disproportionation or cross-linking of the polyhedral molecules frequently occur. Intramolecular oxidation (closure) also takes place when a halide anion is eliminated from (B)-Hal-$C_2B_{10}H_{11}^{2-}$ [128]:

$$(C_2H_{10}H_{11}X)^{2-} \rightarrow C_2B_{10}H_{11}^{-} + X^{-}.$$

Depending on the distribution of electron density in the open face of the polyhedral molecule, reactions with electrophiles can proceed in different ways and the oxidative rearrangement can lead to different products.

Examples of the oxidative rearrangements of open polyhedral compounds are the closure of thioboranes on oxidation and pyrolysis [129]:

$$arachno\text{-}6\text{-}SB_9H_{12}^{-} \xrightarrow{-2e,\,[O]} nido\text{-}6\text{-}SB_9H_{11} \xrightarrow{-H_2\,(t^\circ)} closo\text{-}1\text{-}SB_9H_9,$$

the formation of *closo*-2,3-$C_2B_9H_{11}$ on oxidation of *nido*-7,9-$C_2B_9H_{11}^{2-}$ with stannous chloride [114]:

$$nido\text{-}7,9\text{-}C_2B_9H_{11}^{2-} \xrightarrow{-2e\,(SnCl_4)} closo\text{-}2,3\text{-}C_2B_9H_{11},$$

and oxidative rearrangements of carbaborane(12) dianions and their derivatives.

A characteristic feature of the oxidative rearrangements of the dianions $C_2B_{10}H_{11}^{2-}$ is that they lead to isomers of the icosahedral carbaborane(12), which are in general different from the initial isomers. For example, the oxidation of the dianions of both 1,2- and 1,7-$C_2B_{10}H_{12}$ leads exclusively to 1,2-$C_2B_{10}H_{12}$, [83] while the dianion derived from 1,12-$C_2B_{10}H_{12}$ yields only 1,7-$C_2B_{10}H_{12}$. [130,131] The oxidation of the dianions derived from a series of *C*-derivatives of *p*-carbaborane yields also derivatives of the *o*-isomer together with those of the *m*-isomer, depending on the type and number of substituents [11,75,132,133]. The direction of the rearrangements is greatly influenced by substituents in the carbaborane ring. The oxidative rearrangement of the dianion obtained from 2-Hal-1,12-$C_2B_{10}H_{11}$ leads to a mixture of the two possible isomers of (B)-Hal-1,7-$C_2B_{10}H_{11}$ and unsubstituted 1,12- and 1,7-$C_2B_{10}H_{12}$. Mainly 10-Hal- and 3-NH_2-$C_2B_{10}H_{12}$ are formed together with 1,2- and 1,7-$C_2B_{10}H_{12}$ from 9-Hal-1,7-$C_2B_{10}H_{11}$ under analogous conditions [130]. In many instances the influence of the substituent is so great that the direction of the rearrangement changes; for example, derivatives of the 1,7-isomer are formed together with those of 1,2-$C_2B_{10}H_{12}$ in the oxidation of the dianion obtained from 1-CH_2Hal-1,2-$C_2B_{10}H_{11}$. [134]

Thus the set of experimental data shows that the substituent influences the direction not only of oxidative but also of reductive rearrangements and the occurrence of the rearrangements in the dianions themselves.

Oxidative rearrangements of *nido*-metallocarbaboranes lead to the closure of the polyhedron, as expected [135].

V. THERMAL REARRANGEMENTS

1. REARRANGEMENT OF CLOSED POLYHEDRAL SYSTEMS

The rearrangements of closed polyhedral molecules take place over a wide temperature range. For example, the anions $B_2H_6^{2-}$, $B_{11}H_{11}^{2-}$, and $CB_{11}H_{11}^{-}$ rearrange so fast that the characteristics of the ^{11}B NMR spectra of these species in solution at room temperature and below are averaged out. On the other hand, 1,7-$C_2B_{10}H_{12}$ isomerises to 1,12-$C_2B_{10}H_{12}$ only above 500°C. We have already noted that many thermal rearrangements involve electron transfer between occupied and unoccupied boundary molecular orbitals, which determines the course of the given reaction. In this case the excitation of the electron is apparently associated with an appreciable mutual approach of the HOMO and LUMO levels on deformation of the molecule as a result of the vibrational motion or collision of the molecules. In the limiting case in the transition state there is a possibility of degeneracy of the electronic state of the molecule. Since, according to the Jahn–Teller effect, the excitation of the electron is stereochemically equivalent to the addition of one or two electrons, the deformed molecule may be stabilised to a greater or lesser extent in the open state. The possibility of easy structural rearrangements of an excited molecule and the closure of the polyhedron in a direction which is not the same as that of its opening lead to the isomerisation of the initial molecule. The alternative model of the mechanism of thermal rearrangements is based on the familiar ideas concerning the occurrence of synchronous (concerted) reactions. In the absence of symmetry-dependent prohibitions the energy of the system varies smoothly along the reaction coordinate and does not require the mutual approach of the HOMO and LUMO energy levels.

Evidently, among all the possible deformations of the initial molecule leading to the final product, those which are consistent with molecular symmetry, are minimal, and have the lowest force constants will actually occur. Thus, when the mechanisms of thermal rearrangements are considered, it is useful to employ the second-order Jahn–Teller effect, which imposes certain symmetry-dependent limitations on "soft" deformations. In conformity with this effect, the deformation should not be fully symmetrical and its representation should be included in the product of the representations of boundary molecular orbitals (see Section III).

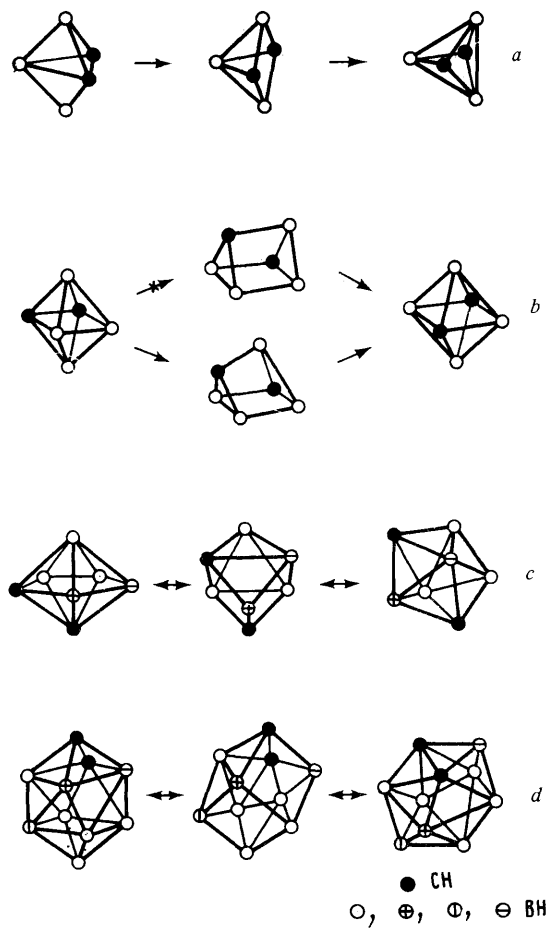

Figure 14. The proposed mechanisms for the thermal rearrangements of *closo*-carbaboranes with different structures: *a*) trigonal bipyramid; *b*) octahedron; *c*) pentagonal bipyramid; *d*) square antiprism with two vertices. In order to represent the rearrangements with greater clarity, the boron atoms in structures *c* and *d* are marked in different ways.

When the system attains equilibrium, the thermodynamically most stable isomer predominates. In the series of carbaboranes the tendency determining the direction of the rearrangement is the endeavour by carbon atoms to occupy positions in which their excess positive charge is compensated to the maximum extent and the molecule has the highest symmetry. This determines the high stability of isomers in which carbon atoms are furthest apart and have the minimum possible coordination number[2,136].

Trigonal bipyramid $C_2B_3H_5$. Dicarba-*closo*-pentaborane(5) has the structure of a trigonal bipyramid. In this structure there is a possibility of three isomers depending on the positions of the carbon atoms in the molecule. According to molecular orbital calculations, the thermodynamic stabilities of the isomers decrease in the sequence 1,5- > 1,2- > 2,3-$C_2B_3H_5$.[20] Only the two isomers 1,5- and 1,2-$C_2B_3H_5$ are known and the latter has been obtained only as the 2,3-dimethyl derivative, 2,3-Me_3-1,2-$C_2B_3H_5$, which does not rearrange to the 1,5-isomer and this served as the basis for the hypothesis that it is stabilised by the presence of methyl substituents[3,137]. The fact that 1,5-$C_2B_3H_5$ is formed in the reaction of diborane or pentaborane(9) with acetylene or in the pyrolysis of the *nido*-carbaborane 2,3-$C_2B_4H_8$, in which the carbon atoms occupy adjacent positions, indicates the intermediate formation of the $C_2B_3H_5$ isomers with carbon atoms in adjacent positions, i.e. 1,2- and (or) 2,3-$C_2B_3H_5$. Under reaction conditions, they rapidly isomerise to the thermodynamically more stable 1,5-isomer[137].

The mechanism of the rearrangements in the systems considered has not been investigated. A possible mechanism involves the rearrangement of the rhomboid fragment, made up of two trigonal faces, to a square, this being followed by the closure of the structure and the reformation of a rhomboid fragment in which the carbon atoms are separated by boron atoms—a *dsd* mechanism (Fig. 14*a*).[3]

Octahedron. $C_2B_4H_6$. An example of a rearrangement of an octahedral molecule is provided by the isomerisation of 1,2-$C_2B_4H_6$ to the 1,6-isomer, which occurs at 250°C.[138] Calculations show that the 1,6-isomer is more stable than the 1,2-isomer by 15 kcal mole^{-1},[139] which agrees with the direction of isomerisation. Lipscomb and coworkers[36] established by molecular orbital calculations that the rearrangement proceeds via the intermediate formation of a compound having the structure of a distorted trigonal prism (Fig. 14*b*). Mechanisms based on the formation in the transition state of a molecule with the structure of a non-distorted trigonal prism or on the opening of the *closo*-molecule to give a *nido*-structure, i.e. a pentagonal pyramid, are ruled out, since they require high activation energies[35,36].

Pentagonal bipyramid. $C_2B_5H_7$. Of the four possible $C_2B_5H_7$ isomers, two have been obtained so far: 2,3-$C_2B_5H_7$[62,122] and 2,4-$C_2B_5H_7$.[125] Rearrangements of this type of polyhedron have not been observed in the series of unsubstituted carbaboranes, although the 2,4-isomer should apparently be more stable. Lipscomb[3] proposed a two-stage mechanism for the possible rearrangement of the 2,3-isomer to 2,4-$C_2B_5H_7$, involving successive application of the *dsd* model (Fig. 14*c*) (see also subsection 3 of this Section).

Dodecahedron. $B_8H_8^{2-}$, $C_3B_5H_7$, and $C_2B_6H_8$. It has been noted that polyhedral systems of this type can readily undergo structural rearrangements of the atoms of the skeleton[140]. The influence of solvents, counterions, and temperature on the nature of the dynamic processes in the system has been investigated by ^{11}B NMR for the anion

$B_8H_8^{2-}$.[141] In solvents of low polarity at a temperature below 10°C the ^{11}B NMR spectrum has three signals with relative intensities of 2 : 4 : 2. On passing to highly polar solvents or on raising the temperature, the spectrum is gradually transformed and at 46°C in 1,2-dimethoxyethane it contains only signal. According to the authors [141,142], these data show that $B_8H_8^{2-}$ in solution has the structure of a trigonal prism with two vertices (solvents of low polarity, low temperature) or a square antiprism (polar solvents, elevated temperature) and not a dodecahedron (Fig. 15*a*). We believe that this interpretation of spectroscopic data is insufficiently justified. For example, the authors' assumption[141] that a change of temperature can lead to a complete conversion of one polyhedral form into another under the conditions of equilibrium between the suggested structures of a trigonal prism with two vertices and a square antiprism is incomprehensible. There is no doubt that rapid rearrangements of the polyhedral molecule (dynamic processes) are characteristic of the given system.

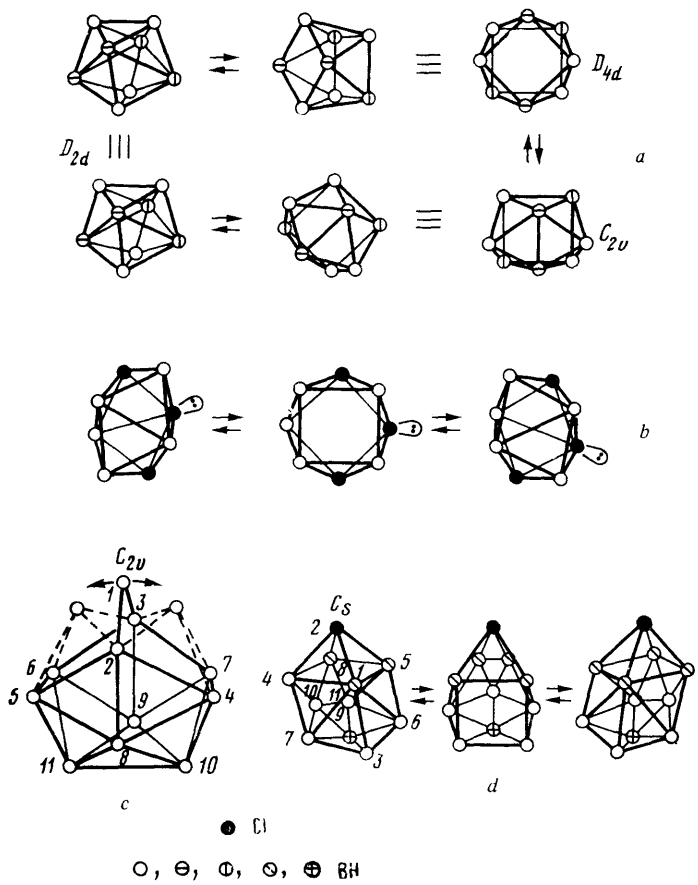

Figure 15. The proposed mechanisms for the dynamic rearrangements of certain closed polyhedral compounds: a) $B_8H_8^{2-}$; b) $C_3B_5H_7$; c) $B_{11}H_{11}^{2-}$; d) $CB_{10}H_{11}^{-}$. To achieve a greater clarity in the representation of the rearrangements, the boron atoms in structures *a* and *d* are marked in different ways.

$C_3B_5H_7$. Tricarba-*closo*-octaborane(7) is a second example of the occurrence of rapid rearrangements of the skeleton of an eight-atom polyhedral molecule. The ^{11}B NMR spectrum of this compound contains three signals with relative intensities 2 : 2 : 1, while the ^1H NMR spectrum consists of three quartets, due to protons linked to the boron atoms, and [a single] signal originating from the proton in the C–H bond with relative [H–B/H–C] intensities of 5 : 2. In order to account for the spectroscopic data, the authors[143] postulate the occurrence of dynamic rearrangements of the molecule with a dodecahedral structure via a transition state having the structure of a square antiprism (Fig. 15*b*).

One may assume that such easy rearrangements in the compounds considered are caused either by the degeneracy of the ground molecular state or by the low value of the energy gap between HOMO and LUMO and, in conformity with the Jahn–Teller effects, the configurational instability of the molecules.

$C_2B_6H_8$. Only one isomer (1,7-$C_2B_6H_8$) of dicarba-*closo*-octaborane(8) has been obtained. According to X-ray diffraction data, it has the structure of a dodecahedron (D_{2d} symmetry). Although the ^{11}B NMR spectrum of 1,7-$C_2B_6H_8$ has only two signals with relative intensities of 4 : 2, the authors[58,142] suggest that this compound undergoes dynamic rearrangements of its molecular skeleton and that the presence of the signal with a relative intensity of 4 is due to a random superposition of two signals having relative intensities of 2 : 2.

Square antiprism with two vertices. $C_2B_8H_{10}$. Of the seven possible isomers of dicarba-*closo*-decaborane(10), only three are known at the present time: 1,2-, 1,6- and 1,10-$C_2B_8H_{10}$. As was to be expected, the stabilities of these isomers increase in the sequence 1,2- < 1,6- < 1,10-$C_2B_8H_{10}$. The compounds 1,2- and 1,6-$C_2B_8H_{10}$ wholly isomerise to the 1,10-isomer on heating to 300°C.[58,88] The mechanism proposed for the rearrangements is based on the *dsd* model and requires several consecutive stages (Fig. 14*d*).[3]

Octadecahedron. $B_{11}H_{11}^{2-}$, $CB_{10}H_{11}^{-}$, and $C_2B_9H_{11}$. As for the dodecahedron, the rearrangement of polyhedral compounds having the structure of an octahedron proceed very readily.

$B_{11}H_{11}^{2-}$. The ^{11}B NMR spectrum of *closo*-undecaborate(2-) contains only one signal[144] and its nature is independent of the solvent employed and the temperature[145]. A decrease of temperature causes only a broadening of the signal in the spectrum, apparently due to the increased viscosity of the solution. Analogous data were obtained for $B_{11}H_7Br_4^{2-}$. The ^{11}B NMR spectrum of this compound has two signals with relative intensities of 4 : 7, caused by substituted and unsubstituted boron atoms. Tolpin and Lipscomb[145] explained the results on the hypothesis that these ion rapidly rearrange in solution via a transition state with the structure of an 11-vertex fragment of an icosahedron (Fig. 15*c*).

$CH_{10}H_{11}^{-}$. Another mechanism of the rearrangement of molecules having an octadecahedral structure has been proposed[146] in a study of monocarba-*closo*-undecaborate(1-). This mechanism is based on the *dsd* model. The ^{11}B NMR spectrum of this compound is characterised by three signals with relative intensities of 1 : 5 : 4, which can be explained by a rapid rearrangement (Fig. 15*d*). As

a result, the boron atoms in the 1-, 4-, 5-, and 8-positions and those in the 3-, 6-, 7-,10-, and 11-positions are indistinguishable in their spectral effects, while the $B_{(9)}$ atom gives rise to a single-intensity signal[146]. It is noteworthy that both mechanisms considered yield equally satisfactory explanations of the observed ^{11}B NMR spectra of $B_{11}H_{11}^{2-}$ and $CB_{10}H_{11}^{-}$.

As in $B_8H_8^{2-}$, the dynamic processes in $CB_{10}H_{11}^{-}$ and $B_{11}H_{11}^{2-}$ are apparently caused by the degeneracy of the ground state or the proximity of the boundary orbitals of the molecule. The lack of data for the energies and symmetries of the molecular orbitals of these compounds makes it impossible at the present time to give preference to one of the two mechanisms proposed for the rearrangements. However, if the deformation leading to the opening of $B_{11}H_{11}^{2-}$ (C_{2v}) and $CB_{10}H_{11}^{-}$ (C_S) has B_2 and A'' symmetry respectively, then the deformation characterising the *dsd* model does not correspond to any of the normal vibrations of the molecules under consideration. On the assumption that the excitation energy required for the rearrangement of the molecule is distributed among the normal vibrational degrees of freedom and that the deformation in the direction of the soft vibrational mode leads to rearrangement, this nevertheless enables us to consider the "opening-closure" mechanism to be more probable for the rearrangements of $B_{11}H_{11}^{2-}$ and $CB_{10}H_{11}^{-}$.[63]

2,3-$C_2B_9H_{11}$. 2,3-Dicarba-*closo*-undecaborane(11) is the only one of the twenty possible isomers obtained at the present time and is theoretically the most stable. This carbaborane is formed from both 7,9-$C_2B_9H_{13}$ and 7,8-$C_2B_9H_{13}$ in which the carbon atoms are in adjacent positions[58]. In the latter case the carbon atoms in the $C_2B_9H_{11}$ formed in the first stage should also apparently be in adjacent positions and the structure is possibly 2,4-$C_2B_9H_{11}$. Its rapid isomerisation to the 2,3-isomer is consistent with the ease of the rearrangements of octadecahedral molecules.

Icosahedron. $C_2B_{10}H_{12}$ and $CHPB_{10}H_{10}$. Numerous studies have been devoted to the thermal rearrangements of carbaboranes(12) and their derivatives. It has been established that the thermodynamic stability of $C_2B_{10}H_{12}$ isomers increases in the sequence 1,2- < 1,7- < 1,12-$C_2B_{10}H_{12}$, and that at approximately 450° C the *o*-isomer isomerises wholly to the *m*-isomer.[147-151] The *p*-isomer is formed at a higher temperature (approximately 600° C and above)[152] and equilibrium is established between the *m*- and *p*-carbaboranes(12)[153]:

$$1,2\text{-}C_2B_{10}H_{12} \xrightarrow{450^\circ} 1,7\text{-}C_2B_{10}H_{12},$$

$$1,7\text{-}C_2B_{10}H_{12} \underset{}{\overset{600^\circ}{\rightleftharpoons}} 1,12\text{-}C_2B_{10}H_{12}.$$

The introduction of bulky substituents into the icosahedral molecule led to a considerable facilitation of the rearrangements in many instances[154].

As a result of systematic studies on the rearrangement of carbaborane(12) isomers their B-halogeno-derivatives, and other icosahedral heteroboranes, six different mechanisms have been suggested to account for the formation of the products of the rearrangement (Fig. 16). The mechanism involving a cubo-octahedral transition state (Fig. 16*a*) explains the formation of 1,7-$C_2B_{10}H_{12}$ from the 1;2-isomer, but cannot account for the formation of 1,12-$C_2B_{10}H_{12}$.[3,34,155,156] The mechanism which is also based on a cubo-octahedral transition state but is modified by the assumption that the trigonal faces in the latter can rotate (Fig. 16*b*) explains the formation of 1,12-$C_2B_{10}H_{12}$ and the composition of the isomer mixture formed in the rearrangements of 9-Br-1,2-$C_2B_{10}H_{11}$[157] and 9-Cl-1,7-$C_2B_{10}H_{11}$.[158] In another modification of the *dsd* mechanism the rotation of tetragonal faces in the transition state is postulated (Fig. 16*c*).

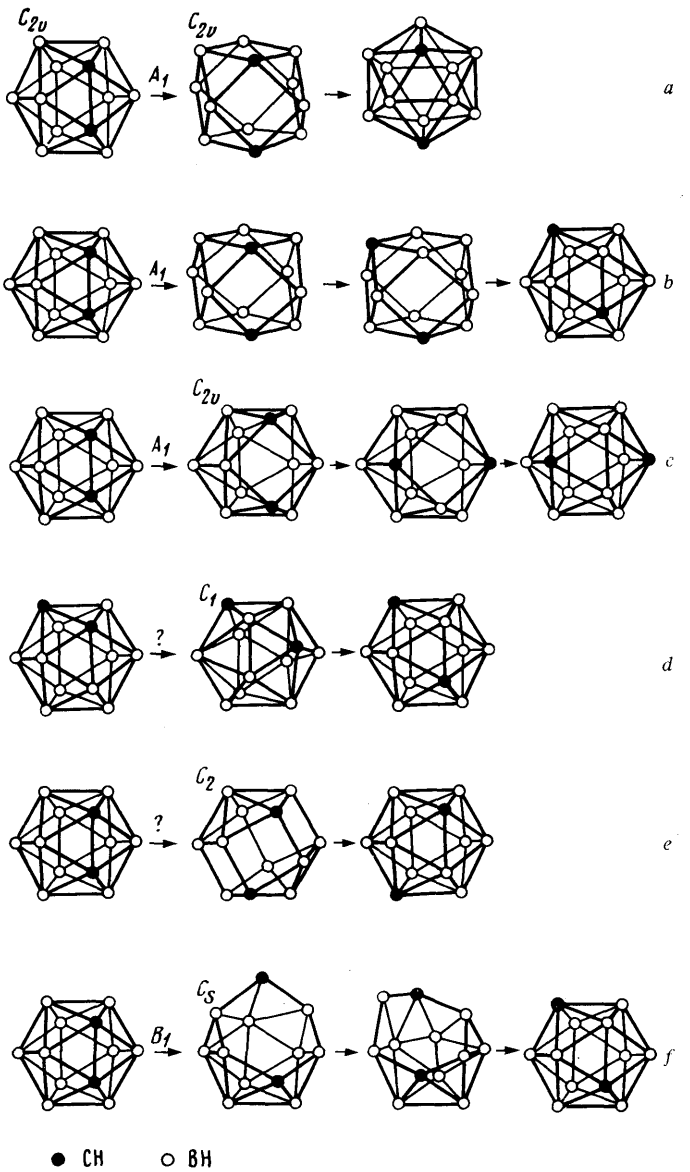

Figure 16. The mechanisms proposed for the rearrangements of icosahedral carbaboranes.

This mechanism has been proposed as one capable of explaining the rearrangements in the series of phosphacarbaboranes[5]. The last two mechanisms involve the rotation of trigonal faces (Fig. 16*d*) and pentagonal pyramidal fragments (Fig. 16*e*) in the ground icosahedral state[6,7]. These mechanisms also explain the formation of 1,12-$C_2B_{10}H_{12}$ and preference is given to the mechanism based on the rotation of pentagonal pyramids in the rearrangement of *B*-halogenophosphacarbaboranes[5]. Thus, according to the

authors[5], the mechanism of the rearrangements of icosahedral molecules should change on passing from the carbaborane system $C_2B_{10}H_{12}$ to the heterocarbaborane system $CHPB_{10}H_{10}$.

Wong and Lipscomb[5] proposed a mechanism for the rearrangements of icosahedral molecules which differs fundamentally from that considered above. It involves the opening of the icosahedral *closo*-structure to give a *nido*-structure which is a fragment of a 13-vertex polyhedron; the reverse closure of the polyhedron in other directions leads to the formation of different isomeric products (Fig. 16*f*). Since this mechanism predicted the occurrence of certain isomers whose formation in the series of phosphacarbaboranes had not been observed experimentally, the authors[5] gave preference to the mechanism involving the rotation of pentagonal pyramidal fragments. However, it is evident that, without the imposition of boundary conditions, the "opening-closure" mechanism, being one of the most general, will predict the formation of all possible isomers.

It was already noted above that the mechanisms involving a cubo-octahedral transition state do not meet the requirements of the symmetry of "soft" deformations. Indeed, if the molecules of 1,2- and 1,7-$C_2B_{10}H_{12}$ with C_{2v} symmetry are considered, the deformation leading to a cubo-octahedral transition state has the A_1 symmetry, i.e. is fully symmetrical (Figs. 16*a*, 16*b*, and 16*c*). On the basis of the symmetry I_h of a regular icosahedron ($B_{12}H_{12}^{2-}$), one can also conclude that this mechanism as well as the mechanism based on the rotation of pentagonal fragments are unlikely, since the direct product of the representations of the boundary orbitals of $B_{12}H_{12}^{2-}$ having the G_u symmetry for HOMO and G_g symmetry for LUMO[14,18] is equal to $A_u + F_{1u} + F_{2u} + G_u + H_u$, i.e. includes only representations which are antisymmetric relative to the inversion operation. On the other hand, the deformations considered are symmetrical relative to inversion (Figs. 16*a* and 16*e*) and their representations cannot therefore be included in the above product. The mechanisms involving the rotation of individual fragments of the icosahedral molecule (Figs. 16*d* and 16*e*) are also unlikely, since in the molecules with the given symmetry there are no normal vibrations corresponding to the required deformations. Furthermore, the mechanisms considered above require large displacements of many atoms. On the other hand, the deformation leading to the opening of the molecule (Fig. 16*f*) has the B_1 symmetry, if one begins with the C_{2v} symmetry for 1,2- and 1,7-$C_2B_{10}H_{12}$, and is minimal.

2. REARRANGEMENTS OF OPEN POLYHEDRAL MOLECULES

As already mentioned, the structures of *nido*-compounds are n-vertex fragments of an $(n + 1)$-vertex closed polyhedron and are characterised by the presence of a tetragonal, pentagonal, or hexagonal face. Neutral polyhedral *nido*-compounds are also characterised by the presence of hydrogen bridge atoms§ in the open face, which determines their thermal instability—*nido*-carbaboranes decompose on heating with evolution of hydrogen and give rise to *closo*-carbaboranes (see Section IV, subsection II).

Thermal rearrangements of *nido*-carbaboranes have been observed only for the corresponding anions. Among the possible conformers, those with the maximum possible number of atoms in the open face are stable on thermal isomerisation. The relative thermodynamic stabilities of isomers with different positions of the heteroatoms in the molecule are determined, as already mentioned, by the possibility of compensating their excess charge. Accordingly, in the thermodynamically more stable *nido*-carbaboranes the carbon atoms are as a rule located in the open face.

Tetragonal pyramid. $C_2B_3H_7$. A distinctive feature of the familiar 1,2-$C_2B_3H_7$ isomer of dicarba-*nido*-pentaborane(7) is that only one carbon atom is located in the open face of the molecule and the second occupies a vertex position (Fig. 17*a*).[159] The stability of this particular isomer can be accounted for by the presence of two hydrogen bridge atoms. If both carbon atoms were in the open tetragonal face, then, in view of the necessity for the formation under these conditions of a CHB bridge, the excess positive charge on the carbon atom would have increased and not decreased. On the other hand, the formation of the BH_2 or CH_2 group is unfavourable in view of the principle governing the stability of polyhedral compounds¶. For this reason, only the 1,2-isomer of the neutral *nido*-carbaborane $C_2B_3H_7$ exists[10]. According to molecular orbital calculation, the dianion $C_2B_3H_5^{2-}$ should also have the structure of a tetragonal pyramid and the stability of the isomers should then vary in the sequence 2,4- > 2,3- > 1,2-$C_2B_3H_5^{2-}$ according to general principles. Calculation shows that the rearrangement of one isomer to another takes place as a result of the migration of an atom from the open face to the site of the missing vertex of the octahedron. This mechanism is symmetry-allowed and energetically more favourable than the *sds* (*square–diamond–square*) mechanism, which is also symmetry-allowed[10].

Pentagonal pyramid. $C_2B_4H_8$. Although two of the three possible isomers of dicarba-*nido*-hexaborane(8), with neighbouring or non-neighbouring carbon atoms in the open pentagonal face, are known (the 2,3- and 2,4-isomers†) (Fig. 17*b*), there are no literature data for the rearrangement of one isomer to the other. At the same time rearrangements of substituted carbaboranes with retention of the positions of the carbon atoms have been observed[65,110,111]:

$$5\text{-}Me_3N\text{-}2,4\text{-}C_2B_4H_6 \rightarrow 3\text{-}Me_3N\text{-}2,4\text{-}C_2B_4H_6\ ,$$
$$4\text{-}R_3Si\text{-}2,3\text{-}C_2B_4H_7 \rightarrow 1\text{-}R_3Si\text{-}2,3\text{-}C_2B_4H_7\ .$$

Calculation showed that the stabilities of the isomeric dianions vary in the sequence 2,4- > 2,3- > 1,2-$C_2B_4H_6^{2-}$.[10]

$C_2B_6H_{10}$. The proposed structure of the known isomer of dicarba-*nido*-octaborane(10) (I) is presented in Fig. 17*c*. ^{11}B and ^1H NMR data are also consistent with the possibility of dynamic transitions between structures (II) and (II′) (Fig. 17*c*).[160]

§ In conformity with the isoelectronic principle, certain *nido*-compounds, for example, *nido*-carbaboranes $C_4B_{n-4}H_n$, are uncharged and have no hydrogen bridge atoms.

¶ Polyhedral systems where, as far as possible, all the $3n$ orbitals of the atoms in the skeleton are involved in the formation of bonds are distinguished by the highest stability.

† The 2,4-isomer is known only as the anion 2,4-$C_2B_4H_7^-$ or the inner trimethylammonium salt[109,110].

$C_2B_7H_{11}$. Dicarba-*nido*-nonaborane(11) is interesting because its structure is greatly influenced by substituents at the carbon atoms of the molecular skeleton. Thus the possible structure of the unsubstituted carbaborane $C_2B_7H_{11}$ (the known isomer) (Fig. 17*d*) is characterised, according to the authors[62], by the presence in the open hexagonal face of two carbon atoms in the *ortho*-positions with respect to one another, and of only one BHB bridge. According to ^{11}B NMR data, another "superfluous" hydrogen atom forms a σ bond with a boron atom, giving rise thereby to the BH_2 structural unit. When methyl substituents are attached to the carbon atoms, the molecule has the usual structure of a fragment of a square antiprism with two vertices according to X-ray diffraction data (Fig. 17*d*). The authors[62] explain the structural differences and the greatest stability of the dimethyl derivative of $C_2B_7H_{11}$ by the steric or electronic influence of methyl groups.

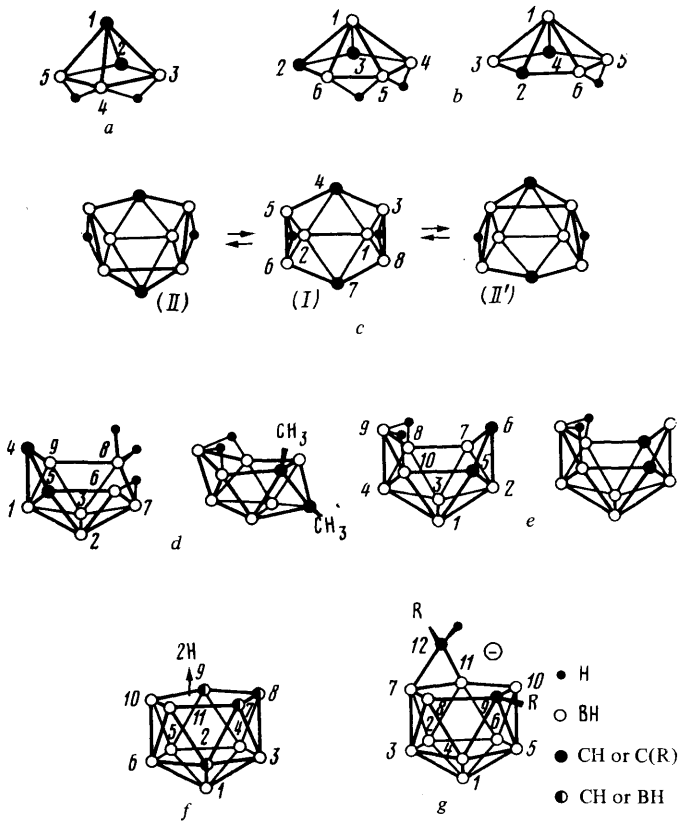

Figure 17. The structures of *nido*-carbaboranes: *a*) 1,2-$C_2B_3H_7$; *b*) 2,3-$C_2B_4H_8$ and 2,4-$C_2B_4H_7^-$; *c*) 4,7-$C_2B_6H_{10}$; *d*) 4,5-$C_2B_7H_{11}$ and 6,7-$Me_2C_2B_7H_9$; *e*) 5,6- and 5,7-$C_2B_8H_{12}$; *f*) 7,8-, 7,9-, 2,7-, 2,8- and 2,9-$C_2B_9H_{13}$; *g*) 9,12-$R_2C_2B_{10}H_{11}^-$ (R = Me or Ph).

$C_2B_8H_{12}$. Two isomers of dicarba-*nido*-decaborane(12) are known—with the carbon atoms in the open face occupying neighbouring positions (5,6-$C_2B_8H_{12}$)[62,122] and separated by one boron atom (5,7-$C_2B_8H_{12}$)[123] (Fig. 17*e*). Thermal rearrangements of $C_2B_8H_{12}$ isomers or their derivatives have not been noted.

$C_2B_9H_{13}$. Five isomers of dicarba-*nido*-undecaborane(13) are known at the present time: 7,8-, 7,9-‡, 2,9-, 2,8-, and 2,7-$C_2B_9H_{13}$ (Fig. 17*f*). These *nido*-carbaboranes are formed on protonation of the corresponding dicarba-*nido*-undecaborates(1-). The first three isomers are obtained on alkaline cleavage of 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$[161-163] and the last two are obtained as a result of chemically initiated thermal rearrangements occurring in the alkylation of 7,8- and 7,9-dicarbollide ions by alkyl halides[12,63,64,69].

Carrett and Hawthorne[164] achieved the thermal isomerisation of 7,8-$C_2B_9H_{12}^-$ to the 7,9-isomer:

$$7,8\text{-}C_2B_9H_{12}^- \xrightarrow{300^\circ} 7,9\text{-}C_2B_9H_{12}^-.$$

The rearrangements of dicarba-*nido*-undecaborates occur much more readily when their electronic structure is altered during the chemical reaction. Thus the rearrangement of the 7,8-isomer to the 2,7-isomer in the alkylation of 7,8-$C_2B_9H_{11}^{2-}$ is so fast that the intermediate Alk-7,8-$C_2B_9H_{11}^-$ cannot be detected even below 0°C:[12,69]

$$7,8\text{-}C_2B_9H_{11}^{2-} \xrightarrow{RX} (\text{R-7,8-}C_2B_9H_{11}^-) \rightarrow \text{11-R-2,7-}C_2B_9H_{11}^- .$$

The structure of 11-R-2,7-$C_2B_9H_{11}^-$ has been demonstrated, together with other methods, by a complete X-ray diffraction investigation of the corresponding protonated derivative 11-Me-2,7-$C_2B_9H_{12}$.[165] The intermediate product μ-Alk-7,9-$C_2B_9H_{11}^-$ of the alkylation of 7,9-$C_2B_9H_{11}^{2-}$ is relatively more stable and has been detected, but not isolated because it rearranges rapidly above 0°C:[64]

$$\begin{array}{l} \text{7-R-2,8-}C_2B_9H_{12} \\ {\scriptstyle +H+}\uparrow\downarrow{\scriptstyle -H+} \\ 7,9\text{-}C_2B_9H_{11}^{2-} \xrightarrow{RX} \mu\text{-R-7,9-}C_2B_9H_{11}^- \rightleftarrows (\text{7-R-2,8-}C_2B_9H_{11}^-) \xrightarrow{-H+} (\text{7-R-2,8-}C_2B_9H_{10}^{2-}) \rightarrow \\ \rightarrow \text{10-R-7,9-}C_2B_9H_{10}^{2-} \xrightarrow{+H+} \text{10-R-7,9-}C_2B_9H_{11}^- . \end{array}$$

In the 2,7- and 2,8-isomers of *B*-alkyldicarba-*nido*-undecaborate(1-) only one carbon atom is located in the open face; the other is in the closed part of the polyhedron, and this is the reason for the low stability of these isomers. The direction and rate of the rearrangements of the 2,7- and 2,8-$C_2B_9H_{13}$ derivatives are determined by the tendency to remove both carbon atoms to the open face and the substituent by the equatorial position when the process is stereospecific[63]. Thus 11-Me-2,7-$C_2B_9H_{12}$ is relatively resistant to rearrangements; the monoanion 11-Me-2,7-$C_2B_9H_{11}^-$ rearranges in solution at room temperature to 8-Me-7,9-$C_2B_9H_{11}^-$, while the dicarbollide ion 11-Me-2,7-$C_2B_9H_{10}^{2-}$ is converted in solution below −30°C (liquid ammonia) into 9-Me-7,8-$C_2B_9H_{10}^{2-}$, yielding 9-Me-7,8-$C_2B_9H_{11}^-$ after protonation (Fig. 18).[12,69] Among the 2,8-isomers, only the compound 7-Alk-2,8-$C_2B_9H_{12}$ is relatively resistant to rearrangements. When a proton is abstracted, the above equilibrium between μ-Alk-7,9- and 7-Alk-2,8-$C_2B_9H_{11}^-$ is displaced towards μ-Alk-7,9-$C_2B_9H_{11}^-$, but the rearrangement as a whole proceeds towards 10-Alk-7,9-$C_2B_9H_{11}^-$. We suggest that the final product is formed as a result of the abstraction of a proton from 7-Alk-2,8-$C_2B_9H_{11}^-$ by a solvent molecule or by a second reactant molecule; as in the isomerisation of 11-Alk-2,7-$C_2B_9H_{11}^-$ to 9-Alk-7,8-$C_2B_9H_{11}^-$ (Fig. 18), the dianion

‡The *nido*-carbaborane 7,9-$C_2B_9H_{13}$ is unstable, because two BHB bonds cannot be formed in the open face, and it has been characterised only in the form of a salt of the corresponding monoanion 7,9-$C_2B_9H_{12}^-$.[161]

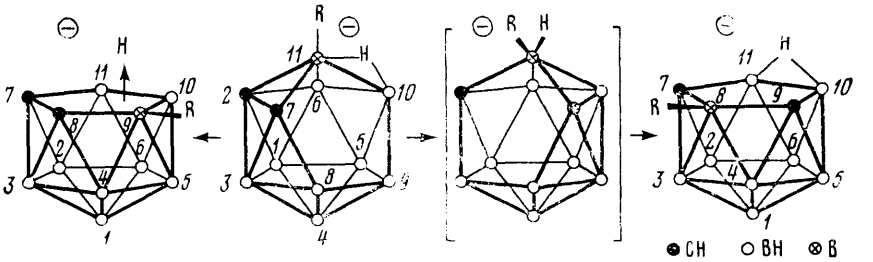

Figure 18. The possible modes of rearrangement of 11-R-2,7-$C_2B_9H_{11}^-$ (R = alkyl).

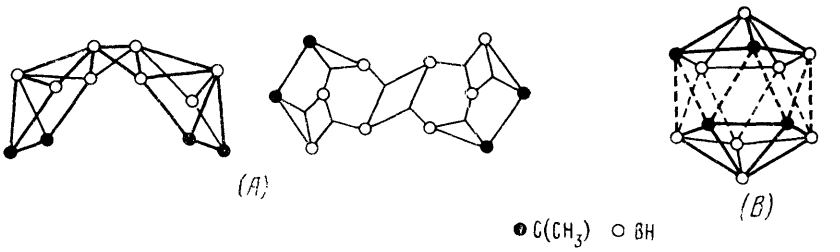

Figure 19. Structures proposed for the isomers of the four-carbon carbaborane $Me_4C_4B_8H_8$.

7-Alk-2,8-$C_2B_9H_{10}^{2-}$ rearranges to 10-Alk-7,9-$C_2B_9H_{10}^{2-}$. On protonation, the latter gives rise to 10-Alk-7,9-$C_2B_9H_{11}^-$.[63]

The rearrangements of 7,8- and 7,9-isomers to 2,7- and 2,8-dicarba-*nido*-undecaborates(1-), discussed above, are facilitated in reactions with electrophiles by the breakdown of the delocalisation of the electrons in the open face of dicarbollide ions and the axial orientation of the substituent on formation of a "π-complexes" and then a "σ-complex".[12] It is possible to distinguish two stages in these reactions: the first involving the addition of the electrophile to the dicarbollide ion (activation of the system) and the second involving a thermal rearrangement of the resulting dicarba-*nido*-undecaborate with an axially oriented alkyl group. Chemical activation is apparently energetically comparable to thermal activation and the rearrangements considered therefore proceed on the whole at lower temperatures.

$C_2B_{10}H_{14}$ derivatives. Owing to their low stability, neutral isomers of the *nido*-carbaborane $C_2B_{10}H_{14}$ have not been obtained. The anions of this carbaborane are relatively stable: the dianions, formed after the addition of two electrons to isomers of *closo*-$C_2B_{10}H_{12}$, and the monoanions obtained on protonation of the dianions. It was noted above that the dianions $C_2B_{10}H_{12}^{2-}$ are apparently not individual species, consisting of sets of dynamic structures based on the open structure of a fragment of a 13-vertex polyhedron. The rearrangements of the dianions are determined, on the one hand, by dynamic processes involving a change in the position of the vertex raised over the plane of the open face, as, for example, in the cobalt complex of the carbaborane ligand $C_2B_{10}H_{12}^{2-}$ (Fig. 20*e*)[166] and, on the other hand, they are determined by the migration of one of the atoms in the open face to the site of the missing vertex of the polyhedron. This type of rearrangement explains the transitions between different sets of dynamic structures, for example, in the isomerisation of the dianions obtained from *o*-, *m*-, and *p*-carbaboranes(12) and their derivatives (Fig. 10). A process with "closure-opening" of the polyhedral system is also possible.

Protonation of the dianions $C_2B_{10}H_{12}^{2-}$ and their derivatives leads to the fixation of the open face and the monoanions can be isolated as individual compounds. On heating to 100°C, one of the isomers isolated is converted quantitatively into the other[76,77]. Depending on the direction of electrophilic attack by the proton, the open structure of the dianion should be retained in its entirety, if the proton occupies a BHB bridge position, or closed to a greater or lesser extent on formation of a B–H or C–H σ bond[2]. The latter process takes place as a result of the transfer of an electron pair from the orbital binding the atoms of the molecular skeleton to an outer σ bond. This type of closure has been demonstrated by an X-ray diffraction study of one of the isomers C,C'-Me_2- and C,C'-Ph_2-$C_2B_{10}H_{11}^-$, which are characterised by the presence of the $C\begin{smallmatrix}R\\H\end{smallmatrix}$ structural unit (Fig. 17*g*).[167,168]

The closure of the structure of the dianion also occurs under the influence of other electrophiles. For example, the alkylation of the aminated dianions derived from 1,2-$C_2B_{10}H_{12}$ proceeds at the boron atom, and, when the latter migrates together with the substituent in the transition state, a hydride ion is evidently ejected (oxidised) from the boron atom with the alkyl group; the molecule undergoes closure to *closo*-2-NH_2-6-Alk-1,7-$C_2B_{10}H_{10}$.[169-172] This mode of reaction is apparently due to the increased hydride mobility of the hydrogen atom linked to the migrating boron atom attached to the substituent.

$Me_4C_4B_8H_8$. The synthesis of the stable four-carbon carbaborane $Me_4C_4B_8H_8$, isoelectronic with the $C_2B_{10}H_{12}^{2-}$ dianions, is of considerable interest in both theory and

practice[173-175]. In solutions $Me_4C_4B_8H_8$ exists in two equilibrium isomeric forms A and B:

$$A \rightleftarrows B,\ K = [B]/[A] = 0.5.$$

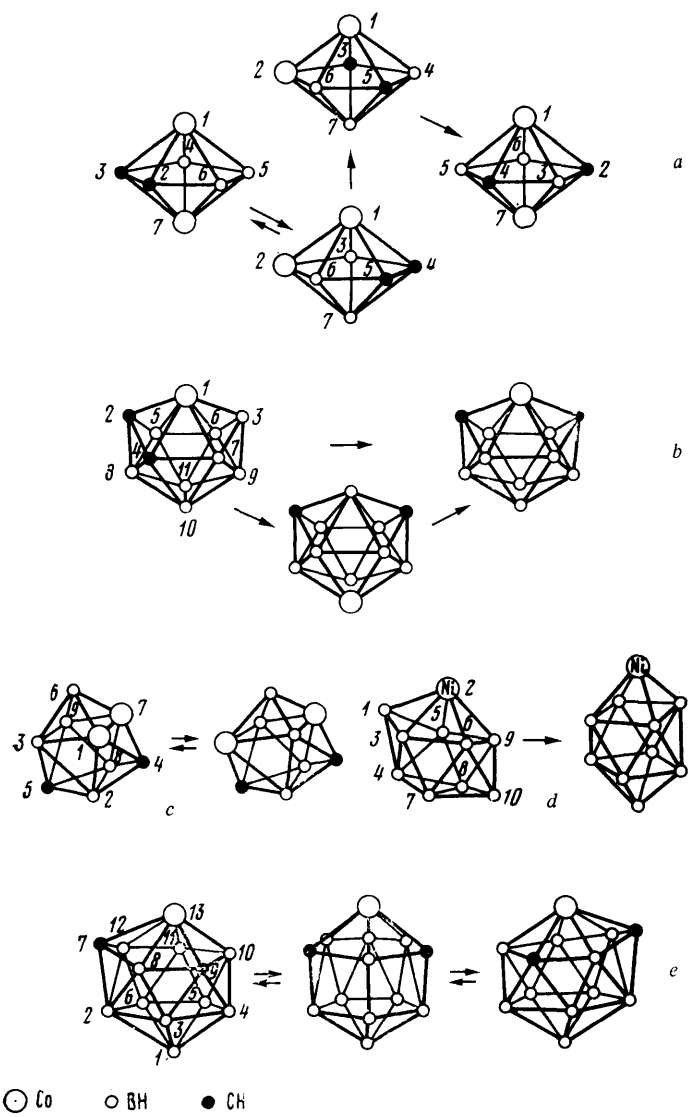

Figure 20. Thermal rearrangements of certain metallocarbaboranes: *a*) $(\eta^5\text{-}C_5H_5)_2Co_2C_2B_3H_5$; *b*) $(\eta^5\text{-}C_5H_5)CoC_2B_8H_{10}$; *c*) $(\eta^5\text{-}C_5H_5)_2Co_2C_2B_5H_7$; *d*) $(\eta^5\text{-}C_5H_5)NiB_9H_9^-$; *e*) $(\eta^5\text{-}C_5H_5)CoC_2B_{10}H_{12}$. The ligands C_5H_5 are not shown in the Figure.

When the solvent is removed, the equilibrium is wholly displaced towards isomer A. The ^{11}B NMR spectrum of isomer A is characterised by four signals of equal intensity distributed over a wide frequency range. The ^1H NMR spectrum has two signals due to the protons of the methyl groups and these are also of equal intensity. The proposed geometrical and valence structure of isomer A is presented in Fig. 19.[174] Compound B is characterised by a more compact ^{11}B NMR spectrum, in which there are two signals with relative intensities of 6 : 2. The ^1H NMR spectrum of this isomer contains, like that of isomer A, two signals, which merge at 40°C into a single narrow signal. On the basis of these data, the authors[173-175] proposed for isomer B the structure of a somewhat distorted icosahedron, having assumed the possibility of the rotation of the pentagonal pyramidal fragments in order to account for the spectroscopic data (Fig. 19). Above we already discussed this mechanism of the rearrangement of icosahedral molecules in terms of the correspondence between the symmetry of "soft" deformations and the symmetry of molecular orbitals and concluded that it is unlikely (Section V, subsection 1). The Wade rule suggests that a *nido*-structure of the fragment of a 13-vertex polyhedron with four carbon atoms in the open face is more likely for the isomers of $Me_4C_4B_8H_8$. Here account must also be taken of the possibility of some deformation of the open face of the molecule, associated, for example, with its narrowing. As a result of such deformation, the excess charge on the carbon atoms might be compensated to a greater extent. The interconversions of the isomers of $Me_4C_4B_8H_8$ can proceed either via a transition state having a structure close to that of the icosahedron, or as a result of consecutive migrations of the atoms in the open face to the sites of the missing vertex of the polyhedron.

3. REARRANGEMENTS OF METALLOCARBABORANES AND METALLOBORANES

The thermal rearrangements of metallocarbaboranes and metalloboranes have many features which are not characteristic of, for example, carbaboranes and are therefore considered separately in this review.

In their studies of the rearrangements of metallocarbaboranes containing between six and ten boron atoms and between one and three cobalt atoms Hawthorne and coworkers[176-178] derived the following empirical rules defining the direction of the rearrangements:

(a) the cobalt atom migrates to the vertex with the maximum coordination number and subsequently remains in this position;

(b) the carbon atoms in the skeleton do not approach one another;

(c) carbon migrates irreversibly to the vertex with the minimum coordination number;

(d) a carbon atom tends to migrate away from a cobalt atom if rules (b) and (c) hold.

Grimes and coworkers[179-181] fully confirmed the validity of these rules for metallocarbaboranes containing between three and five boron atoms, noting at the same time a number of features. Thus, during the rearrangement of $1,7,2,3\text{-}(\eta^5\text{-}C_5H_5)_2Co_2C_2B_3H_5$ there is successive formation of $1,2,4,5\text{-}$ and $1,2,3,5\text{-}(\eta^5\text{-}C_5H_5)_2Co_2C_2B_3H_5$, in which the cobalt atom occupies the position with the smallest coordination number (C.N.) and the rearrangement occurs only at a higher temperature, as a result of which the cobalt atom again occupies the position with the maximum coordination number (Fig. 20*a*).[179] The intermediate formation of the metallocarbaborane isomer in which cobalt has the smallest coordination number was also noted in the isomerisation of $1\text{-}(\eta^5\text{-}C_5H_5)\text{-}1\text{-}Co\text{-}2,4\text{-}Me_2C_2B_8H_8$ (Fig. 20*b*).[180] These examples show that many rearrangements of metallocarbaboranes proceed via a series of stages. The problem of the mechanism of the rearrangements has not been discussed in most studies owing to the insufficiency

of experimental data. A mechanism based on the *dsd* model is possible. For the rearrangement of 1,7,2,3-$(\eta^5\text{-}C_5H_5)_2Co_2C_2B_3H_5$ (Fig. 20*a*), Miller and Grimes [179] give preference to the mechanism involving the rotation of the trigonal faces of the polyhedron, noting correctly that this process, instead of being synchronous, may be a result of several consecutive stages, for example two *dsd* stages or, what is more probable, may occur via an open polyhedral intermediate [179]. A tendency of cobalt atoms to form Co–Co bonds was also noted, but in many instances it is compensated by the effect involving the repulsion of the cyclopentadienyl ligands. This in fact explains attainment of equilibrium between the two isomers of $(\eta^5\text{-}C_5H_5)_2Co_2C_2B_5H_7$ (Fig. 20*c*). [179,181]

An interesting rearrangement has been observed for the nickel–borane complex $(\eta^5\text{-}C_5H_5)NiB_9H_9$. In solution after brief heating to 150°C or irradiation with ultraviolet light the complex, in which the nickel atom occupies the position with the highest coordination number, undergoes quantitative isomerisation to a complex with four-coordinated nickel (Fig. 20*d*). [182] Thus, together with the features noted above, there is apparently a tendency towards the formation of a more symmetrical structure as a result of the rearrangement, in which there is a possibility of a greater delocalisation of electrons.

An interesting example of the configurational instability of a metallocarbaborane molecule is the 13-vertex cobaltcarbaborane 13,7,9-$(\eta^5\text{-}C_5H_5)CoC_2B_{10}H_{12}$; in its solution there are rapid dynamic rearrangements between two enantiomers (Fig. 20*e*), which is manifested by the averaging of the NMR spectra of this compound. With decrease of temperature, the rate of the transitions diminishes and at −90°C the ^{11}B NMR spectrum indicates the absence of symmetry elements. The mechanism of the rearrangement is based on the *dsd* model and involves successive or synchronous formation of two tetragonal faces in the transition state (Fig. 20*e*). [166] The position of the above equilibrium is significantly influenced by substituents. Thus the introduction of a methyl group at one of the carbon atoms shifts the equilibrium towards the isomer in which the unsubstituted carbon atom occupies the position with the smallest coordination number [176].

In general, when the mechanisms of the rearrangements of metallocarbaboranes and metalloboranes are discussed, it is important to take into account the symmetry of the molecule, as for other polyhedral systems.

VI. CONCLUSION

In our discussion of the rearrangements of polyhedral molecules, we endeavoured in the first place to represent the characteristic features of the chemical behaviour of the compounds as the characteristic properties of carbaboranes, boron hydrides, and heteroborates, i.e. we tried to consider them as manifestations of the characteristics of the electronic structures of polyhedral boron compounds. The theoretical models which we employed, such as the model involving electrophilic reactions via two-centre bonds and nucleophilic reactions via three-centre bonds, can be useful only if one clearly realises the limits of their applicability. The latter depend in their turn on the validity in each specific case of concepts such as those of localised two-, three-, and many-centre bonds. Their energetic characteristics are also important. We believe that in a qualitative treatment the models employed are fully justified.

The presence of symmetry elements in the molecules and ions of polyhedral boron compounds and hence the symmetry of the electronic Hamiltonian permit a significant simplification of the selection of the possible directions and mechanisms of many of their reactions and in the first place their thermal rearrangements. In many cases it is sufficient for this purpose to consider the symmetry of the initial molecule and the symmetry of the deformation characterising the given mechanism of the rearrangement. In the more general case it is necessary to know the symmetry of the molecular orbitals, their energies, populations, as well as the types of the normal displacements possible in the given molecule or ion.

In general the use of fundamental concepts, such as the occurrence of the reactions as a result of the interaction of the bonding and antibonding orbitals of the reactants and the decisive role of the energy and symmetry of the boundary orbitals of the reactants and the transition state in determining the direction of the reaction, appear to be most promising in a qualitative discussion of the chemical properties of polyhedral boron compounds.

---o0o---

During the preparation of this review for the press, certain fundamentally important reports devoted to the structures and rearrangements of polyhedral boron compounds were published. Here mention should be made in the first place of the papers by Lipscomb and coworkers [183–185]. Continuing their fundamental studies, the authors carried out quantum-chemical calculations (by the PRDDO method) on the closed borane anions $B_nH_n^{2-}$ and carboboranes $C_{2n}B_nH_{n-2}$ and found that they have localised valence structures, which can be represented by fractional bonds [183]. A topological analysis has been carried out and preliminary calculations have been made for the structures of closed boron hydrides containing between 13 and 24 atoms in the polyhedron and the possible methods of synthesis of such polyhedral compounds have been classified [184]. In order to investigate the rearrangements of polyhedral boron compounds, calculations have been made on the configurational behaviour of the anion $B_{11}H_{11}^{2-}$. [185] Grimes and coworkers [186–189] continued their studies on the four-carbon carbaborane $Me_4C_4B_8H_8$ and transition metal complexes of polyhedral compounds. An X-ray diffraction study has been made of one of the isomers of $Me_4C_4B_8H_8$ [186] and a number of complexes based on it, and their structural rearrangements have been investigated [187,188]. X-Ray diffraction analysis also made it possible to demonstrate that one of the boron atoms in the complex $(\eta^5\text{-}C_5H_5)_3Co_3B_4H_4$, formally containing $2n$ electrons binding the atoms of the molecular skeleton, is located above the plane [189]. Mikhailov and coworkers achieved the rearrangement of icosahedral carbaboranes under the influence of γ-radiation [90]. Photoinitiated rearrangements of nickel dicarbollide complexes have also been observed [191].

Phosphorus Rings, Clusters, Chains, and Layers

V.I.Kosyakov and I.G.Vasil'eva

Phosphorus compounds with P-P bonds (polyphosphides, phosphanes, and organophosphorus compounds) are considered as compounds formed by ions or radicals with a skeleton† consisting of phosphorus atoms linked covalently to one another; the structure of such skeletons depends little on the nature of the ions or radicals attached to them. The simplest structurai elements of such skeletons have been isolated and the rules governing their combination into clusters, chains, layers, and cross-linked structures have been established. A classification is proposed and formulae are presented for homologous matrices of phosphorus skeletons and the wide variety of their structures is demonstrated. Certain aspects of the stereochemistry of polyphosphorus compounds are discussed. Its general features and the way it differs from the stereochemistry of organic compounds have been established. The considerable scope of the chemistry of polyphosphorus compounds is noted. The bibliography includes 47 references.

I. INTRODUCTION

More than twenty years ago J.R.Van Wazer wrote in a foreward to his notable monograph of phosphorus chemistry "...there is a real need for a separate discipline just as there was a need for separating the chemistry of carbon compounds from the rest of chemistry. Instead of being merely a ragbag collection, the compounds of carbon are readily arranged into homologous series, and a small number of ground rules have proved sufficient to describe the relationships and interactions between these homologous series and between members of a given series. This state of affairs also seems to apply to the compounds of phosphorus... Furthermore, a system of ground rules, in some cases quite different from those of organic chemistry, appears to be emerging." (Van Wazer[1], p. 7).

The aim of the present review is to attempt to confirm the above words by analysing the characteristic features of the structure of skeletons consisting of two or more covalently linked phosphorus atoms in compounds of different classes: polyphosphides, phosphanes, and organophosphorus compounds. Analysis of structural data shows that the structure of the phosphorus skeletons in compounds of this kind depends little on the nature of the atoms or radicals joined to the skeleton.

Almost all the information about polyphosphorus compounds has been obtained in the last 15 years and nowadays this field of phosphorus chemistry is developing vigorously: it is therefore useful to examine critically and to arrange schematically the available literature data.

It is of interest to note that, despite the hypothesis of Krebs et al.[2] that many polyphosphides ($ZnPbP_{14}$, $HgPbP_{14}$) have a chain structure, and the available information concerning the complex allotropy of elemental phosphorus and about the existence of solid phosphorus hydrides and lower phosphorus oxides whose structure cannot be represented without assuming that phosphorus atoms are linked to one another, Van Wazer questioned the possibility of the existence of compounds involving a large number of covalently linked phosphorus atoms (Van Wazer[1], pp. 17, 123) and his view was shared by other workers[3,4].

More than 200 polyphosphorus compounds with skeletons comprising a finite (between 2 and 12) or an infinite number of phosphorus atoms are now known. On the other hand, the structures of only half of these compounds have been established, owing to the considerable difficulties of isolating and identifying the individual phases because of the slow attainment of equilibrium in the synthetic reactions, the simultaneous formation of a large number of different polyphosphorus compounds having similar physicochemical properties, and the tendency of the compounds to form amorphous or vitreous phases. However, even these experimental data are sufficient to demonstrate the exceptionally wide variety of the structures of phosphorus skeletons.

In this situation it is timely and useful to develop a classification and to determine the fundamental structural characteristics of the phosphorus skeletons. The first attempt at a classification of the compounds in terms of the structure of the phosphorus skeletons rather than the type of crystal lattice is due to Schnering[5], who achieved successful determinations of structures. However, his classification embraces only some of the polyphosphorus compounds (polyphosphides) and follows the relation between their structure and the structural elements of the lattices of white, red, and black phosphorus. We proposed a wider classification[6,7]; the present review is devoted to a detailed description of this classification and

† The absence of a generally accepted nomenclature in the description of compounds with element–element bonds (organic, cluster, and polymeric compounds of boron, sulphur, phosphorus, etc.) makes it difficult to choose names for groups comprising the atoms of an element joined together by chemical bonds and incorporated in a given compound as a polycation, a polyanion, or a neutral group. We decided to adopt the term "skeleton" for such groups, assuming that it will be understood unambiguously by specialists working in various fields of chemistry.

an examination of the fundamental characteristics of the structure of skeletons in the polyphosphorus compounds of different classes. The classification is based on: (a) quantum-chemical ideas about the configuration of valence orbitals and the length of bonds formed by atomic phosphorus as the structural element of the phosphorus skeletons (Van Wazer, p. 3); (b) the analysis of ~100 structures of different polyphosphorus compounds, invoking data for the structures of phosphorus compounds with bivalent electronegative elements incorporating $\rangle P-E-P\langle$ groups (where E = O, S, Se, or Te) having the same structures as some of the phosphorus skeletons; (c) certain stereochemical ideas in organic chemistry[8]. We shall now formulate the fundamental characteristics defining the structure of phosphorus skeletons.

1. The P–P bond is formed predominantly by p electrons, so that the phosphorus atoms involved in the formation of such bonds are formally tervalent‡. The σ-linked phosphorus atoms are separated by a distance of 2.17–2.30 Å, approximately equal to twice the covalent radius of phosphorus. A decrease of this distance indicates a certain amount of multiple bond character. However, such shortening of the bond is not characteristic of phosphorus and in the present review skeletons with bonds of this kind are not considered at all§. The valance angles of tervalent phosphorus are usually intermediate between 90° and 109°29′, corresponding to the p^3 and sp^3 states; in the P_3 group the valence angle is 60° ("bent" bonds).

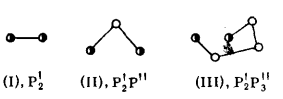
2. The skeleton of a polyphosphorus compound can incorporate phosphorus atoms linked by a single bond with one, two, or three adjoining phosphorus atoms. We shall henceforth refer to such atoms as singly-linked ($\rangle P-P\langle$), doubly-linked ($\rangle P-\underset{|}{P}-P\langle$), and triply-linked ($\rangle P-\underset{|}{\underset{P}{P}}-P\langle$).[5] If the numbers of these atoms are designated by l, m, and n respectively, then a skeleton consisting of x phosphorus atoms and having y free bonds is described by the formula $P_x^y = (P'_l P''_m P'''_n)^{(2l+m)}$.

3. The fundamental structural elements of the phosphorus skeletons are simple chains of finite or infinite length and rings incorporating 3–6 or more atoms. If the frequency of such structural elements in various phosphorus compounds is adopted as a measure of their stability, then the rings should be more stable than the chains with the same number of atoms and among rings those which are five- and six-membered should be the most stable[1,9,10,12,13].

4. Simple chains and rings can play the role of independent phosphorus skeletons in polyphosphorus compounds or can be condensed into more complex skeletons having finite or infinite dimensions.

5. Phosphorus skeletons with infinite dimensions can be constructed by the regular or irregular condensation of structural elements. In the first case the skeletons present in crystalline phosphorus compounds or in crystalline allotropic modifications of elemental phosphorus are formed. In the second case the products are the skeletons of vitreous or amorphous phosphorus-containing phases.

A structural classification of the phosphorus skeletons in various polyphosphorus compounds is presented in the Table. The structures of the phosphorus skeletons presented in the text are illustrated by graph schemes. To facilitate the comparison of various layer or cyclic structures, the distances between neighbouring phosphorus atoms in certain schemes, which are not linked to one another, are represented by the same lengths as those between covalently linked phosphorus atoms. The filled, open, and half-filled circles in the schemes illustrate respectively triply-, doubly-, singly-linked phosphorus atoms. In analysing the structures of phosphorus skeletons having infinite dimensions, we shall confine ourselves to regular structures. The structures are described in terms of arbitrarily selected basic groups, whose repetition by translation or 180° rotation makes it possible to construct the entire structure; the basic groups in the graph scheme are enclosed by dashed lines.



The characteristics of the structures of the phosphorus skeletons of each type are discussed below.

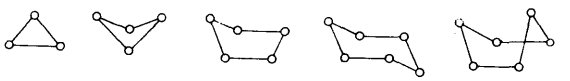
II. "ISLAND" STRUCTURES

We shall assign to "island" structures phosphorus skeletons having finite dimensions: simple chains, rings, clusters, and skeletons formed by the condensation of these simplest elements.

Simple Chains

The successive linking of phosphorus atoms can lead to the formation of unbranched ($P'_2P''_m$) or branched ($P'_{n+2}P''_m.P'''_n$) chains. Simple chains are described by the homologous formula $P_x^{(x+2)}$. It is satisfied by certain phosphanes[14,15] and organic derivatives of di-, tri-, and tetraphosphanes (Mellor[9], p. 912, Baudler et al.[12], and Baudler and Koch[13]). Skeletons comprising two phosphorus atoms [structure (I)] are present in certain phosphorus sulphides (Van Wazer[1], p. 294), in tetraphosphorus trithiodi-iodide[16], in a series of mono- and di-phosphides (Corbridge[10], pp. 17, 18, 62), and certain phosphorus acids (Mellor[9], p. 597). P_3^5 and P_5^7 chains have been found in lanthanum diphosphide[19] [(II) and (III)]:

Rings



Rings consisting only of doubly-linked phosphorus atoms are described by the formula $P_m^n = P_x^x$ [structures (IV) to (VIII)]. According to the phosphorus stereochemistry, when $m > 3$ the rings are bent. The analogy between

---

‡ Skeletons comprising linked quinquevalent phosphorus are less characteristic. They are involved in the structures of the molecules of certain phosphorus acids, for example $H_4P_2O_6$, $H_5P_3O_8$, $H_6P_4O_{10}$, and $H_6P_6O_{12}$, and their salts (Mellor[9], p. 598), as well as the compound $(PO)_4(PPh)_6$ (Corbridge[10], p. 422).

§ The structures of the polyphosphides K_4P_6 and Pb_4P_6 contain planar six-membered P_6^{4-} rings in which the distance between the phosphorus atoms is 2.15 Å, indicating the presence of a non-localised π bond between phosphorus atoms[11].

phosphorus and non-aromatic carbon rings suggests that a six-membered phosphorus ring can exist in the "chair" and "boat" forms [structures (VII) and (VIII)], the former being energetically preferable (Corbridge[10], p. 383):

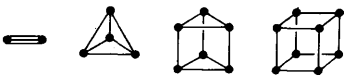
Cross-linked layers	$P'''_{n+2r+3s}$		—	—	—	—	—

Notation: l, m, and n represent the amounts of singly-, doubly-, and triply-linked phosphorus atoms in the skeleton respectively; t is the number of clusters and (or) rings joined together in the basic group; p and q are the numbers of P–P bonds and common edges necessary to construct the basic group; k is the number of atoms in the common sides in condensed clusters or rings; r and s are the numbers of $\rangle P-P-P\langle$ and $\rangle P-P\langle$ bridge bonds in the cross-linked skeletons; i are the indices of rings and clusters; j are indices of common sides or edges; $\alpha = \sum_{i=1}^{t} m_i - \sum_{j=1}^{q} k_j - 2(p+q)$;

$\beta = \sum_{i=1}^{t} n_i + 2(p+q)$; $\gamma = \frac{1}{2}\sum_{i=1}^{t} m_i - 3t$.

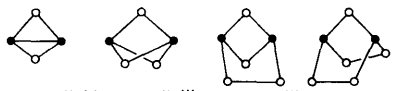
Five- and six-membered rings are the fundamental structural elements of the most stable clusters. We may note that cyclic chains and layers formed by the condensation of six-membered rings or derivatives of these rings comprising an even number of phosphorus atoms have been found in many polyphosphides [structures (IX)–(XIII)]. Rings with m = 4–6 are formed in organophosphorus compounds (Mellor[9], p. 913, and Corbridge[10], p. 383) and apparently in phosphanes having the composition P_XH_X (x = 3–6)¶ [15]:



(IX), P_{10}^{II} (X), P_{12}^{II} (XI), P_{14}^{II} (XII), P_{16}^{II} (XIII), P_{22}^{II}

Clusters

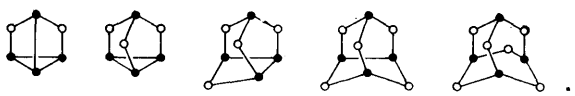
The cluster structures consist of convex polyhedra the vertices of which contain triply-linked atoms and the faces are formed by rings comprising three–six phosphorus atoms. The number of faces in the cluster is determined by the number of triply-linked phosphorus atoms n and is equal to $\frac{1}{2}n + 2$. Consequently cluster structures may be made up of P_n''' skeletons, where n is even, consisting of



¶ The hypothesis[20] that the phosphanes P_XH_X have a chain structure is less probable. On this hypothesis, the phosphane P_3H_3 should have the structure $H_2P-P=PH$ and chains with a larger number of phosphorus atoms should be described by the formula $P'_2P''_mP'''_2$.

an even number of triply-linked phosphorus atoms [structures (XIV)–(XVII)], the bonds between P''' atoms being ruptured and doubly-linked phosphorus being added at the site of rupture. Each of the initial skeletons is the parent of an individual homologous series.

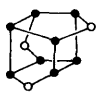
(XIV), P_2''' (XV), P_4''' (XVI), P_6''' (XVII), P_8'''



The homologous series originating from the P_2''' skeleton (XIV) is described by the formula $P_m''P_2''' = P_X^{X-2}$ [(XVIII) to (XXI)]. The phosphanes P_XH_{X-2} ($x = 4-8$, 10) satisfy this formula[14].

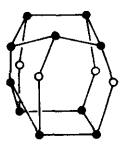
(XVIII), $P_2''P_2'''$ (XIX), $P_3''P_2'''$ (XX), $P_4''P_2'''$ (XXI), $P_5''P_2'''$

In polyphosphides and organophosphorus compounds clusters of this series have not been found in a free form, but the $P_5''P_2'''$ cluster ("boat" configuration whose raised ends are linked by the seventh phosphorus atom) (XXI) is the fundamental structural element in the lattice of crystalline red phosphorus[21] and many polyphosphides[5,22,23].



Clusters based on the tetrahedral molecule P_4''' (XV) are described by the formula $P_m''P_X''' = P_X^{X-4}$ [structures (XXII)–(XXIV)]:

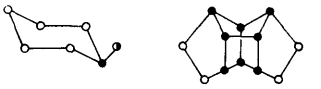
(XXII), $P_2''P_4'''$ (XXIII), $P_3''P_4'''$ (XXIV), $P_4''P_4'''$ (XXV), $P_5''P_4'''$ (XXVI), $P_6''P_4'''$



This formula is satisfied by the phosphanes P_6H_2, P_8H_4, P_9H_5, and P_7H_3. The P_7^{3-} cluster (XXIII) has been found in the polyphosphides Ba_3P_{14} and Sr_3P_{14}. We may note that these clusters have the same structures as phosphorus sulphides and oxides.

The homologous series of the P_X^{X-6} and P_X^{X-8} clusters may be constructed similarly on the basis of the trigonal prism P_6''' (XVI) and cube P_8''' (XVII). The formulae of these series are satisfied by the phosphanes P_9H_3, $P_{10}H_4$, $P_{10}H_2$, $P_{11}H_3$, and $P_{12}H_4$.[14] A representative of the homologous series based on the cube is present in the lattice of the polyphosphide Na_3P_{11} (XXVII)[24] and probably in the compound $[(CH_3)Si]_5P_{13}$.[25]

(XXVII), $P_3''P_6'''$



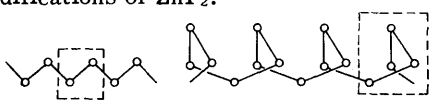
One can imagine clusters consisting of more than eight triply-linked phosphorus atoms which give rise to the homologous series P_X^{X-10}, P_X^{X-12}, etc. For example, the P_{14}^4 cluster in the compound $[(CH_3)Si]_4P_{14}$[25] may be obtained from the P_{10}''' cluster, which consists of a pentagonal prism. The cluster constructed in this way should be represented by formula (XXVIII):

(XXVIII), $P_4''P_{10}'''$

Condensed Structures

Rings containing more than seven phosphorus atoms have not been detected in the structures investigated. The P_8H_8 and P_9H_9 phosphanes have been reported[14,15]. They can be made up of eight- or nine-membered rings, but the formula P_X^X is also satisfied by phosphorus structures (XXIX) having the composition $P_n'P_m''P_n''$ and formed by the addition of singly-linked phosphorus atoms to rings:

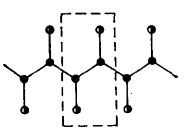
(XXIX), $P'P_5''P'''$ (XXX), $P_4''P_6'''$



An example of the condensed "island" structure is also the P_{12}^4 cluster (XXX) obtained from two clusters (XXI) when the latter are joined via their common edge and a P–P bond. This cluster is the structural element of the phosphorus skeletons in the crystal lattice of red phosphorus[21] and many polyphosphides[5,22,23].

III. CHAIN STRUCTURES

Chain structures are formed when single phosphorus atoms (simple chains), rings (ring chains), and clusters (cluster chains) are joined together to form infinitely long chains. Ordered chains have been found in the crystal lattices of many polyphosphides[5] and in the structure of crystalline red phosphorus[21].

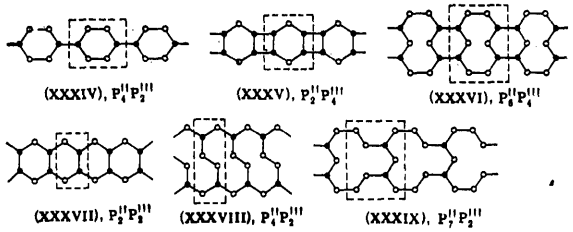


Simple Chains

The consecutive combination of phosphorus atoms can lead to the formation of zigzag or helicoidal chains described by the formula P_X^X (Schnering[5] and Corbridge[10], p.40). Zigzag chains (XXXI) are present in the crystal lattices of titanium, hafnium, zirconium, and palladium diphosphides (Corbridge[10], p.40), helicoidal chains (XXXII) have been found in the LiP,[26] NaP,[26] and α-CdP_2[27] lattices and in the lattices of the tetragonal and monoclinic modifications of ZnP_2.[28,29]

(XXXI), P_2'' (XXXII), P_4''

One may postulate the formation of branched phosphorus chains having the general formula $P_n'P_m''P_n''' = P_1^1$, for example, with $m = 0$ and $n = 1$ as in structure (XXXIII):



(XXXIII), $P_2'P_2'''$

Multiring Chains

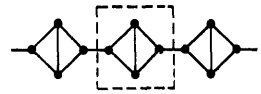
When identical or different rings are joined together in an ordered or non-ordered manner, multiring chains may be formed. Such chains are either independent structural elements or form part of more complex phosphorus structures.

On forming chains, the rings can be joined by one [as in (XXXIV)] or two [as in (XXXV) and (XXXVI)] bonds or by a common side [as in (XXXVII)–(XXXIX)]:

(XXXIV), $P_4''P_2'''$ (XXXV), $P_2''P_4'''$ (XXXVI), $P_6''P_4'''$

(XXXVII), $P_2''P_3'''$ (XXXVIII), $P_4''P_2'''$ (XXXIX), $P_7''P_2'''$

On formation of each bond between the rings, two doubly-linked phosphorus atoms become triply-linked. In order to form a common side, it is necessary to remove k atoms from two rings; the common side then consists of two triply-linked and $k-2$ doubly-linked phosphorus atoms. In the general case the basic group of such an infinite ordered chain, made up of t rings, is described by the formula $P_x^{x-2(p+q)}$, where $x = \sum_{i=1}^{t} m_i - \sum_{j=1}^{q} k_j$, m_i is the number of phosphorus atoms in each initial ring, p the number of new P–P bonds formed when the rings are linked to one another, and q the number of common sides, each of which contain k_j phosphorus atoms.

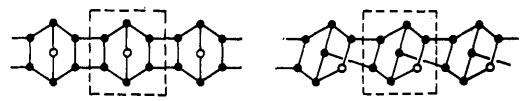


The most typical should be the simplest cases where the chain is made up of identical rings, linked to one another in the same manner. In this case $i = 1$ and, for singly-linked rings ($p = 1$, $q = 0$), we obtain the homologous formula P_x^{x-2} ($x = m$); for doubly-linked rings ($p = 2$, $q = 0$), we have the formula P_x^{x-4} ($x = m$); for rings linked by a common side ($p = 0$, $q = 1$), we have the formula P_x^{x-2} ($x = m - k$). Infinite chains made up of singly-linked six-membered rings in the chair form (XXXIV) are the structural elements of the BaP_3 crystal lattice [30]. The multiring chains (XXXVII) are components of the phosphorus structure in lithium polyphosphide LiP_5. [31]

Cluster Chains

Like rings, clusters can be joined together to form chains via one or two P–P bonds or by the formation of common edges. The linking of clusters by three P–P bonds or by the formation of a common face is unlikely in view of steric hindrance. There is also a possibility that clusters are linked together with formation of both a P–P bond and a common edge [as in (XXX)]. The basic group in an infinite ordered cluster chain consisting of t clusters $P_{m_i}''P_{n_i}'''$, joined by p P–P bonds, and forming q common sides is described by the formula P_x^y, where

$$x = \sum_i (m_i + n_i) - \sum_{j=1}^{q} k_j, \quad y = \sum_i m_i - 2(p+q) - \sum_{j=1}^{q} k_j.$$



In order that the clusters can be connected to form chains, they must contain at least two doubly-linked phosphorus atoms [see (XVIII)–(XXVIII)]. The basic group of a chain consisting of identical clusters $P_m''P_n'''$, linked to one another by a single P–P bond, is described by the formula $P_{m+n}^{m-2} = P_x^{x-n-2}$. Such a chain (XL), obtained by joining together singly-linked clusters (XVIII), can be seen in the structure of amorphous red phosphorus proposed by Pauling and Simonetta [32].

(XL), P_4'''

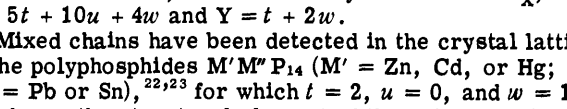
Clusters joined together by two bonds should have at least four doubly-linked phosphorus atoms. The clusters (XX), (XXI), (XXII), and (XXX) may be of this kind. The formula of the basic group of the chain consisting of identical clusters is $P_{m+n}^{m-4} = P_x^{x-n-4}$.

Structures (XLI) and (XLII) consist of chains comprising the $P_5''P_2'''$ cluster (XXI):

(XLI), $P''P_6'''$ (XLII), $P''P_6'''$

Such chains occur in the crystal lattices of the polyphosphides RbP_7 (XLI) and LiP_7, NaP_7 (XLII). [5,31]

Clusters joined together with formation of common sides must have at least two edges containing not less than two P″ atoms. This condition is satisfied only by clusters (XXI) and (XXX). Evidently these clusters are in fact the most convenient structural elements of the cluster chains. The structures of crystalline red phosphorus (XLIII) [21] and a number of polyphosphides, for example KP_{15}^{33} (XLIV), are constructed on their basis:



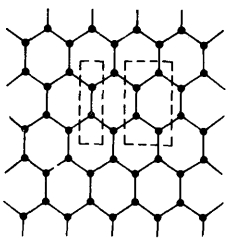
(XLIII), $P_2''P_{10}'''$ (XLIV), $P''P_{14}'''$

If the chain is formed from t clusters of type (XXI) by joining together the latter with formation of p new P–P bonds and q common sides, the formula of the basic group becomes $P_{7t-2q}^{5t-2p-4q} = P_x^{x-2(p+t+q)}$ (for example, in the KP_{15} structure we have $t = 3$, $p = 1$, and $q = 3$).

Mixed Chains

Infinite chains can also be formed by joining together clusters and rings. The formation of mixed chains from P_6^6 [(VII) and (VIII)] and the clusters P_7^5 (XXI) and P_{12}^4 (XXX), joined by their common sides, is most probable. The basic group, consisting of w rings P_6^6, t clusters P_7^5, and U clusters P_{12}^4, is described by the formula P_X^Y, where $x = 5t + 10u + 4w$ and $Y = t + 2w$.

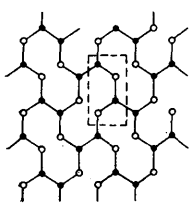
Mixed chains have been detected in the crystal lattices of the polyphosphides $M'M''P_{14}$ (M′ = Zn, Cd, or Hg; M″ = Pb or Sn), [22,23] for which $t = 2$, $u = 0$, and $w = 1$ and which are the structural element of the polyphosphide [34] TlP_5 ($t = 1$, $u = 0$, $w = 1$) [see (XLV) and (XLVI)]:



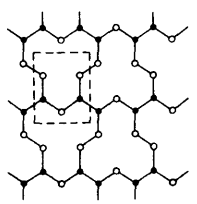
(XLV), $P_4''P_{10}'''$ (XLVI), $P_3''P_6'''$

IV. LAYER STRUCTURES

Regular layer structures can be made up by joining together ring chains via P–P bonds or by the formation of common sides. In the crystal lattice of black phosphorus and many polyphosphides layer structures based on the rings (VII) and (IX)–(XIII) have been detected[5,35]. The formation of layer structures from cluster chains is unlikely for steric reasons.

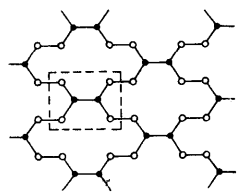


Suppose that a layer is made up of identical chains whose basic group is described by the formula $P''_mP'''_n$. If on formation of the layer two basic groups are joined by p bonds P–P and give rise to k common atoms of which j atoms are triply-linked, the formula of the basic group is P_x^y, where $x = m + n - k$ and $y = m - 2p - j$.



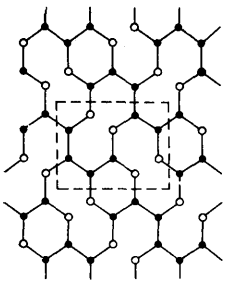
(XLVII), $P_2'''P_4'''$

For example, the structure of the layer in black phosphorus (XLVII) can be represented as a result of the linking of the chains (XXXVII) by P–P bonds (in this case $m = 2$, $n = 2$, $p = 1$, and $k = j = 0$) or by the formation of common sides ($m = 2$, $n = 2$, $p = 0$, $k = j = 2$). The same structure can be made up of the chains (XXXIV) by linking them via P–P bonds ($m = 4$, $n = 2$, $p = 2$, $k = j = 0$) or via common sides ($m = 4$, $n = 2$, $k = j = 4$).

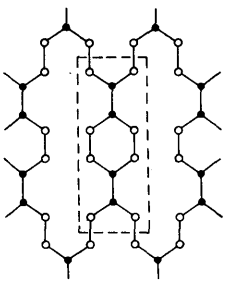


It is simpler to describe layer structures as a result of the joining together of rings of one or more types. It is readily seen that, when the layer is made up of identical rings P''_m, its basic group consists of $\frac{1}{2}(m - 2)$ phosphorus atoms, of which two are triply linked, i.e. the formula of the basic group is P_x^{x-2}, where $x = \frac{1}{2}(m - 2)$. Such layers can be made up only of rings with an even number of phosphorus atoms [the structures of black phosphorus (XLVII) and the polyphosphides CuP_2, AgP_2, CdP_4,[36] MgP_4 [37,38] (XLVIII), LnP_5 [39,40] (XLIX), and CaP_3 (L) [41]].

(XLVIII), $P_2''P_2'''$



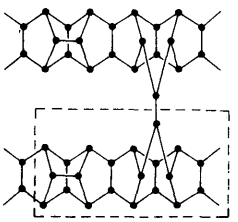
(XLIX), $P_3''P_2'''$



(L), $P_4''P_2'''$

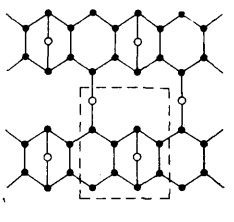
If the layer consists of t rings of type P''_{m_i}, the basic group contains $x = \frac{1}{2}\sum_{i=1}^{t}(m_i - 2) = \frac{1}{2}\sum_{i=1}^{t} m_i - t$ phosphorus atoms, of which $2t$ are triply-linked. The formula of the basic group is P_x^{x-2t}. Examples of layers formed by the condensation of several rings are (LI) ($m_1 = 10$, $m_2 = 10$, $m_3 = 6$) and (LII) ($m_1 = 22$, $m_2 = 6$); the latter structure arises in the crystal lattice of the polyphosphide SrP_3.[40]

(LI), $P_4''P_6'''$



(LII), $P_8''P_4'''$

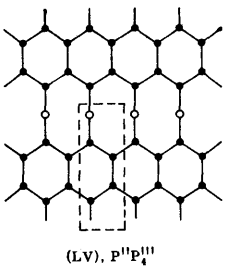
V. CROSS-LINKED STRUCTURES



Elementary phosphorus skeletons can be joined together into more complex entities not only by simple connection but also by cross-linking via bridging doubly- or triply-linked phosphorus atoms. Cross-linked phosphorus structures have been found in the crystal lattices of red phosphorus [21] and certain polyphosphides [5,31,34].

The following variants of cross-linked structures may be postulated: chains, layers, and skeletal structures obtained by the cross-linking of rings or clusters; layers and skeletal structures formed from cross-linked chains; skeletal structures made up of cross-linked layers. However, only layer and skeletal structures obtained by the cross-linking of chains have been found in the crystals investigated hitherto.

The cross-linked chains (XLVI) form phosphorus layers in the crystal lattice of TlP_5 [34] (LIII). In the structure of crystalline red phosphorus the chains (XLIII) are linked by bridges comprising a pair of P''' atoms [see (LIV)] with formation of a double layer:



(LIII), P_{21}'''

(LIV), P_2'', P_8'''

The cross-linking of the chains leads to the formation of skeletal structures made up of phosphorus atoms in the crystal lattices of LiP_5 [31] and LaP_7.[42] The projection of the former onto the plane in which the parallel chains are located is of the form

(LV), $P''P_4'''$

The formation of a skeleton in these structures is due to the fact that the bridging phosphorus atoms link together chains located in different planes.

In cross-linking by bridging doubly linked phosphorus atoms $\rangle P-P-P\langle$ two doubly linked phosphorus atoms become triply-linked for each cross-linked bond and a further doubly-linked atom is added. Therefore, if the basic group which was described by the formula $P''_mP'''_n$. before cross-linking is joined to another similar group by r bridge bonds, the formula of the basic group in the cross-linked structure is $P''_{m-r}P'''_{n+2r} = P^y_x$, where $x = m + n + r$ and $y = m - r$. For example, when chains (XXXVII) of the type $P''_2P'''_2$ are cross-linked by bridge bonds (one bond per basic group), we have $m = 2$, $n = 2$, and $r = 1$, i.e. the formula of the basic group in the cross-linked structure is $P''P'''_4 = P^1_5$ (LV).

In cross-linking by triply linked atoms $\rangle P-P\langle$ each bridging atom is connected to two doubly-linked atoms, converting them into triply-linked atoms. The formula of the basic group after cross-linking is therefore $P''_{m-2s}P'''_{n+3s}$, where s is the number of bridge bonds. For example, cross-linking of the chains P^1_{20} (XLIII) yields the cross-linked structure (LIV) with the basic group P'''_{21}.

VI. CONCLUSION

Using the procedures described above, it is possible to construct a very large number of phosphorus skeletons, including some which have not been considered in this review. It therefore becomes possible to predict the structures of skeletons in polyphosphorus compounds of known composition. As an example, the Appendix presents the development of various procedures for the construction of phosphorus skeletons having the composition P^1_2, the most accurate of which (from our point of view) are then selected. Such phosphorus skeletons should be present in the phosphorus hydride $(P_2H)_x$ and in the polyphosphides having the general formula MP_{2n} (n is the valence of the metal).

Since the same formula corresponds to a whole series of structures, additional information about the properties of the compound is required for an unambiguous selection [6]. Consider an example. The preparation of the solid phosphorus hydride $(PH)_x$ has been reported [9]. Since this compound is resistant to acids and alkalis and decomposes *in vacuo* only at 400°C, it is logical to suppose that it has a polymeric structure. The formula P^1_1 is satisfied only by simple chains and rings, so that one can claim that the phosphorus hydride $(PH)_x$ contains either infinite branched or unbranched phosphorus chains or structures made up of condensed rings formed by a large number of phosphorus atoms, as happens in catenanes [43]; the first hypothesis appears to be more likely.

A greater abundance of comparatively simple skeletons consisting of a small number of structural elements is to be expected for binary compounds of phosphorus with electropositive elements or radicals. The skeletons in polyphosphorus compounds with several different elements or radicals, particularly when these are characterised by different valences, should have a more complex structure.

The ability of phosphorus to form different structures corresponding to the same formula of the basic group reflects the unusual isomerism of phosphorus skeletons. On the basis of this property, one may postulate the possibility of the polymorphism of many polyphosphorus compounds, which may be caused only by changes in the packing of atoms in the unit cell without an alteration of the structure of the phosphorus skeleton (tetragonal [28] and monoclinic [29] modifications of ZnP_2) or may be a consequence of a change in the skeleton [elemental phosphorus and cubic (Corbridge [10], p. 429) and monoclinic [44] modifications of NiP_2].

In the present review we confined ourselves to an examination of regular chain, layer, and three-dimensional structures which are usually present in the crystalline phases. If a statistical distribution of the initial elements in infinite phosphorus structure is postulated, one may investigate different variants of the structures of amorphous and vitreous phases, which are common in the chemistry of phosphorus.

The principles of the construction of phosphorus skeletons described are applicable, as shown above, also to the construction of neutral phosphorus structures consisting solely of triply-linked phosphorus atoms. This makes it possible to build up the probable configurations of polymorphic modifications of elemental phosphorus which have not yet been investigated and which have been mentioned in a number of publications [9,10].

On the basis of the wide variety of structures of phosphorus skeletons, one may postulate the existence of a very large number of different polyphosphorus compounds, since experience gained in the development of chemistry indicates a high reliability of the predictions of the structures of compounds on the basis of the classical theory of valence [45]. In terms of this ability to form polyatomic compounds, phosphorus is inferior only to carbon and possibly to boron [46]. In fact, if the element–element bond energy and the number of covalent bonds are adopted as criteria of the ability to form polyatomic compounds, then, among elements forming more than two bonds, carbon, boron, and phosphorus give rise to the most stable bonds. The smaller number of polyphosphorus compounds compared with carbon compounds is caused both by the tervalence of phosphorus (in contrast to the quadrivalence of carbon) and the smaller energy of the P–P covalent bond (53 kcal mole^{-1}) compared with the energy of the aliphatic C–C bond (83 kcal mole^{-1}). [47] The lower electronegativity of phosphorus and the presence of a lone electron pair and of vacant 3d orbitals in a three-coordinated phosphorus atom lead to a greater reactivity of phosphorus compounds compared with the analogous carbon compounds, which creates definite experimental difficulties.

Homologous series are common in organic chemistry, while in the chemistry of polyphosphorus compounds homologous matrices, consisting of families of homologous series, are abundant. It may turn out that some of the homologous series are represented by a small number of members or even only one member, but one can also encounter skeletons with a similar structure belonging to different homologous series but described by the common formula of the homologous matrix.

The extremely wide variety of structures of polymeric phosphorus molecules noted above, compared with carbon, is associated with the different structures of the two elements.

Rigid tetrahedral sp^3 bonds with a high deformation energy and valence angles differing little from tetrahedral values are characteristic of saturated carbon compounds.

On the other hand, the pyramidal p^5 phosphorus bonds are readily deformed†, which leads to the wide variety of the existing phosphorus skeletons. The tervalence of the phosphorus atom is responsible for the relatively greater abundance of clusters and cluster structures than in the case of carbon. Thus the role of the cluster (XXI) in building up the phosphorus chains has already been noted. The stability of such a cluster is due to the fact that the valence angle in the P–P–P linkage is ~100°. For carbon, which has a greater valence angle, the formation of this type of cluster involves the appearance of strained bonds and carbon compounds involving such a cluster are not typical, although they do exist[8].

The above analysis of the structure of phosphorus skeletons in various polyphosphorus compounds demonstrated, as might have been expected, the existence of homologous series and homologous matrices for the description of which it is sufficient to have a small number of fundamental rules, which in certain cases differ from the rules of organic chemistry. This emphasises yet again the characteristic features of the chemistry of phosphorus and the desirability of separating it as an individual chemical discipline with its own rules governing the description of compounds and the reactions involving them and an individual approach to problems of the specific synthesis of such compounds‡.

VII. APPENDIX (DETERMINATION OF THE STRUCTURES OF P_2^1 PHOSPHORUS SKELETONS)

The P_2^1 phosphorus skeleton is described by the formula $P_l'P_m''P_n'''$ in which $m = n - 3l$. The most typical skeletons do not contain singly-linked phosphorus atoms ($l = 0$) and correspond to the condition $m = n$. We shall confine ourselves to an examination of "island", chain, and layer structures formed by such skeletons.

"Island" Structures

Only $P_2''P_2'''$ (XVIII), $P_4''P_4'''$ (XXIV), $P_6''P_6'''$, etc. clusters as well as condensed structures for which $m = n$ satisfy the formula P_2^1. Since $m = \sum_{i=1}^{t} m_i - \sum_{j=1}^{q} k_j - 2(p+q)$ and $n = \sum_{i=1}^{t} n_i + 2(p+q)$, the relation between the parameters characterising such structures is defined by the equation $\sum_{i=1}^{t} (m_i - n_i) - \sum_{j=1}^{q} k_j = 4(p+q)$. For example, when the condensed cluster is formed from two identical clusters linked by a single P–P bond, we have $t = 2$, $k = 0$, $p = 1$, $q = 0$, and $m_1 - n_1 = 2$. Consequently $P_4''P_2'''$, $P_6''P_4'''$, etc. clusters can be combined into an "island" structure in the way described.

The formation of the following "island" structures is most probable: the $P_4''P_4'''$ cluster all sides of which consist of five-membered rings or the cluster (XXIV) whose sides consist of two five-membered rings, one six-membered ring, and one four-membered ring.

Among condensed structures, the formation of the $P_6''P_6'''$ cluster, obtained when two $P_5''P_2'''$ (XXI) clusters combine with establishment of a common side comprising two atoms, is most probable.

Chain Structures

Multiring, cluster, or mixed chains can correspond to the formula P_2^1. The condition $m = n$ for multiring chains may be formulated as follows: $\sum_{i=1}^{t} m_i - \sum_{j=1}^{q} k_j = 4(p+q)$. For chains made up of identical rings ($t = 1$), this formula assumes the form $m_1 - k_1 = 4(p+q)$. Consequently a singly-linked chain ($p = 1$, $q = 0$, $k = 0$) consists of four-membered rings; a doubly-linked chain ($p = 2$, $q = 0$, $k = 0$) consists of eight-membered rings; a chain formed by the linking together of rings consisting of m_1 phosphorus atoms and involving the establishment of a common side comprising k_1 atoms ($p = 0$, $q = 0$) is described by the formula $m_1 = k_1 + 4$. If $k_1 = 2$ and $m_1 = 6$, we obtain the chain (XXXVII). Chains with $k_1 > 2$ are unlikely for steric reasons.

Cluster and mixed P_2^1 chains are described by the equation $\sum_{i=1}^{t} (m_i - n_i) - \sum_{j=1}^{q} k_j = 4(p+q)$. Analysis shows that the formation of such chains with a simple structure is impossible.

Layer Structures

The condition $m = n$ assumes the following form for layers whose basic group consist of t rings: $m_1 - k_1 = 4(p+q)$. The layer formed by the condensation of identical rings should therefore incorporate P_{10}'' rings (XLVIII). The layer obtained by the condensation of P_{m_1}'' and P_{m_2}'' rings of different kinds must satisfy the condition $m_1 + m_2 = 20$, i.e. it can be formed only for $m_1 = 6$ (VII) and $m_2 = 14$ (XI).

The Present State of the Quantitative Theory of Polycondensation Processes

S.I.Kuchanov and E.B.Brun

The computational and theoretical studies in the field of homogeneous polycondensation are subjected to a critical analysis on the basis of the universal classification of the kinetic and thermodynamic models used in this field. The limits of the applicability of the models are discussed from the standpoint of the physicochemical characteristics of the processes which they describe and the parameters calculated on their basis are compared with the corresponding experimental data. The fundamental problems awaiting solution by the quantitative theory of polycondensation in the present stage of its development are formulated.

I. INTRODUCTION

The polycondensation method for the synthesis of polymers is at present one of the most widely used procedures for the formation of synthetic high-molecular-weight products. The extensive scope of this method is associated with the wide variety of monomers employed as well as the chemical reactions leading to the formation of macromolecules. In view of the practical importance of polycondensation it has been the subject of an enormous number of experimental studies. Here mention should be made of the great contribution made by V. V. Korshak and his School to the development of ideas about polycondensation processes. These studies made it possible to understand many important features of polycondensation and to obtain new polymers with valuable practical properties.

An enormous amount of experimental data on polycondensation has now accumulated. They have been surveyed and arranged systematically in monographs devoted both to individual important classes of polycondensation polymers[1-5] and to general characteristics of polycondensation[6-10]. However, in all these monographs, except Flory's familiar book[11], mainly experimental data are quoted and very little space is devoted to the quantitative theory and computational studies. At the same time, in planning industrial manufacturing processes one of the most important tasks is that of selecting the optimum conditions for polycondensation processes. The successful solution of this problem requires a well developed quantitative theory of such processes[12], which would make it possible to devise for them adequate mathematical models and to seek with the aid of a computer the optimum technological polycondensation régimes in terms of such models.

The present review presents a critical analysis of published computational and theoretical studies devoted to homogeneous polycondensation processes. Attention has been concentrated on the discussion of the initial postulates of the theory, the illustration of the possibilities of various computational methods, and the general problems of the modern quantitative polycondensation theory. Certain results arising from the theory of heterophase polycondensation are quoted in the review of Sokolov and Nikonov[13].

For a detailed statistical description of the products of linear homopolycondensation, it is sufficient to determine their molecular weight distribution (MWD). If cyclisation reactions proceed to an appreciable extent during the process, it is necessary to find also the MWD of the cyclic molecules. The copolymer molecules differ not only in the degree of polymerisation (size) but also in the fractions of units of different types (composition). The inhomogeneity of the copolycondensation products will therefore be described in terms of a size–composition distribution function (SCD). Furthermore, copolymer molecules having the same size and composition can have completely different microstructures characterised by the way in which the units are distributed in the chain. On passing from linear to branched polymers, it is necessary to take into account in their statistical description the fact that, apart from the above characteristics, macromolecules differ also in their steric configurations, particularly in the number and lengths of branches and intermodal chains, although for many practical purposes there is no need to distinguish all possible isomers in the description of the process.

The statistical characteristics enumerated above determine the primary, i.e. the configurational, structure of macromolecules which carries definite information about their possible conformations and secondary supermolecular structures and hence also about the physicochemical properties of polymers. Thus the main task of the quantitative polycondensation theory is the establishment of computational relations corresponding to the statistical parameters of the primary structure of the polymeric specimen as a function of the composition of the initial monomeric mixture and thermodynamic or kinetic parameters, i.e. as a function of the equilibrium constants or rate constants for reactions occurring during the synthesis of the polymer. The solution of this problem will permit an approach on a sound scientific basis towards the selection of the optimum polycondensation conditions in order to obtain polymers with a specified set of practical properties.

In the course of polycondensation there is a possibility of the simultaneous occurrence of different types of elementary reactions. The main one of these is chain

propagation—the interaction of two functional groups in different molecules to form the corresponding linkage between them, which will henceforth be referred to as the "intramolecular bond". This involves the joining together of two reacting molecules of monomers, oligomers, or polymers into a single entity which is frequently (but not necessarily) accompanied by the liberation of a molecule of a low-molecular-weight product. A common feature of polycondensation is [14] that during its course any two molecules of the initial or intermediate product in the reaction mixture, containing interacting functional groups, can be involved in a condensation reaction with one another. The reverse reaction in relation to chain propagation is chain degradation. For fairly high equilibrium constants k corresponding to this pair of elementary reactions, degradation in the course of polycondensation can nevertheless be neglected and their polycondensation can be regarded as an irreversible process. On the other hand, if k is small, the reversibility of polycondensation becomes significant. Whereas irreversible polycondensation is always a non-equilibrium process, reversible polycondensation can proceed under both equilibrium and non-equilibrium conditions. In order to achieve the equilibrium régime, it is necessary to remove the low-molecular-weight side product from the reaction zone at a fairly low rate, so that at each instant the system is in a state of thermodynamic equilibrium corresponding to the current concentration of the side product. The rate of this removal from the reaction zone evidently determines the overall rate of such equilibrium polycondensation. On the other hand, if the rate of removal of the side product is comparable to the rate of its formation in the condensation reaction, then reversible polycondensation will proceed in a non-equilibrium régime.

Apart from the growth and degradation of polymeric chains, elementary reactions involving interchain exchange, chain termination and intramolecular cyclisation are possible in the course of polycondensation. Without influencing the number-average degree of polymerisation, interchain exchange reactions can to a large extent determine the form of the MWD and the SCD for the polymer. Exchange reactions may be of two types. The elementary step in the first type involves the interaction of the terminal functional groups with an intermolecular bond, while in the second type it involves the interaction of two such bonds with one another. Apart from terminal functional groups (for example hydroxy-, carboxy-, or amino-groups), in calculations on reversible polycondensation it is necessary to treat intramolecular bonds [for example, ester(ether) or amide bonds] as "internal" functional groups, because they are involved in elementary degradation and interchain exchange reactions. Chain termination reactions in polycondensation, which consists in chemical deactivation of terminal functional groups, frequently takes place as a result of the interaction of the latter with monofunctional compounds, which are either specially introduced or are present in the system as impurities. In intramolecular cyclisation both reacting functional groups belong to the same molecule so that this type of reaction, which increases the degree of conversion of the group, does not lead to the growth of the molecular weight of the polymer†. In practical calculations there is usually no need to take into account all the elementary reactions, since, under the conditions of a specific process, many of them take place to such an insignificant extent that they can be neglected in setting up a kinetic scheme.

In the calculation of the statistical characteristics of the primary structure of polycondensation products two approaches are used: kinetic and statistical. The first consists in setting up and solving material balance equations for the concentrations of all types of molecules participating in the given process. In the second process the fractions of molecules with specified configurations, among others in reaction mixture, are calculated. These fractions are identified with the probability that a molecule selected at random has the corresponding configuration. There exist various versions of the statistical approach to the calculations of the above probabilities for molecules and even within the same class of processes it is possible to use several of them simultaneously. In the most convenient approach each macromolecule is represented as an individual occurrence of a definite random process involving conventional motion along the polymer chain and the probability of such occurrence is calculated with the aid of the theory of the corresponding process.

The statistical approach to calculations on polycondensation processes was first proposed by Flory as early as the end of the 1930s [11] and has found the widest applications in the quantitative description of many polymers, both linear and branched. The principal advantage of the statistical approach is that it makes it possible to describe exhaustively and at the same time comparatively simply the detailed configurational structure of macromolecules in terms of several probability parameters. However, the problem of the selection of the type of random process for a description of the products of a specific polycondensation system cannot be solved, in principle, within the framework of the statistical method alone. An answer is provided by the kinetic approach, which makes it possible to express simultaneously the corresponding probability parameters of the random process in terms of kinetic constants, reactant concentrations, and other measurable quantities. In order to prove rigorously the applicability of a particular modification of the statistical approach to the description of the primary configurational structure of the products of equilibrium polycondensation, the general principles of statistical physics and chemical thermodynamics, particularly the principle of detailed balancing, are used. Thus at equilibrium the probability of observing an arbitrary molecule in the system is determined by the free energies of formation of all its intramolecular bonds and, according to the principle of detailed balancing, is independent of the order in which the bonds appear, i.e. of the previous history of the system. On the basis of general thermodynamic relations, it is possible to express the free energy of formation of intramolecular bonds in terms of the equilibrium constants of the elementary reactions corresponding to the stoichiometric scheme for the given process. This makes it possible to determine in terms of these quantities the probability parameters used in the statistical approach.

In the course of the development of a quantitative theory of polycondensation two stages may be traced. In the first stage, which originated from Flory's fundamental work [11], only systems which we shall henceforth call ideal are considered. They do not involve intramolecular reactions and Flory's principle applies to the intermolecular reactions. According to this fundamental principle, the activity of any functional group of a particular type in each elementary reaction is the same regardless of which molecule the given group belongs to and in which part of the

†In the present review we are not considering polycondensation processes where only functional groups adjoining the chain can take part in the cyclisation reaction.

molecule it is located. The model of ideal polycondensation systems, to the development of which most published theoretical studies have been devoted, permitted the calculation by various methods of the necessary statistical characteristics of the products of the most general polycondensation processes with participation of many monomers of arbitrary functionality and with functional groups of various types. The problem of devising a theory of ideal polycondensation can now be regarded as largely solved[12]. The next stage consisted in a quantitative description of non-ideal systems. The attempts at calculations on such systems are usually associated with the overcoming of fundamental difficulties and the wide variety of factors tending to cause a departure from ideality precludes the use of a particular single approach. This stage of the development of the theory is therefore still far from complete.

We shall note the physical principles underlying the initial postulates of the model of ideal polycondensation systems and shall point out certain causes which may lead to the breakdown of these postulates. In the first place one should note that polycondensation reactions are comparatively slow and therefore occur under liquid phase conditions in such a way that their rate is not as a rule limited by diffusion factors. Intermolecular reactions are of second order, while intramolecular reactions are of first order, which leads to an increase of the proportion of the latter as the reaction mixture is diluted by an inert solvent. It is easy to achieve a condition where cyclisation reactions may be neglected in the description of the process kinetics. The probabilities, per unit time, that an arbitrary selected functional group of a macromolecule is involved in competing condensation reactions of the intermolecular and intramolecular type are respectively kC and k', where k and k' are the rate constants for bimolecular and unimolecular reactions and C is the concentration of the functional groups in the system. The quantity k' is proportional to the number of conformations of the initial molecule for which another group of this molecule is in the immediate vicinity of the selected group, i.e. is proportional to the effective local concentration c, which all the remaining groups of the molecule set up near the selected group as a result of the conformational rearrangements of the molecule. Since conformational equilibrium is assumed in the system, c is identical with the concentration of the corresponding conformers. If the functional groups in the molecule are separated by a fairly large number of intramolecular bonds, the proportionality coefficient between k' and c is equal to k, because the probabilities of the elementary step in the intramolecular and intermolecular reactions are in this case identical. Consequently $k' \ll kc$ and it is legitimate to neglect intramolecular reactions when $c \ll C$. The quantity C diminishes in proportion to the dilution of the system and c is determined by the configuration and segmental mobility (flexibility) of the polymer chains and is almost independent of the degree of dilution, although it may change on passing from one solvent to another. If it is supposed that the rates of the reverse reactions are independent of the conformational structure of the molecule, the foregoing statements concerning the rate constants for condensation reactions are fully applicable also to the corresponding equilibrium constants k' and k. In particular, if the functional groups involved in the reaction are separated by a large number of intramolecular bonds, the ratio k'/k is equal to the effective concentration c. At equilibrium the ratio c/C determines the contribution to the free energy change of the macromolecule in a given intramolecular reaction associated with the decrease in its course of the number of possible conformations of this molecule. Consequently c is unambiguously determined by the conformational entropy of the macromolecule and can be calculated by thermodynamic methods.

The possible causes of the deviations from Flory's principle can be divided into two classes, by analogy with the conformational properties of macromolecules: the short- and long-range effects. The former include the so called substitution effects associated with steric, inductive, or other types of influence of functional groups which have reacted on the activities of the neighbouring functional groups which have not. One speaks of a first-order substitution effect if the reactivity of the group depends on the state of the functional group only in the same monomer unit. Sometimes it is necessary to take into account also the possibility of higher-order substitution effects where the reactivity of the given group is influenced by the state of the groups in neighbouring units. Long-range order effects are determined by the possible influence of the solvent on the steric conformational structure of macromolecules and hence on the activity of the functional groups contained in them. For example, on passing from "good" to "poor" solvents, there is a possibility of the contraction of the reacting macromolecules accompanied by a reduction of the accessibility of the functional groups and actually resulting in the limit in the complete loss of reactivity by these groups owing to their intramolecular "protection". Such long-range order effects, where the accessibility of each individual group for reaction with other groups is determined by the conformational-configurational structure of the entire macromolecule, are significantly more difficult to take into account in the polycondensation theory than the short-range order effects. In the latter case calculations on polycondensation systems taking into account the substitution effect are carried out using the generalised Flory principle[12], according to which the activity of any functional group in the molecule can depend only on the microstructure of the neighbouring sections of the polymer chain and varies during the process owing to the changes in its microstructure associated with the reaction of neighbouring groups.

There is at present virtually no quantitative theory of polycondensation in which long-range order effects are rigorously taken into account. The difficulties in devising such a theory are due to the inapplicability in this instance of the Flory principle even in its generalised formulation. Such a theory requires the consideration of the conformational-configurational statistics of the reacting molecules. In contrast to intermolecular reactions, calculations on intramolecular reactions within the framework of the theory taking into account only the short-range order effect cannot be made at all. This is reasonable, because the interaction of any pair of functional groups within a single molecule depends significantly on their relative positions in the molecule and possibly on the choice of equilibrium conformations of the molecule, which determine the probability of the steric approach of the given groups to a distance necessary for the chemical reaction step.

An important property of ideal polycondensation systems, associated with the random nature of the reactions occurring in them, should be noted. Any statistical characteristics of the products of ideal polycondensation are independent at any instant of the previous history of the system, i.e. of whether the process takes place under equilibrium or non-equilibrium conditions, whether

degradative or exchange reactions occur, or whether the process is fully irreversible. They are fully determined by the concentrations of the terminal functional groups and the intramolecular bonds of each type at a given instant. In calculations on such systems by any statistical method this makes it possible to choose the numbers of functional groups and bonds of each type in an arbitrary molecule as parameters which unambiguously specify its probability. Thus in non-equilibrium processes the state of the system is independent (as at equilibrium) of its previous history, is associated with the ideality of these processes, and may break down on deviation from the latter; the probability of the appearance of a particular molecule in the absence of equilibrium can then depend also on the order in which its bonds have been formed. In the description by the statistical method of products of non-ideal polycondensation processes in the absence of equilibrium it is therefore always necessary to test the method for the adequacy of the chosen model by means of the corresponding kinetic equations.

Next we shall denote various monomers by a sequence of letters, the first of which (R,S,...) corresponds to the monomer unit and each of the latter (A, B,...) corresponds to a definite type of functional group in the monomer. If the monomer contains several identical groups, their number will be designated by a superscript to the corresponding letter.

II. LINEAR POLYCONDENSATION

In order to obtain macromolecules with a linear structure, bifunctional monomers are used. Depending on their number and type, homopolycondensation, heteropolycondensation, and copolycondensation are distinguished. The products of the first two processes are homopolymers, the elementary units of which consist of one or two monomeric units respectively, while the products of the third process are copolymers whose macromolecules differ in size, composition, and microstructure within the limits of a single specimen. Examples of homopolycondensation are provided by processes involving the formation of polyamides from aminoacids (the initial monomer is RAB and there are reactions only between A and B) and polyethers from glycols (RA^2 monomer). In heteropolycondensation the initial mixture usually consists of two symmetrical monomers RA^2 and SB^2 with groups A and B of different types, although there is a possibility of more general processes involving the reaction between RA_1A_2 and SB_1B_2, where groups of the same type in each asymmetric monomer have different reactivities. The heteropolycondensation products ~RSRSR~, typical examples of which are the formation of polyamides from diamines and dicarboxylic acids or the synthesis of polyesters from dicarboxylic acid chlorides and glycols, consist of rigorously alternating monomeric units R and S, i.e. the elementary unit of the homopolymers formed is in this case RS. With the exception of heteropolycondensation, all the processes involving more than one monomer are copolycondensation processes. The simplest characteristic instances of linear copolycondensation are bipolycondensation and interbipolycondensation. An example of the former process is a reaction where at least one of the initial monomers (for example, an aminoacid or a hydroxyacid) is capable of undergoing homopolycondensation under the given conditions. In the second process three monomers, for example $S_1A_1^2 + S_2A_2 + IB^2$, are involved simultaneously, the first two of which, called comonomers, do not react with one another but each is capable of undergoing heteropolycondensation with the third component (the intermonomer). The reactivities of two functional groups of any monomer can be in general different. Processes of this type with an arbitrary number of comonomers are called intercopolycondensation. Furthermore, unless a special stipulation is made, heteropolycondensation and intercopolycondensation imply processes with participation of symmetrical monomers.

1. Ideal Homopolycondensation and Heteropolycondensation

The first computational and theoretical studies on linear polycondensation were published as early as the end of the 1930s.[15,16] In his fundamental investigation[15] Flory calculated for the first time by a statistical method, on the basis of his principle, the MWD of the products of homopolycondensation and heteropolycondensation on the assumption that there is no cyclisation reaction. The number-average degree of polymerisation P_N, the weight distribution function $f_W(l)$ for molecules in terms of the degree of polymerisation l (MWD), and the polydispersity coefficient K_p characterising its width, which Flory[15] calculated for homopolycondensation, are given by the expressions

$$P_N = (1-p)^{-1},\ f_W(l) = (1-p)^2 l p^{l-1},\ K_P = 1+p \qquad (1)$$

and are determined by a single parameter p, which is equal to the conversion of the functional groups. The same formulae describe the products of the heteropolycondensation of an equimolar mixture of monomers and the corresponding formulae have been derived also for non-equimolar initial mixtures[15]. In the latter case the the formula $a_i b^l$ (where $i = 1, 2, 3$) describes the MWD for each of three types of molecules, differing in the type of terminal functional groups, and each has its own value of a_i. Distributions of this kind can be called generalised Flory distributions.

Subsequently these relations were frequently rederived in several different ways. Thus, using the principle of detailed balance, Schulz[16] calculated the MWD for the products of equilibrium homopolycondensation and derived a theoretical relation between the molecular weight of the polymer and the equilibrium constant of the reaction. Subsequently, Meggy[17] extended these results to equilibrium heteropolycondensation. At the beginning of the 1940s Flory[18,52] proposed two thermodynamic methods for the derivation of MWD in equilibrium systems. In the calculation of the most probable Flory distribution [Eqn.(1)] various modifications of the statistical method were used, in particular the treatment was based on a random migration process along a straight line[19] and the convolution integral[20]. The kinetic method has also been widely used in calculations of MWD for a polymer. The Flory distribution [Eqn.(1)] was derived by this method for the products of irreversible[21] and reversible[22] polycondensation in a closed system and also for equilibrium polycondensation[23], taking into account the possible removal of the side product from the reaction zone. In the kinetic schemes adopted[21-23] no account was taken of exchange reactions. It was suggested[24] that their occurrence leads to a narrowing of the MWD compared with the Flory law. However, the simplified kinetic calculation of the MWD in a system where an exchange reaction of the type of alcoholysis or acidolysis takes place and there is no

growth or degradation of macromolecules leads to equilibrium in the distribution defined by Eqn. (1).[25] Examination of the general kinetic scheme for reversible homopolycondensation[26] with allowance for all the reactions mentioned above shows that the products of this process can be described by the Flory distribution at all its stages. Although this type of general kinetic calculation has not been made for heteropolycondensation, there is every reason to believe that, for an equimolar mixture of the initial monomers (only then is there a possibility of the formation of high-molecular-weight products), the MWD for a polymer obtained in an arbitrary reversible process is also determined by Eqn. (1), because the latter has been proved rigorously for two opposite limiting cases: irreversible and equilibrium heteropolycondensation.

A number of studies have been devoted to the theoretical investigation of the influence of the chain termination reaction on the statistical characteristics of the polymer[27-30]. The MWD and the corresponding values of P_N and K_p for the products of homopolycondensation and heteropolycondensation were first calculated by Case[27] using a statistical method. Sokolov et al.[28] calculated analytically and numerically on a computer the values of P_N for a polymer corresponding to different kinetic schemes and mechanisms of the deactivation of functional groups. In particular, they examined termination both by impurities and by a side product formed in the course of the process. An infinite chain of kinetic equations for concentrations of different individual products of irreversible homopolycondensation has been formulated[29,30] with allowance for chain termination by an impurity. The authors did not find an exact solution for this system; certain approximate results are quoted, showing that the chain termination reaction can lead in certain cases to an appreciable narrowing of the MWD.

Statistical[27,31] and kinetic[32] calculations have been made on the heteropolycondensation of two monomers, one of which contains groups having different reactivities. It was shown that the MWD of the products of such a process is described by the generalised Flory distribution, which (for the same value of P_N) is wider the greater the difference between the reactivities of groups of the same type.

The problem of the influence of the rate of supply of one of the monomers to the reaction zone on the statistical characteristics of the products of irreversible heteropolycondensation was investigated by a computational method[33]. Using the kinetic method, the authors showed that the MWD of the polymer is described by the Flory law and the value of P_N may be large even when the condition of the equimolarity of the initial compounds is appreciably infringed, provided that the rate of supply of the monomer taken in excess is sufficiently low. A simple formula was derived in this case, which makes it possible to determine the rate constant for the condensation reaction from the measurements of the dependence of P_N on the rate of supply.

Attention has been drawn to the fact[34] that, in calculations on polycondensation kinetics, account must be taken of the decrease in the volume of the system during the process. The error arising when this fact is ignored reaches several tens per cent according to the author[34].

2. Non-Ideal Systems

Since the MWD of a polymer under the conditions of ideal polycondensation should be described by the Flory distribution with a polydispersity coefficient K_p close to two, any deviation from this value is associated with the breakdown of the ideality of the system. Analysis of experimental data quoted, for example, in Howard's review[35] shows that, together with ideal polycondensation systems, there are also systems which are not consistent with this model. Their MWD is described by broader ($K_p > 2$) or (and this is observed more frequently) narrower ($K_p < 2$) distributions than the Flory distribution. We shall consider further polycondensation models in which account was taken of particular deviations of the system from ideality.

The simplest of these is the model based on the first-order "substitution effect", according to which the reactivities of the functional group of the monomers differ from those of the remaining groups for which the validity of the Flory principle is postulated. Statistical[27] and kinetic[36] calculations have shown that the MWD of the products of irreversible heteropolycondensation of two symmetrical monomers, $RA^2 + SB^2$, the first of which has dependent groups and the second independent groups, is described by the generalised Flory law. Its statistical parameters are expressed in terms of the conversion p, the initial fractions of the monomers, and the relative reactivity κ of the first reacting group of the monomer relative to the remaining second group which has not reacted. Systems with $\kappa \geqslant 0.5$ have the same width of the MWD of the polymer ($K_p = 2$) as if they were ideal and systems with an appreciable accelerating substitution effect, where $\kappa < 0.5$, are characterised by an appreciably greater polydispersity ($2 < K_p < 4$). It is of interest that the formulae for the MWD of the polymer in this system do not differ in their forms from those for the MWD of the polycondensation products in the $RA_1A_2 + SB^2$ monomer system with independent but different groups in one of them. Irreversible heteropolycondensation, where both monomers contain dependent functional groups, has been examined within the framework of the first-order "substitution effect" model[37,38]. Sokolov et al.[37] evaluated numerically on a computer the values of P_N for a polymer corresponding to four different kinetic constants describing all the possible chain propagation reactions in the selected model. The calculations showed that the greater the reactivity of the second groups of the monomers compared with the first, the higher the molecular weight of the polymer obtained for the same conversion. When the difference between the reactivities becomes sufficiently large in both monomers, the process acquires features characteristic of polymerisation, because high-molecular-weight products can be formed for a non-stoichiometric ratio of the initial monomers and an incomplete conversion. Polycondensation systems of this type have not so far been observed experimentally. Case[38] obtained by a statistical method the MWD function for a polymer in the most general case of irreversible heteropolycondensation, where both monomers not only have dependent groups but also groups with different initial reactivities. This function constitutes a generalised Flory distribution analogous to that derived for the heteropolycondensation of monomers with independent groups. However, since a kinetic justification of this result is lacking, the problem of its validity still remains open. For an equilibrium process, this result can be rigorously justified[39] on the basis of fundamental thermodynamic principles. A general algorithm for the calculation of the MWD of equilibrium polycondensation products has been devised[39] for a model based on the "substitution effect" of arbitrary order and the number of independent thermodynamic parameters of this model was indicated.

There is now no doubt that the approximation assuming ideality does not hold for many polycondensation systems and substitution effects must be taken into account in the calculation[6]. In particular, this applies to the polycondensation of aromatic monomers, which frequently have dependent functional groups. In order to justify the "substitution effect" model and determine its parameters, the kinetics of the reactions of bifunctional monomers with the corresponding monofunctional compounds are usually studied under conditions close to those in polycondensation.

Such studies on model systems[40-42,43-47] made it possible to estimate quantitatively the relative reactivity κ of the first or second groups of monomers (bisphenols, dicarboxylic acid dichlorides, aromatic diamines) participating in acceptor-catalytic polyesterification and polyamidaton processes. The results of these investigations[40-47] have shown that $\kappa > 1$ for the majority of the monomers investigated and the first group can be several times more reactive than the second. A combined approach[46,48], which makes it possible to determine the suitability of the "neighbour effect" model for the description of specific non-equilibrium heteropolycondensation processes and at the same time to determine its parameters, is extremely interesting. On the basis of correlations obtained for reaction series of monofunctional compounds, a correlation equation has been derived[46,48] and has been used to calculate four kinetic constants in both the first and second groups for each of twenty different aromatic diamine + dicarboxylic acid dichloride pairs of monomers. These constants were then substituted in the four kinetic equations for the functional groups, which were next solved on a computer. Comparison of the solutions with the experimental data for the kinetics of the initial polycondensation stage showed[46,48] that the agreement is satisfactory in all the twenty systems investigated. A convincing experimental demonstration of the suitability of the "substitution effect" model for the description of equilibrium polycondensation was apparently achieved for the first time by Challa[49-51] in relation to the synthesis of poly(ethylene terephthalate).

In the above studies the influence of the solvent and long-range volume effects on the statistical characteristics of the polymer was completely ignored. Several attempts were made to take these effects into account in the theory of equilibrium polycondensation[52-57]. The equilibrium MWD of the polymer has been calculated[52-55] by minimising the free energy of the system. A term describing the interaction of the polymer molecules with the solvent was added to the expression for the energy. The form of this term was determined by the choice of the specific model of such interaction among those available in the theory of polymeric solutions. First it has been shown for concentrated solutions[52-54] that, for the Flory–Huggins lattice model, the MWD of the equilibrium polycondensation products is described by the Flory law. If other lattice models are used, it is possible to obtain other distributions[54]. It is easy to show[106] that the Flory distribution is obtained when the free energy of the macromolecule varies linearly with the degree of its polymerisation if account is taken of the interaction with the solvent. Among the models considered[54], this condition is satisfied by the Flory–Huggins model alone. The equilibrium MWD of the polymer in dilute solutions, where interactions between the segments of the different chains may be neglected, has been calculated[55-57]. In order to determine the free energy of this system, a number of workers[55,56] also used the lattice model. It was found[55] that in a poor solvent the MWD obtained are narrower, while in effective solvents they are broader than the Flory distribution. Furthermore, in a good solvent there exists a critical number-average degree of polymerisation above which the MWD becomes bimodal[56]. A fairly dilute solution has been examined[57] with the aid of special statistical physical methods, but only in systems close to θ-conditions. The author[57] arrived at results directly opposed to those of Berlin et al.[55]; in a poor solvent the equilibrium MWD of the polymer broadens, while in an effective solvent it becomes narrower compared to the Flory distribution. This contradiction shows, in particular, that in a quantitative study of the influence of long-range order and solvent effects on the statistical characteristics of the products of even equilibrium polycondensation processes, there are still many controversial questions and unsolved problems.

This applies particularly to non-equilibrium processes where the thermodynamic approach is inapplicable. In order to devise a quantitative theory, it is necessary to determine the dependence of the kinetic constants for the elementary reactions between the functional groups on their location in the macromolecules and on the degree of polymerisation of the latter and then to evaluate the statistical characteristics of the polymer from the solution of the corresponding kinetic equations.

There have been several theoretical studies[58-65] whose authors attempted to calculate the MWD of the products of irreversible polycondensation, specifying several empirical relations between the elementary reaction constants and the degree of polymerisation in the kinetic approach[58,59] or between the probability parameters and the degree of polymerisation in the statistical approach[60-65]. Thus the arbitrary relations $k_0(ij)^{-\epsilon}$ [58] and $k_0[1 - \epsilon(i + j)]$ [59] were adopted for the interaction constants of molecules with degrees of polymerisation i and j; the MWD was not calculated but only approximate (for $\epsilon \ll 1$) and cumbersome expressions were found for the concentrations of dimers, trimers, and tetramers[58] or the formulae for P_N and K_p.[59] In an attempt to extend to non-ideal systems Flory's statistical approach to the calculation of the MWD of ideal polycondensation products, a number of workers[60-65] began with the assumption that all ways leading to the formation of a macromolecule with a given degree of polymerisation l are equally probable. The "history" of the formation of the macromolecule is then unimportant; by considering the successive addition of the monomers to one of the growing chains, the authors therefore obtained the formula $f_N = p(1)p(2)\ldots p(l-1)[1 - p(l)]$ for the numerical MWD of the polymer. The investigators[60-65] then selected empirically two- and three-parameter relations between the probability of the formation of the bond $p(l)$ and the degree of polymerisation l of the reacting molecule and found relations between different molecular weights of the polymer and the parameters of the functions $p(l)$.

It is noteworthy that the assumption of equal probabilities of all ways leading to the formation of a molecule with a fixed length is rigorously justified for non-ideal systems only under the conditions of equilibrium[39]. For non-equilibrium processes, there is no such justification and one can actually quote systems (for example, the irreversible homopolycondensation of a monomer RH^2 with dependent groups) where this assumption is invalid. Consequently the formal application of Flory's statistical method to the calculation of the MWD of the products of non-equilibrium non-ideal polycondensation can lead to erroneous results. All the foregoing considerations apply equally to a study[60] where the assumption of equal

probabilities was effectively also used in the derivation of MWD for this process.

Unfortunately there are at present no experimental data whereby one could establish even for a single system a quantitative relation between the chain propagation rate constant and the length of the reacting macromolecules over the entire necessary range of variation of these quantities. For oligomeric molecules, this problem has been studied experimentally in detail on model systems by comparing the rates of reaction of a hydroxy-group with carboxy- [66,67] and isocyanate [68,69] groups in homologous series of compounds differing from one another solely by their molecular weight. It has been shown that, in all the systems investigated, the functional groups of the molecules separated by a bridge with a length corresponding to more than 2–3 methylene units may be regarded as independent and their reactivities may be regarded as identical regardless of the size of the oligomers containing these groups. Consequently in the absence of the substitution effect, i.e. when the above bridge is sufficiently long, Flory's principle holds in reactions between oligomeric molecules. On passing to high-molecular-weight reactants, there is a possibility of deviations from this principle associated with the macromolecular nature of the reactants, i.e. with long-range order effects. The study [70] whose authors investigated for model systems the dependence of the rate constant for the formation of aromatic polycarbonates on the length of the reacting molecules and the nature of the solvent is therefore of interest. In the range of molecular weights investigated (from 6000 to 28 000) it was shown that the reactivity of the functional groups k_θ is independent of the chain length in the θ-solvent and depends only slightly on the length in an effective solvent, where it diminishes to a constant value k_{eff}. The values of k_θ and k_{eff} are close to the polycondensation rate constants in the corresponding solvents and differ from one another approximately by an order of magnitude. The authors [70] attribute this difference to the difference between the densities of the macromolecular coils and hence to the accessibility of the functional groups, depending on the thermodynamic affinity of the polymer and the solvent.

3. Macrocyclisation Reactions

Linear polycondensation processes are frequently accompanied by the formation of cyclic molecules of different sizes. This usually occurs as a result of the condensation of different terminal groups in the same linear molecule, which has assumed a cyclic conformation as a result of the random motion of its segments. There is also a possibility of attack by one of the terminal groups on an internal bond in the same molecule (for example, intramolecular alcoholysis). In all cases the rate constant (or equilibrium constant when equilibrium has been attained) for the corresponding unimolecular reaction is determined by the effective local concentration c established by one of the groups participating in the reaction in the immediate vicinity of another as a result of various conformational rearrangements of the macromolecule containing them. An important feature of intramolecular reactions, which constitutes a fundamental difference between them and intermolecular reactions, is therefore the dependence of their kinetics on the conformational structure of the macromolecules, i.e. on the possible set (taking into account their probabilities) of steric conformations of the molecules. Examination of conformational statistics shows that, even in the absence of the substitution effect, the cyclisation reaction rate constants depend on the degree of polymerisation of the molecule, the only parameter characterising the configurational structure of the homopolymer. This leads to different types of MWD of the products of equilibrium and non-equilibrium processes. Different approaches are therefore required for a quantitative description of processes in these two classes.

It is usually assumed that the rate of intramolecular polycondensation reactions is not limited by the conformational rearrangement of molecular units, because the characteristic times of these reactions as a rule greatly exceed the time required for the attainment of conformational equilibrium. The effective concentration c therefore agrees with the concentration of the corresponding cyclic conformers of linear molecules. Hence information about the size distribution of the cyclic compounds formed, which may be obtained by gas–liquid and gel permeation chromatography [71], can yield useful data about the equilibrium conformational structure of linear chains, provided that an appropriate theory is available. Calculations on equilibrium polycondensation taking into account cyclisation reactions are based on the thermodynamic principle of detailed balancing [72,73]. Thus the Law of Mass Action for condensation and cyclisation reactions, which are respectively reactions of the exchange type and reactions between terminal groups,

$$C_l + C_m \overset{2k}{\rightleftarrows} C_{l+m} + Z,\ C_{l+m} \overset{k_l}{\rightleftarrows} \tilde{C}_l + C_m,\ C_l \overset{k_l'}{\rightleftarrows} \tilde{C}_l + Z \qquad (2)$$

makes it possible to determine the equilibrium concentrations of linear (C_l) and cyclic ($\tilde{C}_l$) l-mers and to relate the equilibrium constants of these reactions:

$$C_l = Z\nu^l/k,\ \tilde{C}_l = k_l\nu^l,\ k_l' = kk_l. \qquad (3)$$

where Z is the concentration of the side product and the parameter ν is determined from the constancy of the total number of monomeric units in the system. It follows from Eqns. (3) that the MWD of linear chains is described by the Flory law but including a parameter ν which is in general not identical with the conversion. In order to determine the MWD for cyclic species and the parameter ν, it is necessary to know the dependence of the equilibrium constant of the second reaction (2) on l. In conformity with thermodynamics, it is determined by the free energy of this reaction. For fairly large values of l, whereupon the heat of this reaction, i.e. the strain in the corresponding ring, is small, k_l is determined solely by the statistics of the steric conformations of linear molecules and may serve as a measure of their flexibility.

In a theoretical study of these conformations, it is usually assumed that the process takes place in a θ-solvent, neglecting, in particular, the long-range volume effects (i.e. the excluded volume effect) and either the statistics of a freely jointed chain or the more realistic rotational isomer model [75,76], whose parameters are known for many systems [76], are used [72–74]. Both these models lead to a normal (Guassian) distribution of the distances between the ends of a chain with l units and hence to an asymmetric behaviour of $k_l \propto l^{-2.5}$, provided that l is large. The rotational isomer model makes it possible to calculate the proportionality coefficient in this formula for many real chains, which depends on the rigidity [76]. Calculation of k_l for low values of l, when it is necessary to take into account the correlations between the directions of the terminal bonds of linear chains assuming cyclic conformations [73,77] as well as deviations from the normal approximation, can be carried out within the framework of the rotational isomer model, or with the aid of a matrix technique [77–83], or by simulating the conformations of the

chain on a computer by the Monte Carlo method[84-87]. Thus the theoretical treatment in the above studies makes it possible to calculate the equilibrium constants k_l, taking into account the above assumptions for the models selected in the relevant studies and then to evaluate the MWD for the reaction products by Eqns. (2) and (3). Here the initial parameters are only the structural characteristics of the polymer chains: valence angles, interatomic bond lengths, and internal rotation potentials. They have been measured independently for a whole series of polymers[76], which permits calculations without using adjustable empirical parameters.

We shall now formulate certain results obtained within the framework of the above theory. The MWD for cyclic molecules is wider compared with the Flory distribution. For a fairly high degree of polymerisation of linear chains, the concentration of rings is independent of the dilution of the system and depends on temperature to only a very slight extent. On the other hand, the weight fractions of all the cyclic molecules in equilibrium depend significantly on the polymer concentration in solution. Thus there exists a critical value of the latter, below which the polycondensation products are virtually only cyclic species[72-74].

The above theoretical conclusions and results, including the values of k_l calculated on the basis of the corresponding rotational isomer models, were tested by studying (by chromatographic methods) the MWD for cyclic products in a large number of equilibrium systems: polyethers[88], polyesters[89-93], polyamides[94-96], polymeric alkylsiloxanes[97], and polysiloxanes[73,78-81,98-105]. In all the systems investigated, the calculated and experimental values of the constants k_l are in good agreement, with the exception of instances corresponding to very low values of l. Cyclic oligomeric dimethylsiloxanes have been studied both experimentally and theoretically in greatest detail[73,78-81,98-101,104,105]. It was found that the experimental values of k_l obtained when the process is carried out in bulk[79,80,104], agree satisfactorily with the values calculated on the basis of the rotational isomer model in the region $8 \leqslant l \leqslant 200$ [80,81,104] (for long rings, fractionation was not carried out), and the Gaussian approximation is valid (Fig. 1) for $l \geqslant 20$. On the other hand, for low values of l ($4 \leqslant l \leqslant 7$) the experimental data are appreciably higher than the theoretical results[79-81,104]. There is no temperature dependence in the region $4 \leqslant l \leqslant 40$ (the process was not investigated for large values of l). Very similar values of k_l were obtained also when the process was carried out in a poor solvent in the vicinity of the θ-point (diethylene glycol at 333 K).[104] A different behaviour was observed in effective solvents. Thus in toluene the experimental data are described satisfactorily by the rotational isomer model only in the region $8 \leqslant l \leqslant 40$ (Fig. 1), while in xylene the values of k_l are independent of the solvent concentration only when $11 \leqslant l \leqslant 40$ and increase with increasing dilution in the region $4 \leqslant l \leqslant 10$.[80,101] Measurements of the weight fraction of cyclic species at different polymer concentrations[80] confirmed the existence of the critical dilution, predicted by the theory[72,74], which is independent of temperature and above which the system consists solely of cyclic molecules. However, the critical concentrations of the polymer proved to be somewhat higher than the theoretical value[80]. Unduly high observed values of k_l for low values of l are usually attributed to the strain in small rings[106] or to the neglect of correlations between the directions of the terminal bonds in short linear chains which have assumed cyclic conformations[73,77]. However, it has been shown for cyclic polydimethylsiloxanes[107,108] that, for $l \geqslant 4$, the ring strain is virtually zero. Correct allowance for correlations between the directions of terminal bonds within the framework of the rotational isomer model also failed to yield a result for $4 \leqslant l \leqslant 7$.[105] The possible cause of the discrepancy with experiment can therefore be the inapplicability of the model to the description of the statistics of the conformations of such small rings. The unduly low theoretical critical dilution of the polymer, starting from which the latter consists of cyclic molecules, is in all probability associated with an incorrect allowance for small rings. The differences between the theoretical and experimental values of k_l for high values of l in an effective solvent (Fig. 1) can be accounted for by long-range volume effects[71,104]. Thus allowance for the excluded volume effect by means of simulation on a computer[109-112] or analytically[113-115] leads to the relation $k_l \propto l^{-2.8 \pm 0.1}$ or a similar relation[109], which agrees fairly well with the experimental values $k_l \propto l^{-2.86}$ and $k_l \propto l^{-2.69}$ obtained by Brown and Slusarczuk[99] and Wright[104] respectively.

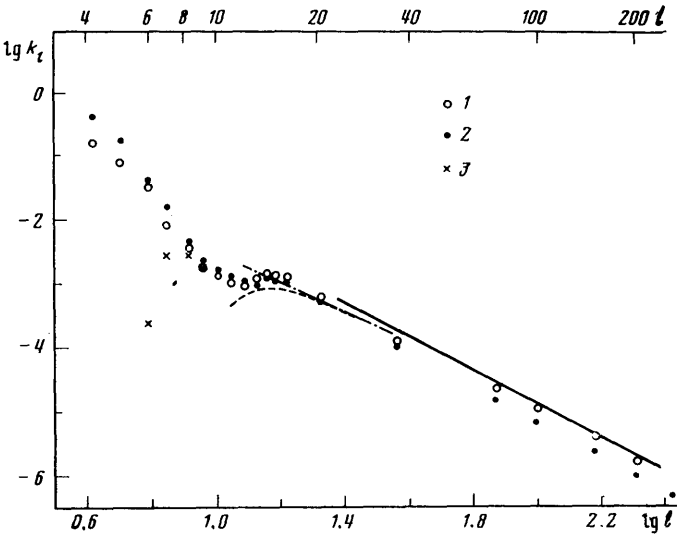

Figure 1. Variation of the equilibrium constants for polydimethylsiloxanes with the degree of polymerisation l. The experimental points were obtained[104] in the absence of a solvent (*1*) and in toluene (*2*) at 383 K. The calculation was performed with the aid of the rotational isomer model in different investigations: continuous line—by Flory and Semlyen[73] (Gaussian approximation); dashed and dot–dash lines—by Suter et al.[105]; 3) by Semlyen and Wright[80].

An important problem is the determination of the relation between the MWD parameters of polymers and their physicochemical properties. An example of this type of study for equilibrium polydimethylsiloxanes is provided by the investigation of Dodgson and Semlyen[116]. Products obtained when the polycondensation was carried out in three different solvents were fractionated to give linear and cyclic components, after which the intrinsic viscosities corresponding to different molecular weights were measured in both fractions. It was found that the relations obtained in a θ-solvent (butanol at 293 K) are very well correlated with the theoretical calculations

predicted previously[117-119]. For example, the ratio of the intrinsic viscosities of the cyclic and linear fractions for identical molecular weights is 0.67, while the theoretical value at the θ-point is 0.662.[116,118,119]

The combined theoretical and experimental studies illustrated above for products of the equilibrium polycondensation of polydimethylsiloxanes make it possible to solve one of the fundamental problems in polymer chemistry: the physicochemical properties of molecules can be determined from their microstructural quantum-mechanical characteristics at least in a θ-solvent. Such studies have been partly carried out also for certain other linear equilibrium polycondensation systems in which cyclisation takes place[71].

The results obtained for irreversible linear polycondensation processes in the presence of intramolecular reactions are much more modest. The MWD for the products of such processes can be calculated only by solving the corresponding kinetic equations, whose form depends on the specific kinetic process mechanism, for example, on whether intramolecular exchange reactions take place or whether cyclisation occurs solely via reactions between terminal functional groups. The rate constant for the reaction between the functional groups of the molecule depends both on its size and on the segmental mobility. As a result of this, even the MWD of linear molecules is not described by the Flory formula in the absence of the substitution effect, which can be readily tested by substituting it in the corresponding kinetic equations.

No general studies have so far been made in order to solve such equations with the aim of investigating the behaviour of the MWD for the products of irreversible polycondensation processes under different conditions, as has been done under equilibrium conditions[72-74]. Solutions of the kinetic equations, derived on the assumption that there are no exchange reactions and no substitution effect, in the interpretation of a specific kinetic experiment[122,123], have been found[120,121]. The kinetics of the formation of lactones from ω-hydroxy acids of the type $HO-(CH_2)l-COOH$ with l between 5 and 24 have been studied[122]. Comparison of the results of this experiment with the solutions of the corresponding kinetic equations made it possible to determine the rate constants for the cyclisation reactions corresponding to different values of l.[120] Sisido[83] showed subsequently that these values are in good agreement with constants which he calculated on the basis of the rotational isomer model for the methylene chain.

The number-average fraction of cyclic polyurethanes, obtained in the reaction of hexamethylene di-isocyanate with poly(ethylene glycols) $HO-(CH_2CH_2O)_{4.5}-OH$ in bulk and in benzene for different dilutions and initial compositions of the monomer mixture, has been measured[123]. By comparing the theoretical expressions with experimental data[123], Gordon and Temple[121] determined the dependence of the cyclisation constants kl on dilution. However, the absence of a rotational isomer model for such chains and the lack of experimental data for the separation of cyclic molecules in terms of their lengths preclude an unambiguous conclusion concerning the applicability of the given theoretical models to the description of the test system.

4. Joint Polycondensation

The molecules of linear copolymers differ, within the limits of the same specimen, by the number of different units (size and composition) and the way in which they alternate in the chain (structure). The equation for the average composition of the products of ideal irreversible interbipolycondensation was obtained independently by Shtraikhman[124] and Beste[125] and the dependence of copolymer composition on conversion for different activities and proportions of the initial monomers was analysed[126] on its basis. If the monomers have dependent functional groups, then in the general case it is not possible to obtain analytical formulae for the composition and the latter must be calculated on a computer[127]. However, it is noteworthy that the problem of calculating the composition of the products of the above process when the initial compounds are supplied simultaneously arises only when their proportions are non-equimolar or when the final reaction products are oligomers. In order to obtain high-molecular-weight products, it is necessary to carry out the reaction between rigorously equimolar amounts of monomers up to nearly 100% conversion. The composition of the copolymer is then always the same as the composition of the initial monomer mixture and the problem of its calculation does not arise.

The first attempt at a quantitative description of the structure of the chains of polycondensation copolymers was undertaken by Beste[125] who calculated the distribution function with respect to length for blocks of various monomeric units in products of ideal intercopolycondensation of a stoichiometric mixture of monomers. For units of the ith type, this function is identical with the Flory distribution having the parameter $b_i = \alpha_i p_i^2$, which depends on the initial fraction of the ith comonomer α_i and the conversion p_i of its groups. It was shown subsequently in relation to interbipolycondensation[128] that this distribution is also obtained in the more general case of an intercomponent with dependent groups, but the parameter b_i is then more complex and is found by numerical calculations on a computer.

A characteristic of the structure of the chains of binary copolymers, which is simple and convenient for theoretical and experimental determination, is the microheterogeneity coefficient K_M, which is expressed in terms of the fractions of different diads of RI and SI elementary units (or triads of monomeric units) by means of the relation

$$K_M = \frac{P(RS)}{P(RS) + 2P(RR)} + \frac{P(RS)}{P(RS) + 2P(SS)}. \quad (4)$$

For a mixture of two homopolymers, $P(RS) = 0$ and correspondingly $K_M = 0$, while for a regularly alternating copolymer $P(RR) = P(SS) = 0$, to which corresponds $K_M = 2$. Between these two extreme cases, corresponding to an ideally ordered arrangement of units in macromolecules, lie all possible values of K_M, $K_M = 1$ corresponding to the fully statistical (i.e. the most disordered) distribution of units. Consequently the degree of order in the copolymer microstructure may be deduced quantitatively from the absolute magnitude of the deviation of K_M from unity, while the tendency of monomeric units towards either a regular alternation in the chains ($K_M > 1$) or (when $K_M < 1$) towards the formation of long blocks of both comonomers can be inferred from the direction of this deviation. The theoretical problem is to express the fraction of the diads in terms of kinetic (for non-equilibrium processes) or thermodynamic (for equilibrium processes) parameters of the system and to find K_M from Eqn. (4).

The kinetic calculation of K_M, carried out for products of irreversible interbipolycondensation[129], showed that the nature of the chain microstructure is determined mainly by the reciprocal relation between the reactivities of the functional groups in the intercomponent. If they are independent, then, according to the theory, $K_M = 1$ and the

distribution of units for any conversion, comonomer ratio, and the activities of the comonomers is always fully statistical. A general correspondence has been established[129], within the framework of a simplified "substitution effect" model, between the nature of the change in the reactivity of the functional groups in the intercomponent in the course of their reaction with the comonomers and the nature of the distribution of the units in the copolymer. If the activity of the second groups of the intercomponent diminishes when the first groups react, a tendency by the chain units to alternate ($K_M > 1$) should be observed; in the opposite case an increase of the reactivity of the second groups should entail the appearance of a tendency towards the formation of blocks ($K_M < 1$). For the same intercomponent with dependent groups, the degree of order in the copolymer microstructure increases with increasing difference between the reactivities of the comonomers. Certain qualitative conclusions concerning the relation between the microstructure of copolymers, the reactivities of the monomers, and the conditions of non-equilibrium interbipolycondensation were reached by Gritsenko[130-132] on the basis of statistical considerations. However, this approach does not make it possible to follow the dynamics of the changes in the microstructure during the process and to relate K_M to the kinetic parameters of the system.

An attempt at a quantitative description of the chain structure in binary copolymers obtained by equilibrium copolycondensation was undertaken by Sawada[133,134], who expressed the fractions of different diads in terms of the thermodynamic parameters of the RR, RS, and SS bonds. K_M for this process was calculated[135] taking into account the non-equimolarity of the initial mixture of monomers.

The use of high-resolution NMR, which makes it possible to determine with a fairly high accuracy (to within ~5%) the fractions of diads of elementary units in the specimen, gives rise to a considerable scope for the investigation of the composition and structure of polycondensation copolymers. The products of both equilibrium and non-equilibrium copolycondensation have been investigated by this method in many specific systems[136,137]. The method has been particularly successful in the latter case, where its use enabled Korshak and coworkers to discover many general features of non-equilibrium interbipolycondensation in relation to acceptor-catalytic copolyesterification[137]. Comparison of the calculated and experimental values of K_M for this case showed that the quantitative agreement between them for different reactivities of the initial compounds and different process conditions was satisfactory[42].

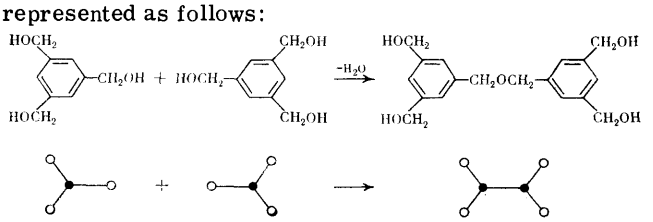
It is noteworthy that the concept of K_M has significance only for copolymers with two types of elementary units, but even in this case K_M does not in general permit an exhaustive description of the copolymer microstructure, i.e. it does not enable one to find the probability of any given sequence of units in it. For arbitrary copolymers, obtained via a polymerisation mechanism, the general problem of the calculation of the microstructure was solved by Price[138], who showed that the molecules of such copolymers may be regarded as individual manifestations of a Markov chain. The mathematical theory of these chains has been thoroughly developed[139], which makes it possible to express the probabilities of any sequences of units in the copolymer in terms of the parameters of the corresponding Markov chain using standard rules and simple algebraic transformations. Kuchanov's study[140], where it was established that the products of an arbitrary homogeneous joint irreversible ideal polycondensation process are described by Markov's chain whose parameters are related in a known manner to the constants of the elementary reactions and the ratios of the initial monomers, is therefore of general importance for the quantitative theory. An analogous result for equilibrium copolycondensation was obtained by Kuchanov and Brun[135], who showed that allowance for arbitrary order in the theory of "substitution effects" does not infringe the Markov nature of the distribution of units in the copolymer. There is no proof that the products of an arbitrary non-equilibrium process have such a property, although it has been obtained[141] for the copolymers formed in the intercopolycondensation of comonomers having independent groups with an intermonomer whose functional groups are dependent.

The problem of the quantitative description of the inhomogeneity of polycondensation copolymers was first considered by Case[27], who calculated by a statistical procedure the distribution function for the molecules with respect to size and composition (SCD) for products of the ideal bipolycondensation of $S_1A_1B_1 + S_2A_2B_2$ monomers. A complete solution of this problem was obtained by Kuchanov[140,141], who proposed a kinetically justified general algorithm for the analytical calculation of the SCD for an arbitrary irreversible ideal copolycondensation, and who derived, as an example, an expression for such distribution in intercopolycondensation. An analogous algorithm for equilibrium processes was devised by Kuchanov and Brun[135]. The demonstration of an unambiguous correspondence between the configurations of the copolymer molecules and the occurrence of a Markov chain enabled the authors[135,140,141] to obtain simple asymptotic formulae for large values of P_N for SCD and the distribution of polycondensation copolymers with respect to composition. For interbipolycondensation, which was considered by the above workers[135,140,141], the above distributions depend solely on the values of three parameters: P_N, the composition of the initial monomer mixtures, and K_M. Analysis of these relations showed that the distribution with respect to composition becomes narrower with increase of P_N and as the block structure of the copolymer becomes more pronounced with increase of K_M.

The study of Korshak and coworkers[142] devoted to the theoretical and experimental investigation of the homopolymers formed in the course of non-equilibrium heteropolycondensation of monomers with an asymmetric distribution of functional groups has a significant bearing on polycondensation theory. In such polymers there is a possibility of the addition of monomers to the chain in two ways—of the "head to head" and "tail to tail" type, on the one hand, and of the "head to tail" type, on the other, as in the homopolymerisation of asymmetric vinyl monomers. It has been shown[142] that a statistical description of such polymers, taking into account the type of addition of their units, can be achieved on the basis of the formulae of copolycondensation theory.

Proceeding now to the consideration of processes involving the formation of block copolymers, the difference between the mechanisms of their formation in equilibrium and non-equilibrium polycondensation reactions is noteworthy. Thus, in the former case, when the mixture of two homopolymers is heated, exchange reactions begin and lead to a redistribution of the monomeric units in the molecules and the formation of block copolymers[6,7]. A quantitative theory of such a process has been developed by Kotlyar[143], who calculated the distribution of blocks with respect to lengths and the content of residual homopolymers in the system. In non-equilibrium interbipoly-

condensation, even of comonomers with markedly different reactivities, statistical copolymers are formed for the simultaneous introduction of all the initial compounds[42,129]. Block copolymers are obtained in such a process when the intermonomer is introduced gradually and fairly slowly into the reaction zone[42,144]. Under these conditions, the average length of the blocks increases to a limit with decrease of the rate of introduction of the intermonomer, the limit being greater the more pronounced the difference between the reactivities of the comonomers. This conclusion and other experimental relations of the parameters of the microstructure of the copolymers and the kinetic constants and methods of introduction of the initial compounds, obtained in non-equilibrium interbipolycondensation, carried out in different ways, are satisfactorily correlated with calculated data[128,136,137].



One of the ways of synthesising linear homopolymers and copolymers, widely used in industry, consists of the following steps. An intermediate product is obtained initially in the form of reactive oligomers having terminal functional groups, which are then cross-linked by the polycondensation procedure. The main task of the theory is in this case the determination of quantitative relations between the statistical characteristics of the oligomers, on the one hand, and the polymers formed from them, on the other. In fact, the calculation on such a system is analogous to the calculation on ideal polycondensation. However, in contrast to the latter, the initial compounds can contain different numbers of monomeric units. This problem was considered for the first time by Case[145,146], who calculated by a statistical method the distributions of macromolecules with respect to the degree of polymerisation and the number of oligomeric chains incorporated in them. Bearing in mind that the intermediate oligomers can be obtained both by polycondensation and by ionic and radical polymerisation, Case specified appropriately the MWD for these oligomers. The calculated MWD for the polymer usually differs little from the Flory distribution (1). Only when the cross-linking agent contains functional groups with markedly different reactivities can the MWD for the polymer be significantly narrower[145]. In subsequent studies[21,147,148] an analogous problem was solved for different systems by the kinetic method.

It is noteworthy that molecules with different numbers of useful functional groups (i.e. capable of involvement in further polycondensation) can be formed in the synthesis of the intermediate oligomers. Consequently the concept of "functionality" for such an intermediate has a statistical significance and its quantitative description requires the introduction of a distribution function with respect to the types of functionality (DTF), which determines the number-average and weight-average functionalities of the oligomers[149]. The review of Entelis et al.[149] discusses in detail the possible methods for the determination of DTF for specific oligomers. Systematic experimental studies, permitting a quantitative test of the computational relations established in the studies quoted above, are apparently lacking. We can only note a recent investigation[150], where the influence of the DTF of the initial oligomers on the MWD of the polyurethanes obtained as a result of the cross-linking by di-isocyanates of oligomeric isoprene–butadiene block copolymers with terminal OH groups is the only one that can be mentioned.

III. BRANCHED POLYCONDENSATION

In contrast to linear macromolecules, branched macromolecules can have different steric configurational structures. In order to distinguish individual products of branched polycondensation, it is convenient to represent them schematically by molecular graphs.

(In mathematics a graph is defined[151] as a set of vertices joined by edges.) Each molecule is associated in a one-to-one correspondence with a graph whose topological structure corresponds to the configuration of the given molecule. For example, molecular "trees", i.e. graphs without cyclic fragments, correspond to the products of ideal polycondensation. Chemical bonds are usually associated with the edges of the graph and monomeric units and functional groups are associated with its vertices. Thus the formation of a dimer from two monomeric molecules of a trihydric aromatic alcohol can be represented as follows:

The vertices corresponding to the monomeric units are called nodes (filled circles) and those corresponding to functional groups are referred to as pendant vertices (open circles). Any two nodes of a molecular graph can be connected by a broken line (trail) consisting of edges whose number defines the length of the trail. A linear molecular fragment connecting two monomeric units, called a chain, corresponds to this trail. In the case of trees any pair of nodes is joined by one trail. A definite graph with l nodes corresponds to an arbitrary homopolymer molecule with a degree of polymerisation l (an l-mer) and the number of edges originating from each node of the graph is equal to the functionality of the initial monomer. If several monomers are involved in the process, then the vertices of the graphs corresponding to them are distinguished by colouring the vertices in different ways so that coloured graphs are used for the description of copolymers. The problem of a detailed statistical calculation of the configurational structure of the polymer involves the calculation of the probabilities of various molecular graphs.

An important characteristic of branched polycondensation is gel formation, i.e. the appearance in the system of enormous infusible and insoluble macromolecules having a three-dimensional steric structure‡. Here one can speak of a macrogel or a microgel depending on whether the dimensions of these structures are comparable to those of the reaction apparatus. In the former case, the three-dimensional polymer network occupies the entire reaction volume, while in the latter particles of the microgel are dispersed in it.

Depending on many physicochemical factors (the chemical nature of the polymer formed, its affinity for the solvent, the rate of the cyclisation reaction, etc.) different ways of forming the microgel in branched polycondensation are possible[152]. The simplest involves "homogeneous" gel formation in which the reaction system remains homogeneous during the process up to a certain instant, referred to as the gel point, where it loses fluidity and solubility

‡Only gels formed as a result of a network of covalent bonds and belonging to the first type in Papkov's specification[154] are considered in the present review. Gels of the second or mixed type are disregarded, because of the lack of a quantitative theory of gel formation applicable to them.

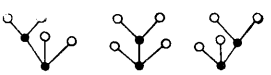
almost instantaneously owing to the formation of the macrogel. Together with systems of this kind (we shall henceforth refer to them as classical), there are also others in which the macrogel formation is preceded by the microgel formation stage [153]. In the course of the latter microlayer formation occurs in the system accompanied by the formation of colloid particles whose number and dimensions may vary with time. As a result of the subsequent cross-linking of the microgel particles, they are combined into a single macrogel network. This gel formation mechanism was proposed by Bobalek et al. [153] to account for data concerning the hardening of alkyd resins and was then convincingly demonstrated experimentally in relation to the formation of cross-linked polyurethanes. All attempts at establishing a quantitative theory of gel formation refer solely to classical systems, and an analogous theory for branched polycondensation accompanied by microgel formation is not available.

1. Ideal Systems

In calculations on ideal branched polycondensation various modifications of the statistical approach were used. Together with direct combinatorial considerations use was made of computational methods taken from statistical physics as well as the modern mathematical theory of the enumeration of graphs and of random branching processes. Initially we shall consider in detail studies where calculations were made by these methods of the statistical characteristics of polymers obtained before the onset of gel formation. Next we shall discuss the existing approaches to the description of the process beyond the gel point, and finally we shall illustrate the possibilities of the quantitative theory of branched polycondensation in relation to a specific ideal polycondensation system, investigated in detail by a number of workers both theoretically and experimentally.

Flory [156] was the first to employ a statistical approach to ideal branched systems, having calculated for this purpose all the necessary probabilities (including the probability of an infinitely large molecule, the instant of the appearance of which indicates the onset of gel formation) by means of direct combinatorial procedures. He showed theoretically that gel formation does indeed have pronounced "explosive" properties and is accompanied by an infinite growth of the weight-average molecular weight of the polymer. The conversion of the functional groups p^* at the gel point (the critical conversion) is then independent of temperature, catalyst, dilution, and other process conditions and is determined solely by the functionality of the initial monomers and their fractions. Flory himself considered theoretically only a few specific polycondensation systems [11,156-159] in which not more than one polyfunctional monomer was present, but the computational method which he proposed was later applied to systems which were more complex mathematically. Thus the polycondensation of a polyfunctional monomer with different functional groups, which all react with only one group, has been considered [160,161]. Apart from the MWD, also the distribution function for molecules with respect to different bonds has been calculated. The critical conversion in polycondensation involving several polyfunctional monomers, between which only one elementary reaction takes place, has been calculated in a number of studies [162-167]. In some investigations [165,166] account was taken also of monofunctional additives. Some workers [168-173] calculated the gel point in the polycondensation of various mixtures of mono-, bi-, and poly-functional monomers.

Thus one of the variants of the statistical method, proposed by Flory, has been used until recently in ideal polycondensation systems. However, the corresponding procedure for the calculation of probabilities requires in each specific instance fairly cumbersome and non-evident steps, which was in all probability the reason for the errors made by some investigators using this approach. Thus an incorrect formula has been obtained [162] for the critical conversion in the polycondensation of a polyfunctional monomer with two types of functional groups. Other workers [165,166] incorrectly took into account the influence of monofunctional impurities on the degree of reaction at the gel point [167], while others [172] were unable to attribute the correct statistical significance to the integrals obtained by solving kinetic equations. Finally an attempt has actually been made [174] to construct a statistical scheme for the process, different from that of Flory, on the basis of the same initial postulates, which led to a revision of Flory's fundamental results, including his relation between the critical conversion and the functionality of the initial monomers. However, it was later shown [175-179] that this new scheme is erroneous.



Another variant of the statistical approach to the calculation of the gel point and the MWD (SCD) for the products in ideal polycondensation systems, similar to methods in statistical physics, was proposed by Stockmayer [180-182], who used the fact that, for a fixed conversion, the total number of ways Ω in which all the N monomeric units may be shared between molecules for a given distribution of the latter with respect to the degree of polymerisation in an ideal system is a measure of the probability of the occurrence of such a distribution. For the most probable distribution, Ω has a maximum and in systems with a macroscopic value of N this distribution determines the MWD for the polymer. In order to calculate Ω, it is necessary to solve the problem of the enumeration of all equally probable ways in which the molecular tree with the given number of nodes can be formed. Stockmayer solved this problem by a direct combinatorial calculation for the products of the ideal polycondensation of an arbitrary number of monomers, but only in the case where each monomer has identical groups and only one elementary reaction takes place in the system [181,182].

The application of Stockmayer's statistical method to ideal equilibrium polycondensation has been justified rigorously in a study [183], where Mayer's diagram method [184], well known from the theory of dense gases, was used in succession. As a result it was possible to relate the MWD of the polymer directly to the intramolecular and intermolecular interaction potentials and to calculate various thermodynamic system parameters. The equation of state obtained by Cohen et al. [183] made it possible to draw an analogy between the gel formation phenomenon in polycondensation and the gas–liquid phase transition in the condensation of vapours. Furthermore, the above study threw light on the physical significance of Flory's initial principle and is therefore particularly valuable.

The direct combinatorial method proposed by Stockmayer for the solution of the enumeration problem as well as the corresponding computational scheme proposed by Flory [11,156] are nowadays considered obsolete. It is much more convenient to use for this purpose the methods of graph theory [175,185-195] or the theory of branching processes [196-201], which permit fairly simple and

general calculations on any ideal branched system. Thus the number of different ways in which a molecular tree with a specified number of nodes can be formed is unambiguously related to the symmetry of its configuration, investigated in the theory of graphs [186,187]. The combinatorial entropy of the graph, introduced for the first time by Gordon and Temple [187], can serve as a quantitative measure of this property of the graph. It is noteworthy that Gordon and coworkers [175,186-189] have developed systematically theoretical graph concepts for the description of the products of polycondensation and certain other processes—the so called chemical combinatorial procedure. On the basis of the principle of detailed balancing, they established, for example, a relation between the equilibrium constants of the chemical reactions of branched macromolecules and the combinatorial entropy of the corresponding molecular graphs in ideal polycondensation.

In order to calculate the combinatorial entropy, it is convenient to replace molecular trees by rooted trees. A rooted tree is understood to be one where one of the nodes is distinguished and called the root of the tree [151]. A number equal to the length of the trail connecting any other node with the root is assigned to the given node. This number is called the number of the generation in which the given node is located. A rooted tree is usually represented by a genealogical tree in which all the nodes of a single generation are distributed on a single horizontal line together with all the pendant vertices connected directly to the nodes of the preceding generation. All the possible rooted trees with two trifunctional nodes are represented below:

Evidently two rooted trees can be regarded as identical only if the number and sequence of their vertices (including pendant vertices) in each generation are the same. Having chosen as the root a particular node of the molecular tree and having arranged its vertices in different ways in each generation, we obtain several different rooted trees with the topological structure of the initial molecular tree. It is found [186] that the combinatorial entropy of the latter is related by a simple formula to the number of different rooted trees obtained from it. This number is defined in a standard way in the theory of the enumeration of graphs.

However, the simplest and most universal method of enumerating rooted (genealogical) trees is provided by the theory of random branching processes or more precisely by the Galton-Watson model for such processes [196,197], developed by Good and Otter [198-201]. The formalism corresponding to this theory permits not only a unique enumeration of all such trees but also allows one to determine the probability of each of them. A branching process is one involving the random generation and destruction of particles arranged in the generations of the genealogical tree starting from its root K (Fig. 2) and each particle can reproduce, independently of others, a particular number of new particles (descendants) in the next generation with a specified probability. In the description of branched polycondensation processes either the nodes or the edges between them can be arbitrarily chosen as the particles. The rooted tree represented in Fig. 2 corresponds to one of the individual products of the polycondensation of a trifunctional monomer, the nodes of the tree having been chosen as the particles. The root particle reproduces all others in the first generation; the left-hand particle gives rise in its turn to two particles, while the right-hand particle gives rise to none at all, etc. In the ideal joint polycondensation of several monomers the corresponding molecular and rooted trees contain nodes of different types (a specific colour is assigned to each monomer). The branching process describing such systems must therefore also involve several types of particles, each with its own probabilities of giving rise to a particular number of descendants.

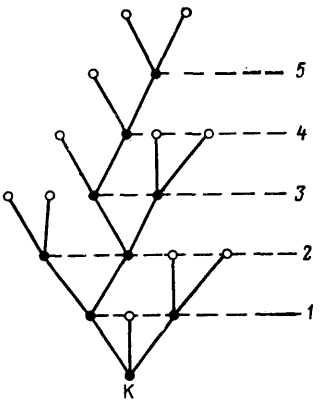


Figure 2. Genealogical tree which is one of the manifestations of a branching process for the ideal polycondensation of a monomer RA^3. The dashed lines connect all the particles of a single generation, whose number is designated by a numeral; K—the root of the tree.

Gordon [202] was the first to suggest that the method of the theory of branching processes be used in calculations on products of ideal branched polycondensation, which led to significant progress in the quantitative description of such systems. Thus the use of a branching process with several types of particles made it possible to calculate [203] fairly simply and uniquely the critical conversions and SCD of a polymer for most general ideal polycondensation systems. Analogous results were obtained independently in some instances by other workers [204,205], who also used for this purpose the theory of branching processes. A rigorous mathematical proof of the applicability of this theory to equilibrium ideal polycondensation processes has been given by Gordon et al. [188]

Another possible approach, which makes it possible to calculate the statistical characteristics of the polymer, consists in the derivation and solution of kinetic equations for the concentrations of various components in a polycondensation process [140,206,207]. When such equations are derived for ideal systems, it is sufficient to distinguish macromolecules solely in terms of the number of functional groups and intramolecular bonds of different types, which significantly facilitates their solution. The results obtained by Kuchanov [140] describe the general irreversible ideal polycondensation process involving an arbitrary number of monomers with any number of types of functional group in each. The SCD of the polymer, found from the solution of the corresponding kinetic equations, agrees

with that calculated with the aid of the theory of branching processes. This confirms that any statistical characteristics of the products of ideal polycondensation processes with specified concentrations of the end groups and intramolecular bonds of all types are independent of whether or not the process takes place under equilibrium conditions. Thus, the critical conversion, MWD, and SCD of the products of ideal branched polycondensation can be calculated in the most general form by both statistical and kinetic methods.

A convenient procedure for the experimental test of the ideality of specific polycondensation systems involves the measurement of the degree of reaction at the gel point, which can be usually done fairly accurately on the basis of the sharp increase of the viscosity of the reaction mixture. The critical conversion has been determined by this method for a fairly large number of systems. When the polycondensation of many of these was carried out in bulk, the experimental values proved to be fairly close to the calculated results obtained by the methods described above. Some of these systems are presented in the Table. The slight discrepancy between theory and experiment can be explained[156] by the occurrence of intramolecular reactions leading to some increase of the critical conversion.

Comparison of the theoretical and experimental conversions at the gel point for certain systems.

The statistical characteristics of the products of polycondensation processes examined above do not by themselves yield complete information about the properties of the polymer obtained. Thus many physicochemical parameters of branched macromolecules in solution (average size, intrinsic viscosity, intensity of light scattering, and hydrodynamic Stokes radius) are determined by their conformational and configurational structures. The problem therefore arises of the calculation of the corresponding statistical characteristics of macromolecules by averaging with respect to all their conformations and configurations. In the solution of this problem it is usually assumed[203,208-212] that each chain in the branched macromolecule is freely jointed and is at the same time capable of assuming different conformations regardless of the positions of other parts of the macromolecule. In addition it is postulated that chemical reactions do not affect the conformational equilibrium. These assumptions permit averaging with respect to all the conformations of the molecule with an arbitrary configurational structure and the problem reduces to the calculation of the probabilities of different configurations. In ideal systems methods of the theory of branching processes are again the most suitable for this process. The average dimensions of branched macromolecules formed in the ideal polycondensation of a monomer RA^f [208] and in the polycondensation of several monomers[203] were calculated for the first time with their aid. The theory of branching processes has been applied most logically and fully to the study of the configurational statistics of polycondensation polymers[209-212]. As a result, all the physicochemical parameters enumerated above were calculated by a single method for any ideal branched polycondensation processes, including multicomponent processes[212]. This greatly extends the scope of the experimental test of the theory of such systems. However, one should note the complete neglect in the above calculations of the excluded volume effect, which may play an even greater role in branched polymers than in linear polymers.

So far our discussion of ideal systems was restricted to the purely homogeneous stage of the polycondensation process, up to the gel point. It is important to determine the properties of a classical polycondensation system after the onset of gel formation during the period of the so called hardening when the reaction mixture contains two fractions: the insoluble gel and the dissolved low-molecular-weight sol, the proportion of which decreases with increase of conversion. If the initial postulates of the theory of ideal systems are formally adopted, it is necessary to "prohibit" all intramolecular reactions, including those in the macroscopic gel molecule. The corresponding model was proposed first by Stockmayer[180] and was later developed in detail by Whittle[213]. Here the complete conversion of functional groups cannot exceed a limiting value (equal to $2/f$ for the polycondensation of a monomer RA^f) and the MWD of the sol fraction as well as its average degree of polymerisation remain constant throughout the "hardening" process[213,214] (Fig. 3*a*). The hypotheses underlying this model correspond to virtually infinite rigidity of the gel molecule, as a result of which the effective local concentrations of its end groups in the vicinity of each of them, which determine the rate of the intramolecular reaction, may remain much smaller than their average concentration in the reaction mixture. It is noteworthy that classical systems obeying such rules are not known at the present time[214].

A more realistic model for the calculation of the statistical characteristics of the polymer beyond the gel point was proposed by Flory[156,215]. Here intramolecular reactions are prohibited only in molecules of the sol fraction and Flory's principle of equal activity is assumed to be valid for all the remaining polycondensation reactions, including the cyclisation reactions in the gel. Hence it is assumed that the intramolecular reactions between the functional groups of the gel fraction proceed, like the intermolecular reactions, in conformity with the Law of Mass Action. With these assumptions, all the statistical characteristics of the sol fraction, including the proportion by weight, as for ideal systems up to the onset of gel formation, and the average degree of polymerisation of the molecules beyond the gel point[217] can be calculated by methods of the theory of branching processes for both polycondensation[205,208,216] and copolycondensation systems[203,212]. The results of some of these calculations

for the polycondensation of a trifunctional monomer are presented in Fig. 3*b*. It is noteworthy that the hypothesis of the validity of the Law of Mass Action for reactions between functional groups belonging to the same macroscopic network is not entirely correct even for infinite flexibility of its chains, because here too the motion of its functional groups is not absolutely free and hence absolutely random. Nevertheless, this model gives a much better description than the previous one of the products of real polycondensation processes, which is confirmed by the experimental values of the statistical and physicochemical characteristics of the sol fraction[212,218].

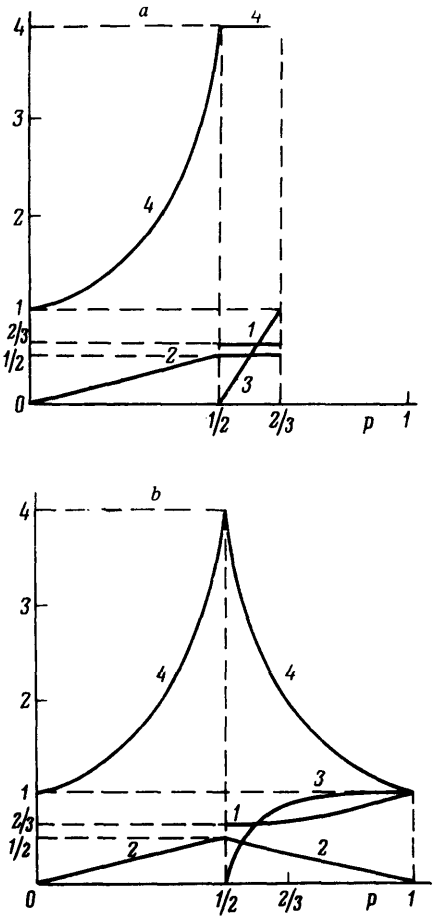

Figure 3. Calculated relations between certain statistical characteristics of the polymer and the conversion of the functional groups in the ideal polycondensation of a monomer RA^3 for the Stockmayer[180] (*a*) and Flory[156] (*b*) models: 1) conversion of the functional groups of the gel fraction; 2) ditto for the sol fraction; 3) proportion by weight of the gel fraction; 4) number-average degree of polymerisation of the sol fraction.

Various theories of the viscoelasticity and swelling of polymer gels[219-221] include as a parameter the number N_e of elastically active chains (EAC)§ of the network. For example, the modulus of elasticity and hence the strain on extension are proportional to N_e.[220] The theory of branching processes makes it possible to calculate N_e and the average length L_e of the EAC in gels formed in ideal polycondensation for the second of the two models discussed above[225]. However, the results obtained can apparently be used only during the initial period of gel formation even in ideal systems. This is because this type of treatment, based on the theory of branching processes, suffers from internal contradictions. On the one hand, a branching process can only be represented by trees, which applies entirely also to the configurational structure of the macroscopic gel molecule. On the other hand, intramolecular reactions in the gel, which are bound to occur beyond the gel point in the model employed, lead to the formation of cyclic fragments. This contradiction entails the so called paradox of "Malthus packing"[214,226,227], consisting in the fact that rooted trees, which are manifestations of the branching process, cannot be accommodated ("packed") in the three-dimensional space beyond the gel point in such a way that the average density of their nodes does not increase without limit as the generation number increases. This follows from the fact that, when $p > p^*$, the average number of particles in each generation, calculated with the aid of the branching process, increases exponentially as $(p/p^*)^n$ with the number n of the generation, whereas the volume in which they must be distributed is proportional to n^3. Only in the immediate vicinity of the gel point ($p/p^* \simeq 1$), where the number of rings in the gel is still relatively small, can one expect the theory to be adequate. Some studies[220,228-230] have demonstrated a satisfactory agreement between the theory and experiment in weakly structured polycondensation gels (Figs. 4 and 5).

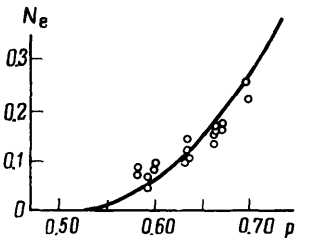

Figure 4. Dependence of the EAC concentration on the conversion determined experimentally from the equilibrium swelling of a phenol-formaldehyde resin[229]. Continuous line—theoretical curve calculated for the corresponding ideal system[220,229].

§This is the name given to any chain bounded by two nodes, each of which has at least three bonds directed to the boundary of the network and containing no other nodes of this kind within it[222-224].

It is noteworthy that the polycondensation reaction in a strongly cross-linked gel cannot proceed under kinetic conditions at all owing to the considerable diffusion-dependent hindrance to the motion of functional groups, which makes it still more difficult to construct an appropriate theory.

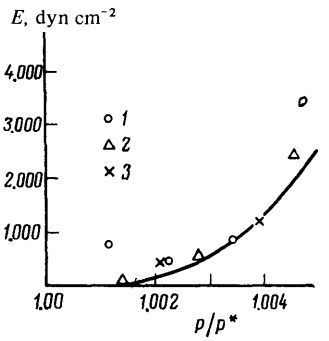

Figure 5. Dependence of the modulus of elasticity E on the conversion of the functional groups for the products of the joint polycondensation of a stoichiometric mixture of decamethylene glycol and benzene-1,3,5-triacetic acid in the melt at 423 K, obtained in three independent experiments (*1–3*) in the "critically branched region" [230]. Continuous line—theoretical curve calculated [230] with the aid of the classical theory of viscoelasticity in which the EAC concentration is evaluated from the formulae for the corresponding ideal system.

Summarising, we may thus say that the theory of ideal branched polycondensation processes is virtually complete only in the field of pre-critical conversions and permits the calculation of the statistical parameters of the reaction products in the immediate vicinity of the gel point. On the other hand, theoretical study of the polymer for higher conversions, particularly of the structure of highly cross-linked gels, constitutes a problem which is still far from being solved. Its solution within the framework of the model of ideal polycondensation is in principle impossible.

The above theoretical results permit the calculation from the known kinetic or thermodynamic parameters of a specific polycondensation system of various statistical characteristics of a polymer obtained for different conversions (both before and after the onset of gel formation) and thus one can obtain extensive information about its structure and about the associated physicochemical and mechanical properties of the products. Combined experimental studies make it possible to establish the adequacy of the ideal model in the process investigated. The initial monomers should then be as far as possible rigid and should have functional groups at a fairly large distance from one another in order to avoid cyclisation and substitution effects. Examples of such monomers have been published [231].

This type of combined study has been recently carried out by Gordon and coworkers [212,218,230,232–236] for the copolycondensation in bulk of a stoichiometric mixture of decamethylene glycol and benzene-1,3,5-triacetic acid. Kinetic measurements established [212] that this reaction is described by a third-order kinetic curve and that its rate is independent of temperature in the range 413–443 K. The weight fractions of both monomers and the dimer, throughout the region up to the gel point, were measured [232] with the aid of gel permeation chromatography and it was possible to compare them with the theoretical values for an ideal system (Fig. 6). The so called critically branched polymer [218], i.e. specimens obtained in the range of conversions directly adjoining the critical conversion both on the left-hand side ($p < p^*$) and on the right-hand side ($p > p^*$), has been studied in particular detail [218]. Thus the value $p^* = 0.720 \pm 0.006$ has been determined with a high accuracy from the measured viscosities of the system in the pre-critical region [230,233] (Fig. 7), which agrees fairly well with the theoretical value $p^* = 1/\sqrt{2} \simeq 0.707$. Hence it was concluded that a "critically branched polymer" contains virtually no rings (not more than one ring bond in one hundred [218]). The modulus of elasticity E was measured by the method developed previously [237] immediately beyond the gel point for different conversions [220,230,233]. Its values also agreed satisfactorily with the calculated results (Fig. 5).

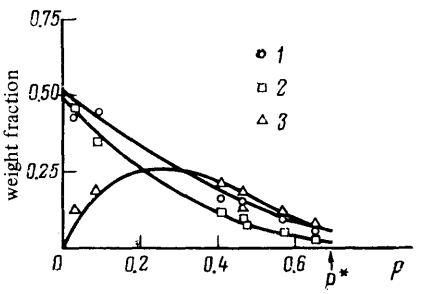

Figure 6. Variation of the weight fractions of decamethylene glycol (*1*), benzene-1,3,5-triacetic acid (*2*), and the corresponding dimer (*3*) with increased conversion of the functional groups in the joint polycondensation of these monomers in the melt at 423 K. The experimental points were obtained [232] by gel permeation chromatography. Continuous lines—theoretical curves for the ideal system [232].

In addition, the following further experiments were performed on the system considered. Specimens of a "critically branched polymer", taken both before the gel point and after it (sol fraction), were stabilised by the addition of monofunctional compounds in order to bind the residual functional groups [234]. The specimens were then dissolved in butanol [236] or ethyl methyl ketone [212,235] at 298 K. The average square of the macromolecular radius z was measured by the light scattering method [212,236] and the sedimentation and diffusion coefficients were determined with the aid of an ultracentrifuge [235] in the solutions thus obtained. The calculation [212,218], carried out with the aid of the theory described above for ideal systems, made it possible to evaluate from these data the weight-average molecular weights of the specimens, which proved to be close to the corresponding values obtained from kinetic and viscometric experiments. In addition, the average distance between the monomeric units in the molecules was calculated. The values of the latter quantity agreed

almost fully for pre-gel and post-gel specimens and were found to be almost independent of the molecular weight[212,218], which also confirms the validity of the theory used in the calculation. Thus extensive experimental and theoretical studies demonstrated the virtually complete adequacy of the ideal polycondensation model for the system under consideration, which gives rise to the hope that the model may be used widely in the investigation of the properties of the products of various branched polycondensation processes.

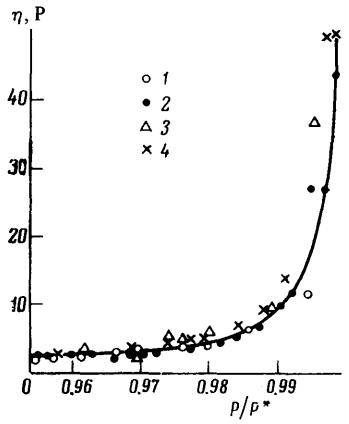

Figure 7. Variation of the viscosity η with the conversion of the functional groups in the "critically branched region" for the same system as in Fig. 5, measured in four independent experiments (*1–4*).[230] The continuous line is described by the theoretical relation between η and the weight-average molecular weight calculated from the formulae for the ideal system [232].

2. The Substitution Effect

As a result of the substitution effect in branched polycondensation, the reactivities of isomers with the same degree of polymerisation may be different. For example, in the first-order substitution effect model, where the activity of an arbitrary functional group depends on the number and positions of groups of each type which have reacted and which are attached to the monomeric unit containing the given group, the reactivity of the molecule is determined by the numbers of its monomeric units with different configurations. It is therefore necessary to distinguish molecules in this model in terms of this feature. Correspondingly, in second-, third-, and higher-order substitution effect models all the molecules are distinguished in terms of the different configurations of pairs, sets of three, etc. adjacent monomeric units present in them. In calculations on the corresponding processes the same methods were used[226,238–246] as for ideal systems but with certain modifications.

The first calculation on a branched polycondensation process taking into account the first-order substitution effect was carried out by Gordon and Scantlebury[238] in the polycondensation of a monomer RA^f. In all the studies published to date, with two exceptions[226,239], the substitution effect was taken into account only within the framework of this model, which will be henceforth assumed to be understood and will no longer be stipulated. Gordon and Scantlebury[238] used the methods of the theory of branching processes in their calculation, but proposed a method for specifying the probabilities of the multiplication of particles different to that in ideal systems. They suggest that the probability that a particle generates a particular number of descendants depends on the configurational structure of the unit corresponding to the particle. Gordon and coworkers believed that their theory describes any polycondensation of a monomer RA^f and they calculate the parameters of the model for two extreme cases: equilibrium and irreversible processes [238]. Gordon and Scantlebury[238] obtained the dependences of the number-average and weight-average molecular weights and of the conversion at the gel point on these parameters, while Dobson and Gordon[208] extended these results to the calculation of the statistical characteristics of the sol fraction of the polymer beyond the gel point. Using a similar computational method, Luby[240] later calculated the distribution of the polymer molecules with respect to the numbers of their monomeric units containing different numbers of groups which have reacted. Gordon and coworkers[238,241] believe that the products of both equilibrium and non-equilibrium polycondensation of any number of arbitrary monomers may be described with the aid of a branching process, taking into account the substitution effect in the monomers, by analogy with ideal systems. In particular, such a process has been indicated[241] for the $RA^2 + SB^f$ system (only groups of different types react) with the substitution effect in both monomers. Since the mathematical apparatus for branching processes makes it possible to calculate all the necessary statistical characteristics of the polymer, Gordon and coworkers thus regard the theory of branched polycondensation with the substitution effect as complete in principle[226].

However, this view is open to objection for several reasons. In the first place the applicability of the methods of the theory of branching processes to calculations on the systems considered was not proved[226,238,241]. The necessity for such proof becomes clear even from an examination of the simplest of these sytems: the polycondensation of a monomer RA^f with allowance for the substitution effect. Analysis showed[239] that the products of the corresponding equilibrium process can indeed be described by methods of this theory. On the other hand, the MWD of the polymer obtained in irreversible polycondensation with the substitution effect does not agree with the formulae of the theory of branching processes. This can be tested by substituting them in the corresponding kinetic equations[12]. Consequently the question of the applicability of the theory of branching processes, like that of any statistical method, to the calculation on each specific polycondensation system with the substitution effect requires separate analysis.

Another statistical approach to the description of the products of equilibrium polycondensation with the substitution effect was proposed by Whittle[242,243]. This method is based on the application of the principle of detailed balancing to specific equilibrium reactions occurring in the system, using in the calculation elements of graph theory. Whittle examined theoretically the polycondensation of both a single monomer RA^f [242] and of several types of monomers $R_iA_i^{f_i}$, but only for the case where the reactions take place between the functional groups of different monomers[243]. His method makes it

possible to calculate the statistical characteristics of the polymer before the onset of gel formation and to calculate the critical conversion at the gel point. For a single monomer, Whittle's results agreed[242] with the corresponding values which follow from the theory of branching processes[238]. For copolycondensation processes, Whittle's study did not reach the stage of computational formulae. Some workers[168,169,244,245] calculated the gel point in specific branched polycondensation processes with the substitution effect by Flory's statistical method having extended it to the case where one of the monomers involved in the process has dependent groups. In these studies[168,169,244] the substitution effect was taken into account only for groups of bifunctional monomers and in that of Durand and Bruneau[245] only for a trifunctional monomer. The study of Kuchanov and Pis'men[246] is the only one where a calculation was performed on the branched polycondensation of monomers with dependent groups by a kinetic method. They proposed a general approach, which makes it possible to derive the corresponding kinetic equations for polycondensation processes in which the substitution effect is significant.

The second-order substitution effect was considered theoretically for the first time by Gordon and Parker[226] for the polycondensation of a monomer RA^f. They suggested that the MWD of the products of the corresponding reactions be described in terms of a branching process. However, as noted above, even in the first-order substitution effect model the statistical characteristics of the products of non-equilibrium polycondensation in such a system cannot be described with the aid of any branching process. This also applies to the second-order substitution effect model. The applicability of the method of the theory of branching processes to the calculation of the products of equilibrium polycondensation within the framework of this model was proved by Brun and Kuchanov[239], who also established a relation between the statistical parameters of the branching process and the thermodynamic parameters of the system. In the formal approach used by Gordon and Parker[226] this relation was not established, which significantly restricted the possibilities for the interpretation of the experiment.

The presence of the substitution effect in branched polycondensation processes was tested in the synthesis of polyesters[241,245,247], polyurethanes[248], and phenol-, melamine-, and urea-formaldehyde resins.[249,250] In particular, a small positive substitution effect, where the bonds formed accelerate the reaction of the terminal groups adjoining the monomeric unit, was established for pentaerythritol, tris(hydroxymethyl)ethane, and tris-(hydroxymethyl)propane in their esterification by adipic or lauric acids[241,247,249]. On the other hand, in the formation of polyurethanes a negative substitution effect was observed[248]. The study of Durand and Bruneau[245] merits most attention among the available experimental investigations. In relation to the polycondensation of tris(hydroxymethyl)propane (SB^3) with adipic (R_1A^2) and lauric (R_2A) acids in the melt, they proposed a general method for testing the adequacy of the substitution model in a specific process and a procedure for determining the parameters of this model. For this purpose, they esterified tris(hydroxymethyl)propane with lauric acid in a preliminary step under the same conditions. The products of this reaction were analysed on a chromatograph and the results were used to determine the fractions of tris-(hydroxymethyl)propane which failed to react and of its mono-, di-, and tri-esters for different conversions. The kinetic constants for the esterification of the functional groups of the same monomers, whose ratios characterise the substitution effect in the triol, were evaluated by comparison with the calculated relations. The conversion at the gel point for the initial process was then calculated from the observed kinetic parameters and was compared with the corresponding value obtained from an independent experiment.

3. Cyclisation in Polycondensation Processes

The intramolecular reactions occurring in the course of branched polycondensation lead to the formation of macromolecules with a particular number of different rings. The corresponding molecular graphs should also contain cyclic fragments. The problem of the identification of such cyclic graphs is much more complex than the corresponding problem for trees. However, its solution is necessary for a complete physically adequate description of intramolecular reactions, because, as already mentioned in the introduction, in contrast to ideal systems the calculation requires allowance for long-range effects in this instance. A rigorous quantitative theory of branched polycondensation accompanied by cyclisation is lacking at the present time, although there have been individual studies[190,206,243,251-261], whose authors attempted to solve the corresponding problem by means of various arbitrary assumptions. However, the latter are more likely to obviate the mathematical difficulties arising in the calculations than to reflect the physical picture of the process. At the same time any scientifically well founded model must take into account to some extent the physicochemical features of the system.

We shall next consider briefly the factors which may influence the course of intramolecular reactions in branched polycondensation and shall point out the possible approaches to their quantitative description. An attempt will also be made to analyse the initial postulates underlying the available models, which permit calculations on the products of the corresponding processes. This is of interest because the authors of the models themselves were not concerned with problems of their physicochemical justification. Although, for the sake of simplicity, we shall discuss only condensation reactions in a homopolymer among all the possible intramolecular transformations, the consideration of analogous reactions in copolymers and also of intramolecular exchange reactions does not alter the qualitative picture of the process.

The elementary step in the intramolecular condensation reaction consists in the interaction of two terminal groups of one molecule with formation of a cyclic fragment in the latter. The probability of such interaction is determined by the relative steric positions of the reacting groups, which depend on the conformational-configurational structure of the molecule. Depending on which pair of functional groups react, particular configurational isomers of the initial molecule will be obtained. Here it is significant that the interaction constants are generally speaking different for each pair. The interconversions of isomers associated with intramolecular reactions therefore have different probabilities. On the other hand, the pair of functional groups which have reacted can be deduced unambiguously from the configurational structures of the initial and final isomers and hence the rate constant for the corresponding unimolecular reaction can be determined (or the corresponding equilibrium constant, if equilibrium is established). Thus, in order to construct

a rigorous theory of branched polycondensation with cyclisation, it is, firstly, necessary to identify in some way all isomers and, secondly, to specify the probabilities of their interconversions. However, the problem can hardly be solved in this general formulation. It is therefore apparently necessary to construct less general models in which the nature of the simplifying assumptions is associated with specific physicochemical characteristics of the system under consideration. These characteristics must determine a particular set of values of constants for the interaction between possible pairs of functional groups in each molecule. By virtue of such model assumptions, there is a possibility of either a significant decrease of the number of transitions between configurational isomers which can occur as a result of intramolecular reactions or many such transitions can become equally probable.

We shall now quote certain considerations concerning the possible selection of these constants. Regardless of whether or not polycondensation is carried out under equilibrium conditions, the probability of the interaction of any two functional groups, say the ith and jth groups, belonging to a macromolecule with a specific configurational structure σ is determined by the effective concentration c_{ij}^{σ} established by one of them in the immediate vicinity of the other for different conformational rearrangements of the molecule in which they are contained. One of the quantities characterising the relative positions of an arbitrary pair of groups in the molecule is the number of chains connecting these groups with one another. In a tree-like molecule, any two functional groups are joined by a single chain. If the fraction of bonds present in cyclic fragments of the molecule (cyclic bonds) is small, a greater proportion of its functional groups possesses this property. It is reasonable to suppose that in this case c_{ij}^{σ} for each pair of such groups depends only on the statistics of the possible conformations of the chain connecting them, which can be determined, as for linear molecules, either by means of the model of a freely jointed chain or the corresponding rotational isomer model. This approximation implies that, in the calculation of the conformational structure, account must be taken only of short-range order effects; the long-range order effects (excluded volume) are neglected. With increase of the number of cyclic bonds, there is an increase of the fraction of functional groups connected by two and more chains. Calculation of the effective concentrations of these groups becomes significantly more complicated. On the one hand, because of the presence of cyclic fragments the corresponding sections of micromolecules contract and become denser, which should lead to an increase of c_{ij}^{σ} and, on the other hand, these sections become more rigid as a result of the appearance of cross-linked structures (skeletons), which prevent the formation of the conformers necessary for the occurrence of the intramolecular reactions. In addition, it is necessary to take into account the possibility of the appearance of loops, nodes, etc.

We shall consider the approaches, described in the literature, to a quantitative description of the products of branched polycondensation accompanied by cyclisation. Here we shall state the conditions which must be imposed on the possible values of c_{ij}^{σ} in a particular model and hence shall define the initial postulates underlying each of them. In the first place we may note that, if we put $c_{ij}^{\sigma} = 0$ for all the functional groups, we arrive at the ideal polycondensation model, naturally subject to the condition that Flory's principle holds for intermolecular interactions, which henceforth will be always understood. In order to carry out calculations on the irreversible polycondensation of a monomer RA^f with allowance for intramolecular reactions, Hoeve[252] extended the statistical Stockmayer method[180]. It was assumed that in the macromolecules formed each monomeric unit may form part of not more than one ring, so that the homopolymer molecules differ not only by the degree of polymerisation, as in Stockmayer's treatment[180], but also by the numbers of monomeric units in rings of different sizes present in them. Hoeve[252] was able to solve the corresponding combinatorial enumeration problem and hence could determine the MWD of the polymer up to the gel point and the critical conversion p^*. His assumption that each monomeric unit belongs to not more than one ring is equivalent to the condition $c_{ij}^{\sigma} = 0$ for all the functional groups connected by two and more chains. It should not influence the result significantly when the number of such groups is comparatively small, i.e. for a small fraction of cyclic bonds. However, the statistical method used in the calculation can be justified only for equilibrium process conditions. On the other hand, the statistical characteristics of the configurational structure of the polymers obtained under the conditions of equilibrium and in its absence should differ in this model (this can be readily shown, for example, for the specific case where $f = 2$). The results obtained[252] for an irreversible process are therefore erroneous. On the other hand, at equilibrium it is possible to deduce from them that the critical conversion p^* is smaller than its value for the corresponding ideal system and to a greater extent the lower of the concentration of monomeric units, i.e. the higher the dilution of the reaction mixture.

In order to deduce the initial postulates underlying other models, we shall consider the effective concentration $c_i^{\sigma} = \sum_j c_{ij}^{\sigma}$ set up in the vicinity of a definite functional group i of a macromolecule by all other groups in this molecule. The quantity c_i^{σ} defines the probability that the ith group is involved in any intramolecular cyclisation reaction and in the general case depends not only on the rigidity and configuration σ of the macromolecule but also on the site occupied by the ith group in the latter.

The same system was considered by Pis'men and Kuchanov[206] as in Hoeve's study[252], but only the kinetic method was used and there were different model assumptions. In the derivation of the corresponding kinetic equations for the concentrations of the macromolecules the authors assumed that the probability of the involvement of a functional group of the molecule in a cyclisation reaction is proportional to the total number of groups in this molecule. Examination of the solution of the equations derived showed[206] that, within the framework of the model considered, the gel point is absent in its classical definition. For a fairly low value of the parameter ϵ (equal to the ratio of the probabilities that the functional groups is involved in intramolecular and intermolecular reactions respectively), the instant of gel formation is defined mathematically not as a point but as a narrow (narrower the lower the value of ϵ) range of conversions, during which there is a sharp change in the weight-average degree of polymerisation, although the latter never becomes infinite[206]. This model corresponds to the assumption that the effective concentration c_{ij}^{σ} for any pair of functional groups in the reaction mixture is the same regardless of, for example, the number and length of the chains

connecting them. Consequently this assumption completely ignores the conformational structure of the molecules. The value of c_i^{σ} for all the functional groups in each macromolecule is then independent of i and is proportional to their total number in the molecule.

On the analogous model assumption, the same system, but under equilibrium conditions, was considered by Harris[251] and Whittle[243] (Harris[251] proposed yet another model, which will be analysed below). In the first of these studies Stockmayer's statistical approach was used[180], but the molecules differed not only by the number l of monomeric units but also by the number s of their intramolecular bonds, so that the probability of any molecule was determined by the values of l and s. It was assumed that any group can form an intramolecular bond without any restrictions, including a cyclic bond, with any group in the system, i.e. no restrictions were imposed on the set of configurations considered. In the second study[243] the calculation was performed with the aid of the principle of detailed balancing together with elements of graph theory. It was found[243] that the weight-average degree of polymerisation of products becomes infinite at an infinitesimal conversion, which is qualitatively inconsistent with the corresponding result[206] for an irreversible process. The absurdity of the value $p^* = 0$ obtained, which the authors themselves noted[243,251], is associated with the complete neglect of the conformational and configurational structure of the molecules in the model. The probability of any molecule with definite values of l and s is in this case proportional to the number of all possible steric configurations with the given values of these quantities. This number increases with increasing l and s (much faster than in the case of trees) and, for macromolecules with a high degree of polymerisation, becomes so large that the probability of a macroscopic gel molecule becomes non-zero however low the conversion.

Another model for calculations on the products of the polycondensation of a monomer RA^f has been proposed by Irzhak et al.[259]. In this case the intramolecular reaction is regarded as one of the variants of chain termination where any functional group can be involved in the cyclisation reaction regardless of the others and can thereby lose the capacity for further participation in the process. In conformity with this hypothesis, it is suggested that the calculation be carried out with the aid of a special branching process. In order to take into account the intramolecular reactions, particles of another type, incapable of multiplication and corresponding to the groups which have reacted with formation of cyclic bonds, were introduced into the model. The model corresponds to the ideal polycondensation of the initial monomer in the presence of a monofunctional impurity giving rise to chain termination, and the model therefore permits a simple calculation of any statistical characteristics of the polymer. Apart from the conversion, a parameter of this model is the probability of cyclisation, i.e. the probability that a group which has reacted is involved in a cyclic bond. The critical conversion p^*, calculated in this way, increases for larger values of this parameter. An attempt has been made[260,261] to calculate it and to justify the proposed model in the case where only groups joined by a single chain can take part in an intramolecular reaction. For this purpose, the probability of the cyclisation of any group is represented by the sum of the probabilities of their reaction with formation of rings of all possible sizes. In the calculation of these probabilities use is made of the conformational statistics of a freely jointed chain and also of the hypothesis that the size of any ring formed when two groups interact is equal to the difference between the numbers of generations of the genealogical tree (Fig. 2) in which they are located. However, such an attempt to calculate the probability parameters within the framework of the same statistical method is incorrect, because two functional groups, even those in the same generation, may be joined by a chain of arbitrary length and therefore the ring formed when they react can also be of any size. In fact the model proposed by the authors[259-261] is based on the hypothesis that the effective concentration c_i^{σ} for any functional group in the reaction system is independent at each instant of the molecule to which the given group belongs and of the site where it is located within the molecule. This is equivalent to the employment of the Flory principle for intramolecular reactions. Hence it follows, in particular, that the statistical characteristics of products, including the critical conversion, are independent, as for ideal polycondensation, of whether or not the process is carried out under equilibrium conditions.

In fact this hypothesis also constituted the basis of an earlier study by Kilb[253], who calculated the critical conversions in the $RA^2 + SB^f$ and $RA^2 + S_1B^2 + S_2B^f$ systems, in which the condensation reaction takes place only between groups of different types. Kilb was able to complete the calculation only for the first of these systems. In contrast to previous workers, he used for this purpose Flory's statistical method, which is fairly cumbersome and is not one most convenient for calculation, having extended it to the case where each functional group can be involved in the cyclisation reaction with a certain probability. Although this computational scheme is technically more complex than that employed in other studies[259-261] (particularly because the assumptions underlying it are less evident), the two schemes are fully equivalent from the standpoint of the final results. All the conclusions and remarks which we have made concerning the initial postulates of the model devised by Irzhak and coworkers[259-261], including the cyclisation probabilities associated with the calculation, are fully applicable also to Kilb's results[253].

Yet another model for calculations on the equilibrium polycondensation of the monomer RA^f accompanied by cyclisation, which resembles, from the standpoint of the initial assumptions, the models just described, was proposed by Harris[251] in order to obtain more likely results than those which follow from his first model. He again used Stockmayer's method, distinguishing molecules in terms of the degree of polymerisation and the number of bonds, but he significantly decreased the number of allowed steric configurations. Harris suggested for this purpose that each functional group of the molecule, having the configurational structure of a tree, can form a cyclic bond with a definite number of other groups of the same molecule, which is independent of the degree of its polymerisation (but not with all the groups, as in the first model). With increase of the number of cyclic bonds in the molecule, the number of groups remaining in it diminishes and there is a proportional decrease of the number of groups capable of forming a bond with the given group. On these assumptions, Harris was able to complete the calculation of only the gel point for the system. It was found that the critical conversion increases with dilution of the reaction mixture and there exists a dilution above which there is no gel formation whatever the conversion. The initial assumptions of Harris's model are as follows. Flory's principle holds for the

intramolecular reactions of the functional groups of tree-like molecules, i.e. the concentration c_i^{σ} for such molecules is independent of both i and σ. For the groups of other molecules, the values of c_i^{σ} depend only on σ and decrease with increase of the number of cyclic bonds in proportion to the number of terminal groups remaining in the molecules.

Finally, we shall consider the computational scheme proposed by Gordon and coworkers [254-258]. It makes it possible to calculate the statistical characteristics of the polycondensation and cyclisation products derived from one and several monomers, both before and after the gel point, including the critical conversion, even in the presence of the substitution effect. For this purpose, the authors [254-258] suggest that a branching process be used with an additional type of particles, corresponding to the functional groups which have reacted with formation of cyclic bonds. However, in contrast to Irzhak and coworkers [259-261], Gordon and coworkers suggest [254] that the probability that an arbitrary particle reproduces a particular number of other particles in the next generation depends, as for the first order substitution effect, on the number of functional groups which have reacted in the monomeric unit corresponding to the given particle. The authors [254-258] believe that the computational scheme which they proposed can describe fairly satisfactorily any branched polycondensation process involving intramolecular reactions regardless of whether or not it is carried out under equilibrium conditions, provided that the probability parameters of the corresponding branching process are specified in the appropriate manner. They also attempted to justify their model for the case where only functional groups linked by a single chain can participate in the cyclisation reaction, so that each edge of the molecular graph can form part of not more than one ring. By cutting any one edge in such a ring in an arbitrary fashion, it is possible to convert the set of such cyclic graphs into the corresponding set of trees. (In the theory of graphs the trees thus obtained are called chord trees, hence the name "the model of chord trees" [257].) Pendant vertices of yet another type, called cyclic, which appear in pairs as a result of each cut, are added in this procedure. It is suggested that [257,258] these trees, represented as rooted trees, are manifestations of the branching process.

However, this interpretation, which does not go beyond the framework of the statistical method itself, is incorrect. Indeed, suppose that two cyclic vertices, separated by a trail of length n, appear on cutting an edge. If one of the vertices is located in a certain generation of the genealogical tree, the other must be present in one of the nearest n generations. However, such obligatory appearance of particles of a specified type cannot be described, in principle, by any branching process whose particles reproduce others independently in each generation. The chord tree model is actually based on the assumption that the value of c_i^{σ} for an arbitrary functional group is determined solely by the number of groups which have already reacted in the monomeric unit containing it and is proportional to this number, i.e. the method is based on one of the variants of the generalised Flory principle for cyclisation reactions.

Thus, despite the fairly large number of models proposed, the problem of the theoretical description of branched polycondensation processes accompanied by intramolecular reactions is virtually in the very initial stage of its solution. In fact all the models now available are based on various arbitrary assumptions in no way related to specific physicochemical features of the systems considered. In particular, Flory's principle for intramolecular reactions, in contrast to intermolecular reactions, still has no physicochemical justification. Because of this, one cannot at present specify even approximately the class of suggested systems described by a particular model among those described above. The only way of testing their adequacy therefore involves a comparison of calculated results with experimental data for specific processes. However, the available experimental data [262-268] do not permit a sufficiently correct solution of the problem for systems investigated in the studies quoted above, since it is not known what contribution arises from intramolecular reactions proper relative to ideal systems. Furthermore, when attempts were made to compare the theory with experiment [263-268], the authors used adjustable parameters whose values were not determined from independent experimental data.

In conclusion we may note that, as shown by recent studies [269-274], the diagram technique of the theory of quantum fields [269] and the simulation of the process on a computer by the Monte Carlo method [270-274] may prove promising in the development of new computational methods for the solution of the problem of taking into account intramolecular reactions in branched polycondensation.

4. Related Systems

The methods for the quantitative description of branched polycondensation analysed above can be applied in the calculation on many other systems. They include the cross-linking of reactive oligomers by the polycondensation method, cyclotrimerisation, certain processes involving the synthesis of inorganic polymers, and others.

The synthesis of a three-dimensional polymer frequently takes place in two stages: oligomeric chains with terminal functional groups are obtained initially and are then structured in the presence of a bifunctional cross-linking agent. If the intermediate oligomers are linear, a polyfunctional branching agent is also added. A quantitative description of the products of such processes requires the solution of two different problems. The first consists in finding the distribution with respect to the lengths of internodal chains and the free ends of the macromolecules, while the second consists in determining the probabilities of various steric configurations of branched polymers.

Virtually all the published theoretical studies [275-278] were devoted to the first, simpler of the two problems. As stated in an early investigation by Case [275], the approach to its solution is analogous to that used in the calculation of the MWD of cross-linked linear polymers. However, in terms of the general formulation, where the initial compounds have arbitrary MWD and functionalities, this type of problem has not been solved. Calculations have only been made on certain specific systems by statistical [275,278] and kinetic [276,277] methods.

The same methods as in calculations on the products of branched polycondensation can be used in the solution of the second problem. In particular, when ideality of the system is assumed, the dependence of the gel point on the functionalities and proportions of the initial compounds may be found from the formulae for the corresponding ideal polycondensation. The justification of this calculation was demonstrated experimentally in relation to structure formation in oligobutadiene di-isocyanates with the

aid of an aromatic triamine.[279] A method has been proposed[280] for the determination of the weight-average functionality of polymers undergoing cross-linking, from the measurement of the gel point during their hardening. It employs computational formulae[181] for the dependence of the critical conversion p^* on the functionality of the initial monomers in ideal polycondensation. This method has been used to determine the functionality of oligobutadienes with terminal carboxy-[281,282] and hydroxy-groups[282] with glycerol[281] and hexamethylene di-isocyanate[282] as the cross-linking agents.

A study by Zabrodin et al.[283] was devoted to the calculation of the statistical characteristics of the branched polymers obtained when oligomers with reactive terminal groups are cross-linked by the polycondensation method. The proportions by weight of the free ends and of the gel fraction as well as the concentrations of its elastically active chains were calculated by the statistical method assuming that the system is ideal.

From the standpoint of the theory, polycyclotrimerisation processes, which constitute a promising method for the synthesis of three-dimensional polymers, are very close to polycondensation[284,285]. Six-membered elementary carbocycles and heterocycles, each of which is formed in the reaction of three functional groups of the monomers, serve as intramolecular linkages in this instance. Since the branching capacity m of an intramolecular linkage in such polymers is three (whereas in polycondensation products it is $m = 2$) gel formation is possible even in the polycyclotrimerisation of bifunctional monomers ($f = 2$). A rigorous quantitative theory of polycyclotrimerisation and of the analogous more general processes with an arbitrary value of m has been developed by Yamabe and Fukui[258-288] on the assumption that the system is ideal. Using Stockmayer's statistical method[180], they calculated the MWD and the gel point of the products of the polycyclotrimerisation of a monomer having an arbitrary functionality f and then extended these results to any value of m and an arbitrary distribution of the initial compounds with respect to the number of their functional groups. The authors[288] then set up a general quantitative theory of reactions involving the simultaneous formation of intramolecular linkages of different functionalities m. In the same study[288] the MWD and the proportion by weight of the sol fraction were calculated. In an attempt to take into account the formation of non-elementary rings in the polymer the authors[286] used in the calculation of the MWD of the cyclotrimerisation product the statistical approach devised by Harris[251], which he used to describe polycondensation processes. Naturally all the critical remarks made above concerning the justification and the limits of applicability of this approach remain in force also for cyclotrimerisation. A calculation on this process without taking into account macrorings can be carried out also with the aid of the methods of the theory of branching processes[289].

The quantitative theory of polycondensation can be applied also to the description of the equilibrium products of processes involving the formation of inorganic polymers. Here it is necessary to establish which structural units in such polymers correspond to the monomeric units, intramolecular linkages, and terminal functional groups in polycondensation macromolecules. Certain ligands usually correspond to monomeric units, while bridging atoms (for example, oxygen or sulphur) or groups of atoms correspond to intramolecular bonds. Thus the theory of ideal branched polycondensation has been applied[290] to silicate melts. The experimental gel point, the weight fraction of the gel beyond the gel point, and the concentrations of mono-, tri-, and tetra-mers were compared with the values calculated from the formulae of this theory. The experimental and theoretical gel points virtually agreed, but no such agreement was obtained for the weight fractions of the gel at some distance from the gel point. According to the author[290], this is associated with the intense cyclisation beyond the gel point.

Numerous experimental studies by Van Wazer and coworkers[291] were devoted to the investigation of various phosphorus-containing polymers, for example, poly-(phosphoryl chloride), polyphosphoryldimethylamide, polyphosphate esters, polyphosphorothioate esters, and others. An appropriate theory, using the methods for the enumeration of graphs, was devised for their quantitative description[292,293]. The results obtained in these studies[292,293] actually correspond to those which arise from the theory of branched equilibrium polycondensation taking into account the substitution effect[238]. This theory makes it possible to calculate the critical conversion at the gel point from the known equilibrium concentrations of the monomeric units with a definite number of linkages. These concentrations for a number of phosphorus-containing polymers have been found experimentally from NMR spectra[294-297]. The conversions at the gel point, evaluated from these experimental data, are in satisfactory agreement with the values determined in the same studies[294-297] by the viscometric method. The results confirm the validity of the "substitution effect" model for the description of the inorganic systems investigated.

o0o

The general quantitative theory of ideal systems, permitting the calculation of the most important physicochemical parameters of the products of many specific polycondensation processes, which may be regarded as ideal with adequate accuracy for practical purposes, can now be regarded as complete. At the same time there are just as many systems which, for different reasons, are not described by this theory. Calculations on such systems require the allowance for various factors in the kinetic model leading to the deviation of the system from ideality. The greatest advances have been achieved in this field in the quantitative description of polycondensation with the substitution effect owing to the possibility of employing the generalised Flory principle. Much more modest results have been obtained in attempts to take into account in the theory the long-range order effects, which are decisive when molecular cyclisation is considered, and also the possible influence of the conformational and configurational structure of the molecules on the reactivity of their functional groups. The number of unsolved problems in this field greatly exceeds the number of those which have been solved, which is due to the necessity to take into account the conformational statistics of macromolecules in kinetic calculations. Progress in the development of the theory of such non-ideal systems is possible only when joint efforts are made by chemists and physicists, since the given problem lies at the boundary between chemical kinetics and the statistical physics of polymers.

Trimerisation Polycondensation of Aromatic Acetyl Compounds and Their Ketals†

M.M.Teplyakov

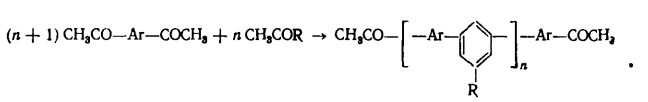
The methods of synthesis, principal properties, and aspects of the application of polyphenylenes obtained by the trimerisation polycyclocondensation (PCC) of aromatic acetyl compounds or their ketals are examined. Attention is concentrated on the analysis of the influence of the conditions of synthesis on the cyclisation process.
The bibliography includes 51 references.

CONTENTS

I. Introduction 189
II. PCC of aromatic acetyl compounds 189
III. PCC of the ketals of aromatic acetyl compounds 190
IV. Practical applications of polyphenylenes based on aromatic acetyl compounds and their ketals 196

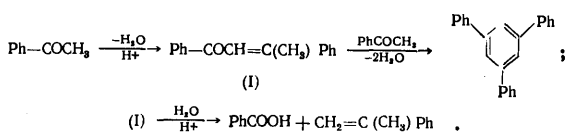
I. INTRODUCTION

One of the promising classes of thermostable polymers comprises polyphenylenes, the high thermal and chemical stability of which make it possible to use them as binders for various reinforced and antifriction materials and for other purposes.



Polyphenylenes are synthesised nowadays in various ways using a wide variety of initial monomers[1,2]. The known methods for the formation of polyphenylenes suffer from various disadvantages. Progress in the field of synthesis and particularly in the application of polyphenylenes will be determined primarily by advances in the synthesis of polymers capable of being easily worked to form various articles, i.e. polymers which are readily soluble in organic solvents, and the methods of their synthesis should be technologically viable and based on available initial monomers.

The present review deals with the synthesis and properties of polyphenylenes obtained by the trimerisation polycyclocondensation (PCC) of acetyl compounds (methyl ketones) or their ketals. On the one hand, trimerisation PCC is genetically related to polycyclotrimerisation processes, which have been considered in detail in a review[3], and on the other, this process is a specific form of PCC, the general characteristics of which have already been examined[4]. In the present review attention is concentrated on factors influencing cyclisation, since, depending on the process conditions, both the degree of completion and specific features of PCC may vary and the contribution of the branching and cross-linking reactions may increase. This can ultimately lead to an increase of the fraction of defective structures which impair the useful properties of polymers (defective sections are as a rule least thermostable and are the first to undergo degradative processes).

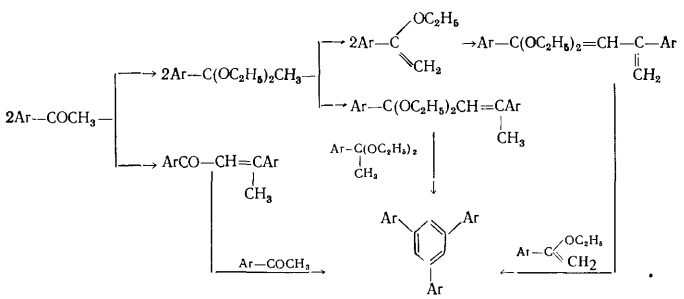


II. PCC OF AROMATIC ACETYL COMPOUNDS

The use of aromatic di- and mono-acetyl compounds as the initial monomers under PCC conditions made it possible to develop a new method for the synthesis of polymers of the polyphenylene type[5]. The method is based on the cyclocondensation of methyl ketones (acetone[6], acetophenone[7], and various aryl methyl or alkylaryl methyl ketones[8,9]) in the presence of acid catalysts, which has been known for a long time in organic chemistry.

Under the conditions of equal reactivities and without allowance for side reactions, polycyclocondensation involving the formation of polyphenylenes can be represented schematically as follows:

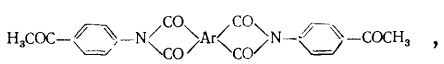
The actual process is complicated by side reactions, mainly incomplete cyclisation, and the unequal reactivities of the monomers. The cyclisation of aryl methyl ketones with formation of a benzene ring in an acid medium[8] proceeds via a dimer stage dypnone (β-methylchalcone), but dypnone can react with the liberated water to form an acid and α-methylstyrene[10]:



Acids or Lewis acids, which can simultaneously bind the water formed (H_2SO_4, $ZnCl_2$, polyphosphoric acid, BF_3, $BeCl_2$, $AlCl_3$, $AlBr_3$, dry HCl, and others) as well as certain other compounds, are therefore used as PCC catalysts[5]. The specificity of the formation of polyphenylenes under these conditions is open to doubt, since the yield of triphenylbenzenes from acetophenone does not exceed 20–50%.[9]

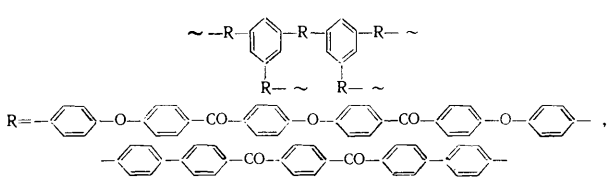
Korshak and coworkers[11,12] suggested that PCC of aromatic di- and mono-acetyl compounds be carried out in the presence of dry HCl and ethyl orthoformate in an inert solvent at approximately 20°C and put forward a

†Review commemorating the 70th Birthday of Academician V. V. Korshak.



mechanism for the elementary step involving the formation of polyphenylenes under the conditions indicated:

The PCC reaction in solution was stopped at the stage of soluble polyphenylenes with a relatively low molecular weight and residual end groups (fore-polyphenylenes), which were isolated and then converted on heating above 250°C into three-dimensional polymers as a result of further condensation of the end groups. By carrying out the process in two stages, it was possible to convert the polymers into finished articles in the second stage. The monomers used were acetophenone, *p*-diacetylbenzene, di(acetylphenyl) ether, diacetylbiphenyl, and other compounds. Equimolar or nearly equimolar proportions of the initial monomers proved to be optimal[12]. A detailed chemical study of pre-polyphenylenes obtained by the above procedure[13] showed that the chain contained approximately two defective dypnone fragments.



The employment of a single bifunctional monomer (diacetylferrocene) by Schlögl and Soukup[14] in an analogous process led to the formation of a three-dimensional product which could not be worked.

The use of bisacetylimides having the general formula

which made it possible to obtained cross-linked thermostable polymers by thermal polycyclocondensation, proved to be of interest[15]. The authors note that, when the process is carried out at 400°C without a catalyst, the product contains a fairly large number of defective structures, namely dypnone structures.

Zaitsev and coworkers[16,17] obtained cross-linked polymers having the general formula

and investigated their thermal stability.

Polymers based on the diacetyldibenzyl derivatives of *o*-, *m*-, or *p*-carbaboranes, obtained in the presence of HCl and ethyl orthoformate, proved to be the most thermostable[18,19]. The pre-polymers obtained with an average molecular weight of 1100–4600 contained, together with 1,3,5-triphenylbenzene units, also dypnone fragments and acetyl and ketal end groups. They were all readily soluble in many organic solvents: chloroform, toluene, dioxan, acetone, and others. After heat treatment at 400–450°C, they were converted into three-dimensional polymers with high thermal stability and heat resistance (according to the results of thermogravimetric analysis, no weight loss was observed on heating in air up to 900°C).

III. PCC OF THE KETALS OF AROMATIC ACETYL COMPOUNDS

Use of ketals of aromatic acetyl compounds makes it possible to carry out the PCC process more specifically and with formation of less defective structures. Korshak et al.[20] proposed a method for the synthesis of polyphenylenes from the ethyl ketals of aromatic di- and mono-acetyl compounds under conditions analogous to the PCC of aromatic acetyl compounds in the presence of ethyl orthoformate.

1. The Study of the PCC of Ketals in Model Reactions

The optimum conditions for the synthesis of polyphenylenes were discovered in the cyclocondensation of the acetophenone ketal[21,22], which simulates the PCC process. The efficiencies of various acid catalysts were estimated in this model reaction[21]. It was found that gaseous hydrogen chloride, the chlorides of inorganic and organic acids which form HCl on interaction with the alcohol liberated in the synthesis, and toluene-*p*-sulphonic acid are the most efficient catalysts. The high catalytic activity of HCl is associated with the ease of its dissociation in aprotic solvents: $HCl \rightleftharpoons H^+ + HCl_2^-$. It was established[22] that the maximum yield of 1,3,5-triphenylbenzene in the presence of HCl is observed at an initial ketal concentration in solution of approximately 1 M, the relation passing through an extremum. It can be accounted for by the complexity of the cyclocondensation process, i.e. by the occurrence, together with trimerisation PCC, of various condensation and cyclocondensation side reactions.

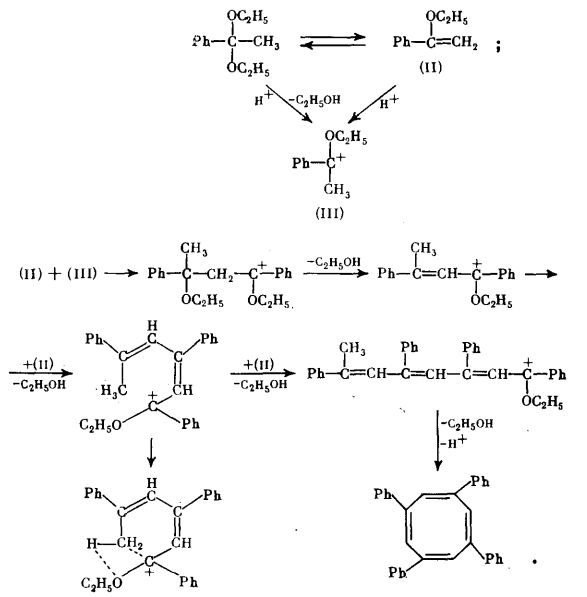


Table 1. The influence of solvent polarity μ on the yield of 1,3,5-triphenylbenzene (catalyst HCl, temperature 20°C, reaction time 1 h).

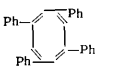
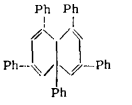
Solvent	μ	Yield %	Solvent	μ	Yield, %
Benzene	0.00	78	*m*-Cresol	1.54	43
CCl_4	0.00	72	Chlorobenzene	1.56	42
Toluene	0.29	76	Dimethylformamide	3.37	27
Dioxan	0.45	69	Nitrobenzene	3.99	29
$CHCl_3$	1.15	60			

The nature of the cyclocondensation of ketals is significantly influenced by the nature of the solvent (Table 1).[21] It was found that with increase of the polarity of the solvent, the yield of 1,3,5-triphenylbenzene falls. In highly polar solvents, such as nitrobenzene and dimethylformamide, the yield was less than 30%.

The study of the kinetics of the cyclocondensation of the acetophenone ketal under optimum conditions with respect to both the 1,3,5-triphenylbenzene formed[23] and the alcohol liberated in the course of cyclocondensation[21] showed that the process is of second order with respect to the ketal. The rate constants at 20°C, calculated by a second-order kinetic equation for various initial ketal concentrations, were approximately 1.2×10^{-1} litre mole^{-1} min^{-1}.





A mechanism for the cyclocondensation of ketals taking into account the kinetic data was proposed[21]. According to this mechanism, the cyclocondensation process proceeds as follows. Equilibrium is established in an acid medium with formation of α-ethoxystyrene from the acetophenone ketals. The addition of a proton to both the acetophenone ketal and to α-ethoxystyrene results in the formation of a carbonium ion. The subsequent interaction involves electrophilic attack by the carbonium ion on the carbon atom of the methylene group in α-ethoxystyrene, which is polarised owing to the presence of an oxygen atom next to the double bond of the vinyl ether group. Intramolecular elimination of the alcohol leads to the formation of a more stable form of the dimer, stabilised as a result of conjugation. Subsequent addition of yet another molecule to α-ethoxystyrene gives a trimer which is either converted into 1,3,5-triphenylbenzene via the formation of an intermediate complex followed by a cyclic electron transfer, or it interacts with a new α-ethoxystyrene molecule to form a tetramer, etc. The process can be represented schematically as follows:

The above scheme is confirmed by many facts, for example, the formation of triphenylbenzene in 68% yield from α-ethoxystyrene in benzene solution on treatment with HCl [21] and in addition by the mass-spectrometric analysis of the products of the cyclocondensation of acetophenone ketal[24]. Table 2 shows that, together with the main product (1,3,5-triphenylbenzene), the mixture contains α-ethoxystyrene, dypnone, 1,3,5,7-tetraphenylcyclo-octatetraene, a linear tetramer, and a cyclic pentamer, which, according to van Tamelen and Burkoth[25], should exist as 9,10-dihydronaphthalene. Analysis of the reaction mixture on a gas chromatograph combined with a mass spectrometer showed that the above compounds give rise to individual peaks corresponding to molecular ions. The presence of ketones is explained by the hydrolysis of the ketals in the course of isolation.

The proposed mechanism explains certain features of the cyclocondensation and polycyclocondensation of ketals. For example, the dependence of the yield of the trimer on the polarity of the medium, indicated above, can be accounted for by the effects of the stabilisation of the carbonium ion and the decrease of its reactivity.

Table 2. Mass-spectrometric analysis of the condensation products of the acetophenone ketal.

m/e	Compound corresponding to the molecular ion	Relative peak intensity, %		
		c_0^*=0.25 M	c_0=1.0 M	c_0=1.5 M
148	α-Ethoxystyrene	8	2.5	11.4
222	Dypnone	17	22	26
306	1,3,5-Triphenylbenzene	66	71	57.5
408		6.2	2.5	1.6
426		1.9	1.5	3.5
510		0.9	0.5	0

* Here c_0 is the initial ketal concentration.

As was to be expected from the Ruggli–Ziegler principle, as the initial acetophenone ketal concentration rises from 0.25 to 1.5 M, the content of macrorings diminishes and that of linear condensation products increases (Table 2).

The study of the temperature dependence of the yield of 1,3,5-triphenylbenzene showed that its maximum amount is formed at approximately 20°C.[21,23] An increase of temperature may prevent the formation of triphenylbenzene both due to the side reaction involving the addition of HCl to the vinyl ether group and in consequence of the decrease of the concentration of gaseous HCl in solution. The decrease of the yield at reduced temperatures can also be explained by factors other than the decrease of the reaction rate. It was found[23] that the kinetic curves for the formation of 1,3,5-triphenylbenzene below 20°C reach a limit and an increase of the duration of synthesis does not alter the yield of triphenylbenzene. The reduction of the temperature of the synthesis also leads to an increase of the inductive period. On the basis of these findings, the decrease of the yield is presumably associated with the difficulty of the formation at reduced temperatures of α-ethoxystyrene, which is formed spontaneously from the ketal at elevated temperatures. The fact that the yield of 1,3,5-triphenylbenzene is independent of whether the reaction is carried out in benzene solution presaturated with HCl or whether HCl is passed through the reaction mass during synthesis is of interest from the technological point of view[23].

In order to investigate the influence of the structure of the initial ketal on the cyclocondensation process, the ethyl ketals of 4-acetylbiphenyl, 4-acetylphenyl phenyl

ether, and 4′-acetyl-1,3,5-triphenylbenzene, as well as the butyl ketal of acetophenone were used[26,27]. At 20°C and with HCl passed through the system the reaction terminates after 25–30 min in all cases and its yield is fairly high (approximately 70%).[27] This may support the view that an increase of the number of benzene rings does not reduce the reactivity of the ketal. It is noteworthy that an increase of the number of benzene rings in the molecules of 1,3,5-trisubstituted oligophenyls reduces sharply their solubility. The introduction of a pivotal oxygen atom between the benzene rings greatly increases the solubility. The replacement of ethyl ketals by other alkyl ketals apparently has little effect on the nature of the cyclocondensation reaction[26].

The condensation of the acetophenone ketal in the range 100–400°C has also been studied[21,23]. Investigation by thin-layer chromatography of the condensation products obtained at 200°C in the presence of various catalysts showed that 1,3,5-triphenylbenzene is formed in the presence of acid catalysts. In the presence of alkaline catalysts and in the absence of a catalyst the condensation products contain only dypnone, α-ethoxystyrene, and the ketal which failed to react. The content of 1,3,5-triphenylbenzene in the reaction mass was estimated quantitatively by gas–liquid chromatography. The efficiency of the catalysts decreases in the sequence $TsOH.H_2O > H_2SO_4 > ZnCl_2 > SnCl_4$. An increase of the temperature of the synthesis leads to a decrease of the content of 1,3,5-triphenylbenzene in the reaction mass, while the overall yield of the condensation products is in all cases constant, i.e. the decrease of the yield of 1,3,5-triphenylbenzene is associated with the enhancement of the role of reactions leading to the formation of polyvinylenes[21].

Summarising the data for the cyclocondensation of the ketals of aryl methyl ketones, one may assume that the optimal conditions for the PCC of ketals obtain when the reaction catalysed by HCl is carried out in non-polar aromatic hydrocarbons at an initial concentration of the ketal groups of approximately 1*N* and at a temperature of 15–25°C or when the process is carried out at a higher temperature in the presence of $TsOH.H_2O$.

2. Characteristic Features of the PCC of Ketals

Taking into account the main features found with the aid of the model reaction, including the property of the PCC involving the possibility of a significant decrease of the solubility of polyphenylenes with increase of their molecular weight and gel formation, the synthesis of polyphenylenes was carried out in two stages[20]. Initially polyphenylenes with a relatively low molecular weight and residual reactive ketal or acetyl end groups were obtained in solution under the conditions of PCC; these fore-polyphenylenes were then converted, on heating under processing conditions (conversion into finished articles), into the final polymers with a cross-linked structure.

The use of the ethyl ketal of *p*-diacetylbenzene as the initial monomer in the reaction carried out in benzene in the presence of HCl as the catalyst leads to the formation of a cross-linked polymer in a quantitative yield[28]. In the first step of the interaction the branching of the polymer already begins and subsequently leads to the rapid formation of a network structure. It is quite understandable that the process should depend on the amount of HCl. It was found that, with increase of the rate of supply of HCl, the duration of synthesis before the attainment of the gel formation point diminishes; the overall consumption of the catalyst remains constant for the given charge in the reactor. This type of relation is associated with the rate of saturation of the solution by hydrogen chloride, which, up to a certain value, is directly proportional to the rate at which hydrogen chloride is passed. It was found[23] that an increase of the rate of supply of HCl within certain limits entails a directly proportional decrease of the time of attainment of the gel formation point. With increase of the charge severalfold, it is necessary to increase by the same factor either the duration of synthesis or the rate of supply of the catalyst. Thus the synthesis of the polymer may be regulated by controlling the amount of catalyst.

In order to obtain polymers with higher molecular weights in the first stage and to suppress the branching reaction, joint PCC of the ketals of mono- and di-acetyl compounds was carried out[28]. Fig. 1, which presents the dependence of the gel formation time and the amount of the gel fraction in the joint PCC of the acetophenone and *p*-diacetylbenzene ketals on their initial molar ratio, shows that, with increase of the fraction of the monofunctional monomer, the rate of gel formation falls and the proportion of the soluble fraction increases. For a molar ratio of 1 : 2, gel formation is not observed in the course of 2.5 h, but an increase of the amount of blocking agent leads to a decrease of the molecular weight of the polymer and of the amount of terminal functional groups, which is undesirable for the subsequent hardening stage. All the polyphenylenes synthesised in this way were therefore obtained mainly with an equimolar ratio of the mono- and bi-functional monomers.

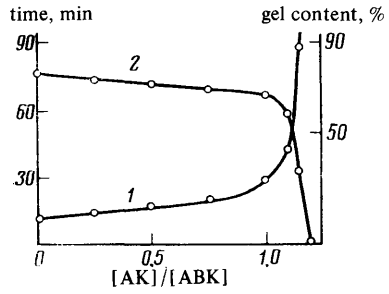


Figure 1. Dependence of the gel formation time (curve *1*) and of the amount of gel (curve *2*) in the PCC of the acetophenone ketal (AK) and the *p*-diacetylbenzene ketal (ABK) on their initial molar ratio.

In order to elucidate the nature of the PCC process, a thermodynamic study was made of the synthesis of polyphenylene from the ketals of acetophenone and *p*-diacetylbenzene[29,30]. The enthalpy of the process and the enthalpies of combustion and heat capacities of the monomers and polymers were determined. The enthalpies, entropies, and Gibbs free energies of formation of polyphenylene by PCC in solution and of its conversion into a three-dimensional polymer on heating were calculated from the results. Both processes are thermodynamically

allowed and their equilibria are almost completely displaced towards the formation of the corresponding polymer. Thus at 298.15 K the equilibrium constants K_e for the two reactions are respectively 1.5×10^{24} and 1.35×10^{5}. Thus the PCC of ketals in solution is known to be a non-equilibrium process, since, according to Korshak's definition[31], non-equilibrium processes are those for which $K_e > 10^3$.

The chain conjugation energy in the three-dimensional polyphenylene has been estimated[31]. Having assumed to a first approximation that the energy of the van der Waals interaction in this polymer is close to the analogous value in crystalline *m*-terphenyl, it was found that the chain conjugation energy is 62.5 kJ mole^{-1}, which agrees with the estimated chain conjugation energy in the polyphenylene obtained by the polycyclotrimerisation of phenylacetylene with *p*-diethynylbenzene[32].

Table 3. Kinetics of the PCC of the ethyl ketal of *p*-diacetylbenzene (20 °C, initial concentration 0.5 M, HCl concentration 0.2 M).

10.0	0.096	—	0.192
		k_{av} = 1.99	k_{av} = 0.18

Taking into account the non-equilibrium nature of the PCC of ketals, the reaction kinetics were studied in benzene solution in the presence of dry HCl,[23,33-35] the aim being to elucidate the sequence of the interactions of the above monomers, to be able to achieve their optimal selection for the synthesis of polyphenylenes, and to elucidate the dependence of the reactivity of the monomers on their structure. The kinetics of the cyclocondensation and polycyclocondensation of the acetophenone, 4'-ethylacetophenone, 2-acetylfluorene, 4'-acetyl-1,3,5-triphenylbenzene, *p*- and *m*-diacetylbenzene, 4,4'-diacetylbiphenyl, and di-(4-acetylphenyl)methane ketals were studied. The cyclocondensation of the monoketals is a second-order reaction and its rate constants are close to the rate constant for the cyclocondensation of the acetophenone ketal, i.e. the rate of reaction is almost independent of the structure of the chosen monoketals. In contrast to this, the kinetics of the PCC of diketals, for example, the diketal of *p*-diacetylbenzene, involve two sharply differentiated regions (Table 3).[23] The rate constant in the second kinetic region shows no tendency to decrease and is an order of magnitude lower than in the first region. Data for other diketals are presented in Table 4.[33] They were calculated in addition by the method of Frost and Schwemer for parallel-consecutive reactions. The different reactivities of the functional groups (cf. No. 1 and No. 4 in Table 4) are associated with the activation of the carbonium ion formed from the first ketal group owing to the electron-accepting properties of the second group transmitted via the conjugation system of the benzene ring. Naturally the introduction of groups which interrupt the conjugation system or the absence of an *M*-effect in the *m*-position of the benzene ring lead to a value of k close to those of the rate constants for monofunctional compounds. Thus the properties of the initial ketal can influence the structure and properties of the polyphenylenes produced by the reaction. It has been shown[36] that, when the ketal of *m*-diacetylbenzene is used, the formation of high-molecular-weight polyphenylenes in PCC in solution is hindered by the formation of *m*-phenylene macrocyclic structures, the smallest of which should be a substituted cyclohexa-*m*-phenylene fragment. This nature of the process also explains the appreciable decrease of k_2 compared with k_1 in the PCC of the *m*-diacetylbenzene ketal (Table 4).

Table 4. The rate constants for the PCC of the ketals of aromatic acetyl compounds*.

No.	Initial compound	k_1, litre mole^{-1} min^{-1}	k_2, litre mole^{-1} min^{-1}	k'_1, litre mole^{-1} min^{-1}	k'_2, litre mole^{-1} min^{-1}
1	Ethyl ketal of *p*-diacetylbenzene	1.99	0.18	2.34	0.49

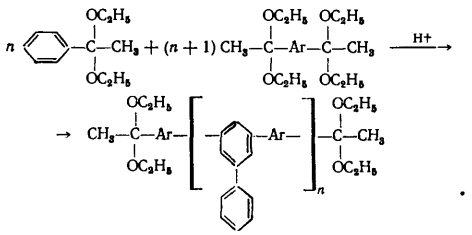
3	Ethyl ketal of di-(4-acetylphenyl)methane	0.16	—	0.175	—
4	Ethyl ketal of 4,4'-diacetylbiphenyl	1.2	0.5—0.7	1.73	**

*Rate constants calculated by the method of Frost and Schwemer are designated by k'_1 and k'_2.
**The value of k_2 for the polycyclocondensation reaction is approximately an order of magnitude lower than k_1.



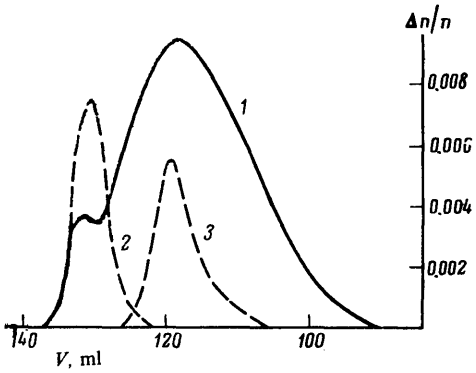
A study by infrared spectroscopy of the hardening of polyphenylenes at 350 °C in the presence of a catalyst showed[37] that it results in an increase of the number of 1,3,5-trisubstituted benzene rings, i.e. further trimerisation PCC of the end groups of the polyphenylene takes place.

The PCC of di- and mono-ketals can be carried out in such a way that polyphenylenes without reactive end groups are formed. For this purpose, one uses an excess of the mono-ketal, whose introduction leads simultaneously to chain termination. Thus when the *p*-diacetylbenzene ketal and a sixfold excess of the acetophenone ketal were used, an oligomer consisting mainly of a branched oligophenyl with 13 benzene rings was obtained. Judging from gel permeation chromatographic data (Fig. 2), the oligophenyl is identical with the model compound synthesised by the trimerisation cyclocondensation of the ketal of 4'-acetyl-1,3,5-triphenylbenzene[50].

3. The Synthesis of Polyphenylenes from Ketals Having Various Structures and Their Properties

If it is assumed that the reactivities of the ketals of mono- and di-acetyl compounds in PCC are close and in addition that there are no side reactions, the hypothetical linear polyphenylene (pre-polymer) should be obtained

for an equimolar component ratio. The syntheses were therefore carried out using equimolar ratios of the initial ketals. In this case the reaction can be represented schematically as follows:



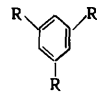


Figure 2. Gel permeation chromatography of the products of the PCC of the ketals of *p*-diacetylbenzene and acetophenone in molar proportions of 1 : 6 (curve *1*), 1,3,5-triphenyl benzene (curve *2*), and the oligophenyl

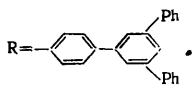
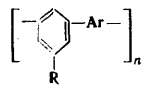
(curve *3*), where





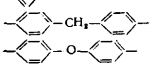


Table 5 presents certain properties of polymers based on the ketals of diacetylarylenes and acetophenone. The pre-polymers synthesised consisted of slightly coloured powders, readily soluble in ordinary organic solvents. The formation of a 1,3,5-trisubstituted benzene ring and the occurrence of the joint polycyclocondensation of the ketals of diacetylarylenes and acetophenone were confirmed by infrared spectroscopic data[37,40]. An increase in the content of *para*-substituted benzene rings in the main chain of the pre-polymer leads to a sharp decrease of the solubility of the polymer, while in the case of the ketal of 4,4″-diacetyl-*p*-terphenyl the pre-polymer is soluble only in nitrobenzene. The introduction of bridge groups such as –O– and $-CH_2-$ increases the mobility of the individual units of the molecule and reduces the softening temperature (Table 5), which is very important for the processing of the polymer. However, the introduction of the above connecting groups reduces the thermal stability of the final three-dimensional polymers obtained by the heat treatment of the fore-polymers.

The modification of the pre-polymers by altering the structure of the monofunctional monomer is of interest from this point of view[38,39] (Table 5). The pre-polymers synthesised in this way from the *p*-diacetylbenzene ketal are readily soluble. The highest solubility was observed in dichloroethane, dioxan, and chloroform. Comparison of the solubilities in toluene (Table 5) showed that the polymer with the most bulky side group, such as that derived from 1,3,5-triphenylbenzene, has the highest solubility.

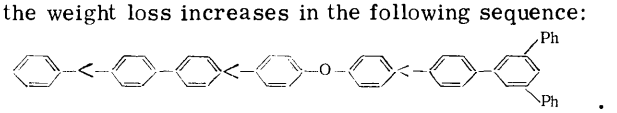
*The measurements were made in nitrobenzene.



The pre-polymers synthesised were heat-treated in order to convert them into the final three-dimensional polymers with high thermal stability and heat resistance[20, 22,23,35]. The polymer may be cross-linked in two ways. Firstly, by the interaction of three end groups it is possible to form a new 1,3,5-trisubstituted benzene ring via the mechanism

Secondly, when two end groups interact, condensation may take place with formation of dypnone fragments and then polyvinylenes:

The second type of interaction leads to the appearance of defective fragments in the polymer structure. It was shown that the highest thermal stability and heat resistance are exhibited by fully aromatic polymers[23,28] or polymers with an aromatic main chain[38,39]. Thus a hardened polymer with the oxygen bridge group in the side chain begins to decompose at a temperature approximately 70°C higher than a polymer with the same group in the main chain. The study of the thermal degradation in an inert atmosphere of the polyphenylenes based on the *p*-diacetylbenzene ketal with various side groups showed that the weight loss increases in the following sequence:

This is apparently associated with the elimination of phenyl side groups.

Together with thermogravimetric analysis, the method involving pyrolysis in a closed volume with subsequent gas-chromatographic analysis of the volatile degradation product was used[23]. In order to discover to what extent the structure of the hardened products resembles that of polyphenylene, a study was made of the thermal stabilities of a number of model compounds containing 1,3,5-trisubstituted benzene rings[27]. The thermal degradation of the model compounds entails the liberation of hydrogen and methane alone, which are the main products of the decomposition of the benzene rings. The hardening of the prepolymers at 450°C gives rise to products in the pyrolysis of which hydrogen and methane are evolved in the same temperature range (>450°C) as for the model compounds. In the pyrolysis of the polymers hardened at 300°C hydrogen and methane appear at lower temperatures compared with the model compounds, which can be explained by the presence of end groups and defective fragments in the structure (Fig. 3).

Polymers based on the ketals of *p*-diacetylbenzene, 4,4′-diacetylbiphenyl, and 4,4″-diacetyl-*p*-terphenyl, hardened under optimal conditions, exhibit the highest thermal stability and heat resistance[23]. However, a disadvantage of these polyphenylenes is their low solubilities in the pre-polymer stage, which seriously limits their practical synthesis and in addition hinders polycyclocondensation to high degrees of conversion. The solution of the second problem, i.e. the synthesis of high-molecular-weight soluble polyphenylenes by one-stage PCC in solution, is undoubtedly a very attractive proposition, despite its entire potential complexity owing to the possibility of the formation of a network structure, since it would make it possible to extend the assortment of systems capable of practical utilisation. Several studies have been devoted to the solution of this problem[35,39,41].

The PCC of the *m*-diacetylbenzene ketal has been investigated[36,41] and polyphenylenes based on it have been synthesised. The choice of this monomer is dictated by the fact that, in view of the angular disposition of the benzene rings, *m*-polyphenylenes have a looser packing compared with *p*-polyphenylenes, which improves their solubility and lowers their melting point. However, the synthesis of high-molecular-weight polyphenylenes was hindered by the formation of macrocyclic *m*-phenylene fragments. The molecular weight (MW) characteristics and the molecular weight distribution (MWD) of the above polyphenylene have been studied[41]. Fractionation of the polymer led to the isolation of five fractions with $\overline{M}_w$ from 1400 to 115 000 and $\overline{M}_n$ from 1100 to 80 500. The MWD curves were plotted for each fraction in terms of the Shulz equation on the basis of the measured $\overline{M}_w$ and $\overline{M}_n$ for the fractions. The fore-polymer investigated has a fairly broad MWD and a coefficient of polydispersity of 7.6 (the coefficient calculated from the MWD curve is 7.3).

Combined with a low intrinsic viscosity, this indicates a branched structure of the macromolecules. The coefficients of the Mark–Kuhn–Houwink equation for the first and second sections of the $\lg[\eta] - \lg\overline{M}$ relation were calculated and these too indicate a branched structure of

the polymers: $[\eta]_1 = 3.16 \times 10^{-4} \overline{M}_w^{0.6}$; $[\eta]_2 = 9.55 \times 10^{-4} \overline{M}_w^{0.22}$. For all the fractions, the increments in the refractive index and the specific partial volumes are similar. In other words, the degree of branching is similar for all the fractions. It is noteworthy that, for a comparatively low molecular weight of the initial pre-polymer, fractionation led to the isolation of a fraction with a fairly high molecular weight ($\overline{M}_w$ = 115 000). Unfortunately the proportion of this fraction proved to be very low, amounting to 2.5%.

The properties of polyphenylenes based on the ketal of 4,4′-diacetylbiphenyl, the most interesting monomer from the standpoint of its technological availability, and the thermal properties of the resulting polyphenylenes have been modified by synthesising copolymers with the *m*-diacetylbenzene ketal[36,39] and by introducing side groups into the polymer chain by altering the nature of the monofunctional monomer[38,39]. The introduction of *m*-phenylene fragments into the polymer chain was achieved by the joint PCC of the ethyl ketals of 4,4′-diacetylbiphenyl, *m*-diacetylbenzene, and acetophenone. The fore-polyphenylenes obtained were readily soluble in organic solvents, particularly when the initial mixture contained more than 75 mole % of the *m*-diacetylbenzene ketal. When mono-ketals having different structures were used (Table 5), it was found that the introduction of bulky substituents, for example, fluorene, triphenylbenzene, and diphenyl ether groups, causes only a slight alteration of the molecular weights and solubilities of polyphenylenes. In contrast to this, the introduction of alkyl substituents into the polymer side chain increases significantly the solubility and makes it possible to obtain polymers with a high molecular weight. For example, the PCC of the 4,4′-diacetylbiphenyl and *p*-ethylacetophenone ketals yields a fore-polymer with a viscosity of 0.25–0.30 dl g^{-1} and its $\overline{M}_w$ reaches 40 000–60 000; according to ^{1}H NMR data, the polyphenylene structure predominates in the polymer. This polymer is highly soluble in benzene and toluene in the cold (>200 g $litre^{-1}$).

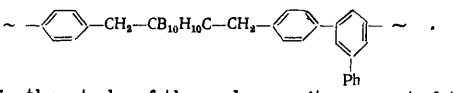

Table 6. The molecular weight characteristics of the fore-polymer based on the 4,4′-diacetylbiphenyl and *p*-ethylacetophenone ketals.

No. of fraction	Content, wt.%	$[\eta]$, dl g^{-1}	$\overline{M}_w$	$\overline{M}_n$	$\overline{M}_w/\overline{M}_n$
1	25.0	0.023	1 300	420	3.10
2	22.4	0.080	4 600	1 600	2.77
3	11.5	0.102	8 700	4 600	1.90
4	15.6	0.130	33 000	11 400	2.92
5	14.3	0.170	143 000	50 000	2.86
6	7.3	0.176	164 000	77 000	2.12
7	2.2	0.194	200 000	100 000	2.00
Initial fore-polymer	100.0	0.120	50 000	7 400	6.80

Polymers with ethyl side groups in the chain, pressed out at a high temperature, are hardly deformed up to the decomposition temperature (500 °C). In order to account for the causes of their very high thermal stability and heat resistance, a pre-polymer with blocked end groups was synthesised and its heat treatment yielded a highly thermostable product with a three-dimensional structure[39]. Consequently the ethyl group participates in the cross-linking process, which confirms the infrared spectroscopic data.

Thus the joint polycyclocondensation of *para*-substituted diketals with the *p*-ethylacetophenone ketal makes it possible to obtain polyphenylenes with a high solubility, a fairly high average molecular weight, and capable of being worked to form final articles with a high thermal stability. The study of the MWD of the pre-polyphenylene based on the ketal of 4,4′-diacetylbiphenyl and *p*-ethylacetophenone[35] demonstrated a fairly high polydispersity coefficient (6.8–9.9). The molecular weights of the polymer fractions isolated are listed in Table 6, which shows that, out of seven fractions, three have high molecular weights ($\overline{M}_w$ = 143 000–200 000), their overall proportion being 25%. The MWD within the fractions were calculated from the Schulz equation and their summation yielded the overall distribution curve for the non-fractionated polymer. The MWD curve proved to be fairly broad, which confirms the branched structure of the polyphenylene investigated. Thus the possibility, in principle, of synthesising high-molecular-weight polyphenylenes with a non-cross-linked structure by the polycyclocondensation of ketals was demonstrated.

Polymers obtained by the PCC of carbaborane-containing ketals have been described recently[18,19,42]. Using the ethyl ketals of di-(4-acetylbenzyl)-*m*-carbaborane and acetophenone, a polymer with the following tentative structure of the elementrary unit was obtained:

However, in the study of the polymer it was noted that the contribution of the trimerisation polycyclocondensation to the overall polycondensation process was much smaller than in previous cases. The polymer was highly soluble in organic solvents at the fore-polymer stage and exhibited a high thermal stability in the final stage, showing no weight loss on heating in air to 900 °C according to thermogravimetric analysis.

IV. PRACTICAL APPLICATIONS OF POLYPHENYLENES BASED ON AROMATIC ACETYL COMPOUNDS AND THEIR KETALS

Polymers based on aromatic acetyl compounds obtained by the method of Korshak et al.[5] are used to make fancy articles and filled plastics exhibiting a high thermal stability and heat resistance as well as resistance to corrosive media[5,43]. They are of interest as binders for the formation of antifriction polymeric materials[45]. The decrease of the coefficient of friction of the composition based on a carbon fabric takes place in parallel with the decrease of the rigidity of the polymer chain. Polymers based on ketals, obtained by the method of Korshak et al.[20], are also of interest for the formation of a wide variety of thermostable and heat resistant materials, particularly glass and carbon plastics[23,44]. The modification of these polymers by the introduction of sulphide bridges into the chain yielded materials with an enhanced mechanical strength without decrease of thermal stability[46,47].

The presence of organoelemental fragments in the chains of polyphenylenes imparts specific properties to the latter. Thus polymers based on di-(acetylbenzyl)-carbaboranes and their ketals[18,19] exhibit an exceptionally high thermal

stability. Glass plastics with a working temperature of 400°C have been made from them. The use of cobaltocenium-containing diacetyls and acetophenones made it possible to obtain thermostable anion-exchange resins[48].

A disadvantage of polyphenylenes based on aromatic acetyl compounds and their ketals from the standpoint of their practical application is the high temperature of their conversion into the final three-dimensional polymers. This problem is solved by replacing the acetyl groups in the fore-polymers, obtained by the trimerisation of PCC, by more reactive groups, for example furfurylidene, hydroperoxy-, or nitrile groups[35], as well as cyanomethyl cinnamate[49] and dicyanopropylidene[51] groups.

---o0o---

Thus the use of the trimerisation PCC of aromatic acetyl compounds and their ketals not only expands our ideas about this process and about the dependence of the properties of polymers on their structure, but also makes it possible to obtain polymeric materials which are extremely valuable in practice.

Oxidative Polymerisation of Vinyl Monomers

M.M.Mogilevich

The results of studies on the kinetics and mechanism of the oxidative polymerisation and copolymerisation of vinyl monomers are described systematically and discussed critically. Attention is concentrated on the elucidation of the relation between the structure and reactivity of the monomers in oxidative polymerisation and on the role of oxygen as an inhibitor in the free-radical chain polymerisation.
The bibliography includes 139 references.

I. INTRODUCTION

Radical polymerisation in the presence of oxygen, called oxidative polymerisation †, is accompanied by oxidation which results in the formation of low-molecular-weight products with oxygen-containing functional groups (aldehydes, ketones, etc.) in addition to the copolymers with oxygen. The specific features and characteristics of the simultaneous occurrence of polymerisation and oxidation have been the subject of numerous investigations, which have led to the establishment (mainly during the last three decades) of oxidative polymerisation as an independent field of radical-chain polymerisation.

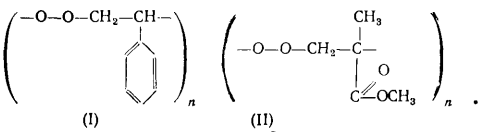
The study of the role of oxygen in radical polymerisation, begun by Lebedev[4] and Staudinger[5] and continued mainly by Medvedev[6], Bovey and Kolthoff[7], and Barns et al.[8], enabled Schulz and Henrici[2], Mayo et al.[9], and Kern[10], to establish the principal features of the mechanism of the oxidative polymerisation of compounds of the vinyl type ‡.

† The term "oxidative polymerisation" is used in the literature usually for the polymerisation of monomers (oligomers) in the presence of O_2 when initiation is achieved as a result of degenerate branching by peroxides (hydroperoxides)[1]. On the other hand, if the initiator is introduced from outside, and degenerate branching does not play a significant role in initiation, the process is called "inhibited polymerisation"[2] or "oxidation"[3]. We believe it to be more logical and rigorous in relation to the reaction mechanism to extend the term "oxidative polymerisation" to all instances of the polymerisation of unsaturated compounds in the presence of oxygen, regardless of the method of initiation.

‡ Compounds of the vinyl type, whose C–O bonds are activated by $\pi-\pi$ conjugation or by electron-donating or electron-accepting substituents [-CN, C(O)-, -C(O)-O, Cl,  , etc.] in the α-position relative to the double bond, are considered. Compounds containing the $CH_3-CH=CH-$, $CH_2=CH-CH_2-$, $CH_2-CH=CH$, and $CH_2=CH-CH$ structural units, in which the substituents in the α-position with respect to the relatively inactive C=C bond are the methyl, methylene, or methylidyne groups, exhibiting a weak electron-donating capacity, are included with allyl compounds[9,11,12].

Studies[13–16] were unable to determine the mechanism of the formation of hydroperoxide and the generation of oxidation chains for compounds of the allyl type. However, the formation of hydroperoxides is most probably only one of the reactions involving the formation of polymers from allyl compounds in the presence of oxygen. On the whole, this process has remained little studied for compounds of the allyl type.

During recent years, there has been a sharp increase of interest in polymerisation in the presence of oxygen. This is associated with the current development of fundamentally new methods for the formation of organic coatings using monomers[17,18] and also with the fact that oxidative polymerisation constitutes the basis for the formation of films of unsaturated compounds. The theoretical aspect of the study of the interaction between oxygen and unsaturated compounds involves the fundamental problem of the relation between the structure and reactivity of organic compounds in radical addition and substitution reactions.



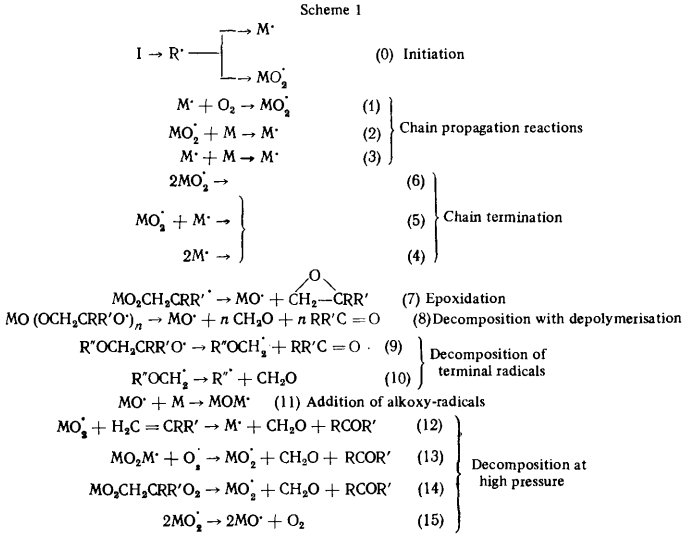
The available review publications are devoted mainly to the chemistry of polymeric peroxides[19–21] with the exception of a recent study in the field of the history of science[22], which reflects fairly completely the establishment of the field of oxidative polymerisation. It has now become necessary to survey and analyse critically studies dealing with the formation of polymers as a result of the interaction of unsaturated compounds with oxygen, to examine the present state of the field of oxidative polymerisation, to deduce the principle trends in its development, and to discover promising pathways to be followed in future research. Such an attempt is made in the present review.

II. KINETICS AND MECHANISM OF OXIDATIVE POLYMERISATION

1. Mono-unsaturated Compounds

Studies on the oxidative polymerisation of styrene[23–26], α-methylstyrene[27], and methyl methacrylate[2,3] have been of fundamental importance for the elucidation of the mechanism of the interaction of vinyl monomers with oxygen. The key to the understanding of the process mechanism has been the isolation[7,8,28] of polymeric peroxides derived

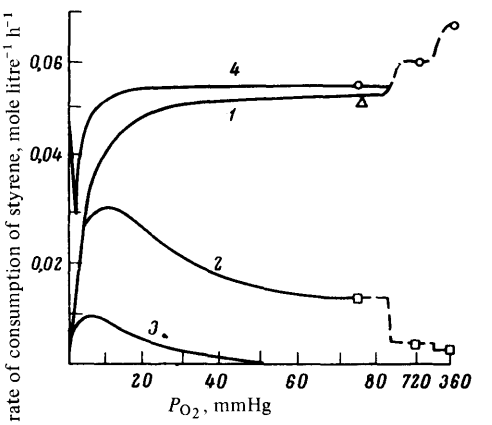
from styrene (I) and methyl methacrylate (II) and the determination of their structure as regular copolymers formed by the interaction of monomers with oxygen:



(I) (II)

It is noteworthy that Staudinger[29] was the first to identify a polymeric peroxide as the product of the interaction of 1,1-diphenylethylene with oxygen.

Styrene. The reaction of styrene with oxygen leads to the formation of a polyperoxide, benzaldehyde, formaldehyde, and styrene oxide (phenyloxiran), the aldehydes being formed in equimolar amounts simultaneously with the polyperoxide from the very lowest degrees of conversion[24,30]. The mechanism of the oxidative polymerisation of styrene [Scheme (1)], proposed by Mayo[25], provides a good explanation of the nature of the accumulation of the reaction products as a function of the partial pressure of oxygen (P_{O_2}) (see Figure). The polyperoxide and low-molecular-weight products are formed as a result of the addition, isomerisation, and decomposition of the radicals M$^{\cdot}$, $MO_2^{\cdot}$, and MO$^{\cdot}$ (I is the initiator).



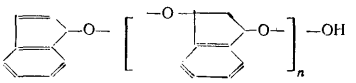
Scheme 1

The formation of the polymeric peroxide by reactions (0), (1), (2), and (6) in the range of oxygen pressures 160 to 3100 mmHg is consistent with kinetic results[24-26]. The rate of consumption of oxygen (W_{O_2}) obeys the equation

$$W_{O_2} = \frac{k_2}{k_6^{1/2}} \cdot k_i^{1/2} [M] [I]^{1/2} \qquad (I)$$

(where M, I, k_i, k_2, and k_6 are respectively the monomer, the initiator, and the initiation, chain propagation, and chain termination rate constants), which follows from the set of elementary reactions with the rate-limiting stage (2), indicated in scheme (1). In this oxygen pressure range W_{O_2} is independent of P_{O_2} and quadratic chain termination takes place at peroxy-radicals, the main reaction product is the polyperoxide, and the yield of low-molecular-weight compounds (phenyloxiran, CH_2O, and benzaldehyde) is approximately 3% (see Figure). Low-molecular-weight compounds are formed in the decomposition of radicals $MO_2^{\cdot}$ and $MO_2M^{\cdot}$ via reactions (11)-(14), whose rate is independent of P_{O_2}. Since $k_1/k_3 = 4.4 \times 10^6$ (at 50°C), all the radicals M$^{\cdot}$ are in fact converted into $MO_2^{\cdot}$ via reaction (1) before they can react with the monomer via reaction (3). The contribution of the MOOM$^{\cdot}$ radical decomposition reaction (7), which also competes with reaction (1), is small judging from the yields of the alkoxy-radicals and phenyloxiran at P_{O_2} = 3200 - 100 mmHg. Correspondingly the aldehyde formation reactions (8)-(10) do not play a significant role. This ensures the formation of the polyperoxide as the main product of the interaction of styrene and oxygen at $P_{O_2} \geq 100$ mmHg.

Dependence of the rates of formation of products in the oxidative polymerisation of styrene on the oxygen pressure[25]: *1*) polymeric peroxide; *2*) benzaldehyde and formaldehyde; *3*) phenyloxiran; *4*) overall rate of consumption of styrene; temperature -50°C; concentration of azobisisobutyronitrile 0.01 M.



With decrease in the partial pressure of oxygen (particularly at P_{O_2} = 80 - 10 mmHg), the rate of formation of the polyperoxide diminishes and the yield of phenyloxiran and the aldehydes increases (see Figure). A decreased concentration of dissolved oxygen increases the lifetime of the radicals $MO_2M^{\cdot}$: $\tau = 1/k_1[O_2]$. This produces an increase in the rate of reaction (3) and in the rates of the isomerisation reaction (7) and the depolymerisation reactions (8)-(10), which gradually displace the polyperoxide formed. Since reaction (7) proceeds with an activation energy E_7 = 8-10 kcal mole^{-1}, [31] while reactions (1) and (3) which compete with it have $E_1 = 0$ and E_3 = 6-7 kcal mole^{-1}, [32] an increase of temperature causes, like a decrease of P_{O_2}, an increased yield of phenyloxiran and aldehydes compared with the formation of the polyperoxide. It has been shown[33] that under certain conditions {100-120°C, P_{O_2} = 160-80 mmHg, [M] = 10-40 vol.%} only oxidative-degradative reactions of styrene take place with formation of phenyloxiran and aldehydes, while the polymeric pathway in the interaction of styrene with oxygen is almost entirely suppressed.

When $P_{O_2} = 5-1$ mmHg, the cross-termination reaction (5) becomes dominant: $W_{O_2} \propto [M]^{1/2}[O_2]^{1/2}$: irregularities of the type ~M–M~, which hinder the depolymerisation reactions (8) and (9) and lower the yield of aldehydes, are encountered in polymer chains with increasing frequency. The rate of formation of phenyloxiran also decreases in view of the decrease of the fraction of ~MOOM~ units owing to the formation of ~MM~ and the overall rate of consumption of styrene falls sharply, since $k_5 \gg (k_4k_6)^{1/2}$. In the absence of oxygen ($P_{O_2} = 0$) polystyrene is formed by reactions (0), (3), and (4).

In terms of its most important features, the mechanism of oxidative polymerisation established for styrene proved to be valid for vinyl monomers such as α-methylstyrene[27,34-37] and methyl methacrylate[2,3,38,39].

Indene. The double bond activated by the aromatic ring and the methylene group in the α-position relative to the double bond are responsible for the ability of indene to interact with oxygen to form both hydroperoxides and polyperoxides[40,41]. Under mild conditions, the oxidation of indene leads to the formation of a hydroperoxide which is unstable above 40° C and is converted into carbonyl compounds[42].

Russell carried out a chemical and kinetic study of the oxidative polymerisation of indene[43,44], which established the structure of the polyperoxide:

and the mechanism of its formation via the reactions in Scheme 2.

Scheme 2

$$I \rightarrow R^{\cdot} \xrightarrow[M]{O_2} MO_2^{\cdot} , \quad (0)$$

$$M + O_2 \xrightarrow{k_{O'}} MO_2^{\cdot} , \quad (0')$$

$$M^{\cdot} + O_2 \xrightarrow{k_1} MO_2^{\cdot} , \quad (1)$$

$$MO_2^{\cdot} + M \xrightarrow{k_2} M^{\cdot} , \quad (2)$$

$$MO_2^{\cdot} + MH \xrightarrow{k_{2'}} MO_2H + M^{\cdot} , \quad (2')$$

$$2MO_2^{\cdot} \rightarrow \text{non-radical products.} \quad (6)$$

In contrast to styrene and methyl methacrylate, initiation reactions via the direct interaction of the monomer and oxygen [reaction (O')] and chain transfer reactions as a result of the elimination of hydrogen from the α-methylene group by the peroxy-radical [reaction (2')] play a significant role in the oxidative polymerisation of indene. The fact that the rate of the overall reaction obeys the equation

$$W_{O_2} = \frac{k_2 + k_{2'}}{k_6^{1/2}}[M](k_i[I] + k_{O'}[M])^{1/2}[O_2]^{1/2} \quad (II)$$

may be regarded as kinetic proof of the validity of the above scheme.

Thermal oxidative polymerisation has been investigated for styrene[23,45], methyl methacrylate[46], n-butyl methacrylate[47], and indene[44]. The rate of reaction obeys the equation

$$W_{O_2} = k[M]^n [O_2]^m \quad (III)$$

with values of n and m (Table 1) close to the theoretical values: $n = 1.5$ and $m = 0.5$. This enabled Mayor and Russell to assume that the reaction proceeds via Scheme 3, from which it follows that $k = k_i^{1/2}k_2/k_6^{1/6}$ in the above equation.

Scheme 3

$$M + O_2 \xrightarrow{k_{O'}} M^{\cdot} , \quad (0)$$

$$M^{\cdot} + O_2 \xrightarrow{k_1} MO_2^{\cdot} , \quad (1)$$

$$MO_2^{\cdot} + M \xrightarrow{k_2} M^{\cdot} , \quad (2)$$

$$2MO_2^{\cdot} \xrightarrow{k_6} \text{non-radical products.} \quad (6)$$

Chain initiation in vinyl compounds apparently proceeds as a result of the addition of oxygen to the double bond via the reaction[48,49]

$$C_6H_5CH{=}CH_2 + O_2 \rightarrow C_6H_5{-}\dot{C}H{-}CH_2OO^{\cdot} .$$

Table 1. Characteristics of oxidative thermal polymerisation of monomers.

Monomer	Reaction order w.r.t. monomer (n)	Reaction order w.r.t. oxygen (m)	Refs.	Monomer	Reaction order w.r.t. monomer (n)	Reaction order w.r.t. oxygen (m)	Refs.
Styrene	1.38	0.37	23	Indene	1.50	0.50	44
Styrene	1.78	0.34	45	Methyl methacrylate	1.70	0.47	46

The thermal oxidative polymerisation of styrene and n-butyl methacrylate at 50° C proceeds at rates smaller by a factor of 3–4 than in initiated oxidative polymerisation[23,45,47] owing to the low rates of initiation and degenerate branching of the chain by the polymeric peroxides.

In contrast to styrene, α-methylstyrene, methyl methacrylate, and indene, the oxidative polymerisation of other monomers of the vinyl type, such as chain-substituted[9,27,44] and ring-substituted[50] styrene, acrylonitrile[9,51-56] and its derivatives[54,57,58], methacrylates[39,59-64] and acrylates[46,57,63,65], vinyl acetate[9,57,66], and halogenoethylenes[67-76], has been studied much less. The kinetics of the interaction of oxygen with all the monomers investigated obey Eqn. (I). The influence of the medium is manifested by the fact that an increase in the dielectric constant of the solvent leads to an increase of the rate of reaction[59,60]. It follows from the kinetic data that the initiated oxidative polymerisation of compounds with activated π bonds proceeds via a mechanism incorporating the elementary reactions (0), (1), (2), and (6) (Scheme 1), in the region of oxygen pressures where the rate of reaction is independent of P_{O_2}. The copolymerisation of monomers with O_2, leading to the formation of polymeric peroxides, takes place via the chain propagation reactions (1) and (2) (Scheme 1). The comparatively few kinetic characteristics of the formation of polyperoxides are presented in Tables 2 and 3 (see also Table 6).

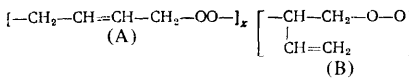
* The values of $k_2/k_6^{1/2}$ were calculated by the expression $k_2/k_6^{1/2} = W_{O_2}/[M]k_i[\bar{A}BIBN]^{1/2}$ from the rates of oxidative polymerisation W_{O_2} quoted in the relevant studies. The rate constants k_i for initiation by azobisisobutyronitrile (ABIBN) were taken from Tüdos[83] for styrene and its derivatives, from Turesanye and Tüdos[84] for vinyl acetate, from the same paper for acrylonitrile and its derivatives, from Sukhov and coworkers[46,85] for methacrylate and acrylate esters, from Turesanye and Tüdos[84] for methyl vinyl ketone, isopropenyl methyl ketone, and isopropenyl acetate, from Van Hook and Tobolsky[86] and Hammond et al.[87] for butadiene, and from Bailey[55] for chloroprene.

The structure of the polymeric peroxides corresponds to the formula -M-OO- when the monomer M reacts with oxygen under conditions (in terms of the O_2 concentration) ensuring quadratic chain termination by $\sim MO_2^{\cdot}$ radicals. The structure of the polymeric chains and peroxides with a regular alternation of -M- and -O-O- units constitutes independent confirmation of the validity of the mechanism of their formation under discussion. The extremely limited information about the structure of polymeric peroxides and some of their properties have been largely reviewed in Refs. 19–21 and 88.

Judging from the products formed, it is most likely that the thermal decomposition of the polymeric peroxides derived from styrene[24], α-methylstyrene[27], methyl methacrylate[38] n-butyl methacrylate[62], acrylonitrile[52], methacrylonitrile[53], vinyl chloride[68], and tetrafluoroethylene[73-75] proceeds via a free-radical chain mechanism.

In the oxidative polymerisation of vinyl compounds via the mechanism illustrated in Scheme 1 chain propagation takes place via the addition reaction (2). Together with addition to the double bond, the peroxy-radical can participate in the homolytic substitution reaction (2′) in Scheme 2, abstracting hydrogen from a monomer molecule. Polymeric peroxides, aldehydes, ketones, and epoxides are formed via the addition reaction[9], while hydroperoxides, alcohols, carbonyl compounds, and acids with the same number of carbon atoms as the initial olefin are formed via the substitution reaction[31,89]. On the basis of the study of the reaction products, Mayo et al.[9] concluded that the addition reaction predominates when the double bond is conjugated with aromatic, vinyl, carbonyl, or nitrile groups or when the saturated compound does not contain an allylic hydrogen atom. According to Buckley and Szwarc[90], the reactivity of unsaturated compounds as free radical acceptors increases sharply when their double bonds are activated by conjugation. Indeed, hydroperoxides or other substances indicating the occurrence of the substitution reactions have not been found in the products of the interaction with oxygen of all the compounds having activated π bonds investigated to date, with the exception of indene and phenylcyclohex-1-ene. It follows from the results of studies on the joint oxidation of styrene, α-methylstyrene, and methyl methacrylate with hydrocarbons such as tetralin and cumene (Tables 4 and 5) that peroxy-radicals add predominately to the double bonds.



Thus the reaction involving substitution by the peroxy-radical plays a subsidiary role for vinyl compounds compared with the addition reaction. At the same time the kinetic chain is transferred to the monomer via the substitution reaction and the latter is probably largely responsible for the decrease of the length of the molecular chains of polymeric peroxides whose degree of polymerisation ($\bar{P}_n$) is as a rule comparatively low: $10 < \bar{P}_n < 30$.

Together with the competition between the substitution and addition reactions, the competition between the polymeric and oxidative pathways in the interaction of oxygen with monomers is extremely important. To date, this pathway has been studied only for styrene[25,31,33] and partly for α-methylstyrene[27,37] and methyl methacrylate[3,38].

2. Dienes and Polyenes

The mechanism of the oxidative polymerisation of hydrocarbons with conjugated double bonds has been established mainly as a result of the work of Kern and coworkers[92-95].

Buta-1,3-diene. The interaction of butadiene with oxygen in solvents gives a high yield of a polymer with $\bar{M}_n = 700-850$. This polymer is formed[96] as a result of the 1,2- and 1,4-addition of oxygen to butadiene, the latter pathway predominating:

(A) (B)

The structure of the polymer was demonstrated by its reduction with LiAlH to but-2-ene-1,4-diols and bute-3-ene-1,2-diols, the hydrogenation of which gave the corresponding butanediols. Formaldehyde and acrolein, identified in the thermal decomposition of the polymeric peroxide, corresponded to structure (B). Structure (A) was demonstrated by the formation of phenylhydrazones on treatment of the polymeric peroxide with phenylhydrazine.

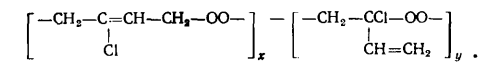
A detailed study of the initiated and thermal oxidative polymerisation of butadiene, undertaken by Mayo and coworkers[82,97], established that, in the temperature range 30–50°C, at $P_{O_2} > 40$ mmHg, and for low conversions, the main product is the polymeric peroxide $(C_4H_6O_2)_n$, consisting of equal numbers of *trans*-buta-1,2-diene and *trans*-buta-1,4-diene units connected by -O–O- bridges. Only at $P_{O_2} < 10$ mmHg is several per cent of 1-ethyloxiran (butadiene 1,2-oxide) and 1-formyloxiran (acrolein

1,2-oxide) formed. The epoxides are formed via reaction (7) in scheme 1, which had been established previously for styrene[25]:

$$\sim MO_2M^{\cdot} \xrightarrow{k_7} MO^{\cdot} + H_2C\overset{O}{\diagup\!\!\diagdown}CH{-}CH{=}CH_2 \ .$$



The rate of this reaction increases with decreased partial pressure of oxygen and the ratio k_1/k_7 is 3×10^{-6} and 20×10^{-6} at $P_{O_2} = 20$ and 3 mmHg respectively. The decomposition of polymeric alkoxy-radicals [reaction (8), Scheme 1] leads to acrolein: $\sim MO_2{-}MO^{\cdot} \rightarrow MO^{\cdot} + CH_2O + O{=}CH{-}CH{=}CH_2$; the radicals are formed via reaction (7) and have terminal buta-1, 2-diene units. The rate of initiation of the oxidative polymerisation of butadiene in the oxygen pressure range from 40 to 900 mmHg, where W_{O_2} is independent of P_{O_2}, obeys Eqn. (I) with the kinetic parameters listed in Table 2.

Isoprene and 2,3-dimethylbuta-1,3-diene. The available information about the interaction of oxygen with isoprene and 2,3-dimethylbuta-1,3-diene is extremely limited[92-94]. It has been shown[92-94] that the polymeric peroxides formed are regular copolymers of dienes with oxygen and have the following structure:

When the reaction of 2,3-dimethylbutadiene with oxygen is continued up to high conversions, hydroperoxy-groups and ether bonds appear in the polyperoxide, while α-isopropenylacrolein and dimethylglyoxal were detected in the volatile product in addition to formaldehyde and isopropenyl methyl ketone[98].

Chloroprene. The main product of the interaction of chloroprene with oxygen is a polymeric peroxide having the following structure[95,99]:

Readily hydrolysable chlorine, in amounts proportional to the amount of absorbed O_2, was detected in the polyperoxide. This led to the conclusion that oxygen undergoes 1,2-addition, which is accompanied, according to the authors[99], by the allylic rearrangement

A more detailed study of the structure of the polymeric chloroprene peroxide showed[55] that units resulting from 1,4-addition predominate. For low conversions, the kinetics of the oxidative polymerisation of chloroprene obey Eqn. (I). The principal kinetic characteristics of the process are listed in Table 2.

Thus, according to structural-chemical and kinetic data, polymeric peroxides of 1,3-dienes are formed via a mechanism incorporating the elementary reactions (0), (1), (2), and (6) (Scheme 1), the peroxy-radical adding to the monomer in the 1,4- and 1,2-positions.

The available information about the oxidative polymerisation of the *esters of acids having conjugated π bonds* is extremely limited. The addition of oxygen in the 1,2- and 1,4-positions of α-eleostearic acid has been demonstrated[100,101], the triene system of conjugated double bonds being converted into a diene system with formation of dimeric peroxy-products[102-104]. The peroxides derived from the methyl esters of octadeca-9,11-dienoic and octadeca-10,12-dienoic acids are regular 1 : 1 copolymers of the esters with oxygen whose degree of polymerisation is 2–4 [88] and which are formed as a result of the addition of polyperoxy-radicals in the 1,2- and 1.4-positions. The rate of oxidative polymerisation of the methyl esters of α-eleostearic[103] and octadeca-9,11-dienoic acids[93,105,106] obeys the equation

$$W_{O_2} = k\,[PP]^{1/2}.[M],$$

where [PP] and [M] are the concentrations of the polymeric peroxide and the monomer respectively.

This equation follows from Scheme 1 [elementary reactions (1),(2), and (6)], provided that the initiators are polyperoxides which decompose unimolecularly. The kinetics of the interaction of β-carotene (a polyene with conjugated π bonds) with oxygen were investigated and the formation of peroxides and epoxides in parallel reactions was established[107].

Table 4. The rate constants (litre $mole^{-1}s^{-1}$) for the reactions of certain peroxy-radicals with hydrocarbons at 30° C. [91]

III. OXIDATIVE COPOLYMERISATION§

The polymerisation process in a system consisting of monomers A and B and oxygen leads to the formation of ternary copolymers having the composition $(\sim AOO\sim)_n{-}(\sim BOO\sim)_m$. Chain propagation and termination proceeds via reactions in Scheme 4:

Scheme 4

$$\sim A^{\cdot}\,(\sim B^{\cdot}) + O_2 \rightarrow AO_2^{\cdot}\,(BO_2^{\cdot}) \qquad (1)$$

$$\left.\begin{aligned} \sim AO_2^{\cdot} + A &\xrightarrow{k_{AA}} \sim AOOA^{\cdot} \\ \sim AO_2^{\cdot} + B &\xrightarrow{k_{AB}} \sim AOOB^{\cdot} \\ \sim BO_2^{\cdot} + B &\xrightarrow{k_{BB}} \sim BOOB^{\cdot} \\ \sim BO_2^{\cdot} + A &\xrightarrow{k_{BA}} \sim BOOA^{\cdot} \end{aligned}\right\} \qquad (2)$$

$$\left.\begin{aligned} 2 \sim AO_2^{\cdot} &\xrightarrow{k_{OA}} \\ 2BO_2^{\cdot} &\xrightarrow{k_{OB}} \\ AO_2^{\cdot} + BO_2^{\cdot} &\xrightarrow{k_{OAB}} \end{aligned}\right\} \text{non-radical products.} \qquad (6)$$

§ By analogy with polymerisation in the absence of O_2, the term oxidative copolymerisation is applied when two and more monomers are involved in the polymerisation process.

* The reaction was initiated in all cases by azobisisobutyronitrile and was carried out in bulk[9,108,111,112,115–117] or in solution[110,114] at P_{O_2} = 760 mmHg [108,110–112,115–117] or 3100 mmHg.[9]

If one of the system components is a saturated hydrocarbon BH, then oxidative copolymerisation is accompanied by joint oxidation:

$$\sim AO_2^{\cdot} + BH \rightarrow \sim AOOH + B^{\cdot},$$

$$\sim BO_2^{\cdot} + BH \rightarrow \sim BOOH + B^{\cdot}$$

with formation of terminal hydroperoxy-units in the polymer chains or of the hydroperoxide BOOH. It has been shown that the familiar equations for the composition of the copolymer and the general equation for the rate of reaction in three-component systems (the case where one of the monomers is incapable of homopolymerisation) are applicable to the oxidative copolymerisation of two monomers[9,108]. The relative chain propagation rate constants $r_A = k_{AA}/k_{AB}$ and $r_B = k_{BB}/k_{BA}$ as well as the ratio of the rate constants for chain termination $\Phi = k_{OAB}(k_{OA}k_{OB})^{1/2}$ can be determined from these equations. The quantity r expresses the selectivity of the peroxy-radicals with respect to the monomers (the ratio of the rates of addtion to its "own" and "foreign" monomers), while the constant Φ represents the difference between the rates of chain termination as a function of the type of reacting peroxy-radicals.

The oxidative copolymerisation and co-oxidation constants for the monomers are listed in Table 5. The small number of publications and the extremely limited number of systems investigated are striking. A comparison of the results obtained by different workers is possibly only for the systems styrene–α-methylstyrene–O_2, styrene–methyl methacrylate–O_2, styrene–tetralin–O_2, and styrene–cumene–O_2. The reason for this is primarily the considerable experimental difficulties associated with a sufficiently accurate determination of the composition of polymeric peroxides, or with the measurement of the concentration of the monomer in the substrate undergoing oxidation[115,117].

* The Table was set up on the basis of published data for butadiene[109], styrene[46,77], acrylonitrile[56,57], methyl vinyl ketone[46] methyl acrylate[56,65], vinyl acetate[56,66] α-methylstyrene[79], methylacrylonitrile[54,56], isopropenyl methyl ketone[54], methyl methacrylate[39,63], and isopropenyl acetate[54,56].

For all the pairs investigated, if $r_A < 1$ then $r_B > 1$ and, conversely, when $r_A > 1$ then $r_B < 1$ (Table 5), i.e. peroxy-macroradicals react predominantly with one of the monomers. The growing peroxide chains add to the "foreign" monomer ($r_A < 1$, $r_B < 1$) only in the oxidative copolymerisation of styrene with *p*-chloro-, *p*-bromo-, or *p*-iodo-styrene. When the comonomers of styrene and oxygen are compounds having conjugated double bonds (butadiene, 2,3-dimethylbutadiene, methyl sorbate, or methyl eleostearate), or α-methylstyrene, then the peroxy-macroradicals react preferentially with these compounds and

not with styrene. On the other hand, in the system butadiene (styrene)–O_2–tetralin (cumene or other hydrocarbons) the addition of peroxy-radicals is always much faster than the rate at which they abstract hydrogen.

The product $r_A r_B \simeq 1$ in the system styrene-butadiene–O_2, styrene-2,3-dimethylbutadiene–O_2, styrene–α-methylstyrene–O_2, and styrene (butadiene)–hydrocarbon–O_2. The product can serve as a measure of the selectivity of peroxy-radicals, because $k_{AB} = k_{BB}$ and $k_{AA} = k_{BA}$ when $r_A r_B = 1$. In the above systems each monomer exhibits approximately the same reactivity in relation to the radicals $AO_2^{\cdot}$ and $BO_2^{\cdot}$, while the reactivities of peroxy-radicals of both types differ insignificantly and depend little on the structure of their penultimate unit A or B. The absence of selectivity in relation to radicals is responsible for the disordered arrangement of the ~BOO~ and ~AOO~ units in the polyperoxide chains.

IV. RELATION BETWEEN THE STRUCTURE AND REACTIVITY OF MONOMERS[88]

The monosubstituted vinyl monomers investigated, which have the structure $CH_2 = CHR$, can be arranged in the following sequence in terms of increasing $k_2/k_6^{1/2}$: methyl acrylate ≃ vinyl acetate < methyl vinyl kentone < acrylonitrile < styrene < butadiene (series I) (Table 6). The corresponding series II formed by 1,1-disubstituted monomers having the structure $CH_2 = C(CH_3)R$ is: isopropenyl acetate < methyl methacrylate < isopropenyl methyl ketone < methylacrylonitrile < α-methylstyrene (Table 6). The chain propagation rate constants k_2, the absolute values of which exert a decisive influence on $k_2/k_6^{1/2}$, increase in the same sequence.

Table 7. The relative reactivities of the monomers ($1/r$) towards the polymeric radicals ~$MO_2^{\cdot}$ and ~$M^{\cdot}$ *

Monomer	~$MO_2^{\cdot}$ radicals (50°C) from				~$M^{\cdot}$ radicals (60°C) from		
	butadiene	α-methyl-styrene	styrene	methyl metha-crylate	butadiene	styrene	methyl methacryl-ate
Butadiene	1.0	—	2.4	—	1.0	—	4.0
α-Methylstyrene	—	1.0	2.1	25	—	0.85	2.0
Styrene	0.46	0.48	1.0	13	0.72	1.0	2.0
Methyl methacrylate	—	0.07	0.13	1.0	—	2.0	1.0

* The Table was set up on the basis of published data for oxidative copolymerisation[9,109,117] and copolymerisation[118].

However, comparison of the values of k_2 yields only a general idea about the efficiency of the elementary addition step for different monomers, since the absolute rate constants depend on the reactivity of both the monomer and the polyperoxy-radical. In order to discover which of the above factors is of decisive importance in oxidative polymerisation, it is necessary to find out how the reactivity of the monomers and the peroxy-radicals varies in the series under consideration. Judging from the form of variation of the reciprocals of the copolymerisation rate constants $1/r$ (Table 7) and the chain propagation rate constants (Tables 4 and 8), the reactivity of monomers as peroxy-radical acceptors increases in the following sequence: methyl methacrylate < styrene < α-methylstyrene < butadiene. For the remaining compounds in series I and II, there is no information about $1/r$ and $k_{AB}(k_{BA})$. This makes it necessary to infer the reactivity of the monomers from the rate of addition of the polymeric radicals ~$M^{\cdot}$ and not ~$MO_2^{\cdot}$, assuming that the monomer activity series do not then change significantly. This assumption may be resorted to on the basis of the concordant results obtained for butadiene, α-methylstyrene, styrene, and methyl methacrylate as regards the rates at which they accept the ~$M^{\cdot}$ and ~$MO_2^{\cdot}$ radicals (Table 7). According to copolymerisation data[118,120], the reactivity of monomers with respect to the radicals ~$M^{\cdot}$ varies in the following way: vinyl acetate < methyl acrylate < acrylonitrile < methyl vinyl ketone < styrene < butadiene (series III) and isopropenyl acetate < methyl methacrylate < methylacrylonitrile < α-methylstyrene (series IV).

According to the available extremely limited data (Table 8), the reactivity of peroxy-radicals ~$MO_2^{\cdot}$ derived from the monomers in reactions involving addition to a double bond decreases in the sequence: styrene > methyl methacrylate > α-methylstyrene. One should also note that secondary peroxy-radicals are more reactive than tertiary radicals not only in the hydrogen abstraction reaction[91], but also in addition to the double bond (Table 8) and in recombination steps (Table 3).

Table 8. The rate constants (litre $mole^{-1}s^{-1}$) of reactions of the ~$MO_2^{\cdot}$ and ~$M^{\cdot}$ polymeric radicals with monomers*

Monomer	~$MO_2^{\cdot}$ radicals (50°C) from			~$M^{\cdot}$ radicals (60°C) from	
	styrene	methyl-metha-crylate	α-methyl-styrene	styrene	methyl-methacrylate
α-Methylstyrene	204	43	28	—	1050
Styrene	98	23	13	170	1050
Methyl methacrylate	12	1.8	1.8	310	520

* The rate constants for the ~$MO_2^{\cdot}$ radicals were calculated from the values of r_A and r_B (Mayo et al.[9]) and from k_2.[63,78,79] Those for the ~$M^{\cdot}$ radicals were calculated from r_A and r_B (Ham[118]) and from k_3.[32,119]

The identical arrangements of the monomers in sequences I and III and II and IV support the conclusion that the main factor in oxidative polymerisation, which determines the overall rate of the process, is the reactivity of the monomers and not peroxy-radicals. This conclusion is consistent with the earlier hypothesis that the activity of the double bond plays a decisive role in oxidative polymerisation[9].

A rigorous justification of the above relation can be achieved at the present time only for α-methylstyrene and methyl methacrylate. ¶ In the oxidative polymerisation of these monomers the increase of $k_2/k_6^{1/2}$ and k_6 on passing

¶ In the oxidative copolymerisation of α-methylstyrene with styrene and of methyl methacrylate with styrene the products are tertiary and secondary peroxy-radicals respectively, having significantly different reactivities, which hinders a rigorous interpretation of the type of variation of $k_2/k_6^{1/2}$ and k_2.

from α-methylstyrene to methyl methacrylate parallels the increased reactivity of the monomers and is in opposition to the decreased reactivity of the radicals.

The increase of the rate of homopolymerisation of vinyl monomers is known to be equal to the increase in the reactivity of the corresponding macroradicals[32]. The inversion of this relation in oxidative polymerisation must be attributed to the nature of the chain-carrier radical resulting from the conversion of ~M· into $MO_2^·$ via the reaction ~M· + O_2 → ~$MO_2^·$. A direct comparison of the reactivities of the polymeric radicals ~M· and ~$MO_2^·$ is at present possible only for styrene and methyl methacrylate, because the required data are lacking for the remaining monomers.

Table 9. The rate constant ratios k_3/k_1 and the rate constants for the reaction ~M· + O_2 $\xrightarrow{k_1}$ ~$MO_2^·$ (at 50°C)*

Radical	Medium	$10^6 k_3/k_1$	k_1, litre mole^{-1} s^{-1}	Refs.
$-CH_2-\dot{C}H-CH=CH_2$	Butadiene	7.0±2.5	$1.0\cdot10^7$	82
$-CH_2-\dot{C}H-C_6H_5$	Styrene	3.7±0.4	$3.3\cdot10^7$	24
	Styrene	1.8	$6.6\cdot10^7$	25
	Styrene-benzene	⩽70	$1.7\cdot10^6$	26
$-CH_2-\dot{C}(CH_3)-C(O)-OCH_3$	Methyl methacrylate	50±3 0	$7.2\cdot10^6$	3
	Methyl methacrylate-benzene	⩽30	$1.2\cdot10^7$	2

* The values of k_3/k_1 were determined[3,24,25,82] from the results of the analysis of the composition of polymeric peroxides. The values of k_3/k_1 were estimated[3,26] from the results of the study of the overall kinetics of the polymerisation reaction. The rate constants k_1 were calculated with k_3 = 70, 120, and 360 litre mole^{-1}s^{-1} for butadiene, styrene, and methyl methacrylate respectively[32].

The peroxy-radical derived from methyl methacrylate is less active in the addition to the double bond than the peroxy-radical derived from styrene, while the opposite relation is observed for the ~M· radicals derived from the same monomers (see Table 8 and Bagdasar'yan's book[32], p.207). The reactivities of the ~M· and ~$MO_2^·$ radicals can be compared directly for each monomer in terms of the chain propagation rate constant ratio k_3/k_2 †. In this case the monomer from which the radicals have been derived serves for them as a comparison standard:

$$\sim M^· + M \xrightarrow{k_3} \sim MM^· \text{ and } \sim MO_2^· + M \xrightarrow{k_2} MO_2M^·.$$

The conversion of the radical ~M· into ~$MO_2^·$ is as a rule associated with a sharp decrease in the reactivity of the radical towards addition to the double bond, the decrease being more pronounced the more reactive was the radical ~M· (Table 10). The validity of this rule for all peroxy-radicals in the monomer series I and II should have the inevitable consequence that the decisive factor in oxidative polymerisation becomes the reactivity of the monomers and not the radicals. The levelling of the reactivities of the radicals on passing from ~M· to ~$MO_2^·$ is most probably caused by the significant decrease in the influence of the structure of the M monomer molecule on the reactivity of a free radical of the type ~$MO_2^·$ compared with a radical of the type M·. This influence does not apparently extend beyond the oxygen atom of the ~$MO^·$ fragement of the ~MOO· unit, because the directions of the orbitals of the lone electron pairs of the oxygen atoms in the -O-O- peroxy-groups are mutually perpendicular[121]. This is probably also the cause of the comparatively small change in the reactivity of primary, secondary, and tertiary radicals $RO_2^·$ in the abstraction of hydrogen atoms as a function of the structure of R [91,122,123] (Table 4).

† k_3/k_2 can be estimated from the ratio $k_3/k_4^{1/2} : k_2/k_6^{1/2}$, because $k_4^{1/2} = k_6^{1/2}$ (to within an order of magnitude).

Table 10. The rate constants for the polymerisation and oxidative polymerisation reactions of certain monomers (at 50°C)*

Monomer	$10^3 k_6/k_6^{1/2}$, litre mole^{-1} s^{-1}	$10^3 k_3/k_4^{1/2}$, litre mole^{-1} s^{-1}	γ	k_2, litre mole^{-1} s^{-1}	k_3, litre mole^{-1} s^{-1}	γ'
Styrene	13.7	15.0	1.1	98	120	1.2
Acrylonitrile	2.20	61.0	28	—	—	—
Methyl methacrylate	1.42	79.3	56	1.8	360	200
Vinyl acetate	0.61	264	430	—	—	—
Methyl acrylate	0.43	510	1200	1.7	980	570

* The values of $k_2/k_6^{1/2}$ and k_2 were obtained from the published data for styrene[46,77], acrylonitrile[56], methyl methacrylate[81,82], vinyl acetate[57,66], and methyl acrylate[57,65]. The values of $k_3/k_4^{1/2}$ and k_3 were evaluated from data of Bagdasar'yan[32]. Notation: $\gamma = k_3/k_4^{1/2} : k_2/k_6^{1/2}$; $\gamma' = k_3/k_2$.

The arrangement of the monomers in series I and II shows that the influence of substituents in these compounds on their reactivity decreases in the sequence $-CH_2=CH_2 \simeq C_6H_5- > -CN > -C(O)-CH_3 > -C(O)-OCH_3 \simeq OC(O)-CH_3$. In radical addition reactions of the same type the influence of substituents is interpreted on the hypothesis of a linear relation between the change in activation energy and the conjugation energy in the reacting molecules and radicals[32,124]. This approach is also possible in oxidative polymerisation. Allowance for other factors (apart from conjugation) capable of influencing the radical reactivity is at the present time still fairly difficult[125,126]. The treatment of the reactivities of monomers in oxidative polymerisation from the standpoint of the influences which the substituents exert on the electron density in π bonds is also acceptable. Calculations of the distribution of electron density in monomers[127,128] showed that the π-electron density in double bonds decreases in the sequence styrene > acrylonitrile > methyl methacrylate > methyl acrylate > vinyl acetate. Thus there is a correspondence between the change in the reactivity of the monomers in oxidative polymerisation and the electron density in their π bonds. This feature is consistent with the electron-accepting properties of peroxy-radicals[9,129].

Judging from the values of $k_2/k_6^{1/2}$ and k_2, unsaturated 1,1-disubstituted compounds having the structure $CH_2 = C(CH_3)R$ as a rule interact with oxygen at higher rates than the corresponding monosubstituted compounds $CH_2 = CHR$ (Table 6). The decrease of k_6 from 3×10^7 litre mole^{-1}s^{-1} to 7×10^5 litre mole^{-1}s^{-1} (at 50°C) makes a significant contribution to the increase of the ratio $k_2/k_6^{1/2}$ for α-methylstyrene relative to styrene, which compensates the

decrease of k_2 (Tables 2 and 3). However, the introduction of a more bulky substituent in the α-position relative to the double bond (for example in α-phenylstyrene) also leads to a decrease of $k_2/k_6^{1/2}$ (Table 2). The introduction of an electron-accepting substituent in the β-position reduces sharply the rate of oxidative polymerisation: β-bromostyrene reacts with oxygen at a rate smaller by two orders of magnitude than styrene or β-methylstyrene (Table 2). The introduction of electron-donating substituents (CH_3, CH_3O, etc.) in the *para*-position in the styrene ring increases the reactivity of the monomers, while electron-accepting substituents (F, NO_2) reduce it significantly (Table 5).

The rate of oxidative polymerisation of α-substituted derivatives of acrylonitrile varies as follows: methylacrylonitrile > ethylacrylonitrile > n-propylacrylonitrile > isopropylacrylonitrile > n-pentylacrylonitrile (Table 2). The hyperconjugation effect, arising owing to the interaction of the σ electrons of the C–H bonds of the substituents with the π electrons of the $H_2C = C(R)-C \equiv N$ conjugated system, probably increases in the above sequence, lowering the electron density in the double bond.

It has been established[46,63] that the quantity $k_2/k_6^{1/2}$ and correspondingly the rates of interaction of monomeric methacrylates and acrylates with oxygen, as well as the chain propagation rate constants k_2 depend only slightly on the size of the substituent R in the alkoxy-group in the esters $CH_2 = C(R_1)C(O)OR$, where $R_1 = H$ or CH_3 and R = CH_3, C_4H_9, C_9H_{19}, or $C_{16}H_{33}$ (Tables 2 and 3). It is most likely that the substituent R has no significant influence on the reactivity of the double bonds in the peroxy-radicals of acrylates and methacrylates. The double bonds in methacrylate esters are more reactive than those in acrylate esters in the addition reactions of both M$^{\cdot}$ [32] and $RO_2^{\cdot}$ [46] radicals. Presumably secondary peroxy-radicals having the structure $-CH_2-CH(R)(O)O^{\cdot}$ are more reactive than the tertiary radicals $-CH_2-C(R)(CH_3)OO^{\cdot}$ not only in the recombination reaction (Table 6) but also in the addition reaction. The opposite variation of the reactivities of the double bonds and free radicals should lead to the mutual approach of the values of k_2 for acrylates and methacrylates.

V. OXYGEN AS AN INHIBITOR OF RADICAL POLYMERISATION[88]

Oxygen is known to be an inhibitor of the polymerisation of vinyl monomers[2,32,130]. Saturation of the monomers with oxygen (air) reduces the rate of polymerisation and leads to the appearance of an inductive period. Inhibition takes place as a result of the highly efficient chain transfer of oxygen via the raction $\sim M^{\cdot} + O_2 \longrightarrow MO_2^{\cdot}$ and slow regeneration of the chain by peroxy-radicals: $\sim MO_2^{\cdot} + M \longrightarrow \sim MO_2M^{\cdot}$, because the rate of addition of the radical $\sim MO_2^{\cdot}$ to the double bond is much smaller than the rate of chain propagation: $\sim M^{\cdot} + M \longrightarrow \sim MM^{\cdot}$.

The available data make it possible to consider the mechanism of the inhibiton process and to observe the relation between the reactivity of monomers and the efficiency of the action of oxygen on radical-chain polymerisation.

Oxygen combines very rapidly with free radicals having an unpaired electron on a carbon atom, which serve as chain carriers in radical-chain polymerisation. The values of k_1 for the radicals M$^{\cdot}$ derived from butadiene, styrene, and methyl methacrylate lie in the range $2 \times 10^6 - 7 \times 10^7$ litre mole^{-1}s^{-1} (at 50° C) and depend little on the structure of the radical (Table 9). In general, the characteristic values of the rate constants k_1 for the reaction $R^{\cdot} + O_2 \xrightarrow{k_1} RO_2^{\cdot}$ are 10^6-10^8 litre mole^{-1}s^{-1}.[119] Judging from the values of k_1 quoted, oxygen reacts with free radicals of the type $R_1R_2R_3C^{\cdot}$ at the same rate as a free radical (typical values of k_4 and k_6 for the recombination reaction $2 \sim M^{\cdot} \xrightarrow{k_4}$ and $2RO_2^{\cdot} \xrightarrow{k_6}$ are 10^6-10^7 litre mole^{-1}s^{-1} [32,119]). This behaviour of oxygen can be accounted for by the characteristics of the electronic structure of its molecule. Oxygen in its ground electronic state is a biradical which has a $\sigma-\pi-\pi$ bonding skeleton and in addition two electrons with parallel spins in antibonding molecular orbitals.[131,132]

The ratio of the rates of the competing chain propagation reactions $\sim M^{\cdot} + M \xrightarrow{k_3} \sim MM^{\cdot}$ and the chain transfer to oxygen $\sim M^{\cdot} + O_2 \xrightarrow{k_3} \sim MO_2$ is given by the expression $W_3/W_i = k_3[M]/k_1[O_2] = \alpha$. Using α as a criterion, it is possible to estimate the probability of non-inhibited polymerisation steps in the presence of oxygen. According to estimates, the reaction $\sim M^{\cdot} + M \rightarrow \sim M^{\cdot}$ is suppressed in the temperature range 20–60° C for all vinyl monomers, including vinyl acetate and methyl acrylate which generate the most reactive radicals under the conditions of saturation with oxygen (according to the data in Table 10, the values of α for butadiene, styrene, and methyl methacrylate are 2.8×10^{-3}, 4.4×10^{-3}, and 5×10^{-2} respectively at 50° C).

Thus, during the induction period, the monomer and oxygen react in equimolar proportions via the mechanism represented by the elementary reactions (0), (1), (2), and (6) in Scheme 1; the rate of consumption of oxygen is constant and the reaction is of zero order with respect to O_2. The kinetics of polymerisation inhibited by oxygen[2,26,133] and also by oxygen and antioxidants present simultaneously[134-139] have been examined in detail. The range of oxygen concentrations in which O_2 exerts the maximum inhibiting effect on the polymerisation of monomers is defined by the relation $[O_2] \geqslant k_3[M]/0.1k_1$. Only at the end of the induction period does the O_2 concentration fall to values such that α proves to be greater than 0.1 and the $\sim MO_2^{\cdot} + \sim M^{\cdot}$ chain cross-termination reaction and the $\sim M^{\cdot} + M \rightarrow \sim MM^{\cdot}$ homopolymerisation steps become insignificant.

Since the efficiency of chain transfer to oxygen is extremely high, the $\sim M^{\cdot} + M \rightarrow \sim MM^{\cdot}$ chain propagation steps take place with a very low probability and the only pathway involving the consumption of the monomer becomes the chain regeneration reaction. The kinetic effect of oxygen on the polymerisation of the monomer is therefore determined by the ratio of the rate of chain propagation W_3 in the absence of O_2 to the rate of chain regeneration W_2, where $W_3 = (k_3/k_4^{1/2})[M]W_i^{1/2}$ for $P_{O_2} = 0$ and $W_2 = (k_2/k_6^{1/2}) \cdot [M]W_i^{1/2}$ when peroxy-radicals are responsible for chain termination: $2MO_2^{\cdot} \rightarrow$ chain termination. When the rates of initiation are equal, we obtain $W_3/W_2 = k_3k_6^{1/2}/k_4^{1/2}k_2 \cdot k_3/k_4^{1/2}$ and $k_2/k_6^{1/2}$ vary in opposite senses (Table 10) in the series styrene, acrylonitrile, methyl methacrylate, vinyl acetate, and methyl acrylate, in full agreement with the fact that k_3 is determined by the reactivity of the radical (homopolymerisation) and k_2 is determined by the reactivity of the monomer (oxidative polymerisation). In the above series of compounds the ratio W_3/W_2 increases sharply by three orders of magnitude, the inhibition of polymerisation being more pronounced the less reactive the monomer. This behaviour is a consequence of the decisive role of the reactivity of monomers in oxidative

polymerisation. Increasing inhibition of polymerisation is inevitable when the relatively unreactive peroxy-radicals interact with increasingly less reactive monomers. In homopolymerisation, where the reactivities of the monomers and radicals vary in opposition, the low reactivity of the monomer is swamped by the high reactivity of the radical[32].

Thus the efficiency of the inhibiting effect of oxygen varies in opposition to the reactivity of the monomer in the polymerisation reaction. This behaviour makes it possible to predict the influence of oxygen on radical polymerisation from the available literature values of $k_3/k_4^{1/2}$ and k_3, having adopted styrene as the reference monomer (since $W_3/W_2 \simeq 1$ for this compound in the temperature range 20–70°C).

* * *

It follows from the data presented that the fundamental elementary reactions in the oxidative polymerisation of vinyl monomers have now been established. The mechanism of the oxidative polymerisation of styrene, α-methylstyrene, methyl methacrylate, and butadiene has been studied comparatively fully. The kinetics of the interaction with oxygen of a series of other monomers have also been investigated, but the available information about the rate constants for the elementary reactions remains extremely limited. The results obtained made it possible to determine the nature of the relation between the structure of a vinyl monomer and its reactivity in oxidative polymerisation, and to discover the characteristics of the behaviour of oxygen as an inhibitor of radical-chain polymerisation. In general, oxidative polymerisation, which represents the boundary between radical-chain polymerisation and oxidation, has still been clearly inadequately investigated. A marked deficiency of data on the chemistry, kinetics, and thermodynamics of the interaction of oxygen with unsaturated compounds is felt. The most urgent task is a quantitative investigation of the mechanism of the oxidative polymerisation of vinyl monomers at advanced stages of the reaction, particularly in highly viscous media, including reactions in the solid phase. In combination with the study of macroscopic process kinetics, further studies on these lines will make it possible to lay the theoretical foundations for the formation of films of unsaturated compounds and will permit an expansion of research on the stabilisation of organic protective coatings.

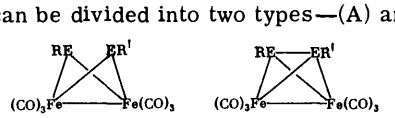
Dinuclear Iron Carbonyl Complexes with Nitrogen-containing Bridges

A.N.Nesmeyanov, M.I.Rybinskaya, and L.V.Rybin



The literature on the synthesis and properties of dinuclear complexes with the $N_2Fe_2(CO)_6$ group is surveyed. It is shown that these complexes are formed in reactions of a wide variety of nitrogen-containing organic compounds with iron carbonyls. The possibility of the formation of nitrene species and their complexes in these reactions is considered. The bibliography includes 123 references

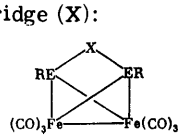
I. INTRODUCTION



Dinuclear iron carbonyl complexes with heteroatomic bridges are widely known in the chemistry of complex compounds. These compounds include also complexes containing the $Fe_2(CO)_6$ group, in which the iron atoms are linked by an intermetallic bond as well as one six-electron or two three-electron heteroatomic bridges. Depending on the electronic structure of the bridge, these complexes can be divided into two types—(A) and (B):

(A) (B)

Among complexes with three-electron bridges [type (A)], compounds with RS bridges have been known longest (see, for example, Refs. 1–4). Analogous nitrogen-containing compounds were discovered comparatively recently. An example of six-electron bridges is provided by the –S–S–, –NR–NR–, and –PR–PR–† groups. Complexes of type (B) are formed with participation of such bridges.

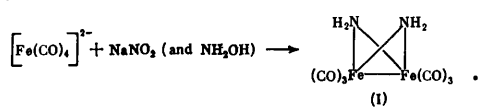
In their turn three-electron heteroatomic groups can also be linked by a bridge (X):

However, as will be shown below, these compounds differ little in their structural parameters from complexes of type (A).

Interest in transition metal complexes with nitrogen-containing ligands was initially due to the fact that the compounds with the diazene ligand (HN=NH) were regarded as possibly intermediates in the enzymatic fixation of molecular nitrogen[5,6]. However, subsequently

† A.H.Cowley and K.E.Hill, Inorg.Chem., 12, 1446 (1973).

interesting data were obtained fairly rapidly, showing that this field of the chemistry of complex compounds may be of independent importance.



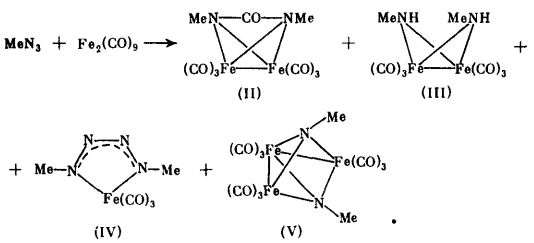
Complexes with nitrogen-containing bridges of types (A) and (B) were obtained by the interaction of various nitrogen compounds with iron carbonyls. During their synthesis, it was found that the formation of complexes of a particular type is controlled by a detailed balance between various factors. Thus it was discovered that the same complex may be generated from a wide variety of types of nitrogen compounds, and, just as surprisingly, compounds of one class, differing from one another merely by the nature of the substituents, can give rise to complexes of different types. This apparent contradiction was resolved on the hypothesis[7] of the intermediate formation in these reactions of either free nitrene species or such species coordinated to the metal. In many cases it was possible to isolate stable nitrene complexes.

Thus the chemistry of these complexes approached very closely that field of coordination chemistry, which has been developing vigorously in recent years, which is concerned with the problems of the stabilisation of unstable organic species as a result of coordination to transition metal complexes[8]. However, it would be incorrect to regard all the reactions of nitrogen compounds with iron carbonyls, leading to dinuclear complexes, as proceeding via the intermediate formation of nitrene species or their complexes. Otherwise the reactions with phenyl azide and azobenzene should have led to the same products, which is not the case. As will be shown below, the electronic and structural factors, the nature of the attacking transition metal complexes, and the reaction conditions determine the chemical behaviour of the nitrogen-containing ligand. It is not at present clear which of these factors predominates, but there is no doubt that the comparatively low strength of the N–N bond, whose dissociation energy is 37 kcal mole^{-1} in certain cases[9] owing to the repulsion of the nitrogen *p* orbitals, does not play the least important role.

In the present review the literature data are classified in terms of the reactions of different organic nitrogen compounds in order to follow more clearly the specific features of the behaviour of each of them. Special reviews devoted to dinuclear iron carbonyl complexes have not yet been published, but these data are considered partially in a number of review articles[8,10–12]. Analogous dinuclear complexes of other transition metals will be briefly mentioned only, for comparison.

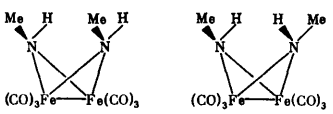
II. REACTIONS OF NITROGEN-CONTAINING ORGANIC COMPOUNDS WITH IRON CARBONYLS LEADING TO DINUCLEAR COMPLEXES

The simplest type (A) complex is obtained (in low yield) in the interaction of the anion $[Fe(CO)_4]^{2-}$ with $NaNO_2$ or hydroxylamine under mild conditions[13–16]. It was assumed initially that this compound contains the N–N group. However, its structure was established as that of complex (I) on the basis of mass spectra[17,18] and X-ray diffraction studies[18]:



(I)

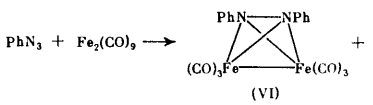
The reactions of organic nitrogen compounds with iron carbonyls lead as a rule to a mixture of different complexes.



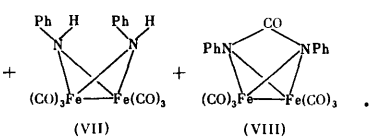
1. Reactions of Azides

Iron carbonyls catalyse the decomposition of organic azides under mild conditions. In most cases these reactions lead to the formation of a mixture of different complexes. The mixture composition varies considerably as a function of the type of organic group in the azide. Thus the reaction of methyl azide with $Fe_2(CO)_9$ gives rise to a mixture of complexes, where the main product is complex (II) with the ligand MeNCONMe‡.[7] The structure of this complex was demonstrated by the diffraction method[19]:

(II) (III) (IV) (V)



Complex (III) was obtained in a low yield and resolved into the stereoisomeric forms (IIIa) and (IIIb):



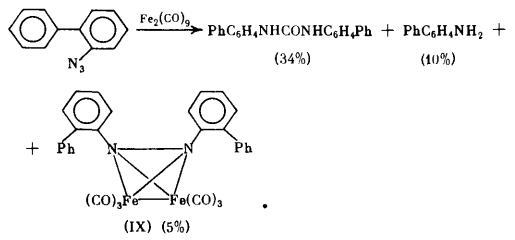
(IIIa) (IIIb)

Complex (IV), with a tetra-azadiene ligand, unknown in a free state, was isolated from the products of this reaction in a high yield (20%). The trinuclear complex (V) is formed in a moderate yield. The yield of the complex in the reaction of $MeNO_3$ with $Fe_2(CO)_9$ [7] is fairly high. Its structure was demonstrated by X-ray diffraction[20].

Phenyl azide reacts just as fast with $Fe_2(CO)_9$, but in this case the main product is the dinuclear complex (VI) with a six-electron ligand containing an N–N bond§[7]. A similar complex was not isolated from the products of the analogous reaction involving methyl azide:

(VI)

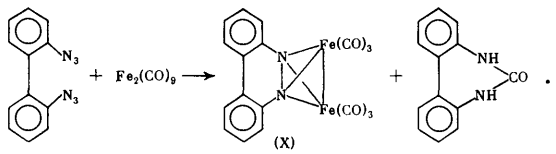
(VII) (VIII)



Furthermore, the reaction gives rise to complex (VII) in a low yield. In contrast to the analogous complex (III), obtained by the reaction with methyl azide, complex (VII) was isolated in only one stereoisomeric form. It is unstable in solution and decomposes spontaneously; the diphenylurea derivative (VIII) formed under these conditions was also isolated from the products of the reaction of phenyl azide with $Fe_2(CO)_9$.[7] The same compound is formed when $Fe_3(CO)_{12}$ is used (heating to 90°C).[21]

---

‡ It is noteworthy that this product is obtained in a higher yield in the reaction of methyl isocyanate with $Fe_2(CO)_9$.[7]

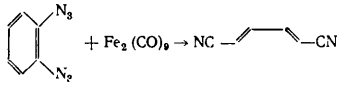


§ Free azobenzene was isolated in this reaction in a negligible yield.

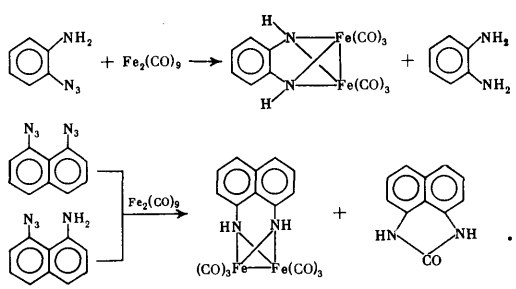
The thermal decomposition of 2-azidobiphenyl is known to result in the formation of carbazole (in a high yield)[22]. However, when this azide decomposes in the presence of $Fe_2(CO)_9$, carbazole is formed in a negligible yield, while the main products of this reaction are *N*,*N*′-bis-(2-biphenylyl)urea (34%), 2-aminobiphenyl (10%), and the dinuclear complex (IX) (5%):[23]

(IX) (5%)

A similar dinuclear complex (X) is formed from a biphenyl derivative containing two azido-groups in the *ortho*-positions in different rings[23]:



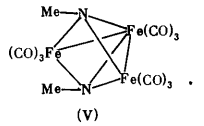
(X)



Together with complex (X), a cyclic urea derivative is also formed in this case. The determination of the structure of (X) and its specific synthesis from benzo[*c*]-cinnoline have already been described[24,25].

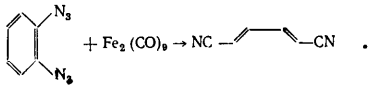
Thus in the above reactions aromatic azides give rise to dinuclear complexes of type (B) with six-electron nitrogen-containing ligands, while methyl azide gives rise mainly to dinuclear complexes of type (A) with three-electron bridges.

The course of these reactions differs somewhat when two azido-groups or an azido- and an amino-group are present in the *ortho*-positions of the benzene ring or in the *peri*-positions in the naphthalene molecule. Only *cis*,*cis*-muconitrile was isolated from the products of the reaction of *o*-diazidobenzene (27%):[23]



Under the same conditions, *o*-azidoaniline, 1,8-diazidonaphthalene, and 1-amino-8-azidonaphthalene form, together with purely organic products, dinuclear complexes in which the nitrogen atoms are linked by *o*-phenylene or *peri*-naphthalene bridges[23]:

These results show that steric factors can also play a significant role in the formation of products.



The hypothesis of the formation of nitrene species in the decomposition of azides in the presence of transition metal compounds does not lack justification, since in many cases complexes with such species have been isolated.

It has been shown by X-ray diffraction[19] that the trinuclear cluster (V), isolated from the products of the reaction of methyl azide with $Fe_2(CO)_9$,[7] is a complex in which each nitrene species $CH_3\dot{N}$: is coordinated to three iron atoms:

(V)

The iron complex (XI) of $Me_3Si\dot{N}$: was isolated from the products of the reaction of trimethylsilyl azide with $Fe_2(CO)_9$. This complex proved to be a trinuclear cluster incorporating a triply coordinated trimethylsilylnitrene species. It is of interest that one of the carbonyl groups in this cluster is also linked to three iron atoms[26,27]:

Stable nitrene complexes have also been obtained by the reaction of a polyfluorinated azide with ruthenium and osmium carbonyls[28]¶:

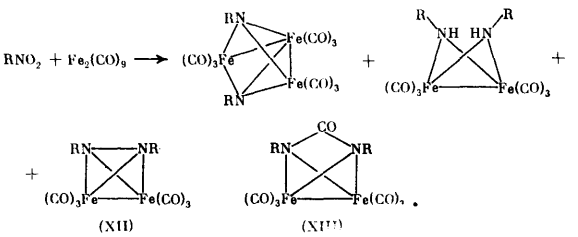
$$Ru_3(CO)_{12} + CF_3CHFCF_2N_3 \rightarrow Ru_3(CO)_9(NCF_2CHFCF_3)_2;$$
$$M(CO)_3(PPh_3)_2 + CF_3CHFCF_2N_3 \rightarrow M(NCF_2CHFCF_3)(CO)_2(PPh_3)_2;$$
$$M = Ru, \text{ or } Os.$$

Azides with other electron-accepting organic groups gave isocyanate complexes on interaction with the same ruthenium compound[29]:

$$RN_3 + Ru(CO)_3(PPh_3)_2 \rightarrow Ru(CO)_2(PPh_3)_2(RNCO);$$
$$R = PhCO,\ p\text{-}MeC_6H_4CO,\text{ or } p\text{-}MeC_6H_4SO_2.$$

In the presence of proton donors these complexes decompose with formation of isocyanate derivatives. It is of interest that the reaction of benzoyl azide or β-benzoylvinyl azide with $Fe_2(CO)_9$, carried out in aqueous alcohol, also led to derivatives of the corresponding isocyanates[30]:

$$RN_3 + Fe_2(CO)_9 \rightarrow [(RNCO)Fe(CO)_4] \xrightarrow[\text{alcohol, water}]{} [RN{=}C{=}O] \rightarrow RNHCOOC_2H_5 + RNH_2;$$
$$R = C_6H_5CO \text{ or } C_6H_5COCH{=}CH$$

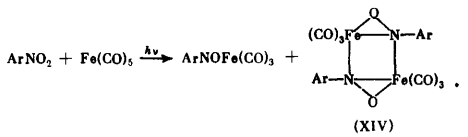


Speaking of the formation of isocyanates, one should bear in mind that, in the absence of transition metal complexes, nitrenes combine with carbon monoxide under very severe conditions[31-34].

The interaction of 1-azidostyrene with $Fe_2(CO)_9$ [35] is examined below in the section dealing with the reactions of azirines.

¶ See the review of Genini and La Monica[8] for information about other stable nitrene complexes of transition metals obtained from azides.

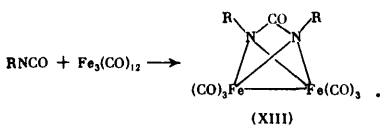
2. Reactions of Nitro-compounds



The reaction of nitromethane with $Fe_2(CO)_9$ gives the same mixture of products as the reaction with methyl azide [7]. Other aliphatic nitro-compounds, such as 1-nitro- and 2-methyl-2-nitropropanes, give rise to complexes (XII) with an N–N bond in addition to all the above products [36]. The main product of the reaction of 1-nitropropane with $Fe_2(CO)_9$ is, as for nitromethane, a trinuclear nitrene complex, while the reaction involving 2-methyl-2-nitropropane gives compound (XIII) in the highest yield:

(XII) (XIII).

Heating of aliphatic nitro-compounds with $Fe(CO)_5$ in diglyme at 120–132°C leads only to organic products—derivatives of formamide and urea [36]. The same products have been obtained on thermal degradation (120–130°C, diglyme) of certain iron carbonyl complexes isolated from the products of reactions with nitro-compounds. This suggested that iron carbonyl complexes may be intermediates in the formation of formamide and urea derivatives [36].



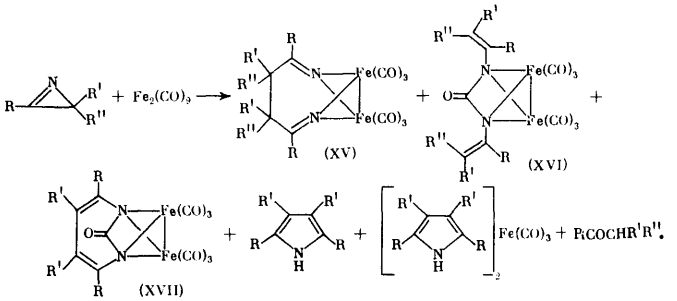
It is of interest that, on reaction with $Fe(CO)_5$ under ultraviolet or γ-irradiation, nitrobenzene forms nitrosobenzene complexes [37,38]. The structure of the dinuclear complex (XIV) was determined by X-ray diffraction [39]:

(XIV)

3. Reactions of Isocyanates

A report of the formation of an isocyanate complex on reaction of isocyanates RNCO (R = Me, n-Bu, or Ph) with $Fe_3(CO)_{12}$ was published in 1964. [21] Later studies established the presence of the ureylene group in these compounds and structure (XIII) was attributed to them [7,40], which was confirmed by X-ray diffraction [41]:

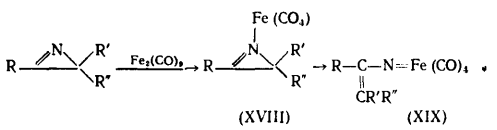
(XIII)



Intermediate complexes containing an isocyanate ligand can probably be formed in reactions with isocyanates. As shown above, such complexes were isolated in some cases [8]. At the same time it is important to note that nitrene complexes can also be obtained from isocyanates: this was observed in the reaction of phenyl isocyanate with $Ru_3(CO)_{12}$: [42]

4. Reactions of Azirines

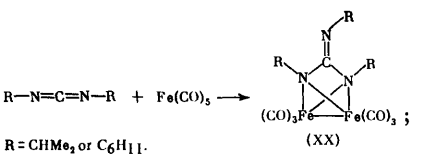
The reactions of azirines with $Fe_2(CO)_9$ have been investigated in detail [35,43]. When these compounds are heated at 50°C (3–4 h) in dry benzene, the dinuclear complexes (XV), (XVI), and (XVII), which are stable in air, and certain organic substances are formed:



Scheme 1

a) R = Ph, R′ = R″ = H; b) R = *p*-$CH_3C_6H_4$, R′ = R″ = H; c) R = *p*-BrC_6H_4, R′ = R″ = H; d) R = Ph, R′ = Me, and R″ = H; e) R = Ph, R′ = C_2H_5, R″ = H; f) R = CH_3, R′ = $CH(Me)_2$, R″ = H; g) R = Ph, R′ = R″ = Me.

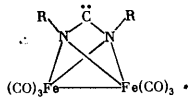
The structure of the products isolated was confirmed by spectroscopic data. It has been suggested [35] that a complex of type (XVIII) is involved in this reaction and is subsequently converted, with ring opening, into the nitrene derivative (XIX), which is the parent compound of all the products formed.



It is important to note that, on reacting with $Fe_2(CO)_9$, 1-azidostyrene gives rise to virtually the same products as phenylazirine, with the exception of pyrrole and its complex, which confirms the importance of the formation of the intermediate nitrene species (free or in the form of a metal carbonyl complex) [35]:

(XVIII) (XIX)

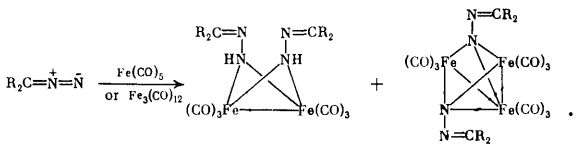
5. Reactions of Carbodi-imides



The reactions of carbodi-imides with $Fe(CO)_5$ give rise to dinuclear complexes (XX), whose acid hydrolysis indicates the presence in their molecules of the trialkylguanidine species linked to the $Fe_2(CO)_6$ group (see Section III). The infrared, NMR, and mass spectrometric data agree with formula (XX):

R = $CHMe_2$ or C_6H_{11}. (XX)

In the course of the discussion of the possible mechanism of the formation of this complex, a scheme involving the intermediate formation of the carbene species (XXI) was put forward. This species reacts further with a second carbodi-imide molecule and forms the complex (XX) and an isonitrile, isolated in the form of the compound



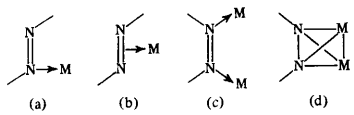
$(C_6H_{11}NC)Fe(CO)_4$:

(XXI)

6. Reactions of Diazo-compounds

Two types of complexes were isolated from the products of the reactions of diphenyl- and di-(*p*-tolyl)-diazomethanes with $Fe(CO)_5$ or $Fe_3(CO)_{12}$: an orange dinuclear complex (XXII) and a black trinuclear complex (XXIII).[44] The structures of the two complexes were confirmed by X-ray diffraction[44,45]:

(XXII) (XXIII)

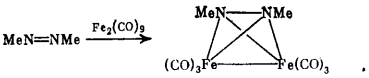


7. Reactions of Azo-compounds

Up to 1963, there was almost no information in the literature about the reactions of transition metal derivatives with azo-compounds, except for the description of certain metal chelate complexes of azo-dyes. However, from 1963, after the publication of the study of Kleiman and Dubeck[46] on the reactions of azobenzene with nickelocene, a series of other publications appeared in which complexes of azobenzene and its derivatives with platinum(II), palladium(II), and zerovalent iron were described[47-49].

Different ways of coordinating the N=N bond to transition metals (see Scheme 2) attracted the attention of chemists[10,11,24,50-54]. Of the four possible types of structures (a–d) of iron carbonyl complexes with azo-compounds, three structures were detected (a, c, and d), in which the nitrogen-containing ligand behaves as a donor of two, four, and six electrons respectively.

The type of coordination (b) is encountered in complexes of other transition metals, for example, $NiL_2(PhN{=}NPh)$[55-62] and $(C_5H_5)_2M(PhN{=}NPh)$ (M = Ti or V),[63] i.e. in those cases where the azo-compound is a comparatively poor σ-donor and the metal-containing fragment is a poor σ-acceptor.

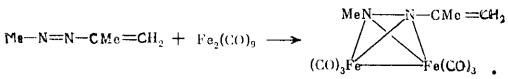


Scheme 2

(a) (b) (c) (d)

Azo-compounds with a wide variety of structures have been made to react with iron carbonyls. Studies have shown that the behaviour of aliphatic azo-compounds differs appreciably from that of azobenzene and its substituted derivatives.

The interaction of azomethane with di-iron nonacarbonyl leads to a dinuclear hexacarbonyl complex in which the initial compound retains its skeleton[64]. The ligand behaves in this case as a six-electron donor. The structure of the complex was demonstrated by X-ray diffraction:



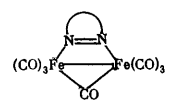
It is noteworthy that the dissociation of the bond between the nitrogen atoms has been observed for hexafluoroazomethane, which gives rise to a mixture of *cis*- and *trans*-isomers of the nitrene complexes $(Ph_2PMe)_2Ir.(CO)(Cl)(NCF_3)$ on treatment with *trans*-$ClIr(CO)(Ph_2.PMe)_2$:[65]

$(Ph_2PMe)_2Ir(CO)(Cl)(NCF_3)$[65]:

$$CF_3N{=}NCF_3 + \textit{trans}\text{-}ClIr(CO)(Ph_2PMe)_2 \rightarrow \textit{cis}\text{- and } \textit{trans}\text{-}(Ph_2PMe)_2Ir(CO)Cl(NCF_3).$$

Unfortunately the reactions of iron carbonyls with hexafluoroazomethane have not been investigated.

The reaction of di-iron nonacarbonyl with 2-(methylazo)propane is very remarkable[66]. In contrast to other butadiene systems, this compound gives rise to a dinuclear complex to which structure (XXIV) was attributed on the basis of spectroscopic data. The vicinal disposition of the nitrogen atoms in this compound has a decisive influence on the structure of the complex, while the C=C double bond is not involved in coordination[66]:

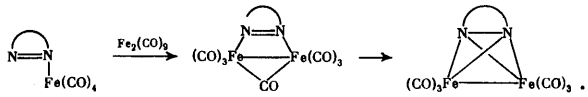


(XXIV)

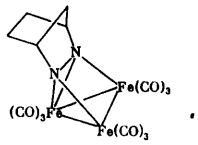
This is not surprising if one takes into account the quantum-chemical calculations on the PhCH=CHPh and PhN=NPh molecules[67,68], where the energies of the highest occupied molecular orbitals (HOMO) are approximately equal, while the lowest unoccupied molecular orbital (LUMO), which is in both cases π^*-antibonding, lies in a far lower position for azobenzene†.

Cyclic azo-compounds also retain their skeleton in reactions with iron carbonyls. Dinuclear iron carbonyl complexes of type (B) have been obtained from 2,3-diazabicyclo[2,2,1]hept-2-ene,[51-53] derivatives of 1,2-diazacyclopent-1-ene,[50,69,70] 1,3,4-thiadiazoline,[53] and dibenzo[1,4,5]oxadiazepine.[24,25]. It is noteworthy that in these reactions the first stage involves the formation of the mononuclear complexes $LFe(CO)_4$,[50,53] in which the metal atom is coordinated to one of the nitrogen atoms[70] and the ligand occupies an axial position.

Together with these compounds, complexes of the type $LFe_2(CO)_7$ were isolated in the reactions involving 2,3-diazabicyclo[2,2,1]hept-2-ene and 1,3,4-thiadiazoline[53]. On the basis of infrared and ^1H NMR spectra, the following structure was attributed to these complexes:



(XXV)

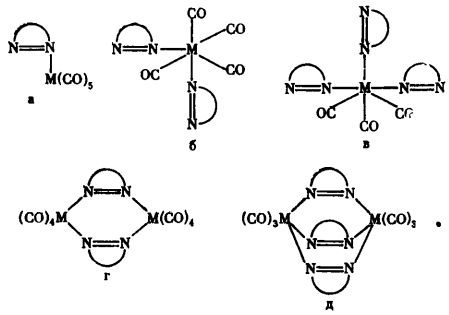


The infrared spectra of these compounds exhibit absorption by the metal carbonyl bridge groups in the range 1770–1820 cm^{-1}.[53] Compounds of type $LFe(CO)_4$ and $LFe_2(CO)_7$ are apparently intermediates[51,53] in the

† For information about the electronic structures of compounds with the –N=N– group, see, for example, Albini and Kisch's review[12].

formation of the dinuclear complexes $LFe_2(CO)_6$, since the conversion of $LFe(CO)_4$ into $LFe_2(CO)_7$ and then into $LFe_2(CO)_6$ can be followed by infrared spectroscopy in the region of approximately 2000 cm^{-1}.

It has been shown recently that a complex of type $LFe(CO)_4$, where L = diazanorbornene, reacts with iron carbonyls and can give rise to the trinuclear cluster (XXVI) together with a dinuclear complex of type $LFe_2(CO)_6$ and the former can also be synthesised by irradiating a dinuclear type (A) complex ($\lambda \geqslant 300$ nm) in the presence of iron carbonyls[51]:



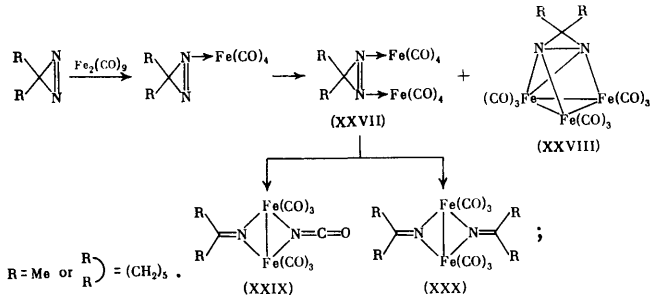
(XXVI)

Bearing in mind that the dinuclear complexes are diamagnetic, it follows that, in conformity with the effective atomic number rule, the metal atoms in them should be linked by an intermetallic bond, whose presence has been confirmed by X-ray diffraction (see below).

It is of interest that Group VIB metal carbonyls react with azo-compounds to give, together with mononuclear complexes (of types a–c, Scheme 3), also dinuclear complexes of types d and e in which the ligand behaves as a four-electron donor and the metal atoms are not linked to one another[6,71–75]:

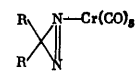
Scheme 3

Thus Group VIB metals form a bond with nitrogen atoms solely via lone electron pairs, while the π electrons of the N=N group are not involved in bonding to the metal, in contrast to iron carbonyl complexes. This can probably be attributed to the fact that the lowest unoccupied antibonding orbital of azo-compounds is located sufficiently low to make possible their interaction with Group VIB metals.



We may note that, instead of a mixed complex of type d, the reaction of $L_2Mo(CO)_4$ (where L = diazanorbornene) with $Fe_2(CO)_9$ gave a dinuclear di-iron hexacarbonyl complex of type $LFe_2(CO)_6$.

The reaction with diazirines, which are strained cyclic azo-compounds, is a special case. Diazirines contain the N=N group in a three-membered ring, and the distribution of electron density in these compounds differs significantly from that in other cyclic azo-compounds.

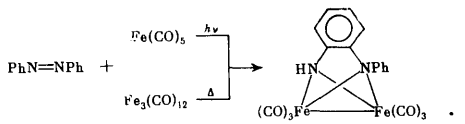


MINDO/2 calculation for 3,3-dimethyldiazirine[76] led to the conclusion that the orbitals of the C–N σ bond are appreciably mixed with a linear combination of those of free pairs of n_- and n_+ electrons of the nitrogen atoms, so that the concept of a "free pair" apparently loses its significance in these compounds. Calculation showed that the electrons are localised on the nitrogen atoms to an extent of only 56%,[76] so that the possibility of the formation of complexes of diazirines with metals appears to be problematical.

However, in reality it was found that[54] 3,3-dimethyl- and 3,3-pentamethylene-diazirines in tetrahydrofuran (THF) react with $Fe_2(CO)_9$ to form unstable complexes of the type $LFe(CO)_4$ (Scheme 4), which are subsequently converted into compounds (XXVII), giving rise also to a small amount of the trinuclear cluster (XXVIII). The diazirine skeleton is retained in all these compounds. Complexes (XXVII) decompose in solution with formation of new, more stable compounds (XXIX) and (XXX), which can be synthesised directly from diazirines and $Fe_2(CO)_9$ or $Fe(CO)_5$ on irradiation. This entails the dissociation of the C–N and N=N bonds and it is postulated that intermediate nitrene species are formed in the latter case[54]:

Scheme 4

Analogous results have been obtained in a study[77] in which the structure of complex (XXX) [where R–R = $(CH_2)_5$] was confirmed by X-ray diffraction. It is of interest that the aquopentammineruthenium derivative $[Ru(NH_3)_5(H_2O)]^{2+}$ used in the above study in the reaction with 3,3-pentamethylenediazirine promotes only the dissociation of the C–N bonds, which results in the formation of a complex with molecular nitrogen, namely $[Ru(NH_3)_5N_2]^{2+}$,[77] while in the reaction with $Cr(CO)_6$ the diazirine skeleton is retained and only complex (XXXI) is formed[54]:

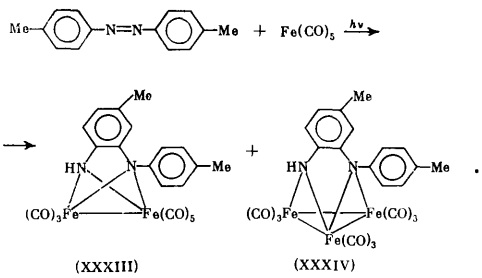


(XXXI)

The above examples provide a good illustration of the major influence of the metal in the attacking complex on the behaviour of the azo-compound.

The cleavage of the N=N bond is a new phenomenon in the chemistry of diazirines. However, a similar phenomenon is fairly usual in reactions of aromatic azo-compounds with iron carbonyls. At the same time it is important to note that the behaviour of such azo-compounds depends in many respects, as will be shown below, on the nature of the substituent in the aromatic ring.

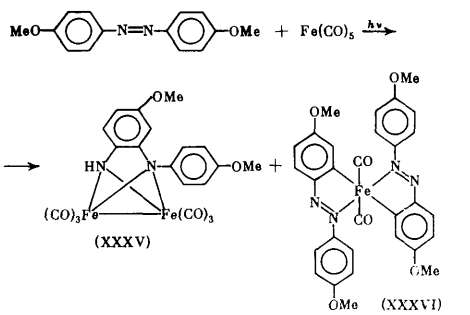
The interaction of azobenzenes with $Fe_2(CO)_9$ was investigated for the first time by Bagga et al.[49] X-Ray diffraction analysis established[78,79] that the complex isolated has the structure (XXXII), indicating the dissociation



of the N=N bond as a result of an orthosemidine rearrangement‡:

(XXXII)

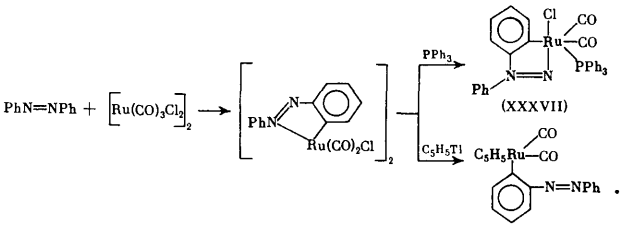
The yields of compound (XXXII) are only 2–3% both in the photochemical reaction of azobenzene with $Fe(CO)_5$ and in the thermal reaction with $Fe_3(CO)_{12}$.[80] At the same time in one of the reports[24] it is stated briefly that the reaction of azobenzene with $Fe_2(CO)_9$ at room temperature results in the formation of an unstable complex in which the azobenzene ligand is probably incorporated without serious changes, since azobenzene is liberated in attempts to purify the complex chromatographically or by sublimation. It is of interest that, as already stated above, a comparatively stable complex of type (B) with the azobenzene ligand is formed in the reaction of phenyl azide with $Fe_2(CO)_9$.[7]



The behaviour of ring-substituted azobenzenes in reactions with iron carbonyls differs from the behaviour of azobenzene itself. Thus, when 4,4′-dimethylazobenzene reacts with $Fe(CO)_5$ under irradiation, two complexes with the *ortho*-semidine ligand are formed: a dinuclear complex (XXIII) in 2% yield and a trinuclear complex (XXXIV), which becomes the sole product when $Fe_2(CO)_9$ is used instead of $Fe(CO)_5$:[80]

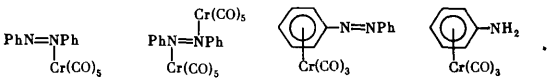
(XXXIII) (XXXIV)

The structures of these complexes were assigned on the basis of spectroscopic studies and data derived from chemical reactions[80].



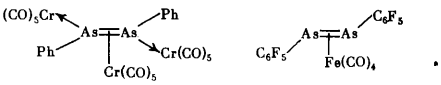
Under the same conditions, 4,4′-dimethoxyazobenzene gives a 22% yield of complex (XXXV) and a small amount of a completely new compound (XXXVI), which is a product of ring metallation[80]:

(XXXV) (XXXVI)



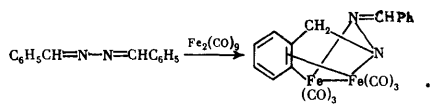
‡ When complexes of the type η^5-$C_5H_5M(CO)_2$, where M = Co (I) or Rh (I), are used in the reaction of azobenzene, dinuclear complexes with the *ortho*-semidine skeleton are also formed[81].

It is important to note that ring-metallated chelate complexes of type (XXXVI) are obtained fairly frequently when other metal carbonyls are used in the reaction with azobenzene[82–87]. Thus $[Ru(CO)_3Cl_2]_2$ yields a dimer, which is converted into complexes (XXXVII) and (XXXVIII) respectively on treatment with Ph_3P and C_5H_5Tl:[84]



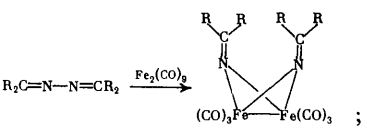
(XXXVIII)

Depending on the conditions, chromium hexacarbonyl yields at the same time four complexes[88]:



It is noteworthy that azobenzene does not react with metal carbonyls to form π complexes via the N=N bond, while its arsenic analogue yielded the π complexes (XXXIX) and (XL):[89,90]

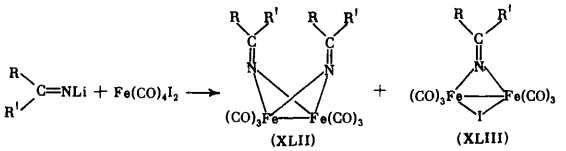
(XXXIX) (XL)



8. Reactions of Azines

There is at present no clear-cut hypothesis concerning the electronic and structural factors responsible for the different types of behaviour of azines in reactions with iron carbonyls. Thus the bond between the nitrogen atoms is retained in benzylideneazine on reaction with $Fe_2(CO)_9$ and a complex is formed to which the following structure was attributed on the basis of spectroscopic data[49]:

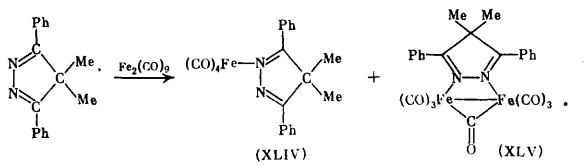
(XLI)



Benzophenone azine and its 4,4′-dimethyl derivative react with iron carbonyls to give low yields of di-iron hexacarbonyl complexes of type (XLII) whose formation involves the dissociation of the N–N bond[49]. The structure of these complexes has been demonstrated by X-ray diffraction in relation to compound (XLIIb):

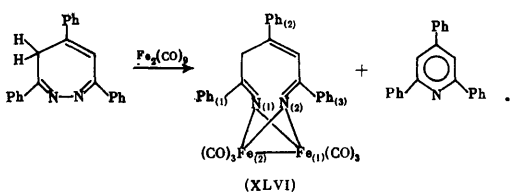
(XLII): a) R = Ph; b) R = *p*-MeC_6H_4.

After unsuccessful attempts to improve this method of synthesis, a different procedure was proposed, which also leads to the formation of a small amount of compound



(XLIII):[92]

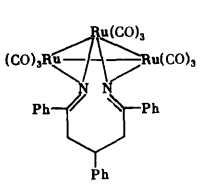
(XLII) (XLIII)



(a) R = R' = Ph; (b) R = R' = *n*-MeC$_6$H$_4$; (c) R = Ph, R' = t-Bu.

The unstrained cyclic azine 5,5-dimethyl-1,4-diphenyldiazacyclopentadiene reacts with $Fe_2(CO)_9$ under mild conditions (25°C) in pentane to form two complexes: a mononuclear complex (XLIV) and a dinuclear complex (XLV):[93]

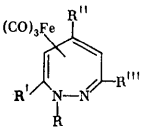
(XLIV) (XLV)



In agreement with infrared spectroscopic data, complex (XLV) incorporates a CO bridge group [ν(CO) = 1736 cm^{-1}]. The nitrogen-containing ligand plays in this case the role of a four-electron donor. A cyclic seven-membered azine, such as 3,5,7-triphenyl-4*H*,1,2-diazepine, gives rise in this reaction to the dinuclear complex (XLVI) with dissociation of the N–N bond[94–96]:

(XLVI)

In the study of the Mössbauer spectra of this complex[94] the iron atoms were found to be non-equivalent, which was explained, after X-ray diffraction study, by differences between the Fe–N [$(Fe_1-N)_{av}$ and $(Fe_2-N)_{av}$] bond lengths (1.920 and 1.965 Å respectively). The differences between the bond lengths can be caused in their turn by the steric effects of the two phenyl substituents in the ring, namely $Ph_{(1)}$ and $Ph_{(3)}$, located on the same side of the ring as $Fe_{(2)}$.

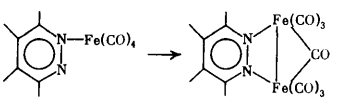


An analogous complex has been obtained as a result of the reaction of 3,5,7-triphenyl-4,5,6-trihydro-1,2-diazepine with $Fe_2(CO)_9$.[84] It is of interest that the use of $Ru_3(CO)_{12}$ in this same reaction led to the trinuclear cluster (XLVII):[94]

(XLVII)

At the same time the reactions of $[Rh(CO)_2X]_2$ (where X = Cl or Br) with seven-membered heterocycles give rise to complexes of type $LRh(CO)_2X$ in which the metal is coordinated to one of the nitrogen atoms[94]; this was confirmed by X-ray diffraction analysis of the compound with the 3,5,7-triphenyl-4*H*-1,2-diazepine ligand (X = Cl).[96]

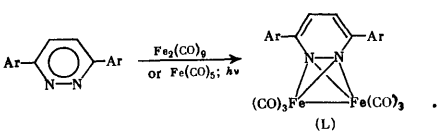
As in the series of *N*-substituted 1(1*H*),2-diazepines, the breakdown of the diazepine system leads to mononuclear complexes of type (XLVIII) with coordination between the metal atom and the diene group in the heterocycle[97–99]:



(XLVIII)

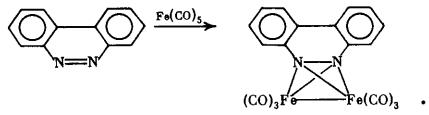
9. Reactions of Aromatic Heterocycles with Two Vicinal Nitrogen Atoms

Since the resonance hybrid of aromatic heterocycles incorporates structures with both N=N and =N–N= groups, it is not surprising that iron carbonyls react with these heterocycles in the same way as with azo-compounds and diazines.



The simplest representative of this class of compounds, namely pyridazine, and also 3,6-dimethylpyridazine react with $Fe_2(CO)_9$ to form in the first stage mononuclear complexes of type $LFe(CO)_4$ in which the metal atom is bound to one of the nitrogen atoms[53,100]. Next, according to Herberhold and Leonard[53], complexes of type $LFe(CO)_4$, formed from pyridazine and phthalazine, are converted into dinuclear compounds (XLIX). In these compounds the ligand behaves as a four-electron donor coordinated to the $Fe_2(CO)_7$ group and containing the CO bridge group in the pyridazine complex [$\nu(CO)_{bridge}$ = 1851 cm^{-1} in KBr and 1775 cm^{-1} in THF solution]. The presence of seven carbonyl groups in the complexes (XLIX) has been confirmed convincingly by mass spectrometry[53]:

(XLIX)



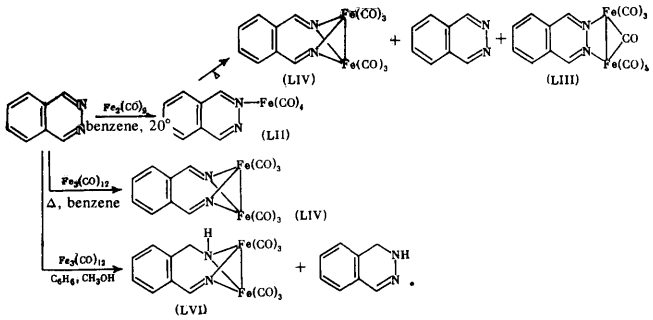
It is noteworthy that the attempt to convert compounds of type $LFe_2(CO)_7$ into $LFe_2(CO)_6$, which was achieved for dinuclear iron carbonyl complexes of aliphatic azo-compounds, was unsuccessful[53]. On heating or irradiation in the presence of CO the complex (pyridazine)$Fe_2(CO)_7$ regenerates (pyridazine)$Fe(CO)_4$.[53]

The reaction of 3,6-diarylpyridazine with $Fe_2(CC)_9$ gives rise to iron carbonyl complexes (L)[123] Their structure was demonstrated by X-ray diffraction analysis of the monotriphenylphosphine derivative[101]:

(L)

An analogous dinuclear complex (LI) was obtained (in 79% yield) from benzo[*c*]cinnoline [24] §:

(LI)

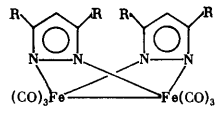


Its structure was also confirmed by X-ray diffraction [25]. In the reaction involving benzo[*c*]cinnoline the formation of an intermediate di-iron heptacarbonyl complex with a CO bridge group was noted [53]. Thermal or photochemical decarbonylation of $LFe_2(CO)_7$ (L = benzocinnoline) leads to complex (LI). The synthesis of dinuclear complexes from 1,10-dichloro- and 3,8-dichloro-benzo[*c*]cinnolines and from 4,5,9,10-tetra-azapyrene has also been mentioned [24], both N=N fragments in the last compound being coordinated to $Fe_2(CO)_6$ groups.

The above examples suggest that the formation of the $N_2Fe_2(CO)_6$ group is energetically fairly favourable, since it occurs despite the losses of resonance energy as a result of the breakdown of the aromatic system of the heterocycle.

Phthalazine forms mononuclear and dinuclear complexes with iron carbonyls (Scheme 5). When it is treated with $Fe_2(CO)_9$ in n-hexane or benzene at 20°C, a mononuclear complex of type $LFe(CO)_4$ (LII) is formed, in which the nitrogen-containing ligand occupies an axial position. Furthermore, a dinuclear heptacarbonyl complex $LFe_2(CO)_7$ (LIII) with a CO bridge group is formed [ν(C=O) = 1745 cm^{-1} in KBr or 1775 cm^{-1} in THF]. [53,104]

According to Alper's data [104], on heating in benzene complex (LII) is converted into a compound $LFe_2(CO)_6$, to which structure (LIV) was assigned. In contrast to di-iron hexacarbonyl complexes of 3,6-diarylpyridazine, there is no bond between the nitrogen atom in compound (LIV). The latter is formed also when phthalazine is heated with $Fe_3(CO)_{12}$ in benzene [104]. The alternative *ortho*-xylylene structure (LV) for this substance has been rejected on the grounds that the ligand in (LIV) retains its benzenoid structure.

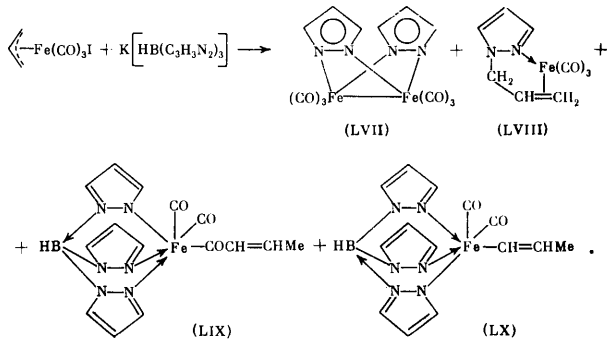


Scheme 5

A dinuclear complex (LVI) (Scheme 5) was detected in the products of the interaction of phthalazine with $Fe_3(CO)_{12}$ in benzene in the presence of methanol [104].

§ It is noteworthy that the reaction of benzo[*c*]cinnoline with Group VIB metal hexacarbonyls gives rise to complexes $LM(CO)_5$, in which the metal is coordinated to one of the nitrogen atoms [102,103].

The reactions of five-membered heterocycles have so far been little investigated. It has been shown that, when pyrazole or 3,5-dimethylpyrazole reacts with $Fe_2(CO)_9$ in ether, dinuclear hexacarbonyl complexes of type (LVII), whose structure has been assigned on the basis of spectroscopic data, are formed together with other products [105,106]:



(LVII) ;

R = H, or Me.

The same dinuclear complex (LVII) (R = H) has been obtained by the interaction of $Fe(CO)_4I_2$ with pyrazolylsodium [106]:

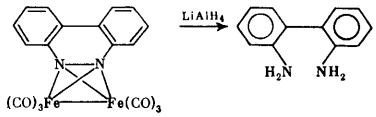
$$2Fe(CO)_4I_2 + 2C_3H_3N_2Na \rightarrow (C_3H_3N_2)_2Fe_2(CO)_6 + 2NaI + 2CO$$

and has also been isolated from the products of the reaction of π-(allyl)$Fe(CO)_3I$ with $K[HB(C_3H_3N_2]_3$. [107] The mononuclear complexes (LVIII)–(LX) were obtained together with this product in the latter case:

(LVII) (LVIII)

(LIX) (LX)

III. CHEMICAL PROPERTIES OF DINUCLEAR COMPLEXES



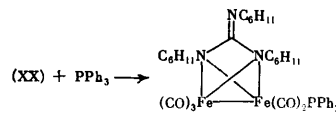
The reactivity of the dinuclear complexes has still been little investigated. Studies have been made mainly on reactions designed to demonstrate the structures of these compounds and, particularly, in order to elucidate the nature of the nitrogen-containing ligand incorporated in them. Thus, *N*,*N*',*N*''-tricyclohexaguanidine, identified as the picrate, was isolated after the acid hydrolysis of complexes of type (XX) (R = C_6H_{11}): [108]

$$(XX) \xrightarrow{H^+} C_6H_{11}NHCNHC_6H_{11} \quad (\text{with } NC_6H_{11})$$

N,*N*'-Diphenylurea was obtained in 50% yield by treating complex (VIII) with $LiAlH_4$, which confirms the presence of this ligand in the complex [41]:

$$(VIII) \xrightarrow{LiAlH_4} PhNHCONHPh$$

On interaction with $LiAlH_4$, the dinuclear benzo[*c*]cinnoline complex forms 2,2-diaminobiphenyl in 56% yield [24]:

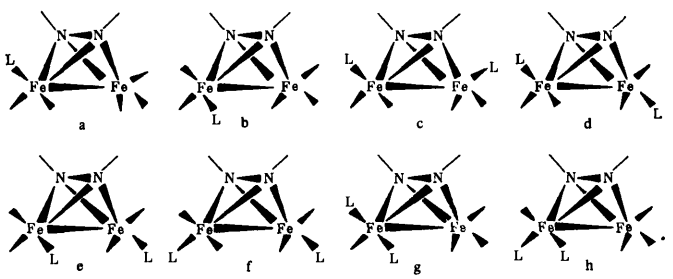


Under the same conditions, free benzo[*c*]cinnoline is resistant to the action of $LiAlH_4$, but, when the complex

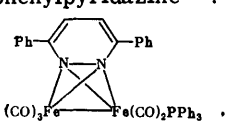
is treated with an oxidant, such as Ce^{4+}, free benzo[*c*]-cinnoline may be produced.

The CO ligand substitution reactions involving these complexes are also striking. It has been shown in many instances that phosphines, phosphites, arsines, and isonitriles substitute one and in some cases two CO groups without change in the main skeleton of the complex.

Triphenylphosphine substitutes one or two CO groups in the complex $[Fe_2(CO)_6(NH_2)_2]$ giving rise to compounds of type $[Fe_2(CO)_5PPh_3(NH_2)_2]$ and $[Fe_2(CO)_4(PPh_3)_2(NH_2)_2]$.[17,109] It is of interest that the latter can be very readily oxidised by iodine with formation of the dication $[Fe_2(CO)_4.(PPh_3)_2(NH_2)_2]^{2+}$.[17] It is also noteworthy that NO completely displaces the CO ligands from the complex $[Fe_2(CO)_6(NH_2)_2]$.[14,15]



Only one CO group is substituted in a complex of type (XX) (R = C_6H_{11}) by PPh_3 even in the presence of an excess of the latter; this reaction results in the formation of a monophosphine derivative, which is very stable in air[108]:

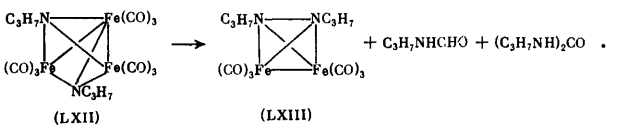


When the di-iron hexacarbonyl complex of benzo[*c*]cinnoline is treated with phosphines, phosphites, arsines, and isonitriles, both mono- and di-substituted derivatives are formed[24,110]. Here it is significant that the substitution of one of the CO groups by another ligand should theoretically lead to two isomers [(a) and (b) (Scheme 6)], while substitution of two CO groups should lead to six isomers [(c)–(h) (Scheme 6)].

Analysis of the infrared spectra of monosubstituted benzo[*c*]cinnoline complexes suggested that these compounds have the structure of the *trans*-isomers (a):[110]

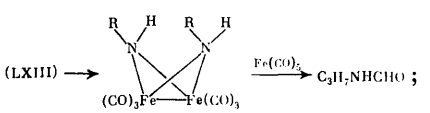
Scheme 6

trans-Substitution¶ relative to the Fe–Fe bond has been demonstrated by the X-ray diffraction study of the triphenylphosphine complex (LXI) obtained from di-iron hexacarbonyl-3,6-diphenylpyridazine[101]:



(LXI)

The problem of the structure of the disubstituted derivatives has still not been finally solved. Isomers of types (g) and (h) (Scheme 6) were ruled out on the grounds that the mass spectra of the diphosphite and di-isonitrile complexes investigated, obtained from di-iron hexacarbonyl–benzo[*c*]cinnoline, failed to reveal fragment ions containing one iron atom linked to two $P(OCH_3)_3$ or $C_6H_{11}NC$ molecules[110]. It is extremely difficult to choose between isomers (c)–(f) (Scheme 6). On the basis of the number of bands in the metal carbonyl part of the spectrum, it was concluded that a mixture of isomers is formed in most instances, but it could not be resolved chromatographically[110].



Extremely useful information about the reactivity of dinuclear iron carbonyl complexes was obtained in a study of the interconversions and thermal degradation of these compounds. The study of the products of the reactions makes it possible to some extent to infer the sequence of stages in the formation of dinuclear complexes.

It has been shown[36] that, when the trinuclear complex (LXII) is heated in diglyme at 120–130°C, complex (LXIII) and traces of C_3H_7NHCHO and $(C_3H_7NH)_2CO$ are formed:

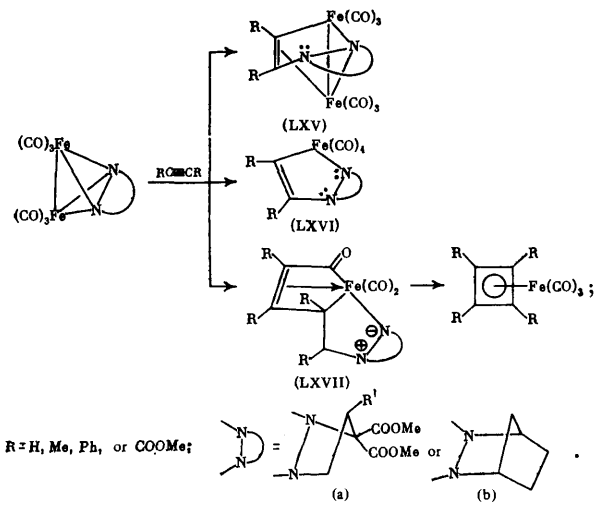
(LXII) (LXIII)

On further heating, complex (LXIII) is converted into (LXIV) with rupture of the N–N bond in the bridge ligand:

(LXIV) R = C_3H_7.

When this compound is heated with iron pentacarbonyl, a formamide derivative is formed. Thermal degradation of complex (XIII) (R = C_3H_7) with a ureylene ligand led to the formation of *N*,*N*′-disubstituted urea and the formation of a small amount of complex (XII):

$$(XIII) \xrightarrow[\text{diglyme}]{} (XII) + (RNH)_2CO .$$

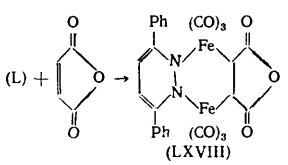


One should note here that the nature of the substituent R can influence the course of the reaction. Thus spontaneous reconversion of complex (XII) into (XIII) for R = Ph has been observed[7]. Prolonged heating of a type (XIII) complex (R = t-Bu) yields substituted formamide and urea[36].

Thus trinuclear complexes of type (LXII) can behave as precursors of binary compounds when the latter are formed from azides and nitro-compounds. Reactions involving insertion in the N–Fe bond can be assigned to the most interesting and hitherto little investigated branch of the chemistry of dinuclear complexes. The insertion of CO molecules in this bond has already been mentioned. Thermal and photochemical reactions of dinuclear complexes with alkynes were investigated recently[111–113] and it was found that alkyne molecules are inserted in the N–Fe bond with formation of complex (LXV)–(LXVII)

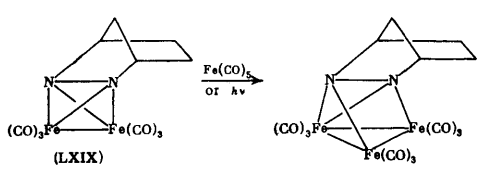
¶ We have in mind the *trans*-substitution relative to the Fe–Fe bond in the distorted octahedron at each Fe atom.

Scheme 7):[111,112]



Scheme 7

It was found that complex (LXV) is readily converted into (LXVI) and the latter into (LXVII). The structures of compounds (LXVa) and (LXVIIa) (R = R′ = Ph) were confirmed by X-ray diffraction. In contrast to compounds with ligands (a) and (b), the complex obtained on the basis of benzo[*c*]cinnoline reacts with alkynes to give only a compound of type (LXV).



It is of interest to note that, when compounds of type (LXVII) (R = Ph) were heated *in vacuo* to 150°C, tetraphenylcyclobutadieneiron tricarbonyl was obtained. This compound can be synthesised in a single stage by heating the initial di-iron hexacarbonyl complex with a sixfold excess of diphenylacetylene (yield 70%).[111] The authors[111] noted that they were unable to obtain analogous results using aliphatic alkynes[12].

The interaction of the dinuclear complex (L) (Ar = Ph) with maleic anhydride has been assigned to reactions of the same type[113]†:

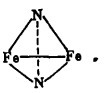
The structure of complex (LXVIII) obtained was demonstrated by X-ray diffraction[113].

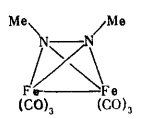
Finally, a very interesting conversion into a trinuclear cluster was observed in the interaction of complex (LXIX) with $Fe(CO)_5$ or simply on its irradiation ($\lambda \geqslant 300$ nm):[51]

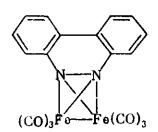
† Other workers[113] regard this reaction as cycloaddition.

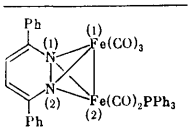
IV. RESULTS OBTAINED BY PHYSICAL RESEARCH METHODS

The common fragment in the dinuclear complexes investigated is the group $N_2Fe_2(CO)_6$, which determines the main properties of these compounds. According to X-ray diffraction studies, the N_2Fe_2 fragment in this group has tetrahedral or a distorted tetrahedral geometry and the presence or absence of the bond between nitrogen atoms‡ in the fragment clearly divides all the complexes into two groups (see Tables 1 and 2):









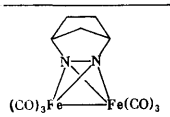


Table 1. Certain structural parameters of dinuclear complexes of type (B) (the bond lengths are quoted in angstroms and the angles in degrees).

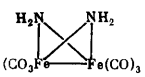
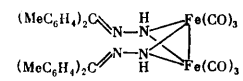
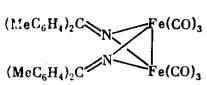
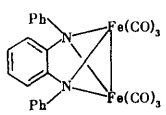
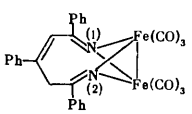
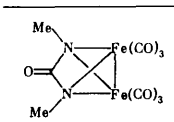


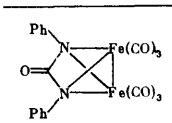


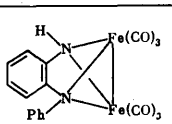








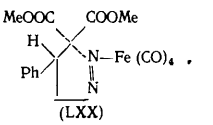




Complex	Fe—Fe	Fe—N	N—N	Fe—N—Fe	N—Fe—N	Refs.
	2.496	1.878	1.366	83.4	42.7	64
	2.508	1.914	1.399	81.9	42.90	25
	2.53	1.93($Fe_{(1)}$—$N_{(1)}$); 1.95($Fe_{(2)}$—$N_{(2)}$)	1.43	82.00	42.0	101
	2.990	1.932	1.405	81.3	43.1	121

The distance between the nitrogen atoms in dinuclear complexes with an N—N bond [(type B), Table 1] is approximately 1.40 Å, which corresponds to a single bond[44,114,115]. The distance between the nitrogen atoms in the other group of complexes [type (A), Table 2] varies in the range 2.15—2.50 Å, which undoubtedly leads to the conclusion that there is no bond between them. It has been observed that in complexes with an N—N bond the length of the Fe—Fe bond (2.50 Å) is always greater by approximately 0.1 Å than in the other group, where the Fe—Fe bond length is approximately 2.40 Å. This tendency was

‡ A dashed line NN implies that a bond between nitrogen atoms is not obligatory.



first noted by Doedens and Ibers [64] and was subsequently confirmed by Doedens [25]. The shortening of the Fe–Fe bond (to 2.40 Å) in complexes without an N–N bond is probably due to the constancy of the Fe–N bond length [116]. In the dinuclear complexes considered this bond length varies from 1.91 to 2.00 Å, but it cannot vary within limits as wide as in the case of the Fe–Fe bond [116–119]. Indeed, Table 3, taken from Vahrenkamp [116], shows that the Fe–Fe bond length can vary from 2.40 to 3.05 Å, i.e. by more than 0.6 Å. Thus, in order to keep the Fe–N bond length constant on passing from complexes of type (B) to those of type (A), the Fe–Fe bond must be somewhat shortened with a consequent obligatory decrease of the Fe–N–Fe angle (from 83° to 72°, cf. Tables 1 and 2).

Table 2. Certain structural parameters of dinuclear complexes of type (A) (the bond lengths are quoted in angstroms and the angles in degrees).

Complex	Fe–Fe	Fe–N	N–N	Fe–N–Fe	N–Fe–N	Refs.
	2.402	1.98	2.50	74.4	77.8	18
	2.40	2.00	—	—	—	44
	2.403	1.94	—	—	—	91
	2.37	2.00	—	72.50	73.00	78
	2.393	1.920 (Fe_1—N) 1.965 (F_2—N)	2.25	—	—	95
	2.39	1.975	—	75.37	65.00	19
	2.402 2.416	2.01 1.99		74 74.5	65 64.9	41 122
	2.372	2.00	2.38	72.5	72.9	79

Furthermore, the data in Table 3 show that the dependence of the Fe–Fe bond length on the Fe–heteroatom bond length is common to dinuclear iron complexes.

At the same time it is important to note that virtually identical Fe–N bond lengths have been found both in dinuclear complexes of types (A) and (B) and in iron tetracarbonyl derivatives $LFe(CO)_4$. X-Ray diffraction studies on complex (LXX) [70] showed that the Fe–N bond length in this complex is 1.979 Å and the nitrogen–nitrogen bond length is 1.242 Å, which corresponds to the N=N double bond:

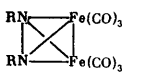
(LXX)

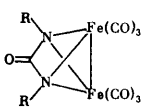
It follows from X-ray diffraction data that the $N_2Fe_2(CO)_6$ group in the complexes considered has C_{2v} symmetry, like other structurally related bridge groups in the compounds $LFe(CO)_6$. [64]

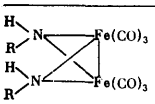
Table 3. Certain results of the X-ray diffraction analysis of dinuclear complexes with heteroatomic bridges [116].

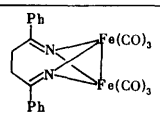
Complex	Bridge heteroatom	Fe–heteroatom distance, Å	Fe–Fe, Å
$[(CO)_3FeNH_2]_2$	N	1.98	2.40
$(CO)_5Fe_2Cp(PMe_2)$	P	2.19	2.63
$(CO)_8FeMnAsMe_2$	As	2.35	2.85
$[(NO)_2FeI]_2$	I	2.58	3.05

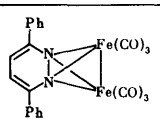
Group theoretical analysis makes it possible to predict five infrared-active vibrations for terminal carbonyl groups: $2A_1 + 2B_2 + B_1$. [120]

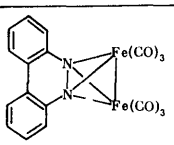


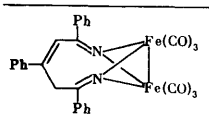


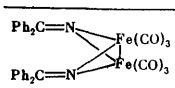












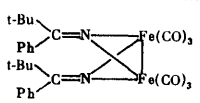


Table 4 presents the stretching vibration frequencies of the CO ligands for certain complexes containing the $N_2Fe_2(CO)_6$ group. It shows that the spectra of the majority of complexes in the region of $\nu(C{\equiv}O)$ are very similar. In a number of studies this similarity between the spectra enabled the presence of the $N_2Fe_2(CO)_6$ group in the complexes to be observed [69,92,94].

It is much more difficult to conclude whether or not the nitrogen–nitrogen bond is present on the basis of infrared spectra. In this instance the influence of the ligand as a whole is probably more important. It may consist both in the breakdown of the symmetry of the metal carbonyl fragment, which leads to an increase of the number of absorption bands [92], and in an enhancement or weakening of the electron-donating properties of the ligand, which causes a band shift [53]. Such a band shift is manifested to an even greater extent on passing to $LF_2(CO)_6$ systems with other bridge heteroatoms (S, P, As, etc.) [120].

At the same time infrared spectra of the complexes $LFe_2(CO)_7$ yield undoubtedly important information. Apart from the four stretching vibration bands of the terminal CO ligands, they include the characteristic absorption at 1820–1730 cm^{-1}, which convincingly demonstrates the presence of a carbonly bridge group [83,93]. The mass spectra of many complexes contain molecular ions

and indicate the successive elimination of all the carbonyl groups[18,53,92,108]. The fragmentation of the LFe_2^+ ions formed in this process is determined mainly by the nature of the ligand L.

Table 4. The stretching vibration frequencies of the CO ligands in certain complexes $LFe_2(CO)_6$.

Lanthanide Titanates

L.G.Shcherbakova, L.G.Mamsurova, and G.E.Sukhanova

Compounds formed in the R_2O_3-TiO_2 binary systems, where R is a lanthanide element, are examined. Methods for the preparation of lanthanide titanates in both polycrystalline and single-crystal form are analysed. Attention is concentrated on the crystal chemistry and the physicochemical properties of lanthanide titanates with quadrivalent titanium. A number of examples of practical applications of these compounds are given.
The bibliography includes 110 references.

I. INTRODUCTION

Interest in lanthanide titanates with the pyrochlore structure arose in connection with the suggestion that they might have ferroelectric properties—by analogy with cadmium pyroniobate $Cd_2Nb_2O_7$, which has a cubic structure of the pyrochlore type and is a unique and unusual ferroelectric material at low temperatures[1,2]. This finding stimulated the study by Roth[3], who was the first to synthesise and investigate a whole series of lanthanide titanates with the pyrochlore structure. Further investigations showed that only some titanates ($La_2Ti_2O_7$ and $Nd_2Ti_2O_7$)[4,5] are effective ferroelectric substances with extremely high Curie temperatures. However, numerous studies on the synthesis and properties of these compounds raised a series of new problems. Thus an investigation of the phase transformations in the high temperature interaction of TiO_2 with lanthanide sesquioxides established the formation of lanthanide titanates with different structures from which new technological materials with a set of interesting properties can be obtained. Their high fire resistance and chemical stability permits their employment in high-temperature chemistry and nuclear power engineering.

However, the available data have not been surveyed hitherto; a monograph[6] deals with only a small range of problems. The present review gives a systematic account of data concerning the methods of synthesis, crystal chemistry, and physicochemical properties of lanthanide titanates with quadrivalent titanium; only compounds formed in the R_2O_3-TiO_2 binary systems are considered.

II. THE SYNTHESIS OF LANTHANIDE TITANATES

A series of methods for the synthesis of lanthanide titanates in the polycrystalline and single-crystal form have now been developed.

1. Solid-Phase Synthesis

The solid-phase synthesis is carried out by heating to high temperatures mechanical mixtures of TiO_2 and lanthanide sesquioxides. In most cases discs are pressed from the mechanical mixtures and are then placed on platinum supports and annealed in electric furnaces in air.

Ceramic technology requires the use of high temperatures, prolonged annealing, and in addition repeated sintering of the product in order to obtain a single-phase titanate. Nevertheless this method of synthesis is widely used[3,7-16], but only as a rule in those cases where the aim was to obtain a compound of the type $R_2Ti_2O_7$ from a mechanical mixture of the oxides having the composition $2TiO_2 + R_2O_3$. This is apparently due to the advantageous feature of the method: the fact that one obtains a product with a more precisely specified composition and also because of the fairly high rate of formation of the given compounds. For example, the compounds $La_2Ti_2O_7$, $Nd_2Ti_2O_7$, $Sm_2Ti_2O_7$, $Gd_2Ti_2O_7$, $Dy_2Ti_2O_7$, and $Y_2Ti_2O_7$ have been obtained[3] by heat treatment for 4 h at 1100°C. However, the same compounds have been synthesised at different temperatures in a number of studies. For example, $Sm_2Ti_2O_7$ has been obtained at 1200°, 1300°, and 1400°C[3,7] and $Gd_2Si_2O_7$ at 1000°, 1350° and 1400°C[3,7], the duration of sintering being determined by the temperature of the synthesis.

2. The Coprecipitation Method

Numerous investigations[7,15,17-33] in the last decade showed that it is useful to obtain polycrystalline lanthanide titanates by coprecipitation and not for mechanical mixtures of oxides. Amorphous hydroxides are as a rule coprecipitated by treating a mixture of an aqueous solution of $TiCl_4$ and a nitric acid (or hydrochloric acid) solution of R_2O_3 with aqueous ammonia. The product is filtered off, washed with water, and dried at approximately 100°C. According to X-ray and electron diffraction data, the freshly obtained precipitates are amorphous. Their characteristic feature is the presence of a considerable amount of chemically bound lanthanide hydroxide. In the general case the rate of chemical reaction between the lanthanide and titanium at the instant of precipitation depends on the nature and composition of the precipitate formed; the amount of product which has reacted may range from 15 to 45%.[31]

Crystalline titanates are formed on further heating of mixtures of the amorphous hydroxides to the crystallisation temperature. Fig. 1*c* presents a thermogram of the coprecipitated neodymium and titanium hydroxides[22]. It is seen that two peaks are characteristic of the precipitated product: an endothermic peak at 290°C corresponding to

dehydration and an exothermic peak at 810°C corresponding to the crystallisation of $Nd_2Ti_2O_7$. It has also been established [22] that the thermograms of precipitates obtained by coprecipitation differ significantly from those of the individual lanthanum and titanium hydroxides, which enabled the authors [22] to suggest that coprecipitation results in the formation of the corresponding lanthanide titanate and not simply a mechanical mixture.

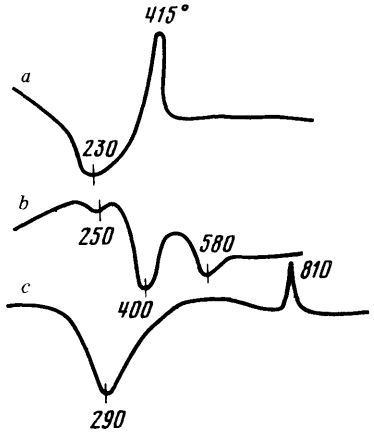

Figure 1. Thermograms: a) titanium hydroxide; b) neodymium hydroxide; c) coprecipitated neodymium and titanium hydroxides [22] (the numerals represent the temperature in °C).

A detailed study has been made [31] of the dehydration process, which showed that the products of the chemical reaction between titanium and lanthanide hydroxides are hydroxo-complexes $R_2[TiO_2(OH)_2]_3.nH_2O$. OH groups are eliminated at approximately 500°C and the residual water (1.5–2%) is lost at approximately the same temperature. The main bulk of water is eliminated at temperatures up to 150°C where the rate of dehydration is extremely high. Because of this, the authors [31] concluded that the interaction between the coprecipitated lanthanum and titanium hydroxides most probably involves the OH groups and proceeds via the hydroxo-complex stage.

The phases in the temperature range 400–800°C, i.e. from the temperature corresponding to the virtually complete removal of water up to the formation of lanthanide dititanates, have been identified [30,31]. The existence of intermediate compounds having the composition $La_{2/3}TiO_3$ having the perovskite structure and crystallising in the orthorhombic system has been established. According to the authors [31], lanthanide metatitanates are the intermediate products which are formed on heating the coprecipitated hydroxo-complexes of the lanthanide and titanium. These compounds are unstable and decompose above 800°C with formation of lanthanide dititanates. It is noteworthy that analogous defect phases having the perovskite structure have been detected earlier on interaction of La_2O_3 and TiO_2 in a reducing atmosphere [33–35]. However, the unit cell parameters of perovskite were in this case [31] somewhat smaller than in the study of Leonov et al. [35] This was explained [31] by the failure to complete the formation of the lattice in the compounds $R_{2/3}TiO_3$ obtained by the moderate heating of the coprecipitated hydroxides.

The temperature of the synthesis of lanthanide titanates is usually somewhat higher than their crystallisation temperature. Thus $Nd_2Ti_2O_7$ and $La_2Ti_2O_7$ crystallise at 810° and 825°C, while the compounds have been synthesised by different workers in the temperature range 1000–1300°C. This is also true of the titanates of the entire lanthanide series. The degree of formation of $La_2Ti_2O_7$ has been studied [21] as a function of temperature and duration of annealing. It was established that the temperature rather than the duration of annealing has a considerable influence on the yield of $La_2Ti_2O_7$. The intensity and distinctness of the lines on the X-ray diffraction patterns increase with temperature for different durations of heat treatment in the range from 1 to 12 h, but above 1100°C they hardly change. At 900°C the complete formation of $La_2Ti_2O_7$ requires an annealing time of 6 h.

Thus the clear advantages of the coprecipitation method are a reduction of the temperature of the synthesis of the compounds and the possibility of the virtually complete binding of R_2O_3 and TiO_2, which can probably be explained by the formation of lanthanide titanates already in the coprecipitation process [22,27].

Phase transformations in the ageing of a charge comprising the coprecipitated hydroxides in air under normal conditions have also been investigated [31]. The investigation showed that the nature of the processes occurring on heating a charge of coprecipitated lanthanide and titanium hydroxides differs from that of the processes occurring during their storage, although the overall composition of the products may be the same in both cases. Thus, when the charge is heated, the chemical interaction between the components proceeds via the hydroxo-complex stage with formation of lanthanide titanates. In the second case (during the ageing of the charge) the hydroxo-complexes of the lanthanide and titanium decompose with the ultimate formation of the individual oxides R_2O_3 and TiO_2.

3. The Method Based on the Decomposition of Nitrate Salts

The technology of the synthesis of lanthanide titanates (for lanthanides ranging from La to Lu and Y) by the thermal decomposition of the nitrate salts has been described [36,37]. The starting materials were the lanthanide oxides and the salt $TiO_2(NO_3)_2.6H_2O$, which were dissolved in separate vessels in hot dilute HNO_3 solutions, which were filtered and then mixed. The resulting solutions were evaporated until the crystallisation of the salt and then heated at 500°C (5–10 h) in order to remove nitrogen. The completion of the reaction was tested by X-ray diffraction and chemical analyses.

It was established [36,37] that lanthanide titanates (2–10% yield) are formed at the instant of the decomposition of the nitrate salts. During annealing, the yield is 55–77% at 900°C and 81–90% at 1200°C. The completion of the reaction requires additional heat treatment at 1500–1600°C for 3 h; after this, the substances did not contain the free oxides. Like the coprecipitation method, the above procedure made it possible to carry out the initial stage of the synthesis at lower temperatures, but in addition it eliminates the operation of filtration and washing of the precipitates.

4. Synthesis of Lanthanide Single Crystals

In the synthesis of lanthanide single crystals the main problem is the attainment of the melting point (approximately 2000°C), which requires a complex apparatus; the problems of the selection of crucibles and the atmosphere for the synthesis are no less important.

According to the literature[38-51], lanthanide titanate single crystals are synthesised by a wide variety of methods, both high-temperature (the Verneuil method, zone fusion, etc.) and low-temperature (hydrothermal, in solution, and in the melt) methods.

(a) High-temperature methods. The Verneuil method, which consists in passing a fine powder of the initial substance through the flame of an oxygen–hydrogen burner, can apparently be regarded as the main high-temperature method for the growing of lanthanide titanate single crystals. After fusion in the flame, droplets of the substance fall on to the upper part of the growing crystal. Crystallisation can begin either on portions of the prefused and crystallised substance or (preferably) on a seed crystal introduced beforehand[52]. La_2TiO_5 [38] and $Nd_2Ti_2O_7$ [46] have been obtained in this way.

In the course of its application to the synthesis of single crystals from refractory oxides the Verneuil method has undergone a series of changes. The improvements involve mainly the heating apparatus. A plasma or electric arc furnace has replaced the oxygen burner. Nd_2TiO_5 [39] and $La_2Ti_2O_7$ [44] single crystals have been grown by the Verneuil method in combination with a plasma furnace.

A vertical version of the zone fusion method (or the floating zone method), which eliminates the possibility of the contamination of the product by the substance of the boat, has been used[4,53] to grow $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ single crystals. Heating was achieved with the aid of a reflection furnace. The crystal is grown by moving the fused zone down a rod of the initial substance clamped at both ends. The quality of the crystal is determined mainly by the rate of migration of the zone. $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ single crystals were grown at zone velocities of 10 and 5 mm h^{-1} respectively.

Among the high-temperature methods for the growing of lanthanide titanate single crystals, the method of direct high-frequency fusion in a cold container, developed at the Lebedev Physical Institute of the USSR Academy of Sciences[54], merits attention. The technological process includes three stages: (1) the preparation of the "seed" melt, which can be achieved by means of an additional source of heat; (2) gradual fusion under the influence of a high-frequency field of the entire charge with the exception of a thin layer directly adjoining the water-cooled walls of the container; (3) slow directional crystallisation of the melt by a gradual decrease of the power of the high-frequency generator or by lowering the container relative to the inductor[54]. The fundamental advantage of the new technology is the absence of contact between the melt and chemically different materials, which ensures a high chemical purity of the product.

Single crystals of almost all the lanthanide titanates, having the general formula $R_2Ti_2O_7$ (except for R = Ce or Pm), have been synthesised in this way[55]. The size of the crystals was 2–12 mm, which enabled the authors to investigate a whole series of their physicochemical properties.

(b) Low-temperature methods. Preference has been given recently to low-temperature methods in which crystals are grown during deposition from solution. Depending on the nature of the solvent, different versions of the method are possible. In a non-aqueous solvent crystals are grown from solution in the melt; if the solvent is water, then the hydrothermal method, based on a high-pressure technique, is suitable for refractory oxides insoluble in water at atmospheric pressure[52]. The following titanates have been obtained by growing from solution in the melt; $R_2Ti_2O_7$ (R = Sm, Eu, Gd, Tb, Ho, Er, or Y)[40,47,48,49]; R_2TiO_5 (R = Dy or Gd);[40] $Nd_2Ti_2O_7$ and $La_2Ti_2O_7$.[50]

Titanates of the type $R_2Ti_2O_7$ have been synthesised[40] in platinum crucibles with closely fitting lids at a constant temperature of 1235°C in the course of 1 week (in order to concentrate the solution by evaporating the solvent); lead oxide PbO was used as a flux. The isotropic crystals obtained had a well-defined octahedral shape (with a diameter of 3 mm). Another variety of the method was used in the same study[40] to synthesise single crystals of the type R_2TiO_5: an increase of the concentration of the solution was achieved by its slow cooling from 1280° to 940°C at a rate of 3 K h^{-1}. Analysis showed that the crystals obtained (lamellar or rod like, up to 3 mm in length) contained 4% of PbO as an impurity. The same variety of the method—slow cooling until the formation of a saturated solution—was used in other studies[47,49,50]. However, careful study of the crystals obtained by Weissenberg's method[50] revealed the occurrence of twinning in the crystals, which significantly hindered their further structural investigation.

The hydrothermal method for the growing of lanthanide titanate crystals has been used in only two studies[32,42] for the synthesis of single crystals of the type R_2TiO_5 (R = Nd, Sm, Dy, or Yb). Mechanical mixtures with the ratio $TiO_2:R_2O_3 = 1:1$, placed in silver tubes, were put in exoclaves of the type designed by Sternberg. The synthesis was carried out over a period of 50–100 h at 700°C and 1000–2000 atm. The solvent was an aqueous 8% NH_4F solution. The crystals obtained were prismatic and their size ranged from 0.1 to 0.5 mm. Shcherbakova et al.[42] also quote the calculated lattice parameters of Nd_2TiO_5, which agree well with other published values for this compound[39]. The small size of the crystals of other titanates R_2TiO_5 precluded structural investigation.

In conclusion one should note yet another method, used[41] to prepare Y_2TiO_5 single crystals. The method is based on the solid-phase reaction between Y_2O_3, TiO_2, and sodium oxalate, which occurs at 1300°C in a sealed tube; the $NaYTiO_4$ formed, having a structure of the K_2NiF_4 type, decomposes on further heating in air at 1500°C and is a heterogeneous product containing a certain number of very small transparent acicular Y_2TiO_5 crystals.

III. HIGH-TEMPERATURE INTERACTION OF TITANIUM DIOXIDE WITH LANTHANIDE SESQUIOXIDES

The interaction of TiO_2 with lanthanide sesquioxides in systems where R = La, Gd, Dy, Er, Yb, or Y has now been investigated in greatest detail; phase diagrams have been constructed for these systems[11,14,15,19,57-59]. The interaction of TiO_2 with other lanthanide oxides has been scarcely investigated; data are available only concerning the isolation in a pure state of certain individual phases.

It is noteworthy that the phase diagrams of the TiO_2–R_2O_3 systems are fairly complex and, despite common features, differ significantly for different lanthanides. As an illustration, one may consider the phase diagrams of the TiO_2–Gd_2O_3, TiO_2–Y_2O_3, TiO_2–Er_2O_3, and TiO_2–Yb_2O_3 systems (Figs. 2–5). Evidently the compounds $R_2Ti_2O_7$, typical for all the remaining lanthanides, exist in the range of compositions close to 33 mole % R_2O_3. However, their crystal structures are not the same; in the range from samarium to lutetium and yttrium the $R_2Ti_2O_7$ structure is cubic and of the pyrochlore type (space group $Fd\,3m$); $La_2Ti_2O_7$, $Nd_2Ti_2O_7$, and $Pr_2Ti_2O_7$ crystallise in the monoclinic system (space group $P2_1$). According to a number of data[57,58,60,61], $Gd_2Ti_2O_7$, $Y_2Ti_2O_7$, $Er_2Ti_2O_7$, and $Tb_2Ti_2O_7$ melt congruently, at 1820° C, > 1900°, 1980°, and 1860° C respectively.

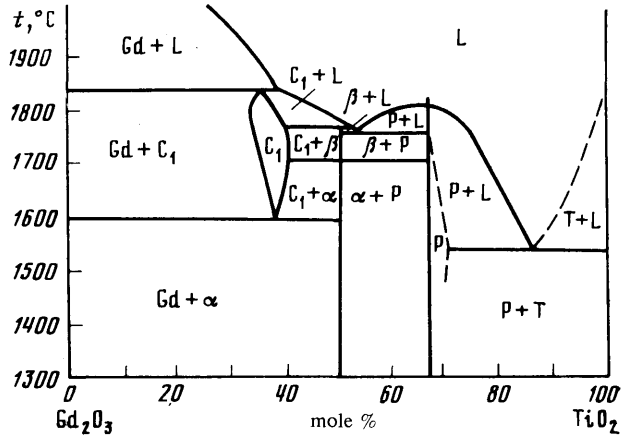

Figure 2. Phase diagram for the Gd_2O_3–TiO_2 system[14]; notation: Gd = Gd_2O_3 (solid solution); T = TiO_2 (solid solution); P = $Gd_2Ti_2O_7$ (pyrochlore); α and β = low- and high-temperature forms of Gd_2TiO_5; C_1 = face-centred cubic solid solution; L = liquid.

The differences between the ionic radii of the elements in the lanthanide series do not apparently influence the region of homogeneity for different $R_2Ti_2O_7$. The smaller scope for the substitution by titanium of "large" lanthanide ions in the range from lanthanum to gadolinium, associated with this fact, leads either to the formation of narrower regions of homogeneity (for example, approximately 3–5 mole % for $Gd_2Ti_2O_7$) or to their complete absence ($La_2Ti_2O_7$). With decrease of ionic radius, the width of the regions of homogeneity of the compounds $R_2Ti_2O_7$ grows, reaching 12 mole % for $Yb_2Tb_2O_7$. The considerable expansion of the region of homogeneity of the phases with the pyrochlore structure in the Dy_2O_3–TiO_2 and Y_2O_3–TiO_2 systems[19,57] at temperatures $\gtrsim$ 1700° C apparently indicates the influence in this case of factors other than the size factor. Figs. 2 and 3 show that the composition with 50 mole % R_2O_3 in the given systems corresponds to the compounds Gd_2TiO_5 and Y_2TiO_5. Compounds of a similar type (R_2TiO_5) are also characteristic of the entire series of lanthanides and as a rule exist in two polymorphic forms: the low-temperature orthorhombic α-form and the high-temperature hexagonal β-form. Only the high-temperature modification of Er_2TiO_5 has a cubic structure of the fluorite type[58]. However, according to the data of Leban et al.,[56] the compound Er_2TiO_5 was not detected in the study of the phase transformation in the Er_2O_3–TiO_2 system in the temperature range 1500–1600° C. Instead two cubic solid solutions of the pyrochlore and fluorite type, undergoing an interconversion at 50 mole % Er_2O_3, were found. The similarity of the structural types of the cubic phases formed at high temperatures in this system was apparently reflected in the interpretation of the data[56,58] and requires further elucidation and investigation of the system.

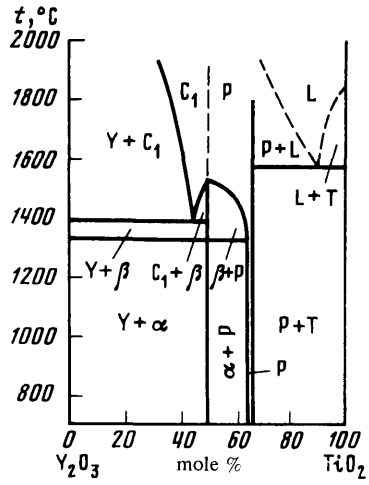

Figure 3. Phase diagram for the Y_2O_3–TiO_2 system[57]; notation: Y = Y_2O_3 (solid solution); T = TiO_2 (solid solution); P = $Y_2Ti_2O_7$ (pyrochlore); α and β = low- and high-temperature forms of Y_2TiO_5; C_1 = cubic solid solution with the fluorite structure; L = liquid.

It is of interest to note a difference in the behaviour of R_2TiO_5 at high temperatures as a function of the nature of the lanthanide[11,14,19,57,58,59]. Thus La_2TiO_5 is a stoichiometric compound, which melts congruently; Gd_2TiO_5 melts incongruently; Dy_2TiO_5 and Y_2TiO_5 are converted at high temperatures into a solid solution of the pyrochlore or fluorite type respectively and the phase diagram of the Yb_2O_3–TiO_2 system altogether fails to reveal the existence of the compound Yb_2TiO_5, as can be seen from Fig. 5. The compounds $2La_2O_3.9TiO_2$ and Yb_6TiO_{11}, which do not arise in other systems, also exist in the La_2O_3–TiO_2 and Yb_2O_3–TiO_2 systems (with the maximum and minimum ionic radii of the lanthanide).

All the diagrams presented in the regions of compositions where the R_2O_3 content reaches up to 33 mole % correspond to simple eutectic systems (the eutectic temperatures and compositions are listed in Table 1). When the R_2O_3 content exceeds 50 mole %, there is a broad region of a cubic solid solution of the fluorite type (C_1), the lattice parameters of these solutions being a function of composition. The existence of a narrow single-phase

region (~ 1 mole %) of a cubic solid solution having a structure of the type $Tl_2O_3(C_2)$ has been noted only for R = Dy, Er, or Yb.

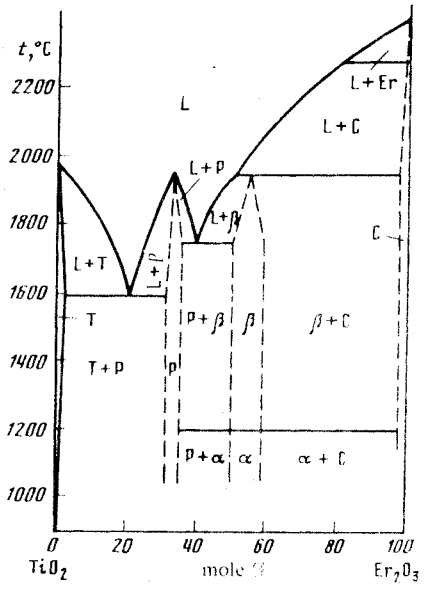

Figure 4. Phase diagram for the Er_2O_3–TiO_2 system[58]; notation: Er = Er_2O_3 (solid solution); T = TiO_2 (solid solution); P = $Er_2Ti_2O_7$ (pyrochlore); α and β = low- and high-temperature forms of Er_2TiO_5; C = solid solution of Mn_2O_3 type; L = liquid.

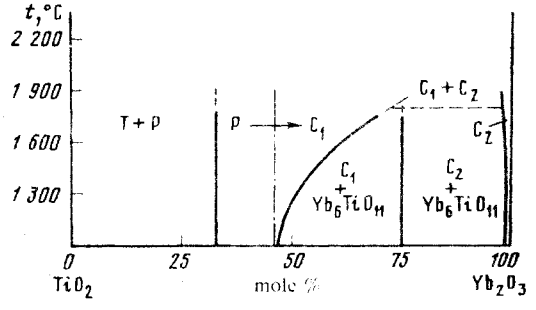

Figure 5. Phase diagram for the Yb_2O_3–TiO_2 system[59]; notation: P = $Yb_2Ti_2O_7$ (pyrochlore); T = TiO_2 (solid solution); C_1 = cubic solid solution with the fluorite structure; C_2 = cubic solid solution of the Tl_2O_3 type.

The presence of such narrow regions of solid solutions was established in the Er_2O_3–TiO_2 system[58] only in connection with the study of a diffusion-dependent interaction involving single-crystal specimens. The diffusion research technique, first used for the TiO_2–Er_2O_3 and TiO_2–Y_2O_3 systems[58,62], undoubtedly made it possible to obtain more complete information about the characteristics of the high-temperature interaction in oxide systems.

IV. CRYSTAL CHEMISTRY OF LANTHANIDE TITANATES

In the first studies[3,13] which initiated the systematic investigation of systems based on TiO_2 and R_2O_3 it was already established that many mixtures of these oxides, taken in proportions of 2 : 1, give rise to the compounds $R_2Ti_2O_7$ with a pyrochlore type structure after appropriate heat treatment. It was found in later investigations[3,19,33,63] that such compounds do indeed exist for lanthanides whose ionic radius satisfies the condition $1.22 < (r_{R^{3+}}/r_{Ti^{4+}}) < 1.5$.

Table 1. The eutectic temperatures and compositions in the R_2O_3–TiO_2 systems.

Composition	Eutectic compn. mole % R_2O_3	Eutectic temp., °C	Refs.
Gd_2O_3–TiO_2	13	1540	51
Tb_2O_3–TiO_2	14	1640	51
Er_2O_3–TiO_2	22	1550	58
Yb_2O_3–TiO_2	10	1580	59

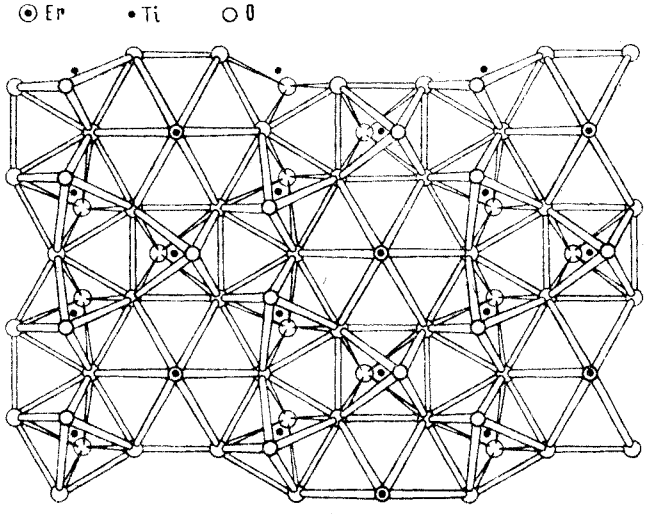

Figure 6. Projection of the pyrochlore structure ($Er_2Ti_2O_7$)[66] along a threefold symmetry axis.

This geometrical criterion, based on analysis of the ionic radius ratios from the standpoint of the theory of close packing, is defective according to some workers[64], because the interatomic interaction in pyrochlores is not purely ionic. However, for lanthanide titanates this criterion gives rise to no doubts. Thus in the $Nd_2O_3 + 2TiO_2$ composition, for which $r_{R^{3+}}/r_{Ti^{4+}} = 1.52$, there is no pyrochlore phase and the compound $Nd_2Ti_2O_7$ crystallises in the monoclinic system. This is also true of $La_2Ti_2O_7$. The remaining lanthanides (from samarium to lutetium) give rise to cubic $R_2Ti_2O_7$ structures of the pyrochlore

type[7-10,16,18,19,36,47,65-68]. There is also a linear correlation between the unit cell parameter a and the ionic radius $r_{R^{3+}}$.

The compounds $R_2Ti_2O_7$ (R represents elements from samarium to lutetium and yttrium) have the same structures as the mineral pyrochlore $NaCaNbTaO_6F$ with the structural formula $A_2B_2O_7$, where A represents sodium and calcium ions and B represents niobium and tantalum ions. Pyrochlore has a face-centred cubic lattice (space group $Fd3m$). The pyrochlore structure is derived[69] from the fluorite structure. When the fluorite structure is converted into the pyrochlore structure, one of each eight oxygen ions is removed from the anionic lattice sites, while the remaining ions are somewhat displaced from their ideal positions. The large A ions are coordinated to eight oxygen ions, which surround them, being located at the vertices of a distorted cube. The pyrochlore structure consists of a three-dimensional skeleton of distorted BO_6 octahedra joined together by their vertices. Series of mutually parallel chains joined by their vertices alternate with series of mutually parallel chains perpendicular to the chains of the first series. The octahedra of neighbouring chains are also joined together via their vertices (Fig. 6). The A ions and one seventh of the oxygen ions, which have not been displaced to the skeleton from the octahedra, are accommodated in the gaps between the octahedra.

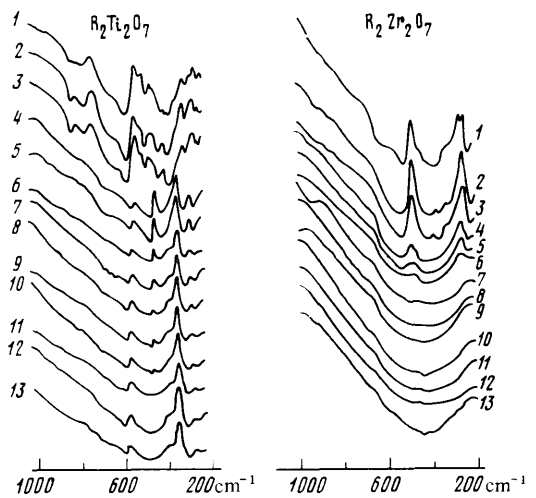

Figure 7. Infrared spectra of lanthanide titanates ($R_2Ti_2O_7$) and zirconates ($R_2Zr_2O_7$)[63]; R: 1) La; 2) Pr; 3) Nd; 4) Sm; 5) Eu; 6) Gd; 7) Tb; 8) Dy; 9) Ho; 10) Er; 11) Tm; 12) Yb; 13) Lu.

The transition from the fluorite structure to the pyrochlore structure is accompanied by the appearance on the X-ray diffraction patterns of superstructure lines corresponding to the establishment of order in the arrangement of the cations and the distortion of the oxygen polyhedra[65,67,69]. The ordering of pyrochlore phases is also indicated by the absorption maxima in the infrared spectra. Fig. 7 presents for comparison the infrared spectra of $R_2Ti_2O_7$ and $R_2Zr_2O_7$. In ZrO_2–R_2O_3 systems only certain compounds have the pyrochlore structure (R = Gd, Eu, Sm, Nd, Pr, or La). For lanthanide ions whose radii are smaller than the ionic radius of gadolinium, an ordered phase is not formed and Fig. 7 shows that in this case the infrared spectra are of a completely different type[63].

A characteristic feature of the phases of the pyrochlore type is their non-stoichiometry, which arises, on the one hand, when some of the Ti^{4+} ions are substituted by R^{3+} ions (this entails the formation of additional vacancies in the anionic sublattice), and, on the other, when some of the R^{3+} ions are replaced by Ti^{4+} ions. The general formula of the pyrochlore phases can be written as follows: $R_{2\pm x}Ti_{2\mp x}O_{7\mp x/2}\square_{1\pm x/2}$.[19]

In the series of lanthanide titanates, the $Er_2Ti_2O_7$ and $Y_2Ti_2O_7$ structures have been investigated most thoroughly[49,66] by X-ray and neutron diffraction methods (Fig. 6). The $Er_2Ti_2O_7$ unit cell contains 16 erbium ions at sites of trigonal symmetry. Each erbium ion is surrounded by 8 oxygen atoms, two of which lie diametrically opposite and are at a distance of 2.185 Å from the erbium ion, while the other six are arranged in the vicinity of the equatorial plane at a distance of 2.471 Å. The erbium ion in localised at the [common?] vertex of two diametrically opposite tetrahedra comprising erbium ions and in this respect the ions are equivalent, i.e. each erbium ion has six nearest neighbours at a distance of 3.562 Å. The Er–O–Er angle is 109°.

As mentioned above, compounds of the type $R_2Ti_2O_7$ are known also for the first members of the lanthanide series from lanthanum to neodymium (for which $r_{R^{3+}}/r_{Ti^{4+}} < 1.2$). However, in contrast to the compounds described above, which have a cubic structure of the pyrochlore type, they have a lower symmetry. This was indicated in an early study[3], where the X-ray diffraction patterns for these compounds were obtained for the first time. The infrared spectra of the compounds $La_2Ti_2O_7$, $PrTi_2O_7$, and $Nd_2Ti_2O_7$ also illustrate the difference between their crystal structure and that of pyrochlore. However, the structures of these compounds were elucidated significantly later[50] when $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ single crystals were obtained. It was found that the crystals have a monoclinic structure with the space group $P2_1/m$; the lattice parameters are listed in Table 2.

Table 2. The unit cell parameters of $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$.[50]

Compound	a, Å	b, Å	c, Å	β	V, Å³
$La_2Ti_2O_7$	7.80±0.01	5.54±0.01	13.01±0.02	98°37′±10′	556
$Nd_2Ti_2O_7$	7.68±0.01	5.46±0.01	12.99±0.02	98°30′±10′	559

It has also been shown[50] that the above compounds are isomorphous with $Ca_2Nb_2O_7$ and that their lattice consists of slightly distorted perovskite blocks. However, these results required further confirmation, since the Weisenberg diagrams revealed twinning of the single crystals investigated. Subsequent studies[43,44] led to two different

interpretations. Thus the $La_2Ti_2O_7$ structure was interpreted[44] on the basis of orthorhombic symmetry; according to Gasperin's data[43], $La_2Ti_2O_7$ has a monoclinic structure close to the orthorhombic structure (and for this reason called by the authors pseudo-orthorhombic) with the space group $P2_1/m$ or $P2_1$. The latter structure can be regarded as consisting of TiO_6 octahedra joined together via their vertices. The presence of planes parallel to the (010) plane and dividing the structure into layers comprising four octahedra between which La atoms are accommodated is also typical.

Also of interest is a study[70] where it was noted that, since the crystal lattice parameters of pyrochlore vary linearly with the ionic radius, extrapolation can yield the parameters a_1 and a_2 which the compounds $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ would have had if their structure had been of the pyrochlore type. The results ($a_1 = 10.418$ Å, $V_1 = 565.4$ Å^3, and $a_2 = 10.286$ Å, $V_2 = 544$ Å^3) showed that under these conditions the volumes V_1 and V_2 are greater than for monoclinic symmetry. Hence the authors[70] concluded that heat treatment under pressure may promote the appearance of the monoclinic form of the compounds $R_2Ti_2O_7$, which are cubic under the usual conditions. The first experiments on $Sm_2Ti_2O_7$, carried out by the quenching method under pressure ($p = 54$ kbar, $t = 1390°$C), showed that the X-ray diffraction pattern obtained is no longer characteristic of pyrochlores, and may be interpreted on the basis of monoclinic or orthorhombic symmetry.

Table 3. The unit cell parameters of compounds of the type R_2TiO_5.

Compound	Structure	a, Å	b, Å	c, Å	β	Refs.
La_2TiO_5	orthorhombic	10.97	11.37	3.937	—	51

*Sm_2TiO_5 and Eu_2TiO_5 were obtained in the study of the phase diagrams of R–O–Ti ternary systems.

Such studies appear promising for the synthesis of compounds of low symmetry with new properties (for example, ferroelectric properties), which the given compounds did not possess in the cubic phase. However, preliminary experiments for the heat treatment of $Dy_2Ti_2O_7$ and $Tb_2Ti_2O_7$ under pressure showed that the pyrochlore structures are fairly stable and for this reason the transition to the monoclinic form of compounds with lanthanide ionic radii smaller than $r_{Sm^{3+}}$ requires fairly high pressures and temperatures (in excess of 2000 °C and 70 kbar).

Studies in recent years[14–16,19–24,38–42,57,58] showed the presence in the R_2O_3–TiO_2 systems also of phases other than those described, namely compounds of the type R_2TiO_5 for the oxide ratio $TiO_2 : R_2O_3 = 1 : 1$. The first of these was obtained[11,24,29] for R = La, Gd, or Dy. Nowadays compounds of this type are known for R = La, Nd, Sm, Eu, Gd, Dy, Er, or Y.

The existence of two R_2TiO_5 modifications—the low-temperature orthorhombic modification (α) and the high-temperature hexagonal modification (β)—apparently created certain difficulties for the determination of the structure and because of this there was no unanimous view on this problem. The X-ray diffraction patterns of the compounds R_2TiO_5 were interpreted[24,60] on the basis of a monoclinic lattice, which was regarded as derived from the fluorite lattice. The unit cell parameters of compounds of the type R_2TiO_5 obtained hitherto are listed in Table 3.

The most detailed structural studies on compounds having the general formula R_2TiO_5 have been made in Refs. 38, 39, 41, and 51. Müller-Buschbaum and Scheunemann[39] examined the structure on the basis of an Nd_2TiO_5 single crystal. The unit cell contains four Nd_2TiO_5 formula units. Structures of this type have characteristic coordination numbers and coordination polyhedra made up of lanthanide and titanium atoms. The lanthanide atoms are surrounded by seven oxygen atoms ($n = 7$), six of which make up a distorted octahedron. A skeleton of octahedra joined together via their faces and nodes is formed, each two octahedra, located along the [001] face with $z = 1/4$ and $z = 3/4$, being joined via the seventh, common oxygen ion. This characteristic seventh ion constitutes simultaneously a vertex and is part of the base of a trigonal pyramid made up of oxygen ions around the Ti^{4+} ion. The same polyhedra as in the hexagonal form A of the pure sesquioxide Nd_2O_3 are distributed in the three-dimensional structure around the neodymium atom.

A coordination number of five, which is characteristic of Ti^{4+}, is observed only in the above compounds and in K_2TiO_5. The crystal structure of Nd_2TiO_5 is analogous to that adopted[41] for Y_2TiO_5. All other lanthanide titanates having the general formula R_2TiO_5 are also isomorphous with Y_2TiO_5 [41,71] and their structures constitute a fairly rare example of the coexistence of 7- and 5-coordination of ions. The unusual 5-coordination for the titanium ion is also noted in a study[71], where the compounds R_2TiO_5 (R = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, or Y) were investigated by infrared and Raman spectroscopy. Two experimental features characteristic of these compounds were noted in particular[71]:

1. In the region of low frequencies (< 350 cm^{-1}) those corresponding to the absorption bands in the infrared spectrum and to the peaks in the Raman spectrum are correlated with the ionic radius of the lanthanide, i.e. as a rule are sensitive to the mass of the tervalent cations R^{3+}.

2. Sharp infrared absorption bands and the most intense peaks in the Raman spectrum are observed in the frequency range 775–875 cm^{-1}. These are unusually high frequencies; thus in compounds of the type β-Ba_2TiO_4 with 4-coordinate titanium the frequencies assigned to the vibrations of the TiO_4 polyhedra are in the range 690–750 cm^{-1}; in compounds with 6-coordination (Sr_2TiO_4) the frequencies are in the range 550–625 cm^{-1}. In order to account for the presence of peaks at such high frequencies in the R_2TiO_5 spectra, a comparison was made[71] with the infrared spectra of the compounds $KTiOPO_4$ and $RbTiOPO_4$ in which titanium atoms are surrounded by six oxygen atoms but one of the Ti–O bonds is shorter than the others. In these compounds the same infrared frequencies (775–850 cm^{-1}), associated with the Ti–O vibrations are observed. On the basis of this analogy, the author concluded that the vibrational frequencies in the R_2TiO_5 spectra, located

above 350 cm^{-1}, refer to the internal vibrations of the TiO_5 groups and that the highest-frequency peaks are due to the fact that one oxygen atom in the TiO_5 polyhedron differs structurally from the other four oxygen atoms. Because of this, one of the Ti–O distances is shorter than the others, which alters the vibration frequency associated with the TiO_5 group.

V. PROPERTIES OF LANTHANIDE TITANATES

The physicochemical properties of lanthanide titanates of type $R_2Ti_2O_7$ have been investigated in a number of studies. Table 5 presents the melting points, densities, thermal expansion coefficients α, refractive indices n, and the microhardness values H_μ of the compounds $R_2Ti_2O_7$, measured for both polycrystalline[36] and single-crystal[55] specimens. It shows that all the above characteristics as a rule increase with increasing atomic number of the elements. It has been stated[55] that the experimental densities of compounds of the pyrochlore type agree satisfactorily with the values estimated from the lattice parameter. We may note that, whereas the difference between the densities of single-crystal and polycrystalline materials is small, the microhardness of the single crystals obtained by Ershova et al.[55] is significantly higher than for polycrystalline compounds. The crystals also have a higher refractive index.

Table 4. Certain properties of compounds of the type $R_2Ti_2O_7$.

*In the temperature range 20–800°C.

There have been fairly numerous studies on the EPR spectra of lanthanide titanates with the pyrochlore structure[72,73], the luminescence and transmission spectra[74,75], the Mössbauer effect, and the Gol'danskii–Karyagin effect[76] in the Mössbauer spectra of compounds of the type $R_2Ti_2O_7$.[77–82] Thus the wavelength range in which the $Er_2Ti_2O_7$, $Yb_2Ti_2O_7$, $Gd_2Ti_2O_7$, and $La_2Ti_2O_7$ crystals are virtually transparent (0.3–15 μm) has been determined[75]. The characteristics of the quadrupole interaction and the spin–lattice relaxation in $Dy_2Ti_2O_7$ at temperatures $\leq 750°C$ have been published[77]. The isomer shift and the effective field at the Gd^{3+} nucleus in $Gd_2Ti_2O_7$ have been determined[78]. The study of $Gd_2Ti_2O_7$ and $Er_2Ti_2O_7$ [80–82] revealed a significant contribution of the Gol'danskii–Karyagin effect due to the asymmetry of the quadrupole doublets in the Mössbauer spectrum. These results indicate a considerable anisotropy of the vibrations of the lanthanide atoms in the titanate lattices. Thus the application of Mössbauer spectroscopy in the study of lanthanide titanates established their dynamic structures (i.e. the characteristics of various atomic motions in the molecules and crystals of substances in this class) and hence made it possible to supplement significantly the results of X-ray diffraction studies, which reveal the "static" structure of crystals[83].

Studies devoted to the magnetic and electrical properties of lanthanide titanates merit much attention.

1. Magnetic Properties

The study of the magnetic properties of the pyrochlore-type compounds $R_2Ti_2O_7$ (R = Gd, Tb, Dy, Ho, Er, Yb, or Nd) with a cubic structure showed that antiferromagnetic ordering takes place in many of them only at very low temperatures[84–89] ($T_N \simeq 1.5$ K).

It is clear from the standpoint of the crystal structure that the magnetic behaviour of the lanthanide ion in titanates with the pyrochlore structure must be similar to that observed in oxides[90] and lanthanide gallate garnets[91], where the closest distances between lanthanide ions are respectively 2.66 and 3.8 Å and the magnetic interaction is relatively weak (the Er–Er distance in $Er_2Ti_2O_7$ is approximately 3.562 Å).

The first measurements of the magnetic susceptibility as well as experiments on the adiabatic demagnetisation of certain compounds $R_2Ti_2O_7$ (R = Gd, Dy, Ho, or Er) with the pyrochlore structure were carried out by van Geuns[84]. In the experimental temperature range (2–80 K) all the compounds proved to be paramagnetic; above 8 K the magnetic susceptibility obeys satisfactorily the Curie–Weiss law with a Curie constant which agrees to within 10% with the theoretical value for the free ion. However, deviations from the Curie–Weiss law are observed for $Dy_2Ti_2O_7$ and $Gd_2Ti_2O_7$ below 8 K. Measurements on the magnetically diluted compound $Dy_{0.2}Y_{1.8}Ti_2O_7$ showed that in this case the deviations of the $\chi^{-1}(T)$ relation from linearity decrease and the Curie–Weiss law holds down to 2 K. This justifies the conclusion that the observed deviations arise mainly as a result of exchange interaction between lanthanide ions. It was shown[84] that the small Curie–Weiss constant and the relatively high ionic density make the compounds suitable for the attainment of low temperatures by the method of adiabatic demagnetisation. This stimulated a number of more detailed studies[88,92,93] on magnetisation and magnetic entropy as a function of temperature and external field.

Apart from the applied aspect described above, the interest in lanthanide titanates is due to the fact that, by virtue of their simple cubic structure they are convenient physical objects for testing various models of the theory of the magnetism of lanthanide compounds. In this connection mention should be made of a study[85] where the magnetic susceptibilities of $Dy_{0.2}Y_{1.8}Ti_2O_7$ and $Yb_2Ti_2O_7$ were examined theoretically. Measurements of the heat capacities of the double oxides $R_2Ti_2O_7$ (R = Dy, Er, or Yb) at ultralow temperatures are of special interest[86].

The principal data on the magnetic properties of the compounds $R_2Ti_2O_7$ (R = Gd, Tb, Dy, Ho, Er, Yb, or Nd), obtained in the above investigations and by Cashion et al.[87] and Mamsurova et al.,[89] are given below.

(a) $Dy_2Ti_2O_7$. According to Flood[88], $Dy_2Ti_2O_7$ passes to the antiferromagnetic state at $T_N = 1.4$ K, which agrees with $T_N = 1.35$ K found for single crystals[87]. The effective magnetic moment $\mu_{eff} = 9.6\ \mu_B$ obtained[88] is close to

$\mu_{eff} = g\sqrt{J(J+1)} = 10.63\ \mu_B$ for the free ion. However, it follows from the measurements of susceptibility at ultra-low temperatures[86] that χ decreases almost to zero when $T \to 0$. This indicates the anisotropy of the properties of $Dy_2Ti_2O_7$. Furthermore, the observed changes in entropy at low temperatures ($\Delta S_{magn} \simeq R \ln 2$) are inconsistent with the higher degeneracy (more than by a factor of 2) of the ground state[86].

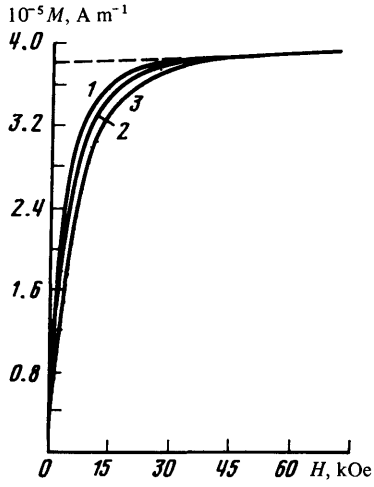

Figure 8. Dependence of the magnetisation of $Dy_2Ti_2O_7$ on the external field[88]; temperature (K): 1) 2.18; 2) 2.95; 3) 4.2.

The crystal field generated at the lattice sites occupied by lanthanide ions due to the 8 nearest oxygen ions is known[49,66] to have a predominantly axial symmetry. The deviation of the positions of the lanthanide ions from cubic symmetry is also greater than that in garnets[66], where the g-factor has been shown[91] to be significantly anisotropic, particularly for Dy and Er. Townsend and Crossley[85] calculated the corresponding parameters of the crystal field and obtained in this way the theoretical susceptibility curve for the magnetically dilute compound $Dy_{0.2}Y_{1.8}Ti_2O_7$ and compared it with experiment. This enabled them to conclude that the ground state of Dy^{3+} consists of a pure Kramers doublet with a projection of the overall moment $J_z = \pm 15/2$. For the pure state with $J_z = \pm 15/2$, there exists only one direction corresponding to easy magnetisation in the single-crystal material, which implies that $g_\perp = 0$ and $g_\parallel = 20$. It is then found that, for high values of J, the susceptibility of the powder is always close to the values for the free ion, since $J^2 \simeq J(J+1)$. However, the saturation magnetisation of the powder should be smaller than for the free ions. This was demonstrated by measuring the magnetisation in strong fields[88]. Fig. 8 illustrates the dependence of the magnetisation on the field strength for several temperatures[88]. The saturation magnetisation obtained is smaller by a factor of 2 than was expected for the isotropic case and agrees well with the fact that the ground state of the Dy^{3+} ion is represented by an orbital doublet: the experimental data presented in Fig. 8 yield $n_B = 9.4$ (where n_B is the number of Bohr magnetons per ion); on the other hand, if the ground state is represented by a pure doublet, then the theoretical values $n_B = g_\parallel J' = 10$. The small difference between these values arises apparently because the wave function for the ground state contains terms due to an admixture of excited levels (Van Vleck paramagnetism).

The absolute magnetic entropy was obtained in the same study[88] as a function of temperature and the external magnetic field. The results show that the compound $Dy_2Ti_2O_7$ can be used as the working substance in the magnetic cooling cycle in the temperature range between the boiling points of liquid hydrogen and liquid helium.

(b) $Yb_2Ti_2O_7$. Fig. 9 presents the temperature dependence of the reciprocal of the susceptibility for $Yb_2Ti_2O_7$ according to the results of Townsend and Crossley[85]. The curve exhibits a significant deviation from linearity, which the authors attribute to the influence of the crystal field. The ground state $^2F_{7/2}$ of the free Yb^{3+} ion is split by the cubic field into three levels Γ_7, Γ_8, and Γ_6. As a result of trigonal distortion, Γ_8 is split further into two Kramers doublets Γ_6 and Γ_7. The authors[85] showed that Γ_7 is the ground state. They calculated the crystal field parameters and the energy gaps $\Gamma_6 - \Gamma_7 = 1040$ cm^{-1} and $\Gamma_8 - \Gamma_7 = 530$ cm^{-1}. The theoretical magnetic susceptibility curves agree well with experiment (Fig. 9).

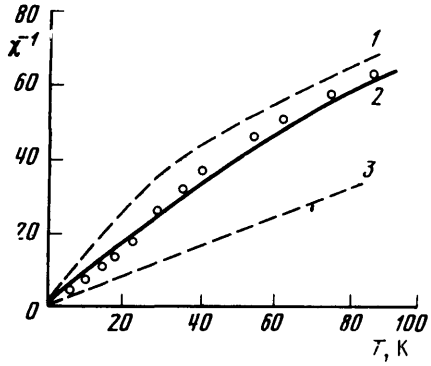

Figure 9. Temperature dependence of the reciprocal of the magnetic susceptibility of $Yb_2Ti_2O_7$;[85] the circles represent experimental points: 1) and 2) theoretical curves with different crystal field parameters; 3) free ion.

Certain parameters of the crystal field obtained[94] from the analysis of the Mössbauer spectra for ^{170}Yb in $Yb_2Ti_2O_7$ made it possible to explain the weak quadrupole interaction in this compound.

The heat capacity curve, illustrated in Fig. 10,[86] exhibits a singularity at 0.214 K, which apparently corresponds to the transition to the antiferromagnetic state. The observed entropy change $\Delta S/R = 0.693 = \ln 2$ corresponds to a Kramers doublet as the lowest state.

The exchange integrals $|J/k| = 1.2$–1.4 K (k is the Boltzmann constant), the nuclear contribution to the heat capacity, $C_{hfs}T^2/R = 0.00011K^2$, and the g-factors ($g = 2.1$–2.4) have been estimated[86].

(c) $Er_2Ti_2O_7$. According to Blote et al.,[86] the heat capacity of $Er_2Ti_2O_7$ exhibits a distinct λ-anomaly at T_N = 1.25 K. The entropy change determined from the heat capacity curves $\Delta S = 0.675R \simeq 0.97 \ln 2$. Consequently the singularity in the heat capacity is presumably due to long-range magnetic ordering (with a Kramers doublet as the ground state). The slope of the $\chi^{-1}(T)$ curve, measured by van Geuns[84] for powdered specimens, corresponds to the slope of the analogous curve for the free ion, while according to Blote et al.[86] the slope is smaller by a factor of approximately 3.5 over the limited temperature range 1.4–4 K. The latter may correspond to $g = 5.5$ if only the Kramers doublet is populated. van Geuns obtained a high Curie–Weiss constant $\theta = 22$ K, the high value of which cannot be due to magnetic interaction. Blote et al.[86] claim that this can be explained by assuming that the Er^{3+} ion has a doublet 10 cm^{-1} above the ground state; the combined effect of the two doublets then makes the susceptibility of the powdered specimen approximately the same as that of the free ions. Estimation of the exchange interaction integrals[86] yields $|J/k| = 0.56–0.63$ K.

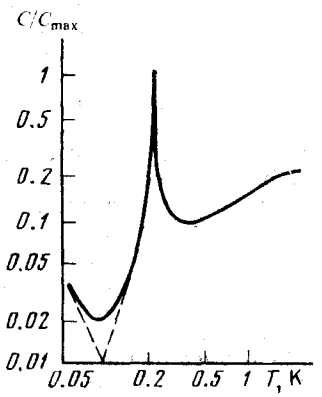

Figure 10. Temperature dependence of the heat capacity of $Yb_2Ti_2O_7$ [86] (left-hand dashed line—nuclear contribution to the heat capacity).

(d) $Gd_2Ti_2O_7$. The splittings of the energy levels in the crystal field for the Gd^{3+} ion with the ground state $^8S_{7/2}$ ($L = 0$) are very small and the magnetic properties of the ion are presumably the same as those of the 8-fold degenerate ground state. Fig. 11 (curve *4*) shows that the susceptibility of $Gd_2Ti_2O_7$ is independent of temperature below 4 K.[87]

(e) $Ho_2Ti_2O_7$ and $Tb_2Ti_2O_7$. The Ho^{3+} and Tb^{3+} ions have an even number of 4*f* electrons. Because of this, their ground state is not a Kramers doublet but two singlets separated by a small gap. The magnitude of the gap enters directly into the expression for the magnetic susceptibility, determines T_N, etc. However, there are no detailed literature data for $Ho_2Ti_2O_7$ and $Tb_2Ti_2O_7$. Fig. 11 (curves *1* and *3*)[87] illustrates the $\chi(T)$ relations for these compounds. The susceptibility of $Ho_2Ti_2O_7$ follows a simple Curie law with $\chi = C/T$ and exhibits an antiferromagnetic transition at $T_N = 1.3$ K. The Curie constant C corresponds to the value for the free ion but can be accounted for (as for $Dy_2Ti_2O_7$) also by the non-Kramers pair discussed above, when $g_\parallel = 20$ and $g_\perp = 0$ (or $\langle J_Z \rangle = \pm 8$).

(f) $Nd_2Ti_2O_7$. Neodymium dititanate belongs to the class of compounds for the magnetic properties of which there are still no literature data. As already mentioned, in contrast to the majority of compounds of the type $R_2Ti_2O_7$, $Nd_2Ti_2O_7$ has a monoclinic structure[50] (space group $P2_1/m$; $z = 4$).

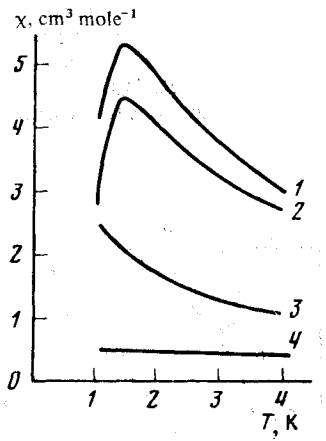

Figure 11. Temperature dependence of the magnetic susceptibilities of different lanthanide titanates: 1) $Ho_2Ti_2O_7$; 2) $Dy_2Ti_2O_7$; 3) $Tb_2Ti_2O_7$; 4) $Gd_2Ti_2O_7$.[87]

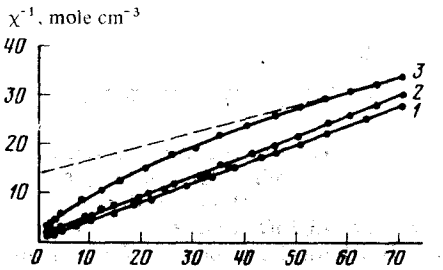

Figure 12. Temperature dependence of χ^{-1} of the compounds $Nd_2Ti_2O_7$ [1) for specimen cut out along the direction of easy magnetisation; 2) for powdered specimen] and Nd_2TiO_5 (curve *3*).

We measured the low-temperature susceptibility of $Nd_2Ti_2O_7$ (in the temperature range 1.6–70 K) and the magnetisation in the field of a superconducting solenoid (up to 55 kOe)[89]. Fig. 12 (curves *1* and *2*) shows that the compound remains paramagnetic up to 1.6 K. The Curie–Weiss law holds over the entire experimental temperature range with the parameters $C = 2.44$ $cm^3 K$ $mole^{-1}$ and $\theta = -3$ K. The value of C obtained yields $\mu_{eff} = 3.12$ μ_B for the effective magnetic moment of Nd^{3+}, which is close to the value for the free ion.

It is noteworthy that the observed values of θ apparently reflect the influence of the crystal field on the orbital moment of $4f$ electrons rather than of the exchange interaction between Nd^{3+} ions. The tenfold degenerate level of the free Nd^{3+} ion is known to be split into five doublets in crystal fields whose symmetry is lower than cubic. Since the Curie–Weiss law holds for $Nd_2Ti_2O_7$ over the entire experimental temperature range, presumably the ground state of the Nd^{3+} ion in this compound (the Kramers doublet) is fairly remote from the nearest excited levels, which are not populated even at 70 K. In this case an effective moment $J' = 1/2$ and $g = \mu_{eff}/\sqrt{J(J+1)} = 3.6$ can be attributed to the Nd^{3+} ion in $Nd_2Ti_2O_7$.[89]

It is noteworthy that all the studies mentioned above were carried out using powdered specimens, which significantly restricts the scope of the magnetic measurements. An exception is the study of Cashion et al.,[87] who used for the investigation very small $R_2Ti_2O_7$ and R_2TiO_5 crystals, but, as already stated, they contained impurities.

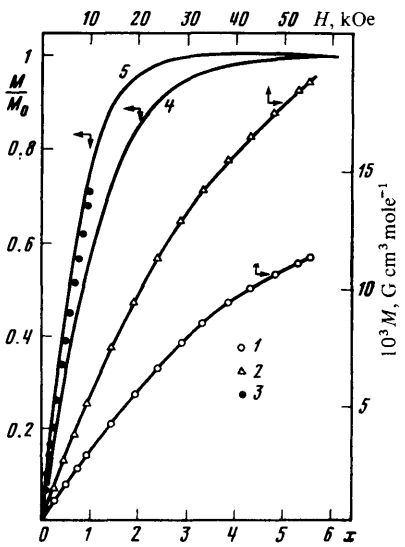

Figure 13. Dependence of the magnetisation on the external field for the compounds $Nd_2Ti_2O_7$ [1) powdered specimen; 2) specimen cut out along the direction of easy magnetisation] and Nd_2TiO_5 (curve *3*). Curves *4* and *5* represent the Brillouin functions for $J = 1/2$ and $J = 1$.

We attempted[89] to investigate a cylindrical $Nd_2Ti_2O_7$ specimen, consisting of small coalesced acicular single crystals, in which the crystallographic directions of all the crystals coincided. The susceptibility and the magnetisation of the specimens along this direction proved to be greater than for the powdered specimen. Although in the maximum field of 55 kOe the magnetisation does not reach saturation (Fig. 13), the nature of the $M(H)$ relations suggests that the saturation magnetisations for the two different $Nd_2Ti_2O_7$ specimens are different. Evidently, the anisotropy in $Nd_2Ti_2O_7$ is of a single-ion type and is manifested in the given case in terms of the anisotropy of the g-factor.

In the same study[89] measurements were made on a polycrystalline Nd_2TiO_5 specimen. Fig. 12 (curve *3*) shows that the Curie–Weiss law does not hold in this case, in contrast to $Nd_2Ti_2O_7$. The slope of the $\chi^{-1}(T)$ curve in the region of 60 K and above corresponds to $\mu_{eff} = 3.54\ \mu_B$, i.e. approaches the value for the free ion. Under these conditions, θ becomes greater than the usual value ($\theta = -45$ K). Since the substance remains paramagnetic down to 1.6 K, θ is evidently determined by the influence of the crystal field.

With decrease of temperature, the slope of the curve changes and $\mu_{eff} = 2.03\ \mu_B$ in the range 1.6–4.2 K. It is natural to suppose that at such low temperatures only the lowest Kramers doublet is populated; the effective value is then $J' = 1/2$ and $g = \mu_{eff}/\sqrt{J(J+1)} = 2.3$. This is confirmed by measurements of the magnetisation of Nd_2TiO_5 in fields up to 55 kOe. Fig. 13 presents the results of measurements as a plot of the relative magnetisation M/M_0 against $x = g\mu_B JH/kT$, where $T = 4.2$ K, $g = 2.3$, $J = 1/2$, and $M_0 = 2\,Ng\mu_B J = 12.84$ CGSM units $mole^{-1}$ (N is the Avogadro number). Evidently the points obtained lie closer to the theoretical Brillouin function of x for $J = 1/2$ and for $J = 1$.

Consequently in the compound Nd_2TiO_5, which has orthorhombic symmetry, the internal crystal field splits the tenfold degenerate ground state of the free Nd^{3+} ion in such a way that the distance between the levels is not as large as in $Nd_2Ti_2O_7$ and, when the temperature is raised from 1.6 to 60 K, all the sublevels of the ground multiplet are populated.

The magnetic properties of other lanthanide titanates of the type R_2TiO_5 can be regarded as virtually uninvestigated. Only one report[87], where the measurements of the magnetic susceptibilities of Gd_2TiO_5 and Dy_2TiO_5 are presented for the temperature range 1–4 K, mentions that the specimens apparently undergo a transition to an antiferromagnetic phase at 1.25 and 1.55 K respectively.

Isomorphous substitution of one set of magnetic atoms by another, which is allowed by the structure of the compounds R_2TiO_5, can significantly increase the phase transition temperature and can also alter other magnetic characteristics of the substance[95]. A study of the magnetic susceptibility of single-crystal $NdFeTiO_5$ in which some of the Nd^{3+} ions have been replaced by Fe^{3+} ions revealed the occurrence of antiferromagnetic ordering at $T_N = 18.5 \pm 0.5$ K. T_N is determined in this case by the cooperative ordering of the spin system of the Fe^{3+} ions. The Nd^{3+} ions remain paramagnetic below T_N, but their magnetic moments are polarised owing to interaction with the Fe^{3+} spin. The principal characteristics of the temperature dependence of the magnetic susceptibility can be explained on the hypothesis that there is interaction between the ordered spins of the Fe^{3+} ions and the electrons populating the lowest Kramers doublet in the Nd^{3+} ions[95].

2. Electrical Properties

The resistivities of all the lanthanide titanates, including scandium and yttrium titanates, were measured for the first time at room temperature and those of certain titanates ($La_2Ti_2O_7$, $Nd_2Ti_2O_7$, $Sm_2Ti_2O_7$, $Ho_2Ti_2O_7$, and $Er_2Ti_2O_7$) at a higher temperature (up to 1000°C) by Brixner[8] in 1964. The resistivity at room temperature was approximately $10^{12}\ \Omega$cm [the lower resistivity ($\sim 10^{10}\ \Omega$cm) obtained for three compounds, with cerium, praseodymium, and terbium, was explained by the author as due to the loss of oxygen by the specimens during heat treatment in an

inert atmosphere]. The order of magnitude of the resistivity apparently shows that ionic conduction, due to the diffusion of ions, predominates, which is characteristic of a defect pyrochlore structure[69]. On raising the temperature to 1000°C, the resistivity falls exponentially to 10^2 Ω cm (Fig. 14). Thus the compounds investigated are *p*-type semiconductors, which means that at high temperatures the electronic mechanism of conduction becomes dominant.

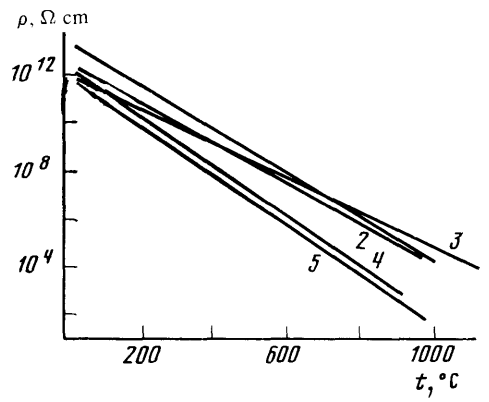

Figure 14. Temperature dependence of the electrical conductivities of lanthanide titanates: 1) $La_2Ti_2O_7$; 2) $Nd_2Ti_2O_7$; 3) $Ho_2Ti_2O_7$; 4) $Sm_2Ti_2O_7$; 5) $Er_2Ti_2O_7$.[8]

The temperature dependence of the dielectric constants of all the titanates has been measured[8]. The author notes the extremely high values of the constants ($\epsilon \simeq 30$–40) at room temperature. The measurement of the temperature dependence of ϵ was undertaken in the hope of observing ferroelectric properties in the compounds investigated. However, the measurements showed that the dielectric constant hardly changes with temperature below room temperature and increases somewhat when the temperature is raised further. The author[8] correctly attributes this increase of ϵ to the exponential decrease of the resistivity of the specimen and not to its ferroelectric behaviour.

The search for ferroelectric materials among complex oxides with a pyrochlore structure has been prosecuted for many years, apparently in connection with the discovery in 1952 of a low-temperature ferroelectric modification of the compound $Cd_2Nb_2O_7$,[1] which has the pyrochlore structure at room temperature. It was found that the properties of this compound differ from those of all other ferroelectrics and are so unusual that they attracted attention to the entire class of compounds of the pyrochlore type[2-4]. It might have been expected that other ferroelectrics with similar structure would have interesting properties. The existence in the pyrochlore-type structure of octahedra distributed in a specified manner and joined together via their vertices (this arrangement is most favourable for the manifestation of ferroelectric properties[2]) makes it very similar to a perovskite type structure, many representatives of which are typical ferroelectrics. After considering chains of oxygen tetrahedra in a pyrochlore type structure, Megaw[96] concluded that cadmium pyroniobate might also have ferroelectric properties.

Nevertheless $Cd_2Nb_2O_7$ is so far the only ferroelectric with the pyrochlore structure which has been investigated in detail, although broad maxima on the curves relating ϵ and tan δ to temperature have been observed for a number of pyrochlore compounds. According to the authors, they are associated with ferroelectric and antiferroelectric transitions[97,98]. Attempts to detect ferroelectricity in a series of lanthanide titanates with the pyrochlore structure were again undertaken in 1969.[7] However, measurements of the dielectric constants of $Sm_2Ti_2O_7$ and $Er_2Ti_2O_7$ in the range from room temperature to the helium temperature also failed to detect ferroelectric transitions.

The existence in the $R_2Ti_2O_7$ series of compounds with a symmetry lower than cubic (R = La, Nd, or Pr) stimulated further investigation of their dielectric properties[4,53]. Monoclinic crystals are known to belong to the class of polar crystals. Very careful studies enabled Nanamatsu et al.[5] to announce that lanthanum titanate ($La_2Ti_2O_7$) is a new ferroelectric with an extremely high Curie temperature, one of the highest among all known ferroelectrics. Similar properties were also discovered in an $Nd_2Ti_2O_7$ single crystal[4].

A hysteresis loop has been observed[4] in the curve relating the electric [dielectric?] shift to the field strength at room temperature in a strong electric field of approximately 300 kV cm^{-1}. The spontaneous polarisation and the coercive field were obtained from these measurements. Ferroelectric domains have been observed in $Nd_2Ti_2O_7$ single crystals when the latter were etched in boiling aqueous nitric acid. The crystals thus grown proved to consist of a single domain; pyroelectricity was clearly revealed along the *b* axis at room temperature and its polarity could be altered by applying to the specimen an electric field of 370 kV cm^{-1}.

Table 5. Ferroelectric, electro-optical, and piezoelectric properties of $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ single crystals.

Parameter	$La_2Ti_2O_7$ (Ref.5)	$Nd_2Ti_2O_7$ (Ref.4)
Size of single crystal	d = 5 mm, l = 50 mm	d = 5 mm, l = 30 mm
Melting point, °C	1790	1800
Crystal lattice	monoclinic	monoclinic
Space group	C_2^2—$P2_1$	C_2^2—$P2_1$
Density, g cm^{-3}	5.79	6.08
Curie temperature, °C	1500	>1500
Spontaneous polarisation, μC cm^{-2}	5	9
Coercive field, kV cm^{-1}	45	200
Dielectric constants (at a frequency of 1 kHz)		
ϵ_{11}	52	31
ϵ_{22}	62	43
ϵ_{33}	42	47
Quality coefficient $1/\epsilon V_\pi^2$, V^{-2}	$27 \cdot 10^{-7}$	$24 \cdot 10^{-9}$
Electromechanical coupling factor k_{22}	0.29	0.15
Piezoelectric constants d_{22}	$16 \cdot 10^{-12}$	$6.5 \cdot 10^{-12}$
Elasticity constant s_{22}	$5.5 \cdot 10^{-12}$	$4.8 \cdot 10^{-12}$

Measurement of the temperature dependence of the dielectric constant of $Nd_2Ti_2O_7$ revealed no anomalies in the range from room temperature to 1500°C. The authors[4] therefore suggested that the Curie point of this specimen lies above 1500°C.

The data obtained by Nanamatsu and coworkers[4,5] are presented in Table 5. The investigations led to the conclusion that both compounds ($La_2Ti_2O_7$ and $Nd_2Ti_2O_7$) are

ferroelectrics with high coercive fields at room temperature and high Curie points; the observed excellent electro-optical and piezoelectric properties of these compounds may be useful for their practical applications.

Similar studies have not so far been made on compounds of the type R_2TiO_5, although they should apparently exhibit dielectric properties of the same type. This was pointed out by the authors of an early investigation [11], who believed that the similarity of the dielectric properties of the compounds $La_2O_3.TiO_2$ and $La_2O_3.2TiO_2$ follows from plots of the temperature variation of tan δ and (Fig. 15).

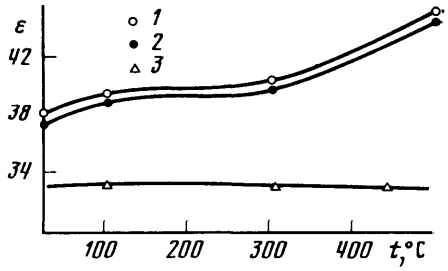

Figure 15. Temperature dependence of the dielectric constants ε (at a frequency of 1 MHz) of three binary compounds [11]: 1) $La_2O_3.TiO_2$; 2) $La_2O_3.2TiO_2$; 3) $2La_2O_3.9TiO_2$.

VI. EXAMPLES OF PRACTICAL APPLICATIONS

The possibility of using lanthanide titanates as dielectrics has been discussed in the literature for a long time. As early as 1946, mixtures of lanthanide oxides, including lanthanum and titanium oxides, were patented [99] as suitable for use in condensers as a dielectric layer with a weak temperature dependence of the dielectric constant.

The development of radioengineering industry and the requirement for new materials with optimal parameters stimulated a number of recent studies [100-106], designed to discover ceramic dielectric compositions suitable for various condensers. The dielectric properties of $La_2Ti_2O_7$ proved to be extremely useful for such purposes. Thus a new dielectric ceramic having the composition $(La_2Ti_2O_7)_{1-\alpha}(Sr_2Nb_2O_7)\alpha$, where $0 < \alpha \leq 0.85$, has been reported [100,101] as suitable for condensers with temperature compensation. This ceramic has a high value of ε, low dielectric losses, and a weak temperature dependence of the dielectric constant. It has been mentioned in almost all the investigations that the addition of different amounts of $La_2Ti_2O_7$, up to 1.2 mole %, to ceramic materials of different composition significantly decreases the temperature dependence of the dielectric constant and improves the properties of the materials.

The ceramic containing 35–50 mole % $PbTiO_3$, 25–35 mole % $SrTiO_3$, 4.5–15 mole % $CaTiO_3$, 3–20 mole % Bi_2O_3, 0.5–20 mole % TiO_2, and 4–12 mole % $La_2Ti_2O_7$ is a material which can be used successfully in a high-voltage condenser [103]. Its dielectric constant is unusually high ($\epsilon = 1850$) and the breakdown potential is 14 kV mm^{-1}.

It has been shown [107,108] that $La_2Ti_2O_7$ can also be used in condensers for the preparation of transistors on thin films of complex structure. A special method for the manufacture of such films has been developed [108].

Yet another aspect of the applications of lanthanide titanates is associated with $Eu_2Ti_2O_7$. Europium is an element suitable for the control of excess reactivity in nuclear reactors because it has a high thermal neutron absorption cross-section and resistance to damage by radiation [109]. The oxide Eu_2O_3 can be used for the same purpose. However, tests for resistance to corrosion carried out in water at 250°C and a pressure of 45.5 atm [110] showed that the best results are obtained when europium and titanium are combined ($Fu_2Ti_2O_7$). The chemical stability of this material, its properties, and behaviour under intense incident radiation have been discussed [109].

The development of laser technology has been accompanied by continuously growing requirements for laser crystals. A high thermal stability and chemical purity, optical transparency, and mechanical strength are qualities characteristic of lanthanide titanates which may prove useful in laser research. Analysis of the transmission spectra quoted [75] for $Er_2Ti_2O_7$, $Yb_2Ti_2O_7$, $Gd_2Ti_2O_7$, and $La_2Ti_2O_7$ demonstrated the suitability of these materials as matrices for various lanthanide additives in the preparation of crystals for infrared lasers.

As already mentioned above, the compounds under consideration can be used successfully as the working substances in the attainment of low temperatures by adiabatic demagnetisation.

Presumably further studies on lanthanide titanates (especially R_2TiO_5) may significantly supplement our knowledge of their physicochemical properties and hence extend significantly the limits of their practical applications.

Non-stoichiometry of the Alkaline Earth Metal Oxides

P.V.Kovtunenko and Ya.L.Kharif

Experimental data on the departure from stoichiometry in the alkaline earth metal oxides (MO) have been summarised and analysed. The $p-T-x$ diagram of BaO, and the equilibrium diagrams of the intrinsic atom defects in BaO and SrO, have been constructed. The relationship between the properties of the surface of MO crystals and their ability to emit electrons has been examined. The bibliography contains 94 references.

I. INTRODUCTION

The alkaline earth metal oxides (MO) are widely used as electron-emitting coatings on thermionic-cathodes, and have been the objects of a large number of physico-chemical studies. The properties of the alkaline earth metal oxides, such as the ability to emit electrons, electrical conductivity, photo-conductivity, luminescence, etc., are extremely sensitive to change in the composition of the MO, that is to departures from stoichiometry. Thus studies of the dependence of the composition of non-stoichiometric MO crystals on the thermodynamic parameters of the state of the "crystal–vapour" system carried out in the past ten years in the Soviet Union and in other countries are of considerable theoretical and practical importance.

The present review summarises available experimental data on the direct determination of the departure from stoichiometry, and compares and analyses the data in order to build up from the isolated fragments, as far as possible, a more complete picture of the state of MO crystals in equilibrium with their vapour. The summary and analysis of the experimental data are also important in relation to the general questions of the chemistry of non-stoichiometric crystals and the problems of investigating the nature of the strong emitting power of MO crystals.

II. EXPERIMENTAL DATA ON THE DEPARTURE FROM STOICHIOMETRY IN ALKALINE EARTH METAL OXIDES

Thermodynamic analysis of the phenomena arising in the distribution of the components of a crystal between the vapour and solid phases shows that a certain quantity of M and O must be present in MO crystals and on their surface in a state different from the usual state of M and O forming the crystal of the compound and occupying regular sites of the crystal lattice. This difference is revealed, in particular, in the difference in the chemical properties of these states of the metal and oxygen in their reactions with water, acids, etc. These components of the MO will subsequently be described as excess if the concentration of one of them is greater than that of the other or quasi-excess if they are equal, irrespective of the location of these components in the crystal. The differences in the chemical and physicochemical properties of the excess components have made it possible to develop methods for their direct quantitative determination[1-8].

1. Excess Metal in MO. Influence of the Surface of the Crystals on the Concentration of Excess Metal in a Non-stoichiometric Specimen

The study of the phenomena leading to the production of an excess of metal in MO began with attempts to determine the factors responsible for the high emitting power of oxide cathodes. A large number of studies in the Soviet Union[1,9-14] and other countries[15-20] showed that the high electron emission of oxide cathodes is in fact due to the production of excess M in the bulk and on the surface of the oxide crystals. The technical difficulties associated with studies of real cathodes, however, made it impossible to obtain reliable quantitative data on the dependence of the equilibrium concentration of the excess metal in MO on the conditions of synthesis of the material, in particular the vapour pressure and temperature. These data were obtained in the study of the physico-chemical properties of the pure oxides away from the cathodes.

The solubility of Ba in the bulk of BaO crystals was first measured in 1937 by Schriel[2], and later by Kane[3] and Libowitz[4], who by chemical analysis measured the excess Ba in BaO crystals grown from a solution of BaO in liquid Ba. According to Schriel, the solubility of Ba in BaO at 1150° is 0.5–1.2 at.%. Libowitz[4] believes that this value is slightly too high, because of experimental errors in the determination of Ba. Kane[3] and Libowitz[4] found that at 890–910° the solubility is 0.07–0.12 at.%.

Studies of importance for understanding the formation of non-stoichiometric MO crystals were carried out using single crystals grown from the vapour phase[3-6,21,22]. In particular, it was shown[5,21,22] that the excess Ba in BaO creates two types of impurity centre, corresponding to two peaks in the absorption spectra, at 2.0 eV (blue crystals) and at 1.2 eV (red crystals). Red BaO crystals were obtained by heating colourless BaO crystals in liquid Ba, and blue crystals by heating in Ba vapour. Timmer[6] found that the concentration of colour centres with an absorption maximum at 2.0 eV, calculated using Smakula's

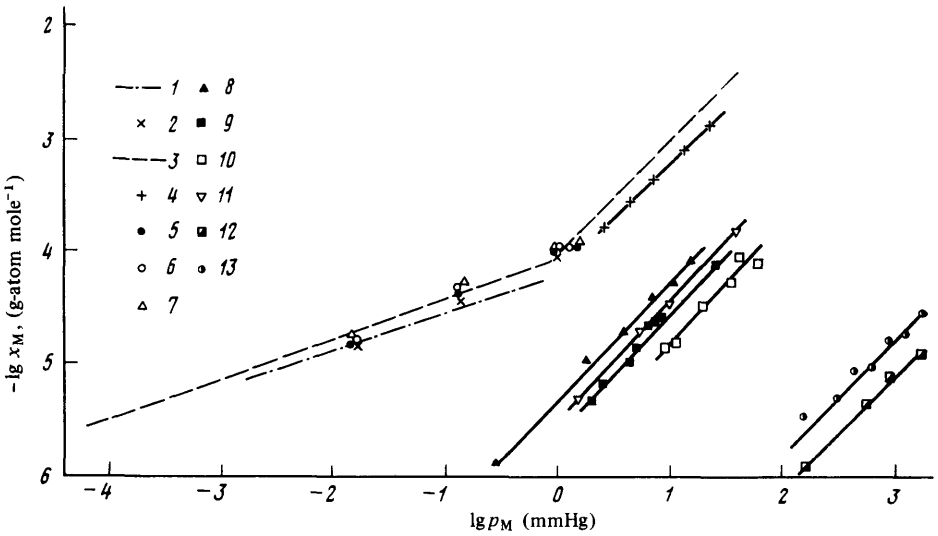

Figure 1. Solubility of excess metal in MO. Solubility isotherms for Ba in BaO at 1150° (*1*—from Ref. 6, *2*—from Ref. 29), at 1200° (*3*—from Ref. 39, *4*—from Ref. 40), at 1250° (*5*—from Ref. 29), at 1350° (*6*—from Ref. 29), and at 1450° (*7*—from Ref. 29). Solubility isotherms for Sr in SrO [28] (*8*— at 1143°, *9*—at 1238°, *10*—at 1320°). Solubility isotherm for Ca in CaO [29] (*11*) at 1700°). Solubility isotherms for Mg in MgO [29] (*12*—at 1612°, *13*—at 1813°).

equation[23], is proportional to the vapour pressure of Ba to the power 1/3. Chemical analysis of the excess Ba in blue BaO crystals[5] showed that its concentration is approximately equal to the concentration of colour centres. Thus Timmer's results were taken to indicate that the solubility of excess Ba in BaO depends on the Ba vapour pressure. The solubility isotherm obtained by Timmer at 1150°, corrected using new data on the vapour pressure of Ba, [24,25] is given in Fig. 1.

Hensley and coworkers[8,26-29] used the same experimental techniques as Timmer to study the non-stoichiometry of MO. The absorption spectra of additively coloured crystals of MgO, CaO, SrO, and BaO showed two impurity absorption bands analogous to those observed by Sproull and coworkers[5]. For the more intense of the two bands, the concentrations of the colour centres were calculated using the equations of Dexter[30] and Smakula[23]. For MgO, [26] CaO, [27] and SrO [28] these were the bands at longer wavelengths, corresponding to photon energies 5.0, 3.1, and 2.5 eV respectively, and for BaO it was the band at shorter wavelength (2.0 eV). The results of the calculations are given in Fig. 1. According to these data, the concentration of colour centres is proportional to p_M to the first power for MgO, CaO, and SrO, and for BaO the exponent lies between 1/2 and 1/3. BaO, [29] SrO, [28] and MgO [26] were studied at several temperatures, to obtain the temperature dependence of the concentration of colour centres. For BaO and MgO, the concentration of colour centres increased slightly with temperature in the range studied, 1150–1450°, and for SrO it decreased.

In the study of the formation of non-stoichiometric crystals, it must be borne in mind that the thermodynamic properties of the crystals are different in the bulk and on the surface of the crystals, that is at the "solid–gas" interface. As a result, the concentration of excess component is different on the surface and in the bulk of the crystals. For single crystals, or large crystals in general, the contribution of the excess component localised on the surface to the total departure from stoichiometry will be negligible. It will be expected to increase, considerably, however, on going to specimens having highly developed surfaces, that is powders. In 1962, the present author[10,31,32] in fact found that in powdered specimens synthesised by heating to equilibrium at 1150° in oxygen at a pressure of 10^{-8} mmHg, not less than 90% of the total excess Ba produced in the crystals was localised on the surface of the crystallites, the average size of which was several microns. The preferential localisation of Ba on the surface of powdered BaO was also established in later work[33]. Approximately the same picture was observed on zinc oxide[34,35].

This phenomenon was studied in detail for BaO and SrO, [36,37] using powdered oxide specimens prepared by the same methods[10,31,32], having a specific surface of 0.6 m^2 g^{-1}. The excess metal was determined by the gas-volumetric method first proposed by Berdennikova[1]. The substance was dissolved in water, and the quantity of hydrogen liberated in the reaction of the excess metal with water was determined. The improved method of measurement gave the analysis a sensitivity of 2×10^{-8} g-atom Ba per mole of BaO. The BaO and SrO specimens were heated for prolonged periods at 1000–1150° and $p_{O_2} = 3\times10^{-8}$–1×10^{-5} mmHg until equilibrium was established. Analysis showed that the product contained excess metal. The isothermal dependence of the concentration of excess metal on p_M (p_M was calculated from the given oxygen pressure and the known dissociation constant of the oxide K_{MO}) is shown in Figs. 2 and 3. The form of the isotherms obtained is typical of adsorption isotherms[38]. It may therefore be assumed that they correspond to processes taking place chiefly on the surface of the crystals and approaching saturation in the region of the inflection on the isotherms. To determine separately the quantities of excess metal located on the surface and

dissolved in the bulk of the crystals, the non-stoichiometric specimens, before the determination of the excess metal, were treated with oxygen at room temperature to remove the excess of metal on the surface without influencing that dissolved in the bulk. As in other experiments[10,31,32], these studies showed that not less than 90% of the excess metal is in fact located on the surface of the crystals, and only about 10% is dissolved in the bulk.

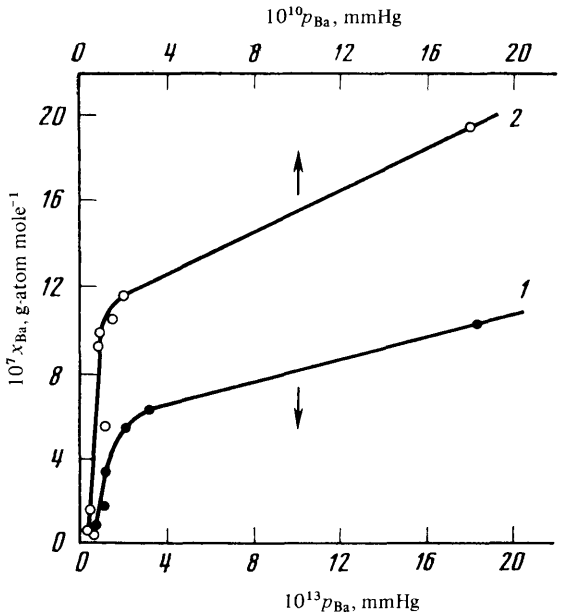

Figure 2. Dependence of the concentration of excess Ba in BaO on the vapour pressure of Ba [36] at 1000° (*1*) and 1150° (*2*).

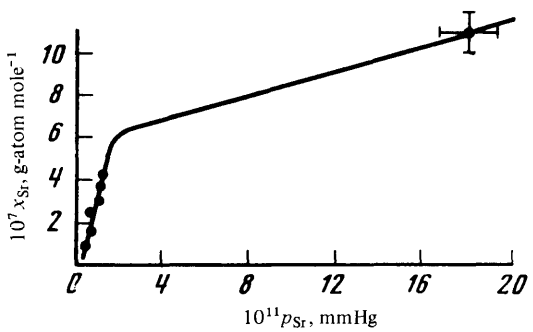

Figure 3. Dependence of the concentration of excess Sr in SrO on the vapour pressure of Sr [37] at 1150°.

At higher M vapour pressures, when the total concentration of excess metal increases chiefly as a result of its dissolution in the bulk, the proportion of excess M due to adsorption on the surface relative to the total concentration of M in the specimen was found to be small. This was confirmed experimentally[39] in a study of the distribution of Ba between the vapour phase and powdered BaO at 1200° in the Ba vapour pressure range 3×10^{-5}–35 mmHg. BaO was saturated with barium using a stream of metal vapour, carried over BaO using helium. The results of the measurements are given in Fig. 1. The experimental points on coordinates $\lg x_{Ba}-\lg p_{Ba}$ are described by two straight lines intersecting at a pressure of ~1 mmHg. In the vapour pressure range 3×10^{-5}–1 mmHg, the equation for the isothermal relationship obtained has the form:

$$x_{Ba} = 7{,}51\cdot10^{-5}p_{Ba}^{0{,}328}, \quad (1)$$

and in the pressure range 1–32 mmHg:

$$x_{Ba} = 1{,}17\cdot10^{-4}p_{Ba}^{1{,}075} \quad (2)$$

(here and subsequently, the solubility is given in g-atom Ba per mole of BaO, and the pressure in mmHg).

In the vapour pressure range 10^{-5}–1 mmHg, the data obtained for powdered specimens[39] show good agreement with the results obtained using single crystals[6,29], indicating that in the pressure range studied, most of the excess Ba is in the bulk of the BaO crystals, and the quantity on the surface is comparatively small. Extrapolation of the data[39] on the solubility of barium in BaO to lower pressures, 10^{-10}–10^{-8} mmHg, shows satisfactory agreement with the data previously obtained for this range[36,37]. In fact, calculation of the concentration of excess barium using Eqn. (1) gives for a pressure of 10^{-9} mmHg the value 0.9×10^{-7} g-atom Ba per mole of BaO, which is about 6% of the total obtained under these conditions in earlier work[36,37] (Fig. 2), and which corresponds approximately to the concentration of excess barium in BaO crystals, remaining in the dissolved state after the surface is cleaned using oxygen. The data[39] for the pressure range above 1 mmHg are close to those obtained earlier[40], but are apparently more accurate, since they were obtained by an improved procedure. The dependence of the solubility on p_{Ba} in this range is the same as for Sr in SrO, [28] Ca in CaO, [27] and Mg in MgO [26] at high metal vapour pressures (see Fig. 1).

2. Excess Oxygen in MO

The most extensive early study of the reaction of BaO with O_2 is that of Hildebrand[41]. In a study of the equilibrium in the BaO–O_2 system in the range 700–800° at oxygen pressures of 10–800 mmHg, Hildebrand found that the solubility isotherms for oxygen in BaO showed two bivariant regions with a univariant region between them, corresponding to equilibrium between two conjugate solid solutions, based on BaO and on BaO_2.

Detailed studies of the solubility of oxygen in BaO and SrO have been carried out in the past ten years in the Mendeleev Moscow Institute of Chemical Technology[42-45]. The equilibria have been studied over a wide range of temperatures and oxygen pressures by a static method in which the quantity of oxygen absorbed by the substance was determined from the decrease in pressure in a known volume.

The solubility of O_2 in BaO was studied at 683–798° and high oxygen pressures (10–500 mmHg).[42] Like Hildebrand[41], the authors cited[42] observed a change in the number of thermodynamic degrees of freedom of the BaO–O_2 system with increase in p_{O_2} under isothermal

conditions (Fig. 4). It was assumed[42] that in the bivariant equilibrium ranges there is one phase in the solid state, interpreted as either a solution of BaO_2 in BaO (first bivariant range) or a solution of BaO in BaO_2 (second bivariant range). For the investigation of the conditions of formation of non-stoichiometric BaO crystals containing excess oxygen, the first bivariant region (I in Fig. 4) is of greatest interest. Under these conditions, the solubility isotherms were described by equations of the form

$$x_O = K_O p_{O_2}^{1/n}; \quad n = 0.88 \div 1.03. \tag{3}$$

The solubility of oxygen in BaO varied in the range 4×10^{-3}–6×10^{-2} mmHg, depending on the conditions of the experiment. Treatment of the data[42] on the solubility of oxygen in BaO in region I (Fig. 4) made it possible to describe them by the analytical equation

$$x_O = 6.6 \cdot 10^{-8} p_{O_2}^{1.0} \exp(+1.61 \cdot 10^4/RT). \tag{4}$$

The temperature coefficient of Eqn. (4) shows that an exothermic chemical reaction takes place when oxygen dissolves in BaO under the above conditions. Thus with increase in temperature the concentration of dissolved oxygen decreases.

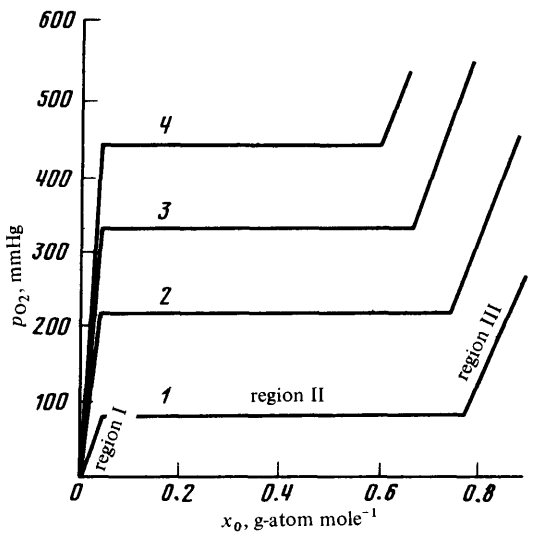

Figure 4. Solubility isotherms for oxygen in BaO [42] at 683° (*1*), 748° (*2*), 773° (*3*), and 790° (*4*).

In the range of the univariant equilibrium (region II in Fig. 4), the temperature dependence of the equilibrium pressure of oxygen above the product of the reaction of BaO with O_2 is given by the equation

$$\lg p_{O_2} = -7500/T + 9.705. \tag{5}$$

The heat of the chemical reaction by which BaO_2 is formed,

$$BaO + 1/2\,O_2 = BaO_2, \tag{6}$$

calculated from the compositions of the conjugate solid solutions and the oxygen pressure in the univariant range, was 18.8 kcal mole^{-1}, in agreement with the value 19.1 kcal mole^{-1}, obtained later[46].

A procedure basically similar to that described above was used to obtain the isothermal dependence of the solubility of O_2 in BaO at 950° and 1150° in the range $p_{O_2} = 2\times10^{-5}$–5 mmHg (Fig. 5).[43] For the oxygen pressure range 5×10^{-4}–5 mmHg, in which the accuracy of the measurements was ±10%, the solubility isotherms were given by the following equations

$$x_O = 1.88 \cdot 10^{-3} p_{O_2}^{1/1.97} \text{ (at 950°)} \tag{7}$$

$$x_O = 9.8 \cdot 10^{-4} p_{O_2}^{1/2.09} \text{ (at 1150°)}. \tag{8}$$

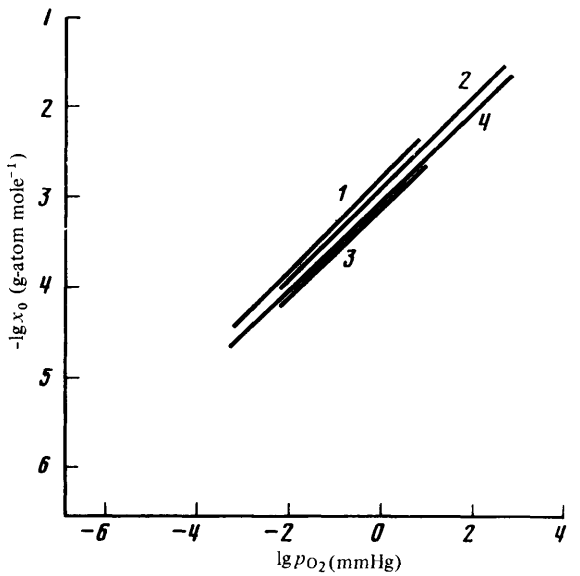

Figure 5. Solubility isotherms for oxygen in BaO at 950° (*1*—from Ref. 43, *2*—from Ref. 47) and at 1150° (*3*—from Ref. 43, *4*—from Ref. 47).

In a later analogous study[47], the solubility of oxygen in BaO was measured at 850–1420° and $p_{O_2} = 5\times10^{-3}$–600 mmHg. The concentration of O_2 absorbed by the oxide was determined by thermogravimetric analysis (TGA) and from the quantity of oxygen liberated when the specimen was dissolved completely in water. The results obtained by these two methods did not coincide, the solubility values obtained from the thermogravimetric measurements being 2–2.5 times those obtained from the gas-volumetric measurements. The former appear more reliable, since in the determination of O_2 by the second method, loss of oxygen as a result of the simultaneous freezing of O_2 and water in the trap cooled by liquid nitrogen is possible. The results obtained by TGA are given in Fig. 6, and are described analytically by the equation

$$x_O = 2.71 \cdot 10^{-5} p_{O_2}^{1/2} \exp(+9080/RT). \tag{9}$$

To measure the bulk absorption of O_2 and its adsorption separately, finely dispersed and coarsely crystalline BaO powders were used[47]. The results of the measurements in the two cases did not differ greatly, indicating that

adsorption makes a relatively small contribution to the measured value of the absorption under the conditions of the experiment.

Comparison shows that these results[43,47] are in agreement (Fig. 5). It should be noted, however, that at $x_O > 2\times10^{-2}$ g-atom O per mole of BaO, the isotherms obtained in one case[47] become steeper (Fig. 6). This apparently indicates that with increase in the concentration of oxygen dissolved in BaO, the law governing the distribution of oxygen between the gaseous phase and the BaO crystals changes.

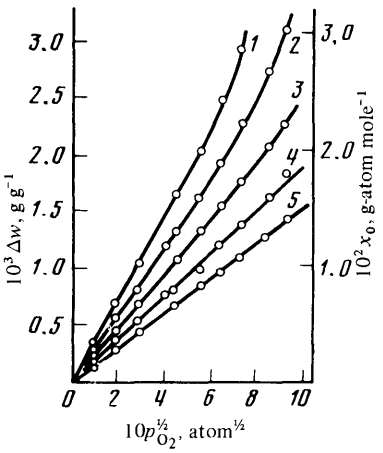

Figure 6. Dependence of the change in weight (Δw) of BaO specimens on the oxygen pressure at 857° (*1*), 927° (*2*), 1027° (*3*), 1127° (*4*), and 1227° (*5*).[47]

Table 1. Coefficients K_O and n in Eqn. (3).[45]

T, °C	700	800	950	1150
10^4K_O	2.77	1.71	1.23	0.93
n	2.37	2.61	2.63	2.66

The SrO–O_2 system was studied in detail at temperatures up to 600° in the range of oxygen pressures 1–100 atm.[48] A range of existence of bivariant equilibria similar to those found in the BaO–O_2 system could not be detected[48]; the stability of SrO_2 was found to be much lower than that of BaO_2.

The solubility of O_2 in SrO was studied[44,45] at 700–1150° and $p_{O_2} = 1\times10^{-5}$–5 mmHg by the method used for BaO.[42,43] The experimental points on coordinates $\lg x_O - \lg p_{O_2}$ were given by straight lines, within the limits of their scatter. The coefficients K_O and n in Eqn. (3), describing the experimental data, are given in Table 1.

Comparison of the solubility of oxygen in SrO and BaO shows that it is lower by approximately an order of magnitude in SrO. As in the case of BaO, however, the solubility of oxygen decreases with increase in temperature.

The data on the solubility of oxygen in MgO [49,50] and CaO [50] are fragmentary and qualitative in character, and give no additional information on the behaviour of excess oxygen in MO.

3. Summary of Data on the Non-stoichiometry of BaO and SrO Specimens Having a Highly Developed Surface

The production of excess M or O in MO both in the bulk of the crystals and on their surface is the factor responsible for the sharp change in the electrophysical properties of the oxides. Thus to select conditions for the synthesis of a substance with required properties, it is necessary to know how the magnitude of the excess of a given component of the compound depends on the vapour pressure and temperature. One method of summarising this relationship is by constructing $p-T-x$ diagrams.

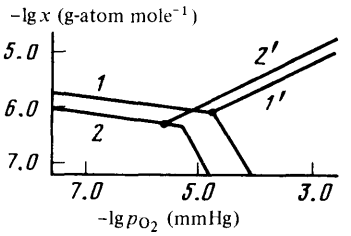

Figure 7. Dependence of the excess component in BaO on p_{O_2}:[51] *1*,*2*) concentration of excess Ba at 1150° and 1000° respectively; *1'*,*2'*) concentration of excess oxygen at 1150° and 950° respectively.

The first attempt to use the results of direct determinations of the excess of the components in BaO to construct this diagram was made by one of the present authors[51]. For this purpose, use was made of the results of measurements using powdered specimens, which are of particular interest since they are used as electron-emitting coatings in thermocathodes. Since in the production of the emitting power of these cathodes, in addition to the excess metal dissolved in the bulk of the crystals, an exceptional role is played by the excess metal localised on their surface, the coordinate reflecting the excess metal in the $p-T-x$ diagram included both the metal dissolved in the bulk of the crystals and the metal situated on the surface. This gave these diagrams the maximum utility for practical applications.

Fig. 7 shows the change in the magnitude of the excess of a component in BaO on p_{O_2} at a given temperature. Lines *1* and *2* show the magnitude of the excess Ba at 1150° and 950°, and lines *1'* and *2'* the excess oxygen at the same temperatures. Taking sections of the isotherms in Fig. 7 along the concentration axis and transferring them to coordinates $\lg p_{O_2} - 1/T$ gave the part of the $p-T-x$ diagram for the pressure range of greatest practical interest[51] (Fig. 8).

The $p-T-x$ diagram for strontium oxide (Fig. 9) was constructed similarly[45], again for specimens having a highly developed surface and for the range of small departures from stoichiometry.

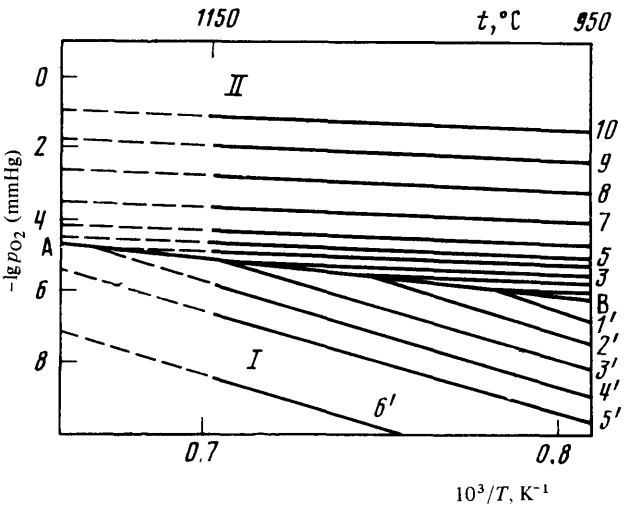

Figure 8. $p-T-x$ diagram for BaO [51] (region *I*—range of excess Ba, region *II*—range of excess oxygen). Concentration of excess components: *1*) 1.8×10^{-6}; *2*) 1.6×10^{-6}; *3*) 1.3×10^{-6}; *4*) 1.0×10^{-6}; *5*) 9.1×10^{-7}; *6*) 7.9×10^{-7}; *7*) 6.3×10^{-7}; *8*) 5.2×10^{-7}; *9*) 2.5×10^{-7}; *10*) 4.0×10^{-6}; *11*) 1.0×10^{-5}.

1. Analysis of Crystal–Vapour Equilibrium

It is of interest to determine the conditions of the crystal–vapour phase equilibrium under which: 1) the overall compositions of the vapour phase and the crystal are the same, and 2) the crystal has the stoichiometric composition.

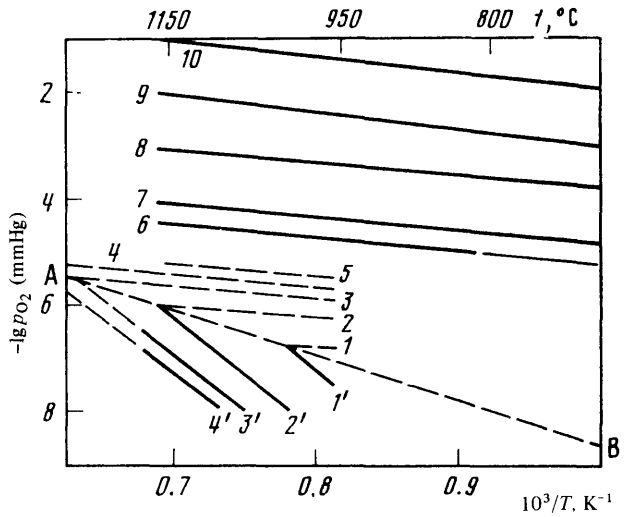

Figure 9. $p-T-x$ diagram for SrO [45] (excess oxygen above line AB, excess strontium below it). Concentration of excess components: *1*) 3×10^{-7}; *2*) 5×10^{-7}; *3*) 6.5×10^{-7}; *4*) 8×10^{-7}; *5*) 1×10^{-6}; *6*) 2×10^{-6}; *7*) 3×10^{-6}; *8*) 7×10^{-6}; *9*) 1.8×10^{-5}; *10*) 4.5×10^{-5}.

III. SOME THERMODYNAMIC PROPERTIES OF MO CRYSTALS

To investigate the nature of the non-stoichiometry of MO crystals, it is useful to draw on experience gained in the thermodynamics of solutions. Thermodynamics makes it possible to regard non-stoichiometric crystals as solid solutions in which the solvent is the main material MO, and the solutes are the excess components, the products of the dissociation of the main substance.

In the thermodynamic analysis of the properties of a non-stoichiometric phase, it is necessary to bear in mind that published data on the departures from stoichiometry do not always contain the required information on the surface area of the specimens studied. This makes it difficult to use these data, since in specimens having a highly developed surface, the magnitude of the departure from stoichiometry is determined not only by pressure and temperature but also by the degree of dispersion of the specimen. Thus the present authors selected from the available experimental data those characterising the excess of the components only in the bulk of the MO crystals, and used the methods of the thermodynamics of solutions in an attempt to analyse various thermodynamic properties of non-stoichiometric crystals and summarise the information in the form of $p-T-x$ diagrams.

With isothermal equilibrium change in the composition of an MO crystal, the vapour pressure above the specimen passes through an extremal value. At the extremal point, the overall compositions of the equilibrium vapour and solid phases are the same, so that volatilisation of the MO crystals at a given temperature can take place without change in the composition of the specimen. The relationship between the concentration of the excess components in MO crystals and the composition of the vapour at the extremal point can be examined.

MO is partly dissociated in the vapour phase. The volatilisation and dissociation of the oxide can be described as follows:

$$\mathrm{MO(solid)} \rightarrow \mathrm{MO(vapour)}, \quad K_{10} = p_{MO}/x_{MO}; \tag{10}$$

$$2\mathrm{MO(vapour)} \rightarrow 2\mathrm{M(vapour)} + \mathrm{O_2}; \quad K_{11} = (p_M^2 p_{O_2})/p_{MO}^2, \tag{11}$$

where x_{MO} is the mole fraction in the solid phase, and K_{10} and K_{11} the equilibrium constants of the corresponding reactions.

The total vapour pressure over the MO crystals is given by the sum

$$p = p_{MO} + p_M + p_{O_2}. \tag{12}$$

To find the vapour pressure extremal point, p_{MO} and p_{O_2} in Eqn. (12) are replaced by p_M, K_{10}, and K_{11}, and the right-hand side of the equation is differentiated with

respect to p_M. The expression obtained is put equal to zero, and transformed to give

$$2p_{O_2}/p_M = 1 + (K_{10} + 2p_{O_2}/x_{MO})\frac{\partial x_{MO}}{\partial p_M}. \quad (13)$$

When the excess components dissolve in MO, processes take place leading to the production of defects of various kinds in the crystal. These processes can be represented in general form as follows:

$$A_{vap} \rightleftarrows (iC + jD + \ldots + rE)_{cryst}, \quad (14)$$

where A represents the metal or oxygen (O_2) in the vapour phase, and C, D, ... E are the new components of the crystal, formed in its interaction with the vapour A.

At the comparatively small departure from stoichiometry observed in alkaline earth metal oxides, their phases can be regarded as very dilute solutions. In this case the equilibrium constant of reaction (14) has the form

$$K = \frac{[C]^i [D]^j \ldots [E]^r}{p_A}. \quad (15)$$

Since

$$[C] = \frac{i}{j}[D] = \ldots = \frac{i}{r}[E], \quad (16)$$

Eqn. (15) can be solved for [C]:

$$[C] = K' p_A^{1/(i+j+\ldots+r)}, \quad (17)$$

where

$$K' = \left[K\left(\frac{i}{j}\right)^j \ldots \left(\frac{i}{r}\right)^r\right]^{1/(i+j+\ldots+r)}$$

Thus the distribution of the excess components between the vapour phase and MO crystals is described in general form by the equations:

$$x_M = K_M p_M^{1/m}, \quad (18)$$

$$x_O = K_O p_{O_2}^{1/n}, \quad (19)$$

where m or n are equal to the sum of the stoichiometric coefficients in the right-hand side of Eqn. (14), or, put differently, are equal to the number of particles and quasi-particles formed in the solid phase from one metal atom or oxygen molecule on going from the vapour to the solid phase. If the particles and quasi-particles formed are regarded as independent chemical components, Eqns. (14) and (15) give the following equation, which is always applicable for a solid solution of the excess components in MO†:

$$x_{MO} + mx_M + \frac{n}{2}x_O = 1. \quad (20)$$

x_{MO} in Eqn. (13) is expressed in terms of x_M and x_O, using Eqn. (20). x_M and x_O are then replaced by their values from Eqns. (18) and (19). Since x_M and x_O are much smaller than 1, this gives the approximate equation

$$2p_{O_2} = p_M - K_{10}\delta, \quad (21)$$

where $\delta = x_M - x_O$. When the homogeneity range of the compound is extremely narrow, that is $\delta = 0$, it follows that at the point of minimum vapour pressure

$$2p_{O_2} = p_M. \quad (22)$$

From published data on the dissociation constant of MO

$$K_{MO} = K_{10}^2 K_{11} = p_M^2 p_{O_2}/x_{MO}, \quad (23)$$

where $x_{MO} \simeq 1$, it is possible to calculate p_M at the vapour pressure extremal point with allowance for Eqn. (22). At the total vapour pressure minimum

$$p_M = (2K_{MO})^{1/3}. \quad (24)$$

Eqns. (18), (19), and (22) can be used to find the vapour pressure of M over MO crystals having the stoichiometric composition at $\delta = 0$, and also the concentration of quasi-excess M and O at this point. For this purpose, Eqns. (18) and (19) are equated, and in Eqn. (19) p_{O_2} is expressed in terms of p_M, using Eqn. (23). This gives:

$$p_M = \left(\frac{K_O K_{MO}^{1/n}}{K_M}\right)^{mn/(n+2m)}. \quad (25)$$

The value of p_M at $\delta = 0$ is substituted in Eqn. (18) to obtain the concentration of quasi-excess components:

$$x_M = x_O = (K_{MO} K_O^n K_M^{2m})^{1/(n+2m)}. \quad (26)$$

The total concentrations of both quasi-excess components in the stoichiometric crystal are obviously equal to $2x_M$.

It is possible to calculate p_M at the total vapour pressure minimum, and also p_M and x_M at $\delta = 0$ for BaO. The dissociation constant of BaO is known[52]:

$$\lg K_{BaO} = -\frac{352.1 \cdot 10^3}{4.57T} + 40.54 - 3.6 \lg T, \ (\text{mmHg})^3 \quad (27)$$

Eqns. (24) and (27) are used to find p_{Ba} at the total vapour pressure minimum

$$\lg p_{Ba} = \lg(2p_{O_2}) = -\frac{117.4 \cdot 10^3}{4.57T} + 13.82 - 1.20 \lg T. \quad (28)$$

To calculate p_{Ba} and x_{Ba} at $\delta = 0$, it is necessary to know not only K_{BaO} but also K_O, K_{Ba}, m, and n. The values of K_O and n are known from Eqn. (9). The solubility of excess Ba in BaO for an infinitely dilute solution is given in general form by the equation

$$x_{Ba} = C p_{Ba}^{1/m} \exp(-A/RT), \quad (29)$$

where A, C, and m are constants. From published data, the parameter $m = 3$ [9,14,22] and $A = 5$–10 kcal mole^{-1}; [29] in the present work it was assumed that $A = 7.0$ kcal mole^{-1}, and the apparently most reliable data[14] then gave

$$x_{Ba} = 8 \cdot 10^{-4} p_{Ba}^{1/3} \exp(-7 \cdot 10^3/RT). \quad (30)$$

p_{Ba} and x_{Ba} are now obtained for $\delta = 0$:

$$\lg p_{Ba} = -\frac{120.0 \cdot 10^3}{4.57T} + 14.10 - 1.35 \lg T; \quad (31)$$

$$\lg x_{Ba} = \lg x_O = -\frac{47.0 \cdot 10^3}{4.57T} + 1.61 - 0.45 \lg T. \quad (32)$$

Comparison of Eqns. (28) and (31) shows that for BaO, the composition of the crystal at the extremal vapour pressure will differ only slightly from the stoichiometric composition, particularly at temperatures above 1000°. The value of x_{Ba} is calculated assuming that $\delta = 0$ at $p_{Ba} = 2p_{O_2}$. For this purpose, the value of p_M from Eqn. (24) is substituted in Eqn. (25):

$$K_M = 2^{-1/3} K_O (K_{MO}/4)^{1/18}. \quad (33)$$

† In the general case, the coefficients of x_M and x_O are equal to

$$\left(\frac{i+j+\ldots+r}{i}\right),$$

where $i = 1$ or 2 for the dissolution of a metal atom or an oxygen molecule respectively.

Thus

$$x_{Ba} = 1.0 \cdot 10^{-3} p_{Ba}^{1/3} \exp(-10.5 \cdot 10^3/RT). \quad (34)$$

At high temperatures, Eqn. (34) gives values of x_{Ba} close to those obtained from Eqn. (30).

Similar calculations can be carried out for strontium oxide. The expression for the dissociation constant of SrO [52] is:

$$\lg K_{SrO} = -\frac{362.0 \cdot 10^3}{4.57T} + 40.40 - 3.27 \lg T \ (\text{mmHg})^3. \quad (35)$$

The extremal vapour pressure of SrO corresponds to the following value of p_{Sr}, calculated from Eqns. (24) and (35):

$$\lg p_{Sr} = \lg(2p_{O_2}) = -\frac{120.1 \cdot 10^3}{4.57T} + 13.75 - 1.09 \lg T. \quad (36)$$

To calculate p_{Sr} and x_{Sr} at $\delta = 0$, the experimental dependence of x_O on p_{O_2}, which is more complex than that for BaO, is first analysed, The parameter n in Eqn. (19) is fractional (see Table 1), apparently indicating that oxygen is distributed by two competing mechanisms[45]. Since n is close to 2, it appears natural to assume that one of the mechanisms, probably the principal mechanism, is described by a distribution law which is similar to that for BaO and has the parameter $n = 2$. Thus the relationship between the concentration of excess oxygen in SrO and the oxygen pressure is represented in the form of the sum:

$$x_O = K_1 p_{O_2}^{1/2} + K_2 p_{O_2}^{1/f}, \quad (37)$$

where the first term on the right-hand side of the equation corresponds to the principal distribution law.

Table 2. Coefficients K_1 and K_2 in Eqn. (34).

T, °C	700	800	950	1150
$10^4 K_1$	2.6	1.9	1.2	0.64
$10^5 K_2$	2.4	3.1	2.3	2.7

Eqn. (37) gives the best description of the experimental data (practically within the range of scatter) if it is assumed that $f = 4$ (for $f = 3$, 5, or 6 greater deviations from the interpolation line are obtained). The calculated coefficients K_1 and K_2 are given in Table 2. The second mechanism makes a practically constant contribution to the value of x_O at a fixed p_{O_2}, irrespective of temperature in the range 700–1150°C. This is possible if it is assumed that the additional absorption is background absorption. The temperature dependence of the solubility of oxygen in SrO for the principal mechanism is described by the equation

$$x_O = 4.0 \cdot 10^{-6} p_{O_2}^{1/2} \exp(+9.0 \cdot 10^3/RT). \quad (38)$$

When K_O and K_{SrO} are known, it is possible to find x_{Sr} from Eqn. (33):

$$x_{Sr} = 1.4 \cdot 10^{-4} p_{Sr}^{1/3} \exp(-11 \cdot 10^3/RT), \quad (39)$$

assuming that, as in the base of BaO, $m = 3$.

At the point $\delta = 0$, the concentration of quasi-excess Sr is given by

$$\lg x_{Sr} = \lg x_O = -\frac{52.2 \cdot 10^3}{4.57T} + 1.08 - 0.41 \lg T. \quad (40)$$

Fig. 10 gives the calculated solubility isotherms for the excess Sr and oxygen in SrO at 1150°, together with experimental data[45] on the solubility of oxygen in SrO and data[28] on the solubility of Sr in SrO at high metal vapour pressures. The calculated isotherms show satisfactory agreement with the experimental isotherms obtained for other vapour pressure ranges.

2. Properties of the Solid Solution of M in MO Close to the Solidus Line

At high metal vapour pressures close to the solidus line, the concentration of excess M in MO is proportional to p_M (see Fig. 1), that is the distribution of M between the vapour and solid phases is described by Henry's law: $x_M \sim p_M$. The influence of temperature on the solubility of M in MO in this range of values of p_M can be examined. For the qualitative discussion of this question, the approximation of regular solutions can be used. In this case the activity coefficient (γ_M) is given by the equation[53]:

$$\lg \gamma_M = \alpha/RT, \quad (41)$$

where α is a constant parameter which has the significance of the differential molar heat of solution. The activity of M in the solid solution is given by the expression

$$a_M = \gamma_M x_M = p_M/(p_M^0)_{\text{solid}}, \quad (42)$$

where p_M is the vapour pressure of M above the solution of M in MO, and $(p_M^0)_{\text{solid}}$ the vapour pressure of the pure solid metal.

Substituting Eqn. (41) in Eqn. (42) gives

$$\ln x_M = -\alpha/RT + \ln[p_M/(p_M^0)_{\text{solid}}]. \quad (43)$$

The value of α calculated using data on the solubility of M in MO, given in Fig. 1, and on the saturated vapour pressure of the solid alkaline earth metals[7,25,54]. For BaO, SrO, CaO, and MgO, the calculated values of the parameter α are 14.1, 18, 19, and 33 kcal mole^{-1} respectively. Analysis of Eqn. (43) shows that if the heat of sublimation of M is greater than α, the solubility of M in MO at a given vapour pressure decreases with increase in temperature. Comparison of the values of α with the heats of sublimation, equal to 42, 36, 41, and 34 kcal mole^{-1} for Ba, [7] Sr, Ca, and Mg [54] respectively, shows that the solubility should decrease with increase in temperature for BaO, SrO, and CaO. This is confirmed by available experimental data for SrO [28] (see Fig. 1). The solubility of atoms of the alkali metals in crystals of their halides shows a similar temperature dependence[55]. For a solution of Mg in MgO, the values of the heat of sublimation and α coincide. The temperature dependence of the solubility in this case is determined by the deviations of the properties of the real solution from those of a regular solution. The solubility of Mg in MgO increases with temperature (see Fig. 1), [26] in contrast to the oxides of the other alkaline earth metals.

Fig. 11 gives the solubility isotherms for Ba in BaO, calculated from Eqn. (30) at low Ba vapour pressures and from Eqn. (43) at high pressures. In Eqn. (43) the vapour pressure over solid Ba was calculated from the equation[7]:

$$\lg(p_{Ba}^0)_{\text{solid}} = 8.34 - (9.2 \cdot 10^3/T). \quad (44)$$

Fig. 11 shows that the isotherms intersect. At the points of intersection, however, the compositions of the solid solutions, which are at different temperatures, are not the same. At a higher temperature, the excess Ba in

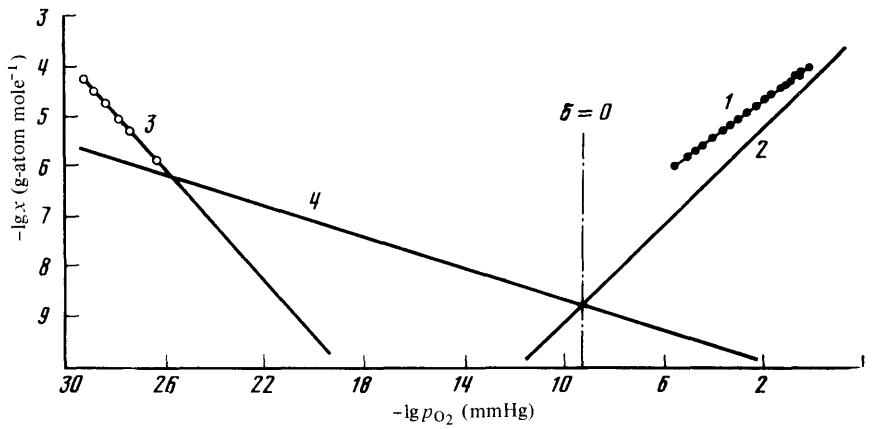

Figure 10. Solubility isotherms for excess strontium and oxygen in SrO at 1150°: *1*) oxygen solubility isotherm[45]; *2*) solubility isotherm for oxygen in the form of the complexes (O_2^{2-})(solid), calculated from Eqn. (35); *3*) Sr solubility isotherm[28], corresponding to the formation of $V_O^{\times}$; *4*) solubility isotherm for Sr in SrO, calculated from Eqn. (36) and corresponding to the formation of defects of the type $V_O^{\cdot\cdot}$ in SrO.

the solution predominates in a form corresponding to the distribution law: $x_{Ba} \sim p_{Ba}^{1/3}$. The points of intersection evidently correspond to identical total concentrations of excess Ba, which is however present in different states in BaO. A similar phenomenon should be observed for solutions of the excess metals in SrO and CaO.

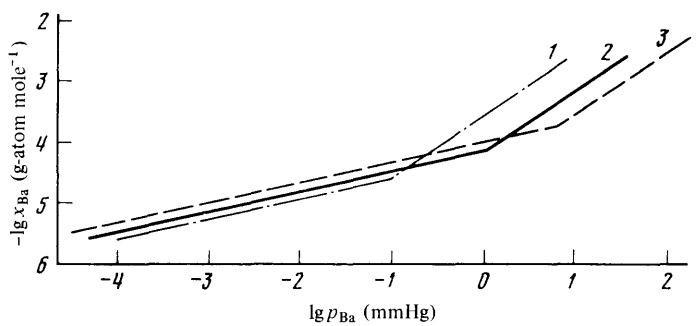

Figure 11. Solubility isotherms for Ba in BaO, calculated from Eqns. (27) and (40) for 1000° (*1*), 1200° (*2*), and 1400° (*3*).

The above discussion dealt only with the change in the properties of the solute—the excess metal—with change in the vapour pressure of M. The analysis of the behaviour of the solvent with increase in the concentration of excess metal in the solution is also of undoubted interest. The Gibbs–Duhem equation is used, with the assumption that at high vapour pressures of M, the system can be regarded as a two-component system consisting of M and MO. At a constant temperature, the Gibbs–Duhem equation has the form

$$dp = c_M d\mu_M + c_{MO} d\mu_{MO}, \qquad (45)$$

where p is the total pressure above the phases; $c_i = n_i/V$ (n is the number of moles of the component in the phase, and V the volume of the phase); and μ_i the chemical potential of the component. In the range of vapour pressure in which the solubility of M in MO obeys Henry's law, the vapour pressure of MO is smaller than p_M by many orders of magnitude[26-29,39,52]. It may therefore be assumed that $p = p_M$. Since the chemical potentials of a given component in the equilibrium phases are the same, $\mu_M = \mu_M^{vapour}$ (μ_M^{vapour} is the chemical potential of M in the vapour phase). Since the vapour phase is ideal,

$$d\mu_M^{vapour} = RT\, d\ln p_M = d\, p_M/c_M^{vapour}, \qquad (46)$$

where $c_M^{vapour} = n^{vapour}/V^{vapour}$ is the molar concentration of M in the vapour phase. Substituting Eqn. (46) in Eqn. (45) gives

$$d\mu_{MO} = \left(\frac{1-\beta}{c_{MO}}\right) p_M, \qquad (47)$$

where $\beta = c_M/c_M^{vapour}$ is a function of temperature alone, as follows from Henry's law.

Integration of Eqn. (47) gives the change in the chemical potential of the solvent with increase in p_M:

$$\Delta\mu_{MO} = \left(\frac{1-\beta}{c_{MO}}\right)\Delta p_M. \qquad (48)$$

This equation (for the change in the quantity p_{MO}) was first derived by Gibbs[56]. From the equation it follows that for $\beta < 1$, the chemical potential of MO, and hence p_{MO}, increase with increase in p_M and the concentration of excess M in MO; for $\beta = 1$, the chemical potential remains unchanged under the same conditions; and finally it decreases for $\beta > 1$. From data on the solubility of M in MO it follows that for solutions of Ba in BaO, Sr in SrO, and Ca in CaO, the parameter $\beta > 1$, so that the chemical potential of MO decreases with increase in the concentration of excess metal in the crystal. On the other hand, in the case of a solution of Mg in MgO, the parameter $\beta < 1$, and the chemical potential of MgO increases.

Thus the thermodynamic properties of a solution of excess Mg in MgO differ from the properties of solutions of the excess metal in the oxides of the other alkaline earth metals. This is quite regular, since the other physicochemical properties of magnesium oxide differ significantly from the properties of the other oxides of this homologous series[57].

3. Range of Existence of BaO on the $T-x$ Diagram

Measurements of the solubility of oxygen in BaO, carried out at low temperatures[42] (Fig. 4), give the position of the solidus line bounding the range of existence of BaO on the BaO_2 side. Fig. 12 shows that the range of existence of BaO increases with temperature, apparently as far as the eutectic temperature (~800° [58]). This part of the solidus line is described analytically by the equation[42]:

$$\lg x_O = -4333/T + 2{,}863. \qquad (49)$$

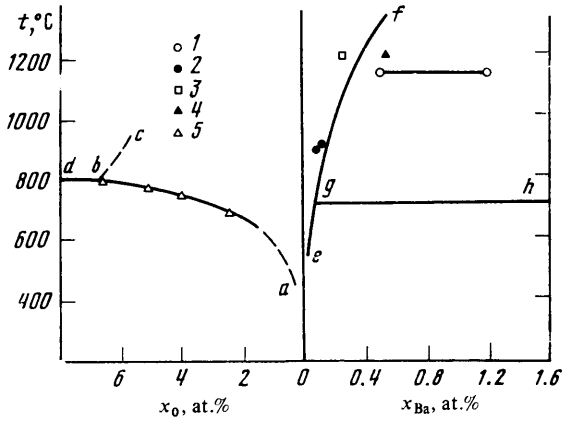

Figure 12. Range of existence of BaO (to the right of the line *abc*, to the left of the line *ef*): *1*) from Ref. 2; *2*) from Refs. 3 and 4; *3*) from Ref. 24; *4*) from Ref. 39; *5*) from Ref. 42; the lines *bd* and *gh* mark the temperatures of the eutectic reactions.

With increase in temperature above the eutectic temperature, a decrease in solubility can be expected, as a consequence of the decrease in the activity of BaO_2 in the melt in equilibrium with the phase BaO.

Several points of the solidus line bounding the range of existence of the phase BaO on the Ba side were obtained by Schriel[2], Kane[3], Libowitz[4], and others[24,35,39,40]. These data are given in Fig. 12. The temperature of the eutectic in the BaO–Ba system is ~710°.[2] Fig. 12 shows that the solubility of Ba in BaO is retrograde. To verify the degree of self-consistency of the published data[2-4,24,25,39,40], the position of the solidus line can be calculated using Eqn. (43), in which α = 14.1 kcal mole^{-1}, and $(p^0_{Ba})_{solid}$ is given by Eqn. (44). The vapour pressure of Ba over BaO crystals in equilibrium with molten Ba [2] should be much lower than the saturated vapour pressure of pure liquid Ba, since BaO is appreciably soluble in liquid Ba. To calculate p_{Ba} it is assumed that the solution of BaO in Ba is ideal. The solubility of BaO in liquid Ba is known[2]. The results of the calculation are given in Table 3. For 1200°, the calculated value of the vapour pressure of Ba, equal to 31 mmHg, is close to the measured value[39,40] (35 mmHg). The solidus calculated from Eqn. (43) is fairly close to the experimental points (Table 3 and Fig. 12).

Unfortunately, for the oxides of the other alkaline earth metals the data on the homogeneity range are even more fragmentary than for BaO. Comparison of the solubility isotherms for M in MO, given in Fig. 1, merely indicate a tendency for the solubility of M in MO to decrease in the order BaO, SrO, CaO, MgO. The same is true of the solubility of oxygen in MO, as can be seen by comparing its solubility in BaO and SrO (see Part I). Thus the range of existence of MO on the $T-x$ diagram becomes narrower from BaO to MgO.

4. $p-T-x$ Diagram of BaO

The experimental and calculated data on the solubility of the excess components in BaO can be conveniently summarised in the form of the $p-T-x$ diagram, constructed on coordinates $\lg p_{Ba} - 1/T$. This diagram is given in Fig. 13. On these coordinates, the solidus line on the Ba side at low temperatures, when the solubility of BaO in Ba is low, practically coincides with the line giving the temperature dependence of the saturated vapour pressure of pure Ba. In Fig. 13 this is taken from published data[24,25]. At higher temperatures, when the solubility of BaO in molten Ba becomes appreciable, the vapour pressure of Ba, corresponding to the solidus line, becomes lower than the vapour pressure over pure Ba. In this range, the solidus line was constructed from the calculated data given in Table 3. Part of the solidus line (the line *aa*), defining the vapour pressure of Ba in the range of equilibrium of the phases BaO and BaO_2, was constructed using Eqn. (5), which gives the value of p_{O_2} in this range. The value of p_{Ba} was calculated from the known value of p_{O_2} and the dissociation constant of BaO [52] using the equation

$$p_{Ba} = (K_{BaO}/p_{O_2})^{1/3}. \qquad (50)$$

The isoconcentrates on coordinates $\lg p_{Ba} - 1/T$ (Fig. 13) were constructed using Eqns. (4), (9), (30), and (43), describing the solubility of the excess components in BaO in different regions of the diagram. The line *bb* in the diagram is described by Eqn. (28) and corresponds to the

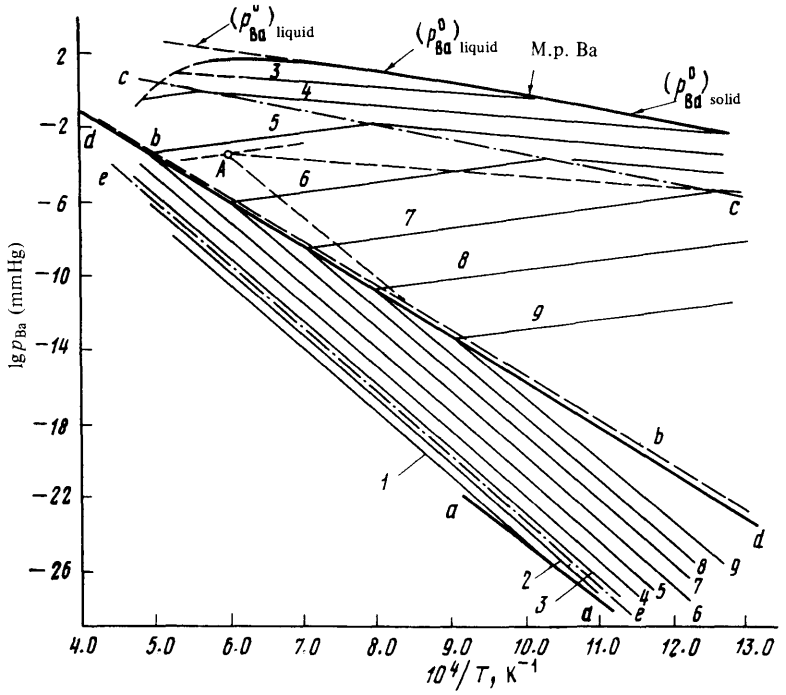

Figure 13. $p-T-x$ diagram for BaO containing excess Ba and oxygen in the bulk of the crystals. The figures at the isoconcentrates give the powers of 10^{-n}, equal to the concentration of the dissolved component.

minimum vapour pressure over BaO crystals. The line *dd* is described by Eqn. (31) and defines the conditions of existence of BaO crystals of stoichiometric composition. The line *cc* gives the change in the distribution law for excess Ba: below this line, $x_{Ba} \sim p_{Ba}^{1/3}$, and above it, $x_{Ba} \sim p_{Ba}$. Its position was calculated from the points of intersection of the isoconcentrates defined by Eqns. (29) and (43).

The isoconcentrates of the excess oxygen are given below the line *dd*. At a concentration of oxygen in BaO greater than $\sim 5 \times 10^{-3}$, the nature of the distribution of oxygen between BaO and the vapour phase changes: the solubility is described by Eqn. (4) at higher concentrations, and by Eqn. (9) at lower concentrations. On coordinates $\lg p_{Ba} - 1/T$, the isoconcentrates described by these equations are parallel to one another. Thus the change in the distribution law takes place fairly smoothly in the concentration range 1×10^{-3}–1×10^{-2}, approximately along the line *ee*.

The isoconcentrates given on the $p-T-x$ diagram (Fig. 13) can obviously be extended beyond the limits of the lines corresponding to the change in the predominant distribution law: *dd*, *cc*, and *ee*. For example, the BaO crystal under the conditions corresponding to point *A* in the diagram contains 8×10^{-6} excess Ba in a form which corresponds to the distribution law (29); 1×10^{-7} excess Ba in a form corresponding to the distribution law (43); 1×10^{-9} excess oxygen in a form corresponding to the distribution law (9), and finally $\sim 10^{-15}$ excess oxygen in a form corresponding to the distribution law (4).

The $p-T-x$ diagram in Fig. 13 can be used to find the conditions for preparing BaO crystals having a given concentration of excess components in a given form. The $p-T-x$ diagram illustrates the mutally unambiguous correspondence between the compositions of the non-stoichiometric crystals under equilibrium conditions and under the conditions of their preparation, completely determined by the vapour pressure of Ba (or O_2) and temperature. In particular, the diagram shows that the fact that the concentrations of an excess component, determined in crystals by chemical methods, are equal cannot be taken as a criterion indicating that the properties of the crystals are identical, since an excess of equal magnitude can be created by an excess component present in different states. The diagram also shows that the form of existence of excess components may change when the crystals are cooled from the temperature of synthesis, when breakdown of the solid solution has not yet taken place.

The $p-T-x$ diagram given in Fig. 13 is to a considerable extent a calculated diagram, and must therefore be regarded as semi-quantitative. To refine it, it is necessary to carry out additional experiments on the direct determination of the concentration of excess components and to study the coefficients of self-diffusion and electrical properties of the crystals under conditions of equilibrium with the vapour phase. A study of the diffusion of barium in BaO at temperatures greater than 1400° indicated that a change in the distribution law for oxygen between the vapour and BaO crystals is possible. The

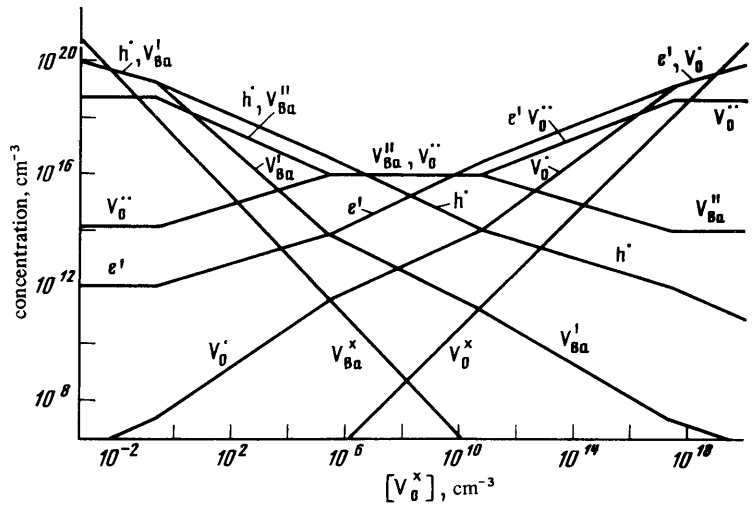

Figure 14. Dependence of the concentration of point defects in BaO on p_{Ba} at 1200° [60] for the case where $K''_S > K_i > K'_S$, where K''_S is the equilibrium constant for the formation of a pair of doubly ionised Ba and O vacancies, K'_S the same for a pair of singly ionised vacancies, and K_i the equilibrium constant for the formation of an "electron–hole" pair.

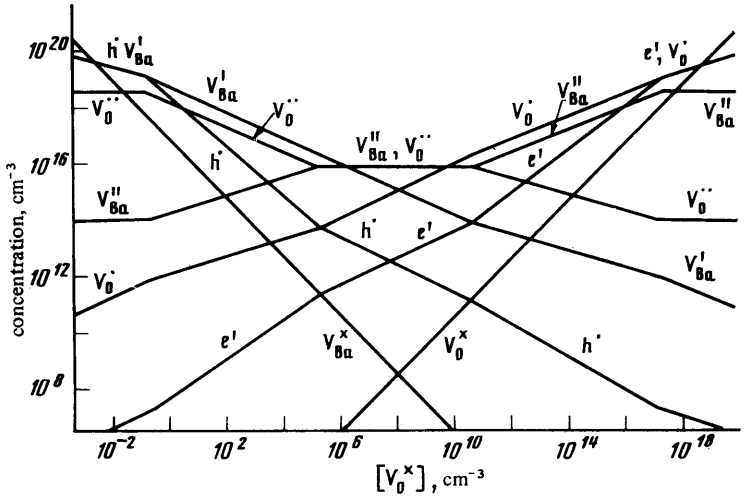

Figure 15. Dependence of the concentration of point defects in BaO on p_{Ba} at 1200° [60] for the case where $K''_S > K'_S > K_i$ (for symbols see caption to Fig. 14).

diffusion coefficient of barium under these conditions became proportional to $p_{O_2}^{1/6}$. The possibility of a change in the nature of the distribution of Ba and O_2 at low temperatures cannot be excluded.

IV. NATURE OF THE INTRINSIC ATOM DEFECTS IN MO

The electrophysical and optical properties of MO, including recent published data, have been reviewed by Kroeger[60], Kofstad[61], and Tret'yakov[62]. Kroeger gave (in the form of diagrams) two possible versions of the equilibrium for the defects in BaO; no refinements were introduced in the later reviews[61,62]. These diagrams are given in Figs. 14 and 15.

Recent papers on the direct quantitative determination of the solubility of M and O in MO give new material from which definite suggestions can be made regarding the nature of the intrinsic atomic defects in MO, and the picture of the equilibrium for defects given by Kroeger[60] can be refined.

1. Defects in BaO

The solubility isotherms for Ba in BaO (Fig. 1) show that Ba atoms dissolved in BaO at low Ba vapour pressures (below 1 mmHg at 1200°) dissociate into several particles. Under these conditions, according to published data[4,5], colour centres having a low rate of diffusion are formed, indicating that the defects produced are vacancies. This is confirmed by data[63] on the concentration of the BaO lattice and the observed[21] absence of any relationship between the absorption spectra of BaO crystals and the nature of the alkaline earth metal dissolved in them. According to Timmer[6] and Kroeger[60], the solution of Ba most probably takes place by the following mechanism:

$$\mathrm{Ba(vapour)} = \mathrm{Ba}_{\mathrm{Ba}}^{\times} + \mathrm{V}_{\mathrm{O}}^{\cdot\cdot} + 2\mathrm{e}'. \qquad (51)$$

If the condition for electrical neutrality of the crystal has the form

$$2[\mathrm{V}_{\mathrm{O}}^{\cdot\cdot}] = [\mathrm{e}'], \qquad (52)$$

then

$$[\mathrm{V}_{\mathrm{O}}^{\cdot\cdot}] \sim p_{\mathrm{Ba}}^{1/3}, \qquad (53)$$

as observed experimentally[6,39].

At higher Ba vapour pressures (above 1 mmHg at 1200°), the introduction of Ba into BaO takes place without dissociation. In the opinion of some authors[9,24], the excess Ba is situated in interstices:

$$\mathrm{Ba(vapour)} = \mathrm{Ba}_i^{\times}, \quad K_{54} = [\mathrm{Ba}_i^{\times}]/p_{\mathrm{Ba}}, \qquad (54)$$

or a solution of Ba_2O "molecules" in BaO is formed:

$$\mathrm{Ba(vapour)} + \mathrm{BaO} = \mathrm{Ba_2O}, \quad K_{55} = [\mathrm{Ba_2O}]/p_{\mathrm{Ba}}. \qquad (55)$$

The distribution law has the same form in the two cases. It can readily be seen that the nature of the distribution law is preserved if it is assumed that the solution of the excess Ba leads to the production of neutral oxygen vacancies which, like the F-centres in alkali metal halide crystals[60], are colour centres in red BaO crystals:

$$\mathrm{Ba(vapour)} = \mathrm{Ba}_{\mathrm{Ba}}^{\times} + \mathrm{V}_{\mathrm{O}}^{\times}, \quad K_{56} = [\mathrm{V}_{\mathrm{O}}^{\times}]/p_{\mathrm{Ba}}. \qquad (56)$$

Additional information is required before preference can be given to either mechanism.

As in the solution of Ba, several insertion mechanisms are observed in the solution of oxygen in BaO. At comparatively low pressures of oxygen, and hence low concentrations of excess oxygen dissolved in BaO, its concentration is proportional to the square root of the oxygen pressure (see Part II). This law should also be observed when the excess oxygen forms an atomic solid solution, and also when it dissolves in BaO as the peroxide. In the first case the following quasi-chemical reactions of solution are possible in principle[47]:

$$\tfrac{1}{2}\mathrm{O_2} = \mathrm{O}_{\mathrm{O}}^{\times} + \mathrm{V}_{\mathrm{Ba}}^{\times}, \quad K_{57} = [\mathrm{V}_{\mathrm{Ba}}^{\times}]/p_{\mathrm{O_2}}^{1/2}, \qquad (57)$$

$$\tfrac{1}{2}\mathrm{O_2} = \mathrm{O}_i^{\times}, \quad K_{58} = [\mathrm{O}_i^{\times}]/p_{\mathrm{O_2}}^{1/2}. \qquad (58)$$

Since however the heat of dissociation of oxygen molecules to oxygen atoms is large, it is to be expected that the total thermal effect of reaction (57) or (58) will be endothermic, and not exothermic, as found experimentally[43,47]. It was therefore suggested[43] that in the solution of oxygen, the formation of barium peroxide takes place preferentially:

$$\tfrac{1}{2}\mathrm{O_2} + \mathrm{BaO} = \mathrm{BaO_2}, \quad K_{59} = x_{\mathrm{BaO_2}}\gamma_{\mathrm{BaO_2}}/a_{\mathrm{BaO}}p_{\mathrm{O_2}}^{1/2}, \qquad (59)$$

where a_{BaO} is the activity of BaO, equal to ~1, and γ_{BaO_2} the activity coefficient of BaO_2 dissolved in BaO (since the solution of BaO_2 in BaO is dilute, γ_{BaO_2} is constant at a given temperature). The same conclusion was reached in later work[47].

Because of the fundamental importance of this question, the enthalpies of various processes taking place when oxygen is dissolved in BaO with the formation of a solid solution of BaO_2 in BaO will be calculated. Differentiation of the expression for $\ln K_{59}$ obtained from Eqn. (59) with respect to temperature at p_{O_2} = const gives

$$\partial \ln K_{59}/\partial T = \partial \ln \gamma_{\mathrm{BaO_2}}/\partial T + \partial \ln x_{\mathrm{BaO_2}}/\partial T. \qquad (60)$$

If both sides of Eqn. (60) are multiplied by RT^2, the term on the left-hand side of Eqn. (60) acquires the significance of the enthalpy of the reaction (ΔH_r) for BaO_2 formation, and the term $(-RT^2\,\partial \ln \gamma_{BaO_2}/\partial T)$ is the differential molar heat of solution of BaO_2 in BaO ($\Delta\bar{H}_{BaO_2}$). Thus from Eqn. (60) it follows that

$$\Delta H_p = -\Delta\bar{H}_{\mathrm{BaO_2}} + RT^2\partial \ln x_{\mathrm{BaO_2}}/\partial T. \qquad (61)$$

From Eqn. (9), $RT^2\partial \ln x_{BaO_2}/\partial T = -9.1$ kcal mole^{-1}, and the published[42] enthalpy of reaction (59) is −18.8 kcal mole^{-1}. Thus $\Delta\bar{H}_{BaO_2}$ = 9.7 kcal mole^{-1}, and the solution of BaO_2 in BaO is endothermic, as expected from the large positive deviations from ideal behaviour shown by the solution of BaO_2 in BaO. The overall heat of solution of oxygen in BaO is exothermic, however, because of the large exothermicity of reaction (59).

According to Swalin and coworkers[47], reaction (58) indicates that combined pairs of oxygen atoms are formed in the BaO lattice

$$\tfrac{1}{2}\mathrm{O_2} + \mathrm{O}_{(\mathrm{solid})}^{2-} = (\mathrm{O_2^{2-}})_{(\mathrm{solid})} \qquad (62)$$

(O^{2-}(solid) is the anion in the site of the BaO crystal lattice), and these pairs should be arranged along the (100) direction in the BaO crystal lattice. In the opinion of the authors cited[47], the formation of these complexes should lead to expansion of the BaO crystal lattice. Their calculated expansion practically coincides with that found experimentally by X-ray diffraction. The complexes (O_2^{2-})(solid) are apparently analogous to the combined pairs of oxygen ions in the crystal lattice of BaO_2.[64] The two O^{2-} ions in the complex are identical, as a consequence of a slight displacement of the O^{2-} ion in the lattice site when the complex is formed.

The equilibrium constant of reaction (62) has the form

$$K_{62} = [(\mathrm{O_2^{2-}})_{(\mathrm{solid})}]/p_{\mathrm{O_2}}^{1/2}. \qquad (63)$$

Thus $[(O_2^{2-})(\mathrm{solid})] \sim p_{O_2}^{1/2}$, which corresponds to the experimentally observed dependence of the solubility of oxygen on p_{O_2}. Recent measurements[59] of the coefficient of self-diffusion of Ba in BaO at comparatively high pressures of oxygen confirm mechanism (62). At 900–1400°, the coefficient of self-diffusion of Ba is independent of p_{O_2} in the range of pressures studied, 1×10^{-5}–1 atm.[59]

At high concentrations of oxygen in BaO (directly adjacent to the solidus line), the distribution law for oxygen between BaO and the vapour phase changes (see Fig. 13). This is apparently due to enlargement of the complexes (O_2^{2-})(solid) and the formation of "molecules" of the type $(BaO_2)_2$ in solution:

$$\mathrm{O_2} + 2\mathrm{BaO} = (\mathrm{BaO_2})_2, \quad K_{64} = [(\mathrm{BaO_2})_2]/p_{\mathrm{O_2}}. \qquad (64)$$

The expression for K_{64} shows that in the case of reaction

(64), the concentration of excess oxygen will be proportional to p_{O_2}, in agreement with experiment[42]. It should be noted, however, that although the experimental data and thermodynamic calculations lead to the conclusion that the reaction of oxygen with MO involves mainly processes leading to the formation of electrically neutral defects in the form of the complexes (O_2^{2-})(solid) and $2(O_2^{2-})$(solid) or, which is the same thing, BaO_2 and $(BaO_2)_2$, this does not prove that reactions (57) and (58), leading to the formation of an "atomic" solution of oxygen in MO, or processes of ionised defect formation[65,66], do not take place. The experiment indicates merely that processes (62) and (64) predominate.

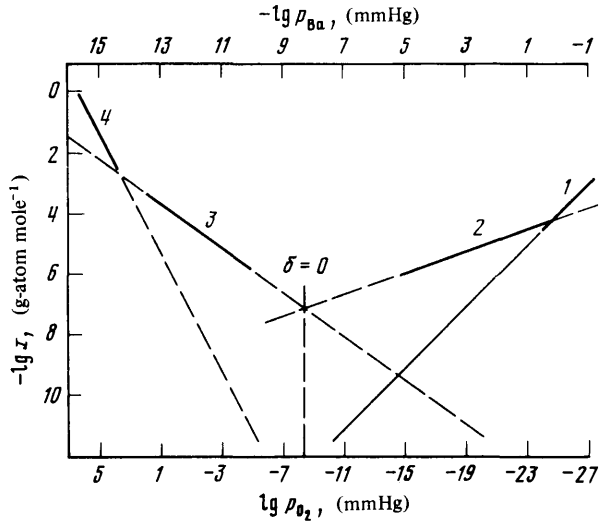

Figure 16. Solubility isotherms for excess Ba and oxygen in BaO at 1200°: *1*) $V_O^{\times}$, *2*) $V_O^{\cdot\cdot}$, *3*) complexes (O_2^{2-})(solid), *4*) complexes $(2O_2^{2-})$(solid).

Fig. 16 gives the solubility of defects of different kinds in BaO at 1200°. The equilibrium diagram for the defects in SrO, given in Fig. 10, is similar. This is quite regular, since BaO and SrO show closely analogous physicochemical properties. This is confirmed by direct measurement of the dependence of the concentration of the excess components on the vapour pressure of metal or oxygen and on temperature, and also by the study of the diffusion of Sr in SrO [67] and of Ba in BaO,[59] and by the absorption spectra of additively coloured crystals of SrO [28] and BaO.[29] These data, and the data for alkali metal halide crystals[60], indicate that the types of intrinsic point defect are similar in crystals of substances in the same homologous series.

The equilibrium diagrams for the defects in MO, given in Figs. 16 and 10, differ considerably from those proposed by Kroeger (see Figs. 14 and 15). Among others, two differences are particularly important: the first concerns the nature of the defects in an MO crystal having the stoichiometric composition, and the other is related to the fact that electrically neutral defects predominate in MO. These differences will be discussed in more detail.

2. Defects in Crystals of Compounds Having the Stoichiometric Composition

According to the hypothetical picture of the equilibrium for defects in BaO, proposed by Kroeger[60], the stoichiometry of BaO is due to the fact that the concentrations of V''_{Ba} and $V_O^{\cdot\cdot}$ or V'_{Ba} and $V_O^{\cdot}$, formed as a result of thermal disorder in the BaO crystal, are equal. The diagrams in Figs. 14 and 15 show that on coordinates $\lg x_i - \lg kp_M$ (where $kp_M = [V_O^{\times}]$), the solubility isotherms for V''_M and $V_O^{\cdot\cdot}$ (or V'_O and $V_O^{\cdot}$) exhibit mirror symmetry with respect to the straight line drawn perpendicular to the abscissa through the point of intersection of these isotherms (at which $\delta = 0$). The symmetry of the isotherms is characteristic of all the diagrams proposed by Kroeger[60] to illustrate the dependence of the concentrations of defects on the vapour pressure of the components in compounds of the type MO. This unavoidably leads to a situation in which, under conditions in which the crystal has the stoichiometric composition, the ratio of the concentrations of defects of "opposite" kinds, ensuring the symmetry indicated, should remain the same as that obtained in the examination of the so-called "internal thermal disorder" in the case where its production is not associated with interaction between the components of the crystal and the external medium[61]. In this approach (for example in the case of Frenkel disorder), the ratio of the concentrations of vacancies and interstitial atoms should be 1 : 1.

This idealised picture is far from reality. As correctly noted by Swalin[94], this relationship is not in fact necessary, and the concentration of vacancies may show absolutely no correlation with the concentration of interstitial atoms. The surface of the crystal may act as an independent source of vacancies, and the surrounding medium as a source of interstitial atoms. These considerations are also applicable to alkali metal halide crystals, which are usually regarded as model objects. In spite of the fact that in crystals having the stoichiometric composition, Schottky disorder, for example of the type[60]:

$$V_K^{\times} + V_{Cl}^{\times} \rightleftarrows O$$

is postulated, $V_{Cl}^{\times}$ and $(V_K^{\times})_2$ have been detected experimentally[60] under conditions of thermodynamic equilibrium between alkali metal halide crystals and their vapour, whereas $V_K^{\times}$ have not been found.

Similarly, it follows from the above experimental data that the stoichiometry of BaO is due to the fact that the concentrations of "unsymmetrical" defects, assumed to be $V_O^{\cdot\cdot}$ and (O_2^{2-}), [7,43,47,60] are equal. Studies of the mechanism of formation of defects in alkaline earth metal oxide crystals[11-14] have shown that their surface is the source of the defects existing in the bulk of the crystals.

Thus the existence of pairs of "symmetric" defects of the Schottky[69], Frenkel[68], or anti-structural[60] types, which are assumed to ensure the stoichiometry of the crystals, is not essential. Neither one-component nor multi-component crystals should be regarded as closed thermodynamic systems. As is usually done in the analysis of the phenomenon of departure from stoichiometry, for any crystals the formation of defects should be regarded as involving heterogeneous reactions including the exchange of material between the bulk of the crystal, its surface, and the coexisting phase (for example vapour). Under conditions of thermodynamic equilibrium,

both the composition of the bulk of the crystal and the composition of its surface layer are determined unambiguously by the temperature and composition of the equilibrium vapour phase.

3. Electrically Neutral Defects in MO

Studies of MO have shown that over a wide range of pressures and temperatures, the compositions of the compounds are determined chiefly by the concentration of electrically neutral defects, which are equivalent to atoms and molecules of the substances detected in the phases conjugate with MO. This last feature indicates that the chemical individuality of the components may be preserved on going from the conjugate phase to the dilute solution based on MO, and this makes it possible to reach certain conclusions regarding the nature of the electrically neutral defects in crystals of chemical compounds. The solid phase of a compound AB should apparently contain, albeit in extremely small quantities, all the components conjugate with it in the original system of phases[70]. When dissolved in AB, these components are electrically neutral defects, and under certain conditions, some of them may be present in appreciable concentrations (for example, Ba and BaO_2 in BaO). In the general case, the number of types of these electrically neutral defects (S) should be equal to the number of individual substances present in the phases conjugate with AB (and AB itself):

$$S = K + r,$$

where K is the number of independent components of the system, and r the number of independent chemical reactions.

Thus if the substances present in the phases in equilibrium with MO are known, it is possible to predict the types of possible electrically neutral defect in MO. Using data on the enthalpy and entropy of the reactions by which these substances are formed, it is possible in a number of cases to determine the conditions under which the appearance of significant quantities of the electrically neutral defects corresponding to these substances is possible. For example, the two possible mechanisms for the insertion of oxygen into MO: as MO_2 (see Eqn.(59)) and in atomic form (see Eqns. (57 and (58)), can be examined. As shown above (see Eqn. (61)):

$$\frac{\partial \ln x_{MO_2}}{\partial T} = (\Delta H_p + \Delta \bar{H}_{MO_2})/RT^2.$$

Similarly, for the solution of oxygen in atomic form,

$$\frac{\partial \ln x_O}{\partial T} = (\Delta H_{diss} + \Delta \bar{H}_O)/RT^2,$$

where ΔH_{diss} is the heat of dissociation of O_2 molecules to form atoms, and ΔH_O the differential molar heat of solution of atomic oxygen in MO.

As a rule, the heats of solution of the products of a chemical reaction in one another are small compared with the heat of the chemical reaction. Thus the temperature dependence of the solubility of the excess oxygen is determined by the sign of the enthalpy of the corresponding chemical reaction. When the excess oxygen dissolves in MO as MO_2, then $(\partial \ln x_{MO_2}/\partial T) < 0$, since $\Delta H_r \ll 0$. For the solution of atomic oxygen, it is to be expected that $(\partial \ln x_O/\partial T) > 0$, since $\Delta H_{diss} \gg 0$. Thus increase in temperature should lead to an increase in the concentration of atomic oxygen in the solid solution and a decrease in the concentration of MO_2. At high temperatures, the former may predominate; in this case the solubility isobar obtained on coordinates $\ln x_O - 1/T$ may pass through a minimum.

Analysis of the equilibrium constants of the reactions involved in the formation of the electrically neutral defects shows that the concentration of all types of electrically neutral defects formed by the introduction of excess oxygen increases with increase in p_{O_2}; similarly, the concentration of electrically neutral defects corresponding to excess Ba increases with increase in p_{Ba}. Close to the solidus line, the composition of the compound is determined chiefly by the concentration of electrically neutral defects. In fact, the separation of a new phase should probably be preceded by the formation of its nuclei within the original phase in the form of electrically neutral defects (one-particle or complex), corresponding to atoms and molecules of the substance being liberated.

V. PROPERTIES OF THE SURFACE AND THE NATURE OF THE EMITTING POWER OF MO CRYSTALS

Studies devoted to the investigation of the physicochemical character of the emitting power of an oxide cathode have a long history, but there is still lack of agreement on this question. One of the most fundamental problems still concerns the role of the bulk and surface properties of MO crystals in the phenomenon of the production of emitting power in the cathode. A widely encountered view, reflected in a number of monographs and reviews[71-73], is that an oxide cathode can be regarded as a semiconductor, the work function of which is determined by the concentration and energy state of the donor centres in the bulk of the crystal. A less widespread view is that the surface plays a decisive role in the phenomenon of electron emission from an oxide cathode[11,12,74-76]. The appearance of new data on the composition of the surface of MO crystals[36,37] and on the influence of the vapour of the alkaline earth metals on the emission and electrical conductivity of an oxide cathode[13,14,77-79] gives grounds for a more detailed examination of the relationship between the emission properties of a cathode and the properties of the surface of its oxide coating.

1. Non-stoichiometry of the Surface of MO Crystals

Experimental proof of the preferential localisation of excess M on the surface of MO crystals under the operating conditions of an oxide cathode were first obtained by the authors of the present review[31,32] and later by others[11,33]. A systematic study was made of the adsorption isotherms for Ba on the surface of BaO and for Sr on the surface of SrO [36,37] at 1000° and 1150° under conditions in which the pressure of oxygen over MO was greater by 4–6 orders of magnitude than the vapour pressure of M (calculated from Eqn. (50)) (the results are described above and given in Figs. 2 and 3). In spite of this, no significant adsorption of oxygen on the oxide surfaces was observed[36,37,47]. Thus in the analysis of the isotherms for the adsorption of M on MO it was possible to neglect the presence of oxygen.

Examination of various equations for the adsorption isotherms showed that the experimental data can be described by Temkin's equation for the adsorption isotherms for the case of a non-uniform surface[38]:

$$\Gamma_M = A \lg p_M + B, \quad (65)$$

where Γ_M is the quantity of adsorbed substance, g-atom cm^{-2}; and A and B are constants at a given temperature. The equations for the adsorption isotherms, given in Fig. 17 on coordinates $\Gamma_M - \lg p_M$, have the form

$$\Gamma_{Ba} = 7.7 \cdot 10^{-13} \lg p_{Ba} + 3.8 \cdot 10^{-12}; \text{ (at 1000° for Ba on BaO)}; \quad (66)$$

$$\Gamma_{Ba} = 9.4 \cdot 10^{-13} \lg p_{Ba} + 10.0 \cdot 10^{-12} \text{ (at 1150° for Ba on BaO)}; \quad (67)$$

$$\Gamma_{Sr} = 6.6 \cdot 10^{-9} \lg p_{Sr} + 8.7 \cdot 10^{-12} \text{ (at 1150° for Sr on SrO)}. \quad (68)$$

The isosteric heat of adsorption[38] of Ba on BaO, estimated approximately from two isotherms, is given by the equation:

$$q_{st} = 1.5 \cdot 10^2 (1 - 3 \cdot 10^{15} \Gamma_{Ba}) \text{ (kcal mole}^{-1}\text{)}. \quad (69)$$

Temkin's isotherm equation is applicable only if the experimental data on coordinates $\Gamma_M - \lg p_M$ are approximated by a straight line and if the slopes of the isotherms are proportional to the absolute temperature and the dependence on Γ_M is linear[38]. These requirements are met approximately by the isotherms for the adsorption of M on MO.

The adsorption of M on the surface of MO can be regarded as the solution of the excess metal in the surface layer of MO to a thickness of 1–3 molecular layers (this is the usual procedure in the analysis of the composition of the surface of solutions[80]). The concentration of M on the surface, calculated for one monolayer of MO ($x_M^{surface}$) is of the order of 10^{19} cm^{-3} (see Fig. 17). Under the same conditions, the concentration of excess M in the bulk of the crystals of BaO and SrO is only 10^{14}–10^{16} cm^{-3}.

For an understanding of the electronic processes taking place in MO specimens having a highly developed surface, it is important to compare the changes in the compositions of the surface and the bulk of MO crystals with change in the conditions of their equilibrium with the vapour of their own components. It may be assumed beforehand that the surface of the crystal contains both excess metal and oxygen in adsorbed form. This makes it possible to apply to the description of the composition of the surface the concept of departure from stoichiometry. The adsorption isotherms in Fig. 17 show that the concentrations of the excess adsorbed metal and oxygen may become of similar magnitude at values of the vapour pressure of M at which $\Gamma_M \simeq 0$. In a first approximation, it is assumed that at this point the concentrations of the quasi-excess components (M and O) on the surface are the same, that is that the surface has the stoichiometric composition. The surface is apparently enriched in excess metal at high values of p_M, and in oxygen at low values.

Comparison of Figs. 13 and 17 shows that at certain vapour pressures, not only the magnitude but also the sign of the departure from stoichiometry in the MO crystals may be different in the bulk and on the surface. The point corresponding to the stoichiometric ratio of the concentrations of quasi-excess M and O dissolved in the bulk of the crystal lies at much lower oxygen pressures than the analogous point for the quasi-excess components localised on the surface. From this it follows, in particular, that in a certain range of values of p_{O_2}, the conductivity of the crystal close to the surface may be different in character from that in the bulk: the surface is enriched in donors, whereas the bulk may be enriched in acceptors.

This phenomenon, described as inversion of the conductivity[81], has been observed experimentally for a number of semiconductors. Measurements of the electrical conductivity (σ) of polycrystalline specimens of alkaline earth metal oxides[82,83] and their solid solutions[84] showed that the isotherms giving the dependence of σ on p_{O_2} (Fig. 18) have a minimum, which corresponds to the point at which the conductivity of the oxide changes sign (if it is assumed that the mobilities of the holes and electrons are the same). Since the concentration of donor centres in the bulk of the MO crystals under the conditions of the measurements was extremely low, the high value of the

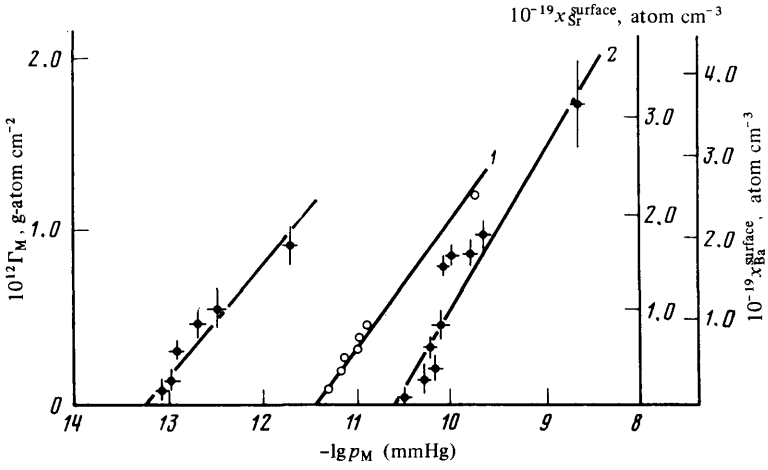

Figure 17. Isotherms for the adsorption of M on MO: *1*) Ba on BaO at 1000°;[36] *2*) Ba on BaO at 1150°;[36] *3*) Sr on SrO at 1150°.[37]

n-type conductivity could only be due to surface donor centres. Thus the minimum point on the graph giving the dependence of σ on p_{O_2} should have been situated in the range of oxygen pressures corresponding to a sharp decrease in the adsorption of M. Comparison of the experimental dependence of the electrical conductivity of BaO on p_{O_2} [82] (Fig. 18) with the p–T–x diagram of BaO for specimens having a highly developed surface (Fig. 8) supports this suggestion. The comparatively small difference (1.5–2 orders of magnitude) between the values of p_{O_2} corresponding to the stoichiometric point on the diagram in Fig. 8 and the electrical conductivity minimum in Fig. 18 may be associated with differences in the degree of ionisation of the donors and acceptors, and a difference in the mobilities of the electrons and holes.

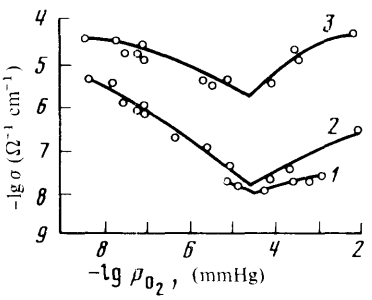

Figure 18. Dependence of the conductivity of BaO on p_{O_2}:[82] *1*) at 617°, *2*) at 637°, *3*) at 757°.

2. Nature of the High Emitting Power of MO Crystals

The adsorption of M on the surface of MO crystals is characterised by a high isosteric heat of adsorption, which is strongly dependent on the degree of covering of the surface. This is characteristic of the processes of chemisorption on semiconductors[81], when the points of adsorption on the surface of the adsorbent are energetically non-equivalent. The adsorption of M on MO may be expected to lead to the formation, on the surface, of several types of donor centre, for which the positions of the energy levels relative to the energy level of electrons in a vacuum will be different[75]. According to Vol'kenshtein[81], the high concentration of donors ($\sim 10^{12}$ cm^{-2}) on the surface of MO crystals makes it possible to regard it, from the viewpoint of its electronic properties, as "quasi-insulated" from the bulk. The existence of these surfaces was first predicted theoretically by Bardeen[85], and it has also been detected experimentally for a number of semiconductors; the work function of electrons from a semiconductor is independent of the position of the Fermi level in the bulk[81].

The conclusion that the surface of MO crystals plays a decisive role in the production of the emitting power of an oxide cathode, which follows from the results of adsorption measurements, is confirmed by studies[13,14,77–79,86–90] of the influence of the vapour of the alkaline earth metal or oxygen on the emission of a cathode and on the high-temperature electrical conductivity of the oxide coating of the cathode.

Nikonov and Beinar[13,14,78] made a detailed study of the emission of oxide cathodes in Ba vapour. The influence of a stream of Ba having an intensity of 1.2×10^{11}–1.6×10^{12} atom cm^{-2} s^{-1} on the emission current of oxide cathodes at 560–1350 K was studied[13]. At low temperatures, when the rate of deposition of Ba on the surface of the oxides of different alkaline earth metals was greater than the rate of its desorption, and the degree of covering of the surface by Ba atoms was much greater than that in the absence of the stream of Ba, a very marked increase in the emission current (I_e) was observed. At high temperatures, when the ratio of the forward and back streams of Ba changed, its influence on the emission decreased sharply, and finally disappeared at the highest temperatures. Measurements[14] at low Ba streams showed that I_e is directly proportional to the concentration of Ba atoms on the surface of the oxide coating (Fig. 19). Similar results were obtained when I_e for oxide cathodes was measured in a stream of Ba.[86–90]

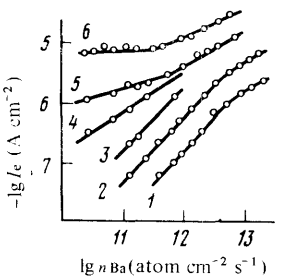

Figure 19. Dependence of the thermo-electronic emission current (I_e) of SrO on the magnitude of the stream of Ba vapour at different cathode temperatures: *1*) 317°, *2*) 347°, *3*) 422°, *4*) 482°, *5*) 537°, *6*) 607°.[13]

In contrast to the above measurements of emission, carried out under obviously non-equilibrium conditions, the influence of Ba on the properties of an oxide cathode has also been studied[77–79] under conditions close to equilibrium. Studies of the dependence of the emission current of an oxide cathode on p_{Ba} [79] showed that I_e changes very little with change in p_{Ba} (Fig. 20). Similar results were obtained in a study[77] of the electrical conductivity and thermo-e.m.f. of a BaO coating. The study[77] was based on the assumption[91,92] that at high temperatures (>800 K), the electrical conductivity of the porous coating of an oxide cathode is determined by free electrons emitted by the granules in the pores of the coating; a correlation should therefore exist between the electrical conductivity of the coating and the emitting power of the cathode. Measurements showed that at temperatures higher than 700°, the electrical conductivity (and also I_e [79]) increase very little with change in p_{Ba} from 8×10^{-7} mmHg to 2×10^{-5} mmHg. Under the same conditions, the thermo-e.m.f. of the oxide coating was only 150–200 μV K^{-1}. This value is typical of semiconductors in which the Fermi level lies at the bottom of the conductivity zone; this corresponds[77] to a high concentration of electrons in the crystal ($\sim10^{19}$ cm^{-3}). Since the concentration of donor centres in the bulk of BaO is lower by several orders of

magnitude, it was suggested[77] that there is an appreciable concentration of defects at the surface of the BaO crystals. In fact, the above concentration of electrons in BaO crystals coincides with that found experimentally from adsorption measurements of the concentration of excess Ba on the surface of BaO (see Fig. 17). The isothermal dependence of the concentration of Ba atoms on p_{Ba} is weak and logarithmic (see Eqns. (66)–(68)), and this explains the weak dependence of I_e and σ on p_{Ba} under conditions close to equilibrium.

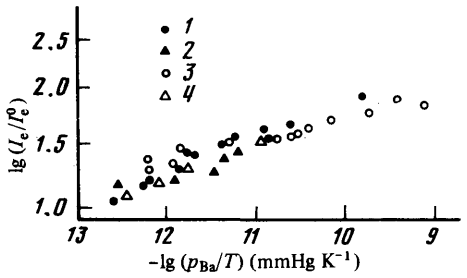

Figure 20. Dependence of the relative increase in the emission for (BaSr)O on p_{Ba} at 800° [79] from four series of experiments (*1–4*).

The change in the state of the surface of MO crystals may also provide a qualitative explanation for the phenomenon of "poisoning" of oxide cathodes by oxygen. The pressure of oxygen over BaO crystals at which a sharp decrease in the quantity of Ba atoms begins can be calculated. At 1150°, $\Gamma_{Ba} = 0$ at $p_{Ba} = 2\times10^{-9}$ mmHg, and at 1000°, $\Gamma_{Ba} = 0$ at $p_{Ba} = 2\times10^{-12}$ mmHg (see Fig. 17). The dissociation constant of BaO (Eqn. (27)) can be used to calculate the oxygen pressures corresponding to these values of p_{Ba}: at 1150°, $p_{O_2} = 7\times10^{-3}$ mmHg, and at 1000°, $p_{O_2} = 2\times10^{-5}$ mmHg. This explains the familiar experimental fact[72] that with increase in temperature, the "poisoning" of an oxide cathode takes place at higher oxygen pressures.

These experimental studies of the properties of the surface and their relationship to the emitting power of an oxide cathode apparently indicate that the state of the surface has a decisive influence on the emitting properties of alkaline earth metal oxides. In recent years, the theory of the oxide cathode having surface donor centres has been actively developed by Nikonov[75,76] and Zalm[93].

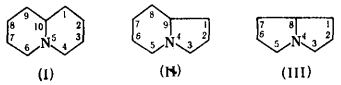
Advances in the Study of the Stereochemistry of Quinolizidines, Indolizidines, and Pyrrolizidines

I.M.Skvortsov



The results of studies on the stereochemistry of quinolizidines, indolizines, and pyrrolizidines are examined. Attention is concentrated on the application of non-spectroscopic methods in the determination of the configurations and preferred conformations. The possibilities and limitations of various physical and physicochemical methods in the study of the stereochemistry of the above 1-azabicyclic compounds are demonstrated.
The bibliography includes 193 references.

IV. The configurations and conformations of the bases and quaternary salts protonated at the nitrogen atom 274

I. INTRODUCTION

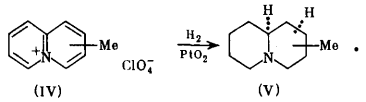
Quinolizidine (I), indolizidine (II), and pyrrolizidine (III) constitute the basis of many plant alkaloids and synthetic medicinal drugs. Interest in the stereochemistry of compounds (I)–(III) and their derivatives, whose specific features are due to the capacity of the bicyclic systems for reversible *cis*–*trans* transformations as a result of the inversion of the pyramidal nitrogen atom, is therefore quite justified.

(I) (II) (III)

Quinolizidines have now been investigated in greater detail as regards their stereochemistry, a comparatively few studies have been made on indolizidines, and the investigation of the conformational behaviour of compounds of the pyrrolizidine series is in essence only just beginning. We shall not consider the structures of quinolizidine, indolizidine, and pyrrolizidine alkaloids, with the exception of a few individual interesting examples, because since 1971 the appropriate compilations are being published annually[1-4]. A number of reviews have been devoted to the stereochemistry of pyrrolizidines.[5-8] In reviews[9,10] of stereochemical studies on compounds with a nodal nitrogen atom by spectroscopic methods quinolizidines,[9,10] indolizidines,[9] and (very briefly) pyrrolizidines [9] are considered among other heterocycles.

Analysis of research on the stereochemistry of compounds in Groups (I)–(III) shows that non-spectroscopic methods for the determination of steric structures have been used continuously. However, despite their evident importance, they have been frequently eclipsed by the effective achievements of infrared and NMR spectroscopy and have not been surveyed in the review literature.

Many similar stereochemical problems in the quinolizidine, indolizidine, and pyrrolizidine series have been solved by the same procedures, which shows that they have common features for the given series of compounds and makes it useful in the subsequent discussion to arrange the studies in groups based on the methods underlying the solution of particular problems.

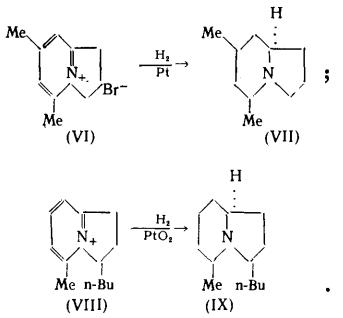


II. CONFIGURATIONAL ASSIGNMENT OF THE BASES

The problems of the configurational assignment and of the determination of the preferential conformations are sometimes closely related and are solved simultaneously. The systematic arrangement of data suggested in the present review is therefore sometimes somewhat conventional. The nomenclature adopted in the stereochemistry of 1-azabicyclic compounds is used in the description of the configurations[9].

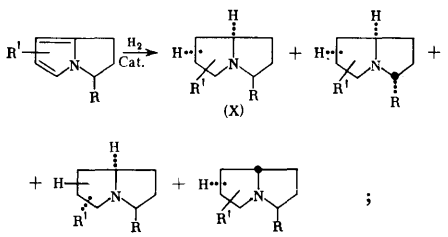
1. The Employment of the Characteristic Features of the Stereochemistry of Catalytic Hydrogenation and of the Dependence of the Physical Properties of Isomers on Their Steric Structure

The configurational assignment of substituted quinolizidines, indolizidines, and pyrrolizidines, obtained by the catalytic hydrogenation of the corresponding quinolizidines, indolizines, and pyrrolizines, is based on the assumption of the preferential *cis*-addition of hydrogen by analogy with other aromatic systems[11].



The hydrogenation of 1-, 2-, and 4-methyldehydroquinolizinium perchlorates (IV) [12] or 4-methyldehydroquinolizinium bromide[13] on PtO_2 resulted in the formation of isomers to which the *cis*-configuration (V) was attributed:

(IV) (V)

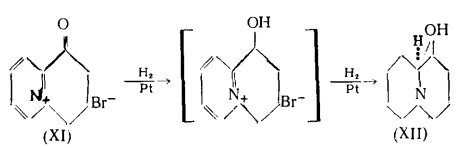


Dehydrogenation of the bromide (VI) in the indolizine series led to the isolation of *cis*-5,9-*H*-*cis*-7,9-*H*-5,7-dimethylindolizidine (VII) as the sole isomer[14] and the

reaction of the salt (VIII) gives *cis*-3,9-*H*-3-n-butyl-*cis*-5,9-*H*-5-methylindolizidine (IX) [15]:

The remaining three isomers of the last compound were obtained from the corresponding pyridine and pyrrole alcohols, the key process determining the configuration being the catalytic hydrogenation of these alcohols accompanied by the *cis*-addition of hydrogen [15].

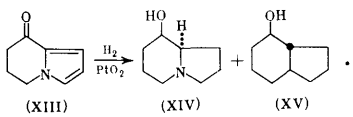
As a result of hydrogenation, 5-methyl-,[16] 3,5-dimethyl-,[17] 5-hydroxymethyl-, 5-hydroxymethyl-3-methyl, [18,19] 5-(β-hydroxyethyl)-, 7-(β-hydroxyethyl)-,[20] and 7-ethoxycarbonyl-1,2-dihydropyrrolizine [21] and 7-ethoxycarbonyl-3*H*-pyrrolizine [22] give rise to mixtures of isomers in which compounds (X)†, with a relative *cis*-configuration at the carbon atom attached to the substituent R′, predominate [18]:



(R = H, Me; R′ = 5-Me, 5-CH_2OH, 5-$(CH_2)_2OH$, 7-$(CH_2)_2OH$, or 7-CO_2Et.

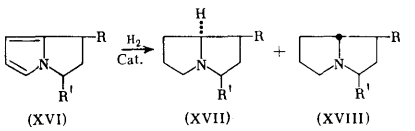
The hydrogenation of 1-methoxycarbonyl-7-oxo-6,7-dihydro-5*H*-pyrrolizine exhibits the same behaviour [23].

Examples of the stereoselective hydrogenation of aromatic systems with substituents in the "non-aromatic" half of the bicyclic system are formally similar but are nevertheless fundamentally different from the instances examined above. Here too isomers with the *cis*-configuration are formed preferentially, but the process selectivity is evidently ensured by the preferential adsorption of the compound hydrogenated from the sterically more accessible side [11].



According to Swan's data [24], the hydrogenation of compound (XI) is completed by the formation of *cis*-1,10-H-1-hydroxyquinolizidine (XII):

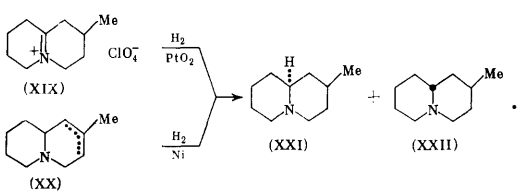
Initially the carbonyl group is converted into a hydroxy-group, after which the ring is hydrogenated, hydrogen being attached to the angular $C_{(10)}$ atom from the side opposite to that of the hydroxy-group [24].



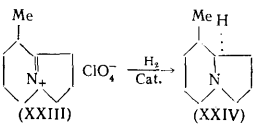
†Here and henceforth the symbol Cat. denotes a metallic catalyst.

The addition of hydrogen to 8-oxopyrrolo[1,2-*a*]piperidine (XIII) is less selective, the *trans*-isomer (XV) (24%) being formed together with the main product—the *cis*-isomer (XIV) (76%) [25]:

The *cis*-configuration at $C_{(3)}$ in the indolizine homologue (IX) is a consequence of the steric effect of the t-butyl group on the hydrogenation of compound (VIII). [15]

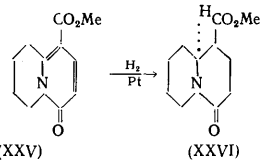


An analogous stereochemical effect is observed in the hydrogenation of 1,2-dihydropyrrolizidines and pyrrolizidines. 1,2-Dihydropyrrolizines (XVI) with alkyl groups in the 1- or 3-position are converted into mixtures of isomers (XVII) and (XVIII), among which compounds with the *cis*-configuration at $C_{(1)}$ or $C_{(3)}$ (XVII) predominate quantitatively [16,26-28]:



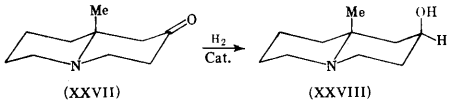
R = H, Me; R′ = H, Me, or t-Bu .

The hydrogenation of 1-methyl-3*H*-pyrrolizine in the presence of rhodium under mild conditions gives rise to *cis*-1,8-*H*-1-methylpyrrolizidine (*d,l*-heliotridane). [29] The stereochemistry of the hydrogenation of 1,2-dihydropyrrolizines with functional groups in the "non-aromatic half" of the bicyclic system [23,30,31] is also kinetically and not thermodynamically controlled, as was suggested by Adams et al. [32] The reaction leads to the formation of thermodynamically less stable isomers with the *cis*-configuration of the substituted atoms of the bicyclic system—the steric effects of the substituent has a decisive influence on the stereochemical result of the hydrogenation.

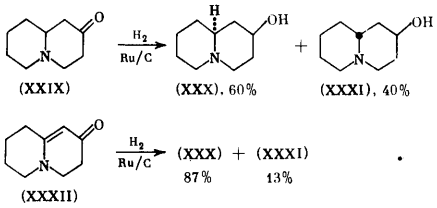


The preferential *cis*-addition of hydrogen in the hydrogenation of compounds with multiple bonds [11] and the adsorption of the substrate on the catalyst from the most accessible side were taken into account in the configurational assignment of quinolizidines, indolizidines, and pyrrolizidines obtained from the corresponding partly unsaturated derivatives. The catalytic addition of hydrogen to compounds (XIX) or (XX) yields mixtures of epimeric 2-methylquinolizidines (XXI) and (XXII). The *cis*-configuration was attributed to isomer (XXI), which is the dominant product in both cases [33]:

The hydrogenation of the perchlorate (XXIII) to *cis*-8,9-*H*-8-methylindolizidine (XXIV) takes place more selectively [34]:



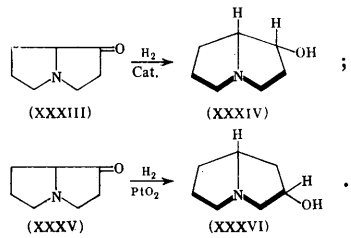
On platinum, hydrogen undergoes *cis*-addition to the $C_{(1)}$–$C_{(10)}$ bond in compound (**XXV**) and the quinolizidine derivative (**XXVI**) with the relative *cis*-configuration at $C_{(1)}$ is obtained[35]:



(XXV) (XXVI)

It has been shown that 10-methyl-2-oxoquinolizidine (**XXVII**) has a *trans*-junction between the two rings[36]. Bohlmann et al.[36] believe that the catalytic hydrogenation of the carbonyl group therefore leads to compound (**XXVIII**) with an axial hydroxyl owing to steric hindrance to adsorption generated by the methyl group:

(XXVII) (XXVIII)



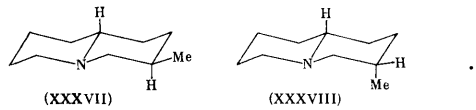
A conclusion has been reached[37,38] about the configurations of the epimeric 2-hydroxyquinolizidines by comparing the ratios of the isomers obtained on catalytic hydrogenation of 2-oxoquinolizidine (**XXIX**) and $\Delta^{1,10}$-2-oxoquinolizidine (**XXXII**) under identical conditions:

The authors attribute the *cis*-configuration (**XXX**) to the epimer whose fraction increases on transition from (**XXIX**) to (**XXXII**), assuming that the bulk of the hydrogen atoms add to molecules of compound (**XXXII**) from the same side in the course of a single adsorption step.

In the general case the hydrogenation of 1-oxoquinolizidine,[24,37] 2-and 3-oxoquinolizidines, and $\Delta^{1,10}$-2-oxoquinolizidine [37] under different conditions is not distinguished by high stereoselectivity and cannot serve as a basis for the configurational assignment of the 1-, 2-, and 3-hydroxyquinolizidines formed.

On the other hand, the catalytic addition of hydrogen to carbonyl-containing pyrrolizidines (**XXXIII**) and (**XXXV**) is characterised by its stereospecificity and, together with data derived from other methods, can serve as evidence in support of the configurations of the aminoalcohols (**XXXIV**) and (**XXXVI**) illustrated below[30]:

(XXXIII) (XXXIV)



(XXXV) (XXXVI)

The different types of behaviour of carbonyl derivatives of quinolizidine and pyrrolizidine during catalytic reduction are probably due to geometrical factors.

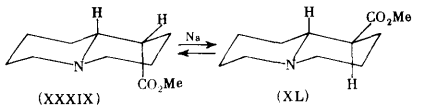
In many other examples dehydropyrrolizidines containing a multiple bond in the ring combine catalytically with hydrogen from the sterically least hindered side of the molecule regardless of the position of the multiple bond, which leads to the *cis*-configuration of the new asymmetric centre in relation to $C_{(8)}$.[39-43] In the solution of the problems of the configurational assignment of isomers of more complex systems—deoxynupharidine,[44] perhydrobenzo[*c*]quinolizine,[45] 9-azasteroid cyclic systems[46], and 6-disubstituted perhydrobenzo[*c*]quinolizines,[47] whose synthesis involves a hydrogenation range—the concept of the catalytic *cis*-addition of hydrogen was taken into account.

Thus the characteristics of the stereochemistry of the catalytic hydrogenation can be used widely in the determination of the configurations of isomers. Caution must be exercised in reaching conclusions primarily in those cases where the hydrogenation is carried out under conditions permitting isomerisation, which is observed at high temperatures and when catalysts (for example, palladium) promoting the isomerisation process are used.

The examples described by Moynehan et al.[12] must be regarded as exceptions. The hydrogenation of 3-methyldehydroquinolinium perchlorate is distinguished by low stereoselectivity. Assuming the conformation with a *trans*-junction for quinolizidine and its methyl derivatives, Moynehan[12] attributed on the basis of the conformational rule[48] the structure (**XXXVII**) (*trans*-configuration) to the 3-methylquinolizidine with the lower refractive index and the *cis*-configuration (**XXXVIII**) to the more strained epimer with the higher refractive index:

(XXXVII) (XXXVIII)

The remaining three pairs of epimeric methylquinolizidines obey the conformational rule[12].



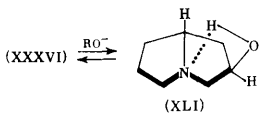
Among the epimeric pairs of 3-hydroxyquinolizidines,[38] 1-,[30] 2-,[30] and 8-hydroxyindolizidines,[25] and 3-hydroxymethylpyrrolizidines,[19] the isomers with an intramolecular hydrogen bond have lower boiling points.

2. Thermodynamic and Kinetic Methods

An *a priori* estimate of the relative thermodynamic stabilities of the isomers of substituted quinolizidines, indolizidines, and pyrrolizidines has served in a number of instances as the starting point for their configurational assignment. If the formation of both epimers is possible in thermodynamically controlled reactions, then the isomer with a larger store of free energy predominates quantitatively.

Assuming a *trans*-junction between the rings for simple monosubstituted quinolizidines, one may reach the conclusion, analogous to that of Leonard and Ryder[49], that the thermodynamically preferred isomer has the substituent in the equatorial position. Evidently among indolizidines this isomer has the equatorial substituent in the six-membered ring or the substituent is in a pseudoequatorial position in the five-membered ring. In the pyrrolizidine series, among the epimers differing in the position of the substituent at any one carbon atom, the isomers with the *trans*-configuration are thermodynamically more stable (see, for example, Refs. 30, 39, and 50) being more favoured by the non-bonding interactions. This rule is apparently valid for all monosubstituted pyrrolizidines.

The epimerisation of 1-substituted quinolizidines—lupinine [49,51-53] and the methyl ester of lupininic acid (XXXIX) [49,54]—under the influence of sodium or sodium methoxide has been described. According to Cookson's data[54], equilibrium is reached when 15% of the *cis*-isomer (XXXIX) and 85% of the *trans*-isomer (XL) is attained:

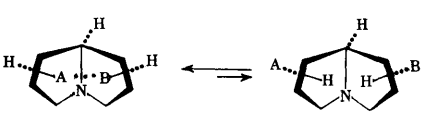


(XXXIX) (XL)

Other examples of the application of the isomerisation reaction in the configurational assignment of quinolizidines have been described[55-58].

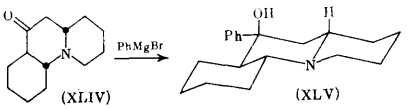
In the pyrrolizidine series epimerisation was completed in most of the known instances by the formation of virtually only one compound and one can therefore attribute to the latter the *trans*-configuration quite reliably. The isomerisation of substituted pyrrolizidines under the influence of acids[50], bases[22,30,42,59], and metallic catalysts[17-20,28] has been investigated. The epimerisation can occur at the first[21,30,42,50,59], third[18-20,28], and third and fifth[18,19] carbon atoms with different substituents—alkyl[17,28] and hydroxyalkyl[18-20] groups as well as hydroxy-,[30] carboxy-,[50] and alkoxycarbonyl [22,42,59] groups.

Incomplete epimerisation of compound (XXXVI) led to a mixture of epimers (XXXVI) and (XLI) in proportions of 2 : 3:



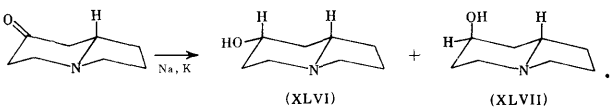
(XLI)

In this particular case the isomer (XLI) is thermodynamically preferred owing to the liberation of energy as a result of the formation of an intramolecular hydrogen bond on transition from (XXXVI) to (XLI) and is not caused by the difference between the non-bonding reactions in epimers (XXXVI) and (XLI).[30]



It has been shown[50] that only the asymmetric centre at $C_{(1)}$ is involved in the isomerisation of optically active pyrrolizidine-1-carboxylic acids and there is no racemisation.

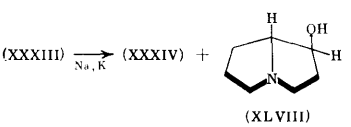
The method described here can be extended to the pyrrolizidine systems in which the difference between the free energies of the epimers is determined mainly by the difference between their non-bonding interactions. The possibility of the existence of di- or poly-substituted pyrrolizidines, in which the attraction energy of the substituents, for example A and B, in isomer (XLII) is greater than their repulsion energy, can be postulated. Under equilibrium conditions, isomer (XLII) then predominates and not isomer (XLIII), as might have been expected on the basis of the formal analogy with the literature data.



(XLII) (XLIII)

The hydride reduction of 1- and 2-oxoquinolizidines yields alcohols with an equatorial hydroxy-group (*trans*-junction between the rings) as the thermodynamically more stable isomers[24,36]. Similarly the configuration (XLV) with the phenyl group in an equatorial position has been attributed to the single isomer formed in the reaction of compound (XLIV) with phenylmagnesium bromide[47]:

(XLIV) (XLV)

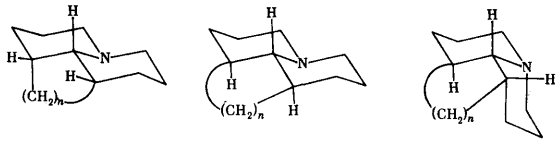


The configurations of 7-hydroxyindolizidines (XLVI) and (XLVII) have been determined from the reduction of 7-oxoindolizidine with sodium or potassium in alcohol:

(XLVI) (XLVII)

Isomer (XLVI) predominates quantitatively (96–98%) in a mixture with (XLVII) owing to its greater thermodynamic stability[25].

Similarly, on reduction with sodium or potassium, 1-oxopyrrolizidine (XXXIII) is converted into a mixture of epimers (XXXIV) (10–20%) and (XLVIII) (80–90%).[30] However, under the conditions of the reduction of compound (XXXIII) with sodium tetrahydroborate in water or with lithium tetrahydroaluminate, isomer (XXXIV) is formed as the main product (60%) [30]:



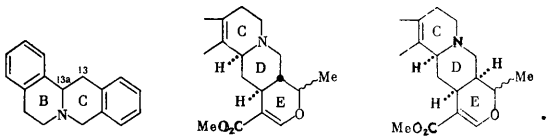
(XLVIII)

The greater reactivity of the substituent occupying the equatorial position compared with the axial position in the quinolizidine and indolizidine series or the greater reactivity of the substituent in the *exo*-position compared with the *endo*-position in pyrrolizidines may lead to the occurrence of side reactions, which alter the initial ratio of the isomers. The relevant findings have been obtained for substituted quinolizidines[60].

Kinetic methods are widely used in studies undertaken to determine the configurations of the 1-azabicyclic substances under discussion. The esters derived from the isomeric 2-hydroxyquinolizidines (XXX) and (XXXI) showed distinct differences in hydrolysis. The isomers with the sterically exposed equatorial functional group are hydrolysed faster than those with the more shielded axially oriented ester fragment[36]. In the acylation of isomeric 1-hydroxy-3-oxoindolizidines by benzoyl chloride the ester gives rise to only one of them[61]. This difference between the reactivities is explained by the fact that the hydroxy-group in the acylated isomer occupies a more accessible equatorial position and it occupies the axial position in the inactive isomer[61]. Comparison of the rate constants for the oxidative dehydrogenation of the three isomeric hexahydrojujolidines permitted a configurational assignment of the isomers[62].

In the solution of stereochemical problems comparison of the rate constants for the quaternisation of the isomers or a qualitative comparison of their reactivities in this reaction proved to be fruitful. The configurational assignment of cyclopenta[*ij*]quinolizidines (XLIX)–(LI) [63] was carried out; among these isomers, compounds (XLIX) and (L) behave in the reaction with methyl iodide similarly to compounds (LII) and (LIII). The configurations of the latter and of (LIV) were found by other methods[62] and are consistent with the rate constants for the reactions with

methyl iodide[64].



(XLIX), $n = 2$; (L), $n = 2$; (LI), $n = 2$;
(LII), $n = 3$ (LIII), $n = 3$ (LIV), $n = 3$

The molecules of the isomer (LI)‡ are chiral; the isomer was partly resolved into optical enantiomers and this fact served as an argument in support of the configuration shown[63].

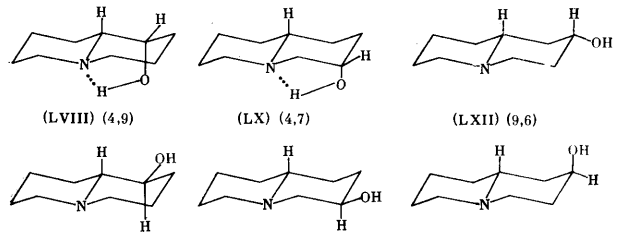
Qualitative comparison of the rates of reaction of isomeric perhydrobenzo[*c*]quinolizines with methyl iodide led to stereochemical assignments in agreement with data obtained by other methods[45].

The rate of quaternisation of tetrahydroprotoberberines—derivatives of dibenzoquinolizidine (LV)—depends on the type of junction between the B and C rings, which is determined by the configuration at $C_{(13)}$.[65]

(LV) (LVI) (LVII)

Information about the junction between the D and E rings in heteroyohimbine alkaloids was obtained from kinetic measurements. Compounds of type (LVI) were methylated at a higher rate than those of type (LVII). The configuration with the *trans*-junction of the D and E rings, in which the nitrogen atom is more accessible than in compounds of group (LVII) having the *cis*-junction between the D and E rings, was attributed to the former compounds[66,67]. Similarly yohimbine reacts with methyl iodide 40 times faster than α-yohimbine.[65]

The configurations of 9-methoxy-3,12*b*-dimethyl-1,2,3,4,6,7,12,12*b*-octahydroindolo[2,3-*a*]quinolizidines[68] and biphenyl alkaloids with quinolizidine fragments—lythrine, vertine,[69] vertaline, and decaline[70]—were determined with the aid of data for the kinetics of reactions of these bases with methyl iodide.



Various criteria for the determination of the stereochemistry of steroid indolizidines were examined by Kolb and Stefanovič[71], who found that the kinetic data for the quaternisation of isomeric compounds by methyl iodide constitute a more reliable basis for stereochemical assignments in the given group of compounds than spectroscopic methods. Qualitative observation of the course of competitive quaternisation of isomeric 3-substituted pyrrolizidines, first proposed for the determination of the configurations of epimeric 3-methyl pyrrolizidines,[72] can apparently be regarded as a general method for the determination of the steric structure of 3-substituted pyrrolizidines. It is based on the fact that isomers with the *trans*-configuration have a more shielded lone electron pair at the nitrogen atom and hence the rate of their reaction with alkyl halides is lower than that of the isomers having the *cis*-configuration. For correct conclusions, it is necessary that the quaternisation reaction should involve a decrease of the content of one of the epimers when its fraction in the mixture of isomers is 50% or less. The steric structure of isomeric 3,5-dimethylpyrrolizidines,[17] 3-hydroxymethylpyrrolizidines,[18,19] and 3-(β-hydroxyethyl)pyrrolizidines[20] were established with the aid of this method.

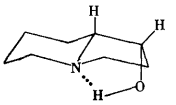
3. Chromatographic Methods

Bohlmann and coworkers[44,73] showed that the adsorbability of many compounds on alumina depends on the degree of shielding of the lone electron pair of the nitrogen atom. Comparison of the values of R_f or of the sequences in the elution of the isomers from the column[44,45,47,62,65,73-75] and examination of their models can therefore be a useful auxiliary method for the determination of the configuration. This same type of dependence has been found for perhydrobenzo[*c*]quinolizidines,[45] epimeric 6-methyl- and 6-ethylindolizidine-2-ones,[76] 3-methylpyrrolizidines,[72] and a number of saturated and unsaturated pyrrolizidine alcohols[77].

The application of gas–liquid chromatography (GLC) is particularly fruitful in the series of quinolizidines, indolizidine, and pyrrolizidine alcohols. The configurational assignments were most convincing for isomers one of which was capable of forming a relatively stable intramolecular hydrogen bond, while the other lacked this capacity by virtue of geometrical conditions.

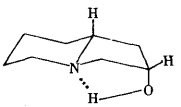
In contrast to 2-hydroxyquinolizidines [compounds (LXII) and (LXIII)], the epimeric 1-hydroxyquinolizidines [compounds (LVIII) and (LIX)] and 3-hydroxyquinolizidines [compounds (LX) and (LXI)] have significantly different retention parameters§ on the polar phase Carbowax-20M.[38] Evidently epimers with stronger intramolecular hydrogen bonds should have shorter retention times than epimers with weaker hydrogen bonds or epimers which do not form such bonds at all. If the form with the *trans*-junction is adopted as the preferred conformation of the compounds considered on the basis of the adsorption observed in the range 2700–2800 cm^{-1}, then an intramolecular hydrogen bond can be formed only by compounds (LVIII) and (LX). The retention data for the isomers (LVIII)–(LXI) also indicate their configurational assignments, which have been confirmed by infrared spectroscopy[38].

(LVIII) (4,9) (LX) (4,7) (LXII) (9,6)



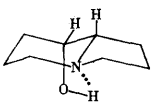
(LIX) (8,5) (LXI) (10,2) (LXIII) (8,6)

A distinct difference between the retention times has been observed for *cis*-3,10-*H*-3-hydroxymethylquinolizidine (LXIV) and *trans*-3,10-*H*-3-hydroxymethylquinolizidine (LXV)[60] and also for the stereoisomeric pairs of 3-hydroxymethyl-3-methylquinolizidines.[75] The configurational assignment of the epimeric 3-(4-chlorobenzyl)-quinolizidines has been made by analogy with compounds (LXIV) and (LXV), but the factors determining the retention of the isomers have not been discussed[60].

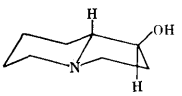


‡For simplicity, the formula of only one enantiomer is shown.

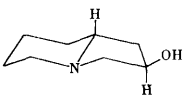
§Here and henceforth in this section the retention times in minutes are given in brackets.



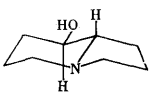
Similarly, comparison of the retention times in the GLC of 1-hydroxyindolizidines [compounds (LXVI) and (LXVII)], 2-hydroxyindolizidines [compounds (LXVIII) and (LXIX)], [30] and 8-hydroxyindolizidines [compounds (LXX) and (LXXI)] [25] permits conclusions about their configurations.



(LXVI) (3,7)



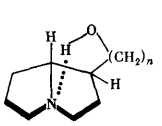
(LXVIII) (4,4)



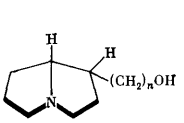
(LXX) (3,0)

(LXVII) (5,4)

(LXIX) (5,8)



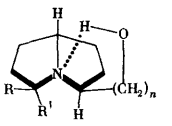
(LXXI) (5,7)



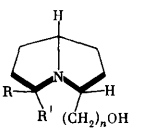
The epimeric 7-hydroxyindolizidines (LXVI) and (LXVII) do not form intramolecular hydrogen bonds and their retention times (6.4 and 7.1 min) [25] differ much less than for the preceding pairs of epimers.

Chalmers et al. [77] investigated the behaviour of pyrrolizidine alkaloids and certain saturated and unsaturated pyrrolizidine alcohols in GLC, thin-layer, and paper chromatography. Empirical correlations were found between the retention time on the siloxane polymer *SE*-30 and the orientation of the hydroxy-group in the 7-position: with the exception of retronecine and heliotridine, bases with a 7-*endo*-OH group (7β-OH). [77] The extremely weak intramolecular hydrogen bond in the isomer with a 7-OH *exo*-group evidently does not play a significant role in the retention of the compound on the stationary phase. The greater steric accessibility of the *exo*-hydroxyl is probably responsible for the greater energy of the interaction with the stationary phase than for the 7-*endo*-OH group. The same effect has been observed in the epimers (XLVIII) and (XXXIV) with the analogous difference between the positions of the hydroxy-group [30]. Even if a very weak intramolecular hydrogen bond is formed in compound (XLVIII), [30] it constitutes an unimportant factor in the interaction of the sorbate and the sorbent. Although weak, the intramolecular hydrogen bond, which is clearly present in the aminoalcohol (LIX), apparently weakens somewhat, compared with the epimer (XXXVI), the interaction with Carbowax-20M, which facilitates the separation of the isomers (XXXVI) and (XLI) by GLC. [30]

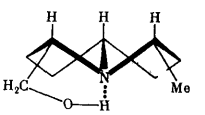
In GLC on both Apiezon L and on the polar stationary phase Reoplex-400, (±)-trachelanthamidine (LXXII), which has an intramolecular hydrogen bond, emerges from the column before its epimer (±)-isoretronecanol (LXXIII) [78] in which an intramolecular hydrogen bond cannot be formed for steric reasons.



(LXXII), $n = 1$;
(LXXIV), $n = 2$(32)



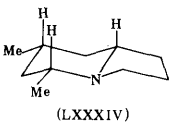
(LXXIII), $n = 1$;
(LXXV), $n = 2$(42)



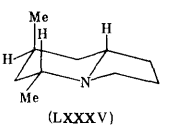
The stereochemistry of the diastereoisomeric 1-(β-hydroxyethyl)pyrrolizidines [compounds (LXXIV) and (LXXV)] [18,20], 3-hydroxymethylpyrrolizidines [compounds (LXXVI) and LXXVII)], [18,19] 3-(β-hydroxyethyl)pyrrolizidines [compounds (LXXVIII) and (LXXIX)], [18,20] 5-hydroxymethyl-2-methylpyrrolizidines, [19] and 5-hydroxymethyl-3-methylpyrrolizidines [compounds (LXXX)–(LXXXIII)]¶ [18,19] determines their different capacities for the formation of intramolecular hydrogen bonds and hence the energy of the interaction with the polar stationary phase.

(LXXVI), $n = 1$, R = R' = H (14);
(LXXVIII), $n = 2$, R = R' = H (16);
(LXXX), $n = 1$, R = Me, R' = H (32);
(LXXXII), $n = 1$, R = H, R' = Me (45).

(LXXVII), $n = 1$, R = R' = H (22);
(LXXIX), $n = 2$, R = R' = H (24);
(LXXXI), $n = 1$, R = Me, R' = H (70)

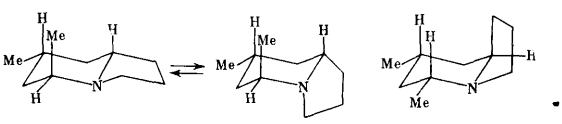


(LXXXIII)



Analysis of the geometries of the isomers and data for the retention on Carbowax-20M were used in the configurational assignment of compounds (LXXIV)–(LXXXIII). [18,20]

The steric structures of the four isomeric 1,7-dimethylquinolizidines were determined [44] on the basis of chromatographic retention times of quinolizidine and 1-methyl-, 3-methyl-, and 1,7-dimethyl-quinolizidines. The shielding of the lone electron pair of the nitrogen in the isomeric perhydrobenzo[*c*]quinolizidines is regarded as a factor determining the difference between their retention times in GLC. [45] In the four isomeric 1-hydroxy-7-methylquinolizidines the orientations of the hydroxy- and methyl-groups are determined from the relative retentions obtained when the compounds are passed over a polar stationary phase [80], the positions of the methyl groups being established from the results of the GLC of methylquinolizidines [81]. An analogous method was used in the more complex case of the isomeric 1-hydroxy-1,7-dimethylquinolizidines. [82]



On the basis of the foregoing considerations, the relative retention times of cyclopenta[*ij*]quinolizidines (LXIX)–(LI), quoted by Schofield and Wells [63] without comment, may be regarded as independent confirmation of their structure, established by other methods. Quoting the results of the GLC of 5,7-dimethylindolizidines on the *SE*-52 stationary phase, Lüning and Lundin [14] do not relate the elution sequence of the isomers (LXXXIV), (LXXXV), (LXXXVI), and (LXXXVII) to their steric structure.

(LXXXIV)

(LXXXV)

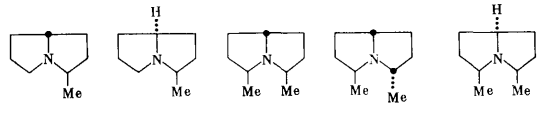
(LXXXVIa) (LXXXVIб) (LXXXVII)

However, if account is taken of the set of data concerning the relation between the retention times and the structure of 1-azabicyclic compounds examined above, one may note that the interaction with the stationary phase is as a rule stronger for the less shielded lone electron pair of the

¶ Isomer (LXXXIII) is represented in the formulae as having a conformation with the *trans*-junction, which may be regarded as preferred according to the data of Skvortsov et al. [18] and by analogy with *cis*-3,8-H-*cis*-5,8-*H*-3,5-dimethylpyrrolizidine. [17,19]

nitrogen. The sequence in which the isomers are eluted from the column (stationary phase Carbowax-20M) is as follows: (LXXXIV)–(LXXXVII), 6-methyl-2-oxoindolizidine, and 6-ethyl-2-oxoindolizidine.[76]

Despite the evidently fruitful nature of the configurational assignment based on chromatographic data, one should note that in specific instances when there are difficulties in choosing the preferred conformation of the sorbate molecules at the instant of interaction with the sorbent, the stereochemical assignment becomes doubtful. A general deficiency of chromatographic methods for the solution of stereochemical problems involves the necessity to have at one's disposal at least two isomers at the same time in order to compare their chromatographic properties.



4. Basicities

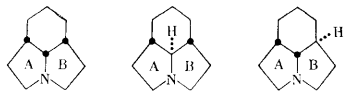
The measurement of the pK_a values for the epimers of a series of quinolizidine and indolizidine alcohols in many cases permits conclusions about their configuration. Distinct differences between the pK_a values are shown by the epimeric pairs of 1-hydroxyquinolizidines [compounds (LVIII) and (LIX)] ($\Delta pK_a = 1.47$), 3-hydroxyquinolizidines [compounds (LX) and (LXI)], ($\Delta pK_a = 1.27$),[38] 1-hydroxyindolizidines [compounds (LXVI) and LXVII)] ($\Delta pK_a = 1.11$), 2-hydroxyindolizidines [compounds (LXVII) and (LXIX)] ($\Delta pK_a = 0.33$),[30] 8-hydroxyindolizidines [compounds (LXX) and (LXXI)] ($\Delta pK_a = 1.47$),[25] 1-hydroxy-1-methylquinolizidines ($\Delta pK_a = 1.1$), and 1-hydroxy-1-phenylquinolizidine ($\Delta pK_a = 0.9$).[83] Assuming the *trans*-junction of the rings in the above compounds, it can be clearly seen that the intramolecular hydrogen bond can be formed by isomers with axial or pseudoaxial hydroxy-groups, so that within each pair the epimer with the higher pK_a has the *cis*-configuration.

On average, smaller differences between the basicities are observed for the isomeric 2-hydroxyquinolizidines [compounds (XXX) and (XXXI)] ($\Delta pK_a = 0.33$),[38] 2-hydroxy-2-phenylquinolizidines ($\Delta pK_a = 0.20$),[84] 7-hydroxyindolizidines [compounds (XLVI) and (XLVII)] ($\Delta pK_a = 0.57$),[25] and 7-hydroxy-7-phenylindolizidines ($\Delta pK_a = 0.09$),[84] none of which forms an intramolecular hydrogen bond for steric reasons. In this case compounds with an axial hydroxy-group are stronger bases than the epimers with an equatorial hydroxy-group. In the series of heteroyohimbine alkaloids the pK_a reflects the degree of shielding of the nitrogen and is determined by the configuration of the compound[66,67].

The epimeric 1-hydroxypyrrolizidines (XXXIV) and (XLVIII) have similar pK_a values (10.35 and 10.25 respectively)[30]. A more distinct difference between the basicities is observed for 2-hydroxypyrrolizidines [compounds (XXXVI) and (XLI)] (pK_a = 10.25 and 10.42). The weak intramolecular hydrogen bond in the isomer (XLI) [30] is probably responsible for its high basicity[85].

Pyrrolizidine (III) and its homologues (LXXXVIII)–(XCII) have respectively pK_a = 11.68, 11.62, 11.94,[86] 11.46, 11.74, and 10.28.[87]

(LXXXVIII) (LXXXIX) (XC) (XCI) (XCII)



The lone pair of electrons on the nitrogen atom in compound (LXXXVIII) is more shielded by the methyl group than in its epimer (LXXXIX), which gives rise to steric hindrance to hydration and explains the weaker basicity of the former compound. The causes of the different basicities of the epimers (XC) and (XCI) are similar. The relatively low pK_a value of the isomer (XCII) is regarded as a direct consequence of its preferential state, in which there is a *trans*-junction[87].

5. Infrared Spectroscopy

The results of the application of infrared spectroscopy to the configurational assignment of numerous alcohols of the quinolizidine and indolizidine series as well as 1- and 2-hydroxypyrrolizidines have been summarised in a review[9].

The configuration of 2-hydroxyquinolizidines (XXX) and (XXXI), established by Bohlmann et al.[36], has been confirmed by a study of the frequencies and shapes of the absorption bands in the spectra of these epimers[38]. Dilute solutions of platynecine and retronecine [88] have 3467 and 3515 cm^{-1} absorption bands, which are characteristic of intramolecular hydrogen bonds, confirming the structure of these aminoalcohols[88]. The strong absorption by the hydroxy-groups involved in the intramolecular hydrogen bond is consistent with the structure of compounds (LXXVI) and (LXXX). The intramolecular hydrogen bond energies are approximately the same in the two compounds [$\Delta\nu$(OH) = 177 and 178 cm^{-1}].[19] A stronger intramolecular hydrogen bond [$\Delta\nu$(OH) = 380 cm^{-1}] is formed in the pyrrolizidine alcohol (LXXVIII) as a result of the more favourable geometry of the hydrogen bridge[20].

One of the three possible diastereoisomers of 1-azatricyclo[6,2,1,$0^{4,11}$]undecane, which absorbs in the range 2700–2800 cm^{-1}, has been isolated[89]. In choosing from the three possible configurations (XCIII)–(XCV), the last one was rejected, because, according to the authors[89], Bohlmann absorption can be manifested only by compounds with the configurations (XCIII) and (XCIV) (evidently with the *trans*-junction of the A and B rings). The structure (XCIII) was adopted tentatively[89].

(XCIII) (XCIV) (XCV)

The construction of models of isomers (XCIII) and (XCV) shows that in both cases the *cis*-junction of the A and B rings is free from strain and is therefore preferred to the *trans*-junction. The skeleton of the tricyclic compound (XCIV) is highly strained for both types of junction between the five-membered rings. We suggest that structure (XCIV) is therefore apparently more probable rather than structure (XCIII), since there should be no Bohlmann bands for the preferential *cis*-junction between the A and B rings in (XCIII). On the other hand, the existence of comparable amounts of conformations of isomer (XCIV) with the *cis*- and *trans*-junctions, the latter of which should be active in the range 2700–2800 cm^{-1}, may be expected.

6. NMR Spectroscopy

The successful application of ^1H NMR spectroscopy in the solution of stereochemical problems involving the series of quinolizidine and indolizidine derivatives is successfully dealt with in a review[9] and is based on the

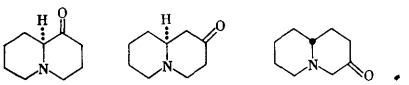
analysis of the chemical shifts of the ring and methyl protons as well as the spin–spin coupling constants and the nature of the splitting of the signals. In studies which have not been included in the above review[9] it is possible to encounter new examples of the analogous use of the given method for the determination of the configurations of quinolizidine[75,90-92], indolizidine,[76,93] and pyrrolizidine[17,28,42,59,94-99] series.

The steric orientation of the methyl groups in the quinolizidine alkaloids of the yellow lily has been found with the aid of the benzene-induced shift of the NMR signal due to these groups[100,101]. The dependence of the shift of the signal of the methyl group induced by an aromatic solvent on the latter's position in the bicyclic system was studied recently[102] for nine monomethylquinolizidines. The conclusions reached in the above studies[100,101] are consistent with the observed empirical correlation[102] and the latter can evidently be useful for the determination of the orientations of the methyl or methylene groups in other quinolizidine derivatives.

New possibilities for the investigation of the stereochemistry of 1-azabicyclic systems arose owing to the introduction of ^{13}C NMR spectroscopy. The ^{13}C chemical shifts in quinolizidine (I),[103-105] indolizidine (II),[104] and pyrrolizidine (III)[106] were determined, which constitutes the essential starting point in the investigation of derivatives of compounds (I)–(III) by ^{13}C NMR.

On the basis of spectroscopic data for quinolizidine (I) and methyldecalins with the *trans*-junction, LaLonde and coworkers interpreted the ^{13}C NMR spectra of eight monomethylquinolizidines[105] and isomeric 3-methyl-3-methylthiomethylquinolizidines.[107] The results were used in the analysis of the ^{13}C NMR spectra of nine *Nuphar* alkaloids[107]. The determination of the chemical shifts in (I), the epimeric 1-hydroxymethylquinolizidines, and their benzoates assisted in the interpretation of the ^{13}C NMR spectra and the determination of the steric structures of 1,9-disubstituted quinolizidines[92].

The consideration of the ^{13}C NMR spectra of lactams of the sparteine series was preceded by a study of the spectra of 3-oxo- and 1-methyl-3-oxoquinolizidines.[108] The signals of the ^{13}C nuclei in 9-hydroxymethyl-3-methyl- and 7-hydroxymethyl-1-methyl-*cis*-2,10-*H*-2-hydroxyquinolizidines and azabenzenecarboxylate esters of 3-hydroxyquinolizidines were assigned in the same investigation[108].



The results obtained can serve as a basis for the study of the steric structures of new and more complex compounds, particularly natural products. The relevant examples have been described in a number of communications[92,107-109].

7. X-Ray Diffraction Analysis

In connection with the automation of X-ray diffraction analysis[110], on the one hand, and the possibility of preparing crystalline salts of quinolizidine, indolizidine, and pyrrolizidine bases, on the other, this method is one of the most promising for the determination of the steric structures and, particularly, the absolute configurations of the derivatives of the 1-azabicyclic compounds under consideration. Studies on the application of X-ray diffraction analysis in the determination of the configurations of salt-like quinolizidines, indolizidines, and pyrrolizidines are reviewed in Section IV.

8. Other Methods

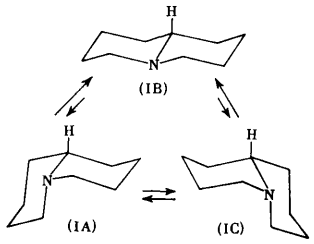
The study of the circular dichroism of optically active (–)-1-oxoquinolizidine (XCVI), (+)-2-oxoquinolizidine (XCVII), and (–)-3-oxoquinolizidine (XCVIII) made it possible to determine the absolute configurations of these aminoketones[111].

(XCVI) (XCVII) (XCVIII)

The identity of the configurations at the $C_{(4)}$ atom in the quinolizidine alkaloids vertaline and decaline follows from a comparison of their optical rotatory dispersion and circular dichroism curves[70]. The circular dichroism data have been used in the determination of the structures of 6-hydroxythiobinupharidine, 6-hydroxythionuphlutine,[112] and the quinolizidine mono-*gem*-aminals from *Nuphar luteum*.[113]

Culvenor and coworkers studied the circular dichroism of a series of simple pyrrolizidine bases and certain pyrrolizidine alkaloids. The sign and magnitude of the Cotton effect for both the simplest bases and open-chain ester alkaloids depend on the configuration at $C_{(8)}$, on the positions of the substituents, and on the degree of saturation of the bicyclic system[114]. Saturated pyrrolizidines with one substituent in the 1-position, namely heliotridane, the enantiomer of isoretronecanol, 1β,2β-epoxy-1α-hydroxymethyl-8α-pyrrolizidine, and 1α,2α-epoxy-1β-hydroxymethyl-8α-pyrrolizidine exhibit a negative Cotton effect. Retronecanol, which has a 7β-hydroxy-group, in contrast to the previous compounds, and the unsaturated bases supinidine, deoxyretronecine, retronecine, and heliotridine exhibit a positive Cotton effect. The magnitude of the effect for the last two compounds apparently depends on the configuration at $C_{(7)}$.[114]

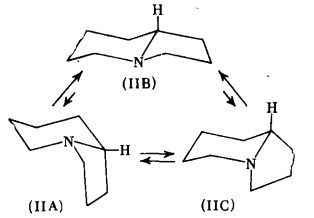
The applicability of the octant rule to the determination of the absolute configurations of α-aminoketones of the quinolizidine, indolizidine, and pyrrolizidine series has been examined[115].



Slight differences have been observed between the mass spectra of lupinine and epilupinine[116] and between those of the four isomeric 4-phenyl-1-quinolizidinols.[117] A mass-spectrometric study of 6-hydroxythiobinupharidine, 6-hydroxythionuphlutine *B*, and 6'-hydroxythionuphlutine *L* assisted in the determination of the configuration at $C_{(6)}$ in these compounds[112]. The mass spectra of the isomeric 7-hydroxy-1-hydroxymethylpyrrolizidines (platynecine, dihydroxyheliotridane, hastanecine, and turneforcidine) are similar, but differ from the spectra of 2-hydroxy-1-hydroxymethylpyrrolizidines[59]. Using mass spectra, it is difficult to reach a conclusion about the orientation of the hydroxymethyl group in the isomeric 1-hydroxymethylpyrrolizidines (trachelanthamidine and lindelofidine).[118] However, it has been suggested[118] that, in a mass spectrometric study of pyrrolizidines with bulky substituents, it might be possible to determine their steric positions.

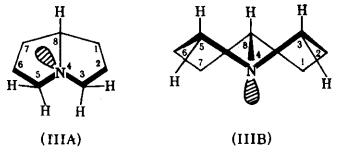
The dipole moment method has not so far been used widely in the determination of the configurations of quinolizidines, indolizidines and pyrrolizidines. Satisfactory results have been obtained by this method in the stereochemical study of 1- and 3-hydroxymethylquinolizidines[60,119] and also 3-(4-chlorobenzyl)quinolizidines.[60] The isomers were assigned by a qualitative interpretation of the vector scheme for each pair of epimers, which makes it possible

to predict higher dipole moments for compounds with the *cis*-configurations. The equatorial location has been attributed to the hydroxyethyl group of 6-hydroxyethyl-3,9-dimethylquinolizidine on the basis of its dipole moment[120].



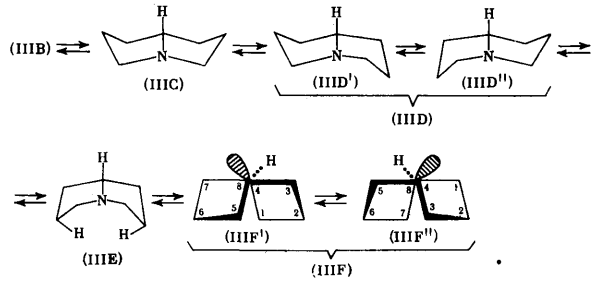
III. CONFORMATIONAL ANALYSIS OF THE BASES

The central problem of the conformational analysis of quinolizidines is the ratio of forms having *cis*- and *trans*-junctions, which can undergo interconversions by virtue of the inversion of the nitrogen atom. For quinolizidine itself, these ratios are reflected in the following scheme:



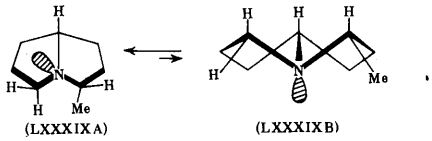
The flexible forms (IA) and (IC) with the *cis*-junction are interconvertible enantiomers and henceforth will be treated as a single conformation (IA). The conformations with one or two rings in the boat form are not discussed because they are known to be unfavourable owing to non-bonding interactions. However, among certain quinolizidine derivatives compounds are encountered where the boat conformation of one of the rings is possible.

Indolizidine (II) also has two conformations (IIA) and (IIC) with a *cis*-junction and a conformation (IIB) with a *trans*-junction:



It is readily seen that, in contrast to the quinolizidine conformers (IA) and (IC), the *cis*-conformers (IIA) and (IIC) are energetically non-equivalent.

Of the two forms of pyrrolizidine (IIIA) and (IIIB), the (IIIA) form with a *cis*-junction was chosen because, in contrast to (IIIB), it is free from appreciable strain[121].

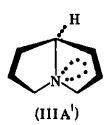


Subsequently the idea of a *cis*-junction between the rings in pyrrolizidines was adopted in many investigations[30,72,122-124]. However, it was shown[125] that in certain intramolecular quaternisation reactions there is a possibility of the formation of quaternary salts with a fixed pyrrolizidine skeleton having a *trans*-junction.

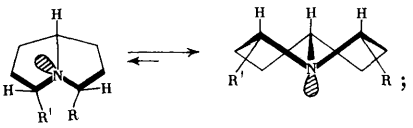
trans-Fused (IIIB), open (IIIC), half-folded (IIID)†, and folded (IIIE) conformations have been postulated[126] for pyrrolizidine (III):

As a result of unfavourable non-bonding interactions, the conformation (IIIE) resembles the cyclohexane boat form and, by analogy with cyclohexane and derivatives of *cis*-bicyclo[3,3,0]octane,[127] it can be assumed that, in an "endeavour" to weaken non-bonding *trans*-2-*H*...*trans*-6-*H* interactions, the (IIIE) conformation undergoes a twisting deformation. This results in two enantiomeric twisted conformations (IIIF′) and (IIIF″) (the five-membered ring exists in the half-chair form) and these acquire some angular strain, which relates them to the twist-form of cyclohexane. The (IIIC) and (IIID) conformations are free from strong non-bonding interactions and angular strain and their enthalpies are apparently similar, which is a feature resembling the insignificant difference between the energies ($\Delta H \simeq 0.1$ kcal mole^{-1}) of the C_{2v} (open) and C_s (half-folded) conformations of *cis*-bicyclo[3,3,0]-octane.[128]

The change in the conformational equilibrium between the (LXXXIXA) and (LXXXIXB) forms of the free pyrrolizidine base with *cis*-‡ and *trans*-junctions under the influence of a change in temperature has been observed[126] by NMR in relation to (LXXXIX):



Analogous conformational effects may be expected also in those cases where a hydroxymethyl[18,19] or a β-hydroxyethyl group is introduced instead of the methyl group[20].

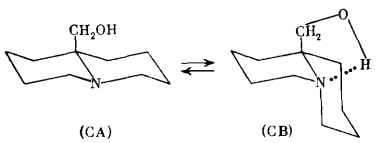


---

†Each pair of enantiomeric conformations (IIID′), (IIID″), and (IIIF′), (IIIF″), will be treated for simplicity as (IIID) and (IIIF) forms.

‡In those cases where the *cis*-fused conformations are not distinguished, their families are nevertheless designated by schematic diagrams of type (IIIA) or (IIIA′):

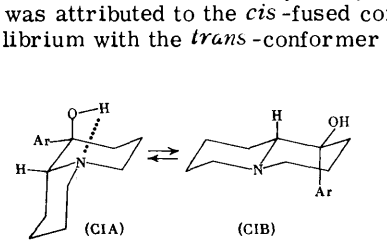
Evidently the fraction of the *trans*-fused form can be significantly increased by intensifying the non-bonding interactions in the *cis*-fused conformations of pyrrolizidines. This was achieved in two ways: by introducing a t-butyl group instead of the *trans*-3-*H* atom and by introducing two methyl groups instead of the *trans*-3-*H* and *trans*-5-*H* atoms in the pyrrolizidine molecule. The non-bonding interactions in the *cis*-fused conformations (XCIXA) and (XCIIA) of pyrrolizidines (XCIX) [28] and (XCII) [17] are so intense that the compounds exist mainly in the *trans*-fused forms (XCIXB) and (XCIIB) despite the marked angular strain in them [17,28,79]:



(XCIXA), R = t-Bu, R'=H; (XCIXB), R= t-Bu, -Bu, R'=H;
(XCIIA), R = R' = Me; (XCII), R = R' = Me .

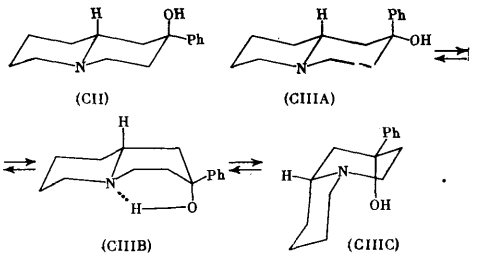
The idea of an appreciable contribution by the *trans*-fused form to the equilibrium mixture of the conformations of compound (XCV) has been confirmed by experiments on its oxidative dehydrogenation by mercury acetate [129].

1. Determination of the Preferred Conformations. A Qualitative Approach



(a). Vibrational spectroscopy. The application of infrared spectroscopy in the conformational analysis of quinolizidines and indolizidines has been described in detail in a review [9]. In the range 2700–2800 cm^{-1} (in the region of the stretching vibration frequencies of the hydroxy-group) "spectroscopy" proved to be particularly valuable in the determination of the preferred conformations of alcohols of the quinolizidines [9,56,74,84,100,117] and indolizidine [9,83,84] series.

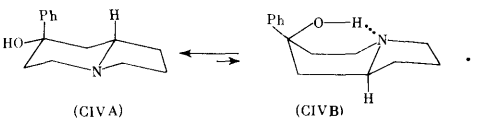
In contrast to other simplest quinolizidine alcohols [9], 10-hydroxymethylquinolizidine (C) in a dilute solution exhibits absorption bands due to both free and bound hydroxy-groups, which indicates the existence of an equilibrium between conformations (CA) and (CB) with *trans*- and *cis*-junctions respectively [130]:



(CA) (CB)

The appreciable absorption typical of intramolecular hydrogen bonds in the spectra of 1-aryl-1-hydroxyquinolizidines (CI) was attributed to the *cis*-fused conformation (CIA) in equilibrium with the *trans*-conformer (CIB) [56];

(CIA) (CIB)



The structures of 2-hydroxy-2-phenylquinolizidines (CII) and (CIII) [84,131] were examined almost simultaneously and independently:

(CII) (CIIIA) (CIIIB) (CIIIC)

The spectrum of isomer (CII) in dilute solutions has only one peak corresponding to the free hydroxyl, while the spectrum of its epimer (CIII) has a weak absorption band characteristic of the vibrations of an intramolecular hydrogen bond. This observation enabled the authors [84,131] to conclude that the equilibrium mixture contains, together with form (CIIIA), also the conformation (CIIIB), in which the six-membered ring with substituents is in the boat form. The (CIIIC) conformation was not discussed [84,131], although it can apparently make a contribution, by analogy with (CIA).

Similarly the spectrum of 7-hydroxy-7-phenylindolizidine (CIV) in dilute solutions has absorption bands due to free [(CIVA) conformation] and bound hydroxyls [(CIVB) conformation with the six-membered ring in the boat form] [84]:

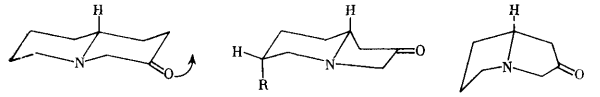
(CIVA) (CIVB)

Vibrational spectroscopy is in essence only just beginning to be applied in the study of the conformations of pyrrolizidines. Comparison of the infrared and Raman spectra of pyrrolizidine and *cis*-bicyclo[3,3,0]octane and also the results of the calculation of the frequencies and modes of the normal vibrations of these compounds show that, under the usual conditions, pyrrolizidine is a mixture of mainly two conformations—the open conformation (IIIC) and the half-folded conformation (IIID). [132,133]

In the region of the skeletal-deformation vibrations the Raman spectra of the strained pyrrolizidines (XCII) and (XCIX) have a smaller number of frequencies than the spectra of the corresponding isomers with a *cis*-junction between the rings, which is interpreted as a consequence of the preferential *trans*-junction in the (XCIIB) and (XCIXB) states [28,133,134]. From the standpoint of the study of the region of applicability of the Bohlmann correlation, discussed in a review [9], it is of interest to observe the absorption in the range 2700–2800 cm^{-1} characteristic of the strained preferentially *trans*-fused pyrrolizidines (XCII) and (XCIX). [79,134] The contribution of the $C_{(8)}$–H bond to the effect was demonstrated by introducing deuterium instead of hydrogen in the 8-position [79].

(b) NMR spectroscopy. The chemical shifts of the protons attached to the α-carbon atoms and the gemina (α-methylene group) and vicinal spin–spin coupling constants for protons are used as criteria for the determination of the preferential type of junction between the rings in quinolizidines, indolizidines, and pyrrolizidines.

The spectra of *trans*-fused 1-azabicyclic compounds contain the signal due to the angular proton at a higher field than the corresponding *cis*-fused bases[9,126,135]. Measurement of the chemical shifts of the signals due to the protons attached to the bridgehead carbon atoms serves as a fairly general procedure for the investigation of the conformations of 1-azabicyclic compounds[57,136,138]. Under these conditions, a comparison of the chemical shifts obtained for the test base and its isomer or another compound used as a standard (with a definite type of junction between the rings) is as a rule required. In certain instances[17,28,92,139] difficulties are encountered owing to the localisation of the angular proton multiplet in the ^{1}H NMR spectra.



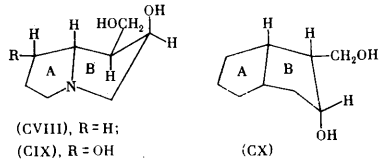
The virtual invariance of the pyrrolizidine spectrum in the temperature range from −17° to +190° leads to the conclusion that the compound is largely if not entirely in the *cis*-fused conformation (IIIA).[126] The ^{1}H NMR spectrum of compound (LXXXIX) exhibits, in contrast to the spectra of its epimer (LXXXVIII) and pyrrolizidine (III), a distinct dependence of the chemical shifts of a number of signals, which reflects a change in the equilibrium between the *cis*-fused and *trans*-fused forms [(LXXXIXA) and (LXXXIXB)] respectively. The upfield displacement of the 8-H proton signal with increase of temperature serves as a criterion indicating an increase of the content of the *trans*-fused conformation (LXXXIXB).[126] The similarity of the chemical shifts of the 8-H protons in pyrrolizidine (3.33 p.p.m.) and in the epimers (LXXXVIII) (3.45 p.p.m.) and (LXXXIX) (3.31 p.p.m.) as well as the results of measurements of the temperature variation show that the *cis*-fused conformations of compound (LXXXIX) predominate[126].

When the methyl group in (LXXXIX) is replaced by the t-butyl group as in (XCIX), a significant diamagnetic shift of the 8-H proton signal is observed ($\delta \leqslant 2.95$ p.p.m.).[28] The H-8 proton resonates at a higher field also in compound (XCII) ($\delta < 3$ p.p.m.).[17] The preferentially *trans*-fused conformations (XCIXB) and (XCIIB) have been attributed to these pyrrolizidine homologues[17,28].

The position of the signal due to the 4-H proton in 4-arylquinolizidines serves as a diagnostic characteristic of the *cis*- or *trans*-fused conformation—in the former the signal is at a lower field than in the latter[58,69,70,135,140,141]. Comparison of the ranges of the chemical shifts for *cis*- or *trans*-fused 4-arylquinolizidines[69] shows that they can overlap for different groups of compounds, but, according to the literature, the determination of the preferential conformations of epimers is fairly reliable.

The preferential *trans*-junction between the rings in lupinine is evident from the chemical shifts of the axial and equatorial protons at $C_{(4)}$ and $C_{(6)}$.[142]

The amount of information about the geminal spin–spin coupling constants in the quinolizidine, indolizidine, and pyrrolizidine series is still relatively limited[143,144] and the influence of different types of junction between the rings on J_{gem} is apparently small[145] as long as the CH_2 group is not located between nitrogen and another heteroatom[9] or a carbonyl group[76]. The contribution of π electrons ($\Delta J = -3.2$ Hz) to $^2J_4$-CH_2 was determined by comparing the geminal constants for the 4-CH_2 group in 3-oxoquinolizidine (CV) and [3D_2]quinolizidine, whence it was found that the ring with the carbonyl group is deformed; the carbonyl group is slightly rotated towards the 10-H atom owing to the dipole repulsion interaction between it and the nitrogen atom[76]:

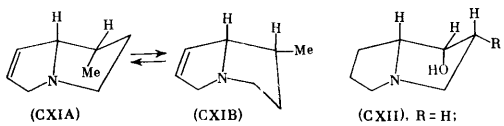


(CV) (CVI), R = Me; (CVII), R = Et (XXXVA)

Having investigated the geminal constants for the 3-CH_2 group and in certain cases the 5-CH_2 group in 3-, 5-, 6-, 7-, and 8-alkyl-2-oxoindolizidines, Cahill and Crabb[76] concluded that they exist in *cis*-fused conformations. The problem of the contribution of the *cis*-fused forms was studied specially in relation to compounds (CVI) and (CVII). The conformational homogeneity of compounds (CVI) and (CVII) was inferred on the basis of the constant $^2J_5$-CH_2 = −11.0 Hz. The contributions of the lone electron pair of the nitrogen atom and the π electrons of the carbonyl group to the constant $^2J_3$-CH_2 for 3-, 5-, 6-, 7-, and 8-alkyl-2-oxoindolizidines were separated. According to the last contribution (−6.7 Hz), the $C_{(1)}$, $C_{(2)}$, $C_{(3)}$, and N atoms are located in the same plane[76].

The very low geminal constant J_3-CH_2 = −18.5 Hz in compound (XXXV) was attributed to the bisector location of the carbonyl group in relation to the 3-CH_2 group and the conformation with an *endo*-puckered N, $C_{(5)}$, $C_{(6)}$, $C_{(7)}$, $C_{(8)}$ ring (XXXVA).[76]

The splitting of the signal due to the angular proton in benzo[*a*]quinolizidine, indolo[*a*]quinolizidine,[137] and dibenzo[*a*,*g*]quinolizidines[136,138] was used to choose one of the possible conformations with a *cis*-junction between the rings.

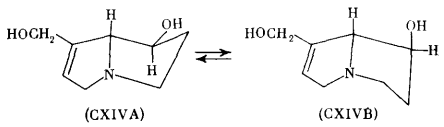


In the study of *cis*-fused conformations of pyrrolizidines considerable progress has been achieved as a result of the investigation of substituted and partly unsaturated bases, from the ^{1}H NMR spectra of which the spin–spin coupling constants for the vicinal protons were determined and their dependence on the geometry was employed. Thus it was found from the values of $J_{H,H}$ for the B rings in compounds (CVIII)–(CX) that the first two compounds[59,98] have conformations with an *exo*-puckered B ring, while the last compound[59] has a conformation with an *endo*-puckered ring.

(CVIII), R = H; (CIX), R = OH (CX)

In all three cases the conformation of the B ring is apparently dictated by the preferential pseudoequatorial orientation of the hydroxymethyl group in the 1-position; the conformation of the A ring has not been discussed.

Detailed analysis of the ^{1}H NMR spectrum of heliotridene (CXI) showed that the free base in solution in $CDCl_3$ consists of an equilibrium mixture of two conformations, (CXIA) and (CXIB), in proportions of approximately 1 : 1[97]:



(CXIA) (CXIB) (CXII), R = H; (CXIII), R = OH

The angle of pucker§ of the saturated ring in conformations (CXIA) and (CXIB) is 45°.

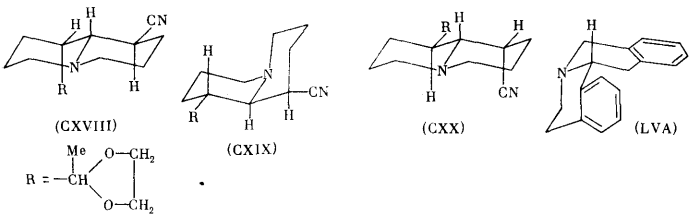
The retronecine molecules have the (CXII) conformation with an *exo*-pucker of the saturated ring (angle of deflection 40°) and a pseudoaxial 7-OH hydroxyl; furthermore, they undergo additional twisting of the bicyclic system about the axis passing through the $C_{(2)}$ and $C_{(6)}$ atoms in a direction such that the 3β-H atom tends to occupy a pseudoequatorial position and the saturated ring approaches the half-chair form[96]. Crotanecine has a similar form (CXIII) in aqueous solution[99].

Agreement between the experimental and calculated vicinal spin–spin coupling constants for heliotridine (CXIV) is achieved if it is assumed that the compound is an equilibrium mixture of the (CXIVA) and (CXIVB) conformations with angles of pucker of the saturated ring equal to 40° [96]:

(CXIVA) (CXIVB)

The application of modified Karplus equations, taking into account the influence of nitrogen and oxygen atoms in (CXIV), made it possible to obtain a very satisfactory agreement between the calculated and experimental values of $^3J_{H,H}$ for the (CXIVA) : (CXIVB) = 35 : 65 mixture[97].

On the basis of the results of the calculation of the geometries of the molecules with the aid of a mechanical model and analysis of the geminal, vicinal, and allyl spin–spin coupling constants, Van Binst et al.[146] concluded that the geometry of the bicyclic system in compounds (CXV)–(CXVII) is virtually the same—the nitrogen is in the sp^2-hybridised state and the bicyclic system has a rigid highly strained (17.2 kcal mole^{-1}) skeleton.



(CXV), X=Y=O;
(CXVI), X=Y=CHCN;
(CXVII), X=O, Y=$CHCO_2Et$.

Whereas the identification of the signals in the ^1H NMR spectra which cannot be interpreted initially sometimes constitutes a very complex problem[92,139], ^{13}C NMR spectra are frequently fairly simple. In the determination of the type of junction between the rings in quinolizidine, lupinine, epilupinine, their benzoate esters, and the isomeric compounds (CXVIII)–(CXX) the positions of the signals due to $C_{(4)}$, $C_{(6)}$, and $C_{(10)}$ are instructive. The shift of the signal due to the $C_{(4)}$ and $C_{(6)}$ nuclei in the *trans*-fused isomers (CXVIII) and (CXX) is approximately constant (57 p.p.m.). On the other hand, in the *cis*-fused compound (CXIX) the signals due to the $C_{(4)}$ and $C_{(6)}$ nuclei are significantly displaced in the upfield direction. According to Wenkert et al.[92], the location of the $C_{(4)}$ signal of this isomer at an anomously high field (47.1 p.p.m.) is a consequence of two γ-effects generated by the carbon atoms of a neighbouring ring, i.e. caused by 1.3-diaxial non-bonding interactions of one of the 4-H atoms with the hydrogen atoms of the neighbouring ring.

The chemical shift of the $C_{(10)}$ nucleus in compound (CXIX) is approximately 6 p.p.m. higher than in the *trans*-fused bases (CXVIII) and (CXX).[92,104] This finding can be given an explanation analogous to that quoted above for the $C_{(4)}$ and $C_{(6)}$ nuclei.

The stereochemistry of tetrahydroprotoberberines, which are derivatives of dibenzo[*a*,*g*]quinolizidine (LV), can be readily inferred from the chemical shifts of the $C_{(6)}$ nuclei: compounds with a *cis*-junction between the B and C rings have chemical shifts of 48.3 p.p.m. or less, while compounds with a *trans*-junction give rise to signals at lower a field (51.4 ± 0.1 p.p.m.). The position of the signal due to the angular $C_{(13a)}$ atom depends just as clearly on the nature of the junction between the rings[136,147]. Tetrahydroprotoberberines with a methoxy-group at $C_{(1)}$ assume preferentially the *cis*-fused conformation of type (LVA) in which non-bonding interactions between the methoxy-group and 13-H, which occur in the *trans*-fused and the second *cis*-fused conformations[136,147], are eliminated[136,147]:

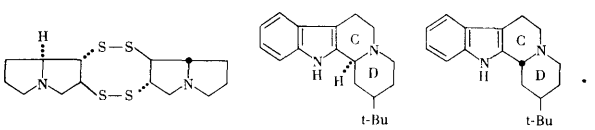
(CXVIII) (CXIX) (CXX) (LVA)

The chemical shift of the $C_{(6)}$ atom in capaurimine is 49.3 p.p.m. and the compound consists of a mixture of *cis*- and *trans*-fused conformations[36].

The symmetry and stereochemistry of the isomeric perhydropyrido[2,1,6-*de*]quinolizidines have been inferred from the number of signals in their ^{13}C NMR spectra[109].

The similarity of the conformations of the strained pyrrolizidines (XCII) and (XCIX) is clearly seen from their ^{13}C NMR spectra. The signals due to the $C_{(8)}$ nuclei in these compounds are in the range 70.1–72.7 p.p.m., while other unstrained *cis*-fused pyrrolizidines are characterised by shifts of the $C_{(8)}$ signals in the range 64–66.6 p.p.m.[106]

Other methods. The rate of methylation of alkaloids of the yohimbine and heteroyohimbine series is satisfactorily correlated with their stereochemistry[66,67]. Yohimbine reacts with methyl iodide more slowly approximately by two orders of magnitude than does pseudoyohimbine, which, in contrast to the former compound, has a *cis*-fused quinolizidine fragment and a sterically more accessible nitrogen atom[65].



The 1-H and 13-H atoms, which are in the *cis*-positions relative to 13a-H, are closer together in dibenzoquinolizidine (LV). The introduction of a more bulky substituent in place of one of these atoms gives rise to intense non-bonding interactions, which forces the molecule to assume the conformation with a *cis*-junction between the B and C rings. Study of the kinetics of the quaternisation of dibenzoquinolizidine derivatives (tetrahydroprotoberberines) served as a means for determining the conformations of these compounds in solution. It has been shown in this way that capaurine and capaurimine exist in solution in conformations with a *cis*-junction between the B and C rings[65]. Vertine and vertaline, which have a *cis*-fused quinolizidine fragment, react with methyl iodide much faster than their epimers lythrine and decaline, in which the quinolizidine rings are *trans*-fused[69,70]. The relative inertness of compound (XCII) compared with its isomers (XC) and (XCI) in the reaction with n-propyl iodide can be

§The angle between the planes passing through the $C_{(1)}$, $C_{(3)}$, N, and $C_{(8)}$ atoms, on the one hand, and through the $C_{(1)}$, $C_{(2)}$, and $C_{(3)}$ atoms, on the other[97].

accounted for by the considerable contribution of the *trans*-fused form (XCIIB) (see the beginning of this section) to the equilibrium mixture of its conformations[17].

According to X-ray diffraction data, the free base of capaurimine *p*-bromobenzoate has a *cis*-junction between the B and C rings in the crystalline state[148]. In crystalline cassipourine (CXXI) the pyrrolizidine rings have a half-folded conformation of type (IIID), the angle between the planes passing through the $C_{(1)}$, $C_{(3)}$, N, and $C_{(8)}$ atoms, on the one hand, and the $C_{(5)}$, $C_{(7)}$, $C_{(8)}$, and N atoms, on the other, is 123°.[149]

A difference has been observed between the mass spectra of compounds (CXXII) and (CXXIII). On electron impact, the epimer (CXXII) loses the oxygen at $C_{(12)}$ much more readily than the epimer (CXXIII), since the 12-H atom and the lone electron pair of the nitrogen atom are in the *trans*-diaxial positions and there is a *trans*-junction between the C and D rings only in the former epimer[150]:

(CXXI) (CXXII) (CXXIII)

The dependence of the mass spectra of the stereoisomeric alkaloids matrine, allomatrine, isosophoridine, and sophoridine on the steric structure has been demonstrated and studies on the mass spectrometry of these and other quinolizidine alkaloids have been reviewed[151].

By studying the ultraviolet spectra of compounds (XCVI)–(XCVIII), Mason et al.[111] found that the carbonyl group in compounds (XCVI) and (XCVIII) absorbs more intensely than that in (XVII) and other carbocyclic ketones owing to the interaction of the carbonyl π orbitals and the lone pair of electrons of the nitrogen. Such interaction can occur only in *trans*-fused forms of compounds (XCVI) and (XCVIII), whence it is concluded that this conformation is preferred[111].

The type of junction between the rings in pyrrolizidines has a fairly marked influence on their basicity. While the *cis*-fused compounds (I), (LXXXVIII), (LXXXIX), heliotridane (pK_a = 11.48),[152] (XC), and (XCI) are some of the strongest saturated bases with a tertiary nitrogen atom (for the values of pK_a see Section II, subsection 4), the predominantly *trans*-fused (XCII) has a relatively low pK_a = 10.28,[87] close to the pK_a values of related typically *trans*-fused 1-azabicyclic compounds, such as quinolizidine (10.19)[64] and indolizidine (10.15).[86]

The comparatively high basicity of *cis*-fused pyrrolizidines[86,123,152,153] can be explained by their stereochemical characteristic feature consisting in the steric accessibility of the nitrogen[123,153] and a geometry which is unfavourable for the delocalisation of the lone electron pair of the nitrogen[86]. This property of the pyrrolizidine *cis*-fused bicyclic system can be readily discovered by comparing the basicities of quinolizidine, indolizidine, and pyrrolizidine alcohols with the hydroxy-group in the 2-position relative to the nitrogen, which do not form intramolecular hydrogen bonds (Table 1). Thus one may reach a conclusion about the sequence of increasing basicities of unsubstituted bicyclic systems. Quinolizidine and indolizidine are virtually equivalent as bases, whereas pyrrolizidine is significantly stronger. This conclusion is confirmed by recent direct observations for the free bases (I)–(III),[86] whose pK_a values are 10.19,[64] 10.15, and 11.68[86] respectively. In aqueous solution base (III) differs in strength from compounds (I) and (II) by more than an order of magnitude.

Table 1. The basicities of certain quinolizidine, indolizidine, and pyrrolizidine alcohols.

(LXIX)	8.82	30	(XXXVI)	10.25	30

2. Quantitative Results

Certain results of the quantitative study of the *cis–trans* interconversion of quinolizidine and indolizidine have been published[9]. We arranged systematically and compiled in Table 2 data for the conformational equilibria involving both the bases (I)–(III) themselves and their derivatives.

The conflicting results obtained in the determination of the thermodynamic parameters of the *cis–trans* interconversion in quinolizidine led us to calculate the enthalpy of this process in two independent ways[159]. The calculation was based on the enthalpy of the *cis–trans* isomerisation of decalines. Ultimately, as a result of this treatment[159], the energy of the additional stabilisation of the *trans*-fused form of quinolizidine relative to *trans*-decaline was obtained from data for piperidine and calculated from the results of the determination of the energies of hydrogen bonds in the quinolizidine–phenol and quinuclidine–phenol systems[159]. It was shown[158,162] that at least in the gas phase the values of ΔG°_{25} for the *cis–trans* interconversions in quinolizidine and indolizidine differ more significantly than is believed in the literature[157,163].

At the present time there have been no rigorous determinations of the thermodynamic parameters of the *cis–trans* interconversion in pyrrolizidines. It has been suggested[126] that there is a difference between the heat contents of the *cis*- and *trans*-fused pyrrolizidines, which is close to that described for the isomeric *cis*- and *trans*-bicyclo[3,3,0]octanes (6.0 kcal mole^{-1}).[164]

Assuming that an increase of the content of the *trans*-fused form of pyrrolizidine to 5% on heating its vapour from 20° to 300°C would be observed from the appearance of Bohlmann bands in the range 2700–2800 cm^{-1} and having failed to observe this effect with increase of temperature, Skvortsov et al.[158] calculated $\Delta H < -3.4$ kcal mole^{-1} for the *trans–cis* conversion in pyrrolizidine.[158]

IV. THE CONFIGURATIONS AND CONFORMATIONS OF THE BASES AND QUATERNARY SALTS PROTONATED AT THE NITROGEN ATOM

The quinolizidinium cation in trifluoroacetic acid has a *trans*-junction between the rings; its ^1H[165] and ^{13}C[103] NMR spectra have been described. A *trans*-junction

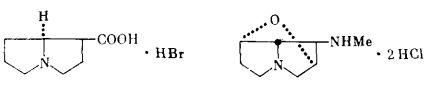
between the rings has been attributed to protonated quinolizidine, *trans*-1,10-*H*-1-methylquinolizidine, 2-methylquinolizidine, 3-methylquinolizidine, and *cis*-4,10-*H*-4-methylquinolizidine in aqueous solution[12], i.e. the cations have the same configuration as the conformations of the corresponding free bases. Two doublets due to the methyl group were observed for *cis*-1,10-*H*-1-methylquinolizidine. This was explained by the tautomeric equilibrium between approximately equal amounts of the *trans*- and *cis*-fused forms of the cation[12]. According to the authors[12], the *trans*-4,10-*H*-4-methylquinolizidinium cation has a *cis*-junction between the rings.

Whereas according to NMR spectra protonated epilupinine exists in the *trans*-fused form[166], the protonation of lupinine (CXXVI) gives rise to cations with a *cis*-junction [compound (CXXVII)] and a *trans*-junction [compound (CXXVIII)] junction between the rings, which can undergo interconversions in solution; the equilibrium position depends on the concentration, the pH, and temperature[166]:

(CXXVII) (CXXVI) (CXXVIII)



Protonated 1-hydroxy-7-methyl- and 1-hydroxy-1,7-dimethyl-quinolizidines in trifluoroacetic acid retain the *trans*-fused form of the free bases according to ^{1}H NMR spectra[167]. Protonation of 5,7-dimethylindolizidines (LXXXIV)–(LXXXVII) leads to salts whose configurations are claimed[14] to consist of the fixed preferred conformation of the bases, compound (LXXXVI) giving rise to a mixture of the *cis*- and *trans*-fused forms[14].

The ^{1}H NMR spectrum of protonated pyrrolizidine agrees with the hypothesis of a *cis*-junction between the rings in the cation of compound (CXXIX).[126] Protonation of the nitrogen atom in heliotridene leads to an increase, relative to the free base, of the fraction of the conformation with an *endo*-puckered saturated ring; (CXXXA):(CXXXB) = 1 : 3.[97]

(CXXIX) (CXXXA) (CXXXB)

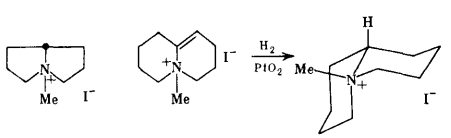
The structures of the quinolizidine alkaloids neothiobinupharidine,[168,169] thiobinupharidine[170] (hydrated dihydrobromides), poranthericine,[171] porantherine,[172] and vertaline[173] (hydrobromides) were elucidated by X-ray diffraction. It has been shown that the quinolizidine rings in capaurine hydrobromide[138] and isocapaurimine hydrobromine monohydrate[174] have a *cis*-junction between the rings[138,174].

Analogous studies have been made on compounds of the pyrrolizidine series. The absolute configuration was found and the bond lengths and valence angles were determined in the hydrobromide of *cis*-1,8-*E*-1-carboxypyrrolizidine (CXXXI).[175] Application of the method of anomalous dispersion made it possible to establish the absolute configuration of the dihydrochloride (CXXXII).[176]

(CXXXI) (CXXXII)

The structure of nitropolyzonamine, in the form of its perchlorate, has been elucidated. The pyrrolizidine rings in this compound have the envelope conformation (C_s).[177]

It has been shown[178] that the 1,2-dehydropyrrolizidine skeleton in jacobine hydrobromide exhibits has an *exo*-puckered and twisted saturated ring.



The conversion of the tertiary nitrogen in quinolizidines, indolizidines, and pyrrolizidines into a quaternary form leads to the fixation of the *cis*- or *trans*-junction between the rings[9]. A convenient criterion for the determination of the configurations of *N*-methylquinolizidinium and *N*-methylindolizidinium ions is the chemical shift of the protons in the methyl group attached to the nitrogen [9,12,179]. The reliability of this criterion demonstrated the agreement between NMR and X-ray diffraction data[180-182]. However, this method is applicable only to methiodides without a substituent in the angular position. If different substituents (except CN) are located in the 10-position in quinolizidinium salts, the signal of the $\geq^{+}$N–Me group in the *cis*-fused salts occurs at a higher field than for the *trans*-fused compound[183]. At the same time the configurational assignment of quaternary quinolizidinium salts can be achieved on the basis of the measurements of the half-widths of the signals of the $\geq^{+}$N–Me group. Thus *trans*-fused *N*-methylquinolizidinium has a half-width of the methyl singlet of 1.53 Hz, while the *cis*-fused salt has a corresponding width of 0.96 Hz.[184] It has been suggested that this criterion is applicable to other *N*-methylated heterocycles of a similar type[184].

The stereochemistry of quinolizidine methiodides with a single substituent in the 10-position can be readily inferred from the number of signals in their ^{13}C NMR spectra—the *trans*-fused salts have a plane of symmetry which gives rise to four signals due to the ring nuclei.[183]

One must note that the type of junction between the rings in the quaternary salt and in the free base may be the same[69,70], but in the general case this is not necessarily so[179]. Instances are known where the base has a preferentially *trans*-fused conformation, but gives rise either to a *cis*-fused salt [166,185,186] or to a mixture of epimers[12,64,186].

With the exception of the case of intramolecular quaternisation, which is possible only for a *trans*-junction between the rings[125], it is believed that pyrrolizidines usually form unstrained *cis*-fused salts[7]. On reaction with methyl iodide, pyrrolizidine gives a single *cis*-fused quaternary salt (**CXXXIII**), which has been confirmed by its ^{1}H NMR spectrum[126].

The *cis*-junction between the rings in the quaternary salt (**CXXXV**) is regarded as a consequence of the catalytic hydrogenation of the unsaturated compound (**CXXXIV**) from the sterically least hindered side of the molecule[81,187].

(CXXXIII) (CXXXIV) (CXXXV)

By comparing the optical rotations of (+)-epilupinine and (–)-lupinine and the methiodides obtained from the bases, it has been shown that the quaternary salts have respectively *trans*- and *cis*-junctions between the rings. The configurations (*cis*- and *trans*-) of the methiodides prepared from optically active 1-methylquinolizidines have been demonstrated similarly[81].

Crystalline quaternary salts have been investigated by X-ray diffraction. In the quinolizidine series an example of this type of investigation is provided by the determination of the nature of the junction between the rings in α- and β-methiodides of hunterburnine.[180,181] The study of the steric structures of the methiodides of alkaloids with an indolizidine fragment–kopsanone [189] and tylophorinidine [190]—yielded data for the absolute configurations of these alkaloids. In the pyrrolizidine-based thelepogine methiodide *exo*-puckering of the saturated five-membered ring is observed (angle of deflection 55°),[191] while in the cation of the diester of 8-hydroxymethylretronecine the unsaturated ring exhibits *endo*-puckering and is somewhat twisted[192].

The arsenal of available physical and physicochemical methods makes it possible to determine the configurations and preferred conformations of both the simplest bases and complex natural products of the quinolizidine, indolizidine, and pyrrolizidine series. In many of the studies quoted, a combined application of various methods was achieved in the course of stereochemical investigations, which yields the most reliable results.

A quantitative description of the conformational equilibria of 1-azabicyclic systems in liquid and gaseous phases has remained difficult hitherto. In the immediate future the situation is most likely to change in connection with the introduction of the interesting method of the kinetically controlled protonation of amines,[193] which has been studied in detail and which makes it possible to detect invertomers in the form of the corresponding cations. The ratio of the latter is determined by NMR.[193]

Preparation and Reactions of Chloro-derivatives of Nitriles

E.M.Movsum-zade

Published information on the synthesis and reactivity of chloro-derivatives of nitriles is summarised, and methods are examined for the preparation of such derivatives of acetonitrile, acrylonitrile, methacrylonitrile, crotononitrile, and benzonitrile. Research on the mechanism of reactions undergone by the derivatives is reported. A list of 113 references is included.

CONTENTS

I. Introduction 282
II. Preparation of chloro-derivatives of nitriles 282
III. Reactions and practical application 285

I. INTRODUCTION

The use of nitriles, in particular acrylonitrile, in aeronautics, motorcar manufacture, building, light industry, and agriculture, as well as exploitation of the high calorific value of several nitriles in special fuels, explains the continuously increasing production of several nitriles.

The presence of a chlorine atom in nitriles increases the synthetic and practical possibilities of this class of compounds. Chloro-derivatives of nitriles are of both theoretical and practical interest, and have therefore attracted the attention of research workers. Such compounds are intermediates in various organic synthesis, while unsaturated chlorinated nitriles find application in the production of polymers having interesting properties.

The little information available on the synthesis of chlorinated nitriles has appeared mainly in the patent literature. Only two books have been published on fundamental aspects of the reactivity of nitriles[1,2]. No systematic results are available on the preparation and reactivity of the halogeno-derivatives. Since 1960 papers have appeared on the synthesis of chloro-derivatives of nitriles, and during the past 5-7 years several investigations of the reactivity of chloroacrylonitriles have been published. The present Review summarises results for the preparation of chloro-derivatives of nitriles and investigations of their reactions.

II. PREPARATION OF CHLORO-DERIVATIVES OF NITRILES

Direct chlorination is one of the main methods for obtaining chloro-derivatives of nitriles. The earliest papers on this process appeared during the nineteenth century[3-5]. Acetonitrile is readily chlorinated to give a high yield of trichloroacetonitrile:

$$CH_3CN + 3Cl_2 \rightarrow Cl_3CCN + 3HCl\ .$$

Chlorination can be initiated photochemically with natural or artificial radiation (at 50-80°C), catalysed by platinum or silver chloride on asbestos, or effected by a combination of these treatments[6,7,9]. The reaction is also accelerated by preliminary saturation of the acetonitrile with hydrogen chloride.

Publications on liquid-phase chlorination reflect no generally accepted view on why interruption of the process does not prevent the formation of completely chlorinated products. Analysis of the reaction mixture shows the absence of mono- and di-chlorinated derivatives of acetonitrile. Stepanov and Shirokova[8] explain such discrepancies on the assumption that the rate of chlorination of the starting material is considerably lower than those of the partly chlorinated products. In the Reviewer's opinion such a hypothesis is implausible as it is devoid of analgies. Carboxylic acids and their derivatives can readily be chlorinated in stages, which applies also to many other compounds containing activated methyl and methylene groups. A more plausible hypothesis is that hydrogen chloride liberated on chlorination adds to the partly chlorinated nitrile, and the resulting nitrilium salt or tautomeric imidoyl chloride is chlorinated considerably more rapidly than is the initial nitrile:

$$CH_3CN + Cl_2 \xrightarrow{\text{slow}} (ClCH_2{-}C{\equiv}NH)^+Cl^-$$
$$(CH_2Cl{-}C{\equiv}NH)^+Cl^- + Cl_2 \xrightarrow{\text{rapid}} (CHCl_2{-}CNH)^+Cl^- + HCl$$
$$(CHCl_2{-}CNH)^+Cl^- + Cl_2 \xrightarrow{\text{rapid}} (CCl_3{-}CNH)^+Cl + HCl$$
$$(CCl_3{-}CNH)^+Cl^- \rightarrow CCl_3{-}CN + HCl.$$

On this hypothesis it was deduced[9] that preliminary treatment of the nitrile with hydrogen chloride should increase its rate of chlorination, which was fully confirmed by experiment.

A process suggested[10] for the continuous catalytic production of chloroacetonitrile CH_2ClCN consists in the gaseous chlorination of acetonitrile. The latter is treated with chlorine diluted with an inert gas at temperatures from 50°C to the boiling point of acetonitrile, with simultaneous exposure of the mixture to light from a mercury lamp or ionising rays[11]. Acetonitrile vapour and chlorine can also be passed through a turbulent-flow reaction vessel[12].

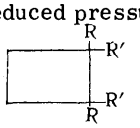
Several publications have appeared on the preparation of chloro-derivatives of acrylonitrile. Methods are based either on direct chlorination or on the dehydrochlorination of $\alpha\beta$-dichloropropionitrile[13,14]. Table 1 lists conditions for the chlorination of acrylonitrile[15-32]. The action of a hydrohalic acid on propiolonitrile in the presence of a copper salt has been claimed[18] to give a 75% yield of a β-halogeno-derivative of acrylonitrile. Processes have been reported for obtaining α-halogenoacrylonitriles[19] by the dehalogenation of $\alpha\alpha\beta$-trihalogenopropionitriles by treatment with a trialkyl or a triaryl phosphite:

$$XCH_2CX_2CN + (RO)_3P \rightarrow CH_2{=}CXCN + (RO_2)POX + RX$$
$$(X{=}Cl, Br, I)\ .$$

A 91% yield of $\alpha\alpha\beta$-trichloropropionitrile has been claimed[21] when a hydrogen halide is introduced into the chlorination of acrylonitrile. The action of chlorine on

propiolonitrile in an alcoholic or aqueous-alchoholic solution of a copper(II) halide at 30–60°C is stated[22] to give di- and tri-halogenated derivatives of acrylonitrile. Another method has been suggested[23] for obtaining $\alpha\alpha\beta$-trichloropropionitrile, which is very effective in suppressing the growth of weeds among broad-leaved plant crops (Table 1).

Table 1. Conditions of chlorination of acrylonitrile (ACN).



Starting materials	Temp., °C	Catalyst	Contact for	Yield, wt.%			Ref.
				α-ClACN	β-ClACN cis + trans	α,α,β-trichloropropionitrile	
ACN + Cl_2	200—550	activated carbon	—	68	—	—	15
ACN + Cl_2 (1-3:1)	450—850	—	0.001-1 s	90	—	—	16
ACN + Cl_2	100—600	chlorides or oxides of Cu, Cr, Ni, Mn, Mg, Al, Fe, Ca, Pd, V	—	90	—	—	17
α-Acetoxy-β-chloropropionitrile (pyrolysis)	535	—	—	28	35	35	26
ACN + Cl_2	50—70	CCl_4, $CHCl_3$ soln.	—	—	—	95	23
αβ-Dichloropropionitrile (pyrolysis)	60 (12 mm)		0.7 s	93	—	—	29
αα-Dichloropropionitrile + NH_3	0—15	—	0.5-1 h	64	—	—	31
ACN + O_2 + HCl	150—160 (0.1-10 atm)	—	1-30 s	32.6	—	—	32

A paper on the synthesis and polymerisation of several α-substituted acrylonitriles has reported[25] preparations of α-bromoacrylonitrile, α-chloroacrylonitrile, methylenemalononitrile, methacrylonitrile, and other alkylated acrylonitriles. Isomeric mixtures of *cis*- and *trans*-β- and -α-chloroacrylonitriles can be obtained[26] by the pyrolysis of α-acetoxy-β-chloropropionitrile. Chlorination of acrylonitrile in dimethylformamide will give an approximately 90% yield of αβ-dichloropropionitrile[27]:

$$CH_2{=}CH{-}CN + Cl_2 \xrightarrow{DMF} CH_2Cl{-}CHCl{-}CN .$$

An interesting study[28] of the influence of gaseous hydrogen chloride on the chlorination of acrylonitrile showed that, depending on the concentration of the gas evolved, either a mixture of β-mono- and ααβ-tri-chloropropionitriles or αβ-dichloropropionitrile is formed. If chlorination is continued after the solution has become saturated with hydogen chloride, the mixture is formed; continued chlorination of this mixture yields only ααβ-trichloropropionitrile. If the reaction is terminated before the solution begins to be saturated with hydrogen chloride, the main product is αβ-dichloropropionitrile.

Nitriles of α-halogenoacrylic compounds can be obtained by the pyrolysis under reduced pressure of compounds of general formula

where R = Cl and R′ = CN.[29] Clorination of acrylonitrile with a mixture of carbon monoxide and chlorine yields αβ-dichloropropionitrile[30]:

$$CH_2{=}CH{-}CN \xrightarrow{CO+Cl_2} CH_2Cl{-}CHCl{-}CN ,$$

The patent literature[31,32] gives several methods for obtaining α-chloroacrylonitrile (Table 1).

The first publications on the preparation of chloro-derivatives of methacrylonitrile appeared around 1950.[34,35] A proposed method was to chlorinate αβ-unsaturated nitriles at high temperatures (up to 600°C). A mixture of βω-dichloromethacrylonitrile with a 61% yield of ω-chloromethacrylonitrile was obtained:

$$CH_2{=}\underset{\displaystyle CH_3}{\overset{\displaystyle CH_2Cl}{\overset{|}{\underset{|}{C}}}}{-}CN + Cl_2 \xrightarrow{585-600^\circ C} \underset{8\%}{CHCl{=}\overset{\displaystyle CH_2Cl}{\overset{|}{C}}{-}CN} + \underset{61\%}{CH_2{=}\overset{\displaystyle CH_2Cl}{\overset{|}{C}}{-}CN} + HCl .$$

Kondratenko and Khaskin[36] have obtained isomeric chlorohydroxyisobutyronitriles by reaction between methacrylonitrile and chlorine in an aqueous medium. Nitriles of 2-chlorocyclobutanecarboxylic acids have been claimed[37] as products of the cycloaddition of vinyl chloride to acrylonitrile. ω-Chloromethacrylonitrile can be obtained[38] by the action of anhydrous liquid ammonia on αβ-dichloro-α-methylpropionitrile. Lower (C_{3-7}) ω-chloro-nitriles result[39] from the telomerisation of cyanogen chloride and ethylene in the presence of azoisobutyronitrile or di-t-butyl peroxide under 52.5–70 atm.

The few publications that have appeared on halogeno-derivatives of the isomeric crotononitrile relate mainly to the formation of γ-chlorobutyronitrile, αβ-dichlorobutyronitrile, and a small quantity of α-chlorocrotononitrile. Table 2 gives several methods for obtaining chloro-derivatives of crotononitrile under various conditions[40–46].

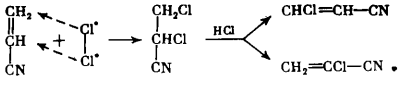
Table 2. Conditions of treatment of crotonitrile with chlorine.

Temp., °C	Catalyst	Yield of chloro-derivative, wt.%		Ref.
		β-mono	αβ-di	
20—250	—	55—61	—	40—42, 44
595—700	—	57,7	—	43
400—600	—	62	—	45
680	metal oxides	—	91	46

Halogeno-derivatives of aromatic nitriles are used for the synthesis of dyes distinguished by excellent fastness, as well as herbicides, insecticides, etc. The very few publications on the preparation of halogenobenzonitriles relate mainly to the *o*-chloro-derivative, which is the principal starting material for the production of azo-dyes, e.g. Basic Bordeaux, Disperse Violet, etc. Several methods are known for obtaining halogenobenzonitriles by the oxidative ammonolysis of halogenated aromatic hydrocarbons. Application of this process to *p*-chlorotoluene on a catalyst comprising arsenic and vanadium oxides promoted with alkali metals at 250–300°C gives a 66.5% yield of *p*-chlorobenzonitrile[47]. A catalyst comprising vanadium(V) and

iron(III) oxides on alumina can also be used[48]. Table 3 lists conditions for the oxidative ammonolysis of chlorotoluene[49–52].

Table 3. Conditions of formation of chlorobenzonitriles*.



Starting materials	Temp., °C	Catalyst	Yields of isomers, wt.%			Ref.
			ortho	*meta*	*para*	
o-, *m*-, *p*-$ClC_6H_4CH_3$ + O_2 + NH_3 + H_2O*	455	V, Ti, Sn oxides	—	50–80	47	49

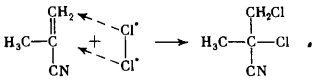
p-ClC_6H_4CN + Cl_2	450	V, Sb, Bi, Al oxides	25	45	30	52

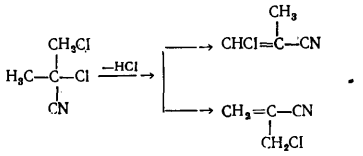
* Proportions of starting materials $ClC_6H_4CH_3 : O_2 : NH_3 : H_2O = 1 : 83 : 19 : 105$.

However, the technical complexity of the suggested methods and the need for expensive catalysts led to the proposal that interesting monomers should be obtained by a single-stage method[53–55] of chlorination of nitriles. A technical scheme has been put forward[57] for the chlorination of C_{2-4} nitriles, in which the reaction vessel contains a stationary layer of catalyst. Since the type of catalyst (perlite, quartz, AG-3 activated carbon) had no clear effect on the yield of products[56], and perlite is inexpensive and readily available, subsequent investigations were made on this catalyst. The highest yields of chloro-nitriles have been observed[57–61] with a molecular ratio of nitrile to chlorine of 2 : 1. With a short period of contact, however, dichloro-derivatives are formed: i.e. chlorine is added. As the time of contact lengthens, α- and β-chloro-nitriles are formed; the maximum yield (80–85 wt.%) is achieved with a time of contact of 5–6 s. Chlorination thus follows an anomalous course, as a consequence of dehydrochlorination of $\alpha\beta$-dichloropropionitrile: i.e. substitutive chlorination takes place. The influence of temperature on the yield of chloro-nitriles is similar to that of the time of contact: at low temperatures dichloro-derivatives are formed, but with rise in temperature their yield diminishes, and that of monochloro-nitriles increases in proportion. Experiments and calculations[62,64] have made it possible to establish optimum conditions for obtaining chloroacetonitrile, α-chloroacrylonitrile, and ω-chloromethacrylonitrile.



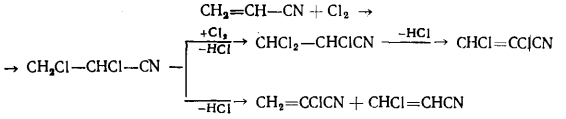
The kinetic and other studies of the chlorination of acrylonitrile and methacrylonitrile have led to a tentative reaction mechanism[57,63,64] in which these nitriles are regarded to a first approximation as unsaturated hydrocarbons[65]. The unusual course of chlorination of the latter was first observed during the nineteenth century[66–69]. Tishchenko[70–74] later found that anomalous chlorination of unsaturated hydrocarbons is observed when a quaternary carbon atom is adjacent to the double bond; the main product is then an isomeric monochloride in which the double bond has been displaced, accompanied by only a small quantity of the dichloride.

On the basis of the mechanism of the anomalous chlorination of hydrocarbons it has been suggested[57–64] that the chlorination of acrylonitrile can be represented by the scheme

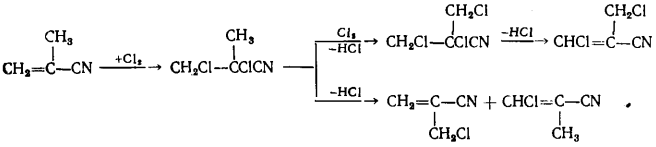


Chlorine adds to the acrylonitrile molecule, the double bond opens, and $\alpha\beta$-dichloropropionitrile is formed. At high temperatures this is accompanied by dehydrochlorination of the dichloro-derivative to give α- and β-chloroacrylonitriles. This scheme is supported by experiment, since at sufficiently high temperatures (350–380°C) with contact lasting for 6–7 s the competitive addition of both chlorine atoms to acrylonitrile diminishes, and a monochloro-nitrile is formed.

The chlorination of methacrylonitrile can probably be represented

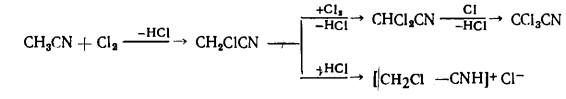


However, the product is unstable, and stabilisation occurs by elimination of hydrogen chloride to form ω-chloromethacrylonitrile:



The direction of the dynamic effect is opposite to that of the static effect of conjugation. Therefore methacrylonitrile undergoes chlorination under more severe conditions than does acrylonitrile.

On the basis of the above investigations and the classical interpretation of the anomalous chlorination of unsaturated hydrocarbons it has been suggested[57,64] that the chlorination of acrylonitrile can be represented by the scheme

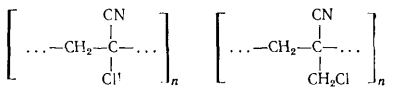


and that of methacrylonitrile by

Adequate attention has been paid to aspects of the liquid-phase chlorination of acetonitrile[33,75,76]. Chlorination involves intermediate formation of a nitrilium salt to give finally trichloroacetonitrile.

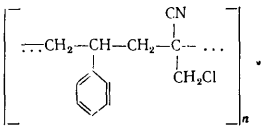
The vapour-phase chlorination of acetonitrile with a molecular ratio nitrile : chlorine = 2 : 1 at 350°C for 5–6 s gives mainly chloroacetonitrile with a small quantity of trichloroacetonitrile[57,58,100]. Two fractions corresponding to these products were isolated. Hardly any dichloroacetonitrile was observed. Traces of a nitrilium salt are also formed[100]. The salt decomposes at high temperatures, so that it cannot be formed in vapour-phase chlorination at 350–360°C. The nitrilium salt is most probably formed on cooling, when chloroacetonitrile reacts with hydrogen chloride. From the above considerations the mechanism

has been suggested for the chlorination of acetonitrile.



It has thus been ascertained that the vapour-phase chlorination of nitriles follows the anomalous chlorination mechanism of unsaturated hydrocarbons. This method can be used also to obtain unsaturated monochloro-derivatives of other classes of compounds.

III. REACTIONS AND PRACTICAL APPLICATION



Chloro-derivatives of nitriles find application as insecticides. They also exhibit bactericidal properties[24], and are very effective against soil pests[109].

Chloro-derivatives of nitriles are a little investigated class of compounds. Few papers have appeared on the reactions of the unsaturated representatives, since hitherto they have been unavailable. Development of methods for the preparation of chloro-derivatives of aliphatic and aromatic nitriles has made it possible to study their reactions. A process has been claimed[20] for obtaining derivatives of α-chloro-β-p-hydroxyphenylpropionitrile, which can be used as intermediates in the production of medicinals.

Polymeric materials obtained from chlorine-containing monomers possess valuable properties, in particular fire resistance. The presence of a nitrile group together with a chlorine atom in a monomer may confer on the polymers also frost resistance, gas impermeability, and resistance to corrosive media. It is therefore of practical interest to study the polymerisation of chloroacrylonitrile and chloromethacrylonitrile as examples of such monomers. α-Chloroacrylonitrile has been used[77-81] to obtain polyconjugated polymers both of linear (polyvinylene) structure and of ladder structure with fused naphthyridine rings. As well as the synthesis of homopolymers

the possibility has been investigated of the copolymerisation of chloromethacrylonitrile with styrene to give

Chloroacrylamides have been obtained[82] by conversion of the nitriles into amides under conditions of acid hydration:

$$CH_2{=}CCl{-}CN \xrightarrow{HOH} CH_2{=}CCl{-}C(=O)NH_2 .$$

Chloro-derivatives of nitriles are interesting starting materials for the single-stage preparation of chloro-derivatives of unsaturated acids by hydration in the presence of 75% sulphuric acid. Such acids can be formed also[82-85,105] by direct chlorination of acrylic and methacrylic acids:

$$CH_2{=}CCl{-}CN \xrightarrow{HOH} CH_2{=}CCl{-}COOH \xleftarrow[150-170^\circ]{Cl_2} CH_2{=}CH{-}COOH .$$

Addition of alcohols to α-chloroacrylonitrile in the presence of AV-17 anion-exchange resin, sodium methoxide, and amines is catalysed by the amines themselves[86-89]:

$$ROH + CH_2{=}CCl{-}CN \rightarrow ROCH_2CHCl{-}CN$$

R=CH_3, $CH_2{-}CH{=}CH_2$, $CH_2C{\equiv}CH$

$$R_2NH + CH_2{=}CCl{-}CN \rightarrow R_2NCH_2CHCl{-}CN$$

R′=R=C_3H_7; R=R′=CH_3; R=R′=C_2H_5; R=R′=C_4H_9 .

Nucleophilic substitution by treatment with alcohols has been used to examine the reactivity of the chlorine in chloro-nitriles and to develop a procedure for obtaining hydroxy-derivatives of aliphatic nitriles[90,91]. The reactions of C_1–$_7$ aliphatic alcohols and of cyclic and unsaturated alcohols have been studied[110]:

$$ClCH_2CN + ROH \xrightarrow{NaOH} NCCH_2OR + NaCl + HOH$$

R=CH_3, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, C_6H_{13}, C_7H_{15},

, $CH_2{-}CH{=}CH_2$, $CH_2{-}C{\equiv}CH$,

$C(CH_3)_2{-}C{\equiv}CH$.

Organosilicon nitriles are obtained by condensing incompletely substituted silanes with alkenes[107,108]. Unsaturated nitriles react with silicochloroform and with alkylchlorosilanes:

$$CH_2{=}CH(CH_2)_n CN + CH_3SiCl_2H \xrightarrow{n\geqslant 1} (CH_3)Cl_2SiCH_2CH_2(CH_2)_n CN .$$

Petrov et al.[92] studied the addition of alkoxysilanes to but-3-enonitrile, β-allyloxypropionitrile, and acrylonitrile, and established that addition conforms to the equation

$$R'(RO)_2SiH + CH_2{=}CHCH_2X \rightarrow R'(RO)_2SiC_3H_4CH_2X$$

R′=CH_3, OC_2H_5, OCH_3; R=CH_3, C_2H_5; X=OCH_2CH_2CN, —CN.

Condensation of acrylonitrile, 2-vinylpyridine, and methacrylaldehyde with triethoxysilane and several other partly substituted silanes in the presence of activated AV-16 anion-exchange resin yields β-triethoxysilylpropionitrile and other silicon-containing nitriles[94-99].

Golubtsov et al.[93] investigated the reactions of methyldichlorosilane with acrylonitrile in the presence of various catalysts (pyridine, chloroplatinic acid), but did not achieve satisfactory results.

The action of a silicon–copper catalyst on β-chloropropionitriles forms β-trichlorosilylpropionitrile[101]:

$$ClCH_2CH_2CN \xrightarrow{Si/Cu} \begin{cases} \rightarrow HSiCl + SiCl_4 \\ \rightarrow CH_2{=}CH{-}CN \\ \rightarrow Cl_3SiCH_2CH_2CN \end{cases} .$$

Mono-, di-, and tri-nitriles containing chlorine attached to silicon have been obtained[102,103] directly from chloroacetonitrile, α-chloroacrylonitrile, and ω-chloromethacrylonitrile:

$$RCl \xrightarrow{Si/Cu} \begin{cases} \rightarrow HSiCl_3 + SiCl_4 \\ \rightarrow R_nSiCl_{4-n} \end{cases}$$

R=CH_2CN, $CH_2{=}C(CN){-}$, $CH_2{-}C(CN){=}CH_2$; $n = 1$–3 .

These workers[103,104] examined the reactions of chlorosilylated nitriles, and have established[111] that silicon-containing nitriles can be obtained by condensation of a silanol with a chlorinated nitrile:

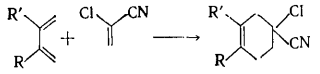
$$R_3SiOH + ClR'CN \rightarrow R_3SiOR'CN$$

R=CH_3; R′=$-CH_2-$, $-C(=CH_2)-$, $-CH_2-C(=CH_2)-CH_2-$, $-CH{=}CH-$, $-CH{=}C(CH_3)-CH_2-$, $CH_3-CH{=}C(\ )-$.

The products can be converted by hydration into unsaturated organosilicon acids:

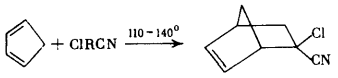
$$R_3SiOR'CN \xrightarrow[H_2SO_4]{HOH} R_3SiOR'COOH .$$

An original synthesis of organosilicon nitriles was suggested by Chernyshev and his coworkers[112,113]. *o*-, *m*-, and *p*-Trichlorosilylbenzonitriles and the corresponding methyldichlorosilyl compounds have been obtained[112] from a hydrolytic mixture of trichlorosilane or methyldichlorosilane with the appropriate chlorobenzonitrile in the gas phase at 500–650° C for a very short period of contact (10–90 s), after which the products were separated:



$R'=R^2=Cl$; $R'=CH_3$, $R^2=Cl$.

The same workers suggested[113] gas-phase pyrolysis of silicochloroform or methyldichlorosilane with β-chloroacrylonitrile or αβ-dichloroacrylonitrile at 500–650° C for 10–100 s to obtain the chlorosilylacrylonitriles:



Like acrylonitrile chloro-derivatives of nitriles condense with dienes. The diene condensation of α-chloroacrylonitrile with butadiene, isoprene, etc. can be represented[87]

R=R′=H; R=H, R′=CH_3; R=H, R′=Cl; R=Cl, R′=CH_3; R=R′=Cl.

Bicyclic chloro-nitriles have been synthesised[106] by the diene condensation of α-chloroacrylonitrile and ω-chloromethacrylonitrile with cyclopentadiene:

The above survey shows that development of the preparation of chloro-derivatives of nitriles offers great promise, since the resulting monomers possess wide synthetic possibilities and have important applications.

Advances in the Chemistry of 1,2-Azoles

S.D.Sokolov

Data obtained during 1960-1977 on the physical, physicochemical, and chemical properties of 1,2-azoles are surveyed. For the first time such data are subjected to comparative discussion to reveal common features and differences in properties. A list of 304 references is included.

I. INTRODUCTION

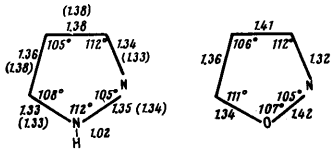
1,2-Azoles include pyrazole, isoxazole, and isothiazole. Their derivatives have long found practical application: it is sufficient to mention the medicinal products—antipyretics of the pyrazolone series[1], sulphanilamides, and semi-synthetic penicillins containing the isoxazole ring[2]. During recent years isoxazole derivatives have come to be widely used in organic synthesis to obtain various heterocycles, peptides, steroids, and other naturally occurring compounds[3,4].

The chemistry of each of the 1,2-azoles has been considered in detail in a series of reviews published during the past 15 years—three on pyrazoles[1,5,6], five on isoxazoles[2-4,7,8], and two on the "youngest" class, the isothiazoles[9,10]—but they contain no comparative analysis of the properties of 1,2-azoles. Such comparison has been made in the books by Katritzky and Lagowski[11] and by Paquette[12], although the very condensed treatment results in a fragmentary description, which is accompanied also by inaccuracies and simple errors[12].

The nature of the heteroatom distinguishing one 1,2-azole from another not only determines the character of the bond between this atom and the nitrogen atom, of course, but also influences the properties of the molecule as a whole. The present Review has been written with the aim of revealing common and distinguishing features in the physical and chemical properties of heteroaromatic 1,2-azoles: it contains neither methods of preparation of azoles nor the properties of their hydrogenated derivatives. Considerable difficulties in compiling the Review arose from the need for selection from the ~800 publications on the properties of 1,2-azoles that have by now appeared (Autumn 1977). In order to avoid greatly increasing the length of the Review, references are given to existing reviews and attention is directed to information from publications not mentioned in them, as well as the most important fundamental work that has appeared since 1960.

II. ELECTRONIC STRUCTURE WITH PHYSICAL AND PHYSICOCHEMICAL PROPERTIES

1. Quantum-chemical Calculations and Molecular Geometry



The simple LCAO-MO method has been used in the Hückel approximation to calculate molecular diagrams for pyrazole[13,14], isoxazole[15,16], and isothiazole[17]. The calculations showed that all the 1,2-azoles possess 6π-electron shells, and are therefore heteroaromatic systems. Since different values were used by different workers for the Coulombic and resonance integrals, only qualitative comparison of their molecular diagrams is possible. In all the 1,2-azoles the excess π-electron density is concentrated on the "pyridine" nitrogen and the $C_{(4)}$ atoms, while the second heteroatom bears a positive charge. The π-electron charges on the $C_{(3)}$ and $C_{(5)}$ atoms are either positive or negative depending on the heterocycle and on the parameters α and β. The highest bond orders have been found for the $C_{(3)}-N$ and $C_{(4)}-C_{(5)}$ bonds, and the lowest order for the bond between the heteroatoms. Calculations have also been made by the Pariser–Parr–Pople (PPP)[18,19] and other semi-empirical methods[20]. Especially noteworthy are the calculations which Witanowski et al.[18] made on all three 1,2-azoles by the same method.

More accurate results have been obtained by taking the σ electrons into account[21]. During the 1970s improved methods of calculation, including CNDO/2 have been used to elucidate the electronic structures of pyrazole and isoxazole[22], alkylpyrazoles[23], and phenylisothiazoles[24].

Many experimental characteristics of 1,2-azoles correlate well with quantities calculated by quantum-chemical methods. Thus the LCAO-MO method has yielded values agreeing with experiment for dipole moments[16,25], $\pi \rightarrow \pi^*$ transition frequencies in absorption spectra[14,19], and quadrupole interaction constants in the gas phase[25]. The PPP method gives good results for calculating the first ionisation potential[19] and the π-electron density on the nitrogen atoms[18]; and the CNDO/2 method for determining the total electron density on the "pyridine" nitrogen atom[23] and the carbon atoms[22,26], as follows from determinations of basicity and the hydrogen-1 and carbon-13 chemical shifts. Thus, as for other systems, no single method of quantum chemistry can be recommended for predicting all experimental results.

The literature contains much information on bond lengths and angles in the pyrazole ring, less on the parameters of the isoxazole ring, and hardly any on those of the isothiazole ring[280]. Such data have usually been obtained by X-ray diffraction[27,28] (see diagram); the parentheses in the diagram enclose bond lengths determined for pyrazole by neutron diffraction[29]. A striking feature of the parameters given in the diagram for the pyrazole ring in the crystalline state is the equalisation of carbon–nitrogen and carbon–carbon bond lengths, which indicates smoothing of the difference between "pyridine" and "pyrrole" nitrogen atoms and a high degree

of delocalisation of π bonds. Nevertheless, it has been firmly established that the hydrogen atom forming the nitrogen–hydrogen bond is attached solely to $N_{(1)}$.[29] The nitrogen–carbon bond lengths are close to the length 1.35 Å of the corresponding bond in pyridine; the carbon–carbon bonds in pyrazole are shorter than those in benzene (1.395 Å); and the nitrogen–nitrogen bond is shorter than the sum of the covalent radii of the nitrogen atoms (1.40 Å). All these data are evidence of the stability of the pyrazole molecule, which is confirmed by the chemical reactions of the heterocycle. For the variation in the bond lengths of the ring in the vapour state see Ref. 30.

Bond lengths (in Å) and angles in 1,2-azoles.

Since unsubstituted isoxazole is a liquid, X-ray diffraction has been applied to its crystalline derivatives[28,31], the results of which have given the mean bond lengths and angles indicated in the diagram for the ring. The nitrogen–oxygen bond is noteworthy, for its length (1.42 Å) exceeds considerably the sum (1.36 Å) of the covalent radii. This is clear evidence of the "looseness" and chemical instability of the bond, in good agreement with the chemical behaviour of isoxazole and its derivatives. On the other hand, the $C_{(5)}-O$ bond is shorter than in furan (1.37 Å). The three remaining bonds are similar in their parameters to the corresponding bonds in pyrazole. In contrast to the latter the largest angles in the isoxazole ring (111–112°) are the $N-C_{(3)}-C_{(4)}$ and $C_{(4)}-C_{(5)}-O$ angles. For variation in bond lengths in the rings of arylazoles see Refs. 32 and 33.

2. Basicity and Ionisation Potentials

1,2-Azoles are Hammett bases[34,35], weaker than pyridine. The pK_a values fall in the sequence from pyrazole through isothioazole to isoxazole (respectively +2.5,[36] −0.5,[35] and −3.0[35]), probably as a consequence of increasing polarisation of the bond between the heteroatoms. Isoxazole derivatives are the weakest bases among all 1,2- and 1,3-azoles, with negative pK_a values[35,37–39]. Their basicities have been determined spectrophotometrically: the potentiometric method used previously would give incorrect results.

French chemists have examined the pK_a values for 90 pyrazoles, and found linear relations of the type $pK_a^{calc} = pK_a^0 + \Sigma\Delta pK_m^n$, where pK_a^0 is the value for the pyrazole ring in which the carbon atoms are unsubstituted, while ΔpK_m^n is the effect of a substituent m at position n, which is more correctly characterised by the Hammett σ_{meta} constant[36]. The resulting equations describe the basicity of derivatives of pyrazole and of 1-methyl- and 1-*p*-nitrophenyl-pyrazoles. More complicated correlations have been revealed between basicity and substituent constants in the isoxazole series[37,39].

Pyrazoles in which the nitrogen atoms are unsubstituted are at the same time also weak acids. The acidity of pyrazole itself is extremely slight ($pK_a' \simeq 14$).[40] It is increased by factors of 10^4 when a nitro-group is introduced into the 4 position[41].

The ionisation constants of hydroxy- and amino-derivatives of 1,2-azoles, as well as those of azolecarboxylic acids[42,43], suggest that the azole rings (with the exception of pyrazole at position 4) tend to attract electrons more strongly than does the benzene ring.

The π_3- and n-ionisation potentials of 1,2-azoles and pyridine increase in the sequence[44,45]

pyridine < pyrazole < isothiazole < isoxazole

The N potentials provide an approximate measure of the basicity of these heterocycles, which diminishes in the same sequence.

3. Dipole Moments

A large quantity of data have now accumulated on the dipole moments of pyrazole and isoxazole derivatives: most of the work has been reviewed in Ref. 46. Dipole moments of unsubstituted azoles have been determined from measurements of the dielectric constant in benzene solution[46–48] and from the microwave spectra of the vapours[49–51]; similar results were obtained by the two methods. Special attention must be paid to the necessity of working with dilute solutions of N–H pyrazoles[47,52], owing to the occurrence of association in concentrated solutions. The dipole moments of 1,2-azoles increase on passing from pyrazole to isoxazole, also as a consequence of enhancement of the polarisation of the bond between the nitrogen atom and the other heteroatom. A method proposed recently for calculating dipole moments of azoles gives results that are extremely close to experimental values[53].

Several studies have been made on the influence of substituents on the dipole moments of pyrazole and isoxazole derivatives[48,52,54]. Substituents at position 5 in the ring of isoxazole and 1-methylpyrazole exert a strong influence; a phenyl group has a $+M$ effect in both rings[48,52]. In 1-phenylpyrazole strong $+M$ effects are observed from substituents (amino, chloro, bromo) at positions 3 and 5[54] and from a nitro-group at the *para*-position of the benzene ring[52]. Interesting deductions have been made from the dipole moments (experimental and calculated) of di- and tri-substituted pyrazoles and isoxazoles: a correlation coefficient of 0.982 has been found[48] for 4-substituted 3,5-dimethylisoxazoles between the dipole moment of the group and the Hammett σ_{meta} constants of the substituent. Results for the dipole moments of 4-substituted 3,5-dimethyl(or diphenyl)pyrazoles suggest that structures having a fixed nitrogen–hydrogen bond are present in solution[54].

4. Ultraviolet and Infrared Spectra

The ultraviolet spectra of 1,2-azoles, like those of other five-membered heteroaromatic compounds, contain only absorption bands corresponding to $\pi \rightarrow \pi^*$ transitions[55]. The presence of absorption corresponding to $n \rightarrow \pi^*$ transitions in the spectra of pyrazoles has been a matter of controversy[55,56].

Pyrazole and isoxazole possess similar ultraviolet spectra, but the presence of the sulphur atom in isothiazole leads to absorption at longer wavelengths, as with

other sulphur-containing heterocycles. Most data are available on the spectra of pyrazoles among 1,2-azole derivatives; noteworthy work was done by Grandberg[57] and especially by French chemists, who studied and classified the ultraviolet spectra of 170 pyrazole derivatives[56]. Considerably less work has been done on derivatives of the other 1,2-azoles; mention must be made of a study on the spectra of nitroisoxazoles[58], and also papers on the ultraviolet spectra of substituted isothioazoles[59-61]. The influence of substituents in heterocycles on the position and the intensity of absorption can readily be traced from the ultraviolet spectra. A 4-methyl group causes a bathochromic shift in λ_{max} by 8–9 nm;[56,59,61] the opposite relation—a hypsochromic shift—is observed in the spectra of 3-methylisoxazoles and 5-methylpyrazoles. Such shifts are far larger when acceptor substituents (nitrophenyl groups) are attached to nitrogen in the pyrazoles[56]. Auxochromes (halogen, alkyl, amino) present in a pyrazole ring cause a slight bathochromic shift in λ_{max}; pyrazoles containing chromophoric groups (carbonyl, aryl, nitroso, nitro) absorb at far longer wavelengths (242–282 nm) than occurs in the benzene series[57]. An analogous band in the spectra of alkyl-4-nitroisoxazoles was attributed to conjugation between the nitro-group and the heterocyclic ring[58].

Certain conclusions on conjugation in phenylated azole systems can be drawn from a detailed analysis[16,62] of the ultraviolet spectra of *C*-phenyl derivatives of isoxazole and pyrazole supplemented by spectral data on phenylisothiazoles[59]. In 3- and 4-phenylisoxazoles and in 4- and 5-phenylisothiazoles the benzene ring is conjugated with multiple bonds in the heterocycles. Yet 3-phenylpyrazoles (whether or not *N*-substituted), 3-phenylisothiazole, and 5-phenylisoxazole are single conjugated systems, an effect which is more strongly developed than in biphenyl. Hypsochromic shifts in the spectra of arylpyrazoles observed on passing from mono- to 1,5-di-substituted rings are attributed to diminished conjugation in *C*- and *N*-arylpyrazoles owing to disturbance of coplanarity between the benzene and heterocyclic rings as a consequence of steric interaction between $N_{(1)}$- and $C_{(5)}$-substituents[56,57]. Depolarisation of the Rayleigh scattering indicates[63] that the angle between the planes of the rings in the preferred conformation of 1-phenylpyrazole is 11°; any substituent at position 5 increases the angle and diminishes conjugation. Grandberg et al. studied the fluorescence of 300 pyrazole derivatives[64], and used the spectra to determine the angle between the planes of the rings in 5-substituted 1-phenylpyrazoles[65]. Spectrophotometry has also been employed to investigate steric effects in 4-phenylpyrazoles[66] and 3(5)-arylisoxazole-4-carboxylic acids[67].

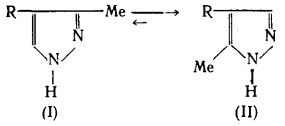
The infrared spectra of unsubstituted 1,2-azoles have by now been quite fully studied[68-73]. In the range 1200 to 1600 cm^{-1} three or four characteristic frequencies of each ring are fairly close to frequencies of the other, although simultaneous consideration of the frequencies permits accurate identification of the heterocycle. Absorption in the region of carbon–hydrogen stretching vibrations (3100 cm^{-1}) of variable intensity, which is observed in unsubstituted azoles, may be greatly strengthened in aryl derivatives[74-76].

Systematic investigations have been made also on the infrared spectra of derivatives of isoxazole[42,69,77-79], pyrazole[80], and isothiazole[61,81,82]. From the results general conclusions have been reached on the influence of the number and nature of substituents on the characteristic frequencies of the rings. For example, the raising of the frequency to 1630–1640 cm^{-1} in the spectra of trisubstituted isoxazoles indicates steric interaction between the substituents; in phenylisoxazoles the coplanarity of the rings is disturbed[69].

Raman spectra have been obtained for 1,2-azoles[71-73] and several of their derivatives[73,81,82]. At the present time hardly any use is made of these spectra for solving structural problems or identifying azoles.

5. Nuclear Magnetic and Quadrupole Resonance Spectra

The rapid development of nuclear magnetic resonance spectroscopy during the 1960s led to the appearance of a large number of papers containing results for 1,2-azoles and their derivatives. These related mainly to ^{1}H n.m.r. spectra of pyrazoles[83-85], isoxazoles[86], and isothiazoles[87], but magnetic spectra were also published for resonance on carbon-13[26,88-90] and nitrogen-14[18] nuclei. In the ^{1}H n.m.r. spectra of 1,2-azoles the signals due to 4-protons appear in the highest fields, whereas those due to the two remaining protons of each heterocycle, located in the immediate vicinity of the electronegative heteroatoms, are displaced down field. Certain difficulties arise in assigning signals from the 3- and 5-protons, especially in pyrazole derivatives. The signals of 3-protons in isoxazoles and isothiazoles are broadened owing to incomplete removal of spin–spin interaction between nitrogen and 3-hydrogen atoms as a consequence of quadrupole relaxation of the nitrogen-14 nucleus[91]. The broadening of the 3-hydrogen signal served as a reference in interpreting the 1H n.m.r. spectra of 4-arylisothiazoles, in which the chemical shifts of the 5-protons may be smaller than those of the 3-protons (on the δ scale)[92]. Assignment of the 3- and 5-proton signals in pyrazole derivatives necessitated the preparation of isomers whose structure had been rigorously established, as in the work of Habraken[66,93]. Under the influence of acceptor substituents the signals due to 3- and 5-protons in the ^{1}H n.m.r. spectra of isothiazoles and especially of pyrazoles may change places: the signals due to 5-protons appear down field[84,85,94,95]. Detailed and systematic studies have been made of this inversion[84,95]. The effects of solvents differing in polarity were used to assign the proton signals: dipolar aprotic solvents exert a very strong influence[84,96], and may shift 5-proton signals down field[84].

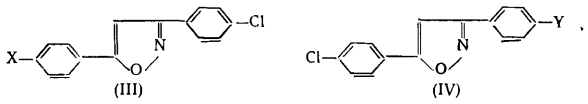


Study of the ^{1}H n.m.r. spectra of arylisoxazoles revealed a linear dependence of the chemical shift of the 4-proton in 3,5-diarylisoxazoles on the Hammett σ_{para} constant at $C_{(5)}$ in the benzene ring[97,98]. Rather earlier a more general relation

$$\delta_4 = \delta_4(s) + \alpha_1 + \alpha_3 + \alpha_5$$

had been discovered in the pyrazole series, in which $\delta_4(s)$ is the chemical shift of the 4-proton of 1,3,5-trimethylpyrazole in a given solvent and δ_4 is the chemical shift of the 4-proton in the substituted pyrazole in the same solvent, while α_1, α_3, and α_5 are the constants of substituents at positions 1, 3, and 5 (they correlate with the Hammett constants)[94].

Spin–spin interaction constants can usually be measured for neighbouring protons in 1,2-azoles[59,85-87]. Their values (1.6–2.3 Hz) are characteristic of all carbon–carbon bonds in azoles other than the $C_{(4)}=C_{(5)}$ bond in isothiazoles ($J_{4,5}$ = 4.5–5.0 Hz). The low values of the constants are probably due to strong polarisation of the bonds of the heteroatoms. The constants $J_{3,5}$ and J_{H,CH_3} are still smaller[99].

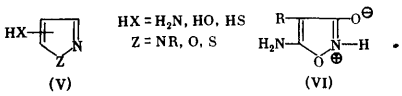


Preferred tautomeric forms and conformations of several substituted pyrazoles in solution have been established from the ^{1}H n.m.r. spectra. Analysing the chemical shifts of ring protons and of methyl groups in *N*-hydro- and *N*-methyl-pyrazoles, Habraken and Moore[93] found that the equilibrium

(I) (II)

is displaced to the right. On the basis of the ^{1}H n.m.r. spectra it is proposed to describe the structure of pyrazolium salts in terms of analogous resonance structures[100].

In contrast to n.m.r. spectroscopy the second type of microwave spectroscopy—nuclear quadrupole resonance—has hitherto been little used for studying derivatives of 1,2-azoles. Only n.q.r. spectra on nitrogen-14 nuclei in pyrazole and *N*-acetylpyrazole have been described; an asymmetry parameter has been found for the "pyrrole" nitrogen atom, which is proportional to the degree of double-bondedness of this atom (~45%).[101] Quadrupole nitrogen-14 nuclear interaction constants have been calculated for pyrazole and isoxazole[102]. Interesting possibilities of the n.q.r. method have been demonstrated by Soviet authors, who find correlations between the chlorine-35 signal frequency and electronic effects of substituents in 3,5-diarylisoxazoles of types



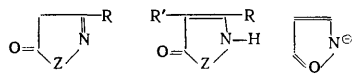
(III) (IV)

which are conjugated systems[103].

6. Tautomerism

This subsection contains a brief account of the tautomerism of hydroxy-, mercapto-, and amino-derivatives of 1,2-azoles, which has been studied by ultraviolet, infrared, and n.m.r. spectroscopy and also by determination of basic or acidic properties. During the past decade Katritzky's reviews and monographs have repeatedly summarised the factual information that has accumulated[11,104,105]. The most recent of these publications[105] gives a clear and concise report on the preferred tautomeric forms of these functional derivatives, but it is based on results that appeared only up to 1968 inclusive, with no references to the work of Soviet scientistis. Below is given a short discussion of the most general data on tautomerism based on work published during 1969–1974.

Azoles containing an amino-group at position 3, 4, or 5, a hydroxy-group at position 3 or 4, or a mercapto-group at position 5 exist as heteroaromatic structures (V)[38,106-110]



(V) (VI)

Equilibrium formation constants of the zwitterions have been calculated for 4-hydroxyazoles[111]; these are the preferred structures for 5-amino-3-hydroxyisoxazoles (VI).[112]

Complicated tautomerism has been observed in azol-5-ones, especially in *N*-unsubstituted pyrazolones[113].

Quantum-chemical calculations for unsubstituted isoxazol-5-one have shown[114] that the Δ^2(C–H) structure (VII)

(VII) (VIII) (IX)

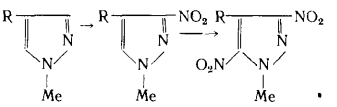
is advantageous, in agreement with experimental results[115]. 3-Substituted dihydro-5-oxoazoles exist in the same form; in the presence of a 4-substituent these compounds exist in the solid state and in aqueous solution as the Δ^3(N–H) form (VIII), and in non-polar solvents the equilibrium is displaced in favour of the C–H structure[106,116-119]. If the 4-substituent is electron-accepting, the oxo-compounds are strong N–H acids: $pK_a < 2$.[120]

The above results show that 1,2-azoles are heteroaromatic compounds, which are characterised by substitution reactions. However, the presence in every azole of a bond between the heteroatoms that differs from the other bonds leads to variation in the stability of the rings in redox reactions. The nitrogen–oxygen bond in isoxazoles should break the most readily. The peculiarities of the heteroaromatic isoxazole system are probably best explained by Kamiya[19]: stabilisation of the π electrons is caused by electrostatic interaction of two oppositely polarised atoms—nitrogen and oxygen (limiting structure IX)—despite the diminished conjugation in the ring.

III. REACTIONS WITH RETENTION OF HETEROCYCLIC RING

Reactions of this type are in considerable measure characteristic of 1,2-azoles as heteroaromatic compounds. They include substitution in the heterocyclic ring and in a side-chain, and also addition to the ring.

1. Substitution in the Ring



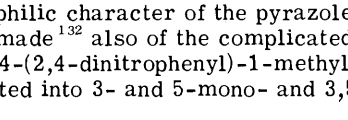
The reactivity indices (localisation energy[14,60], π or total electron density[23,60]) suggest that electrophilic substitution in bases and conjugate acids of pyrazoles and isothiazoles should take place preferentially at carbon atom 4. On the other hand, attack by radicals is directed at positions 5 and 3.[14] For isoxazole the localisation energies indicate preferential substitution at carbon atom 5, independently of the nature of the reactant species; correct conclusions on the direction of attack can be reached on the basis of the calculated π-electron density[15].

(*a*) Electrophilic substitution

Electrophilic substitution is most characteristic of aromatic and heteroaromatic compounds. In the case of nitrogen heterocycles, including 1,2-azoles, the ease of occurrence of such reactions is determined not only by the activity of the reactant species but also by the basicity of the compound and the acidity of the medium. Only in the past decade has study of the reactions of nitrogen-containing heterocycles on the basis of criteria elaborated by Katritzky and Johnson[121] permitted precise establishment of the form (base or conjugate acid) in which the compound reacts. Because of this specific effect it is helpful to discuss separately the electrophilic substitution of 1,2-azoles occurring in strong acids (isotopic exchange of hydrogen, nitration, sulphonation).

Reactions in acid medium (isotopic hydrogen exchange, nitration, sulphonation). In conformity with quantum-chemical calculations and the chemical shifts of nuclei in the n.m.r. spectra, which indicate maximum electron density on the "pyridine" nitrogen atom and carbon atom 4, these are the positions in 1,2-azoles that are attacked by electrophilic species. Attack by a proton on a nitrogen atom gives a protoned base (conjugate acid), whose stability depends on the basicity of the initial azole and the acidity of the medium. Electrophilic substitution at carbon atom 4 then takes place either in the base or in the conjugate acid. Its ease falls in the sequence pyrazole $\gg$ isothiazole $\geqslant$ isoxazole. Thus 4-deuteropyrazole can be obtained by the action of CH_3COOD,[122] but 3,5-dimethylisoxazole undergoes deuterium exchange only under more severe conditions—in a mixture of deuterotrifluoroacetic and dideuterosulphuric acids[123]: both compounds react as the base. On the other hand, the nitration of pyrazole involves the conjugate acid[124]. The first comparative study of the reactivities of 3,5-dimethyl derivatives of *N*-methylpyrazole, isoxazole, and isothiazole towards nitration and isotopic hydrogen exchange in a strongly acid medium was published in 1971.[35] Pyrazole and isothiazole are nitrated as the conjugate acids; deuterium exchange occurs either in the bases or (with an acidity function D_0 exceeding -4.5 to -6.0) in the conjugate acids of these azoles. 3,5-Dimethylisoxazole, the weakest base of the three isosteres, undergoes both reactions as the base. Similar results have been obtained for deuterium exchange in six *N*-methylpyrazoles[125]. French workers[60] have given quantitative data on the reactivities of isothiazole and of its 3- and 5-methyl and 3,5-dimethyl derivatives; their relative rates of nitration are 1 : 2.3 : 4 : 67, i.e. the effect of a substituent is transmitted more strongly from position 5; in 3,5-dimethylisothiazole the effects are non-additive.

Habraken et al.[128–130] and Coburn[131,132] have shown that 1,4-disubstituted pyrazoles (X) can be nitrated at both 3 and 5 positions—compounds (XI) and (XII):

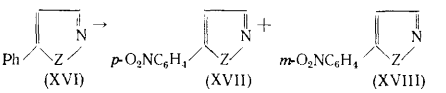


(X) (XI) (XII)

R=Alk, Ar, Br

This unusual orientation on nitration is attributed to the strongly nucleophilic character of the pyrazole ring. A study has been made[132] also of the complicated kinetics of the nitration of 4-(2,4-dinitrophenyl)-1-methylpyrazole, which is converted into 3- and 5-mono- and 3,5-di-nitro-derivatives.

When nitrated in acetic anhydride 5-methyl-1-phenylpyrazole, in contrast to its isomers, gives a mixture of mononitro-derivatives containing 75% of 3-nitropyrazole.[127]. 3(5)-Substituted pyrazoles (XIII) form *N*-nitro-derivatives (XIV), which when heated rearrange into 5-nitropyrazoles (XV):[130]



(XIII) (XIV) (XV)

Nitration of 2-hydroxy-1-methylpyrazole yields, as in the case of *N*-hydroxypyridine, a γ-nitro-derivative, i.e. 5-nitropyrazole[133]. The form undergoing the reaction is the base, for which first-order kinetics is observed in the H_0 range from -5 to -6.5; a dinitro-derivative is also formed in a more acid medium.

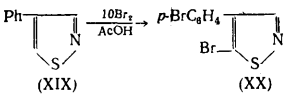
Unusual orientation—at the 5 position—has been observed also in the sulphonation of 4-methylisothiazole[87]. In the isoxazole series no single example has yet been found of electrophilic substitution at carbon atom 3 or 5 in the ring.

Various physical methods have shown the presence of conjugation in *N*-phenylpyrazole, which favours electrophilic attack at position 4 in the pyrazole base, as follows from nitration in acetic anhydride[1] and the action of chlorosulphuric acid in chloroform[134]. In sulphuric acid the conjugate acid—the *N*-phenylpyrazolium cation—reacts,[127] and the substituent enters the *para*-position of the benzene ring[134], which has only 1% of the activity of unsubstituted benzene[127]. Comparative activities towards nitration have been given[135] for substituted *N*-phenylpyrazoles. In sulphuric acid the nitration of *N*-arylpyrazoles is a first-order reaction; disturbance of the coplanarity of the two rings by $N_{(2)}$- or $C_{(5)}$-substituents in the pyrazole ring diminishes the activity of the benzene ring[127].

Numerous papers have appeared on the nitration and the sulphonation of other mono- and poly-phenylated 1,2-azoles; several later publications have reviewed results obtained earlier[24,92,130,136–141]. Substitution in isomeric 3- and 5-phenyl-azoles occurs in the *para*- and *meta*-positions of the benzene ring, usually with predominant formation of *para*-derivatives:

(XVI) (XVII) (XVIII)

An exception is the preferential appearance of *meta*-isomers in the nitration of 3-phenylisothiazole[24] and the chlorosulphonation of 5-phenylisoxazole[135]; both compounds evidently react as the conjugate acids. In 4-phenylazoles the *para*- and *ortho*-positions of the benzene ring are the most active, and dinitro-derivatives are also readily formed[92,130,139].



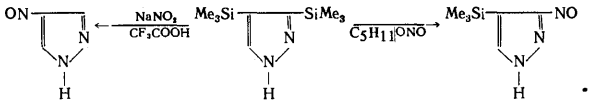
The presence of acceptor substituents in the heterocyclic ring of phenyl-azoles often changes the orientation of an incoming nitro-group[126,142]. Several papers have appeared[129,143,144] on substitution in arylazoles; among such reactions the nitration of 3- and 5-arylisoxazoles has been studied in the greatest detail[144]. With respect to ease of nitration aryl and heterocyclic substituents in arylazoles can be arranged in the sequence—fur-2-yl[145] > pyrazol-4-yl > phenyl $\simeq$ pyrazol-3(5)-yl > pyrazol-4-yl in the pyrazolium cation > isoxazol-4-yl > isothiazol-4-yl > *p*-nitrophenyl.

Halogenation. The nucleophilic character of the pyrazole ring is clearly developed during halogenation. Kinetic investigation of the iodination[146,147] and the bromination[148] of pyrazole and its methyl homologues has established that these compounds react as neutral molecules or conjugate bases. Isoxazole derivatives are halogenated in non-protonated form not only in acetic[2] but also in sulphuric[149] acid.

Treatment with molecular chlorine or bromine in water or an organic solvent yields 4-halogeno-derivatives of all 1,2-azoles[1,2,118]. With the less active isoxazoles and isothiazoles, however, the reaction is slow and incomplete. The iodination of 1,2-azoles, including pyrazole, goes similarly. The use of buffered solutions is sufficient to obtain 4-iodopyrazole[146,147], but the iodination of isoxazoles goes smoothly only in the presence of nitric acid[2]. Whereas in pyrazoles a halogen atom can be introduced at any position in the ring (to obtain trihalogeno-derivatives

it is convenient to use silver salts of pyrazoles[150]), with isothiazoles halogenation at positions 3 and 5 is exceptional[10,92]. Alkyl- and aryl-pyrazoles undergo thiocyanation at position 4 in the ring[151].

The greater selectivity of halogen molecules and ions than of the nitryl ion results in diverse products of the halogenation of phenylazoles. The aggregate effect of several factors—the activity of the halogen species, the electron density on the carbon atom involved, the energetic advantage of the transition state (intermediate compound)—probably determines the direction of attack. Complexes formed by azoles with halogens undoubtedly have an important role in halogenation. The process is most unambiguous with phenylisoxazoles: in all cases only 4-halogenoisoxazoles have been obtained, uncontaminated by isomers[2]. Among pyrazoles and isothiazoles examples are known in which halogenation occurs even in the benzene ring of the phenylazoles[92,152]:

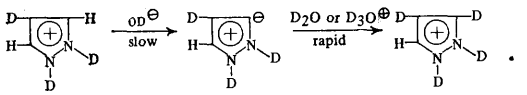


(XIX) (XX)

The bromination of phenylisoxazoles in aqueous acetic acid is a second-order reaction[153]. The activity of the isoxazole ring is significantly greater than that of benzene, and is determined by the nature and the position of substituents in the ring.

Other electrophilic substitutions. Pyrazoles and isoxazoles undergo hydroxy- and chloromethylation at the 4 position in the ring[1,2]. Carbonium ions, in contrast, attack the heterocycle at the nitrogen atom to form isoxazolium cations[154,155]. The highly nucleophilic character of the pyrazole ring is confirmed by the possibility of thermal and Friedel–Crafts acylation[1], and also Vilsmeier formylation[156]. Derivatives of isoxazoles do not undergo Friedel–Crafts acylation[157].

The presence of a labile carbon–silicon bond in a pyrazole derivative (XXI) enables a nitroso-group to be introduced at position 3 or 4 of the non-activated ring (XXII and XXIII):[158]



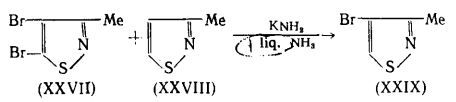
(XXIII) (XXI) (XXII)

Among isothiazoles only the 3,5-bismethylthio-derivative undergoes nitrosation[159].

(*b*) Protophilic substitution

At the present time protophilic substitution of hydrogen includes isotopic exchange in the presence of bases and metallisation by alkali-metal compounds[160]. The reactions involve intermediate formation of carbanions after detachment of a proton.

Only during recent years have studies been made on basic hydrogen exchange in pyrazole[122,161] and isothiazoles[10,162] catalysed by CH_3C^- and OD^- ions. The reaction involves the hydrogen atoms at positions 5 and 3. Isotopic exchange of the 5-proton in isothiazoles is a second-order reactions[162]. In the isothiazolium cation both protons are exchanged at high rates ($k \simeq 10$–6000 $M^{-1}\ s^{-1}$), but the 5-proton always the more rapidly[163]. Kinetic investigation of the deuteration of pyrazole has shown[161] that the reaction velocity is independent of the pD value; a mechanism with intermediate formation of an ylid was suggested:



(XXIV) (XXV) (XXVI)

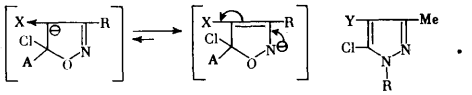
In pyrazole and isothiazole derivatives the 5-proton is always the most easily detached by n-butyl-lithium[10,164,165]. In monosubstituted isoxazoles strong bases attack the 3-proton first, and the resulting carbanion immediately rearranges into an open-chain enolate anion (see below). 3,5-Disubstituted isoxazoles containing functional groups (alkoxy, alkylthio, chloro) can be metallated at the 4 position[166,167].

The great reactivity of lithium derivatives of azoles has enabled many syntheses to be made. Organometallic synthesis is especially valuable for introducing various substituents at position 5 in the isothiazole ring[10,165,168], since the most widely used methods for obtaining isothiazoles yield 3- and 4-derivatives[10]. During this reaction such reactive groups as cyano and carboxy at position 4, as also halogen atoms, remain unaffected[10], which indicates the high kinetic acidity of the 5-proton in the isothiazole ring, and is fully consistent with kinetic data for isotopic hydrogen exchange.

The interesting migration of halogens from the 5 to the 4 carbon atom in 5-halogenoisothiazoles on treatment with potassamide in liquid ammonia is due to the greater stability of the isothiazol-5-yl than of the isothiazol-4-yl anion[169]. This was explained by a five-stage mechanism, supported by the quantitative debromination of the 4,5-dibromoisothiazole (XXVII) by the unsubstituted compound (XXVIII) to the 4-bromoisothiazole (XXIX):

(XXVII) (XXVIII) (XXIX)

A similar mechanism to the above reactions underlies that reported by Begtrup between pyrazolium salts and sodium hydride in the presence of oxygen or sulphur, with intermediate formation of an ylide of type (XXV) to yield pyrazolones or pyrazolethiones respectively[170,171].



(*c*) Nucleophilic substitution

Reactions involving nucleophilic substitution by an S_N2 mechanism have been reported mainly for halogeno-derivatives of 1,2-azoles. In contrast to the inert 3- and 5-halogenopyrazoles and 5-halogenoisothiazoles, the isoxazole analogues undergo such reactions when heated to 100°C.[2,172] A 3-nitro-group in isoxazoles is also readily substituted by hydroxy- and alkoxy-groups[173,174]. Reaction with copper(I) cyanide has great value for the preparation of isothiazole derivatives; 5-bromoisothiazoles react more readily than do the 4-isomers[10].

Introduction of an electron-accepting 4-substituent increases appreciably the mobility of a 5-halogen, especially in the isoxazole ring[1,2,10,118,175,176]. Even the two nitro-groups in 4-bromo-1-methyl-3,5-dinitropyrazole activate the halogen atom[131] far more weakly than the benzoyl substituent in 4-benzoyl-5-chloroisoxazoles[2].

The ^1H n.m.r. spectra of 4-nitro-azoles indicate that unreactive molecules have approximately equal electron densities on the 5-carbon atom. Therefore the decisive

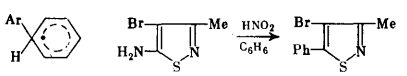
factor for easy occurrence of S_N2 reactions in the isoxazole series should be a lower activation energy, whose magnitude is undoubtedly governed by formation of the transition state (XXX). Isomerisation of the carbanion (XXX) into the energetically favourable anion (XXXI) is promoted by strong polarisation of the nitrogen–oxygen bond in the heterocycle:

(XXX) (XXXI) (XXXII)

Nucleophilic substitution takes place readily also in 3-halogenoisoxazolium [177] and 3- and 5-halogenopyrazolium [178] cations.

Kost and Grandberg [1] studied the kinetics of the action of excess of hexamethyleneimine on 5-chloropyrazoles of type (XXXII). Under the given conditions the reaction was pseudounimolecular. The influence of substituents Y diminishes in the sequence

$$NO_2 \gg C_6H_5N : N > C_6H_5CO \gg Br > H .$$



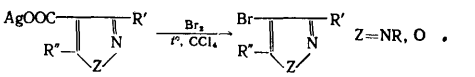
(*d*) Homolytic substitution

Arylation. It was established during the 1960s that arylation takes place by the same mechanism involving a σ complex (XXXIII) independently of the source of the radicals. Results obtained on the phenylation of 1-methyl- and 1-phenyl-pyrazoles and of isothiazole and its methyl homologues have been summarised in a French review on the homolytic arylation of heterocycles [179]. Decreasing rates of phenylation in a neutral medium give the sequence

$$\text{4-MeIth } (1.85) > C_6H_6\ (1) \simeq \text{Ith } (0.95) > \text{3-MeIth } (0.65) \simeq \text{1-MePyr } (\sim 0.6) > \text{5-MeIth } (\sim 0.3)$$

where Ith and Pyr represent isothiazolyl and pyrazolyl respectively. Individual positions in the heterocyclic ring differ greatly in activity: in isothiazole the carbon atoms 3 and 5 are attacked by the phenyl radical five times as frequently as carbon atom 4; in 1-methylpyrazole attack occurs almost exclusively at position 5. In *N*-phenylpyrazole reaction occurs to ~55% at the *ortho* position of the benzene ring and 30% at the 3-carbon atom of the pyrazole.

The reverse reaction to arylation—attack on aromatic compounds by azolyl radicals—has been reported in several papers [180–182]. Such a reaction has been used [10] to obtain 4- and 5-phenylisothiazoles from the corresponding amines, e.g. (XXXV) from (XXXIV):



(XXXIII) (XXXIV) (XXXV)

Organometallic compounds from halogeno-azoles. During the past decade a radical mechanism has been firmly established by various methods for the reaction of halogeno-derivatives with magnesium, and also for the exchange of organo-magnesium and -lithium compounds with halides, which occurs "in a cage".

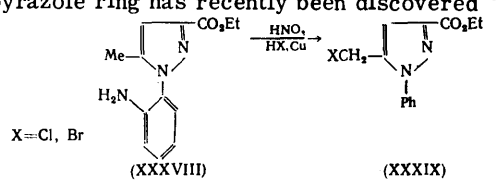
Halogeno-derivatives of pyrazole and isoxazole do not react with magnesium except in the form of another Grignard reagent [1,2]. The activities of halogenopyrazoles fall in the sequences 5-Hal > 4-Hal >3-Hal and I > Br > Cl. [1] The same rules apply to isoxazole derivatives [2,183], with the exception of 5-halogenoisoxazoles, whose reactivities have not been finally elucidated. As noted above, pyrazol-5-yl- and isothiazol-5-yl-lithium can be obtained by direct metallisation. Exchange therefore finds application in the preparation of 4-derivatives of pyrazole [1] and isoxazole [184] that cannot be obtained in other ways, e.g. 4-deuteroisoxazoles.

Other homolytic reactions. Diazo-reactions, which probably occur by a radical mechanism, have proved especially important for obtaining 5- and 4-halogenoisothiazoles by the Sandmeyer reaction [10]. During recent years 3(5)-halogeno-derivatives of pyrazole and isoxazole have been obtained by the diazo-reaction; for the reaction to proceed normally the ring must contain electron-accepting substituents, which enhance the stability of the diazo-compounds [185–187].

The Borodin–Hunsdecker reaction also takes place by a free-radical mechanism. It has been used to convert *N*-substituted pyrazole-4(5)-carboxylic [1,152] and isoxazole-4-carboxylic [188] acids into bromo-derivatives:

(XXXVI) (XXXVII)

The isomeric pyrazole-3-carboxylic acids do not react, and isoxazole-3(5)-carboxylic acids decompose [188]. Isoxazol-3(5)-yl radicals are probably unstable, and isomerise with cleavage of the ring [189].



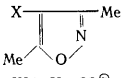
2. Substitution in a Side-chain

(*a*) Preparation and reactions of halogeno-derivatives

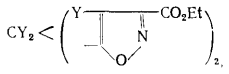
Two different methods—halogenomethylation and the halogenation of methyl groups—can be used to obtain halogenomethyl-azoles, which find widespread application for the preparation of various derivatives. The latter method can be regarded as effective only for the selective introduction of one or two halogen atoms. Therefore chlorination in acetic acid is not employed for this purpose, for it yields mixtures of chloro-derivatives of pyrazole [1] and isoxazole [190]. In polymethyl-azoles methyl groups are completely chlorinated at positions 5 and 3, but not at 4. This reaction must therefore be regarded as electrophilic substitution at a saturated carbon atom.

N-Bromosuccinimide, which reacts by a radical mechanism, is most convenient for obtaining monohalogenomethyl-azoles. Great differences in the activity of methyl groups are observed depending on the nature of the heterocycle, the position of the groups in the ring, and other substituents. The reactivity of methyl groups in different positions in isoxazole derivatives falls in the sequence $C_{(4)} > C_{(5)} \gg C_{(3)}$; [2,191] the reaction is completely inhibited by strong acceptors of electrons (nitro, benzoyl). In the isothiazole series, on the other hand, a 3-methyl group is highly active: mono-, di-, and tri-bromo-derivatives can be obtained by the action of *N*-bromosuccinimide, with no bromination of the heterocyclic ring [10,192].

An unusual homolytic halogenation of a 5-methyl group in the pyrazole ring has recently been discovered [193]:



(XXXVIII) (XXXIX)

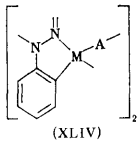


Nucleophilic substitution of the halogen atom in halogenomethylated azoles has been used to obtain physiologically active compounds, especially amines, in the isoxazole [2,194] and isothiazole [10,195] series. Dihalogenoazoles are converted smoothly into aldehydes either by direct hydrolysis or with preliminary formation of intermediate products [2,10,196].

(*b*) Protophilic substitution

Isotopic hydrogen exchange. Such exchange in the presence of bases has been studied mainly in azoles containing methyl groups and acceptor substituents in adjacent positions. Deuterium exchange catalysed by the OD^- ion has been accomplished [10] only in methylisothiazoles. The activity of methyl groups falls in the sequence of positions 5 ≫ 3 > 4, with relative rate constants $10^2 : 1 : 10^{-4}$. In the isoxazole series deuterium exchange in methyl groups has been investigated in the 4-substituted 3,5-dimethylisoxazoles (XL)–(XLII) [197,198] and in diethyl methanebis-5-isoxazole-3-carboxylate (XLIIIa) [199]

(XL), X = $CO_2^{\ominus}$;
(XLI), X = C_6H_5N : N
(XLII), X = NO_2;

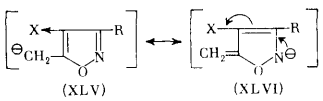


(XLIII) a) Y = H,
b) Y = D

Under the most severe conditions (catalysis by the OD^- ion) reaction occurs in the carboxylate anion (XL). Isotopic hydrogen exchange is greatly facilitated in compounds (XLI) and (XLII), and the rate could not be measured for the reaction of the nitroisoxazole (XLII) with *N*-deuterodiethylamine. Entry of deuterium into the 5-methyl groups was demonstrated by ^1H n.m.r. spectroscopy for all three compounds. Only the ^1H n.m.r. spectrum will reveal instantaneous deuterium exchange in compound (XLIIIa), which yields (XLIIIb) via methineisoxazoles.

Metallation. The metallation of methyl groups by butyl-lithium and organometallic synthesis from the resulting lithium derivatives have been reported in the isoxazole [165,166,200–203] and pyrazole [164,165] series. In methylisoxazoles a 5-methyl group always reacts, being more active than the 4-proton, but in methylpyrazoles an *N*-methyl group reacts. The influence of the 1-heteroatom is clearly evident here: it carries a definite positive charge, and governs the kinetic acidity of adjacent protons. In pyrazole derivatives the activity of individual positions and substituents diminishes in the sequence 5-H > *N*-C_6H_5 > *N*-CH_3, 5-CH_3 ≈ 5-Cl.

In contrast to methylpyridines, in which selective metallation can be achieved by the use of various reagents, 3,5-dimethylisoxazole reacts with any strong base only at the 5-methyl group. Treatment with metal amides followed by alkyl halides gives good yields of 5-n- and 5-iso-alkylisoxazoles [204], as well as di- and tri-isoxazolylalkanes [205].



(XLIV)
M = Pd, Mn, Rh, Ir

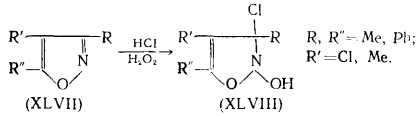
During recent years selective metallation of *N*-phenylpyrazole in the *ortho*-position of the benzene ring has been accomplished not only with ethylmagnesium bromide [206] but also with compounds of heavy metals [207–209], which gives rise to intramolecular complexes of type (XLIV).

Condensation. Most of the condensation reported for methyl derivatives of 1,2-azoles are catalysed by bases and can also be included among protophilic substitutions (for the condensation of 5-methylisothiazole in acetic anhydride see review [10]). Selective activation of a 5-methyl group is achieved in the presence of an electron-accepting substituent at position 4 in the heterocycle. The most marked effect is observed among the isoxazole derivatives (XL) and (XLII); the catalysts and conditions of condensation are similar to those discussed above for deuterium exchange [2,210]. 5-Methyl-4-nitroisothiazoles react with aldehydes under more severe conditions [10], but 3,5-dimethyl-4-nitropyrazole does not condense at all with aldehydes in the presence of amines [1].

Michael addition of activated methylene and methyl groups in isoxazole derivatives has also been described [2,199]. In 1,2-azolium cations 3-methyl groups are also active [1,2].

Results for protophilic substitution in methyl groups indicate that 5-methylisoxazoles tend to form isoxazol-5-ylmethyl anions (XLV). This occurs especially readily in the compounds (XL)–(XLII), in which X is an electron-accepting substituent. They obviously contain a localised $C_{(4)}=C_{(5)}$ bond, which transmits the effects of substituents. However, the low activation energy, associated with resonance stabilisation of the resulting carbanion

(XLV) (XLVI)

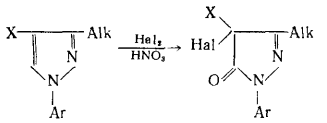


is probably the decisive factor in the ready occurrence of protophilic substitution.

3. Addition to the Heterocyclic Ring

Reactions involving addition have been studied far less thoroughly than those involving substitution. Here we shall consider only reactions which enable di- and tetrahydro-derivatives to be obtained, as well as those in which isomerisation into 3*H*- or 4*H*-pyrazoles takes place.

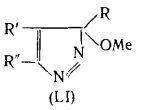
(*a*) Electrophilic addition



In 1964 Sokolov and Kochetkov described the first reaction involving addition to the isoxazole ring [211,212], in which hypochlorous acid adds at the $C_{(3)}-N$ bond of the heterocycle (XLVII) to form 3-chloro-2-hydroxy-Δ^4-isoxazolines (XLVIII):

(XLVII) (XLVIII)

R, R″ = Me, Ph;
R′ = Cl, Me.

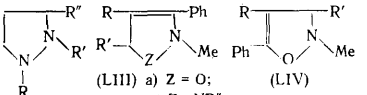


Under corresponding conditions 3-alkyl-*N*-(2,4-dinitrophenyl) pyrazoles react with hypohalous acids at the $C_{(4)}=C_{(5)}$ bond with intermediate formation of 4-halogeno-5-hydroxy-Δ^2-pyrazolines, which undergo further oxidation to the pyrazol-5-ones (L):[213,214]

(XLIX) (L)

Ar=2,4-$(O_2N)_2C_6H_3$; X=Br, Cl, Me; Hal=Br, Cl.

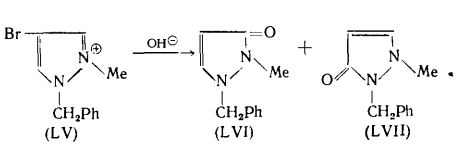
The unstable structure of 4-alkyl-4-bromopyrazoles is confirmed by ^{1}H n.m.r. spectroscopy for products of the reaction of 3,4,5-trialkylpyrazoles with bromine or *N*-bromosuccinimide[215,216]. In the presence of methanol 3*H*-pyrazole derivatives



(LI)

are formed.

In all the above reactions the attacking halogen-containing species are evidently electrophilic. Dichlorocarbene, which is also an electrophile, reacts with the ring of 3,4,5-trimethylpyrazole to give a whole range of products, including a quite stable 4*H*-pyrazole derivative[217].

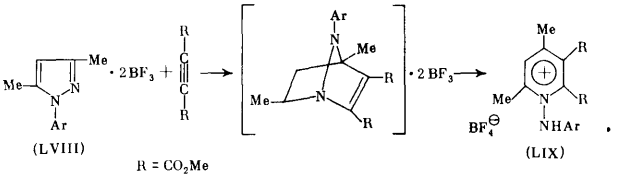


(*b*) Nucleophilic addition

Like quaternary salts of various nitrogen heterocycles 1,2,3-substituted pyrazolium and isoxazolium cations readily add hydride ions. Sodium tetrahydroborate reduces pyrazolium ions to pyrazolidines (LII),[218-220] whereas reduction of isoxazolium ions usually halts at the stage of formation of Δ^3- and Δ^4-isoxazolines (LIIIa) and (LIV).[221] Δ^3-Pyrazolines (LIIIb) can be obtained by means of lithium tetrahydroaluminate[218]. Adachi et al.[222,223] have been able to add carbanions from organomagnesium compounds to 3*H*- and 5*H*-isoxazolium ions at 0°C to form (LIIIa) and (LIV). Under the same conditions secondary amines also add to the 5-carbon atom in the 5*H*-isoxazolium ion[222].

(LII) (LIII) a) Z = O; b) Z=NR". (LIV)

An interesting reaction involving addition and elimination begins with attack by the hydroxide ion at positions 3 and 5 in the cation (LV) followed by detachment of hydrogen bromide to give the pyrazol-3- and -5-ones (LVI) and (LVII):[224]

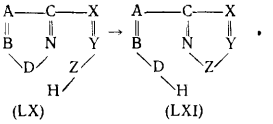


(LV) (LVI) (LVII)

(*c*) Molecular addition

Catalytic hydrogenation, which can be regarded as a homolytic process, yields di- and tetra-hydro-derivatives only in the case of pyrazoles[1]: the isoxazole and isothiazole rings undergo hydrogenolysis under these conditions (see below). Electrochemical reduction of the $C_{(4)}=C_{(5)}$ bond in the pyrazole ring has also been described[225].

In 1974 the possibility was discovered of effecting diene synthesis in the pyrazole series, catalysed by boron trifluoride[226]:

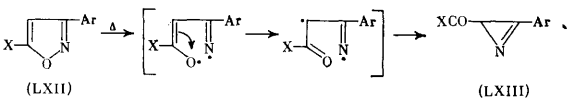


(LVIII) R = CO_2Me (LIX)

IV. REACTIONS WITH CLEAVAGE OF HETEROCYCLIC RING

Reactions of isoxazole derivatives accompanied by cleavage of the heterocyclic ring have found widespread application in organic synthesis. The numerous publications on this topic have been systematically surveyed in the reviews of Nishiwaki[3] and Subrahmanyam[4], which are complementary: the former covers syntheses of various heterocycles based on isoxazoles, and the latter the preparation of peptides and carbocyclic systems, including steroids and terpenes. The following account will make considerable use of these reviews, with references only to the main publications covered, as well as to papers that have appeared since.

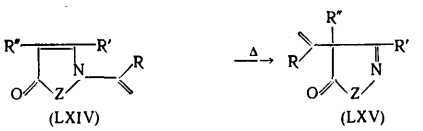
1. Rearrangement



Rearrangements of isoxazole derivatives, the greatest contribution to whose study has been made by Adachi and Kano[3], had already become known by the end of the 1930s. More recently data have been summarised[227] on one of the rearrangements, termed[227] "monocyclic" and occurring under the influence of bases:

(LX) (LXI)

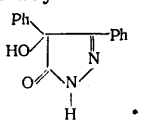
The conversion of isoxazoles into furazans, 1,2,3- and 1,2,4-triazoles, and tetrazoles takes place by the same mechanism.



Nishiwaki made a detailed study of the thermal isomerisation of isoxazoles (LXII) containing alkoxy, alkylthio, or amino at the 5 position[3]. In contrast to 3,5-dialkyl(or aryl)isoxazoles these compounds are converted at 150–230°C into azirine derivatives (LXIII):

(LXII) (LXIII)

Komendantov and Bekmukhametov have discovered a catalytic isomerisation of 5-methoxy-3-phenylisoxazole[228], for which they suggest homolytic fission of the nitrogen–oxygen bond with intermediate formation of biradicals[3], which is supported by kinetic results[228]. Reactions of (LXII) with arylamines and trialkyl phosphites also involve formation of azirine derivatives[3].

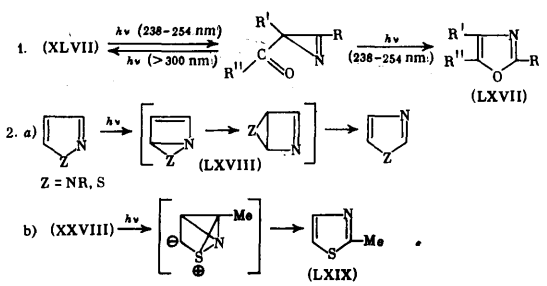


N-Allyl-azol-5-ones (LXIV) when heated undergo an amino-Claisen rearrangement through a cyclic transition state into 4-allyl-azolones (LXV),[229,230] with inversion of the allyl group:

(LXIV) (LXV)

Z=NPh, O

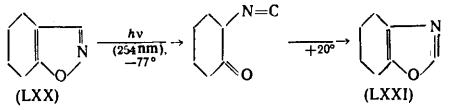
Among alkali-catalysed rearrangements note must be taken of the acyl–lactone rearrangement of 4-acylisoxazol-5-ones [2,231] and the oxidation of 4-hydroxy-3,5-diphenylpyrazole to the acylion [232]



(LXVI)

The mechanism of the latter complicated process has not yet been established.

The lability of the isoxazole ring is evident also in the rearrangement accompanied by fragmentation occurring when di(or tri)alkylisoxazoles are treated with diphenylcyclopropenone [3].

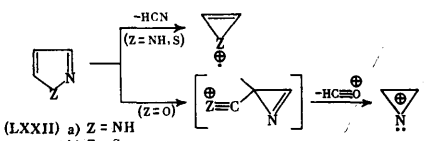


2. Photolytic Isomerisation

Whereas heating and chemical reagents cause rearrangement mainly of isoxazole derivatives, exposure to ultraviolet radiation causes the isomerisation of all 1,2-azoles, on which the first publications appeared during the mid-1960s. From the vast quantity of information that has now accumulated we must single out results on the isomerisation of pyrazoles [233,234], isoxazoles [3,235], and isothiazoles [236–238]. Photorearrangements of 1,2-azoles can occur in two ways—(1) ring contraction–expansion (XLVII) ⇌ (LXVII) [3] or (2) ring isomerisation through (*a*) bicyclic transition states (LXVIII) or (*b*) intermediate zwitterions (XXVIII) → (LXIX):

Isomerisation of pyrazoles into imidazoles sometimes also follows the first route [234], but such rearrangement usually takes place according to Scheme 2*a*. [233,234] Modes of transition of isothiazoles into thiazoles are the most diverse, owing to the tendency of the sulphur atom to form a sulphonium ion, but path (1) is not followed at all by isothiazoles.

The course of the photoisomerisation of 1,2-azoles may vary depending on the nature and the position of substituents in the heterocycles. Thus, whereas 5-amino-3-phenylisoxazoles are converted into the corresponding oxazole derivative, aminoisoxazoles unsubstituted at the 3 position rearrange into acyclic compounds [3]. Photoinduced attack by the solvent on intermediate products of the isomerisation of isoxazoles also yields polyfunctional acyclic compounds [3,239]. In 1973 a novel photoisomerisation was discovered, of the isoxazole (LXX) into the oxazole (LXXI) via a β-keto-isocyanide [3]:



(LXX) (LXXI)

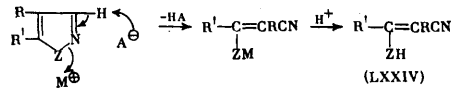
As a result of photoinduced redox reactions *N*-*o*-nitrophenylpyrazoles are converted into *N*-oxides of benzotriazoles [240].

3. Mass Spectra of 1,2-Azoles

The first bonds to break under mass-spectroscopic conditions are the most unstable, which in 1,2-azoles are those between the heteroatoms. Indeed, the most intense peaks in the mass spectra of the unsubstituted azoles

(LXXII) a) Z = NH
b) Z = S
c) Z = O

are due to the molecular ions and the $[M-HCN]^+$ ions for pyrazole [241,242] and isothiazole [243] or $[M-HCO]^+$ ions for isoxazole [244]. Removal of the ring carbon atom 3 (or 5) has been proved [242] for such fragmentation of pyrazole. The molecular ion of isoxazole (LXXIIc) is the least stable [244]. As with other isomerisations, an intermediate azirine derivative (LXIII) is formed here. Conversion of 5-substituted isoxazoles into azirine derivatives under the influence of electron bombardment has been studied by Nishiwaki [245] in comparison with corresponding thermal and photoinduced isomerisations.



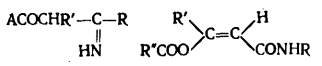
Differences in behaviour are observed between *C*-methyl homologues of pyrazole and isothiazole and of isoxazole: whereas in the first two series a hydrogen atom is removed from the methyl groups of the molecular ions with the formation of six-membered rearranged ions [61,241,243], the molecular ions of methylisoxazoles first undergo rupture of the cyclic nitrogen–oxygen bond [246]. The position in the ring of the substituent in the isomeric monomethylisothiazoles can be determined from the mass spectra [243]. In contrast, the peaks due ionic fragments in the mass spectra of three dimethylpyrazoles differ only in intensity [241]. The stability of the pyrazole ring on electron impact (the quantity W_M) falls in the sequence pyrazole > 1-methylpyrazole > 3(5)-methylpyrazole.

The fragmentation of phenyl derivatives has been discussed in several papers [184,243,247,248]. Isomeric arylphenylisoxazoles can easily be distinguished by their mass spectra [249].

4. Nucleophilic Cleavage

The numerous studies of various aspects of the nucleophilic cleavage of 3*H*-isoxazoles (LXXIIIa) and of the 5*H* isomers, which was discovered as early as 1891, have been summarised in reviews [2,7,8]. Nucleophilic fission of the pyrazole ring unsubstituted at the 3 position (LXXIIIb)

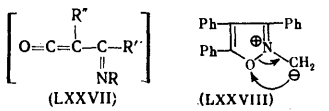
is possible under severe conditions [250,251]. The scission products of isoxazoles and pyrazoles are respectively β-keto-nitriles (LXXIVa) and β-aminoacrylonitriles (LXXIVb):



(LXXIII) a) Z = O, b) Z = NR
M = Na, K; A = OH, OR'' .

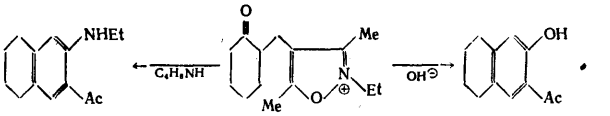
The products (LXXIVa) are used in organic synthesis [2,4,154].

Electron-acceptor substituents diminish the electron density on the 3-carbon atoms and facilitate nucleophilic cleavage. Thus potassium t-butoxide affects ring opening only in 1-phenylpyrazoles containing benzoyl, cyano, or toluene-*p*-sulphonyl at position 4.



Pino et al. established the mechanism of the cleavage of isoxazoles [2,252]. Overall the reaction has kinetic second order; for the isomerisation of 5-arylisoxazoles a good correlation has been found between $\lg K$ and σ ($\rho = 0.51$, $r \simeq 1$). The nucleophilic cleavage of pyrazoles probably has the same mechanism.

3,4-Disubstituted isoxazoles open with greater difficulty in the presence of bases; 5-methylisoxazole cleaves more rapidly than the 3-isomer [252] by a factor of 14. A review [2] has given different decomposition paths for such compounds, which depend on the stability of the intermediate product (LXXV).

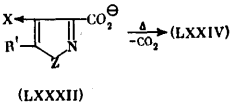


(LXXV) (LXXVI)

In isoxazolium and isothiazolium cations the acidity of the 3-protons has so increased that ring cleavage takes place under mild conditions. 2-Alkylisothiazolium salts on treatment with hydroxide ions at 20°C break down with the formation of resins [253]. The action of weaker nucleophiles is often accompanied by recyclisation into 1,2-azoles [10]. Ring opening takes place in 3*H*-isoxazolium ions even under the influence of carboxylate anions. The true mechanism of this multistage reaction was established by Woodward and Olofson by spectroscopic methods [254]. The enolic esters (LXXVI) formed during the reaction, which possess strong acylating power, have found application in the synthesis of peptides [4,255,256] and nucleotides [257] and in the modification of enzymes [258]. These esters are easily reduced by sodium tetrahydroborate, which forms the basis of a new method for preparing alcohols from acids [259].

(LXXVII) (LXXVIII)

Cleavage of 5*H*-isoxazolium can occur either in the presence of a strong base with detachment of the 5-proton and formation of the keten (LXXVII) or with addition of a weaker base (phenylhydrazine) to the 5-carbon atom followed by transcyclisation [3]. In the case of tetrasubstituted isoxazolium ions the direction of ring opening and subsequent reactions is determined by the nature of the substituents. Treatment of 2-methyl-3,4,5-triphenylisoxazolium with alkali forms 4,5,6-triphenyl-2*H*-1,3-oxazine, presumably via the ylid (LXXVIII). [2,3] Transformation of the heterocycle in the cation (LXXIX) has a completely different course: this compound can be selectively converted into functional derivatives of tetralin (LXXX) and (LXXXI): [4,260]



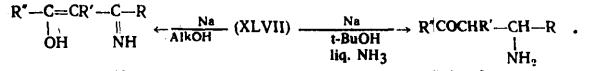
(LXXX) (LXXIX) (LXXXI)

This reaction has been used also for the synthesis of terpenes [260].

Ring opening is probably a consequence of attack by the base on the nitrogen atom. A similar cleavage mechanism—nucleophilic substitution at the sulphur atom—is assumed for the action of butyl-lithium on (XXVIII). [10,165]. The sulphur–nitrogen bond in 3-hydroxyisothiazoles has proved very labile: it is broken not only by carbanions but also by cyanide ions [10]. The ring in 3-chloro-4-nitroisothiazole is also opened by amines [261].

The decarboxylation of isoxazole-3-carboxylic acids is akin to nucleophilic ring cleavage in 3*H*-isoxazoles, since the same β-keto-nitrile products (LXXIVa) are formed. No special investigation has been made of the reaction mechanism, but intermediate formation of a zwitterion can be assumed [2]. The carboxylate anions formed in solution or in the presence of arylhydrazines are decarboxylated under milder conditions:

(LXXXII)



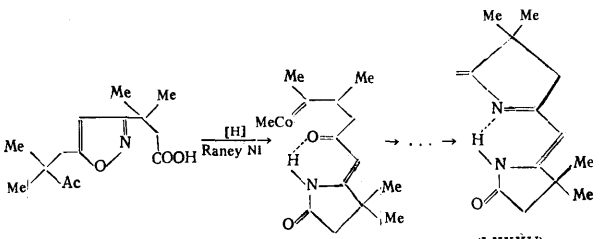
a) Z = O; b) Z = NPh; X = R .

The presence of an electron-accepting 4-substituent in the acid (LXXXIIa) so facilitates decarboxylation that it occurs even on alkaline hydrolysis of the esters; this reaction was used by Woodward et al. in synthesising polycondensed systems [4]. In boiling quinoline ring cleavage takes place even in the pyrazole analogues (LXXXIIb). [262]

5. Reductive and Oxidative Cleavage

The labile nitrogen–oxygen bond in the isoxazole ring is ruptured by very many reducing and oxidising agents. The behaviour of isoxazole derivatives is determined by the reaction conditions and the comparative activities of this bond and multiple bonds in a side-chain. In the absence of functional groups in a side-chain, for example, even lithium tetrahydroaluminate destroys the isoxazole ring [263]. An exocyclic double bond, on the other hand, can be subjected to ozonolysis without affecting the heterocycle [264].

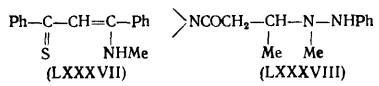
Reductive cleavage of alkali-stable 3,4,5-trisubstituted isoxazoles (XLVII) by the action of sodium in alcohols yields β-imino-ketones (LXXXIII), [2] but reaction with t-butyl alcohol in liquid ammonia gives β-amino-ketones (LXXXIV): [265]



(LXXXIII) (LXXXIV)

Vinyl ketones [266] and β-diketones [204,205] can also be obtained.

It has been established during recent years that the acidity of the medium is a decisive factor in the selective hydrogenation of alkenylisoxazoles. Use of palladium as



catalyst in an acid medium enables hydrogenation to be confined to the double bond in the side-chain[260,267]. In an alkaline medium, on the other hand, the cyclic nitrogen–oxygen bond is easily ruptured[4,268]. Applying this reaction to 4-chloromethylisoxazoles[269], Stork et al. developed a method for building up cyclohexanone rings in polycyclic systems[4] and used it to accomplish a complete synthesis of *dl*-*D*-homotestosterone[4,270]. The method of annellation has been further developed for the synthesis of steroids by Scott et al.[268,271,272] Numerous carbocyclic[4,273-275] and heterocyclic[3] systems have also been obtained from the hydrogenolysis products. An elegant method for obtaining semicorrins (LXXXV), devised by two groups of chemists[276,277] using the same polyfunctional isoxazole derivative (LXXXVI) as starting material,

(LXXXVI) (LXXXV)

can rightly be regarded as a great success for this trend in the synthetic use of isoxazoles. The electrochemical reduction of phenylisoxazoles, in contrast to that of pyrazoles, also leads to rupture of the heterocyclic nitrogen–oxygen bond[278].

Individual products cannot be obtained by the catalytic hydrogenation of isothiazole derivatives[10]. On the other hand, the 2-methyl-3,5-diphenylisothiazolium ion can be easily reduced by benzenethiol to the 2-aminovinyl thioketone (LXXXVII).[253] 5-Amino-2-methyl-1-phenylpyrazolium cations are reduced by lithium tetrahydroaluminate with rupture of the $N_{(1)}-C_{(5)}$ bond to β-hydrazino-amides (LXXXVIII).[219]

(LXXXVII) (LXXXVIII)

The course of the oxidation of 1,2-azole derivatives depends on the nature of the rings and the substituents. Pyrazoles and isothiazoles are quite stable when heated with alkaline potassium permanganate, so that this method can be widely used to obtain azolecarboxylic acids[1,10]. The cleavage of the isoxazole ring under these conditions has been used to establish orientation on electrophilic substitution in arylisoxazoles[2].

---o0o---

During preparation of the manuscript for press several important publications have appeared—on the physical and physicochemical properties of 1,2-azoles[279-283], substitution in ring and side-chain[284-296] and addition to double bonds in azoles[297-299], and ring cleavage with syntheses based on the cleavage products[300-304] (the sequence of topics in this list corresponds to the treatment in the Review).

Electrochromism for the Investigation of Slow Movements in Macromolecules

F.P.Chernyakovskii

An account is given of the most important theoretical principles of electrochromism, and the possibility of its application is discussed. Apparatus and method of measurement are described. Results are considered for linear polymers in elastic and vitreous states over the range of relaxation times 10^{-3} - 10^{6} s. A list of 31 references is included.

I. INTRODUCTION

Use of especially sensitive apparatus reveals that an external electric field deforms absorption bands associated with solutions of organic molecules. This phenomenon occurs throughout the solution and is caused by interaction between the solute molecules and the field. Such interaction is apparent in the absorption spectra as optical anisotropy of the medium—dichroism of the solutions—and as spectral shifts in the bands caused by Stark effects. The broad absorption bands of complicated organic molecules exclude the possibility of applying the techniques of observation and interpretation that have been developed in studying Stark effects on line emission spectra. Some authors therefore consider it advisable to apply the term *electrochromism* to the deformation of molecular absorption bands in solution. The most complete description of electrochromism will be found in the works of Liptay, who as early as the 1960s suggested its use as a method for determining molecular excitation parameters[1].

Our work has shown[2-4] that electrochromism has another use—to study slow molecular mobility in condensed media, in particular in polymers—for which purpose molecules are introduced into the test medium to act as probes, and their rotational movements are observed by means of electrochromism. As in all other probe methods for studying molecular dynamics, it is in turn assumed that movements of the probes are determined solely by the thermal motion of molecules of the medium.

An obstacle to investigating slow movements by the paramagnetic probe method[5] is the so called relaxation conditions, which imposes a lower frequency limit at 10^{-7} s. During recent years paramagnetic probe methods have been devised in which the frequency limit has been lowered to 10^{-4} s.[6] An advantage of electrochromism over paramagnetic probes is the absence of theoretical limits in the low-frequency region. We have investigated molecular mobility in polymers between 10^{-3} and 10^{6} s. The approximately six frequency ranges thus covered are typical of the vitreous state. A relaxation time of 10^{6} s corresponds to a period of ~2 weeks, but this does not mean that such is the lower frequency limit of the method. The hypothetical possibility remains of using electrochromism to study even infinitely long relaxation processes. On the other hand, extending the range to short times (10^{-5}–10^{-6} s) leads merely to fully surmountable technical difficulties. There was no need in our work to raise the frequency, firstly because the dielectric method and the paramagnetic probe method are successfully used in the respective ranges 10^{-1}–10^{-10} and 10^{-7}–10^{-8} s, and secondly because the low-frequency range is the most interesting and promising, for it characterises mainly the relaxation processes that govern the properties of most polymer materials.

Electrochromism, like the Stark effect, is due to orientation polarisation of the probe molecules, which makes it akin to dielectric methods for investigating molecular mobility. The advantages of electrochromism are due to its high selectivity: since the method is based on observing the absorption spectra of probes, measurement can be confined to their orientational mobility, and other types of polarisation of the medium, which make a contribution in dielectric measurements, can be excluded.

Electrochromism can in principle be studied using probes that have been grafted on or even included in the main polymer chain. Another possible and extremely promising method of measuring inherent absorption involves observing that of chromophoric groups in the macromolecule, and directly determining their mobility. For the majority of polymers such investigation are possible only in the far ultraviolet.

II. THE PHENOMENON OF ELECTROCHROMISM

The action of an electric field on an absorption spectrum was first detected experimentally in 1939 by Kuhn et al.[7] for nitrosodimethylaniline dissolved in dioxan. Kuhn suggested that considerable orientation polarisation of the dissolved dipolar molecules might be produced in a strong electric field of $\sim 10^{4}$ V cm^{-1}. Since there is a fixed angle γ between the directions of the dipole moment of the molecule in the ground state $\bar{\mu}_g$ and that of the transition moment (unit vector $\bar{m}$), under certain conditions the orientation polarisation of the moments $\bar{\mu}_g$ may

be accompanied by anisotropy in the distribution of transition moments observable by means of special apparatus, together with dichroism of the solution. The optical density measured by means of a light ray parallel to the field strength vector $\bar{F}$ then differs from that measured perpendicular to this direction. The aim of the early work[7] was to evaluate the angle γ in organic molecules from the experimental dichroism.

Considerably later Labhart[8], Czecalla[9], and mainly Liptay and his coworkers[10] established that in Kuhn's experiments the expected orientation effect was accompanied by other effects, resulting from Stark displacements of the energy levels of ground and excited electronic states of the molecules. The shift in the levels is determined by interaction of a molecule possessing dipole moments $\bar{\mu}_g$ and $\bar{\mu}_e$ and polarisability tensors α_g and α_e with the external field (here and subsequently the subscripts g and e denote ground and excited states respectively). Furthermore, Liptay subsequently examined the action of a field on the transition moment of the molecules, and showed that this effect is also included in the observed electrochromism[1].

We consider the absorption of light by one of the molecules in the ensemble under investigation, whose orientation relative to the vector $\bar{F}$ is rigidly fixed. The shift in the absorption band in the field is determined by the displacement of the ground and excited electronic levels. Fig. 1 illustrates how the mutual arrangement of the vectors $\bar{\mu}_g$, $\bar{\mu}_e$, and $\bar{F}$ influences (disregarding the contribution of polarisability) the magnitude and the direction of the spectral shift in the bands (which for clarity has been greatly exaggerated).

From the above considerations the shift of the band in the field can be calculated by means of the formula

$$\Delta\bar{\nu} = \bar{\nu}^0 - \bar{\nu}^F = -\frac{\bar{\mu}_e - \bar{\mu}_g}{hc}\bar{F} - \frac{1}{2hc}(\alpha_e - \alpha_g)\bar{F}^2$$

where $\bar{\nu}^0$ and $\bar{\nu}^F$ are wave numbers of the electron transition in the absence and in the presence of the field, h is Planck's constant, and c is the speed of light. Writing $\Delta\bar{\mu} = \bar{\mu}_e - \bar{\mu}_g$ and $\Delta\alpha = \alpha_e - \alpha_g$, we obtain

$$\Delta\bar{\nu} = \frac{\Delta\bar{\mu}\bar{F}}{hc} + \frac{\Delta\alpha\bar{F}^2}{2hc} \quad (1)$$

In the maximum practicable fields (10^5 V cm^{-1}) the shift in the bands is a fraction of an Ångström unit under optimum conditions. Direct measurement of such small shifts in wide spectral bands is an extremely complicated task, so that measurements are made not of the band shifts but of the increase in luminous flux at a fixed wave number due to the action of the field. According to Eqn. (1) in an electric field transitions will be observed at a wave number $\bar{\nu}$ that are observed at wave number $\bar{\nu}-\Delta\bar{\nu}$ in the absence of a field. A low-frequency alternating field is usually applied to the specimens, and only the modulated part of the luminous flux, due solely to electrochromism, is measured.

The absorption of light by one molecule in the absence of a field is[11]

$$\pi(\bar{\nu}) = 3|\bar{e}\bar{m}|^2 \epsilon(\bar{\nu})/\bar{\nu},$$

where $\bar{e}$ is the unit vector in the direction of the electric vector of luminous flux, and $\epsilon(\bar{\nu})$ is a function describing the form of the absorption band. Since the displacement of ground and excited levels in the field is much smaller

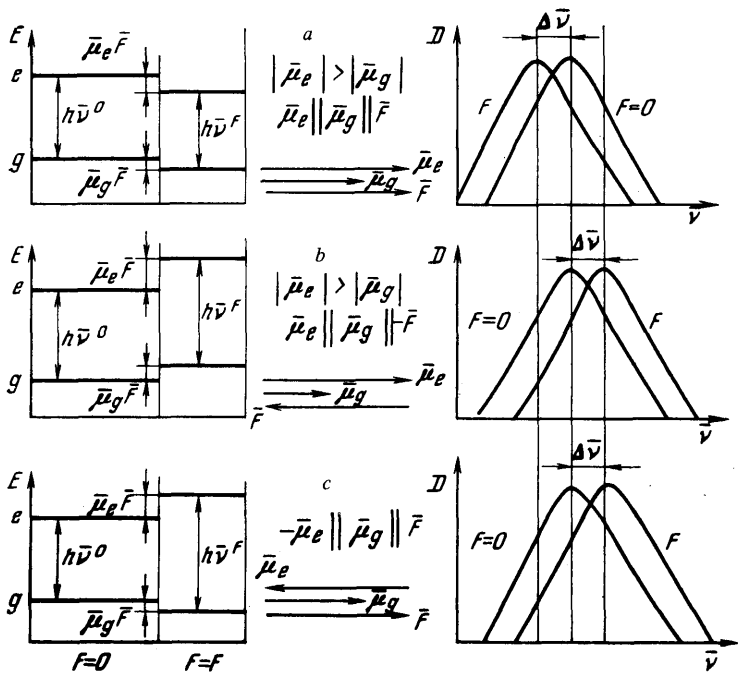

Figure 1. The effect of the mutual orientation of the vectors $\bar{\mu}_g$, $\bar{\mu}_e$, and $\bar{F}$ on the direction of displacement of the absorption band in the field: *a*) red shift; *b*), *c*) violet shift.

than the distance between them, the effect of the field can be estimated by a perturbation method:

$$\pi(\bar{\nu}^F) = \pi(\bar{\nu}^0) + \frac{d\pi(\bar{\nu}^0)}{d\bar{\nu}}\Delta\bar{\nu} + \frac{1}{2}\frac{d^2\pi(\bar{\nu}^0)}{d\bar{\nu}^2}\Delta\bar{\nu}^2 + \dots$$

Substituting for $\Delta\bar{\nu}$ from (1), we obtain

$$\pi(\bar{\nu}^F) = \pi(\bar{\nu}^0) + \frac{d\pi(\bar{\nu}^0)}{d\bar{\nu}}\left(\frac{\Delta\bar{\mu}\bar{F}}{hc} + \frac{\Delta\alpha\bar{F}^2}{2hc}\right) + \frac{1}{2}\frac{d^2\pi(\bar{\nu}^0)}{d\bar{\nu}^2}\left(\frac{\Delta\bar{\mu}\bar{F}}{hc} + \frac{\Delta\alpha\bar{F}^2}{2hc}\right)^2 + \dots \quad (2)$$

To determine the absorption of light by an ensemble of molecules it is necessary to add up the contributions by all molecules situated in the path of the light ray. Fig. 1 shows (*a* and *b*) that the spectral shifts of bands due to molecules whose dipole moments $\bar{\mu}_g$ are oriented along and against the field occur in opposite directions. As a consequence, only a slight broadening of the absorption bands, instead of a spectral shift to one side, is observed in a medium that is isotropic with respect to the directions of $\bar{\mu}_g$ and contains many molecules. This corresponds to the electrodynamic principle that effects which are linear with respect to the field cannot be observed in isotropic media. When the absorption of light by isotropic solutions is calculated, such linear effects are excluded because of the parity of the function of the cosine of the angle α between $\bar{\mu}_g$ and $\bar{F}$, and there remain only effects whose magnitude depends on $\bar{F}^2$. Effects proportional to higher powers of $\bar{F}$ can be neglected. Those proportional to $\bar{F}^2$ are termed *quadratic electrochromism*, in contrast to the linear electrochromism proportional to $\bar{F}$, whose nature will be examined in Section V.

In dilute solutions of polar molecules in a non-polar solvent an external field produces orientation polarisation, which Liptay[10] calculated from the Boltzmann distribution. In an electric field the medium becomes anisotropic, and effects that are linear with respect to the field become observable.

The final form of Liptay's equation is[11]

$$K = K_0 + A\frac{1}{\varepsilon(\bar{\nu})/\bar{\nu}}\frac{d(\varepsilon(\bar{\nu})/\bar{\nu})}{d\bar{\nu}} + B\frac{1}{\varepsilon(\bar{\nu})/\bar{\nu}}\frac{d^2(\varepsilon(\bar{\nu})/\bar{\nu})}{d\bar{\nu}^2}, \quad (3)$$

with the notation

$$K_0 = \frac{1}{10(kT)^2}\mu_g\frac{3\cos^2\gamma - 1}{2};$$

$$A = \frac{1}{5kThc}\left[\mu_g^2\frac{3\cos^2\gamma - 1}{2} - \mu_g\mu_e(\cos\gamma\cdot\cos\delta - \frac{1}{2}\sin\gamma\cdot\sin\delta)\right];$$

$$B = \frac{1}{10(hc)^2}\left[\mu_g^2\frac{3\cos^2\gamma - 1}{2} - 2\mu_g\mu_e(\cos\gamma\cdot\cos\delta - \frac{1}{2}\sin\gamma\cdot\sin\delta)\right] + \mu_e^2\frac{3\cos^2\delta - 1}{2};$$

$$K = -p_E\left[2{,}3D\left(\frac{\varepsilon_{DK}+2}{3}\right)^2\bar{F}^2\right]^{-1};$$

$\bar{\nu}$ (in cm^{-1}) the wave number, $\epsilon(\bar{\nu})$ the extinction coefficient, γ the angle between $\bar{m}$ and $\bar{\mu}_g$ with δ that between μ_e and $\bar{m}$, as before c the speed of light, ϵ_{DK} the dielectric constant of the medium, D the optical density, and p_E the measured degree of polarisation of light by the solution in the electric field. The field acting on the dissolved molecules had been calculated[10] by means of the Lorentz formula, but in later work Onsager's equation was used[12]. The theory of electrochromism and several of its applications have been discussed also in reviews[13-15].

Phenomena akin to electrochromism can be observed on application of an electric field to solutions whose components are in chemical equilibrium, provided that starting materials and final products differ in the sum of the products of the dipole moments of the ground state and the corresponding stoichiometric coefficients[16]. Electrochromism has been used to investigate charge-transfer complexes[17], conformational equilibria in which the components differ in polarity[18], and phenomena due to excitons[19].

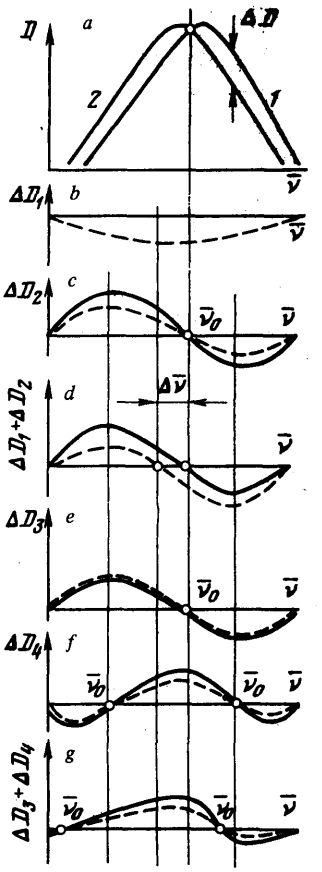

Figure 2. (*a*) Absorption spectra of solution: 1) in absence of a field; 2) under the influence of a field (the change in the spectrum has been greatly exaggerated for clarity). (*b*)–(*g*) Electrochromism spectra with $\theta = 55°$ and 90° (respectively full and broken curves), including (*b*)–(*d*) effects depending on orientation and (*e*)–(*g*) Stark effects: *b*) orientation effect ΔD_1 for molecule with $\gamma < 55°$ (when $\theta = 55°$ we have $\Delta D_1 = 0$, and the electrochromism spectrum coincides with the ordinate axis); *c*) orientation effect ΔD_2; *d*) spectral sum $\Delta D_1 + \Delta D_2$, with parameters of the electrochromism spectra $\Delta\bar{\nu}$ and $\Delta D_V/\Delta D_r$; *e*) quadratic Stark effect ΔD_3; *f*) linear Stark effect ΔD_4; *g*) spectral sum $\Delta D_3 + \Delta D_4$ (drawn with opposite sign to *f*).

Attention has been directed[2-4] to the dependence of the terms K_0 and

$$\frac{A}{\varepsilon(\bar{\nu})/\bar{\nu}}\frac{d(\varepsilon(\bar{\nu})/\bar{\nu})}{d\bar{\nu}}$$

in the Liptay equation (3) on the rotational mobility of the molecules. Quasi-stationary conditions are established in experiments on dilute solutions of polar molecules in a liquid non-polar solvent at external field frequencies far lower than those determining the movements of the solvent

molecules: dipole polarisation of the dissolved molecules is able to follow changes in the external field, and such molecules were termed "free". In other solvents or at other frequencies of the electric field "hindered" molecules may exist, for which the opposite frequency relation holds. Formula (3) characterises free molecules, whose orientation in the field obeys Boltzmann statistics. For hindered molecules the terms K_0 and A, containing the factor μ_g/kT, must be equated to zero.

Inspection of Eqns. (3) indicates that the electrochromism of free molecules has clearly defined features. The dependence of the electrochromism of polar probe molecules on the character of the molecular mobility of the test solvent forms the basis for application as a method of investigating molecular mobility in polymeric media. The Liptay equations were brought into line with the aims of the investigation by isolating as a separate group those effects of electrochromism that depend on the rotational mobility of the molecules (Fig. 2). The increase in optical density ΔD in the field, taken along the absorption band envelope, is measured as a function (termed the *overall electrochromism spectrum*) of the wavelength, frequency, or wave number (Fig. 2*a*):

$$\Delta D_{\theta=90^\circ} = (\Delta D_1 + \Delta D_2 + \Delta D_3 + \Delta D_4)_{\theta=90^\circ};$$

$$\Delta D_1 = \frac{1}{15}\left(\frac{\mu_g F}{kT}\right)^2 (1-3\cos^2\gamma)\, D;$$

$$\Delta D_2 = \frac{1}{5}\left(\frac{\mu_g F}{kT}\right)\frac{\Delta\bar{\mu}F}{hc}(2-\cos^2\gamma)\cdot\bar{\nu}\frac{\partial(D/\bar{\nu})}{\partial\bar{\nu}};$$

$$\Delta D_3 = \frac{1}{2}\frac{\Delta\alpha F^2}{hc}\cdot\bar{\nu}\frac{\partial(D/\bar{\nu})}{\partial\bar{\nu}}; \qquad (4)$$

$$\Delta D_4 = \frac{1}{10}\frac{\Delta\bar{\mu}^2\bar{F}^2}{h^2c^2}(2-\cos^2\delta)\,\bar{\nu}\frac{\partial^2(D/\bar{\nu})}{\partial\bar{\nu}^2}.$$

These equations show that the overall spectrum is the sum of the contribution ΔD_1–ΔD_4, which are also electrochromism spectra, whose nature and dependence on molecular mobility and experimental conditions will be discussed below.

Equations (4) have been written for the case in which the relative directions of the electric vector of the light ray in the medium (unit vector $\bar{e}$) and the electric field $\bar{F}$ form the angle $\theta = 90^\circ$. We can vary the angle θ and select experimental conditions under which the contribution ΔD_1 can be eliminated from the overall electrochromism spectrum. The orientation effect ΔD_1 is due to orientation polarisation of the probe molecules and disregards Stark effects. It appears as Kuhn dichroism, for which[7]

$$\Delta D_{\theta=0^\circ} = -2\Delta D_{\theta=90^\circ}. \qquad (5)$$

For any angle θ we have

$$\Delta D_\theta = \Delta D_{\theta=0^\circ}\cdot\cos^2\theta + \Delta D_{\theta=90^\circ}\cdot\sin^2\theta. \qquad (6)$$

From (5) and (6) we find that

$$\Delta D_\theta = \Delta D_{\theta=90^\circ}(1-3\cos^2\theta).$$

The expression in brackets vanishes when $\theta = 54^\circ 44' \simeq 55^\circ$. Under these conditions $\Delta D_1 = 0$, and no orientation effect is observed (Fig. 2*b*). The probes usually chosen are molecules in which under conditions of symmetry the vectors $\bar{\mu}_g$, $\bar{\mu}_e$, and $\bar{m}$ are mutually parallel, while $\bar{\mu}_e > \bar{\mu}_g$ in absolute magnitude; we then have $\gamma = 0$ and $\delta = 0$, and for such molecules with $\theta = 55^\circ$ Eqns. (4) simplify to

$$\Delta D_{\theta=55^\circ} = (\Delta D_2 + \Delta D_3 + \Delta D_4)_{\theta=55^\circ};$$

$$\Delta D_2 = \frac{1}{3}\frac{\bar{\mu}_g\bar{F}}{kT}\frac{\Delta\bar{\mu}F}{hc}\bar{\nu}\frac{\partial(D/\bar{\nu})}{\partial\bar{\nu}};$$

$$\Delta D_3 = \frac{1}{2}\frac{\Delta\alpha\bar{F}^2}{hc}\bar{\nu}\frac{\partial(D/\bar{\nu})}{\partial\bar{\nu}}; \qquad (7)$$

$$\Delta D_4 = \frac{1}{6}\frac{\Delta\bar{\mu}^2\bar{F}^2}{h^2c^2}\bar{\nu}\frac{\partial^2(D/\bar{\nu})}{\partial\bar{\nu}^2}.$$

Furthermore, an orientation effect is not observed under any conditions with molecules having the angle $\gamma = 55^\circ$, since the factor $1 - 3\cos^2\gamma = 0$ then vanishes (see formulae 4). Finally, an orientation effect is absent from media in which the rotational mobility of the probe molecules is hindered.

We have termed ΔD_2 (Fig. 2*c*) a *cross* electrochromism spectrum, since it results from two simultaneous effects of the field[3]. When the field is switched on, the original isotropic distribution of dipoles with respect to direction is disturbed, and anisotropy due to the factor $\bar{\mu}_g\bar{F}/kT$ appears. This permits observation of the Stark effect, linear with respect to the field and proportional to $\Delta\bar{\mu}\bar{F}$. As a consequence, the inherently linear Stark effect becomes proportional to $\bar{F}^2$. Obviously, no cross effect is observed in media with hindered mobility of the probes. When the angle θ changes from 90° to 55°, the cross effect diminishes by a factor $5/3 = 1.66$, as is evident from the coefficients in Eqns. (4) and (7).

Fig. 2*d* illustrates the spectral sum of the two contributions $\Delta D_1 + \Delta D_2$, which it is advisable to consider separately from the others, since only they depend on the rotational mobility of the molecules. The clearest indication of free rotation of the probes is a shift in the electrochromism zero point $\bar{\nu}_0$ with change in the angle θ from 90° to 55°. This is accompanied by a change in the ratio $\Delta D_V/\Delta D_R$ of the increases in the electrochromism signal on violet and red sides of the absorption band.

The contribution ΔD_3 (Fig. 2*e*) is made by the quadratic Stark effect, caused by the change in polarisability accompanying excitation of the molecule. The quadratic effect can be arbitrarily imagined to consist of two parts—an induced dipole moment $\Delta\alpha\bar{F}$ and a linear Stark effect—the former always lies in the direction of the field irrespective of the rotational mobility of the molecules, and the latter depends on the interaction of the induced moment with the same external field $(\Delta\alpha\bar{F})\bar{F}$. With $\alpha_e > \alpha_g$ this leads to a red shift of the band.

For every moment $\Delta\bar{\mu}$ in an isotropic medium containing a large number of molecules it is always possible to find another molecule having the same moment but oriented in the opposite direction. If one orientation corresponds to a red shift of the absorption band in the field as a consequence of a first-order Stark effect, the opposite orientation corresponds to a violet shift. Only a slight broadening of the band can then be observed, proportional to $\partial^2(D/\bar{\nu})/\partial\bar{\nu}^2$. We have termed the ΔD_4 effect *linear* in conformity with its nature (Fig. 2*f*), although it is found to be proportional to $\bar{F}^2$. It does not depend on rotational mobility, so that a sensible procedure is to combine it with ΔD_3 and henceforward consider another spectral sum $\Delta D_3 + \Delta D_4$ (Fig. 2*g*). A characteristic feature of $\Delta D_3 + \Delta D_4$ spectra in media with free rotational mobility of probe molecules whose dipole moments $\bar{\mu}_g$ and $\Delta\bar{\mu}$ are a few Debyes is their low intensity in comparison with $\Delta D_1 + \Delta D_2$ (Fig. 2*d*). In this case effects depending on orientation exceed Stark effects by factors of $\sim 10^{1.5}$. In media with hindered rotation of probe molecules, on the other hand, only Stark effects can be observed with two zero points $\bar{\nu}_0$, whose positions are independent of the angle θ.

Thus, if the originally free rotation of molecules is gradually hindered, e.g. by freezing the solvent, the electrochromism spectra change from the spectral sum $\Delta D_1 + \Delta D_2 + \Delta D_3 + \Delta D_4$ to the spectrum $\Delta D_3 + \Delta D_4$ with a corresponding decrease in intensity by factors of $10^{1-1.5}$.

Inspection of Eqns. (4) and (7) shows that orientation-dependent effects diminish at different rates with rise in temperature: the orientation effect falls more rapidly. With rise in temperature to infinity both orientation and cross effects tend to zero.

For the study of slow movements in macromolecules it is very important to examine the frequency dependence of individual effects. Only molecules whose rotational relaxation time is shorter than the period of the alternating field $\bar{F}$ reveal $\Delta D_1 + \Delta D_2$ effects. Thus probe molecules are arbitrarily divided into two groups—free and hindered—by the frequency of the external field. In very high-frequency fields all molecules may be hindered, and at very low frequencies all can be regarded at least hypothetically as free. These considerations show that, by examining electrochromism spectra over a wide range of field frequencies, information can be obtained on the spectrum of relaxation times of probes in polymers. Frequency begins to influence Stark effects only in the range in which relaxation processes are appreciable in the electron shells of the molecules[20]. As a consequence, under normal conditions Stark effects make a constant contribution and provide a kind of standard, with which effects depending on orientational mobility can be compared.

Thus the concept of overall electrochromism spectra as a sum of contributions, together with specific observed features, underlies a technique for their separate determination, which is based on the following principles[2].

1. Cross and orientation effects are not observed in media with completely hindered rotational mobility. In this case the form and the intensity of the electrochromism spectra are determined by Stark effects. Parameters of the electrochromism spectra due to the latter effects, which are characteristic of media with hindered mobility, are maintained in media with free motion of the same molecules.
2. No orientation effect is observed when the polarisation of the light ray corresponds to $\theta = 55°$.
3. The cross effect and the quadratic Stark effect are zero at the peak of the absorption band, where $\partial (D/\bar{\nu})/\partial \bar{\nu} = 0$.
4. The linear Stark effect is zero at points at which $\partial^2(D/\bar{\nu})/\partial \bar{\nu}^2 = 0$.
5. For molecules having $\gamma = 0°$ the cross and linear effects increase by factors of 1.66 as the angle θ diminishes from 90° to 55°.

III. INVESTIGATION OF AMORPHOUS POLYMERS IN VITREOUS-ELASTIC TRANSITION RANGE BY QUADRATIC ELECTROCHROMISM

Electrochromism effects can be determined separately in a polymer matrix at a temperature in the region of transition from elastic to vitreous states. Fig. 3*a* illustrates the absorption spectrum (curve *1*) and the electrochromism spectra of *p*-dimethylamino-*p'*-nitrobisazobenzene in polystyrene at room temperature (below the glass point). It is evident that the electrochromism spectra for $\theta = 55°$ and 90° differ merely in intensity, with

$$\Delta D_{\theta=55°}/\Delta D_{\theta=90°} = 1.66.$$

It follows from theory that these spectra correspond to complete hindrance of probe molecules in the polystyrene. This is supported also by the presence of two electrochromism zero points, whose positions are independent of the angle θ, as well as by the similarity of the spectra to those illustrated in Fig. 2*g*. The ΔD_3 and ΔD_4 effects can be separated by means of the difference in shape between the corresponding electrochromism spectra. The ΔD_3 spectrum is proportional to the first derivative of optical density with respect to frequency, so that at the peak of the band $\Delta D_3 = 0$: the ordinate of the $\Delta D_3 + \Delta D_4$ electrochromism spectra at this wavelength gives only the ΔD_4 contribution (see Fig. 2*f*). With the second derivative $\partial^2(D/\bar{\nu})/\partial \bar{\nu}^2$ available we can normalise its value at the band maximum and then calculate the ΔD_4 contribution throughout the spectrum. The ΔD_3 contribution is found similarly from the vanishing of ΔD_4 at zero points of the second derivative, when the effects are determined solely by the ΔD_3 signals. Another possible method is based on the additivity of the optical densities: ordinates of the ΔD_4 contribution calculated throughout the spectrum can be subtracted from the $\Delta D_3 + \Delta D_4$ spectrum. The electrochromism spectra should be taken at corresponding angles θ.

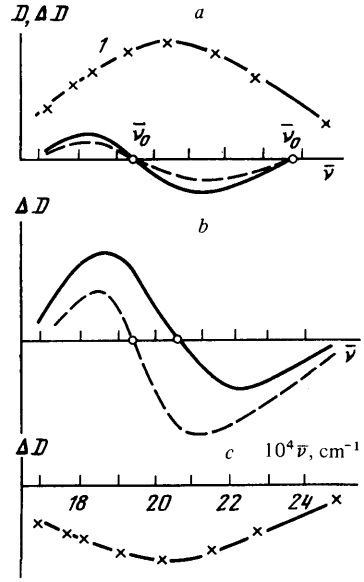

Figure 3. (*a*) Electrochromism spectra of (III) (Fig. 5) in polystyrene at room temperature: -----) $\theta = 55°$; - - -) $\theta = 90°$; 1) absorption spectrum; ×) form of contribution by orientation effect coinciding with absorption band. (*b*) Electrochromism spectra of the same specimen above the glass point. (*c*) Calculation of orientation effect.

When a specimen is heated the electrochromism spectra gradually change in the transition range (75–90°C). Fig. 3*b* shows overall electrochromism spectra for the same specimen heated to 92°C, i.e. above the glass point. Comparison with Fig. 2*d* reveals that these spectra correspond to orientational mobility of the probes. The spectra contain a single zero point, whose position depends on the angle θ: when $\theta = 55°$, the zero point is close to the peak

of the band. The slight displacement from the band maximum is attributed to a contribution by Stark effects. To determine the ΔD_1 and ΔD_2 contribution it is necessary to subtract the Stark effects obtained for the vitreous state from the overall electrochromism spectra at corresponding angles θ. After such subtraction the electrochromism spectrum at $\theta = 55°$ corresponds to the cross effect ΔD_2 with its zero point at the peak of the band. Determination of ΔD_1 requires subtraction from the electrochromism spectra at $\theta = 90°$ of $\Delta D\theta = 55°/1.66$, since the cross effect decreases by the factor 1.66 when the angle θ changes from 55° to 90° (Fig. 2*c*).

As a check we must compare the ΔD_2 contribution with the form of the first derivative of optical density with respect to frequency, and ΔD_1 with the form of the absorption band (bearing in mind that the ΔD_1 effect is negative for molecules having $\gamma < 55°$). The agreement between ΔD_1 (Fig. 3*c*) and the absorption band is shown by the points (×) on Fig. 3*a*.[21] The calculations were based on the hypothesis that the reaction field remains unchanged when specimens are heated above the glass point from room temperature. This hypothesis holds quite well for polystyrene, whose dielectric constant is only slightly dependent on temperature. With other polymers, e.g. poly(vinyl acetate), the dielectric constant increases rapidly with temperature, so that spectra obtained at different temperatures must be corrected for the reaction field when they are subtracted or added.

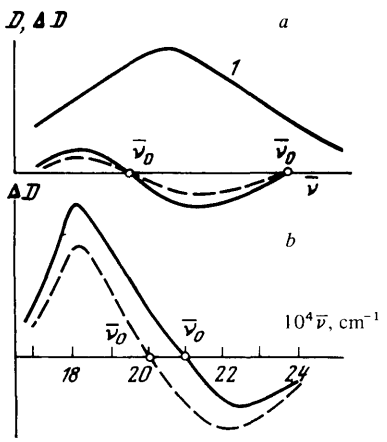

Figure 4. Effect of solvent (benzene) residues on electrochromism spectra of (II) (Fig. 5) in polystyrene specimen with different angles θ: -----) 90°; - - -) 55° at different temperatures: *a*) 20°C (specimens dried in air at room temperature for 24 h, and then in a vacuum at 60°C); 1) absorption spectrum; *b*) 95°C (dried only in air for 24 h).

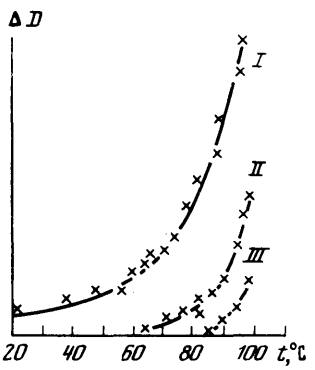
A spectrophotometer is used to obtain the absorption spectrum, but the derivatives $\partial(D/\nu)/\partial\bar{\nu}$ and $\partial^2(D/\bar{\nu})/\partial\bar{\nu}^2$ are calculated from the spectrum, either by using a Gaussian function to approximate to the absorption band or by numerical differentiation on an electronic computer. Probe molecules are introduced into polymers by mixing separately prepared solutions of polymer and dye in a suitable solvent. The solvent is then removed initially by evaporation and then by drying the coloured polymer mass (Section VI). Benzene is a solvent for polystyrene, and therefore exerts a plasticising action on the latter; the benzene remaining in the specimen after drying affects the mobility of the probes. Specimens having different benzene contents can be obtained by varying the drying conditions.

Fig. 4*a* illustrates the electrochromism spectra of an azo-dye in polystyrene at room temperature for a specimen from which benzene has been completely removed by drying. Molecular mobility in the specimen is hindered, as indicated by the form of the electrochromism spectra and the unchanged position of the $\bar{\nu}_0$ points when the angle θ is varied. Fig. 4*b* gives electrochromism spectra for a specimen from which removal of solvent is incomplete as a consequence of milder drying conditions. The difference in mechanical properties between the two specimens is slight, with the former slightly more brittle. Yet the mobilities of probes in them differ substantially. The electrochromism spectrum (Fig. 4*b*) has clearly defined features indicating rotational mobility of the probes in polystyrene[2].



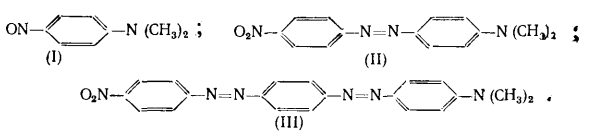


Figure 5. Temperature dependence of orientation effect in polystyrene film for the three probe molecules differing in size

The electrochromism spectra depend on the size of the probes (Fig. 5). The smallest probes—nitrosodimethylaniline (I) molecules—possess appreciable rotational mobility at a frequency of 240 Hz in polystyrene even at room temperature. *p*-Dimethylamino-*p'*-nitroazobenzene(II) molecules are able to rotate at 64°C, but the largest probes—*p'*-dimethylamino-*p*-nitrobisazobenzene(III) molecules containing three benzene rings—begin to rotate at 85°C. The results are well explained by the theory of the dynamic free volume[22].

IV. STUDY OF ELASTIC STATE OF AMORPHOUS POLYMERS BY QUADRATIC ELECTROCHROMISM

Fig. 6 illustrates absorption and electrochromism spectra of probe (II) obtained under the same conditions in certain rubbers. The form and the intensity of the electrochromism spectra obviously depend on the type of polymer. The ratio of the contributions made by two groups of effects—(i) $\Delta D_1 + \Delta D_2$, depending on the rotational mobility of the probes, and (ii) Stark effects, which are the same in all specimens—is found to determine the whole variety of spectral forms. Differences in intensity depend also on the strength of the field acting on the molecules with the same external electric field. In the investigation of molecular mobility the reaction field for media of dielectric constant ~2 can be calculated[2-4] by means of the Lorentz formula. In media of high dielectric constant (in SKN-26 and Nairit rubbers), however, this formula is inapplicable. Fröhlich calculation[12] of the field shows that the reaction field in SKN-26 of dielectric constant 11 is one-third of the Lorentz field, which diminishes the densities of field-quadratic effects by ~90%. In order to estimate rotational mobility in such cases it is advisable to compare the parameters $\Delta D_V/\Delta D_R$ and $\Delta\bar{\nu}$, which determine only the form of the spectrum (Fig. 2). It follows from these that rotational mobility of probe (II) in SKN-26 and Nairit rubbers does not greatly differ from that of the same probe in other rubbers.

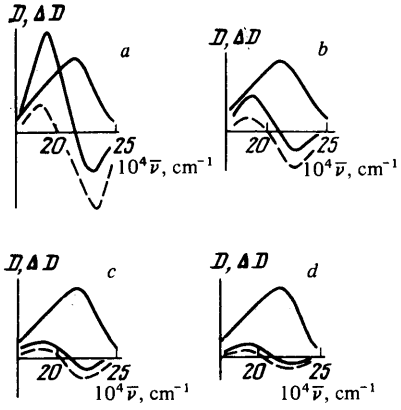

Figure 6. Absorption and electrochromism spectra of (II) at room temperature in various rubbers: *a*) SKS-30 [styrene-butadiene]; *b*) SKS-30-1; *c*) SKN-26 [butadiene-nitrile]; *d*) Nairit [chloroprene].

A very interesting question is the mechanism of the motion of probe molecules in a polymer. According to one view the polymer is a continuous, structureless medium, characterised by a single parameter—its viscosity—and thus having one rotational relaxation time of probes†. A second view assumes a broad spectrum of relaxation times[23], in which the same molecule is able to change sharply its relaxation characteristics, passing abruptly from free to hindered states and back. The two views lead to the same electrochromism spectra, so that additional information is required to make a choice between them‡. For this purpose our experiments[2] included examination of the phase shift between electrochromism signal and external field. In the former case, with viscous flow of the probes, the phase shift should differ from zero, since the proportions of free molecules $1 > \sigma > 0$ (Table 1) would appear to indicate that electrochromism measurements are made in a region of dispersion of rotational mobility of the probe. In the latter case, with a broad spectrum of rotation relaxation times of the probes, the phase shift should be zero, as was observed in all the rubbers investigated. The experiments with polystyrene (Figs. 3 and 4) and poly(methyl methacrylate) show that the rotational mobility of the probes changes significantly in the region of vitrification. It might have been expected that a phase shift would have been detected between the electrochromism signals and the external field with slow variation in temperature over the transition range. However, even in these experiments the phase shift was zero. It must thus be supposed that macromolecules in amorphous linear polymers have a broad spectrum of relaxation times. In terms of the theory of free volume[22] this implies that the probe is free at those instants in which a free volume—a cavity large enough to permit rotation of the probe—is formed around the probe as a consequence of the thermal motion of the macromolecules. In the next instant the cavity "collapses", and the probe passes into the hindered category.

Table 1.

Polymer	σ	$10^{-16}a$	$10^{-5}k_{tr}$, min^{-1}
SKS-30-1	0.22	74	3.4
Polyethylene	0.26	93.5	350
Natural rubber	0.40	137	250
SKMBP-5	0.44	153	2.9
SKB [butadiene rubber]	0.44	153	16.5
SKS-30	0.49	180	8.0

Interpretation of the electrochromism spectra as the summation of contributions by Stark effects and effects depending on orientational mobility enables the proportion of free molecules to be found. This requires comparison of $\Delta D_1 + \Delta D_2$ electrochromism spectra obtained under the same conditions in the test medium and in a liquid solvent of low molecular weight and closely similar dielectric constant, in which rotational mobility has characteristic times of 10^{-10}–10^{-12} s and all probes can be regarded as free. Instead of determining the spectra in the liquid we can use formulae (4) and (7) to calculate $\Delta D_1 + \Delta D_2$ for probes whose parameters have already been measured. Table 1 lists proportions σ of free (II) molecules at 240 Hz in various rubbers at room temperature. It includes the

† Actually, three relaxation times are possible for non-spherical molecules, corresponding to rotation about the three principal axes, but this does not affect the generality of the argument.

‡ Criteria for establishing whether the motion of molecules in liquids occurs by diffusion or in jumps were defined in Ref. 24.

corresponding orientation coefficients $a = \Delta D_1/DF^2$, which contain the contribution ΔD_1 isolated from the overall electrochromism spectrum by the method described above. The proportion of free molecules σ was obtained by comparing the intensities of the electrochromism spectra of the probe (II) in the rubbers and in benzene. It may be supposed *a priori* that the ratio a/σ of the values in Table 1 should be constant for all the rubbers: in fact, the relative variation in the ratio is ~3%, which supports the general physical significance of a and σ.

It was of interest to establish the relation between rotational and translational diffusion of probe molecules in polymeric media. A method was therefore devised for studying translational diffusion by measuring rates of crystallisation of the probes from polymeric media[25]. Table 1 gives true crystallisation rate constants k_{tr}, which characterise the translational mobility and must be compared with the orientational coefficients or the proportions of free molecules σ. The comparison reveals no correlation between parameters characterising slow rotational and translational diffusion for the probe (II) in the rubbers at room temperature.

V. INVESTIGATION OF VITREOUS STATE OF AMORPHOUS POLYMERS BY LINEAR ELECTROCHROMISM

When a specimen is subjected to the simultaneous action of two electric fields—an alternating field $\bar{F}\sin\omega t$ and a constant field $\bar{F}_0$—the resultant field $\bar{F}\sin\omega t + \bar{F}_0$ produces in quadratic electrochromism effects proportional to

$$\bar{F}^2\sin^2\omega t + 2\bar{F}\bar{F}_0\sin\omega t + \bar{F}_0^2 = -1/2\bar{F}^2\cos 2\omega t + 1/2\bar{F}^2 + 2\bar{F}\bar{F}_0\sin\omega t + \bar{F}_0^2.$$

The first term defines the quadratic electrochromism considered above; it is observed in the frequency channel 2ω, i.e. at double the frequency of the electric field. The second and fourth terms are responsible for effects independent of the frequency of the field, which can be detected in the channel $\omega = 0$. The third term represents effects that are linear with respect to the alternating field, which are recorded in the frequency channel ω, i.e. at the frequency of the field. Thus the combined action of two fields produces electrochromism effects that are recorded in different frequency channels and have several specific features. By superposing the fields $\bar{F}\sin\omega t + \bar{F}_0$ we can investigate all the electrochromism effects discussed already—Eqns. (4) and (7)—but examination of the ΔD_2 effect is of especial interest for determining molecular mobility. This effect has a dual nature (Fig. 2*c*): one component factor $\Delta\bar{\mu}\bar{F}$ is due to the linear Stark effect, and the other $\bar{\mu}_g\bar{F}/kT$ to the degree of anisotropy in the directions of dipole moments resulting from the action of the same electric field $\bar{F}$. Anisotropy can in principle be produced by the additional independent constant field $\bar{F}_0$. The formula for the effect that is linear with respect to the field can then be written for $\theta = 55°$ in the form

$$\Delta D_2^l = \frac{1}{3}\frac{\bar{\mu}_g\bar{F}_0}{kT}\frac{\Delta\bar{\mu}\bar{F}}{hc}\bar{\nu}\frac{\partial(D/\bar{\nu})}{\partial\bar{\nu}}. \qquad (8)$$

Elongated probe molecules having $\bar{\mu}_g$ and $\Delta\bar{\mu}$ of a few Debyes and the angles $\gamma = 0$ and $\delta = 0$ are usually chosen for the investigation of molecular mobility. With $\theta = 55°$ the orientation effect ΔD_1^l is not observed, while ΔD_3^l and ΔD_4^l are small in comparison with ΔD_2^l. The ΔD_2^l effect therefore predominates, and the contributions by other effects can be neglected. It has been suggested[2,3,26] that linear electrochromism can be used to investigate very slow relaxation processes in vitreous polymers. For this purpose a procedure was devised in which a polymer specimen into which probes had been introduced was heated above the glass point and placed in an alternating field $\bar{F}$. Only quadratic electrochromism at frequency 2ω can then be observed: no linear effect is observed at the frequency of the field $\bar{F}$. If at the same time a constant field $\bar{F}_0 = 10^3$–10^4 V cm^{-1} is applied to the specimen, anisotropy appears in the directional distribution of dipoles $\bar{\mu}_g$, observation of the linear effect for molecules oriented by the constant field becomes possible, and a linear electrochromism signal is produced.

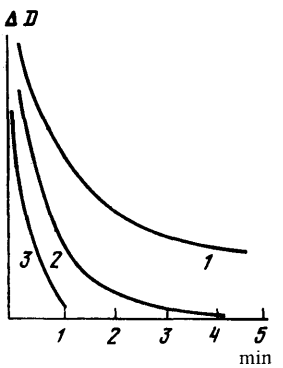

Figure 7. Kinetic curves for the decay of the linear electrochromism signal of (II) in polystyrene at (°C): 1) 78; 2) 85; 3) 99.

The specimen can then be cooled below the glass point (to the experimental temperature) without removal of the constant field $\bar{F}_0$; this freezes the rotational mobility, after which the constant field is removed. At the instant at which the field $\bar{F}_0$ is switched off the anisotropy begins to disappear at a rate depending on the molecular mobility in the medium at the experimental temperature; at the same time the linear electrochromism signal becomes weaker. In liquid solvents of low molecular weight this signal disappears almost instantaneously when the constant field is switched off. In polymeric plastics with sufficiently dense packing at temperatures below the glass point it remains for a long time[2]. The variation in the linear electrochromism signal with time gives a kinetic curve characterising the dynamics of molecular movements in the medium (Fig. 7).[26] One of the most interesting experimental results is the discrete spectrum of relaxation times of molecular motions in vitreous polystyrene, poly(methyl methacrylate), and poly(vinyl acetate) with substantially different characteristic times. The corresponding processes can easily be separated by a simple method based on isolating the straight segment in the terminal regions of the kinetic curves plotted in the semi-logarithmic coordinates $\ln\Delta D$ against time on the assumption that all the relaxation processes forming the spectrum begin simultaneously at the instant the field $\bar{F}_0$ is switched off. The first component $\Delta D'$ isolated in this way, with the longest relaxation time τ', is subtracted from the overall spectrum, and the procedure is repeated for the difference $\ln(\Delta D - \Delta D')$; and so on, until the whole kinetic curve has been exhausted[27].

To estimate the lower frequency limit to the determination of relaxation times by means of linear electrochromism we assume the possibility that a specimen can exist with an infinitely long relaxation time, in which the anisotropy of the directional distribution of dipole moments of probes always remains the same. Theory shows that this case corresponds to a linear electrochromism signal that remains unchanged with time. It is evident from this example that the method has no lower frequency limit. A polystyrene specimen containing the probe (III) exhibited a linear electrochromism signal at room temperature for a month, after which observation was discontinued[2]. Calculation showed that the decay process corresponded to a mean relaxation time of about 2 weeks or 10^6 s. The most rapid processes that can be observed with our apparatus (see below) have relaxation times of a few seconds (this limit is determined by the time constant of the recording instrument). Table 2 gives relaxation times τ for three exponential processes isolated from the kinetic curves, together with their contributions δ, at various temperatures. These data can be used to calculate energies corresponding to the two slowest processes, by means of the equation

$$\tau = \tau_0 \exp(-\Delta E/kT),$$

which gives for ΔE_1 and ΔE_2 the respective values 1.87 and 0.78 eV. These quantities are difficult to interpret, since information on the mechanisms of relaxation processes in vitreous media is extremely limited. From Table 2 it can be concluded that the structure of the spectrum of relaxation times changes with rise in temperature, in such a way that the contribution by rapid relaxation processes increases, while that by slow processes diminishes. Analogous changes in spectra of relaxation times are observed in the plasticisation of specimens[2].

Table 2. Relaxation times τ (s) and contributions δ of rotational motions of *p*-dimethylamino-*p'*-nitrostilbene in polystyrene at various temperatures, isolated from the relaxation-time spectrum.

VI. EXPERIMENTAL PROCEDURE

The electrochromism of molecules having large dipole moments in ground and excited states can be detected with a mass-produced spectrophotometer designed for chemical analysis using electric fields of limiting permissible strength $\sim 10^6$ V cm^{-1}.[28] This method is completely unsuitable for recording electrochromism spectra in the most common cases, in which the signals do not exceed 10^{-4}–10^{-5} unit of optical density. Several types of equipment have been described for special purposes, mainly for investigating excited states of molecules[29]. An idea of the simplest apparatus for recording electrochromism spectra in the investigation of molecular mobility in polymers can be found in a previous paper[30]; an improved form will be described below, together with the procedure.

1. Preparation of Specimens

Probes are introduced into linear polymers—plastics and rubbers—by dissolving the latter in a suitable solvent, e.g. benzene, and mixing the resulting solution with a solution of the probe dye in the same solvent[28]. The relative volumes of the solutions are so chosen that specimens having a dye content of 10^{-3}–10^{-4} mole per 1000 g polymer are obtained after the solvent has vaporised. Firstly the solvent evaporates from a Petri dish at room temperature, and then the coloured film is dried in a vacuum drying vessel at 50–60°C for 24 h. Under these conditions benzene is completely removed from the polymer, as can be checked from the electrochromism spectra (Fig. 4). Films having plane-parallel surfaces are formed by placing the coloured mass between small sheets of pure transparent mica free from cracks, air bubbles, or foreign inclusions. The sheets are separated by gaskets 100 μm thick located along the edges of the sheets, and are compressed in a press heated to 100–110°C. On softening, the polymer fills the space between the mica sheets and bonds to them firmly. The mica prevents the films from buckling and determines the breakdown voltage of the specimen. The coloured film together with the mica sheets is glued by means of an epoxy-resin between transparent ground-glass electrodes 20 × 20 mm in size. A conducting coating is obtained by depositing tin dichloride vapour on the glass surfaces heated to 400–420°C.[31]

2. Apparatus for Recording Electrochromism Spectra

The probe molecules chosen for studying molecular mobility in polymers are dyes, whose absorption spectra are located in the visible spectrum. Therefore an overrun lamp *1* (Fig. 8) was used as source, the luminous flux from which was stabilised by using a device *2* to stabilise the current. The polychromatic light from the lamp is directed to the inlet slit of a monochromator *3*, the ray first passing through a light modulator *4*, which is necessary to record the action spectra of the apparatus (the modulator is disconnected for the determination of electrochromism spectra). The monochromatic light passes through an inclined quartz plate to balance the inherent polarisation of the monochromator (not shown in Fig. 8), and then falls on the Polaroid film *5*. The polarised monochromatic light is directed on the specimen *6* placed in a thermostat *7* filled with mineral oil as heat-transfer agent. The temperature of the specimen can be varied from 20 to 150°C and maintained constant to 0.5 deg by means of a thermostatic unit *8* connected to an electric heater immersed in the thermostat and provided with a resistance thermometer. The light ray emerging from the specimen, modulated to an extent of 10^{-4}–10^{-5}, falls on a photocell *9* placed in a detachable photometric head *10*. The electric signal is fed to the input of the low-frequency amplifier *11*, which has an amplification band of 420 Hz with band-width 0.8 Hz and amplification factor 12000. The amplified signal reaches the phase-sensitive detector *12* and the oscillograph *13*; the latter is designed

to record the most intense electrochromism signals, but is used mainly to observe the noise in the apparatus. From the phase-sensitive detector the signal enters an *RC* circuit (not shown in the diagram), which determines the time constant of the system, and then the input of a direct-current amplifier *14* followed by the pen-recorder *15*. The motion of the chart of *17* is synchronised with the spectrum-scanning device *16*.

An alternating voltage of frequency 210 Hz is fed from an oscillator *18* through a step-up transformer *19* to the specimen. By controlling the output of the oscillator the voltage on the specimen can be varied over the range 0–2 kV. Linear electrochromism effects are observed at the field frequency ω, but quadratic effects at the doubled frequency 2ω. In order to be able to use in both cases the same amplifier tuned to the frequency 420 Hz, the field frequency was set at 210 Hz for the investigation of quadratic effects. As a consequence, measurement of such effects required that the frequency of the reference signal should also be doubled, which was achieved by means of the unit *20*. In the investigation of linear effects the frequency doubler *20* was disconnected. The signal of the reference voltage is fed through the phase shifter *21* to the phase-sensitive detector *12*. In the investigation of linear electrochromism a constant voltage from a high-voltage source *22* is superimposed on the alternating field on the specimen.

The field-modulated luminous flux is

$$I_F = I_0 T T' T_F,$$

where I_0 is the luminous flux incident on the specimen, T the transmission of light by the specimen, T' the light losses due to the cuvette, and T_F the transmission of light by the specimen that is due to the action of the field $\vec{F}$. Expanding T_F as a series and retaining only the first two terms in view of the smallness of $\Delta D'$, we obtain

$$T_F = e^{-\Delta D'} = 1 - \frac{\Delta D'}{1!} + \frac{\Delta D'^2}{2!} - \ldots;$$

on passing to a decadic base, we find that

$$I_F = I_0 T T' - 2{,}3 I_0 T T' \Delta D.$$

The first term is a constant component of the luminous flux, which is not recorded by the instrument. The second term includes the alternating unknown quantity ΔD, whose variation with wavelength gives the electrochromism spectrum.

The luminous flux I_0 depends on the action spectrum of the apparatus, which must be corrected for. However, it is more expedient to correct not the incident but the transmitted luminous flux, thereby allowing for the transmission both of the specimen and of the cuvette. Two methods are employed for this purpose[26].

1. In order to correct the form of the electrochromism spectra the luminous flux of the instrument with the specimen fitted in it is modulated by means of a light chopper with the electric field switched off. The signals from the chopper are recorded on the pen-recorder chart as a function of wavelength. This involves switching the unit *12* from a phase-sensitive to an amplitude detector. A particular wavelength is then selected within the electrochromism spectrum, the chopped signal at which is taken to be unity, and signals obtained at other wavelengths are normalised to this value. The true form of the electrochromism spectrum is obtained by dividing its ordinates by the normalised values of the chopped signals at corresponding wavelengths. Such plots can be used in most cases in investigating molecular mobility on specimens for which the relative intensities of the electrochromism spectra are quite high. Absolute increases in optical density can be found by comparing the electrochromism spectrum of the test substance with that of a standard substance recorded under the same conditions. *p*-Dimethylamino-*p'*-nitrostilbene, for whose molecules the parameters of ground and excited states are well known, has been used as standard in our work.

2. The electrochromism spectrum is drawn through points obtained at 10–15 selected wavelengths. The specimen is placed in the instrument, and the light chopper is switched on with the field switched off. For all these wavelengths monochromator slit widths are then selected to correspond to signals having the same amplitude. The slit openings thus found are then used in determining the electrochromism spectrum, which will give directly ordinates of the corrected spectrum. Absolute values of the signals are found, as in the first method, by comparison with the electrochromism spectrum of a standard substance.

3. Measurement of the Angle θ

The specimen is fixed in the thermostatted cuvette at an angle to the luminous flux (Fig. 9) such that the angle between the surface of the specimen and the direction of

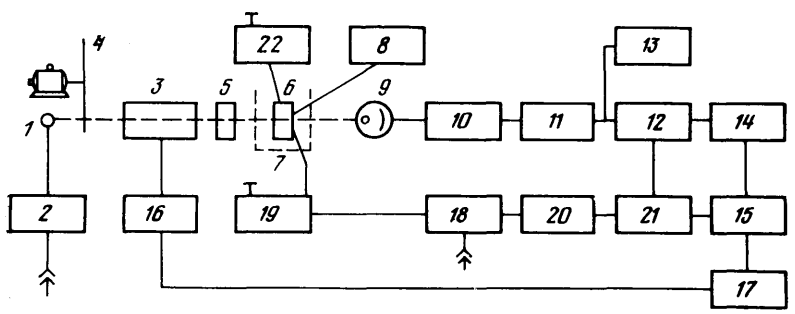

Figure 8. Block diagram of apparatus for recording electrochromism spectra (key in text).

the ray in the test medium is 54°44′ ≈ 55°. With the light polarised in a vertical plane the angle between the vectors $\bar{e}$ and $\bar{F}$ is then $\theta = 90°$, but with horizontal polarisation this becomes 55°.

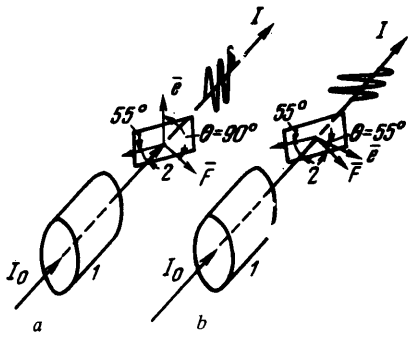

Figure 9. Diagram illustrating the variation of the angle θ as the Polaroid is rotated: 1) Polaroid; 2) specimen; $\bar{e}$) unit vector in direction of electric vector of light wave; I_0), I) luminous fluxes; *a*) vertically polarised light; *b*) horizontally polarised light.

The direction of light in the medium depends on the ratio of the refractive indices of the medium and of the oil filling the thermostat. If the refractive indices differ greatly, the angle at which the specimen is fitted must be corrected.

---o0o---

The above survey shows that the study of electrochromism will yield important information on movements in polymer molecules. The method can be developed firstly to investigate proper motions of fragments of macromolecules containing chromophores absorbing in the visible and ultraviolet, when the need for interpretation of indirect results obtained by the probe method is eliminated. A second development would be to record spectra of relaxation times of molecular movements, which can be obtained with wide variation in the frequency of the electric field and by means of the quadratic electrochromism spectrum or by analysis of kinetic curves from linear electrochromism spectra. The value of relaxation-time spectra lies in their relationship both to the motion of definite groups of atoms and to the thermodynamic properties of the medium, i.e. the properties of polymeric materials.

Photochemical Methods for Recording Information. Primary Photoprocesses

M.V.Alfimov and O.B.Yakusheva

The principal photographic characteristics of non-silver materials, whose activity is based on photochemical reactions, are presented. The nature of the first stage in the photochemical processes involving the recording of information (the primary photochemical reaction) are analysed and the kinetic approach to the estimation of some of their limiting characteristics is discussed. Materials are classified in terms of the primary photochemical reactions and the threshold of the energetic light sensitivity and the red limit of the region of spectral sensitivity are estimated for each primary reaction.
The bibliography includes 163 references.

I. INTRODUCTION

Among the problems of modern photographic science, the following occupy a central position: the search for highly effective light sensitive materials, the prediction of their properties, and estimation of the limiting values of the principal characteristics of such materials. The properties of individual non-silver chemical materials and processes have been examined in reviews devoted to specific photographic materials: photochromic materials[1-21], materials with physical development[22-30], light-sensitive polymers[31-34], photopolymerisation materials[34-43], diazotype materials[44-52], vesicular materials[52-55], and free-radical materials[56-63]; they are also considered in general reviews[64-78].

In order to solve the problems indicated above, it is necessary to establish a relation between the photographic characteristics of light-sensitive materials and the physicochemical properties of the initial light-sensitive substances.

We shall consider a general approach to the solution of this problem. Fig. 1 presents a scheme for the production of an image when chemical non-silver photographic processes are used. Evidently the production of an

image with the aid of these materials involves several stages. Stage (1) is a photochemical reaction with formation of the primary photoproduct. In individual instances (pathway *A*) the primary product already constitutes a centre for the formation of the image. However, as a rule (pathway *C*) the primary product initiates in stage (2) further dark reactions with formation of a latent image. As a result of stage (3), the latent image is developed (or intensified) and centres of the final image are produced. Sometimes (pathway *B*) the primary photoproduct constitutes the latent image and in this case there is no second stage in the production of the image. The properties of the resulting image are determined by all three stages, so that the determination of a relation between the photographic characteristics of light-sensitive materials and the physicochemical properties of the initial sensitive system is a complex problem and involves the analysis of each stage.

It is in general impossible to carry out a complete analysis of the entire set of processes. This review is devoted to the analysis of the first stage of the production of the image—the primary photochemical reaction. On the basis of this analysis, certain limiting parameters of photographic materials are estimated. The second and third stages in the production of the image (dark reactions and intensification processes) as well as sensitisation problems are not discussed.

If the image formation process has only one stage (pathway *A*, Fig. 1), then the estimates yield the limiting characteristics in the materials. In the presence of other stages (cases *B* and *C*) the estimates constitute the lower limits of the values of these characteristics.

The group of non-silver photographic processes for the recording of information is very large and includes photochemical reactions in non-silver light-sensitive materials based on organic and inorganic compounds, photochemical

processes in semiconductors, etc. We shall isolate from this large group of processes those which involve photochemical transformations in the molecule, i.e. are unimolecular or bimolecular reactions in the initial organic or inorganic compounds, and shall define them as photochemical processes for the recording of information. In the present review attention is concentrated on organic compounds.

Analysis of the activity of the light-sensitive non-silver materials known hitherto showed that processes in the following fourteen materials can be assigned to the subclass of photochemical processes for the recording of information: diazo-type materials, vesicular materials, light-sensitive polymers (positive and negative), photochromic materials, photopolymerisation materials, materials with physical development, free-radical materials, chromium-treated colloids, photodeformation materials, photothermopolymerisation cyanotype materials, luminescent materials, and photoenzymographic materials; the properties and photographic characteristics of these materials are discussed in the next Section.

II. PHOTOGRAPHIC CHARACTERISTICS OF NON-SILVER MATERIALS WHOSE ACTIVITY IS BASED ON PHOTOCHEMICAL REACTIONS

Table 1 presents the main characteristics of fourteen types of the above materials: the method of development of the latent image, the region of spectral sensitivity, the maximum values of energetic sensitivity and resolving power, the number of rerecording cycles, and the types of recording. Table 1 shows that different methods are used to develop and fix the image in non-silver light-sensitive materials of the type under consideration: treatment with a gas, "wet" development (treatment in an appropriate solution), thermal, and optical. The range of spectral sensitivity ($\Delta\lambda$) of the materials is 200–700 nm.

The energetic light sensitivity of a photographic material Q is defined as the minimum amount of energy (in J cm^{-2}) giving rise to a definite photographic effect) i.e. the change in the optical density of the image ΔD (for example $\Delta D = 1$ is adopted for materials Nos. 5 and 8, and $\Delta D = 0.2$ is adopted for material No. 7) or in the depth of the relief (0.1 and 0.2 μm for materials Nos. 10 and 11 respectively). The energetic light sensitivities of the materials listed in Table 1 are in the range 10^{-1}–10^{-7} J cm^{-2}. The resolving power $R = 400$–5000 mm^{-1} is more than enough for the majority of technical applications of the given materials. The number of rerecording cycles is 1 to 10^4; the materials permit amplitude, phase, and phase-amplitude recording.

The problems of the application of the materials are not considered in this review; they are dealt with in other reviews and monographs[3,4,15,32,36,73]. It is noteworthy that only the resolving power of these materials satisfies all the practical requirements. In terms of important characteristics such as the region of spectral sensitivity and energetic light sensitivity, these materials are greatly inferior to silver halide materials and can replace the latter only in a limited number of instances.

III. GENERAL SCHEME FOR THE KINETIC ANALYSIS OF THE PHOTOCHEMICAL STAGE IN THE RECORDING OF INFORMATION. PRINCIPAL APPROXIMATIONS

We shall consider a general scheme for the kinetic analysis of the photochemical stage in the recording of information. Since the efficiency of the photochemical process is determined by the quantum yield, it is necessary to establish how the principal photographic parameters of the light-sensitive material are related to the quantum yield, namely the energetic light sensitivity Q and the red limit of the region of spectral sensitivity λ_{lim}. Having analysed subsequently the dependence of the quantum yield of the photochemical reaction on the properties of the initial light sensitive system, we can relate Q and λ_{lim} to the initial parameters of the substance and hence can estimate the limiting values of these parameters.

The primary photochemical reaction can be unimolecular or bimolecular. The unimolecular reaction can be represented in the following form:

$$A^0 \xrightarrow{h\nu} A^*,$$
$$A^* \xrightarrow{k} B \text{ (product)},$$
$$A^* \xrightarrow{k_d} A^0,$$

where A^0 is the initial substance in the ground electronic state and A* is the initial substance in the excited state. The quantum yield in the formation of the photoproduct is

$$q_B = k/(k + k_d), \quad (1)$$

i.e. is determined by the ratio of the rate constants for the photochemical reaction (k) and for the deactivation of the excited state (k_d).

A bimolecular photochemical reaction can be regarded in the most general form as a process involving a random approach of the reacting molecules to a distance necessary for the occurrence of the reaction (this event will be called an "encounter") and the chemical reaction proper. At the instant of the "encounter" the molecules are surrounded by a cage of solvent molecules. Diffusion-controlled processes are usually understood as those whose rate is controlled by the frequency of "encounters". The mechanism of a bimolecular reaction can be represented as follows:

$$A^0 \xrightarrow{h\nu} A^*,$$
$$A^* + C \underset{k_r}{\overset{k_{diff}}{\rightleftharpoons}} [A^* \ldots C],$$
$$[A^* \ldots C] \xrightarrow{k} B \text{ (product)},$$
$$A^* \xrightarrow{k_d} A^0,$$
$$[A^* \ldots C] \xrightarrow{k_d} A^0 + C,$$

where k_{diff} is the rate constant for the enclosure of the reactants in the solvent cage and k_r the rate constant for the emergence from the cage. The quantum yield in the formation of the photoproduct is

$$q_B = \frac{k_{diff}[C]}{k_{diff}[C] + k_d} \cdot \theta_1, \quad (2)$$

where θ_1 is the probability of the reaction in the cage.

Thus the dependence of the quantum yield of the product of the primary photochemical process on the properties of the initial light-sensitive system is determined by its dependence on a number of constants. The rate constant for the photochemical reaction k is in the general case a function of the symmetry and energy $\epsilon_{S(T)}$ of the electronic state, the distribution of electron density in the excited

state, and the properties of the medium in which the reaction takes place (viscosity, temperature, etc.). For each specific photochemical reaction, different parameters among those enumerated can assume the main role, and the exact calculation from the constants for photochemical reactions is at present impossible.

According to this scheme, the rate constant k_d characterises the rate of radiative and non-radiative deactivation of the excited state. It is determined both by the properties of the reacting molecule (symmetry, spin–orbit interaction, vibronic interaction, etc.) and the properties of the matrix (temperature, viscosity, concentration of excitation quenching agents, etc.). However, if we confine ourselves to the case of viscous solutions, which are of main interest in the practical application of light sensitive materials, then many factors become insignificant and it is possible to obtain an answer to the main question—how k_d changes on passing from one compound to another. It is then assumed *a priori* that there is a possibility of synthesising compounds absorbing light and having an energetically predetermined reactive state. Theory[108] and experiment[109] showed that, for conjugated organic molecules with $\epsilon_S(T) < 20\,000$ cm^{-1} (in the estimation of the red limit of the region of spectral sensitivity this energy range is of interest), the constant k_d is determined by a non-radiative process, i.e. $k_d = k_{nr}$, where k_{nr} is the rate constant for the non-radiative deactivation of the excited state. For different compounds belonging to a single class, the constant k_{nr} is fully determined by the energy of the excited state $\epsilon_S(T)$ and the dependence of its values on $\epsilon_S(T)$ is exponential. The empirical dependence of the rate constant k_{nr}^T on the energy of the triplet state ϵ_T of aromatic compounds is described by the formula

$$k_{nr}^T = {}^0k_{nr}^T \exp(-\varepsilon_T/\varepsilon_0), \tag{3}$$

where ${}^0k_{nr}^T$ and ϵ_0 are constants within a single class of compounds and their numerical values (${}^0k_{nr}^T = 10^{7.5}$ s^{-1} and $\epsilon_0 = 1000$ cm^{-1}) have been calculated[109]. According to the theory, the above relation breaks down for $\epsilon_T \leqslant \epsilon_{vib}$.

We shall now proceed to the specific estimation of the long-wavelength limit of the region of spectral sensitivity. The region of spectral sensitivity of the material is determined by the dependence of the quantum yield in the primary photoprocess q on the frequency of the incident light, since the remaining stages in the production of the image as a rule take place in the dark. It should be noted that, only when a vibrationally unexcited singlet (or triplet) state is involved in the photochemical reaction, does the spectral sensitivity coincide with the absorption spectrum of the light-sensitive substance[110]; in many instances these spectral curves may not coincide[111]. In order to determine the red limit of the region of spectral sensitivity of materials, it is necessary to estimate the minimum energy of photons ϵ^{lim} which cause an excitation of the photochemical reaction such that the latter has an adequate quantum yield, for example $q = 10^{-1}$. This choice is arbitrary, but, for $q < 10^{-1}$, the overall light sensitivity of the material becomes low (for an insignificant or zero intensification coefficient), and the region where the material can be used is restricted.

The minimum energy of photons required for the occurrence of a unimolecular photochemical reaction ϵ_T^{lim} can be obtained from Eqn. (1) after substituting in the latter the values of k and k_{nr} as a function of the energy of the reactive state ϵ_T (in the given case the triplet state) and after solving the equation for ϵ_T when $q = 10^{-1}$. In the most general case it is probably possible to assume that, on passing from one molecule to another within a given class, the rate constant for the photoprocess is zero when the energies of the electronic state ϵ_T are smaller than the energies expended on the primary photochemical reaction $\epsilon(I)$ [i.e. $k = 0$ for $\epsilon_T < \epsilon(I)$] and, when $\epsilon_T > \epsilon(I)$, k increases with increase of ϵ_T [i.e. $k = f(\epsilon_T)$ when $\epsilon_T > \epsilon(I)$]. Unfortunately it is as a rule not known how k depends on ϵ_T. If the dependence of the rate constant k_{nr} for a non-radiative transition on the energy of the excited state ϵ_T is described by Eqn. (3), then, when account is taken of the foregoing considerations, Eqn. (1) yields the following minimum energy of the reactive triplet state:

$$\varepsilon_T^b = \varepsilon_0 \ln({}^0k_{nr}^T/9k). \tag{4}$$

In order that the above expression should have a physical significance, the following boundary condition must hold: the energy of the absorbed photon must be greater than or equal to the energy $\epsilon(I)$ required for the occurrence of the primary photochemical reaction $\epsilon_T^b \geqslant \epsilon(I)$. Consequently the red limit of the region of spectral sensitivity in photochemical processes involving the recording of information is determined by two restrictions—energetic and kinetic. If the limits of the estimate based on energetic conditions are known, it is possible to claim *a priori* that allowance for kinetic limitations can lead to a hypsochromic shift of the red limit of the region of spectral sensitivity.

For a bimolecular reaction, the minimum energy of photons required to ensure the occurrence of the reaction can be obtained analogously from Eqn. (2) having substituted in the latter k_d and θ_1 as functions of the energy of the reactive state ϵ_T.

When the reaction proceeds via a singlet molecular state, the approach to the determination of the limiting characteristics remains the same with the sole difference that ${}^0k_{nr}^T$ in Eqn. (4) is replaced by the rate constant ${}^0k_{nr}^S$, the numerical value of which is determined by the ratio ${}^0k_{nr}^S/{}^0k_{nr}^T \simeq 10^6$.[112]

In those cases where the image is determined by the absorption of light by the final products of the overall reaction (photochemical or chemical) the energetic sensitivity of light can be estimated from a formula analogous to that quoted by Jackson[18]:

$$Q = 96DE/qN\varepsilon, \tag{5}$$

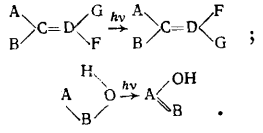
where ϵ is the molar extinction coefficient of the substance (litre mole^{-1} cm^{-1}) which gives rise to the final image, E the energy of the photon in eV, D the optical density of the image ($D_0 = 0$), and N the coefficient of the intensification of the primary action of light. The maximum value of N is determined by the ratio of the reactivities of the initial substance and the photoproduct in relation to the reaction involving the intensification of the primary image.

Thus Eqn. (5) shows that the light sensitivity is determined mainly by the product qN. Evidently, for low quantum yields in the primary photoprocess q but an effective intensification process (i.e. a high value of N), the material can exhibit a high light sensitivity.

If it is assumed that the quantum yield in all primary reactions is unity, the final product has an extinction coefficient $\epsilon = 10^5$ litre mole^{-1} cm^{-1} (this is virtually the limiting value for molecular systems), and the primary image intensification stage is absent, then the limiting energetic light sensitivity of the material, calculated by Eqn. (5) for $\lambda = 400$ nm, is $Q_{D=1}^{400} = 3 \times 10^{-3}$ J cm^{-2}.

In order to estimate the red limit of the region of spectral sensitivity in specific systems by the scheme described above, it is necessary to establish beforehand the type of primary photochemical reactions in the light-sensitive materials employed and to classify these materials in terms of such reactions.

IV. CLASSIFICATION OF LIGHT-SENSITIVE MATERIALS IN TERMS OF PRIMARY PHOTOCHEMICAL REACTIONS



The materials will be classified and their characteristics within each group will be compared†. For this purpose, the primary photochemical reactions of the light sensitive materials listed in Table 1 were analysed. It was found that four primary photochemical reactions are characteristic of materials in this group.

I. Photoaddition:

$$A + B \xrightarrow{h\nu} AB .$$

Here and henceforth A and B are radicals, ions, or molecules. This group includes light-sensitive polymers (negative materials) and photochromic, photodeformation, and luminescent materials.

II. Photorearrangement:

Photochromic materials and materials with physical development belong to this group.

III. Phototransfer of an electron:

$$A + B \xrightarrow{h\nu} A^+ + B^- .$$

The third group includes cyanotype materials, chromium-treated colloids, materials with physical development, and photopolymerisation, photochromic, and free-radical materials.

IV. Photodissociation:

$$AB \xrightarrow{h\nu} A + B .$$

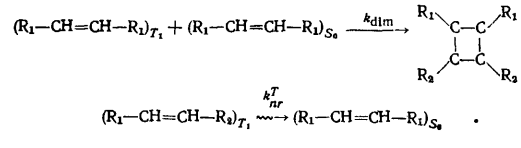
The fourth group includes diazotype and vesicular materials, light-sensitive polymers (negative or positive), and photodeformation, photochromic, photopolymerisation, and photothermopolymerisation materials with physical development.

All four possible elementary photochemical reactions employ only photochromic materials in the production of an image. This is natural, since a property common to all photochemical reactions (reversibility) is used in photochromic materials. In materials with physical development three elementary photochemical reactions are employed: photorearrangement, phototransfer of an electron, and photodissociation. The activity of photopolymerisation materials is based on two elementary photoprocesses: electron transfer and dissociation. Materials of this type cannot be synthesised on the basis of photoaddition and photoisomerisation reactions. Indeed two types of photopolymerisation are known: ionic and radical. In order to initiate polymerisation, it is necessary to generate (by irradiation with light) radicals or ions, which cannot be obtained in photoaddition and photoisomerisation reactions.

Table 2 presents the principal characteristics of materials for each elementary photochemical reaction occurring in them. Evidently materials involving different primary reactions have significantly different energetic light sensitivities, in particular materials with minimum sensitivity have been obtained on the basis of the photoaddition reaction. The observed difference is associated with the fact that the photoprocesses enumerated can generate primary products with the same or different reactivities. Because of this, in some cases there is a possibility of processes involving the intensification of the primary image, while in others there is no such possibility. It will be shown below that the type of primary photochemical reaction determines to a large extent also the red limit of the region of spectral sensitivity of materials.

Table 2.

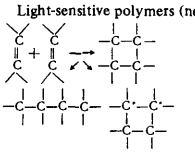
Parameters of materials	Type of reaction			
	I	II	III	IV
R, mm^{-1}	200—3000	2000	400—5000	50—5000
q	10^{-1}—1	10^{-1}—1	10^{-1}—1	10^{-1}—1
N	1	$\geqslant 1$	$\geqslant 1$	$\geqslant 1$
Q, J cm^{-2}	10^{-1}—10^{-2}	10^{-1}—$5\cdot10^{-4}$	10^{-1}—10^{-7}	10^{-1}—10^{-4}

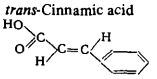


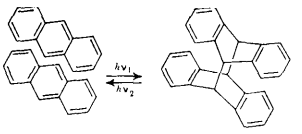
V. RELATION BETWEEN THE RED LIMIT OF THE SPECTRAL SENSITIVITY OF MATERIALS AND THE KINETIC AND SPECTROSCOPIC CONSTANTS OF LIGHT-SENSITIVE SUBSTANCES

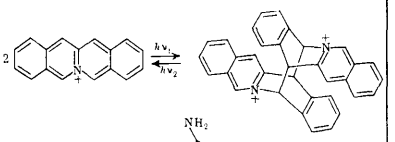
We shall consider in succession the primary photochemical reactions enumerated above, which occur in the recording of an image on light-sensitive materials.

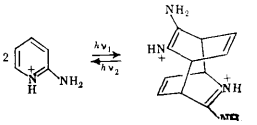
1. Photoaddition

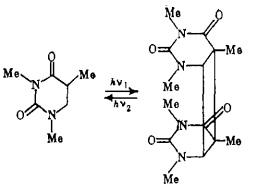












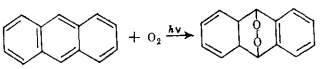


Table 3 presents the principal properties of specific light-sensitive materials in which the primary photochemical reaction is photoaddition. We shall consider photoaddition to an ethylenic double bond, which takes place, for example, in negative photoresistors based on cinnamates and constitutes a model photoaddition reaction. The transition from the primary photochemical reaction to the final parameters of the material will be discussed in relation to this reaction.

Dimerisation involving an ethylenic double bond is a bimolecular reaction in which an excited molecule is added to an unexcited molecule with formation of a cyclobutane ring. Experiments on the sensitisation of this reaction by the triplet–triplet energy transfer showed that it can proceed via an excited triplet state[123–125]. The kinetic scheme for the photodimerisation process can be formulated as follows:

† The classification of inorganic light-sensitive materials in terms of primary photoprocesses has been described[74,75] without the analysis of the limiting characteristics.

Table 3. Photoaddition.

Light-sensitive substance	Primary photochemical reaction	Type of reaction	Region of spectral sensitivity $\Delta\lambda$, nm*	Refs.
Light-sensitive polymers (negative)				
Cinnamic acid derivatives R_1—C(=O)—(CH=CH)$_x$—C$_6$H$_4$—R_2 R_1 — polymer chain; x = 1,2,... = 1, 2 ...		Photodimerisation involving an olefinic double bond	275**	31, 33, 69, 85, 113—115

* λ_1 represents the region of spectral sensitivity of the initial substance and λ_2 the region of spectral sensitivity for the reverse reaction.

** The values of λ_{max} are quoted.

There are no energetic restrictions in the dimerisation reaction, since it proceeds after each "suitable" collision of excited and unexcited molecules. It is probably possible to consider two cases of dimerisation: dimerisation controlled by diffusion and addition of molecules "prepared" beforehand in a cage of matrix molecules. The first instance occurs in reactions in liquid and gas phases and also in a solid–gas system. The second obtains in reactions of molecules in solid solutions and polymers.

The second case is characteristic of the majority of light-sensitive materials, whose activity is based on the photoaddition reaction. Only in photodeformation (abietic acid) and luminescent materials is the addition reaction diffusion-controlled. When the reacting molecules have been enclosed in cages beforehand and the bimolecular reaction proceeds after the collision of species in the cage, the quantum yield can be formulated thus:

$$q = \frac{k_{col}}{k_{col} + k_{nr}}\,\theta_2,$$

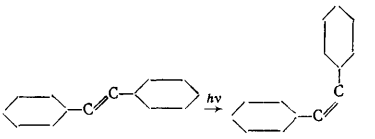
where k_{col} is the rate constant for the collision process in the cage and θ_2 is the probability of reaction on collision. If it is assumed that $\theta_2 = 1$ for the photoaddition reaction in the cage, then the overall quantum yield of

the reaction is equal to the probability of the collision of excited and unexcited molecules in the cage, whereupon $k_{dim} = k_{col}$. The constant k_{col} is determined by the mobility of the reacting molecules, i.e. ultimately by the size and shape of the cage and the dimensions of the reacting molecules, as well as the energy of the intermolecular additive–matrix interaction. In the general case, for a reaction in the cage, it is given by the formula

$$k_{col} = k^0_{col} \exp(-E/RT), \quad (6)$$

where k^0_{col} is the frequency of collisions of two molecules and E is the activation energy for the collision of molecules in the cage. The red limit of the region of spectral sensitivity of materials operating on the basis of the photoaddition reactions can be obtained in this case from Eqn. (4) after substituting in the latter $k = k_{col}$ from Eqn. (6).

For numerical estimates of values of ϵ^{lim}_T, it is necessary to know the specific values of the rate constants and activation energies E. The recombination in a radical pair incorporated in a matrix is a model addition reaction for molecules in a cage. The recombination process itself, like the addition reaction, proceeds without activation energy and the observed activation energy E is due to kinetic causes—it is the activation energy for the mutual approach of molecules. The rate constant for the recombination of radicals of the type $\dot{N}\!\!<^{Ph}_{Ph}$ has been found[126] ($k^0_{rec} = 10^{8.5}$ s^{-1}, E = 7000 cal mole^{-1}).



The same value of the rate constant, i.e. $k_{dim} = k_{rec}$, can probably be adopted for the addition reactions of compounds in which R_1 and R_2 are substituents such as phenyl rings. For compounds where more rigid matrices are used as the substituents, the dimerisation rate constant k_{dim} may be much smaller, mainly as a consequence of the increased activation energy for the collision process. If it is assumed that $k^0_{dim} = 10^9$ s^{-1} and E = 7 kcal mole^{-1} for all dimerisation reactions in solid solutions, then we have $\epsilon^{lim}_T = 6000$ cm^{-1} from Eqn. (4).

On photoexcitation of the system, the triplet state is formed from the singlet state as a result of the $S-T$ transformation. Since $\epsilon_{S-T} = 2000$–3000 cm^{-1} for molecules with low-lying triplet states, the red limit for the photochemical reaction involving the triplet state is defined as follows: $\nu^{lim} = \epsilon^{lim}_T + \epsilon_{ST} = 8000$ cm^{-1}, so that $\lambda_{lim} = 1250$ nm.

The dependence of the limiting energies of the triplet and singlet state ϵ_T and ϵ_S on the activation energy E for different constants k^0_{col}, $^0k^T_{nr}$, and $^0k^S_{nr}$ is illustrated in Fig. 2.

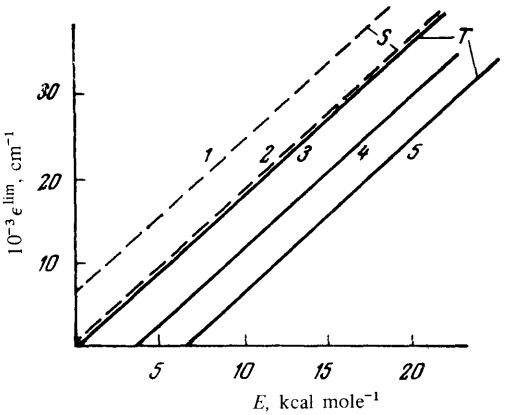
2. Photorearrangement

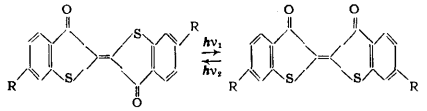
Table 4 lists the light-sensitive materials employing the photorearrangement reaction. The most thoroughly investigated case is that of *trans–cis* isomerisation, namely the *trans–cis* isomerisation relative to ethylenic bonds. Examples of such compounds are provided by aryl derivatives of ethylene and thioindigo dyes. The characteristics of the isomerisation of arylethylenes are in broad outline typical of the isomerisation of other classes of compounds. We shall consider the *trans–cis* isomerisation process in relation to the stilbene molecule. For stilbene and arylethylenes, it has been shown that the *trans–cis* isomerisation can proceed via both triplet[131,132] and singlet[133–135] excited states. The general process mechanism can be represented as follows:

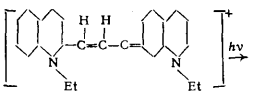
$$trans\text{-form}^{S(T)} \xrightarrow{k_{tc}^{S(T)}} cis\text{-form}^{S_0},$$

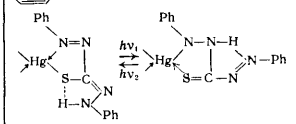
$$trans\text{-form}^{S(T)} \xrightarrow{k_{nr}} trans\text{-form}^{S_0}, \quad (7)$$

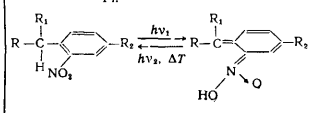
where k_{tc} is the rate constant for the *trans–cis* isomerisation.

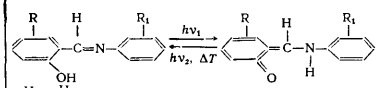


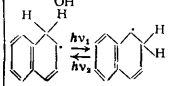


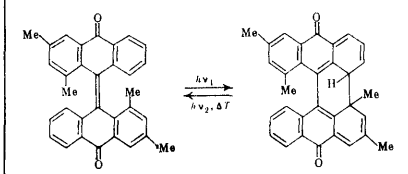


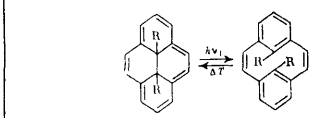












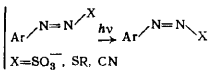


Figure 2. Dependence of the limiting energies ϵ^{lim} of the triplet and singlet states of the molecules on the activation energies; k^0_{col} (s^{-1}): 1), 4), and 5) 10^9; 2) and 3) 10^{12}; $^0k^S_{nr}$ (s^{-1}): 1) and 2) 10^{13}; $^0k^T_{nr}$ (s^{-1}): 3) and 4) $10^{7.5}$; 5) 10^{10}.

Scheme (7) shows that a molecule in the excited state can be either converted into the *cis*-form, which corresponds to the rotation of one fragment relative to the connecting bond, or it can relax to the ground state. For arylethylenes in the triplet state, rotation about the central bond (without taking into account the interaction with the medium) is virtually free from an energy barrier (its height amounts to several kcal)[136,137] and the rotation frequency of the fragment is close to the rotation frequency of the molecule as a whole. It can be assumed that, for identical matrices, the rate constant for the isomerisation of electronically excited molecules is the same as the frequency of the thermal rotation of a molecule of similar size, i.e. it can be formulated as follows:

$$k_{tc} = k^0_{tc} \exp(-E_{rot}/RT), \quad (8)$$

where E_{rot} is the activation energy for rotation determined by the interaction of the molecule with the matrix.

** The values of λ_{max} are quoted.

Thus in making the estimate we assume that the activation energy for an electronically excited molecule is determined, regardless of the energy of the excited states, by the activation energy for the rotation of the molecules in the given matrix. On the assumption that the reaction rate constant $k = k_{tc}^{S(T)}$ is independent of the energy of the excited state $\epsilon_{S(T)}$, the red limit of the region of spectral sensitivity can be estimated from Eqn. (4) after substituting in the latter the numerical values of the reaction rate constant.

There are no data for the parameters of the rotation of aromatic molecules (benzene, naphthalene, etc.) in polymeric matrices. On the other hand, there is much information about the pre-exponential factors and activation energies for the rotation of iminoxy-radicals in

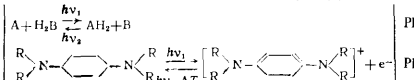
various polymers. For the estimates, we shall assume that the characteristics of the rotational motion of iminoxy-radicals simulate the corresponding parameters for the simplest aromatic compounds. This assumption is probably valid, since the dimensions of the radicals and the compounds which they simulate (for example, arylethylenes and the simplest thioindigo dyes) are approximately the same, and in both cases there is no specific additive–matrix interaction. Having assumed for the *trans–cis* isomerisation in the polymer the activation energy and pre-exponential factor obtained for the rotation of the iminoxy-radical in polystyrene (E_{rot} = 18.2 kcal mole^{-1} and $k^0_{tc} = 4\times10^{18}$ s^{-1} [138]), we can calculate from Eqn. (4), for k_{tc} derived from Eqn. (8), the quantity $\epsilon^{lim}_T = 3000$ cm^{-1} at 300 K. This result is comparable to ϵ_{vib}.

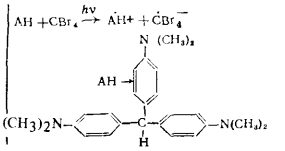
The red limit for a photochemical reaction involving the triplet state with the direct excitation of the molecule to the singlet state and subsequent $S-T$ transition to the triplet state is determined as follows: $\nu lim = \epsilon^{lim}_T + \epsilon_{ST} = 5000$ cm^{-1}; $\lambda_{lim} = 2000$ nm.

It is most probable that the red limit of the region of the spectral sensitivity obtained is too high. The main cause of this is the assumption of the absence of an internal barrier to rotation. For polymethine dyes, the activation energy increases several fold with decrease of the energy of triplet levels[139]. Allowance for this factor leads to a hypsochromic shift of the red limit.

3. Phototransfer of an Electron

Materials whose activity is based on the phototransfer of an electron are listed in Table 5. In the general form the phototransfer of an electron can be represented schematically as follows[148]:





$$A^{S(T)} + H_2Y \xrightarrow{k_e} A^{\cdot}e^- + H_2Y^{\cdot+},$$
$$A^{S(T)} \xrightarrow{k^{S(T)}_{nr}} A^0,$$

where k_e is the rate constant for electron transfer.

As in photoaddition, the process consists of two stages—the mutual approach to a distance R_0 and subsequent electron transfer over this distance. It has now been established that phototransfer of an electron is a tunnel process and to a first approximation its rate constant varies exponentially with the distance. However, for the estimates in the present review, one can assume that, when $r \leq R_0$, the rate constant for electron transfer is large (the estimate yields $k_e = 10^{14}$ s^{-1} for $r < R_0$ [149]) and the probability of electron transfer over such distances $\theta_1 \simeq 1$, because the constants for the deactivation of the singlet ($k^S_{nr} = 10^{13}$ s^{-1}) and triplet ($k^T_{nr} = 10^{7.5}$ s^{-1}) states (see above) are smaller than the rate constant for electron transfer indicated above.

Thus the overall quantum yield in the phototransfer of an electron is determined by the probability of the mutual approach of the donor and acceptor to the transfer distance

*λ_1 represents the region of spectral sensitivity of the initial substance and λ_2 the region of spectral sensitivity for the reverse reaction.

and can be calculated from Eqn. (2), where $c = H_2Y$ and $\theta_1 = 1$.

Two cases are possible in this reaction.

1. The distance between the donor and acceptor is small ($r \leq 5$) and the mutual approach stage is not required for the occurrence of the reactions; the process involves solely electron transfer. In this case there are no kinetic limitations, i.e. the first multiplier in Eqn. (2) is unity and the red limit of the region of spectral sensitivity is determined solely by energetic limitations: $\epsilon^{lim}_{S(T)} = \epsilon(I)$.

2. The reaction is controlled by diffusion and its quantum yield is determined by the probability of encounters. This case corresponds to low concentrations of the acceptor or a low rate constant k_{diff} for the diffusion of the donor to the acceptor. In this case the stage involving the mutual approach of the donor and acceptor is rate-limiting. The red limit of the region of spectral sensitivity is determined from Eqn. (4), which in this case assumes the following form:

$$\varepsilon^{lim}_T = \varepsilon_0 \ln (k^T_{nr}/9k_{dif}[H_2Y]) \quad . \tag{9}$$

Fig. 3 presents the dependence of ϵ^{lim}_T on $[H_2Y]$ plotted on the basis of Eqn. (9). It is noteworthy that the dependence has a physical significance only for $\epsilon^{lim}_T > \epsilon(I)$. The necessary energetic limitation of the electron phototransfer reaction $\epsilon(I)$ is determined (without taking into account the interaction with the medium)[150] from the condition:

$$\varepsilon(I) = I_{H_2Y} - Q_A - W_e, \tag{10}$$

where W_e is the energy of the Coulombic interaction of the charges in the ion pair (the dissociation energy of the ion pair), Q_A is the electron affinity of the electron acceptor, and I_{H_2Y} is the ionisation potential of the electron donor.

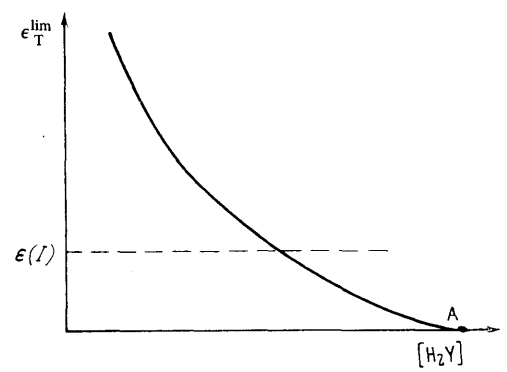

Figure 3. Dependence of ϵ^{lim}_T on the concentration of the electron donor H_2Y. $[H_2Y] = k^T_{nr}/9k_{dif}$ at point A.

Since experimental relations between k^T_{nr} and ϵ_T were used in the given study for conjugated hydrocarbons, in the estimates it is useful to employ as the electron acceptor (excited molecule) a substance in the class of conjugated hydrocarbons for which $Q_A = 0$–1.0 eV.[151]

For the zinc oxide ($I_{ZnO} = 6.6$ eV) [152]–conjugated hydrocarbon donor–acceptor pair, the estimate of the minimum value of $\epsilon(I)$ based on Eqn. (10) for $W_e = 3 - 4$ eV yields $\epsilon(I) = 1.6$ eV and correspondingly $\lambda(I) = 770$ nm.

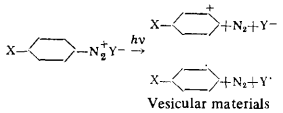
4. Photodissociation

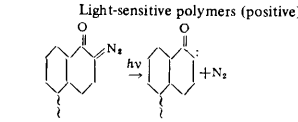
Table 6 presents data whose employment is based on the photodissociation reaction. This elementary reaction embraces the largest number of light sensitive materials. It has been established that the photodissociation of organic compounds can proceed via several mechanisms[162].

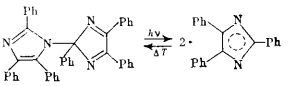
Dissociation into a continuum. In this case the molecule is excited directly to the repulsive state. The molecule excited from the ground to a non-bonding state decomposes during the period of one vibration, which is approximately 10^{-13} s. This mechanism of the decomposition reaction is characteristic of simple molecules (Fig. 4*a*).

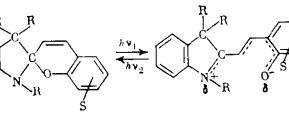
Thermal or quasi-equilibrium dissociation. The molecule is excited to a bonding state, which lies above the bond dissociation energy Fig. 4*b*). After the electronic energy has been transformed into the vibrational energy of the entire molecule, the latter is concentrated in a single bond and causes its rupture. As a rule this is the weakest bond.

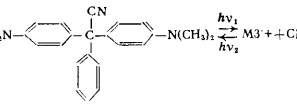
Non-adiabatic dissociation. In this case the electron energy is concentrated in one specific vibration (or in several vibrations). As a rule, this is the most anharmonic vibration. For example, in hydrocarbon molecules, the most anharmonic vibration is that of the C–H bond.

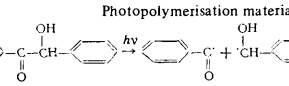








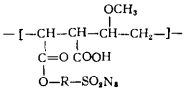




Predissociation. This dissociation mechanism obtains in complex organic molecules. The molecule is excited to a higher bonding state, i.e. the electronic excitation is delocalised over the entire molecule (Fig. 4*c*). This high bonding state intersects the repulsive state associated with any one bond and the interaction of the states leads to a transition of the molecule from a bonding to a repulsive state. This is followed by the dissociation of the given bond as a result of the concentration of the electron energy in the latter.

Dissociation involving a multistage intramolecular process. In complex molecules containing several chromophoric groups the dissociation process can consist of several intramolecular stages. In the first stage intramolecular charge transfer takes place, which results in the weakening or dissociation of one of the bonds. The next stage involves the decomposition of the unstable form into molecular fragments.

In order to determine the red limit of the region of spectral sensitivity of materials whose employment is based on the photodissociation reaction, it is necessary to examine the energetic and kinetic limitations in this reaction.



From the energetic point of view the minimum energy of the absorption of a photon, giving rise to photochemical activity, is limited by the dissociation energy of the weakest bond and in thermal dissociation of light-sensitive substances is directly equal to the energy of the weakest bond (Fig. 4*b*)[163]: $h\nu^{lim}(I) = D_{A-B} = 30$ kcal mole^{-1} = 1.3 eV, so that $\lambda_{lim}(I) = 1000$ nm. On the other hand, if the predissociation mechanism operates, the minimum energy of the photon must be about 1.5 times greater than the energy of the bond undergoing dissociation (Fig. 4*c*).

***SO_2N_3 is the light-sensitive group of the polymer 

However, if $k_{diss} \ll k_{nr}$, then the quantum yield in the primary photochemical reaction may be close to zero even when the photon energy exceeds the bond energy. In this case kinetic limitations operate and $\lambda_{lim} < 1000$ nm. It is not possible to obtain a kinetic estimate of the red limit of spectral sensitivity owing to the lack of sufficiently well developed models of the photodissociation of complex molecules. If the photodissociation reaction proceeds by

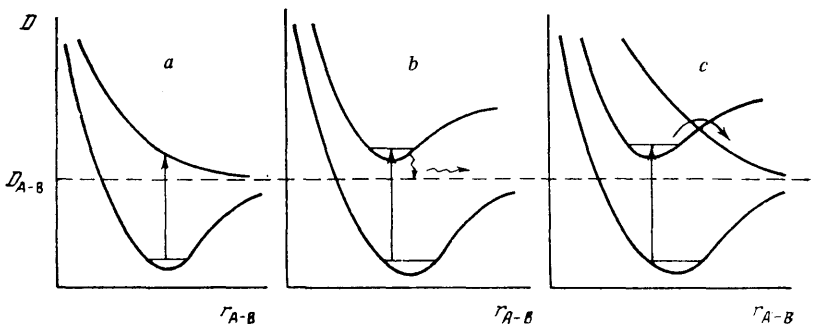

Figure 4. Mechanisms of the photodissociation of molecules: *a*) dissociation into continuum; b) thermal or quasi-equilibrium dissociation; c) predissociation. The arrows indicate the two stages of the process–conversion of electron energy into vibrational energy and bond dissociation.

dissociation into a continuum, then the condition $k_{diss} \gg k_{nr}$ holds and such photochemical reactions will have the energetic red limit calculated above.

VI. CONCLUSION

This review examines the properties of non-silver light-sensitive materials whose activity is based on photochemical reactions, analyses the nature of the primary photochemical reactions employed, and classifies the materials in terms of primary photochemical reactions. The classification shows that the type of primary photochemical reaction determines the nature of the primary photoproduct, i.e. the possibility of subsequent chemical intensification and hence the energetic light sensitivity of the material. The importance of assessing the possibility of intensifying the primary effect follows from the fact that the experimental energetic light sensitivities of such materials do not usually exceed 10^{-1} J cm^{-2}. This difference from the limiting calculated light sensitivity is apparently associated with the fact that the quantum yield of the photochemical reactions of the substances employed $q < 1$ and the extinction coefficient of the photoproduct $\epsilon < 10^5$ litre mole^{-1} cm^{-1}.

Thus the importance of seeking possible intensification processes is evident. Chemical intensification reactions are in principle possible only subject to the condition that the initial substance and the product have different reactivities. We shall consider which photochemical reactions permit further intensification.

According to Table 3, a photoaddition reaction as a rule gives rise to stable products and both the initial substance and the final product have no catalytic activity and cannot initiate oxidation-reduction or polymerisation processes. Consequently the occurrence of a chemical intensification process in such materials is unlikely.

Photorearrangement as a rule results in the formation of stable products. However, cases are known where reaction products are also formed. For example, Jonker and coworkers[24,29] found that the primary action of light may be intensified. They used the ability of the *cis*-benzenediazo-sulphides and -sulphonates, obtained as a result of *trans–cis* isomerisation, to disproportionate mercurous ions with formation of metallic mercury nuclei—centres for physical development. This made it possible to attain a light sensitivity $Q = 5 \times 10^{-4}$ J cm^{-2} for materials with physical development based on the *trans–cis* isomerisation reaction.

The phototransfer of an electron leads to the formation of products, which have reactivities markedly different from those of the starting materials and which are capable of initiating oxidation–reduction reactions, polymerisation, etc. Because of this, materials whose employment is based on electron phototransfer have the highest energetic light sensitivity—up to 10^{-7} J cm^{-2}.

Photodissociation gives rise to radicals, biradicals, or radical-ions, which can initiate polymerisation processes ensuring high values of the coefficient of the intensification of the primary action of light.

The approach proposed in this review, which takes into account both kinetic and energetic limitations in the primary photochemical reaction, has made it possible, in conjunction with several specific models, to estimate the red limit of the region of spectral sensitivity for primary photochemical reactions. However, one should note that the values obtained are only approximate. It is better to regard them as an illustration of the fact that the proposed approach permits a quantitative analysis of the properties of light sensitive materials on the basis of the characteristics of photochemical reactions.

Catalytic Ionic Hydrogenation

M.I.Kalinkin, G.D.Kolomnikova, Z.N.Parnes, and D.N.Kursanov

Data on the catalytic hydrogenation of unsaturated organic compounds in acid media are examined and discussed. A new method of catalytic hydrogenation in acid media, in which the catalyst activates hydrogen and the substrate is activated by the acid which converts it into a positively charged intermediate, is proposed. The role of catalysts as agents transferring hydride ions from molecular hydrogen to carbonium ions is considered.
The bibliography includes 58 references.

IV. Heterogeneous catalysts as hydride ion transferring agents 339

I. INTRODUCTION

Hydrogenation is one of the most general and common reactions in organic chemistry. It is widely used both in organic synthesis (among other purposes, for the preparation of important substances) and in the study of the reactivities and structures of compounds. A multiplicity of different methods for the hydrogenation of unsaturated organic compounds belonging to different classes have now been developed. Some of them, for example hydrogenation over heterogeneous catalysts, are extremely effective; they are widely used in chemistry and chemical engineering.

One of the main requirements which must be met by hydrogenation methods is selectivity, i.e. the possibility of hydrogenating some unsaturated groups in the molecule without affecting others. The majority of studies on hydrogenation have been devoted recently to the solution of this problem. The fundamental factor which determines a particular type of selectivity of the given hydrogenation method is the reaction mechanism. However, the mechanism of various hydrogenation reactions has not always been established or has been elucidated only in the very broadest outline. In particular, the determination of the mechanism of hydrogenation in the presence of heterogeneous catalysts constitutes a problem which has still not been fully solved, to a large extent because these reactions are accompanied by a number of complex physicochemical processes on the catalyst surface.

We believe that hydrogenation reactions can be classified in terms of the properties of the unsaturated substrate, which largely determine the mechanism of the given reaction, and the nature of the selectivity of the hydrogenation process can be predicted for groups of reactions based on the same property of the substrate. In this approach all the known hydrogenation processes are divided into three broad groups.

The first group comprises methods based on the ability of the unsaturated compound to be coordinated to the catalyst metal atom. It includes all hydrogenation reactions in the presence of homogeneous or heterogeneous catalysts. A common feature of the mechanism of these reactions is coordination of the unsaturated substrate to the metal or its complex, which activates hydrogen. We shall not discuss here the exact meaning of the term "coordination" and we shall only note that, whatever the mechanism of the interaction of the substrate with the catalyst, the mutual approach of the species involved in this interaction is postulated. The extensive experimental data accumulated on catalytic hydrogenation show that an increase in the number and bulk of substituents at the hydrogenated bond leads to a decrease of the rate of hydrogenation. Catalytic hydrogenation methods therefore make it possible to hydrogenate selectively less shielded multiple bonds. For example, in the series of olefins the rate of hydrogenation decreases in the sequence: terminal olefins > disubstituted ethylenes with a double bond within the chain > trisubstituted ethylenes > tetrasubstituted ethylenes.

For certain catalysts, the difference between the rates of reaction is so great that selective hydrogenation of terminal olefins is possible in the presence of olefins having a large number of substituents at the ethylenic carbon atoms. The carbonyl group and the benzene ring are hydrogenated much more slowly than the ethylenic double bond, but the shielding of the latter by bulky substituents sometimes permits the selective hydrogenation of these groups without involving the ethylenic bond. Certain catalytic systems permit the selective hydrogenation of double bonds activated by electron-accepting substituents.

One should note that catalytic hydrogenation in most cases gives rise to products of the *cis*-addition of hydrogen to the unsaturated compound.

The second large group of methods for hydrogenation processes comprises those based on the electron (or hydride ion) affinity of the unsaturated compounds. It includes methods such as reduction by active metals in alcohols, acids, and amines, reduction by complex metal hydrides, lithium tetrahydroaluminate, or sodium tetrahydroborate, boranes, or alanes, and electrochemical hydrogenation methods. A characteristic feature of the mechanisms of these reactions is initial attack on the unsaturated compound by a nucleophile—an electron or a hydride ion†; this makes it possible to combine all such reactions in a single group and to expect them to have similar selectivities in the hydrogenation of unsaturated systems.

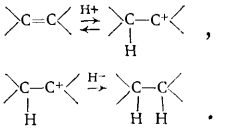
† We believe that the hydride ion transfer process involves the overall transfer of a proton and two electrons from one molecule to another. However, the detailed mechanisms of such reactions will not be considered in the present review.

Polar groups and polarised double bonds are readily reduced by these methods. Ethylenic bonds can be reduced fairly successfully in those cases where they are conjugated to electron-accepting substituents such as carbonyl, carboxy-, nitro-, and cyano-groups, aromatic rings, and other groups. In olefins under optimum conditions there is a possibility of the selective hydrogenation of a double bond activated by an electron-accepting substituent in the presence of compounds of other types. Furthermore, the addition of aluminium and boron hydrides to olefins permits the selective hydrogenation of the terminal double bonds in the presence of double bonds within a chain or olefinic groups with branching at the ethylenic carbon atom.

The third group consists of methods for the electrophilic ionic hydrogenation‡. The reaction mechanism is based on the ability of the unsaturated compound to combine with a proton to form an active intermediate—a carbonium ion, which, by abstracting a hydride ion from a suitable donor, is converted into the hydrogenation product. For a given acidity of the medium, this reaction permits the selective hydrogenation of unsaturated compounds capable of existing in equilibrium with the corresponding carbonium ions, in the presence of other unsaturated compounds which do not form carbonium ions in the reaction medium.

For example, in acids with $H_0 \simeq -3$ (trifluoroacetic acid) the use of a hydrogen-containing silane as a hydride ion donor results in the selective hydrogenation of olefins branched at the ethylenic carbon atom. Such olefins are capable of forming tertiary alkyl cations as a result of protonation by trifluoroacetic acid; at the same time, unbranched olefins with a double bond within the chain, whose protonation might give rise to less stable secondary carbonium ions, are not hydrogenated under these conditions. The introduction of electron-donating substituents, stabilising the carbonium centre, permits the hydrogenation also of monosubstituted olefins, for example styrene, vinyl ethers, and vinyl sulphides.

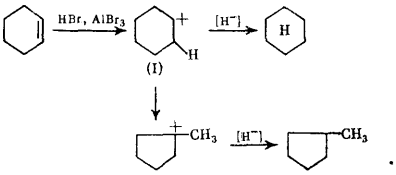
The selectivity of electrophilic hydrogenation is thus fundamentally different from the selectivity of the groups of hydrogenation reactions described above, in which unsaturated substrates activated by electron-accepting substituents are hydrogenated preferentially. Yet another characteristic feature of the electrophilic ionic hydrogenation is the preferential *trans*-addition of hydrogen; in molecules with a rigid skeleton, for example, in certain steroids, *trans*-addition products are formed exclusively.



Thus all known hydrogenation methods are based on three properties of unsaturated compounds: tendency towards coordination to the catalyst metal atom, the ability to combine with a nucleophilic species (solvated electron, hydride ion, the anion of a complex hydride), and finally the tendency towards electrophilic attack—towards the initial protonation of the substrate. We believe it is difficult to imagine yet another fairly general property of unsaturated compounds which might constitute the basis of a fundamentally new hydrogenation process. It therefore appears extremely promising to combine the advantages characteristic of different groups of hydrogenation processes.

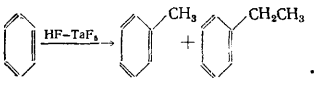
By virtue of the availability of the hydrogenating agent (molecular hydrogen), catalytic methods are greatly superior to procedures based on other hydrogenation processes. As stated above, the usual catalytic hydrogenation methods and methods based on the electron affinity of the unsaturated compound manifest similar selectivities, while the selectivity of electrophilic ionic hydrogenation is in principle unattainable when the first two methods are used. It was therefore of interest to develop a catalytic ionic hydrogenation process which would possess the advantages of catalytic methods and the selectivity of ionic hydrogenation.

‡ In contrast to this, reduction by complex metal hydrides might be called nucleophilic ionic hydrogenation.



II. INTERACTION OF CARBONIUM IONS WITH HYDROGEN. HYDRIDE ION TRANSFERRING AGENTS

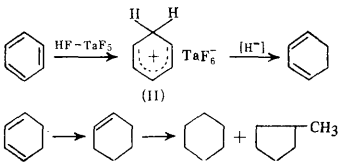
The mechanism of ionic hydrogenation includes two stages: protonation of the unsaturated compound with formation of an active intermediate (carbonium ion) and irreversible interaction of the latter with a hydride ion donor, leading to hydrogenation products:



Hydrogen-containing silanes with organic substituents or hydrocarbons having a suitable structure are normally used as hydride ion donors[1]. The simplest and most readily available hydride ion donor is molecular hydrogen, but it is extremely inactive in relation to carbonium ions.

When a solution of $AlBr_3$ in cyclohexene is heated in a hydrogen atmosphere (150°C, pressure 80 atm, 26 h), only 2% of cyclohexane and 4% of its isomerisation product (methylcyclopentane) are formed[2]; the main bulk of the product consists of unidentified high-boiling hydrocarbons. The authors[2] believe that the reaction mechanism involves a stage in which a hydride ion is split off from hydrogen by a secondary carbonium ion (I), formed as an intermediate under these conditions:

A stable, i.e. relatively unreactive, cation such as triphenylcarbonium does not interact with hydrogen under the conditions indicated. A solution of $AlBr_3$ in benzene at 180°C and a hydrogen pressure of 68 atm absorbs a slight amount of hydrogen, but neither cyclohexane nor methylcyclopentane were detected in the reaction products[2].



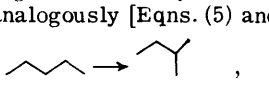
When benzene reacts with the $HF-TaF_5$ system, the main products are toluene and ethylbenzene in a yield of approximately 40% (relative to the benzene which has reacted)[3]:

The authors believe that the hydrogen required for this reaction is formed in the condensation of benzene to polycyclic compounds under the reaction conditions. When the reaction is carried out under hydrogen pressure, the yield of toluene and ethylbenzene increases by 15–25%.

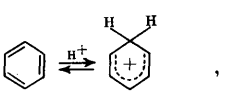
The hydrogenation of benzene in the presence of the $HF-TaF_5$ system in hydrocarbons (for example in n-hexane) at 50°C leads to cyclohexane as the main product[4]. The reaction mechanism with the intermediate formation

of the carbonium ion (II) and the migration of a hydride ion towards it from hydrogen or, what is more likely, from the solvent has been proposed:

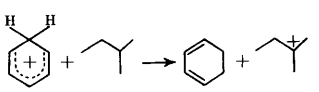
Certain cycloalkanes undergo hydrogenolysis, i.e. the cleavage of the ring with subsequent hydrogenation, in the same system at 50°C and a hydrogen pressure of approximately 15 atm.[5] Thus cyclohexane readily isomerises to methylcyclopentane, which is cleaved with formation of a mixture of t-hexyl cations. Their reduction by hydrogen leads to a mixture of isomeric hexanes. Cyclopentane gives a mixture of straight-chain pentane and isopentane. The rate of hydrogenolysis of cycloalkanes depends on the steric strain in the ring and on the nature of the carbonium ion formed during the cleavage process.



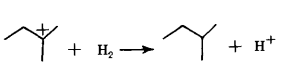
A more detailed study of the hydrogenation of benzene by hydrogen in strong acid media showed[6] that the hydrogenation proceeds at 50°C and a hydrogen pressure of approximately 30 atm in the presence of the $HF-TaF_5$, $HF-SbF_5$, $HBr-AlBr_3$, and $HCl-AlCl_3$ systems. Benzene is hydrogenated only in the presence of hydrocarbons having tertiary carbon atoms. Molecular hydrogen, unbranched alkanes, and cycloalkanes cannot serve as hydride ion donors in this reaction. Straight-chain reactions are first isomerised to isoalkanes, which are in fact the true hydride ion donors in relation to carbonium ions formed in the protonation of the benzene ring. At a hydrogen pressure >14.8 atm the reaction proceeds in the presence of catalytic amounts of isopentane, the role of hydrogen consisting in the reduction of the isopentyl cation formed from isopentane when a hydride ion is transferred to protonated benzene.



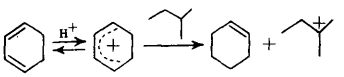
It was shown in an earlier study of the isobutane–trimethylcarbonium equilibrium in a strong acid medium[7] that this entails the reduction of the tertiary alkyl carbonium ion by hydrogen:



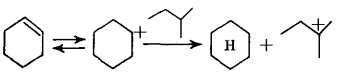
$$(CH_3)_3CH \underset{H_2}{\overset{HF,\,SbF_5}{\rightleftharpoons}} (CH_3)_3C^+SbF_6^- + H_2 .$$



The benzyl[8], norbornyl, and methylcyclohexyl cations[9] are also reduced by hydrogen ion superacids.



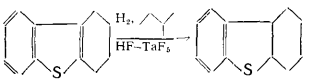
A mechanism of the hydrogenation of benzene by hydrogen in the presence of alkanes has been proposed on the basis of these data[6]: isomerisation of n-pentane to isopentane (1), protonation of benzene (2), transfer of a hydride ion from isopentane to the cationic σ-complex (3), and the reduction of the isopentyl cation by hydrogen (4). The subsequent hydrogenation of dihydrobenzene to cyclohexene takes place analogously [Eqns. (5) and (6)]:



(1)

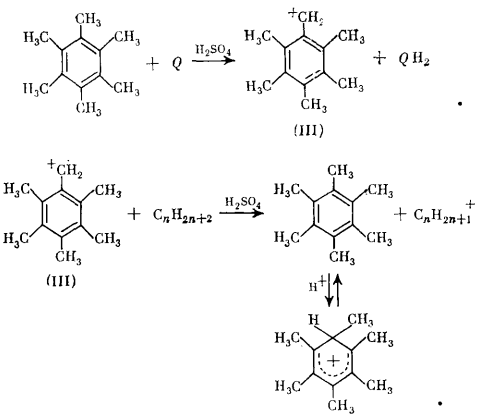
(2)

(3)



(4)

(5)



(6)

Isopentane behaves in this reaction as the catalyst—the agent which transfers a hydride ion from molecular hydrogen to carbonium ions.

It has also been shown[10] that naphthalene is hydrogenated to tetralin and the latter partly isomerises to methylindan. Anthracene is not hydrogenated under these conditions. Thiophen gives up to 40% of thiophan and dibenzothiophen is reduced to hexahydrodibenzothiophen. The same product is formed in a high yield on hydrogenation of tetrahydrodibenzothiophen in the $HF-TaF_5$ system in the presence of isopentane and hydrogen[10]:

It is of interest to note that hexamethylbenzene can serve as an agent for transferring a hydride ion from alkanes to quinones in a highly acid medium[11]. It is oxidised by the quinone to the pentamethylbenzyl cation (III), which is capable of abstracting a hydride ion from the alkane, regenerating hexamethylbenzene:

where Q = quinone.

It follows from above data that hydrogen is an extremely inactive hydride ion donor in relation to carbonium ions and, because of this, branched hydrocarbons are relatively ineffective as agents for the transfer of a hydride ion from molecular hydrogen to protonated unsaturated compounds.

III. HOMOGENEOUS HYDROGENATION CATALYSTS AS AGENTS TRANSFERRING HYDRIDE IONS FROM MOLECULAR HYDROGEN TO CARBONIUM IONS

The study of the chemistry of carbonium ions shows that one of the most characteristic reactions of these species is their ability to behave as hydride ion acceptors. The hydride mobility of hydrogen in various E–H bonds has been examined in detail in a monograph[12]. We shall only note that even strong acids such as hydrogen bromide and iodide, are capable of behaving as hydride ion donors in relation to sufficiently reactive carbonium ions.

A number of individual transition metal hydride complexes have been synthesised in recent years, many of these behaving as homogeneous hydrogenation catalysts[13,14]. Some of them are capable of transferring a coordinated hydride ion to an unsaturated substrate. Thus the isomerisation of alkyl allyl ethers to alkyl propenyl ethers catalysed by platinum hydrides[15] involves the initial addition of the platinum hydride to the double bond contrary to the Markovnikov rule, which indicates polarisation of the $Pt^{\delta+}-H^{\delta-}$ type.

It might have been expected that many transition metal hydride complexes are capable of transferring a hydride ion not only to an unsaturated compound, but also to carbonium ions; however, in the literature there are only a few isolated examples of such reactions. Thus ruthenium(IV) dihydrides reduce triphenylcarbonium, being converted into cationic complexes of ruthenium(V)[16]:

$$\underset{(IV)}{H_2RuL_3} + Ph_3C^+PF_6^- \rightarrow \underset{(V)}{(HRuL_3)^+PF_6^-} + Ph_3CH ,$$

where L = Ph_3P.

It has been asserted[17] that platinum(VI) and iridium(VII) hydride complexes reduce diphenylmethyl and triphenylmethyl cations in 60–80% sulphuric acid:

$$Ph_3C^+ \xrightarrow{(Et_3P)_2Pt(H)Cl(VI)} Ph_3CH ,$$

$$Ph_2CH^+ \xrightarrow{(Et_3PhP)_2IrH_5Cl(VII)} Ph_2CH_2 .$$

The reliability of these data[17] is open to some doubt, since a large (approximately 100-fold) excess of the metal hydride complex was used and the authors noted the decomposition of the complex in sulphuric acid. The reaction was followed solely from the change in the intensity of the band in the electronic spectrum corresponding to the absorption by the carbonium ion; the reaction products were not identified.

For the catalytic reduction of carbonium ions, the transition metal complex must be able not only to transfer a hydride ion but also to activate hydrogen with formation of a metal hydride complex in acids which are sufficiently strong to generate carbonium ions. Data demonstrating the possibility of using homogeneous catalysts to activate hydrogen in media with the required acidity for ionic hydrogenation, particularly in trifluoroacetic acid, were not available in the literature.

In 1974 the authors of the present review suggested that certain platinum-group metal complexes be used as agents for transferring a hydride ion from molecular hydrogen to stable carbonium ions[18]. The role of the catalyst in this reaction (in relation to platinum) is as follows:

(1) The platinum complex reacts with hydrogen to form the corresponding hydride complex:

$$L_2PtX_2 + H_2 \rightarrow L_2Pt(H)X + HX .$$

(2) The hydride complex then reacts with the carbonium ion, formed from the substrate in the acid medium, and converts it into the corresponding hydrocarbon:

$$L_2Pt(H)X + \diagdown\!\!\diagup C^+X^- \rightarrow L_2PtX_2 + \diagdown\!\!\diagup CH .$$

Triphenyl- and diphenyl-methanols are not reduced in trifluoroacetic acid by platinum hydride complexes, either in equimolar proportions or with a 100-fold excess of hydride, but, when the reaction is carried out under hydrogen pressure, triphenyl- or diphenyl-methanes are formed in yields exceeding 1 mole per mole of the catalyst. Consequently in trifluoroacetic acid these complexes are capable of activating molecular hydrogen and of transferring it in the form of hydride ions to stable carbonium ions.

The results of the study of the influence of the ligands and the central metal atom on the activity of catalysts in the reduction of triphenylmethanol are presented in Table 1. Comparison of data obtained for catalysts Nos. 4, 7, and 8 shows that, depending on the nature of the metal, the activity of the catalyst decreases in the sequence Pt > Pd > Ni.

Thus the possibility of using homogeneous hydrogenation catalysts (platinum, palladium, and nickel complexes of phosphine) to activate hydrogen in strong acid media and to reduce stable carbonium ions has been demonstrated.

Ruthenium salts also catalyse the reduction of triphenylmethanol by hydrogen in an acid medium[19]. In concentrated hydrochloric acid at a hydrogen pressure of 100 atm and 80°C (28 h) triphenylmethanol is converted in the presence of $RuCl_3$ into 1-(diphenylmethyl)-4-(triphenylmethyl)benzene (VIII) in 97% yield (4.2 moles per mole of the catalyst):

$$Ph_3COH \xrightarrow{HCl} Ph_3C^+ \xrightarrow{H_2,RuCl_3} Ph_3CH ,$$

$$Ph_3CH + Ph_3C^+ \rightarrow \underset{(VIII)}{Ph_2CH{-}C_6H_4{-}CPh_3} .$$

Evidently Ph_3C^+ attacks the triphenylmethane formed on reduction, giving rise to (VIII), which is stable in hydrochloric acid.

Table 1. Reduction of Ph_3CCH (0.3–0.4 g) in CF_3COOH (3 ml) (amount of catalyst 0.04–0.05 g, p_{H_2} = 100 atm, 20°C, 150 h).[18]

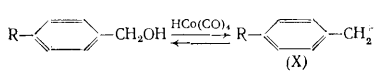
No.	Catalyst	Yield of Ph_3CH, mole/mole of catalyst
1	*cis*-$(Ph_3P)_2Pt(OCOCF_3)_2$	39
2	*cis*-$(Et_3P)_2Pt(OCOCF_3)_2$	27
3	*trans*-$(Ph_3P)_2Pt(H)Cl$	23
4	*cis*-$(Ph_3P)_2PtCl_2$	19
5	*cis*-$(Et_3P)_2PtCl_2$	19
6	*cis*-$(n\text{-}Bu_3P)_2PtCl_2$	14
7	*cis*-$(Ph_3P)_2PdCl_2$	15
8	*cis*-$(Ph_3P)_2NiCl_2$	10
9	*trans*-$(n\text{-}Bu_3P)_2PtCl_2$	5

The interaction between triphenylmethanol and hydrogen in trifluoroacetic acid in the presence of $RuCl_3$ leads to triphenylmethane in 96% yield. Other ruthenium salts, such as the acetate and trifluoroacetate, also catalyse the hydrogenolysis of triphenylmethanol, and are more active than $RuCl_3$. Thus under identical conditions $RuCl_3$, ruthenium acetate, and ruthenium trifluoroacetate give rise to 68, 87, and 97% of triphenylmethane. Among ruthenium salts, the trifluoroacetate is the most active. When this catalyst is used, the reduction of Ph_3C^+ is accelerated with increase of temperature. The yield of triphenylmethane was 26% (5 moles per mole of the catalyst) at 20°C, 78% (14 moles per mole of catalyst) at 50°C, and 96% (18 moles per mole of the catalyst) at 80°C. At a hydrogen pressure of approximately 1 atm, there is no reduction but, when the pressure is raised from 5 to 90 atm, the yield of triphenylmethane increases from 35 to 98%. The results show that the ruthenium salts investigated are capable of catalysing the transfer of a hydride ion from hydrogen to the carbonium ion.

The authors of the present review showed recently[20] that certain phosphine complexes of iridium (IX) also catalyse the reduction of triphenylmethanol in an acid medium, the iridium trihydride complex being the most active:

$$Ph_3COH \xrightarrow[70^\circ C,\ p_{H_2}=100\ atm]{L_3IrH_nX_{3-n}(IX),\ CF_3COOH} Ph_3CH ,$$

$$L = Ph_3P;\ X = Cl;\ n = 1-3 .$$



The ability of certain hydrogenation catalysts to activate hydrogen in an acid medium and to transfer it in the form of hydride ions to carbonium ions made it possible to propose a new mechanism for catalytic hydrogenation, in which the catalyst activates hydrogen and the unsaturated substrate is activated by the solvent—an acid, which converts it into the active intermediate (the carbonium ion). This permits catalytic hydrogenation with a selectivity characteristic of electrophilic ionic hydrogenation.

1. Catalytic Ionic Reduction of Alcohols

The relative rate of homogeneous reduction of substituted benzyl alcohols under hydroformylation conditions in the presence of cobalt tetracarbonyl hydride decreases in the following sequence of substituents[21]:

$$p\text{-}OCH_3 > p\text{-}CH_3 > m\text{-}CH_3 > p\text{-}C(CH_3)_3 > H > p\text{-}Cl > m\text{-}OCH_3 > m\text{-}CF_3.$$

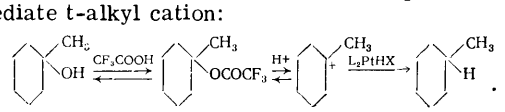
This sequence corresponds to that expected for reactions with the intermediate participation of carbonium ions (X): it is suggested that they are formed from benzyl alcohols under the influence of the acid $HCo(CO)_4$:

(X)

The mechanism of the reduction of carbonium ions was not established in the above investigation.

It has been found[22] that, in trifluoroacetic acid under hydrogen pressure and in the presence of phosphine complexes of platinum, a primary alcohol (2-ethylhexanol) and a secondary alcohol (cyclohexanol) are not reduced, while tertiary alcohols (tri-n-butylmethanol and 1-methylcyclohexanol) are converted under these conditions into the corresponding hydrocarbons. The yield of 5-n-butylnonane and methylcyclohexane were 56 and 80% respectively under identical conditions. Thus, when hydrogen is used as the hydride ion donor and phosphine complexes of platinum are used as hydride ion transferring agents, there is a possibility of the selective catalytic ionic hydrogenolysis of tertiary alcohols.

The influence of certain factors on the reduction of tertiary alcohols has been studied[22] in relation to 1-methylcyclohexanol. Methylcyclohexane is formed only when the reaction mixture contains simultaneously an alochol, trifluoroacetic acid, hydrogen, and the catalyst. Methylcyclohexane is the only product of the reduction of methylcyclohexanol; skeletal isomerisation products were never detected. After the reaction, the mixture remains homogeneous and metallic platinum is not formed. This reaction is catalytic. When bistriphenylphosphineplatinum bistrifluoroacetate is used as the catalyst in trifluoroacetic acid (hydrogen pressure 200 atm, 50°C, 35 h), the catalytic yield of methylcyclohexane is 103 moles per mole of the catalyst. After the removal of volatile mixture components, the reuse of the catalyst gives rise to similar results: the yield after 25 h under analogous conditions is 73 moles per mole of the catalyst.



In the reduction of methylcyclohexanol, as in the reduction of triphenylmethanol, $(Ph_3P)_2Pt(OCOCF_3)_2$ is the most active of the catalysts investigated. The platinum hydride chloride and dichloride complexes exhibit similar but smaller activities. The phosphine complexes of palladium and nickel are almost inactive in the hydrogenolysis of both tertiary and secondary aliphatic alcohols.

The reduction of 1-methylcyclohexanol is greatly influenced by the solvent (Table 2). In neutral and weakly acid media (tetrahydrofuran, acetic acid, and formic acid) the reduction of 1-methylcyclohexanol is not observed. The increase of the polarity of the medium on passing from benzene to nitrobenzene and the increase of the concentration of trifluoroacetic acid appreciably increase the yield of methylcyclohexane.

Table 2. Reduction of 1-methylcyclohexanol (0.2 g) in the presence of trifluoroacetic acid (0.4 ml), the solvent (2 ml), and the $(PPh_3)_2PtCl_2$ catalyst (0.05 g) (p_{H_2} = 100 atm, 27 h, 50°C).[22]

Solvent	Yield of methylcyclohexane, %
Tetrahydrofuran	0
Acetic acid	0
Formic acid	0
Benzene	5
Toluene	6
Chloroform	14
Nitrobenzene	32
Trifluoroacetic acid–toluene (1:1)	35
Trifluoroacetic acid	96

The results permit the conclusion that the reduction of tertiary alcohols under these conditions involves hydride ion transfer from the platinum hydride complex to the intermediate t-alkyl cation:

The reduction of tertiary alcohols alone in the presence of secondary and primary alcohols confirms the ionic reaction mechanism, since in trifluoroacetic acid only tertiary alcohols are in equilibrium with the corresponding alkyl carbonium ions. In the above reaction mechanism the function of the catalyst is restricted to the activation of hydrogen, while the substrate is activated by being converted into a carbonium ion.

Ruthenium salts activate via an analogous mechanism the selective reduction of a tertiary alcohol (methylcyclohexanol) in the presence of a secondary alcohol (cyclohexanol)[19].

Thus many homogeneous hydrogenation catalysts are capable of catalysing the reduction of tertiary alcohols, and the same selectivity is observed as in the ionic hydrogenation by the silane–trifluoroacetic acid system.

2. Catalytic Ionic Hydrogenation of Olefins

Protic or Lewis acids are usually employed in homogeneous hydrogenation processes to rupture the carbon–metal σ-bond. They also facilitate the dissociation of the

ligand with liberation of a vacant site in the coordination sphere of the metal as a result of the coordination of the acid to the ligand or to the metal atom. Even in those cases where there is a possibility, in principle, of the formation of carbonium ions in the reaction [for example, in the homogeneous hydrogenation of cyclohexene with the aid of $RhCl(PPh_3)_3$ in the presence of aluminium bromide[23] or in the homogeneous hydrogenation of a series of olefins catalysed by $Rh(OCOCH_3)(PPh_3)_3$ in the presence of toluene-*p*-sulphonic acid[24]], their involvement in the reaction has not so far been discussed.

The homogeneous hydrogenation of olefins via an ionic mechanism has been described[25]. Data for the homogeneous hydrogenation of olefins in the presence of ruthenium trifluoroacetate are presented in Table 3. Evidently, when the reaction is carried out in toluene, a disubstituted ethylene (cyclohexene) is hydrogenated, while a trisubstituted ethylene (1-methylcyclohexene) does not react; the relative reactivities of these olefins in trifluoroacetic acid are reversed. Consequently, the hydrogenation of olefins in the solvents investigated proceeds via different mechanisms.

Table 3. Hydrogenation of olefins (0.1 g) in the presence of the $Ru(OCOCF_3)_3$ catalyst (0.05 g) (p_{H_2} = 85 atm, 50°C, 20 h).[25]

Olefin	Yield of saturated hydrogenation products			
	%	mole/mole of catalyst	%	mole/mole of catalyst
	in CH_3COOH		in toluene	
Cyclohexene	0	0	55	9
1-Methylcyclohexene	46	6	0	0
1,2-Dimethylcyclohexane	14	1.5	—	—
Tetramethylethylene	13	2	—	—

When the reaction takes place in toluene, the usual homogeneous hydrogenation, involving the coordination of the olefin to the ruthenium atom, occurs. Ruthenium homogeneous hydrogenation catalysts are known to be capable of the selective hydrogenation of terminal double bonds in compounds containing double bonds also within the chain or branches at ethylenic carbon atoms[26]. In trifluoroacetic acid methylcyclohexene is hydrogenated, while cyclohexene is not, which conflicts with the above rule and, in order to explain it, another hydrogenation mechanism, an ionic mechanism, must be resorted to. Since only tertiary alkyl carbonium ions are capable of existing in trifluoroacetic acid, the selectivity observed in this case can be readily accounted for from the standpoint of an ionic hydrogenation mechanism, involving the transfer of a hydride ion from the reduced form of the catalyst to the carbonium ion. One should note that even tetrastituted olefins—tetramethylethylene and 1,2-dimethylcyclohexene—are hydrogenated under these conditions. This is the first instance of the homogeneous hydrogenation of tetrasubstituted olefins catalysed by ruthenium compounds.

As in the reduction of alcohols, it was found that the hydrogenation of olefins occurs only when the reaction mixture contains all the components: the olefin, trifluoroacetic acid, the catalyst, and hydrogen. One should also note that the mixture remains homogeneous during hydrogenation and that the catalysts are insensitive to oxygen and atmospheric moisture.

The use of phosphine complexes of platinum as catalysts also permits the catalytic ionic hydrogenation of olefins. This reaction occurs only in trifluoroacetic acid; in toluene, in acetic and formic acids, in the benzene–methanol mixture, and in nitrobenzene with added hydrochloric acid the formation of alkanes is not observed.

As in the reduction of triphenylmethanol, in the hydrogenation of olefins bistriphenylphosphineplatinum bistrifluoroacetate is the more active catalyst. The results for the hydrogenation of a series of olefins in its presence are presented in Table 4. Evidently substitution of hydrogen atoms at the ethylenic bond by methyl groups has a small influence on the hydrogenation process. It is noteworthy that, in contrast to the data in Table 3, in this case the cyclohexene is also hydrogenated. Presumably the hydrogenation of cyclohexene occurs at the instant of the protonation of the substrate and some of the cyclohexyl carbonium ions have sufficient time to split off a hydride ion from the platinum hydride and to be converted into cyclohexane, while others combine irreversibly with the trifluoroacetate anion, forming cyclohexyl trifluoroacetate, which is incapable of further reduction. Indeed, with increase of the reaction time under the conditions indicated in Table 4, the yield of cyclohexane does not increase, while in the reaction of olefins branched at an ethylenic carbon atom the yield of the hydrogenation products continues to rise.

Table 4. Hydrogenation of olefins (0.1 g) in the presence of the $(Ph_3P)_2Pt(OCOCF_3)_2$ catalyst (0.02 g) and CF_3COOH (1 ml) (p_{H_2} = 100 atm, 50°C, 20 h).[25]

No.	Olefin	Yield of alkane	
		%	mole/mole of catalyst
1	Tetramethylethylene	84	50
2	1,2-Dimethylcyclopentane	56	30
3	1,2-Dimethylcyclohexene	41	22
4	1-Methylcyclohexene	45	23
5	Cyclohexene	35	20

The above data confirm the homogeneous catalytic ionic hydrogenation mechanism which involves a transfer of a hydride ion from the metal hydride complex to the carbonium ion. The ease of hydrogenation of unsaturated compounds is in this case determined by the stability of the corresponding carbonium ions and not by their tendency to coordinate to the metal atom. This leads to easier hydrogenation of trisubstituted olefins compared with olefins containing a terminal double bond or a double bond within the chain without a branch at the ethylenic carbon atom. This type of selectivity of hydrogenation is not attainable, in principle, when any other catalytic hydrogenation method is used.

3. Catalytic Ionic Hydrogenation of Carbonyl Compounds

The homogeneous hydrogenation of carbonyl compounds has been developed to a much lesser extent than the hydrogenation of olefins. The phosphine complexes of cobalt,

iridium, and rhodium may be mentioned as catalysts for the homogeneous hydrogenation of carbonyl compounds [27]. All these catalysts are capable of initiating the reduction of other functional groups as well. The following substrate activity series is then observed: olefins with a terminal double bond > disubstituted ethylenes with a double bond within the chain > trisubstituted ethylenes > aldehydes > ketones.

When homogeneous hydrogenation catalysts are used, the carbonyl group must be activated. Thus $H_3Ir(PPh_3)_3$ is an effective catalyst for the hydrogenation of aldehydes to alcohols only in acetic acid [28]. The cationic hydrides $RhH_2L_2S_2^+$ [L = PPh_3, PPh_2CH_3, $PPh(CH_3)_2$, or $P(CH_3)_3$; S is the solvent], in the presence of small amounts of water as a promoting agent, are capable of hydrogenating the carbonyl group of ketones under mild conditions [29]. It has been shown [29] that the neutral complexes $RhHL_2S_2$ do not reduce carbonyl compounds. Hydrogenation occurs only when HBF_4 is added to these catalysts, i.e. when the carbonyl group is activated either by an excess of acid or by the complex itself.

The above data show that the catalytic hydrogenation of the carbonyl group under mild conditions requires its activation by protic or Lewis acids.

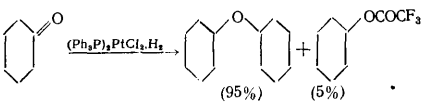
Carbonyl compounds are readily reduced by hydrogen-containing silanes in trifluoroacetic acid and the mechanism of this reaction involves a stage in which the hydride ion is transferred from the silane to the intermediate carboxonium ion (XI): [1]

$$R_2C{=}O \xrightleftharpoons{CF_3COOH} \underset{(XI)}{[R_2C{=}OH]^+} \xrightarrow{R_3SiH} R_2CH{-}OH .$$

Table 5. Dependence of the yield of isopropyl trifluoroacetate on the catalyst (~0.1 g of acetone, ~0.02 g of catalyst, 3 ml of CF_3COOH, p_{H_2} = 85 atm, 30 h, 50°C). [30]

Catalyst*	Yield	
	%	mole/mole of catalyst
$(PPh_3)_2PtCl_2$	80	63
$(PPh_3)_2Pt(OCOCF_3)_2$	34	27
$(PPh_3)_2PdCl_2$	⩽1	—
$(PPh_3)_2NiCl_2$	⩽1	—

*There is no hydrogenation in the absence of the catalyst.



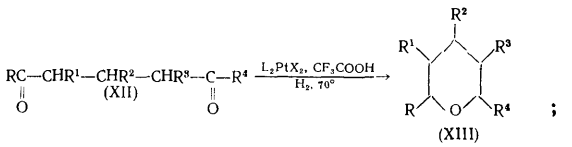
It has been shown [30] that phosphine complexes of platinum, which do not catalyse the homogeneous hydrogenation of carbonyl compounds, acquire this capacity in trifluoroacetic acid. In the ionic hydrogenation of acetone by silane and trifluoroacetic acid a mixture of 60% of isopropyl alcohol (in the form of isopropyl trifluoroacetate) and 25% of di-isopropyl ether is formed. The catalytic ionic hydrogenation of acetone gives rise to only one product–isopropyl trifluoroacetate. Data for the dependence of the yield on the nature of the catalyst are presented in Table 5. An increase of the acidity of the medium leads to an increase of the yield of the hydrogenation product (Table 6); in the absence of acid there is no hydrogenation. When trifluoroacetic acid is replaced by formic or acetic acid, the hydrogenation of acetone slows down. Under the same conditions, the yields of isopropyl trifluoroacetate, formate, and acetate, are 45, 32, and about 10% respectively.

Thus, in the homogeneous catalytic ionic hydrogenation of acetone the highest yields of product (isopropyl trifluoroacetate) were obtained when trifluoroacetic acid was used as the proton donor and solvent and the catalyst and hydride ion transferring agent was bistriphenylphosphine-platinum dichloride. The rate of ionic hydrogenation increases with increase of temperature, hydrogen pressure, duration of heating, and acidity with the medium.

Table 6. Dependence of the yield of isopropyl trifluoroacetate on the amount of trifluoroacetic acid [~0.1 g of acetone, 0.02 g of $(Ph_3P)_2PtCl_2$, p_{H_2} = 85 atm, 55°C, 23 g]. [30]

Composition of solvent, ml		Yield, %	Composition of solvent, ml		Yield, %
CF_3COOH	benzene		CF_3COOH	benzene	
0	3	0	1	2	31
0.3	2.7	5	3	0	45

As in ionic hydrogenation by the $R_2SiH-CF_3COOH$ system, in the catalytic ionic hydrogenation cyclohexanone is reduced much faster than acetone. Thus the complete reduction of cyclohexanone at 50°C and a hydrogen pressure of 85 atm takes place over a period of 21 h, whereas acetone is hydrogenated over a period of 40 h under the same conditions. The reaction gives rise to a mixture of dicyclohexyl ether (95%) and cyclohexyl trifluoroacetate (5%):



Catalytic homogeneous ionic hydrogenation of cyclohexanone can serve as a preparative method for the synthesis of dicyclohexyl ether, while other methods for its formation give low yields. For example, one of the known methods for the synthesis of this ether, from cyclohexanol and cyclohexene in hydrofluoric acid, gives only 12% of dicyclohexyl ether [31], while the yield in ionic hydrogenation by the $Et_3SiH-CF_3COOH$ system is 15%. [1]

The catalytic ionic hydrogenation of n-butyraldehyde results in the formation of only one product—n-butyl trifluoroacetate [30]. A mixture of 33% of dibutyl ether and 60% of n-butyl trifluoroacetate is obtained in the ionic hydrogenation of n-butyraldehyde by the $Et_3SiH-CF_3COOH$ system [1]. n-Butyraldehyde is hydrogenated faster than acetone. At 50°C and a hydrogen pressure of 85 atm the yields of isopropyl and n-butyl trifluoroacetates after 22 h are 42 and 67% respectively. The catalytic ionic hydrogenation of benzaldehyde gave benzyl trifluoroacetate in approximately 70% yield [30]. The yield of dibenzyl ether in the reduction of benzaldehyde by silane was 80%. [1]

The catalytic ionic hydrogenation of aromatic ketones, like their ionic hydrogenation by silanes, involves the more far-reaching reduction of the carbonyl group to the methylene group, which can be accounted for by the stability of carbonium ions in which a benzene ring adjoins the carbonium centre [30]. When benzophenone was reduced under a hydrogen pressure of 150 atm at 60°C over a period of 135 h, diphenylmethane was isolated in 93% yield. It was found [32] that, in the catalytic ionic

hydrogenation of acyclic and bicyclic 1,5-dicarbonyl compounds (XII), the corresponding tetrahydropyrans (XIII) are formed in high yields:

(XII) (XIII)

$RR^1=R^3R^4=(CH_2)_4$, $R^2=H$ (85%);
$R=R^4=C_6H_5$, $R^1=R^3=H$, $R^2=CH_3$ (97%);
$R=R^4=C_6H_5$, $R^1=R^3=CH_3$, $R^2=H$ (80%);
$R=R^2=R^4=C_6H_5$, $R^1=R^3=H$ (82%) .

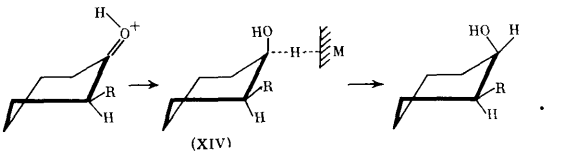
The above method for the hydrogenation of 1,5-diketones is suitable also for the synthesis of tetrahydropyrans, which are of interest as plasticisers and solvents. The methods described previously for their synthesis are preparatively difficult, because in most cases they involve the addition of various compounds to the double bond of dihydropyrans, which are relatively difficult to obtain.

IV. HETEROGENECUS CATALYSTS AS HYDRIDE ICN TRANSFERRING AGENTS

Hydrogenation in the presence of heterogeneous catalysts still remains the most widely used hydrogenation procedure in industry and laboratory practice. It is highly efficient and usually presents no difficulties. The determination of the mechanism of hydrogenation in the presence of heterogeneous catalysts is extremely difficult, largely because hydrogenation is accompanied by phenomena occurring on the surface of the catalyst.

The main role of the catalysts consists in the activation of molecular hydrogen and the substrate. According to the generally accepted theory of Horiuchi and Polanyi [33], the process can be divided into the following stages:

(a) $Cat + H_2 \rightleftharpoons Cat.HH$ (adsorption of hydrogen);
(b) $Cat.HH + S \rightleftharpoons Cat.HH.S$ (adsorption of substrate);
(c) $Cat.HH.S \rightleftharpoons Cat.H.SH$ (hydrogenation);
(d) $Cat.H.SH \rightleftharpoons Cat.SH_2$;
(e) $Cat.SH_2 \rightleftharpoons Cat + SH_2$ (desorption of product).

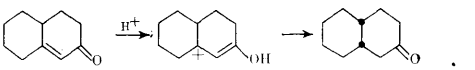


(Here Cat is the catalyst and S the substrate). It follows from the above scheme that the hydrogen activated by the catalyst adds in steps to the adsorbed substrate via the stage with a semihydrogenated state. As a rule stage (c) or (d) is rate-limiting.

The nature of the activation of hydrogen on the surface of the transition metal is still not clear, although its investigation has remained in the centre of attention of many investigators [34-36]. Without going into the details of this complex field, we shall only note that it has now come to be regarded as established than an M–H bond is formed on the metal surface [37]. The removal of hydrogen from the metal takes place via both homolytic and heterolytic mechanisms, depending on the nature of the substrate. If the substrate is a positively charged species, for example, a carbonium ion, then chemisorbed hydrogen can be transferred to the substrate in the form of a hydride ion. The reaction can then be represented by the usual scheme for ionic hydrogenation, as in the homogeneous catalytic hydrogenation in acid media (see Section III):

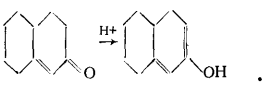
$$S + H^+ \rightleftarrows SH^+ ;$$
$$Cat + H_2 \rightleftarrows Cat \cdot HH ;$$
$$Cat \cdot HH + SH^+ \rightleftarrows CatH^+ + SH_2 ;$$
$$CatH^+ \rightleftarrows Cat + H^+ .$$

Under these conditions hydrogen is activated by the catalyst and the substrate by the acid, which converts it into a cation. The catalyst behaves as an agent transferring a hydride ion from molecular hydrogen to the substrate.



This section deals with hydrogenation reactions occurring on heterogeneous catalysts in acid media, for which an ionic mechanism has been suggested. The hypothesis of a possible ionic hydrogenation mechanism on heterogeneous catalysts was first put forward by Brewster [38] in 1954. In order to explain the influence of the medium on the stereochemistry of the hydrogenation of α-substituted cyclohexanones, he suggested that a protonated form of the ketone (XIV), coordinated in such a way that the bulky substituent (the metal) occupies a sterically less hindered equatorial position, exists in an acid medium on the catalyst surface. The hydride transfer from the catalyst to the protonated form of the ketone leads to axial alcohols:

(XIV)



McQuillin [39,40], who studied the hydrogenation of cholestenone and testosterone over Pd/C and PtC_2 in various solvents, also found that the stereochemistry of the reaction product (the formation of 5α- or 5β-steroids) depends on the polarity of the medium. In order to account for the stereochemical results in an acid medium, he adopted Brewster's hypothesis of an ionic hydrogenation mechanism.

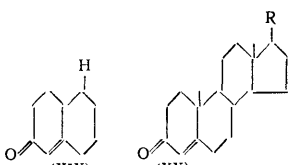
The concept of hydride transfer from the catalyst surface was used to interpret data obtained in the hydrogenation of a series of unsaturated cyclopropanes [41]. When $\Delta^{1,9}$-2-octalinone is hydrogenated over Pt/C or Pt/C in media with pH < 2, mainly *cis*-2-decalinone (XV) is obtained [42-44]. It is suggested that at the above pH values the protonated form (XVI) is formed as an intermediate and is more effectively adsorbed on the catalyst surface than the initial ketone:

(XVI) (XV)

Coordination of the metal from the sterically less hindered side of the carbocycle ensures a direction of attack by the hydride ion on the adsorbed carbonium ion which leads to (XV). It has been noted [42-44], however, that a similar stereochemical result can be obtained in the hydrogenation of the homoannular dienol (XVII), which can isomerise in an acid medium:

(XVII)

At low concentrations of ketones the rate of their hydrogenation over PtO_2 greatly increases on passing from acetic to trifluoroacetic acid or when strong acids (for example, $HClO_4$) are added to acetic acid [45]. Assuming the possibility that the reaction in strong acids proceeds via either one of the two mechanisms mentioned above, i.e. with formation of carboxonium ions or homoannular enols, Peterson and Casey [45] gave preference to the reaction mechanism involving the enol. They believe that this view is confirmed by the hydrogenolysis of t-butyl alcohol



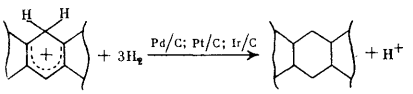
over PtO_2 in trifluoroacetic acid, which proceeds, in their view, via the hydrogenation of the isobutene in equilibrium with the initial alcohol. The equilibrium involves the intermediate formation of the t-alkyl cation (XVIII), but the possibility of the transfer of a hydride ion from the catalyst to the carbonium ion is not considered:

$$(CH_3)_3COH \overset{CF_3COOH}{\rightleftharpoons} (CH_3)_3COCOCF_3 \rightleftarrows (CH_3)_3C^+ \rightleftarrows (CH_3)_2C{=}CH_2 .$$
(XVIII)

The hydrogenation of $\Delta^{8,9}$-dihydropimaric acid over PtO_2 in acetic acid with formation of *trans,anti,trans*-tetrahydropimaric acid (instead of the expected *trans,anti,cis*-acid) was explained by a carbonium ion reaction mechanism [46].

The accelerating effect of the addition of acids (HCl and $HClO_4$) to aqueous solutions of methanol and acetic acid in the hydrogenation of nitrobenzene, acetophenone, and cyclohexene over Pt/C was explained by the formation of protonated species [47].

The ideas developed in the studies quoted above are hypothetical and are open to many objections. Firstly, the acidity of the solvents employed is insufficient for the formation of carbonium ions in the absence of the catalyst, which, however, does not rule out the possibility of the protonation of the unsaturated compound already coordinated to the catalyst. It may be that the acid has an activating effect on the catalyst, altering its properties, and not on the substrate [46]. Secondly, on the basis of the stereochemistry of the hydrogenation products, one cannot decide whether the reaction proceeds via an ionic mechanism, since the stereochemical result of heterogeneous hydrogenation is a consequence of several factors: the adsorption of the unsaturated substrate alters its geometry, which therefore entails a change in the torsional strain and intramolecular interactions; there is a possibility of the isomerisation of the substrate on the catalyst; furthermore, the surface of the catalyst is not planar, as assumed in the classical theory [49]. For example, in the study of the hydrogenation of the enones (XIX) and (XX) in acids a very large difference was observed between the stereoselectivities (i.e. between the ratios of the *cis*- and *trans*-products) when the catalyst and hydrogenation conditions were altered [50]. This effect for similar compounds cannot be accounted for solely by the formation of protonated species.

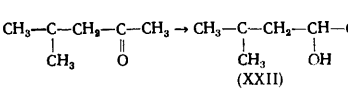


(XIX) (XX)

The reduction of stable carbonium ions can serve as direct evidence for the possibility of an ionic hydrogenation mechanism. It was observed in 1975 [51] that the hydrogenation of the triphenylcarbonium cation formed from triphenylmethanol in trifluoroacetic acid over Pt/C at 50 atm leads to triphenylmethane. This reaction can take place also over other catalysts, namely PtO_2 and Pd/C. In non-polar solvents, for example, in ether, there is no hydrogenation of triphenylmethanol.

It was later shown [52] that the catalytic hydrogenation of the triphenylcarbonium ion can take place not only in acids, but also in aprotic solvents, for example, in acetic anhydride over Pt/C, Pd/C, Ir/C, and Rh/C at 27 atm. Subsequently several more studies were published in which convincing data are presented concerning the possibility of an ionic hydrogenation mechanism on heterogeneous catalysts.

Wristers [52] observed a very large increase in the rate of hydrogenation of aromatic compounds, for example, benzene, mesitylene, hexamethylbenzene, *p*-di-(t-butyl)-benzene, and ethyl phenyl ether over Pt/C, Ir/C, and Pd/C in the presence of superacids $HF-BF_3$ or $HF-TaF_5$ (Table 7). It was found that the main product of the hydrogenation of mesitylene is 1,3,5-trimethylcyclohexane; other trimethylcyclohexane isomers are also formed, as well as insignificant amounts of alkanes with nine carbon atoms. In the hydrogenation of different aromatic hydrocarbons the rate increases with increasing concentration of the protonated aromatic compound (XXI):

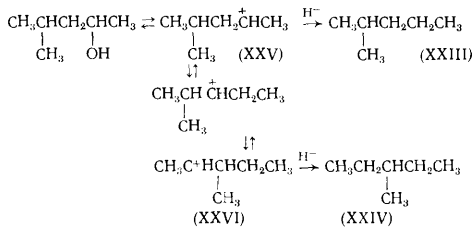


(XXI)

It has been suggested [52] that the catalyst initially activates hydrogen. The subsequent interaction of the activated hydrogen with the carbonium ion, i.e. with the cationic σ-complex (XXI), leads to the formation of a hydrocarbon and a positively charged metal. The interaction of the latter with molecular hydrogen regenerates the species with an M–H bond and the proton.

Table 7. Hydrogenation of mesitylene (0.1 mole) in acid [52].

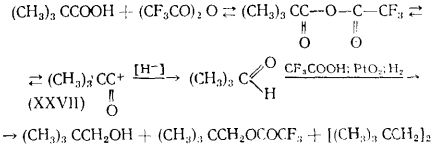
Acid (moles)	Catalyst (5% on charcoal), g	$t_{1/2}$, min	Relative increase of rate for acid-catalysed reaction
Without acid	Pd; 1.0	12 720	1
HF (2,2)	Pd; 1.0	88	144
HF (2,3) + BF_3 (0,23)	Pd, 1.0	3.5	3630
HF (2,3) + TaF_5 (0,20)	Pd, 1.0	4.5	2830
Without acid	Ir; 1.8	1 300	1
HF (2,2) + TaF_5 (0,20)	Ir; 1.8	8.5	153
Without acid	Pt; 1.83	299	1
HF (2,4) + TaF_5 (0,20)	Pt; 1.83	22	14



The formation of saturated products characteristic of reactions occurring with participation of carbonium ions, particularly alkylation and isomerisation reactions [53], was observed in the hydrogenation of a number of aromatic hydrocarbons over PtO_2 and RuO_2 in anhydrous hydrogen fluoride [53]. For example, the hydrogenation of benzene leads to 92% of cyclohexane as well as a small amount of cyclohexylbenzene and bicyclohexyl; the hydrogenation of *m*- and *p*-xylenes gives rise to six isomeric dimethylcyclohexanes, etc. It has also been shown [53] that PtO_2 catalyses the hydrogenation of 4-methylpentan-2-one to the corresponding alcohol (XXII) in a mixture of HF with ether:

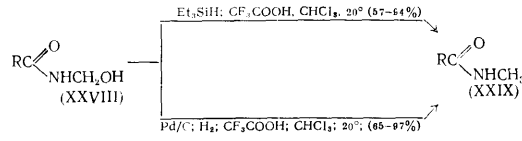
(XXII)

In a highly acid medium (anhydrous HF) the alcohol (XXII) undergoes further reduction to a mixture of hydrocarbons (XXIII) and (XXIV). This result may be expected for the



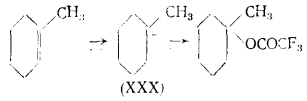
intermediate involvement of the carbonium ions (XXV) and (XXVI) in the reaction

Under the conditions indicated, cyclohexanone is reduced to a mixture of cyclohexane and methylcyclopentane. Electronegative substituents suppress hydrogenation. On the basis of these data, the author[53] believes that hydrogenation proceeds via hydride ion transfer from hydrogen on the surface of the catalyst to the intermediate carbonium ion.



The use of anhydrous HF as the solvent, in which there is a possibility of ionic processes, permits the hydrogenation of even carboxylic acids—the class of compounds which are most difficult to hydrogenate. However, the reaction requires fairly severe conditions (300 atm) and a considerable amount of PtO_2. Dodecanecarboxylic acid is hydrogenated to a mixture of 21% of dodecane, 42% of dodecyl ether, and 6% of dodecyl dodecanoate. Acetic anhydride gives rise to ethyl acetate and diethyl ether. Succinic anhydride and oxalic acids are not reduced. It has been suggested[53] that acylium ions behave in this instance as hydride ion acceptors.

In trifluoroacetic acid, which is a weaker acid than anhydrous HF, carboxylic acids are not reduced over PtO_2. Acylium ions cannot apparently be formed in this solvent. However, the authors of the present review found[54] that, in the presence of equimolar amounts of trifluoroacetic anhydride, pivalic acid is reduced to a mixture of neopentyl alcohol, dineopentyl ether, and neopentyl trifluoroacetate in trifluoroacetic acid over PtO_2. The products of the reaction of the CF_3CO group are not formed under these conditions. The reaction evidently proceeds via the mixed anhydride of pivalic and trifluoroacetic acids, which dissociates with formation of the pivaloyl cation[53] (XXVII). The latter is reduced with abstraction of a hydride ion from the hydrogen activated by the catalyst:



The reduction of pivalic acid in mixtures with trifluoroacetic anhydride by the triethylsilane–CF_3COOH system proceeds analogously[56]. As stated above, this system is widely used in ionic hydrogenation reactions.

N-Hydroxymethylamides of carboxylic acids (XXVIII) are converted into *N*-methylamides (XXIX) just as readily under the influence of triethylsilane as in hydrogenation in the presence of the Pd/C heterogeneous catalyst in trifluoroacetic acid[57]:

The ease of reduction of the amides (XXVIII) can be explained by the fact that the corresponding cations $RCONHCH_2^+$ are stabilised by conjugation with the free electron pair of the nitrogen atom.

A study of the competing hydrogenation of cyclohexene and 1-methylcyclohexene over Pd/C revealed[58] a change in the hydrogenation selectivity as a function of the acidity of the medium. In acetic acid both olefins are quantitatively hydrogenated, the hydrogenation of methylcyclohexene beginning only after all the cyclohexene has reacted. In trifluoroacetic acid only cyclohexene is hydrogenated, while methylcyclohexane was not detected in the reaction products. An increase of the acidity of the medium by the addition of 10% of toluene-*p*-sulphonic acid to trifluoroacetic acid leads to the quantitative hydrogenation of methylcyclohexene, while cyclohexene is hydrogenated only to the extent of 43%. These data are consistent with the ionic mechanism of the hydrogenation of methylcyclohexene under the conditions indicated. Indeed in trifluoroacetic acid methylcyclohexene combines with the acid almost quantitatively, being converted into the corresponding trifluoroacetate:

The equilibrium concentration of the carbonium ion (XXX) is low, and the adduct of hydrogen and palladium is probably a less active hydride ion donor than triethylsilane or ruthenium and platinum complexes (see Section III), and is incapable of reducing methylcyclohexene under these conditions. The addition of toluene-*p*-sulphonic acid increases sharply the concentration of carbonium (XXX) and promotes ionic hydrogenation. Under these conditions, cyclohexene combines irreversibly with CF_3COOH to form cyclohexyl trifluoroacetate, which entails a decrease of the yield of the hydrogenation product (cyclohexane).

On the basis of the foregoing, one may conclude that hydrogenation on heterogeneous catalysts in fairly acid media can proceed via an ionic mechanism, the catalysts behaving as hydride ion transferring agents.

---o0o---

Catalytic ionic hydrogenation constitutes a new procedure for catalytic hydrogenation in which the unsaturated substrate is activated by the solvent (acid), which converts it into a protonated form (a carbonium ion), while the catalyst activates hydrogen and transfers it in the form of a hydride ion to the cation formed. This process permits catalytic hydrogenation with a selectivity characteristic of ionic hydrogenation reactions. There is reason to believe that many of the known hydrogenation catalysts can undergo a change in the mechanism of their action in media where there is a possibility of the formation of active protonated forms of unsaturated substrates and can behave as ionic hydrogenation catalysts.

The Synthesis and Structure of Telluranes

I.D.Sadekov, A.Ya.Bushkov, and V.I.Minkin

Data concerning the methods for the synthesis of organic derivatives of tellurium—σ- and π-telluranes—are surveyed and described systematically. Problems of the electronic and steric structures of their molecules, the results of structural determinations, quantum-chemical calculations, and experiments by spectroscopic and other physical research methods are examined. The bibliography includes 214 references.

I. INTRODUCTION

The chemistry of organotellurium compounds has been investigated in considerably less detail than the chemistry of organic compounds of higher neighbours of tellurium in the Periodic Table—sulphur and selenium. The studies by Lederer and Morgan in the 1920s (see the relevant reviews[1,2]) made an important contribution to the field of organotellurium chemistry and in essence established it as a separate branch of the chemistry of organoelemental compounds. However, subsequently there was a decrease of activity in research on the methods of synthesis and reactions of organic compounds of tellurium. In the last 10–15 years there has been a renewal of interest in the organic chemistry of tellurium and there has been a sharp increase of the number of publications in this field. Most of them are described systematically in a review[2] and also in periodic collections[3,4]. Finally, a separate monograph devoted to the organic chemistry of tellurium has been published recently[5].

The study of the synthesis, reactions, and structures of various organotellurium compounds is being prosecuted on an increasing scale. It is now necessary to examine in detail data for organotellurium chemistry differentiated into individual classes rather than surveying the results for the entire field of such chemistry.

This review is devoted to tetra- and tri-coordinate organic derivatives of tellurium–telluranes. In tellurane structures the tellurium atom expands its electronic valence shell to ten electrons (or five electron pairs). The ability to form stable compounds in this hypervalent state is also manifested by sulphur and selenium, but there is no doubt that it is shown most strikingly by tellurium. The latter not only gives rise to stable π-telluranes (π-sulphuranes and π-selenuranes are as a rule also entirely stable) but also σ-telluranes. In contrast to their tellurium analogues, σ-type sulphuranes are usually stable only in cyclic structures[6-8].

The difference between σ- and π-telluranes is that in the former all five valence electron pairs occupy localised σ orbitals (I), while in π-telluranes one electron pair of tellurium forms a π bond with a neighbouring element in the Second Period (II).

(I) (II)

In agreement with predictions of valence shell electron pair repulsion theory[9], σ- and π-telluranes have different bond configurations at the central tellurium atoms, which is responsible for large differences between their physical properties and reactivities. Nor is there any similarity between the methods of synthesis of these compounds. Because of this, data for σ- and π-telluranes are examined in separate sections of the review. Initially a systematic account is given of the methods of synthesis of different telluranes and then the results of experimental and theoretical studies on their structures and reactivities are discussed.

II. THE SYNTHESIS OF σ-TELLURANES

In the series of σ-telluranes (I) we shall examine below only true organotellurium compounds, i.e. those in which at least one of the four σ bonds is linked to a carbon atom. In terms of the number of such bonds, it is convenient to subdivide σ-telluranes into mono-, di-, and tetra-organo-derivatives. Such subdivision is particularly useful, since the synthetic approaches to compounds of these types are significantly different.

1. METHODS OF SYNTHESIS OF MONOORGANO-DERIVATIVES OF TELLURIUM(IV)

The most important monoorgano-derivatives of tellurium(IV) are the trihalides, the methods of synthesis of which are extremely varied.

(a) Telluration of an Aromatic Ring

The direct method of synthesis of aryltellurium trichlorides—the telluration reaction (1)—is based on the interaction of $TeCl_4$ with benzene derivatives having fairly powerful electron-donating substituents. This reaction was achieved by Rust[10] as early as 1897 and was later investigated by Rohrbaech[11] and Lederer[12], but a correct interpretation of the structures of the compounds obtained was given only by Morgan[13,14]. When equimolar amounts of tellurium tetrachloride and phenetole were allowed to react in dry chloroform, *p*-ethoxyphenyltellurium trichloride was obtained[13]. Anisole, certain other alkyl aryl ethers, and other compounds also undergo this reaction (Table 1)[15-18]:

(I.1)

On the other hand, *p*-nitroanisole, the aromatic ring of which is highly deactivated by the nitro-group, does not react in this way[14].

Table 1. Mono-organo-derivatives of tellurium(IV) of the type $RTeX_3$.

The telluration of an aromatic ring by tellurium tetrachloride is a typical electrophilic substitution reaction. It proceeds only when the benzene ring is strongly activated by electron-donating substituents and the electrophile is probably the cation $TeCl_3^+$. The tendency of $TeCl_4$ to undergo ionisation of the type $TeCl_3^+Cl^-$ or $TeCl_3^+TeCl_5^-$ in the crystalline phase and in solution is confirmed by Raman spectroscopic[19,20] and conductimetric[21] data. The stabilisation of the cation $TeCl_3^+$ on formation of tellurium tetrachloride complexes with Lewis acids, particularly with $AlCl_3$ in the form of $TeCl_3^+AlCl_4^-$,[22,23] was used by Bergman[24], who was able to achieve the interaction with tellurium tetrachloride, in the presence of catalytic amounts of $AlCl_3$, of a number of compounds (benzene, toluene) which had previously been believed to be inert in relation to this reagent. This gave small yields of the corresponding aryltellurium trichlorides (see Section 2 for a description of the synthesis of diaryltellurium dichlorides by this method). By carrying the reaction between benzene and tellurium tetrachloride in the presence of a twofold–threefold excess of $AlCl_3$, Günther et al.[25] later obtained phenyltellurium trichloride (isolated as the ditelluride), diphenyltellurium dichloride, and triphenyltelluronium chloride, depending on the reaction time.

In an early study Morgan already showed that the $TeCl_3$ group enters exclusively in the *p*-position (evidently owing to its large size) relative to the electron-donating substituent in the benzene ring, occupying the *o*-position only if the *p*-position is already occupied[13]. This was demonstrated by the fact that, when di-(*p*-ethoxyphenyl) ditelluride—the product of the reduction of the corresponding tellurium trichloride obtained by the reaction of $TeCl_4$ with phenetole—is treated with nitric acid, *p*-nitrophenetole is formed exclusively. The high selectivity of *p*-substitution by the trichlorotelluro-group in reactions of monosubstituted benzenes with tellurium tetrachloride has also been confirmed by infrared and ^1H NMR spectroscopic data[16,26]. The high selectivity of the telluration reaction and the fact that only one $TeCl_3$ group can be introduced into the ring during it constitute an appreciable difference between this process and the mercuration reaction in which the formation of polymercurated products is a normal phenomenon[27].

The study of the telluration reaction, starting with early investigations, involved a gradual expansion of the range of compounds with electron-donating functions which can be made to undergo this reaction—alkyl aryl ethers and then thioethers[17,18], acetanilide[15], etc. As already stated, compounds with a smaller π-electron density in the aromatic ring (benzene, toluene) could be made to react with $TeCl_4$ only by enhancing the electrophilic properties of the latter as a result of the formation of the complex $TeCl_3^+AlCl_4^-$. On the other hand, when the most powerful electron-donating substituent (the dimethylamino-group) is introduced into the aromatic ring, the corresponding telluration product cannot be obtained, since dimethylaniline forms a complex with tellurium tetrachloride (for its composition and reactions, see Section 2). For the same reason, *C*-derivatives are not formed with $TeCl_4$ by other nitrogen-containing bases: aromatic amines[28,29], pyridines[30-32], quinolines[31], acridines[31], and Schiff bases[33]. In contrast to these compounds, certain polycyclic hydrocarbons (naphthalene, fluorene, and fluoranthene) readily interact with tellurium tetrachloride without additional activation of its rings by electron-donating substituents and form respectively 1-naphthyl-, 2-fluorenyl-, and 3-fluoranthyltellurium trichlorides[18].

The synthesis of other aryltellurium trihalides—tribromides, and tri-iodides—by direct telluration is difficult

owing to the lower reactivity of the corresponding tellurium tetrahalides compared with the tetrachloride. The results of a study[34] where it is claimed that in the interaction of tellurium tetrabromide with benzoquinone, naphthoquinone, anthraquinone, and pyrrole the corresponding tellurium tribromides were isolated therefore require additional confirmation.

The possibilities of the telluration reaction are far from exhausted: hitherto, the main tellurating agent has been tellurium tetrachloride, but, by analogy with mercuration and thallation reactions, in which mercury and particularly thallium halide are relatively inactive, the study of the possibility of employing instead of $TeCl_4$ another tellurating agent, for example tellurium tetra-acetate or tetrakistrifluoroacetate, may extend the region where the direct telluration reaction is applicable.

(b) Telluration of Aliphatic Compounds

Organotellurium trichlorides can be synthesised also by the interaction of tellurium tetrachloride with aliphatic compounds containing active methyl and methylene groups[35]:

$$RCOCH_2R' + TeCl_4 \xrightarrow{-HCl} RCOCH(TeCl_3)R' .$$

The early publications by Morgan and coworkers[36] contain interesting but insufficiently firmly demonstrated data concerning the interaction of tellurium tetrachloride with acetic anhydride. One of the possible pathways in this reaction, according to the authors, involves the formation of a mixture of trichlorotelluroacetic acid Cl_3TeCH_2COOH, its anhydride $(Cl_3TeCH_2CO)_2O$, and methylenebis(tellurium trichloride) $CH_2(TeCl_3)_2$. The pathways followed in the formation of the latter are, however, obscure and the reliability of the structure attributed to it is open to doubt.

The ability of tellurium tetrachloride to react with homologues of acetic anhydride diminishes rapidly with increase in the size of the hydrocarbon chain. Whereas trichlorotelluropropionic acid was obtained in the reaction with propionic anhydride and identified as the ditelluride, the reactions with butyric and isovaleric anhydrides involve the reduction of tellurium tetrachloride and the products formed could not be identified[14].

(c) The Addition of $TeCl_4$ to Multiple Bonds

Organotellurium trichlorides can also be obtained by the electrophilic addition of tellurium tetrachloride to a double bond:

$$R{-}CH{=}CH{-}R' + TeCl_4 \rightarrow R{-}\underset{TeCl_3}{CH}{-}CHCl{-}R' \quad (I.2)$$

Campos and Petragnani[37,38] showed that tellurium tetrachloride reacts with cyclohexene in carbon tetrachloride, yielding 2-chlorocyclohexyltellurium trichloride. On the other hand, styrene, di-isobutene, and 1,4-diphenylbuta-1,3-diene only reduce tellurium tetrachloride to tellurium in carbon tetrachloride[38]. It is of interest to note that $TeCl_4$ is reduced to tellurium also when cyclohexene interacts with tellurium tetrachloride in the absence of a solvent[38,39]. Tellurium tetrachloride can add also to propene[40,41], giving rise to 2-chloropropyltellurium chloride or di-(2-chloropropyl)tellurium dichloride, depending on the reaction conditions. Earlier data for the addition of $TeCl_4$ to butene[42], where the formation of only two isomeric di(chlorobutyl)tellurium dichlorides was postulated and the formation of 2-chlorobutyltellurium trichloride was ruled out, were later revised[40].

Tellurium tetrachloride adds comparatively readily also to a triple bond, forming substituted 2-chlorovinyltellurium trichlorides[43]:

$$C_6H_5C{\equiv}CR + TeCl_4 \rightarrow C_6H_5\underset{Cl}{C}{=}\underset{R}{C}{-}TeCl_3 . \quad (I.3)$$

On the whole, one should note that the addition of the tetrahalides and other tellurium compounds to multiple bonds has still been little investigated.

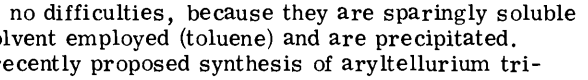
(d) Exchange Reactions of Organoelemental Compounds with $TeCl_4$

In order to obtain organotellurium trichlorides by this method, organic mercury compounds are usually employed. Thus the commonest method for the synthesis of aryltellurium trichlorides[44] is based on the interaction of arylmercury chlorides with tellurium tetrachloride:

(I.4)

The best solvent in this case is dioxan, which forms a complex with mercury(II) chloride, precipitated on cooling the reaction mass. The $ArTeCl_3$ derivatives obtained in this way are usually contaminated by a small amount of mercury(II) chloride, which necessitates their careful purification. In contrast to direct telluration, which leads exclusively to *p*-substituted $ArTeCl_6$ derivatives with electron-donating substituents in the aromatic ring, this method makes it possible to obtain compounds with any relative disposition of substituents, including electron-accepting substituents[17,18,44-47].

Organic compounds of lead[48] and tin[49] have been used recently to synthesise $ArTeCl_3$:



$$(C_6H_5)_3PbCl + TeCl_4 \rightarrow C_6H_5TeCl_3 + (C_6H_5)_2PbCl_2 ; \quad (I.5)$$

$$(C_6H_5)_3SnCl + TeCl_4 \rightarrow C_6H_5TeCl_3 + (C_6H_5)_2SnCl_2 ; \quad (I.6)$$

$$(C_6H_5)_4Sn + TeCl_4 \rightarrow C_6H_5TeCl_3 + (C_6H_5)_3SnCl . \quad (I.7)$$

The reaction of $(C_6H_5)_3PbCl$ with $TeCl_4$ proceeds with virtually quantitative yields. Since $(C_6H_5)_2PbCl_2$ is insoluble in dioxan, this makes it possible to separate it readily from $C_6H_5TeCl_3$. Triphenyltin and tetraphenyllead chlorides also give high yields on reaction with $TeCl_4$. The separation of $C_6H_5TeCl_3$ from organotin compounds presents no difficulties, because they are sparingly soluble in the solvent employed (toluene) and are precipitated.

The recently proposed synthesis of aryltellurium trichlorides from aryltrimethylsilanes is related to these reactions. The compounds $ArTeCl_3$ are obtained in high yields on boiling $ArSi(CH_3)_3$ with $TeCl_4$ in toluene[50]:

(I.8)

(e) Synthesis from Diorganoditellurides

An important method of synthesis of organic tellurium trihalides is based on the interaction of ditellurides with halogens:

$$RTe{-}TeR + 3X_2 \rightarrow 2RTeX_3 ; \quad (I.9)$$

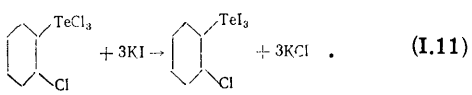
X=Cl, Br, or I.

Sulphuryl or thionyl chloride is used instead of chlorine in the synthesis of tellurium trichlorides.

The importance of this method of synthesis consists in the possibility of employing it to obtain aliphatic tellurium trihalides: methyltellurium trichloride[51], tribromide[52], and tri-iodide[53], ethyltellurium tribromide, and tri-iodide[53], and tribromotelluropropionic acid[14]. In the synthesis of aromatic aryltellurium trichlorides this reaction has been used only when the corresponding ditelluride was comparatively readily available. However, the method is perhaps the only convenient procedure for the synthesis of aromatic tellurium tribromides and tri-iodides[14,17,54,55].

In the case of ditellurides the reaction products are as a rule tellurium trihalides, while the reaction of diorganodiselenides with halogens yields mono- and tri-halides depending on the amount of halogen employed. 2-Naphthyltellurium iodide was isolated only in the reaction of di-(2-naphthyl) ditelluride[56]. However, according to some workers[54], aryltellurium monoiodides are obtained together with tri-iodides on treatment of diphenyl and di-*p*-tolyl ditellurides with iodine in solution in carbon tetrachloride at 10–15°C. These relations can apparently be accounted for by the tendency of tri-iodides towards dissociation with liberation of free iodine, which has been noted for arylmethyltellurium di-iodides[55].

The earlier[57] claim that phenyltellurium triacetate can be synthesised by the interaction diphenyl ditelluride with lead tetra-acetate was not confirmed in a more detailed investigation[58].

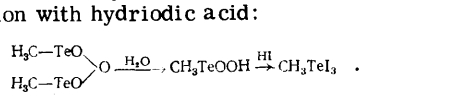


(f) Other Methods of Synthesis

In this section we shall note mainly halogen exchange reactions involving organotellurium trihalides. These reactions have still been comparatively little investigated but nevertheless in certain cases they are of preparative value, particularly when the corresponding ditellurides are not available[57]:

(I.10)

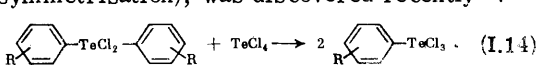
Chlorine is readily exchanged for iodine in 2-chlorocyclohexyltellurium trichloride[38]:



(I.11)

Methyltellurium trifluoride[59] and certain aryltellurium trifluorides[26] have been obtained by the exchange reactions (I.12)–(I.13) with AgF:

$$CH_3TeI_3 + 3AgF \rightarrow CH_3TeF_3 + 3AgI \quad ; \qquad (I.12)$$

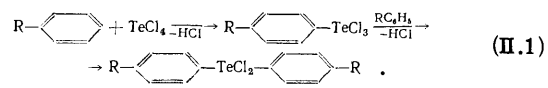


$$ArTeCl_3 + 3AgF \rightarrow ArTeF_3 + 3AgCl \quad . \qquad (I.13)$$

In an early study Drew[60] noted the formation of CH_3TeI_3 from the anhydride of methyltelluric acid on treatment of its aqueous solution with hydriodic acid:

Reactions of this type have been used more frequently to synthesise organoselenium trihalides[61].

The conversion of diaryltellurium dichlorides into aryltellurium trichlorides, based on the reaction of diaryltellurium dichlorides with $TeCl_4$ (a reaction which is the reverse of symmetrisation), was discovered recently[62]:

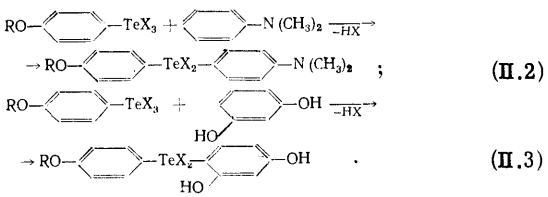


(I.14)

2. METHODS OF SYNTHESIS OF DIORGANO-DERIVATIVES OF TELLURIUM(IV)

(a) Aryltelluration of Aromatic Compounds

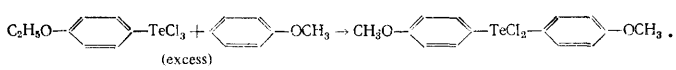
If the telluration reaction is carried out in the presence of an excess of an aromatic compound and under conditions more severe than those required to substitute one chlorine atom (a higher temperature), the reaction may proceed further and can lead to diaryltellurium dichlorides.



Thus, when $TeCl_4$ is refluxed with a large excess of anisole or phenetole, high yields of di-(*p*-anisyl)tellurium dichloride[13] and di-(*p*-phenetyl)tellurium dichloride[14] are obtained:

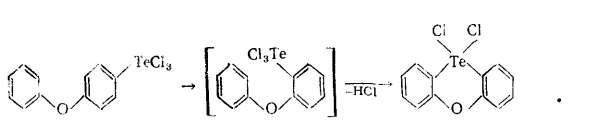
(II.1)

The two-stage mechanism of the substitution reaction is demonstrated by the fact that the interaction of *p*-methoxyphenyltellurium trichloride, prepared beforehand, with anisole and of *p*-phenoxyphenyltellurium trichloride with phenyl ether lead to di-(*p*-anisyl) and di-(*p*-phenoxyphenyl)-tellurium dichlorides respectively[16].



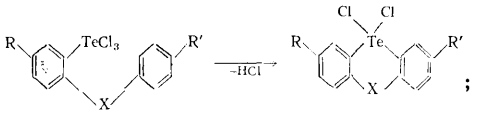
Petragnani[63] used this reaction to synthesise certain asymmetric diaryltellurium dihalides. He established that aryltellurium trichlorides and tribromides (but not tri-iodides) react with dimethylaniline and resorcinol to give aryl-(4-dimethylaminophenyl)- and aryl-(2,4-dihydroxyphenyl)-tellurium dihalides respectively:

(II.2)



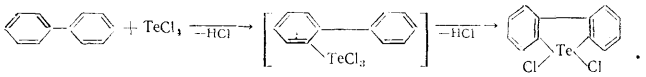
(II.3)

Interesting results were obtained by Bergman[24] in an attempt to reproduce certain earlier studies[13] of the interaction of aryltellurium trichlorides with alkyl aryl ethers. Thus, when *p*-ethoxyphenyltellurium trichloride (1 M) is heated for 6 h with anisole (4 M) at 160°C, only the symmetrical di-(*p*-anisyl)tellurium dichloride is obtained:

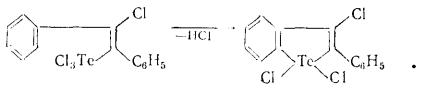


Other compounds of the type $RC_6H_4TeCl_3$ undergo a similar reaction (R = 4-Br or 4-CH_3), but the causes of the exchange of the substituent in the *p*-position relative to the trichlorotelluro-group are still obscure.

If the second aromatic ring attacked by the TeX_3 group is part of the same molecule, intramolecular electrophilic substitution takes place, leading to the formation of heterocyclic tellurium dihalides. Drew[16] observed that heating of *p*-phenoxyphenyltellurium trichloride at a high temperature leads to its conversion into 10,10-dichlorophenoxatellurin, evidently via an intermediate stage in which the *p*-isomer is converted into the *o*-isomer, which could not be isolated:



Substituted 10,10-dichlorophenoxatellurins[44,64], and 10,10-dichlorophenothiatellurin[17] were obtained analogously:



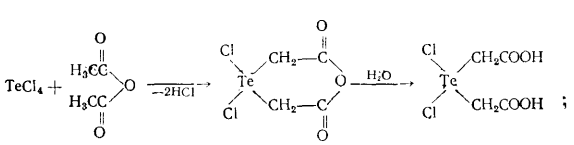
X=O or S.

A similar reaction probably occurs also when tellurium tetrachloride or tetrabromide interacts with biphenyl at a high temperature, the tellurium trichloride formed initially being converted into dichlorodibenzotellurophen[65]:

The cyclisation of 2-chloro-1,2-diphenylvinyltellurium trichloride (the product obtained by the addition of $TeCl_4$ to tolan[43]) has been used to synthesise 1,1,3-trichloro-2-phenylbenzotellurophen[66]:

Bergman[24] used the interaction of $TeCl_4$ with an excess of aromatic compounds (benzene, chlorobenzene, and bromobenzene) in the presence of $AlCl_3$ (see Section 1 concerning the role of $AlCl_3$ in the telluration reaction) in order to synthesise certain symmetrical diaryltellurium dichlorides. According to the author, their yields ranged from 30 to 45%.

As stated above, dimethylaniline does not undergo the telluration reaction directly, since its interaction with $TeCl_4$ gives rise to the complex $[PhNMe_2]_2.TeCl_4$, which is converted into di-(*p*-dimethylaminophenyl)tellurium dichloride on heating with water[28]:

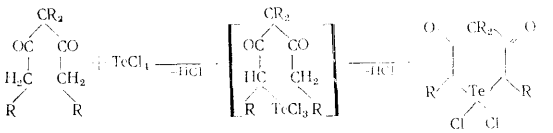


(II.4)

The mechanism of this unexpected reaction has not been studied but the structure of the final product has been clearly demonstrated both by its chemical properties and by ^1H NMR.[67]

(b) Electrophilic Substitution in Methylenecarbonyl Compounds

If the electrophilic substitution reaction involving aliphatic compounds, considered above, is carried out with compounds containing not one but two activated methyl or methylene groups, then the substitution can occur in both groups. Double substitution is also promoted by an excess of the methyl- or methylene-carbonyl compounds. Thus the interaction of $TeCl_4$ with a large excess of acetic anhydride gives rise to dichlorotellurodiacetic acid (evidently as a result of the hydrolysis of the intermediate anhydride[36]), while the reactions with methyl ketones yield the corresponding diorganotellurium dichlorides[35]:

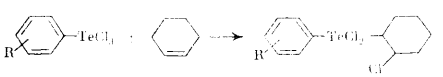


$$TeCl_4 + 2RCOCH_3 \xrightarrow{-2HCl} (RCOCH_2)_2TeCl_2 .$$

In the analogous reactions of aryltellurium trichlorides with acetone and acetophenone the products are respectively acetonyl- and acetophenonyl-aryl tellurium dichlorides[63]:

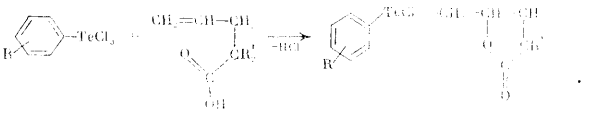
(II.5)

The formation of derivatives of tellurin-3,5-dione by interaction of $TeCl_4$ with β-diketones evidently proceeds via an intermediate organotellurium trichloride, which is converted into a cyclic diorganotellurium dichloride[68-71]:



(c) The Addition of $TeCl_4$ and Organotellurium Trichlorides to a Double Bond

The involvement of two olefin molecules in the electrophilic addition of $TeCl_4$ to a double bond leads to diorganotellurium dichlorides. Various workers have shown that, by reacting with an excess of cyclohexene[40,42,72] or ethylene[41,72] in boiling CCl_4, $TeCl_4$ gives rise to addition products:



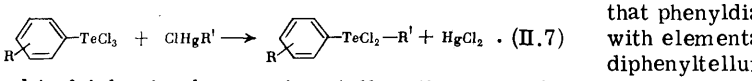
(II.6)

Petragnani[37,38] showed that, like tellurium tetrachloride, certain aryltellurium trichlorides are capable of adding to the double bond of cyclohexene to form aryl-2-chlorocyclohexyltellurium dichlorides:

However, like the reaction of tellurium tetrachloride, this reaction is not general. Unsaturated compounds such as styrene, di-isobutene, and 1,4-diphenylbutadiene are not involved in it and the initial aryltellurium trichlorides are recovered unchanged from the reaction mixture[38].

When aryltellurium trichlorides interact with γ, δ-unsaturated acids, the addition to the double bond is accompanied by cyclisation[37,38,73] with formation of 5-aryldichlorotelluro-2,2-diphenylpentanolactones:

2-Chlorocyclohexyltellurium trichloride undergoes an analogous reaction[38]. The structure of the above dichlorotellurolactone was confirmed by its specific synthesis[38] from an aryltellurium trichloride and 5-chloromercuri-2,2-diphenylpentanolactone, known previously. A study was also made of the interaction of $TeCl_4$ with but-1-ene[40,42], propene[40,41], and butadiene[41], leading to the formation of organotellurium trichlorides and diorganotellurium dichlorides.



The interaction of 1,1-diarylethylenes with $TeCl_4$ is unusual. The high electrophilicity of the conjugated methylene group in compounds of this type leads to the preferential substitution of a methylene hydrogen atom. When the

reaction was carried out in ether, bis-(1,1-diarylethylene)-tellurium dichlorides were obtained in low yields instead of the products of the addition of $TeCl_4$ to the double bond:

$$(RC_6H_4)_2C{=}CH_2 + TeCl_4 \rightarrow \begin{matrix}(RC_6H_4)_2C{=}CH\\ (RC_6H_4)_2C{=}CH\end{matrix}\!\!>TeCl_2 \quad .$$

(d) Exchange Reactions of Aryltellurium Trihalides and $TeCl_4$ with Organoelemental Compounds

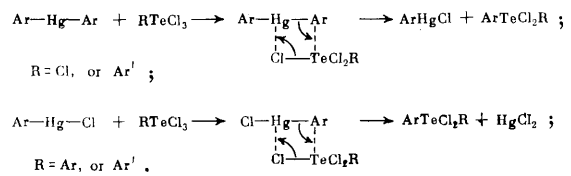
The reaction of aryltellurium trichlorides with aryl(alkyl)-mercury chloride is very important preparatively. Depending on the structure of the initial reactants, it leads to symmetrical or asymmetric diaryltellurium dichlorides[46,75] or alkylaryltellurium dichlorides[75]:

(II.7)

The method is fairly simple experimentally; the best solvent for the reaction is dioxan, which not only dissolves aryltellurium trichlorides effectively but also gives rise to a molecular compound with mercury(II) dichloride, which is precipitated on cooling the reaction mass. The use of aryltellurium tribromides and tri-iodides in this synthesis has not been studied.

In order to obtain symmetrical diaryltellurium dichlorides, it is possible to employ the reaction of arylmercury chlorides with $TeCl_4$ taken in molar proportions of 2 : 1:[2]

$$2ArHgCl + TeCl_4 \rightarrow Ar_2TeCl_2 + 2HgCl_2 \quad .$$



However, in this case diaryltellurium dichlorides are obtained in a less pure form than in the reaction of equivalent amounts of an arylmercury chloride and an aryltellurium trichloride. It has been shown recently that diaryltellurium dichlorides can be obtained in high yields by the reaction of a substituted diarylmercury with tellurium tetrachloride or aryltellurium trichlorides[76]:

(II.8)

R^1 = Cl, or Ar .

According to the view adopted[77], the mechanism of the above reactions involves the formation of a four-centre transition state:

It is of interest to note that the reaction of di-(*p*-nitrophenyl)mercury stops at the first stage: when $TeCl_4$ was introduced into the reaction, *p*-nitrophenylmercury chloride was obtained in 64% yield. This is probably associated with the reduction of the nucleophilic properties of the Mg–Ar bond in *p*-nitrophenylmercury chloride and with the weakening of the electrophilic properties of the trichlorotelluro-group (particularly in *p*-nitrophenyltellurium trichloride) compared with tellurium tetrachloride.

Organolead[48], organotin[49], and organosilicon[50] compounds have also been used to synthesise both symmetrical and asymmetric diaryltellurium dichlorides:

$$Ar_4Pb + TeCl_4 \rightarrow Ar_2TeCl_2 + Ar_2PbCl_2 \quad ; \qquad (II.9)$$

$$Ar_2Pb(CH_3)_2 + TeCl_4 \rightarrow Ar_2TeCl_2 + (CH_3)_2PbCl_2 \quad ; \qquad (II.10)$$

$$Ar_3PbCl + Ar'TeCl_3 \rightarrow ArTeCl_2Ar' + Ar_2PbCl_2 \quad ; \qquad (II.11)$$

$$Ar_4Sn + TeCl_4 \rightarrow Ar_2TeCl_2 + Ar_2SnCl_2 \quad ; \qquad (II.12)$$

$$Ar_3SnCl + Ar'TeCl_3 \rightarrow ArTeCl_2Ar' + Ar_2SnCl_2 \quad ; \qquad (II.13)$$

$$ArSi(CH_3)_3 + Ar'TeCl_3 \rightarrow ArTeCl_2Ar' + (CH_3)_3SiCl \quad . \qquad (II.14)$$

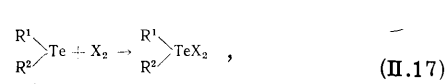
(e) The Diazo-method

The diazo-reaction for the synthesis of organic derivatives of tellurium(IV) was first used by Waters, who showed that phenyldiazonium chloride in acetone reacts on cooling with elemental tellurium, giving rise to a low yield of diphenyltellurium dichloride[78]:

$$2RC_6H_4N_2Cl + Te \rightarrow (RC_6H_4)_2TeCl_2 + 2N_2 \quad . \qquad (II.15)$$

According to Waters' observation, the yield of diphenyltellurium dichloride can be increased somewhat by employing instead of phenyldiazonium chloride its double salt with zinc chloride. Subsequently Tanijama et al.,[79] who used Waters' method, obtained a series of diaryltellurium dichlorides in low yields.

It has been shown that the principal version of Nesmeyanov's diazo-method[27], based on the decomposition of double salts of an arenediazonium chloride with tellurium tetrachloride, having the formula $(ArN_2)_2TeCl_6$,[80-82] under the influence of powdered copper in acetone[83], can be used to synthesise diaryltellurium dichlorides



$$(ArN_2)_2TeCl_6 + 4Cu \rightarrow Ar_2TeCl_2 + 2N_2 + 4CuCl \quad . \qquad (II.16)$$

The double salts were obtained in yields of 85–95% on mixing solutions of an arenediazonium chloride and tellurium tetrachloride in concentrated HCl. The yields of diaryltellurium dichlorides are between 20 and 50% depending on the nature of the substituent.

Nesmeyanov et al.[84] proposed another version of the diazo-reaction. Benzenediazonium tetrafluoroborate was treated with zinc dust in acetone solution in the presence of $TeCl_4$. The reaction probably proceeds via diphenyltellurium dichloride and leads directly to diphenyl telluride. The yield of the latter, isolated as diphenyltellurium dibromide, is only 6%.

(f) The Synthesis of Diorganotellurium Dihalides from Other Organotellurium Compounds. The Synthesis from Diorganotellurides and Diorganoditellurides

A widely used method for the synthesis of diorganotellurium dihalides involves the addition of halogens to diorganotellurides:

R^1, R^2 = Ar or Alk; X = Cl, Br, or I. (II.17)

The addition of chlorine, bromine, and iodine proceeds readily under the influence of free halogens in an inert solvent (benzene, CCl_4, and, more rarely, chloroform and ethyl ether) with slight cooling. Thionyl or sulphuryl chlorides are also frequently used to synthesise diorganotellurium dichlorides. The above reactions are used particularly frequently in converting diorganotellurides into

diorganotellurium dibromides and di-iodides[85], since direct introduction of these tellurium-containing functional groups into aromatic and aliphatic fragments is difficult.

The considerable affinity of diorganotellurides for halogens can be used in the synthesis of olefins. Like diaryl ditellurides[86], diaryl tellurides debrominate vicinal dibromides, which leads to the formation of olefins in high yields[87]:

$$ArTeAr' + \underset{Br}{\overset{|}{R}}CH-\underset{Br}{\overset{|}{C}}HR' \rightarrow ArTeBr_2Ar' + RCH=CHR' \quad .$$

Even metal salts can serve as donors of halogens. Thus the following reaction takes place on heating di-(*p*-tolyl)-telluride with certain metal chlorides in glacial acetic acid (sealed tube, 100–140°C)[88]:

$$a\,Ar_2Te + b\,MX_n \rightarrow a\,Ar_2TeX_2 + b\,MX_{n-2} \quad ;$$
$$M=Fe^{3+},\ Cu^{2+},\ \text{or}\ Hg^{2+};\ X=Cl.$$

The interaction of diaryl ditellurides with tellurium tetrahalides[86], aryltellurium trichlorides, and diarylselenium dihalides[86] also leads to diaryltellurium dihalides:

$$2Ar_2Te_2 + TeX_4 \rightarrow 2Ar_2TeX_2 + 3Te\ (X=Cl,\ Br,\ I)\ ;$$
$$2ArTeCl_3 + 2Ar_2'Te_2 \rightarrow 3Ar_2'TeCl_2 + 3Te\ ;$$
$$Ar_2SeBr_2 + Ar_2'Te_2 \rightarrow Ar_2'TeBr_2 + Ar_2Se + Te\ .$$

The study of the kinetics of the exchange of halogen atoms in diaryltelluride–diaryltellurium dihalide systems[89], demonstrated by Nefedov et al.,[90] was begun recently by NMR:

$$Ar_2Te + Ar_2'TeX_2 \rightleftarrows Ar_2TeX_2 + Ar_2'Te\ ;$$
$$X=F,\ \text{or}\ ClBr\ .$$

Di-(*p*-anisyl)- and di-(α-naphthyl)tellurium difluorides have been obtained by treating the corresponding diaryl tellurides with tri-(*p*-tolyl)bismuth difluoride[91,92], but they have been identified only chromatographically.

The conversion of diaryl tellurides into the corresponding difluorides is best achieved by the interaction of diaryl tellurides with SF_4 in boiling benzene[93]:

$$Ar_2Te \xrightarrow{SF_4} Ar_2TeF_2. \qquad (II.18)$$

It is of interest that the same compounds are obtained by the reaction of diaryl ditellurides with SF_4; this involves the elimination of one tellurium atom[93]:

$$Ar_2Te_2 \xrightarrow{SF_4} Ar_2TeF_2 + Te\ . \qquad (II.19)$$

Diorganotellurides can be converted not only into the corresponding dihalides but also into diacyloxy-derivatives with the aid of the addition reaction. Compounds of this type have been obtained by the reaction of dialkyl tellurides with benzoyl peroxide[94,95]:

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!Te + (C_6H_5COO)_2 \rightarrow \begin{matrix} R \\ R' \end{matrix}\!\!>\!Te\,(OCOC_6H_5)_2 \qquad (II.20)$$

and by the oxidation of diaryl tellurides with lead tetraacetate[57,58,96]:

$$Ar_2Te + Pb\,(OCOCH_3)_4 \rightarrow Ar_2Te\,(OCOCH_3)_2 + Pb\,(OCOCH_3)_2\ . \qquad (II.21)$$

The most convenient method for the preparation of aliphatic di-iodides is the interaction of tellurium and alkyl iodides[4,97,98]:

$$2RI + Te \rightarrow R_2TeI_2\ . \qquad (II.22)$$

These reactions, which apparently proceed via the dialkyl telluride stage, are carried out over a period of several days on heating in sealed tubes.

Exchange of halogens in diorganotellurium dihalides. Diorganotellurium dibromides and di-iodides can also be obtained by the exchange of chlorine atoms in diorganotellurium dichlorides. For example, di-(*p*-dimethylaminophenyl)tellurium di-iodide can be obtained from the dichloride on treating the latter with an aqueous KI solution[28]:

$$(CH_3)_2N-C_6H_4-TeCl_2-C_6H_4-N(CH_3)_2 + 2KI \xrightarrow[-2KCl]{} (CH_3)_2N-C_6H_4-TeI_2-C_6H_4-N(CH_3)_2\ . \qquad (II.23)$$

and aryl-(*p*-dimethylaminophenyl)tellurium bromides can be synthesised by the reaction of the corresponding dichlorides with hydrobromic acid[63]:

$$R-C_6H_3-TeCl_2-C_6H_3-N(CH_3)_2 \xrightarrow{2\,HBr} R-C_6H_3-TeBr_2-C_6H_3-N(CH_3)_2\ . \qquad (II.24)$$

Similarly the chlorine atoms in (di-2,2-diphenylvinyl)tellurium dichlorides can be readily exchanged for bromine or iodine atoms on treatment with KBr or KI solutions[74]; according to the authors, this can involve the exchange of one or both chlorine atoms:

$$(Ph_2C=CH-)_2TeCl_2 + KX \xrightarrow[-KCl]{KX} (Ph_2C=CH-)_2TeClX \xrightarrow[-KCl]{KX} (Ph_2C=CH-)_2TeX_2$$
$$X=Br,\ \text{or}\ I\ .$$

Di-(2-chloro-2-phenylvinyl)tellurium dichloride also readily exchanges the chlorine atoms attached to the tellurium atom in the reaction with potassium iodide[43]:

$$(C_6H_5CCl=CH-)_2TeCl_2 + 2KI \xrightarrow[-2KCl]{} (C_6H_5CCl=CH-)_2TeI_2\ .$$

The exchange reactions are particularly useful in those cases where the corresponding diorganotellurides are unstable and direct halogenation is therefore impossible. Thus certain arylbenzyltellurium dihalides have been synthesised[75] in accordance with the following scheme:

$$ArTeCl_2CH_2C_6H_5 \xrightarrow[-2KCl]{2KI} ArTeI_2CH_2C_6H_5 \xrightarrow[-AgI]{2AgBr} ArTeBr_2CH_2C_6H_5\ . \qquad (II.25)$$
$$\xrightarrow[-2AgCl]{2AgBr}$$

The same method has been used to synthesise aryl-(2,4-dihydroxyphenyl)tellurium dibromides and di-iodides[63], since aryl-(2,4-dihydroxyphenyl)tellurium dichlorides give rise to the corresponding ditellurides on reduction.

One must also note that diorganotellurium dibromides and di-iodides can be converted into the corresponding dichlorides by treatment with thionyl chloride or chlorine and di-iodides can be converted into dibromides on treatment with bromine or phosphorus tribromide[99].

Halogen atoms are also substituted comparatively readily by fluorine atoms and acyloxy-groups. Thus, treatment of the corresponding dihalides with AgF in a suitable solvent can yield diorganotellurium difluorides[26]:

$$R_2TeX_2 + 2AgF \rightarrow R_2TeF_2 + 2AgX\ ;$$
$$R=Ar,\ \text{or}\ Alk;\ X=Cl,\ \text{or}\ I. \qquad (II.26)$$

On the other hand, when silver salts of carboxylic acids were allowed to react with diaryltellurium dichlorides, the corresponding diaryltellurium diacylates were isolated[88]:

$$Ar_2TeCl_2 + 2AgOCOR \rightarrow Ar_2Te\,(OCOR)_2 + 2AgCl\ . \qquad (II.27)$$

Synthesis from diorganotellurium oxides. The reaction of diorganotellurium oxides with hydrogen halides in an aqueous medium is sometimes also used to

synthesise diorganotellurium dihalides:

$$R_2TeO + 2HX \rightarrow R_2TeX_2 + H_2O \quad ; \qquad \text{(II.28)}$$

R=Ar, or Alk; X=F, Cl, Br, or I.

This reaction is used most frequently in relation to aliphatic compounds, which makes it possible to avoid the synthesis of dialkyl tellurides, which have an extremely unpleasant smell. Thus, when dimethyltellurium di-iodide is acted upon by moist silver oxide, a solution of the hydrated form of dimethyltellurium oxide is formed and its treatment with hydrogen halides results in the formation of dimethyltellurium dihalides [100]. Among aromatic compounds, the interaction of aqueous solutions of diaryltellurium oxides with hydrofluoric acid to form diaryltellurium difluorides is of preparative importance [67].

A general method for the synthesis of diaryltellurium diacylates, based on the interaction of diaryltellurium oxides with carboxylic acid anhydrides was discovered

Table 2. Diorgano-derivatives of tellurium(IV) of the type $R^1R^2TeX_2$.

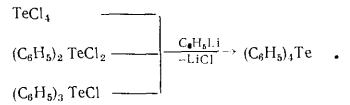
recently [101,102]; the reaction probably involves electron transfer via a four-membered transition state:

(II.29)

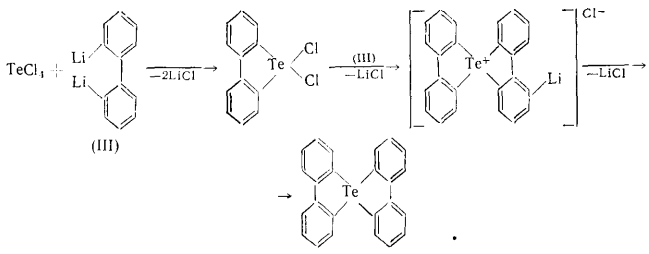
Synthesis from aryltellurium trichlorides. Apart from the telluration of aromatic and aliphatic systems leading to diorganotellurium dihalides (see above), an unusual method of synthesis of these compounds, involving the symmetrisation of organotellurium trichlorides, will be described in this Section. In certain cases (2-chloro-2-phenylvinyltellurium trichloride) it proceeds fairly readily under the influence of hydroxylated solvents. However, usually such reactions require the use of a symmetrising agent [62]:



$$2ArTeCl_3 + 4Cu \rightarrow Ar_2TeCl_2 + 4CuCl + Te \ . \qquad \text{(II.30)}$$

Data on diorgano-derivatives of tellurium(IV) are compiled in Table 2.

3. SYNTHESIS OF TETRAORGANOTELLURANES



In contrast to tellurium trihalides and dihalides, triorganotellurium halides have an ionic structure in the crystalline state and in solutions [3], i.e. they are telluronium salts and do not therefore belong to telluranes. However, if all four σ bonds are of the Te–C type and are covalent, the corresponding compounds are tetraorganotelluranes.

The synthesis of tetraorganotelluranes is based on the interaction of halogen-containing compounds of tellurium with aryl-lithium derivatives. The first representative of this class (tetraphenyltellurium) has been obtained [103] by the interaction of $TeCl_4$, $(C_6H_5)_2TeCl_2$, or $(C_6H_5)_3TeCl$ with phenyl-lithium:

Tetrakis(pentafluorophenyl)tellurium was obtained similarly [104].

Bis-(2,2-diphenylene)tellurium was synthesised by the reaction of 2,2'-dilithiobiphenyl (III) with $TeCl_4$. [105,106] It is formed via the following mechanism:

This compound was also obtained by the reaction of 2,2'-dilithiobiphenyl with tetra- and hexa-methoxytellurium [105,106].

In order to synthesise tetra-alkyltellurium derivatives, studies were made of the reactions of the corresponding alkyl-lithium derivatives (butyl, methyl) with $TeCl_4$ or trialkyltelluronium iodides [105]. However, tetra-alkyl derivatives of tellurium were never isolated, although their existence in solution as unstable intermediates was postulated on the basis of the study of the composition of the reaction mixture. Other attempts to synthesise tetra-alkyltellurium derivatives [alkyl–aryl exchange between bis(diphenylene)tellurium or triphenyltellurium iodide and butyl-lithium] led to the same results [106].

III. THE SYNTHESIS OF π-TELLURANES

In contrast to σ-telluranes, the methods of synthesis of which have now been developed in fair detail, the synthetic approaches to π-telluranes of different structure have been very little investigated.

1. ATTEMPTS TO PREPARE DIARYLTELLURIUM OXIDES

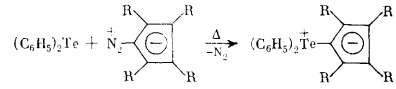
The commonest method for the synthesis of diaryltellurium oxides is hydrolysis of diaryltellurium dihalides by dilute alkalis or ammonia [107-112]:

$$(RC_6H_4)_2TeX_2 + 2OH^- \rightarrow (RC_6H_4)_2TeO + H_2O + 2X^-;$$

R = H[107-108,110], 4-CH_3[108], 2,3-C_4H_4[111], 2,4,6-$(CH_3)_3$[112], or 4-OC_2H_5[109].

When dialkyl tellurides are oxidised [95] with hydrogen peroxide in an alkaline medium or with nitric acid, the dihydroxide $R_2Te(OH)_2$ and the basic nitrate $R_2TeOH(NO_3)$ are obtained. Complex compounds, for example $R_2TeO.3RTeOOH$, are formed in air or on interaction with other oxidants. On the other hand, when diaryl tellurides are oxidised by nitric acid, the products are the dinitrates $Ar_2Te(NO_3)_2$, whose hydrolysis by alkalis gives rise to diaryltellurium oxides [113].

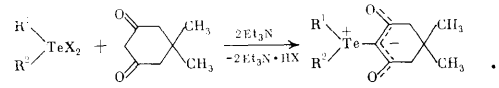
2. THE SYNTHESIS OF TELLURIUM IMIDES



The only method known at the present time for the synthesis of tellurium imides involves the interaction of diaryltellurium oxides with sulphonamides in boiling chloroform [114]:

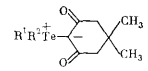
$$(4\text{-}CH_3OC_6H_4)_2TeO + H_2NSO_2R \rightarrow (4\text{-}CH_3OC_6H_4)_2\overset{+}{T}e-\overline{N}SO_2R;$$

R = 4-$CH_3C_6H_4$, C_6H_5, or $C_6H_5CH_2$.



3. THE SYNTHESIS OF TELLURONIUM YLIDS

The methods of synthesis and properties of telluronium ylids have been studied comparatively little. Stable telluronium ylids (cyclopentadienylides) were obtained for the first time [115,116] in the thermal decomposition of the corresponding diazocyclopentadienes in an excess of diphenyl telluride:



R = H, or C_6H_5.

Later, a large series of dicarbonyl-stabilised telluronium ylids, containing both alkyl and aryl substituents at the tellurium atom, were obtained by a method common to Group VI elements, based on the interaction of diorganotellurium dihalides (chlorides, bromides) with dimedone in the presence of two equivalents of triethylamine [117,118]:

Data for ylids of this type are compiled in Table 3.

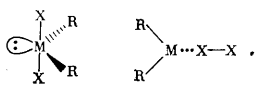
IV. THE STRUCTURE OF ORGANIC DERIVATIVES OF TELLURIUM (IV)



The data accumulated at the present time on the structure of tellurane molecules and their relation with physical and physicochemical properties are at present extremely

limited. In their discussion, it is therefore useful to resort to information about the structure and properties of sulphuranes and selenuranes, which helps to discover certain regularities or tendencies in the structure of tetracoordinate compounds of Group VI elements as a function of the nature of the central atom.

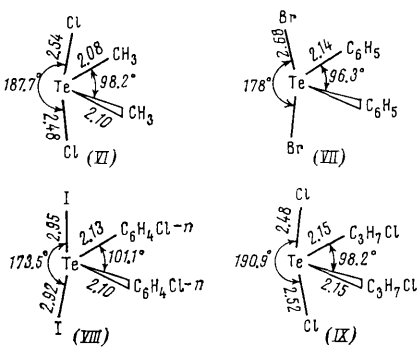
1. THE STERIC STRUCTURE OF σ-TELLURANES

(a) X-Ray Diffraction and Spectroscopic Studies of Molecular Structures

When the halides (X = Cl, Br, or I) react with compounds of the type R_2M (M = S, Se, or Te), there is a possibility, in principle, of the formation of two types of structures: (1) a bisphenoid structure with covalent M–X bonds (IV) and (2) a molecular σ-complex (V):

(IV) (V)

The study of the infrared Raman spectra of the adducts of halogens with R_2M (R = CH_3, M = S, Se, or Te)[119] as well as investigation of the ^1H NMR spectra and electrical conductivities of the products of the interaction of halogens with thiane and selenane[120] led to the conclusion that there is a clear-cut relation between the structure of these adducts and the nature of M and X. Whereas only structure (V) obtains for sulphur derivatives with X = Br or I, for selenium the adducts have structures (IV) with X = Cl or Br and (V) when X = I. For any X, diorganotellurides have the bisphenoid structure (IV) (a trigonal bipyramid) both in the solid phase and in solution, in which the lone electron pair of the tellurium atom plays the role of a third equatorial phantom ligand.



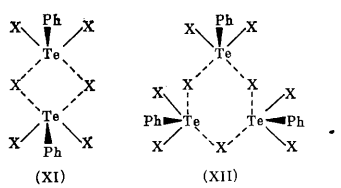


Figure 1. The results of an X-ray diffraction study of dimethyltellurium dichloride (VI)[122], diphenyltellurium dibromide (VII)[123], di-(4-chlorophenyl)tellurium di-iodide (VIII)[124], and di-(2-chloropropyl)tellurium dichloride (IX)[133].

This structure of σ-telluranes with equivalent Te–X bonds (see also data for the NQR spectra of dimethyltellurium dichloride[121] and isotope exchange in the $Ph_2TeCl_2^*$ + Ph_2Te system[90]) has been clearly confirmed by X-ray diffraction studies of dimethyltellurium dichloride (IV)[122], diphenyltellurium dibromide (VII)[123], di-(*p*-chlorophenyl)-tellurium di-iodide (VIII)[124], and di-(2-chloropropyl)tellurium dichloride (IX)[125] (Fig. 1).

Certain data for the Te–C and Te–X bond lengths in the dihalides of a series of tellurium-containing heterocycles have been published[126–131].

On the basis of a comparison of the infrared and Raman spectra of substituted diaryltellurium dihalides of the type R_2TeX_2 (R = *p*-tolyl, *o*-tolyl, *p*-anisyl, or pentafluorophenyl and X = Cl, Br or I) with the spectra of diphenyltellurium dihalides, it has been concluded[132] that in all cases the halogen atoms occupy the axial positions in the trigonal bipyramid.

An X-ray diffraction study has so far been made of only one trihalide—2-chloroethyltellurium trichloride (X)[133,134], obtained by the addition of $TeCl_4$ to ethylene (Fig. 2). Whereas diorganotellurium dihalides are monomeric in the crystal, compound (X) forms in the crystal a polymeric chain with bridge bonds via a chlorine atom. Because of this, the tellurium atom acquires a coordination number of 5 and the chlorine atoms are located at the vertices of a square pyramid. The Te–Cl distance is 2.39 Å and the Te–Cl$_{bridge}$ distance is 2.72 Å. In terms of the Te–Cl bond type, this compound lies between the monomeric dimethyltellurium dichloride[122] and the tetrameric tellurium tetrachloride[135], which is reflected in the average Te–Cl distance (2.39 Å) (2.51 Å in dimethyltellurium dichloride and 2.31 Å in tellurium tetrachloride). Examination of the low-frequency infrared and Raman spectra of various compounds $RTeX_3$ (R = phenyl, *p*-tolyl, *p*-anisyl, *p*-phenetyl, or *p*-phenoxyphenyl; X = Cl, Br, or I) also led to the conclusion that in compounds of this type the tellurium atom is pentacoordinate[54]. According to the authors, the trichlorides and tri-iodides are isomorphous and dimeric in the solid state [structure (XI)], while structure (XII) is quite probable for the tribromides (R = phenyl, *p*-tolyl, or *p*-phenoxyphenyl), which are more associated according to the authors' data. On the other hand, other results[51] showed that the tri-iodide is associated to the greatest extent in the series of methyltellurium trihalides. The structures proposed for the trihalides, based on the donor–acceptor interaction of the $PhTeX_2$ units with bridging halogen atoms, are fairly unstable because aryltellurium trichlorides are monomeric in solution (in dioxan)

(XI) (XII)

The available data suggest that the tendency towards tetracoordination increases appreciably in the sequence S < Se < Te. The influence of the halide ligand on the capacity of the chalcogen for involvement in tetracoordination is appreciable. On passing from F, Cl to Br and I, σ-telluranes are somewhat destabilised. Thus iodotelluranes of the type R_2TeI_2 show a tendency in solutions in polar solvents towards dissociation with a transition from structure (IV) to structure (V).[55] Nevertheless, in the crystalline state the compounds R_2TeI_2 exist as the σ-telluranes (IV). Apart from the X-ray diffraction data for diaryltellurium di-iodides[124], this is indicated by data obtained recently for dimethyltellurium di-iodide[136,137] from ^{125}Te Mössbauer spectra. The parameters of the Mössbauer spectra show clearly that even dimethyltellurium tetrahalides, particularly Me_2TeI_4, are also derivatives of tellurium(IV), i.e. the latter compounds probably have the structure $Me_2TeI_2.I_2$.[137]

(b) The Polarity Rule and the Conformational Effects of Substituents in the Molecules of σ-Telluranes

The above data concerning the molecules of σ-telluranes show that in all the compounds (VI)–(X) the more electronegative substituents occupy the axial positions, which reflects the polarity rule. According to this rule, in polyhedral molecular structures with topologically different bond types, derived from the configuration of a trigonal bipyramid, topomers containing more electronegative substituents in the axial positions exhibit the greatest stability [138–140]. The axial bonds in the corresponding structures are loosened and lengthened by 0.2–0.3 Å compared with the equatorial bonds.

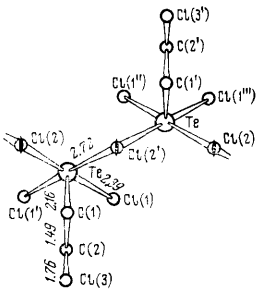

Figure 2. The results of an X-ray diffraction study of 2-chloroethyltellurium trichloride (X) [133].

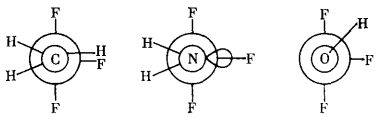


The polarity rule, established initially for phosphoranes, has now received theoretical justification also for tetracoordinate compounds of Group VI elements—sulphuranes and their analogues [141–144]. A clear explanation of the loosening of the diaxial bonds in σ-sulphuranes and their analogues is associated with the structure of the highest occupied molecular orbital, which is regarded, in terms of the perturbation theory, as a combination of a bonding molecular orbital of the angular MR^1R^2 molecule with the antibonding molecular orbital of the extended linear R^3R^4 molecule, where R^3 and R^4 are axial ligands [139,140].

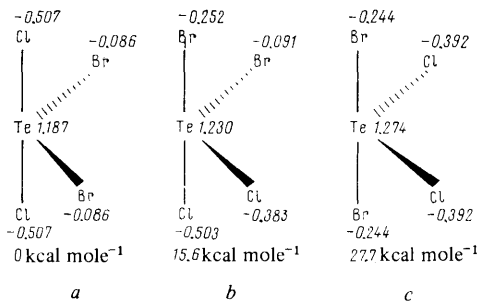
The high stability of configurations in which the most electronegative ligands occupy axial positions is independent of the inclusion in the basis set of the *d* orbitals of the central atom and is determined by the form of the molecular orbital which permits the concentration of electron density at the axial bonds and leads to the accumulation of negative charges at the axial centres.

The fulfillment of the requirements of the polarity rule for σ-telluranes is illustrated, for example, by calculations on the topomers of dibromodichlorotellurium (Fig. 3), which show that tellurane structures with the most electronegative substituents in the axial positions are preferable [144]. In this connection it is interesting to note that, on the basis of Raman spectra, Ozin and Voet [145] initially concluded that $TeCl_2Br_2$ exists in configuration *b* (Fig. 3), but later [146] a more exact calculation led them to attribute conformation *a* to this compound (Fig. 3).

The conformational effects in sulphurane, selenurane, and tellurane molecules, due to the complexity of the dependence of the total energy of the molecule on the rotation of the ligands with lone electron pairs and axial and equatorial π bonds have also been analysed [142,144,147,148]. The general conclusions arising from the theoretical calculations reduce to the following postulates:

1. The introduction of a strong π-acceptor substituent into the molecules of σ-telluranes can stabilise, regardless of the electronegativities of the remaining ligands, its axial conformation in which the axes of the vacant π molecular orbitals of the acceptor and the localised orbital of the lone electron pair are parallel.
2. π-Donor ligands always occupy equatorial positions.
3. In bisphenoid structures of telluranes, as in the systems of analogues located in the highest positions in the Periodic System, the conformational *gauche*-rule holds [149], i.e. the conformation with the greatest number of *gauche*-interactions has the minimum energy. Indeed it follows from calculations [144,147] that the most stable rotational isomeric forms of MF_3R molecules (R = CH_3, NH_2, or OH; M = S, Se or Te) are the conformations (XIII)–(XV).

The above conclusions are so far based exclusively on theoretical calculations and await experimental studies on the new and interesting field of the conformational analysis of tetracoordinate structures of Group VI elements.



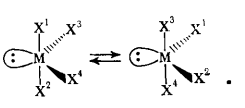


Figure 3. The relative stabilities of various configurations (*a*–*b*) and atomic charges in tellurium dibromide dichloride obtained by the extended Hückel method [144]. (The numerals under the structures indicate their relative energies and those opposite the atoms indicate the atomic charges.)

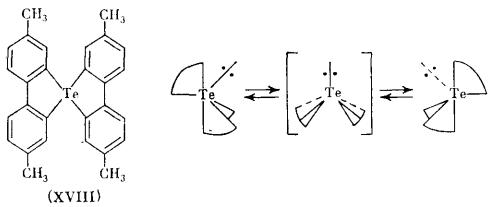
(c) Polytopic Rearrangements

The stereochemical non-rigidity at the bisphenoid structures of the molecules of σ-sulphuranes and their analogues leads to the possibility of a rapid exchange of the axial (X^1,X^2) and equatorial (X^3,X^4) ligands—topomerisation:

The most convenient method for the investigation of the mechanism and kinetics of such polytopic rearrangements is dynamic NMR. ^{19}F NMR is particularly useful because of the high sensitivity of the ^{19}F nuclei to the characteristics of their chemical environment. The polytopic rearrangements in MF_4 (M = S, Se, or Te) molecules have been investigated [150-154]. It was observed that the topomerisation of SF_4 takes place at a high rate even at room temperature (the separation of the signals of the axial and equatorial fluorine atoms is achieved only at $-98°C$, [150] which corresponds to a barrier of 4.5 ± 0.8 kcal mole^{-1}). For SeF_4, there are only two unresolved peaks even at $-200°C$, which are broadened and merge into a singlet at a temperature $> -190°C$; consequently the exchange in SeF_4 is faster than in SF_4. [150] There is only one sharp peak in the TeF_4 spectrum up to $-100°C$ (the freezing point of the solution). Thus the rate of the axial–equatorial exchange in molecules of the type MF_4 increases in the sequence S < Se < Te. [150]

The rate of ligand exchange is extremely sensitive to the catalytic influence of impurities (H_2O, HF). [154] Indeed, when bis(trimethylsilyl)amine, which binds water, is added to SF_4 solutions, the separation of the signals due to the axial and equatorial fluorine atoms in the ^{19}F NMR spectrum is achieved already at $-60°C$ (this temperature is reproducible, in contrast to earlier studies), which yields an activation energy of 16.3 ± 5 kcal mole^{-1}.

Table 4. The σ constants of tellurium-containing groups.



Substituent	δ^F_m, p.p.m.*	δ^F_p, p.p.m.	σ_I	σ_c	σ_n
$Te(CH_3)Cl_2$	−2.93	−4.67	0.50	0.06	0.56
$Te(CH_3)Br_2$	−3.15	−4.86	0.53	0.06	0.59
$Te(CH_3)I_2$	−3.50	−4.79	0.58	0.04	0.62
$Te(C_6H_5)Cl_2$	−3.06	−5.08	0.52	0.07	0.59
$Te(C_6H_5)Br_2$	−3.21	−5.09	0.54	0.06	0.60
$TeCl_3$	−3.28	−6.62	0.55	0.11	0.66
$TeBr_3$	−3.05	−6.43	0.51	0.11	0.62

*The position of the centre of the multiplet relative to the chemical shift of the fluorine signal in fluorobenzene is indicated; the "minus" sign indicates a downfield shift and the "plus" sign indicates an upfield shift relative to δ in C_6H_5F.
