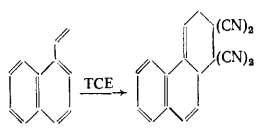
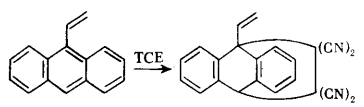
(XXII) (4)

As an example, mention may be made of studies by Huisgen and coworkers on the cycloaddition of TCE to substituted cyclo-octatetraenes[79–81]. TCE has found extensive applications for the identification of unstable dienes formed in thermal, photochemical, or catalytic isomerisation reactions. An interesting example of this kind is provided by the thermal isomerisation of 1-dimethylvinylidene-2-isopropylidene-3,3-dimethylcyclopropane[82]:



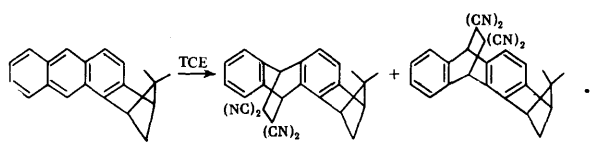
Among the dienes introduced into the Diels–Alder reaction with TCE, a wide variety of systems have been investigated: phenafulvenes to which TCE adds in the 8- and 10-positions[83], dimethylene derivatives of bi- and tri-cyclic hydrocarbons having the general formula (XXIII)[84–86], thioacetals[87], phencyclone[73,88], *N*-methylisoquinolinone[89], dialkyl butadien-2-yl phosphates[90], biscyclopentadienylmercury[91], as well as divinylallene[92], 1,2,3,5-hexatetraene[93], spiro[2,4]heptatriene[94], and spiro[4,4]nonatriene[95], which combine with only one equivalent of TCE [adducts (XXIV)–(XXVII)]:



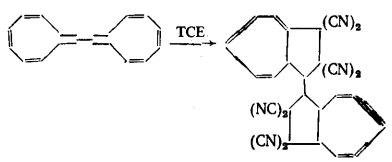
(XXIII) (XXIV) (XXV) (XXVI) (XXVII)

The diene and ene synthesis reactions involving polyene systems have also been studied in relation to derivatives of vitamin A_1 and steroid alkenes[96,97].

Aryl-substituted olefins give rise as a rule to [2 + 2]-adducts (see above). On the other hand, 1-vinyl- and 2-vinyl-naphthalenes react via the Diels–Alder mechanism[29,53], for example:

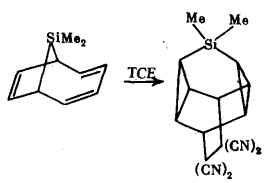


while 9-vinylanthracene[53] reacts like anthracene itself[98], combining with TCE in the 9- and 10-positions, i.e. the vinyl group is not involved in the reaction. Adduct (XXVIII) dissociates readily in solution:

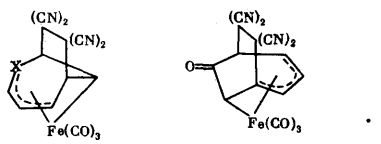


(XXVIII)

The reaction of TCE with apopinanthracene reacts anomalously—the addition to the sterically hindered part of the molecule takes place preferentially [(XXIX) : (XXX) = 1.5][99]:

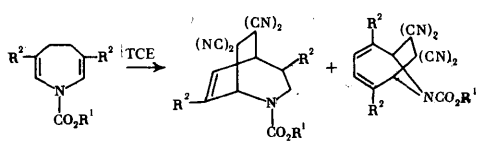


(XXIX) (XXX)



The reaction of 8,8-biheptafulvenyl with TCE leads to a mixture of adducts, which has not been separated, believed to contain, on the basis of spectroscopic data, the products of [8 + 2]-cycloaddition[100]:

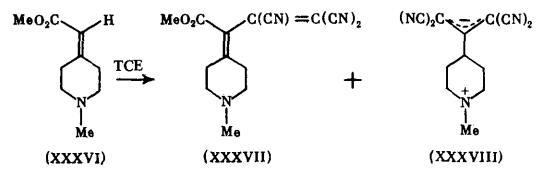
Among unusual reactions of TCE, mention may also be made of the reaction with 9,9-dimethyl-9-silabicyclo[4,2,1]nona-2,4,7-triene[101]:



The reactions of TCE with polyene systems are also of special interest for the study of the influence of transition metals on the reactivity of coordinated olefins. Investigations[102–104] have shown that tricarbonyliron complexes of cycloheptatriene and cyclooctatetraene readily undergo 1,3-exo-cycloaddition with formation of the σ,π-complexes (XXXI) and (XXXII) respectively:

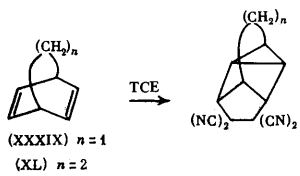
(XXXI), X = CH_2; (XXXII), X = —CH=CH— (XXXIII)

while the reaction of troponetricarbonyliron with TCE gives the 1,5-cycloaddition product (XXXIII).



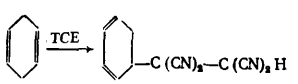
The addition of TCE to azepines[105–107] proceeds via mechanism (5), the formation of the 1,6-adducts (XXXV) being observed only for 3,6-di(isopropyl or t-butyl)azepines; it has been shown[107] that it is a kinetically controlled process, the 1,4-adducts (XXXIV) being thermodynamically more stable:

(5)



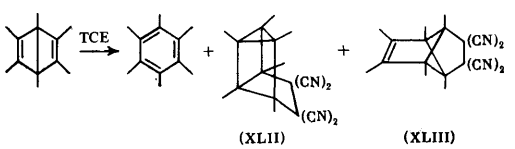
(XXXIV) (XXXV)

It is of interest that the formation of cyclic adducts is not observed at all in the reaction with dihydropyridine (XXXVI). The principal reaction products are compounds (XXXVII) and (XXXVIII)[108]. The mechanism of this reaction has not been studied:



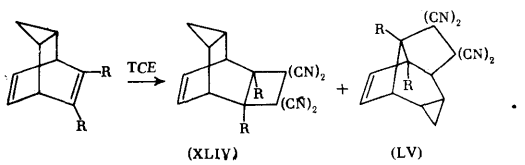
(XXXVI) (XXXVII) (XXXVIII)

Homodiene structures. The study of the interaction of homoconjugated dienes with TCE showed that the reactivity of bicyclo[2,2,*n*]alkadienes (*n* = 1,2,3, or 4) decreases with increasing *n* and that, whereas compounds (XXXIX) and (XL) react with TCE via the [2*s* + 2*s* + 2*s*] mechanism [Eqn. (6)], cyclohexa-1,4-diene forms adduct (XLI), which readily loses a molecule of tetracyanoethane to form benzene[109] [mechanism (7)]:



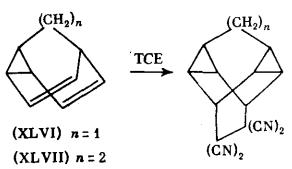
(XXXIX) *n* = 1
(XL) *n* = 2

(6)



(7)

The reaction with hexamethylbicyclo[2,2,0]hexadiene gives a mixture of hexamethylbenzene (12–15%) and adducts (XLII) and (XLIII) in proportions of 10 : 1:[110]

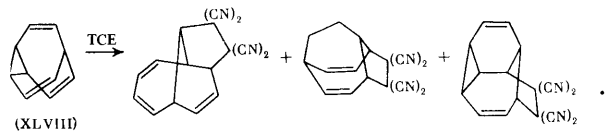


(XLII) (XLIII)

The photoaddition of TCE to tricyclo[3,2,2,$0^{2,4}$]nonadiene derivatives leads to a mixture of adducts (XLIV) and (XLV)[111]:

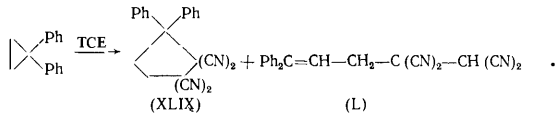
(XLIV) (LV)

Bridged homotropylidenes combine with TCE via the mechanism of the Diels–Alder reaction. Thus barbaralane (XLVI) and dihydrobullvalene (XLVII) react with TCE via the following mechanism[112]:



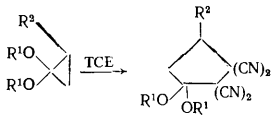
(XLVI) *n* = 1
(XLVII) *n* = 2

The photochemical reaction with barbaralone proceeds analogously[113].



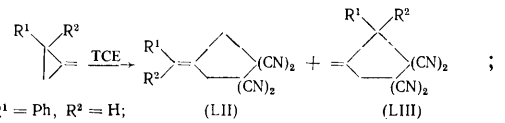
The reaction of bullvalene (XLVIII) with TCE leads to the formation of products whose relative amounts depend on the

polarity of the solvent#:

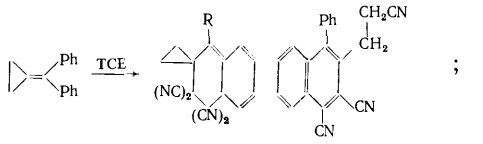


(XLVIII)

Reactions with strained hydrocarbons. Whereas cyclopropane itself does not react with TCE, the reaction with 1,1-diphenylcyclopropane leads to a mixture of products (XLIX) and (L) in proportions of 1 : 1.3[114]:

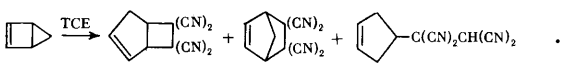


(XLIX) (L)

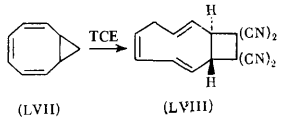


The cycloaddition of cyclopropanone and phenylcyclopropanone acetals proceeds via the $[2\sigma + 2\pi]$ mechanism[115]:

Methylenecyclopropanes (LIa) and (LIb) react with TCE to form the 1 : 1 adducts (LII) and (LIII); the introduction of aromatic substituents into the methylene component of the molecule of (LIV) leads (via a zwitter-ionic intermediate) to adduct (LV)[116]:



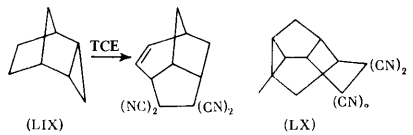
(LI) (a) $R^1 = Ph$, $R^2 = H$; (LII) (LIII)
(b) $R^1 = R^2 = Ph$.



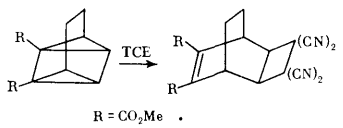
(LIV) (a) R = H; (LV) (LVI)
(b) R = Ph.

It has been shown[117] that compound (LVb) is then aromatised with the opening of the three-membered ring and the loss of HCN; the final product has the structure (LVI).

The reaction of TCE with bicyclo[2,1,0]pent-2-ene in THF leads to a mixture of products via the following mechanism[118]:



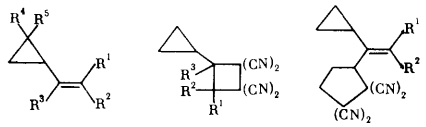
The electrophilic addition of TCE to *cis*-bicyclo[6,1,0]nonatriene (LVII) also proceeds with the simultaneous expansion of both rings[119]. Kinetic measurements have shown that compound (LVII) does not react directly with TCE; the latter adds to the valence isomer of this compound—1-*cis*, 3-*trans*, 5-*cis*, 7-*cis*-cyclononatetraene, with formation of adduct (LVIII)[120]:



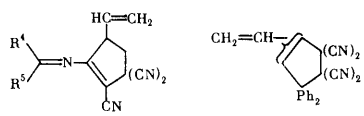
(LVII) (LVIII)

The non-concerted polar cycloaddition of TCE to *endo*-tricyclo[3,2,1,$0^{2,4}$]oct-6-ene (LIX) proceeds with the opening of the three-membered ring[121]. It is of interest that the introduction of a methyl group in the 2-position of compound (LIX) results in the formation of an adduct having the structure (LX)[122]:

(LIX) (LX)



The reaction of TCE with tetracyclo[4,2,$0^{2,8}$,$0^{5,7}$]octane-1,6-dicarboxylate[123] leads to the stereospecific addition to the bis(homocyclobutane) system:



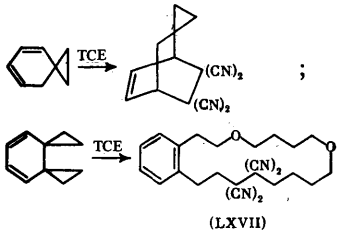
R = CO_2Me.

The reaction with quadricyclane proceeds in the same way[124]. On the other hand, the structure of the adduct with hexamethylprismane[125] has not so far been established.

Cyclopropylalkenes. The mode of reaction of TCE with cyclopropylethylenes has been found to depend markedly on the structural characteristics of the latter. Whereas the reaction with cyclopropylethylene (LXIa) and 1,1-dicyclopropylethylenes (LXI, b and c) leads exclusively to the products of [2 + 2]-cycloaddition (LXII), the replacement of the methyl groups by phenyl groups or cyclopropyl groups [compounds (LXI, d and e)] gives rise to adducts having the structure (LXIII). The reaction of compound (LXIf) leads to a 7 : 1 mixture of compounds (LXIV) and (LXV), while the reaction of compound (LXIg) yields, apart from adduct (LXIV), also compound (LXVI) [the reaction with compound (LXIh) proceeds analogously].

(LXI) (LXII) (LXIII)

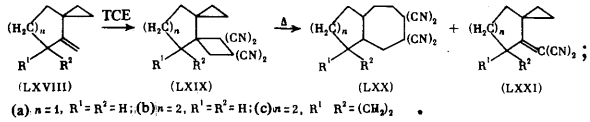
(LXIV) (LXV)



(LXVI)

(a) R = H; (b) R = H, R^3 = cyclopropyl; (c) R = H, $R^1 = R^2$ = Me,
R^3 = cyclopropyl; (d) R = H, $R^1 = R^2 = R^3$ = cyclopropyl;
(e) R = H, $R^1 = R^2$ = Ph, R^3 = cyclopropyl; (f) R = H, $R^4 = R^5$ = Ph;
(g) R = H, $R^4 = R^5$ = *o*-biphenylene; (h) R = H, R^3 = Me, R^4, R^5 = *o*-biphenylene.

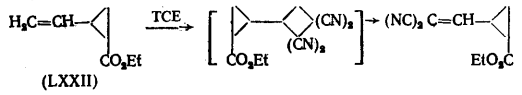
The latter finding suggests that cycloadditions of this type take place with formation of a zwitter-ionic intermediate[126-128]. However, the formation of a TCE radical-anion in reactions with cyclopropylethylenes has been confirmed spectroscopically in a number of instances[127].



See P.Cernuschi, C.De Micheli, and R.Gandolfi, Tetrahedron Letters, 3667 (1977).

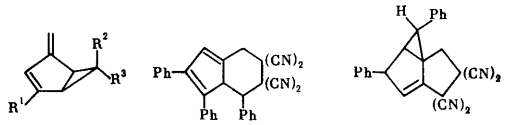
The reaction of spiro[2,5]octa-4,6-diene with TCE[129] led to the normal [4+2]-adduct, while the reaction of dispiro-[2,0,2,4]deca-7,9-diene in THF is accompanied by the opening not only of both three-membered rings but also of two solvent molecules, so that structure (LXVII) has been assigned to the final product[130]:

(LXVII)



Vinylcyclopropanes (LXVIII, a–c) react with TCE to form the [2+2]-adducts (LXIX) whose thermal rearrangement results in a mixture of compounds (LXX) and (LXXI), the relative amounts of which depend strongly on the nature of the solvent[131,132]:

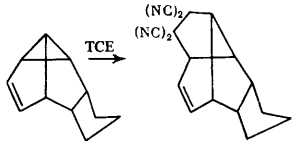
(LXVIII) (LXIX) (LXX) (LXXI)



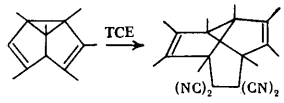
(a) $n=1$, $R^1=R^2=H$; (b) $n=2$, $R^1=R^2=H$; (c) $n=2$, R^1 $R^2=(CH_2)_2$.

A metathetical reaction, analogous to the conversion of (LXVIII) into (LXXI), also takes place in the case of cyclopropylethylene (LXXII)[133]:

(LXXII)



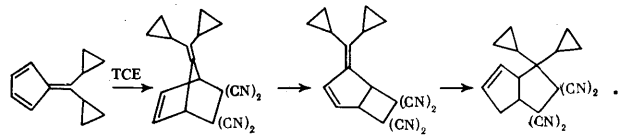
The mode of reaction of TCE with homofulvenes depends markedly on the structure. Whereas compound (LXXIIIa) gives rise to adduct (LXXIV), the reaction with compound (LXXIIIb) leads to adduct (LXXV)[134]:



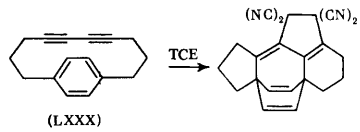
(LXXIII) (LXXIV) (LXXV)

(a) $R^1=R^3=Ph$, $R^2=H$; (b) $R^1=R^3=H$, $R^2=Ph$.

The cycloaddition of TCE to 3,7-*endo*-1-methoxytetracyclo-[6,3,0,$0^{2,11}$,$0^{3,7}$]undec-9-ene proceeds via the [$\pi_\sigma^2+\sigma_s^2+\pi_s^2$] mechanism[135]:

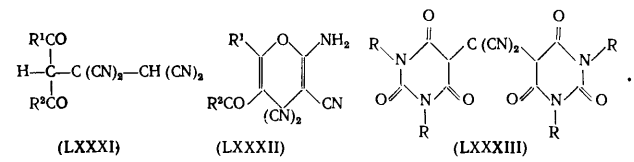


The reaction of octamethylsemibulvalene with TCE leads to adduct (LXXVI)[136]:



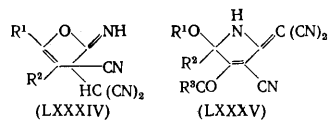
(LXXVI)

The study of the competitive reactivities of diene, ene, and cyclopropyl systems in relation to the reactions of TCE with dicyclopropylfulvene led to the discovery of the phenomenon of the "reaction cascade": the product of the [4+2] diene synthesis (LXXVII) rearranges to the more stable [2+2]-adduct (LXXVIII), which then isomerises quantitatively to the [2+6]-adduct (LXXIX)[137]:



(LXXVII) (LXXVIII) (LXXIX)

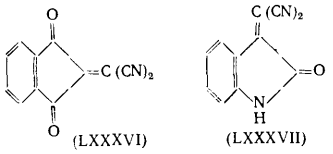
Reactions with alkynes. The only example of a reaction of TCE with conjugated diynes is the reaction with compounds of type (LXXX) via the [$\pi 1s+\pi 2s+\pi 2s+\pi 2a$] mechanism[138]:



(LXXX)

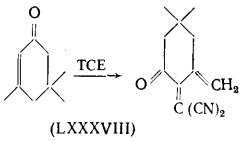
Reactions with carbonyl compounds and their analogues. The reactions of TCE with active methylene compounds lead to the formation in the first stage of non-cyclic Michael adducts (LXXXI), which then undergo at least four different types of reactions. Reactions with cyclic β-diketones (4-hydroxycoumarin, 4-hydroxycarbostyril[139], dimedone, and cyclohexane-1,3-dione)[140] lead to derivatives of the 4*H*-pyran (LXXXII). The analogous reaction with barbituric acid derivatives leads to the simultaneous formation of the bipyrimidyl derivative (LXXXIII), whose content increases with increasing reaction temperature, although adduct (LXXXII) is not converted into (LXXXIII) on heating[141]:

(LXXXI) (LXXXII) (LXXXIII)



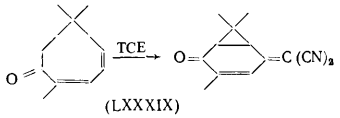
The reactions with 1,3-disubstituted 5-pyrazolones[141] and 2-indanone[142] also involve the formation of disubstituted malononitriles of type (LXXXIII). The reaction of TCE with acetylacetone yields adduct (LXXXI) in ethanol, but in acetonitrile the product is adduct (LXXXII)[143]. On the other hand, when the reaction was carried out in benzene, the only product proved to be the dihydrofuran (LXXXIV), which rearranges to dihydropyrrole (LXXXV) on heating[144]:

(LXXXIV) (LXXXV)



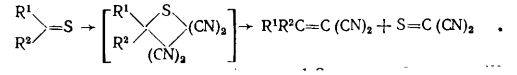
It has been shown[144] that the reactions of other acyclic β-diketones with TCE also lead to dihydropyrroles (LXXXV) via the stage involving the formation of dihydropyrans (LXXXIV), which cannot be isolated in most instances owing to their instability.

On the other hand, the reactions of TCE with indan-1,3-dione and oxindole[145,146] gives rise to the dicyanomethylene derivatives (LXXXVI) and (LXXXVII):



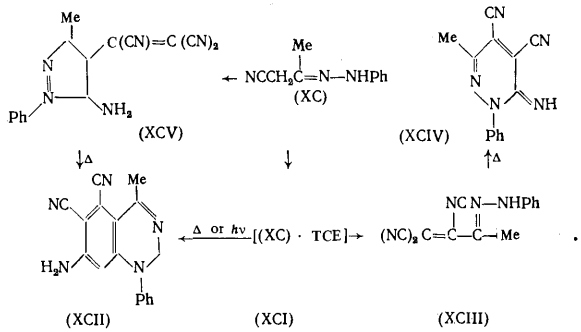
(LXXXVI) (LXXXVII)

The product of the reaction with anthrone in acetonitrile is the normal Michael adduct, but the latter is converted under the influence of a base into 10,10′-bianthrone, which is also formed directly when anthrone is acted upon by TCE in a neutral medium (ethanol–chloroform)[143]. The causes of the differences between these reactions of TCE have still not been completely elucidated. Cyclic α,β-unsaturated ketones do not give rise to bicyclic adducts despite the possibility of enolisation to a planar diene. The reactions of TCE with isophorone[147] and eucarvone[148] proceeds in an acid medium and lead to the formation of the dicyanomethylene derivatives (LXXXVIII) and (LXXXIX), the reaction in the latter case being accompanied by the formation of a three-membered ring:



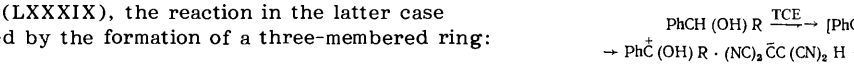
(LXXXVIII)

(LXXXIX)



On the other hand, 5-substituted cyclohexa-2,4-dienones do not react with TCE, which is believed to be due to steric factors[149].

Thioketones react with TCE via a cycloaddition–cyclofragmentation mechanism with formation of dicyanomethylene derivatives:

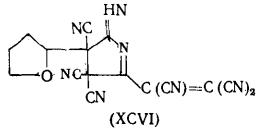


Reactions of this type have been described for 5-aryl-1,2-dimercapto-3-thiones[150], tropothione[151], and thioacetals of thioacylketens[152].

The mode of reaction of TCE with cyanoacetone hydrazones depends markedly on the nature of the solvent and the reaction temperature. Thus the corresponding phenylhydrazone (XC) gives rise in benzene to a 1 : 1 complex (XCI), which is converted into pyrazolopyridine (XCII), either thermally or under irradiation, whereas in ethanol or acetonitrile (at 20 °C) it loses a malonitrile molecule to form the hydrazone (XCIII), which cyclises to compound (XCIV) on heating. On the other hand, the reaction in boiling ethanol leads directly to compound (XCII)—it is believed to proceed via adduct (XCV), undergoing thermal cyclisation to compound (XCII), and not via a stage involving the formation of the complex (XCI)[153]:

(XCV) (XC) (XCIV) (XCII) (XCI) (XCIII)

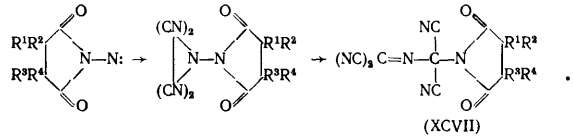
Dehydrogenation reactions. The reactions of TCE with alkylarylmethanols, tetrahydroquinoline, and 2,5-dihydrofuran lead to the formation of tetracyanoethane and the corresponding dehydrogenated compound, in many instances in almost quantitative yield (the yield of furan is 95%)[154]. It has been shown that the reaction with alcohols proceeds via the mechanism[154]



The dehydrogenation reactions of 1,4-dihydrobenzene[109] [see Scheme (7) above] and 9(11)-dihydroergosteryl acetate[155] belong to the same type.

Other addition reactions. The use of TCE as an inhibitor of the radical polymerisation of olefins is based on its ability to combine with free radicals, for example, via the mechanism

(8)

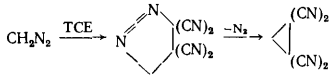


It is believed that the photoaddition of tetrahydrofuran to TCE takes place via a radical mechanism; the structure

(XCVI)

has been assigned to the final product[156].

Carbenes[2,157] and imidonitrenes[158] readily add to TCE to form respectively cyclopropanes and unstable aziridines, which rearrange quantitatively to imines of type (XCVII):

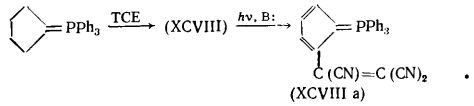


(XCVII)

TCE is hydrogenated to tetracyanoethane[159] and is oxidised by hydrogen peroxide in acetonitrile[160] to tetracyano-oxiran. Tetracyano-oxiran can also be obtained from TCE and primary ozonides[161]. This also results in the formation of the corresponding aldehydes and ketones and in higher yields than in the standard ozonisation procedure, which makes the above reaction particularly useful in structural studies with the aid of ozonolysis.

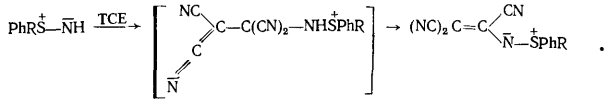
The addition of chlorine[162] is catalysed by chloride ions, which confirms the electrophilic nature of the bond in TCE. The reaction of TCE with diazomethane[163], leading to pyrazoline which loses a nitrogen molecule on heating, is of interest from the standpoint of the synthesis of nitrogen–carbon

compounds:



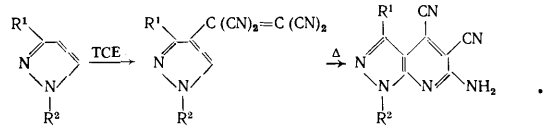
Sulphuric acid and bisulphites add reversibly to TCE even in water[159]. The reactions of alkali metal cyanides leads to the formation of the corresponding pentacyanopropanides[2].

(c) Reactions Involving the Substitution of a Cyano-Group in TCE

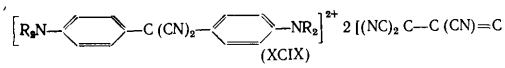


Treatment of TCE with alcohols and primary and secondary aliphatic amines can lead to the successive elimination of one or two HCN molecules and the formation of tricyanovinyl or dicyanomethylene derivatives[2]. However, in the majority of cases the reactions of TCE involving the elimination of a cyano-group stop at the first stage and lead to tricyanovinylation products. Such reactions take place with ammonia and hydrazine, *o*-alkylphenols, pyrrole, phenanthrene, phenylhydrazones, 2-methylfuran, and azulenes[2].

The reaction of TCE with cyclopentadienylphosphorane in the presence of bases leads to tricyanovinylation in the sterically hindered 2-position[164]. In the absence of bases the reaction yields the unstable product (XCVIII), which is converted photochemically or under the influence of bases into compound (XCVIIIa). It has not so far been possible to determine the structure of compound (XCVIII)[164].



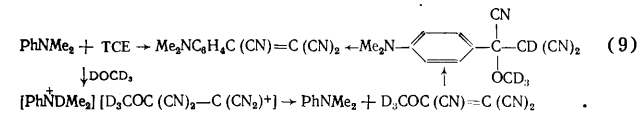
(XCVIII a)



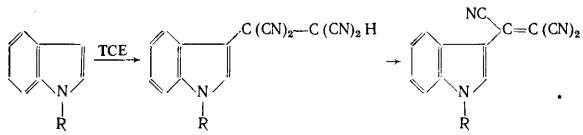
The interaction of TCE with *N*-unsubstituted arylsulphilimines proceeds via an addition–elimination mechanism[165]:

The reaction of 3-aminopyrazoles with TCE also leads to the elimination of HCN and the formation of tricyanovinylpyrazoles, which cyclise on heating to pyrazolo[3,4-*b*]pyridines[141]:

Whereas treatment of aniline with TCE leads to *N*-tricyanovinylaniline (it is believed to proceed via a stage involving the formation of a π-complex, which then reacts with one or two aniline molecules[166]), the product of the reaction with *N*,*N*-dimethylaniline (DMA) is *N*,*N*-dimethyl-4-(tricyanovinyl)-aniline, while *N*,*N'*-dialkylanilines with a higher molecular weight react with TCE to form complex mixtures containing bispentacyanopropenides of substituted malononitriles of type (XCIX) as the main components[167]:



(XCIX)

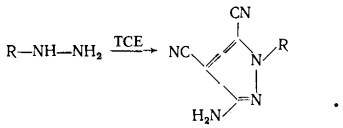


Compounds of this kind have also been detected as admixtures in TCE–DMA reaction mixtures[167].

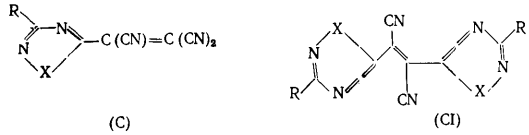
EPR data indicate the formation of the TCE radical-anion in reactions with *N*,*N*-disubstituted anilines and its virtually complete absence in the case of aniline[166].

The study of the reaction of TCE with DMA in deuteromethanol[168] led to the detection of the intermediates indicated below:

On the other hand it has been shown synthetically and spectroscopically that the intermediate in the reaction of TCE with DMA is not a zwitterion, as was believed previously, but a neutral substituted tetracyanoethane[169]. The same intermediate is formed in the tricyanovinylation of indoles[170]:



The detailed mechanism of these reactions is still the subject of controversy[171].



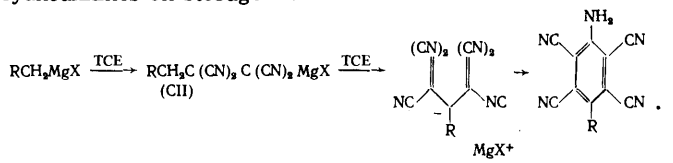
(d) Reactions Involving Addition to a Cyano-Group of TCE

Only a small number of reactions involving addition to a cyano-group of TCE are known. At first sight, this appears unexpected, because a cyano-group in TCE is formally linked to the strongly electron-accepting tricyanovinyl group and should therefore be more reactive than, for example, in dicyanogen. However, the even greater reactivity of the double bond in TCE is responsible for the preferential occurrence of reactions involving this bond.

The reaction of TCE with monosubstituted hydrazines leads to the formation of 3-amino-4,5-dicyanopyrazoles[172,173] and not 5-amino-3,4-dicyanopyrazoles as reported previously[2]:

Nitrile sulphides and nitrile oxides undergo 1,3-dipolar addition to a cyano-group of TCE with formation of mono- and bis-thiadiazoles and mono- and bis-oxadiazoles [(C) and (CI)][157]:

(C) (CI)

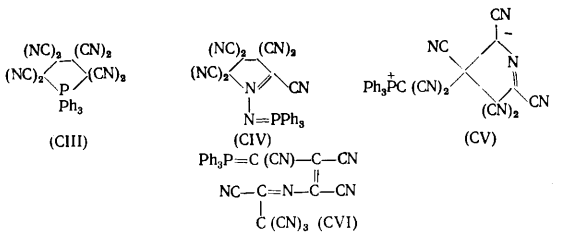


X = O or S.

It is believed that these reactions proceed via a concerted mechanism[174].

(e) Mixed Reactions

Reactions with Grignard reagents. Treatment of Grignard reagents with one equivalent of TCE leads to adduct (CII), whose treatment with trifluoroacetic acid results in the formation of a high yield of substituted tetracyanoethanes, while



interaction with a second equivalent of TCE gives rise to 3-substituted hexacyanopentadienides, which rearrange to tetracyanoanilines on storage[175]:

The reaction of TCE with phenyl-, isopropyl-, and t-butylmagnesium halides proceeds analogously in the first stage but reaction of adducts (CII) with a second TCE molecule leads to complex mixtures containing, apart from the TCE radical-anion, tricyanovinylbenzene in the case of phenylmagnesium bromide and 3-amino-6,6-dimethylhexacyanocyclohexene in the case of isopropylmagnesium bromide. An electron transfer stage has been discovered in the reaction of TCE with tritylmagnesium bromide[176]:

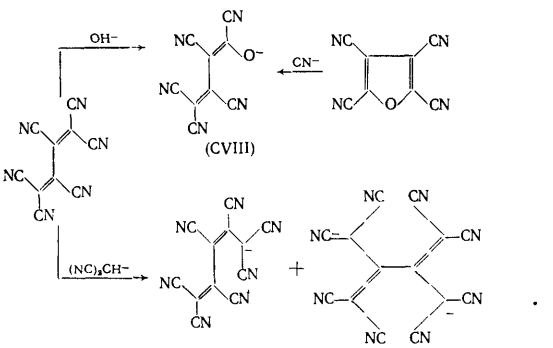
Reactions with aromatic phosphines. The reactions of TCE with triarylphosphines lead to the formation of 2 : 1 adducts, which hydrolyse to tetracyanoethane and racemic phosphine oxides (in the case of optically active phosphines)[177]. It has been suggested that the hydrolysis involves a stage in which a phosphinium radical-cation is formed[177]. The structure of the adduct of TCE with triphenylphosphine still remains unknown. Instead of the phosphole structure (CIII) proposed initially, which is inconsistent with ^{31}P NMR data[178], the aminoylid structure (CIV) and the betaine structures (CV) and (CVI) are nowadays considered as the most likely[177]:

(f) Polymerisation of TCE

Compared with acrylonitrile and vinylidene cyanide, TCE polymerises with much more difficulty. However, when TCE is heated to a sufficiently high temperature in the presence of metals, metal complexes, alcohols, phenols, amines, and amides, it undergoes degradation with formation of dark-coloured polymeric materials with semiconducting and catalytic properties[2].

A careful study of this type of polymerisation has been carried out[179] for a series of salts of polycyanohydrocarbons, which on heating also undergo spontaneous rearrangements with rupture of the $-C\equiv N$ triple bond and the formation of black powders with a crystalline lustre. Studies by differential thermal analysis showed that the first stage probably involves the formation of radical-ions which then undergo thermal rearrangements.

The polymerisation of TCE in the presence of organotin catalysts takes place with formation in the first stage of addition products having Sn—N bonds and subsequent chain growth as a result of the reaction of these bonds with the cyano-groups[180]. TCE itself can also serve as a catalyst of the polymerisation reaction; thus tricyanoethanol containing TCE initiates the polymerisation of alkyl vinyl ethers[181] [while pure TCE reacts to form cyanobutanes (see above)]. TCE is added in the synthesis of thermostable polyoxymethylenes[182] and in the cationic copolymerisation of olefins (to increase the reactivity of the less reactive component[183]), and also in order to inhibit anionic polymerisation processes[184].



2. Hexacyanobutadiene

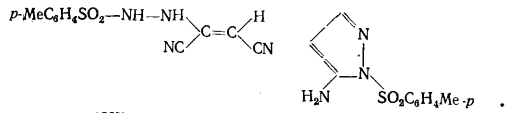
The condensation, catalysed by the addition of tetracyanoethane and tricyanoethylene, of the tetracyanoethanedi-ide anion, formed when TCE is treated with sodium hydride in acetonitrile, gives rise to the hexacyanobutenedi-ide anion (CVII), which can also be readily obtained by heating salts of the TCE radical-anion in solution[185]:

The oxidation of the anion (CVII) with bromine or concentrated nitric acid leads to the formation of hexacyanobutadiene (HCBD)—the only known example of the series of percyanoalkadienes.

Being a strong π-acid, HCBD undergoes the diene synthesis reaction as a dienolphile[185] and forms readily complexes with aromatic compounds as well as an unusual complex with tetrathiafulvalene (TTF), in which TTF exists in two oxidation states (0 and +1) and which exhibits a high electrical conductivity at room temperature (its resistivity is $10^{-3}\ \Omega$ cm)[186]. The HCBD radical-ion is formed readily even in the presence of mild agents such as sodium bromide and metallic mercury[185]. Treatment of HCBD with aqueous sodium bicarbonate leads to substitution of one of the terminal cyano-groups by a hydroxy-group. It is of interest that product (CVIII) is also formed when tetracyanofuran reacts with the cyanide ion[185]:

On the other hand, the reaction of HCBD with the malononitrile anion yields products of the substitution of the cyano-groups in both 1- and 2-positions[2,185].

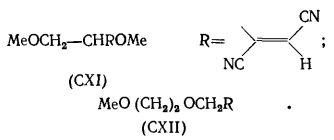
A number of physicochemical properties of HCBD and its radical-anion have been reviewed[2].



V. PERCYANOALKYNES

The chemistry of dicyanoacetylene (DCA) and dicyanodiacetylene (DCDA), synthesised before all other percyanohydrocarbons (1908), has been developing most vigorously only in the last 15 years. The sharply increased interest in these compounds can be explained not only by the great variety of their chemical properties and of their synthetic possibilities but also by their ability to generate ultrahigh temperatures on combustion in oxygen or ozone. The latter

factor stimulated a detailed investigation of the reactions of DCA not only with oxygen[187-189] but also with active nitrogen[190].



The review of cyanoacetylenes[191] published in 1977 gives a virtually exhaustive description of studies on the physical chemistry and chemistry of DCA and DCDA, so that the list of the main types of reactions of percyanoalkynes can only be supplemented by certain data not considered in the above review and new results.

It has been shown recently that DCA is capable of adding not only to alcohols, thiols, and aromatic amines[191] but also to tosylhydrazine[192]. The adduct has the structure (CIX), while the analogous reaction with cyanoacetylene yields mainly the cyclic adduct (CX)[191]:

(CIX) (CX)

Ethers, normally employed as solvents (tetrahydrofuran, diethyl ether, and monoglyme) also add to DCA. For example, the reaction with monoglyme leads to a 1:1 mixture of compounds (CXI) and (CXII)[193]:

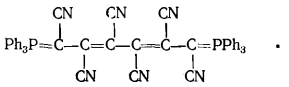
(CXI)

(CXII)

It is believed that the reaction is preceded by the formation of a charge-transfer complex.

The reactions of cyanoacetylenes with hydrogen halides and halogens are more unexpected. The addition of HX (X = Cl or Br) to the acetylenic bond takes place even at room temperature with formation of a mixture of isomers of dicyanohalogenoethylene[194,195]. The addition of bromine to DCA also takes place at room temperature with formation of dibromofumaronitrile[196]. The addition of iodine is much slower even in the presence of iron iodide[196]. The mechanism of this reaction is obscure; it has been suggested[2] that it is more likely to proceed via a radical than an ionic mechanism.

The attempt to obtain DCA from HCN and cyanoacetylene also led to the formal addition of HCl and HCN to cyanoacetylene:

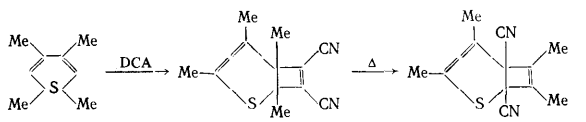


The mechanism of this reaction has still not been elucidated[197]. Bearing in mind the known electrophilic properties of the molecule, the ready formation of a 1:1 complex of DCA with aluminium bromide is fairly unexpected[198]. Although the structure of the complex is unknown, by analogy with many complexes of nitriles with Lewis acids[2] the complex is believed to involve the coordination of aluminium bromide to the cyano-group. The complex is extremely sensitive to moisture and readily reacts with dienes, giving rise to Diels–Alder products.

The study of the ultraviolet spectra of colourless solutions of DCA in aromatic hydrocarbons demonstrated the absence of charge-transfer complexes even for hexamethylbenzene, which forms intensely coloured complexes with tetracyanoethylene[2].

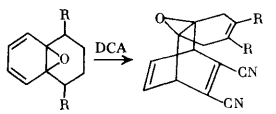
On the other hand, it has been reported[199] that solutions of DCDA in benzene are blue. However, since toluene, being a stronger π-base, gives rise to a blue solution much more slowly, it is believed that the colour of the benzene solution is caused by some other factors, for example, the presence of impurities[2].

DCA reacts vigorously with metal compounds: it is reduced by tributylstannane in methanol, is inserted in the C–Au bond in the reaction with the ferrocenylgold–triphenylphosphine complex, combines with mercury(II) chloride in aqueous solution (in proportions of 2:1), and forms compounds containing C–Co bonds with pentacyanocobalt and octacarbonyldicobalt[191].



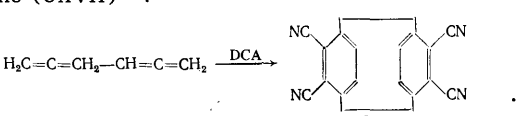
The 3:2 adduct of DCA with triphenylphosphine, formed at room temperature, is believed to have structure (CXIII)[2]:

(CXIII)



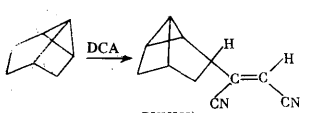
The 1,4-cycloaddition of DCA to dienes has been studied most extensively at the present time and is frequently used to synthesise a wide variety of polycyclic compounds[2,191]. Apart from aliphatic dienes and cyclodienes, DCA reacts with aromatic compounds (benzene, naphthalene, and anthracene) and with heterocycles (derivatives of furan and pyridine). Thiophens are an exception; the structures of thiepins and [2+2]-adducts have been attributed to the products of their reactions with DCA[200].

The latest studies have shown that the adduct of DCA with tetramethylthiophen undergoes the Cope thermal rearrangement, so that the final product has structure (CXIV)[200]:



(CXIV)

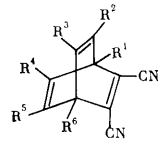
Arene oxides of type (CXV) react with DCA to form the tricyclic adducts (CXVI)[201]:



(CXV) (CXVI)

The reaction with hexa-1,2,4,5-tetraene leads to [2,2]paracyclophane (CXVII)[202]:

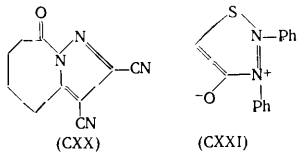
(CXVII)



Like TCE, DCA is capable of transannular addition to norbornadiene and barrelene and of reactions, involving ring opening, with strained alicyclic systems of the type of bicyclo[2,1,0]pentane[191]. However, the reaction with tricyclo[4,1,0,$0^{3,7}$]heptane leads to a substituted maleonitrile (CXVIII) and not to a cyclic adduct[203]:

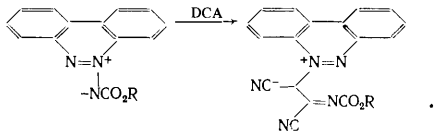
(CXVIII)

A study of the ultraviolet spectra of adducts of DCA with aromatic hydrocarbons (CXIX) revealed the presence of absorption bands corresponding to the formation of intramolecular charge-transfer complexes, where the dicyanoethylene bridge functions as the acceptor and the remaining two double



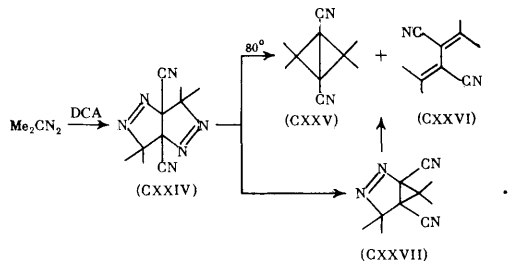
bonds are donors[29]:

(CXIX)



Being an active dipolarophile, DCA undergoes 1,3-cycloaddition reactions with diazomethane, diazocyclopentadienes, ethyl diazoacetate, benzonitrile oxide, and isoquinolinium ylids; it also reacts with 1,4-dipoles—for example, with 2-hydroxy-1,6,8-trimethyl-4-oxopyrimido[1,2-*a*]pyrimidinium[191].

The reaction of DCA with 2-diazocyclohexanone, which proceeds via a 1,3-dipolar addition stage, includes a sigmatropic (1,5)-acyl shift and leads to 1,10-diazabicyclo[5,3,0]deca-7,9-dien-2-one (CXX)[204]:



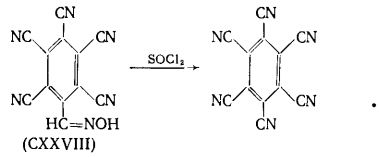
(CXX) (CXXI)

Phosphoryldiazo-compounds[205], anhydro-4-hydroxythiazolium hydroxide (CXXI)[206], and azimines [for example, compound (CXXII)] have also been made to react with DCA as 1,3-dipoles. In the last instance the resulting [1,3]-adduct undergoes a spontaneous electrocyclic opening of the triazoline ring and is converted into the azomethine (CXXIII)[207]:

(CXXII) (CXXIII)

Treatment of DCA with an excess of dimethyldiazomethane gives rise to pyrazoline (CXXIV) and the latter loses on heating two nitrogen molecules with formation of a mixture of products whose main components are the dicyclobutane (CXXV) and the diene (CXXVI):

(CXXIV) (CXXV) (CXXVI) (CXXVII)



The latter is formed quantitatively when compound (CXXIV) is irradiated and particularly in the thermolysis of compound (CXXV). When the bisadduct (CXXIV) was heated cautiously, it was possible to obtain also cyclopropanopyrazoline (CXXVII), whose thermolysis also gives rise to a mixture of compounds (CXXV) and (CXXVI) but with a higher content of the diene[208].

Cyanoacetylenes have attracted particular attention as potential monomers for semiconducting polymers. Thus DCA–olefin copolymers[209] have semiconducting properties and are thermally stable, which permits their use in the manufacture of transistors, thermoelectric devices, and as casings for rocket engines.

Furthermore, DCA polymers proved to be convenient objects for the study of the electrophoretic behaviour of polyconjugated systems[210].

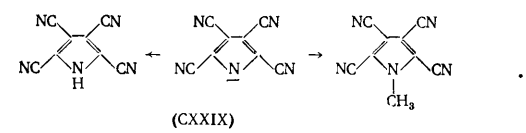
VI. PERCYANOARENES

The only example of aromatic percyanohydrocarbons is hexacyanobenzene (HCB), which was synthesised for the first time in 1963 by the dehydration of the oxime (CXXVIII) in accordance with the reaction[211]:

(CXXVIII)

The synthesis of HCB from 1,3,5-tricyano-2,4,6-trifluorobenzene and calcium cyanide in dimethylformamide in a yield of approximately 50% was described later[212].

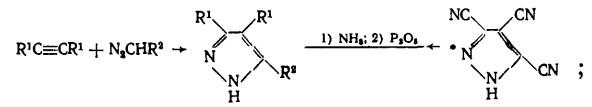
Treatment of 2,4,6-trichloro-1,3,5-tricyanobenzene with sodium methoxide or ethoxide (at −20 °C) followed by treatment with sodium cyanide (at −5 °C) and refluxing in a $POCl_3$–pyridine mixture gives rise to a mixture of HCB and chloropentacyanobenzene (in proportions of 1 : 9 in the former case and 1 : 3 in the latter)[213].



The molecular orbitals of HCB were calculated by Shwarts[214]. HCB readily forms coloured complexes with aromatic hydrocarbons[211] and a black 1 : 2 complex with pyrene[215].

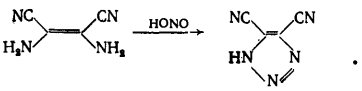
Spectroscopic studies on complexes of this composition with aromatic methoxy- and methylthio-compounds led to the establishment of the following series based on the strength of "electron-accepting" properties: tetracyanoquinodimethane > TCE > HCB > tetracyanobenzene[216]. The hydrolysis of HCB leads to the formation of pentacyanophenol—a very strong acid whose methylation with diazomethane yields pentacyanoanisole and whose halogenation gives rise to the corresponding halogenopentacyanobenzenes[217]. The reactions of HCB with alcohols and amines take place even at room temperature[218,219]. In the former case there is slow formation of alkoxypentacyanobenzenes, which react with the excess alcohol even following a moderate temperature rise, forming the corresponding ether and pentacyanophenol[218]. The reactions of HCB with ammonia and dimethylamine also proceed under exceptionally mild conditions and lead to products of mono- and 1,3-di-substitution in the aromatic ring. However, the analogous reaction with aniline and o-diaminobenzene requires heating to 80 °C.[219]

As regards condensed aromatic percyano-systems, there have been no reports of compounds containing more than two cyano-groups, with the exception of tricyanoperylene[220].



VII. PERCYANO-DERIVATIVES OF NITROGEN HETEROCYCLES

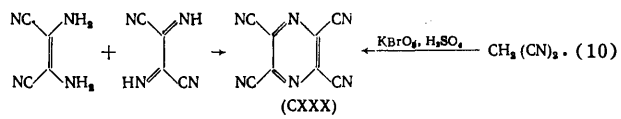
Although salts of tetracyanopyrrole (CXXIX) can be obtained by treating tetracyano-1,4-dithiine with azide ions[221] and can be converted into the corresponding pyrrole (on ion exchange resins) and *N*-methylpyrrole, the percyano-compound has not so far been synthesised:



(CXXIX)

Tetracyanopyrazole and tricyanotriazole have not been synthesised either, although 3,4,5-tricyanopyrazole has been prepared in two ways[222]:

(a) R^1=CN, R^2=CO_2Et;
(b) R^1=CO_2Et, R^2=CN .

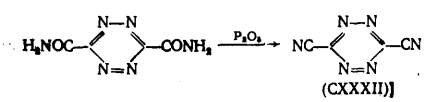


It is of interest that it is not impossible to carry out the direct synthesis (for $R = R^1 = CN$)[222]. 4,5-Dicyanotriazole can be obtained by treating diaminomaleonitrile with nitrous acid[223-227]:

Both compounds are strong acids and readily form stable salts.

The reports of the synthesis of pentacyanopyridine have not so far been confirmed by the description of the relevant experiment, although the pentacyanopyridine radical-anion was studied by EPR in 1966.[228]

Tetracyanopyrazine (CXXX) can be obtained by the condensation of diaminomaleonitrile and diiminosuccinonitrile[229] or by the direct oxidation of malononitrile[230] via reaction (10). In both cases 1-aminotricyanopyrazine and 1,2-diaminodicyanopyrazine are formed simultaneously:

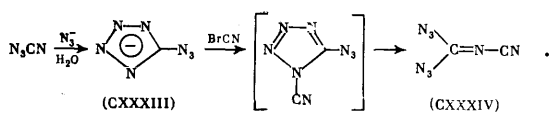


(CXXX)

Tetracyanopyrazine itself is used as a regulator of plant growth[231] and derivatives of 3,5-diamino-2,4-dicyanopyrazine, obtained by treating compound (CXXX) with ammonia and primary and secondary amines, are used to synthesise fluorescent materials, dyes, and "ladder" polymers[232,233]. The reaction of compound (CXXX) with *N,N*-disubstituted anilines leads to the corresponding 2-(4-aminophenyl)-3,5,6-tricyanopyrazines, which are used as dyes[234]. The mass spectra of polycyanopyrazines have been investigated[235].

The most thoroughly investigated six-membered heterocyclic pernitrile, which has been known for a long time, is tricyano-1,3,5-triazine[131]. In contrast to the usual method for the synthesis of *sym*-triazines, compound (CXXXI) cannot be obtained by the trimerisation of dicyanogen. It was synthesised in a very low yield in 1919 via the triamide of cyanuric acid[236]. Pyrolysis of compound (CXXXI) gives rise to dicyanogen[236,237] and treatment with alcohols leads to the successive substitution of cyano-groups by alkoxy-groups and the formation of the corresponding cyanurates[236,238]. Reduction with alkali metals or irradiation of a mixture of compound (CXXXI) and hexamethylmelamine results in a stable blue radical-ion[239,240].

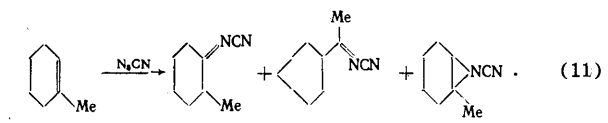
The synthesis of 3,6-dicyano-1,2,4,5-tetrazine (CXXXII) was achieved in 1961[241] via the reaction



(CXXXII)]

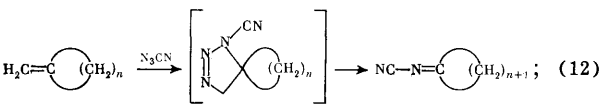
Compound (CXXXII) was obtained in an amount of 0.15 g and a yield of 12–18%; being extremely unstable, it decomposed fully after several days even in an atmosphere of argon and in the absence of moisture[241]. The latest studies are limited to a description of the mass-spectrum[242] and the calculation of the molecular orbitals of the radical-anion (CXXXII)[243].

VIII. PERNITRILES WITH A NITROGEN–CARBON SKELETON



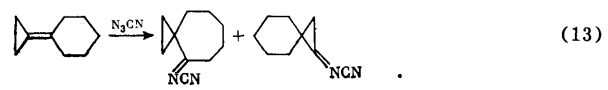
The simplest pernitrile of this series—tricyanamide—has not so far been synthesised. The attempt to obtain it from silver dicyanamide and chlorocyanogen was unsuccessful[244], while reports of the synthesis of this compound by the pyrolysis of mercury thiocyanate[245] and mercury dicyanamide[246] are apparently erroneous.

One of the most thoroughly investigated "azapernitriles", namely, cyanogen azide, is a colourless oily liquid which detonates on mechanical, electrical, and thermal shock and can be obtained in virtually quantitative yield when sodium azide is treated with chlorocyanogen in an anhydrous medium[247]. When cyanogen azide, obtained by the analogous reaction with bromocyanogen in an aqueous medium, is acted upon by the azide ion, the anion of 5-azidotetrazole (CXXXIII) is formed and reacts in its turn with bromocyanogen to form the *gem*-diazide (CXXXIV)—the product of the rearrangement of an unstable cyanazidotetrazole. Treatment of cyanogen azide with aqueous alkali at room temperature can also lead to the formation of the salt (CXXXIII). Hydrogen sulphide readily reduces cyanogen azide to cyanamide[247]:



(CXXXIII) (CXXXIV)

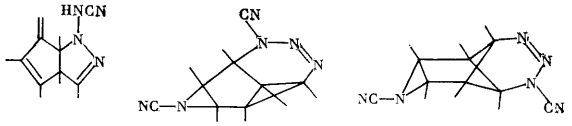
Below 60 °C, cyanogen azide reacts as a powerful electrophilic azide, adding to olefins with formation of unstable triazolines, which decompose to alkylidenecyanamides and (or) *N*-cyanoaziridines, whose proportions can be varied within wide limits depending on the type of olefin and the solvent employed[248]:



(11)

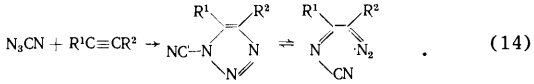
Cycloalkenes can also undergo ring contraction[248,249] [for example, via reaction (11)]; on the other hand, the reactions of methylenecycloalkanes are accompanied as a rule by ring expansion[243] [reaction (12)]. Alkylidenecycloalkanes give rise to a mixture of isomers [for example, via reaction (13)]:

(12)



(13)

We may note that the attempt to catalyse these reactions by the introduction of silver ions did not lead to an increase of the rate of reaction, but altered (in many cases considerably) the proportions of the isomers formed[249]. Alkylidenecyanamides hydrolyse extremely readily to the corresponding ketones, which makes these reactions the basis of a valuable synthetic method.



The time and temperature variation of the reaction of cyanogen azide with hexamethylbicyclo[2,2,0]hexadiene is of interest; the reaction gives rise to adduct (CXXXV) after 10 h at 20 °C, to compound (CXXXVI) at 0 °C over the same

period, and to compound (CXXXVII) at 0 °C after 20 min[250]:

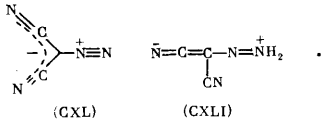
(CXXXV) (CXXXVI) (CXXXVII)

The reaction of cyanogen azide with acetylenes leads to the formation of an equilibrium mixture of triazoles and diazoamines via the reaction[251]

(14)

The photolysis and thermolysis of cyanogen azide above 50 °C[248,252,253] give rise to cyanonitrene, which is a convenient intermediate in processes involving the modification of polymers[254] and in the synthesis of aziridines, alkylidenecyanamides, and azepines from olefins and aliphatic and aromatic hydrocarbons respectively[248,255].

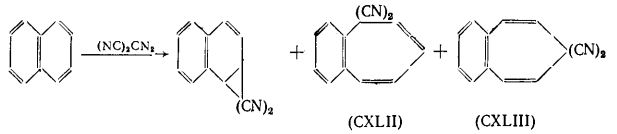
Cyanogen azide reacts with tertiary phosphines to form *N*-cyanophosphinimides which are effective repellents, insecticides and hematocides[256]. The reactions with aromatic arsines and phosphites proceeds similarly[257,258]. The method for the synthesis of *N*-alkoxyalkylcyanamides is based on the reaction of cyanogen azide with ethers and polyethers[259].



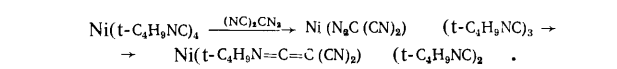
The molecular[260] and electronic[261,262] structures, ionisation potentials[263], and microwave[264,265], infrared[266,267], and Raman[267] spectra of cyanogen azide have also been calculated and investigated.

The pyrolysis of cyanogen azide in the gas phase at 200 °C leads to the formation (apparently as a result of the reaction of cyanonitrene with the unreacted cyanogen azide) of azodinitrile NC–N=N–CN[268]—a red-orange volatile explosive compound, which was subsequently synthesised from hydrazine and chlorocyanogen in the presence of sodium azide[269]. The study of the infrared and Raman spectra of this compound showed that it exists exclusively in the *trans*-form (it has been shown by calculation to be more stable than the *cis*-form by 20 kcal mol^{-1}[270–272]). Azodinitrile is a powerful dienophile, which reacts instantaneously (even at room temperature) with cyclopentadiene, 2,3-dimethylbutadiene, and even (albeit slowly) anthracene[268].

Dicyanodiazomethane (CXXXVIII) was first synthesised from dibromomalononitrile via the hydrazone (CXXXIX)[73]:



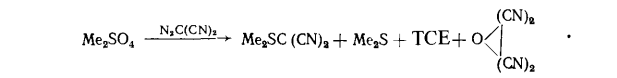
Here one should note the unusual stability of the hydrazone (CXXXIX). The high dipole moments of compounds (CXXXVIII) and (CXXXIX) (5.82 and 3.8 D respectively) together with NMR and ultraviolet spectroscopic data confirmed the contribution of the betaine structures (CXL) and (CXLI).



(CXL) (CXLI)

In contrast to other diazo-compounds, dicyanodiazomethane oxidises primary and secondary amines even at 20 °C, being itself reduced to the hydrazone (CXXXIX). While it is resistant to the action of even 2 *N* sulphuric acid, it readily reacts with nucleophiles such as triphenylphosphine and Grignard reagents[2]. The thermolysis and photolysis[2] of compound (CXXXVIII) yield dicyanocarbene, which makes it possible, for example, to obtain cyclopropanes by reaction with olefins[274] and norcaradiene derivatives from benzene and xylene[275]. However, it is of interest that the thermolysis of dicyanodiazomethane in naphthalene yields in addition products (CXLII) and (CXLIII)[275]:

(CXLII) (CXLIII)



The reaction of compound (CXXXVIII) with isonitrile complexes proceeds via a substitution stage and leads to the formation of keten imines[276]:

A method for the synthesis of sulphonium and ammonium dicyanomethylides is based on the interaction of compound (CXXXVIII) with sulphides and amines[277,278]:

The reaction of compound (CXXXVIII) with dimethyl sulphoxide proceeds via the mechanism[277]

The infrared spectra of compound (CXXXVIII) and of the free radical $C(CN)_2$ have also been studied[279].

Treatment of TCE with sodium hydride in acetonitrile yields the hexacyanobutenediide anion (CVII), which cyclises in aqueous solutions to the aminotetracyanocyclopentadienide anion via 1-amino-2,3,4,5,5-pentacyanocyclopentadiene. The diazotisation of the cyclopentadienide anion yields diazotetracyanocyclopentadiene[280]—the initial compound for the synthesis of various salts of substituted tetracyanocyclopentadienes which are used as propellants, weed killers and pesticides, sensitisers and, dyes[281]—in particular the salts of pentacyanocyclopentadiene and cyanodiazotetracyanocyclopentadiene as well as the salts of azobis(tetracyanocyclopentadiene), which are used in the syntheses of organic conductors[282].

---o0o---

Thus analysis of the literature data shows that the chemistry of polycyano-compounds has been the subject of increasing attention by investigators for more than half a century and that approximately four-fifths of the total number of publications dealing with these compounds have appeared in the last fifteen years.

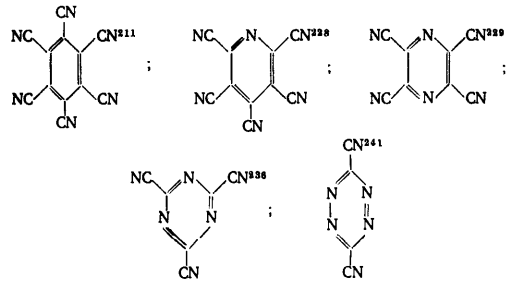
The range of reactions in which pernitriles can be involved is extremely wide. They can be reduced and oxidised, can undergo various kinds of fragmentation, are capable of undergoing reactions involving addition to double bonds (when these are present) and to cyano-groups, which can participate in their turn in substitution reactions. The majority of pernitriles are extremely sensitive to nucleophilic attack and readily give rise to radical-anions.

The stability of these compounds varies within very wide limits, ranging from that of tetracyanoethylene, which can be isolated from solution in fuming nitric acid, to compounds of the type of cyanogen azide or azodinitrile, which decompose explosively. The reactions of pernitriles proceed in most cases at room temperature, but the identification of certain products of these reactions is sometimes extremely difficult because of their instability or their tendency to polymerise.

Thus not a single instance of the identification of dicyanogen, formed in reactions of polynitriles, has been described hitherto and the products of the reactions of percyano-anions are frequently unidentified coloured amorphous substances which probably have a polymeric structure.

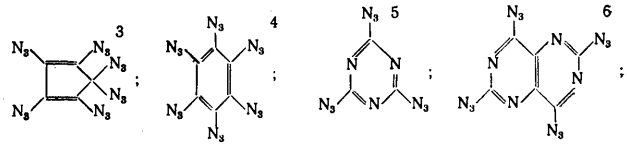
There is no doubt that further development of the chemistry of pernitriles may prove to be extremely fruitful for the synthesis of compounds with valuable properties (for example, organic conductors, ingredients of fuel mixtures, thermostable polymers, etc.), and for the development of new synthetic methods and methods for the investigation of problems in theoretical and physical organic chemistry.

IX. APPENDIX



1. NITROGEN–CARBON COMPOUNDS§

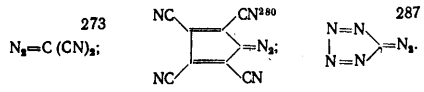
I. Pernitriles:



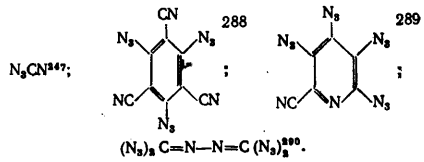
$(CN)_2^{263}$; $C(CN)_4^{14}$; $C_2(CN)_6^{28}$; $(NC)_2C{=}C(CN)_2^{264}$;

$(NC)_2C{=}C(CN){-}C(CN){=}C(CN)_2^{265}$;

$NCC{\equiv}CCN^{266}$; $NCC{\equiv}C{-}C{\equiv}CCN^{265}$; $NCN{=}C{=}NCN^{266}$; $NCN{=}NCN^{268}$;

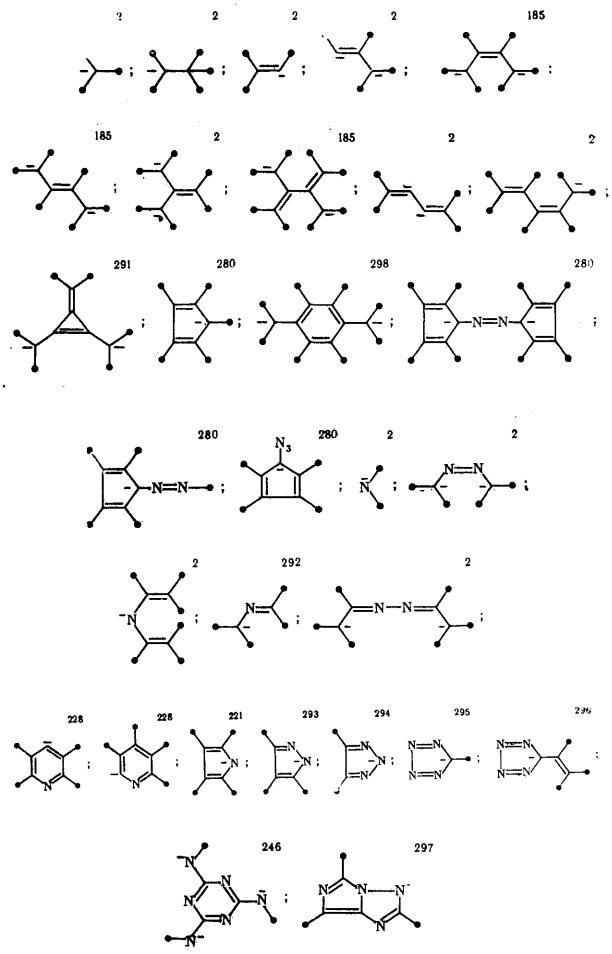


II. Perazides:



$(N_3)_2C{=}N{-}N{=}C(N_3)_2^7$.

III. Diazo-Compounds



IV. Mixed Nitrogen–Carbon Compounds:

$(N_3)_2C{=}N{-}N{=}C(N_3)_2^{290}$.

§ The literature references are to publications in which the synthesis was described for the first time.

2. NITROGEN–CARBON PERCYANO-ANIONS¶

¶ The symbol ⇀ always designates the $-C{\equiv}N$ group.

Organometallic Derivatives of Diazoalkanes

O.A.Kruglaya and N.S.Vyazankin

The methods of synthesis and properties of organometallic derivatives of diazo-compounds are examined, attention being concentrated on the influence of the metal or the organometallic fragment on the structure and reactivity of the diazo-compounds. Studies on the use of metal-containing diazoalkanes as precursors of carbynes and α-metallated carbenes as well as studies on the reactivity of the latter are discussed.
The bibliography includes 165 references.

I. INTRODUCTION

Two types of organometallic derivatives of diazoalkanes are known. The first includes only two compounds: 1-diazo-3-triethylsilyl-2-propanone and ferrocenyl(phenyl)diazomethane[1,2]; in these compounds the metal atom and the diazo-group are separated by hydrocarbon fragments. The second type includes α-metallated diazoalkanes in which one of the carbon atoms is linked both to the diazo-group and to the metal atom. The chemistry of these compounds is developing vigorously, because, apart from their continuously expanding applications in organometallic synthesis, they are a potential source of carbynes—unstable derivatives of univalent carbon. Furthermore, they are used extensively as precursors of α-metallated carbenes—short-lived species with a high and unusual reactivity. For example, singlet α-silylcarbenes frequently isomerise to sila-alkanes $R_2Si{=}CR'_2$—unstable intermediates with a $(p{-}p)\pi$ bond between the carbon and silicon atoms.

The considerable advances in the studies on the structure and reactivity of carbynes, α-metallated carbenes, and sila-alkanes are closely related to the progress in the chemistry of organometallic derivatives of diazo-compounds. The most complete compilation of data on the chemistry of α-metallated diazoalkanes (up to 1969) is given in Lappert and Poland's review[3]. Latest advances in the chemistry of organophosphorus diazo-compounds are discussed in other reviews[4,5].

II. METHODS OF SYNTHESIS

1. Metallation of Aliphatic Diazo-Compounds

In consequence of the enhanced CH acidity of diazoalkanes of the type $HC(N_2)R$, the latter are readily metallated by methyl-, n-butyl-, and phenyl-lithium. Diazomethyl-lithium[6-9], which is involved in a tautomeric equilibrium with lithium isocyanamide[10,11], trimethylsilyldiazomethyl-lithium[12-15], ethyl lithiodiazoacetate[16-20], and dialkyl lithiodiazomethylphosphonates[15] have been obtained in this way:

$$R'Li + HC(N_2)R \rightarrow LiC(N_2)R + R'H \quad ;$$
$$R{=}H,\ Me_3Si,\ COOEt,\ (MeO)_2P(O){-},\ \text{or}\ (EtO)_2P(O){-}$$

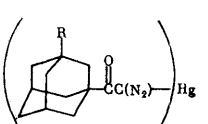
The metallation of diazoacetic ester requires low temperatures (between −110° and −65°C), while Me_3SiCHN_2 is smoothly metallated at 0 °C. The reaction of methyl-lithium with diazoethane in ether at 20 °C leads to a complex mixture of products[21]. Lithium diisopropylamide smoothly metallates α-diazoketones[17]. The reaction of the latter with butyl-lithium is complex:

$$\text{iso-Pr}_2NLi + HC(N_2)COR \xrightarrow[-70^\circ]{THF} LiC(N_2)COR \quad .$$

$Me_3SiC(N_2)K$ and $(EtO)_2P(O)C(N_2)K$ have been obtained by treating diazoalkanes with potassium t-butoxide[15].

Silver oxide metallates diazoacetic ester[22-24], diazoketones, and phosphorus-containing diazoalkanes[25,26], but the yield of silver derivatives depends greatly on the quality of the oxide[17]:

$$Ag_2O + 2HC(N_2)R \rightarrow H_2O + 2AgC(N_2)R \quad .$$



The reaction of silver acetylacetonate with dimethyl diazomethylphosphonate leads to a quantitative yield of $AgC(N_2)P(O)(OMe)_2$.[27] Treatment of silver acetate with an excess of CH_2N_2 in ether in the presence of pyridine at −5 °C yielded the complex $Ag_2CN_2.C_6H_5N$. When the complex is kept in vacuo at 25 °C, Ag_2CN_2, an explosive light-sensitive compound, is formed[28].

Diazoacetic ester is metallated at −70 °C by alkylmagnesium halides and dialkylmagnesium compounds[17], while at 0 °C Grignard reagents attack the diazo-group[29,30].

Yellow mercury(II) oxide reacts under mild conditions with the nitrile and esters of diazoacetic acid, diazoketones, and ethyl diazomethylphosphonate[25,31-37]:

$$HgO + 2HC(N_2)R \rightarrow H_2O + Hg[C(N_2)R]_2$$

Mercury derivatives of adamantoyldiazomethane (I) were obtained recently by this procedure[38]:

(I)

R = H, Cl, or Br .

Mercuration of dimethyl diazomethylphosphonate by mercury acetylacetonate leads to $Hg[C(N_2)P(O)(OMe)_2]_2$ in 80% yield[27].

Asymmetric alkyl- and aryl-mercuridiazoalkanes have been obtained by the reaction of diazo-compounds with arylmercury hydroxides[39], arylmercury silylamides[40], and organomercury

ethoxides[39]. The last compounds were synthesised *in situ* by treating RHgCl with alcoholic potassium ethoxide:

$$PhHgOH + HC(N_2)COMe \xrightarrow{-H_2O} PhHgC(N_2)COMe$$

$$RHgN(SiMe_3)_2 + HC(N_2)COOEt \rightarrow RHgC(N_2)COOEt + (Me_3Si)_2NH$$

$$RHgCl + EtOK \xrightarrow{+EtOH} RHgOEt \xrightarrow[-EtOH]{+HC(N_2)R'} RHgC(N_2)R' \quad ;$$

R = Me, t-Bu, $PhCH_2$, or Ph; R′ = CN, Me, Ph, COMe, COOMe, or COOEt.

We may note that the reactions of diazomethane with $RHgN(SiMe_3)_2$ and RHgOEt lead to crystalline readily detonated disubstituted derivatives of diazomethane regardless of the reactant ratio[39,40], for example:

$$2\,RHgN(SiMe_3)_2 + CH_2N_2 \rightarrow (RHg)_2CN_2 + 2(Me_3Si)_2NH \quad .$$

When bis[bis(trimethylsilyl)amide]mercury or mercury acetate is treated with diazomethane[40,41] in ether, the highly explosive polymeric diazomethylenemercury $(HgCN_2)_n$ is formed. According to Wright et al.[41], the latter reaction also leads to bis(diazomethyl)mercury $Hg(CHN_2)_2$, but attempts to repeat the synthesis of this diazomethane derivative were unsuccessful[33,40]. Polymeric diazomethylenezinc and diazomethylenecadmium have been obtained similarly[40]:

$$M[N(SiMe_3)_2]_2 + CH_2N_2 \rightarrow (MCN_2)_n + 2(Me_3Si)_2NH \quad ;$$

M = Hg, Zn, or Cd.

The above method of synthesis is fairly universal. Thus the interaction of diazomethane with organometallic compounds containing metal–nitrogen bonds leads to diazomethane derivatives of the type $(Me_nM)_2CN_2$, where M = germanium, arsenic, and their analogues, as well as thallium[6,40,42–45], for example:

$$(Me_2TlNMe_2)_2 + CH_2N_2 \rightarrow (Me_2Tl)_2CN_2 + 2Me_2NH \quad ;$$

$$2Me_2BiN(Me)SiMe_3 + CH_2N_2 \rightarrow (Me_2Bi)_2CN_2 + 2Me_3Si(Me)NH \quad .$$

Monometallated diazomethane derivatives Me_3GeCHN_2 and Me_2AsCHN_2 have been obtained in the same way but at controlled temperatures, using Me_3SnCl as the complex-forming agent and in the prsence of a large excess of diazomethane[44,46], for example:

$$Me_3GeNMe_2 + CH_2N_2 + Me_3SnCl \xrightarrow[-80°]{Et_2O} Me_3GeCHN_2 + Me_3SnCl \cdot Me_2NH \quad .$$

Diazo-compounds with two different organometallic fragments have been obtained analogously[47]:

$$R_nM{-}NR_2' + Me_2AsCHN_2 \rightarrow \begin{matrix} Me_2As \\ \diagdown \\ R_nM \end{matrix}\!\!>CN_2 + R_2'NH \quad ;$$

$R_nM = Me_3Si$, Me_3Ge, Me_3Sn, Me_3Pb, Me_2Sb, or Me_2Bi;

$$Hg[N(SiMe_3)_2]_2 + 2Me_2AsCHN_2 \rightarrow Hg[C(N_2)AsMe_2]_2 + 2(Me_3Si)_2NH \quad .$$

A large series of α-metallated diazocarbonyl compounds, derivatives of zinc-subgroup elements[40,48], germanium[40,45,49–53], and arsenic[43,54], have been obtained by treating compounds having metal–nitrogen bonds with α-diazoketones and diazoacetate esters, for example[50]:

$$R_{4-n}Sn(NR_2')_n + n\,HC(N_2)COOEt \rightarrow R_{4-n}Sn[C(N_2)COOEt]_n + n\,R_2'NH \quad ;$$

R = Me, Et, t-Bu, or Ph; R′ = Me or Et; n = 1, 2.

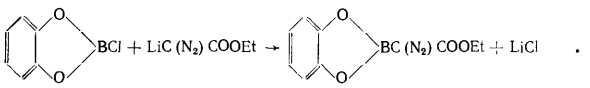
Methyl diazoacetate is readily metallated by trialkylmethoxystannanes[52], but this reaction requires more severe conditions than the previous ones (≥100 °C):

$$R_3SnOMe + HC(N_2)COOMe \rightarrow \underset{(85\%)}{R_3SnC(N_2)COOMe} + MeOH \quad ;$$

R = Et or n-Bu.

Bromotrimethylsilane silylates diazoacetate esters in the presence of amines[52], while chlorotrimethylsilane does not enter into similar reactions[6]:

$$Me_3SiBr + HC(N_2)COOR + Et_3N \xrightarrow[C_6H_6]{80°} Me_3SiC(N_2)COOR + Et_3N \cdot HBr \quad ;$$



R = Me or Et.

2. Synthesis from α-Metallated Diazoalkanes

Ethoxycarbonyldiazomethyl-lithium reacts under mild conditions (below −50 °C) with halogenotrimethylsilanes, halogenotrimethylplumbanes, and chlorotributylstannane[16,17,49]:

$$R_3MCl + LiC(N_2)COOEt \xrightarrow{THF} R_3MC(N_2)COOEt + LiCl \quad .$$

A boron-containing diazoacetic ester has been obtained analogously[17]:

The interaction of trimethylsilyldiazomethyl-lithium $Me_3SiC(Li)N_2$ with Me_3SiCl in a pentane–hexane mixture at temperatures between −90° and −100 °C leads to bis(trimethylsilyl)diazomethane[14]. The reactions of diazomethyllithium with Ph_3GeCl, Me_3SnCl, and Ph_3SnBr also lead to dimetallated derivatives of diazomethane $(R_3N)_2CN_2$ (M = Ge or Sn).[6] It has been suggested[6] that the R_3MCHN_2 formed initially is metallated by a second mole of diazomethyl-lithium, this being followed by the reaction of $R_3MC(Li)N_2$ with the initial organogermanium or organotin halide. The attempts to obtain diazomethyl derivatives of zinc and cadmium by treating $ZnCl_2$ or $CdCl_2$ with diazomethyl-lithium were unsuccessful[33].

α-Mercurated diazoalkanes have been used widely for the synthesis of metal-containing diazo-compounds. Thus lithium-,[16,55] silicon-,[56–59] germanium-[49] and tin-containing[49,58] derivatives of diazoacetic ester have been obtained by transmetallation:

$$Hg[C(N_2)COOEt]_2 + 2RLi \xrightarrow[-70°]{THF} R_2Hg + 2LiC(N_2)COOEt$$

R = n-Bu, Ph, EtS, t-BuS.

$$Hg[C(N_2)COOEt]_2 + (R_3M)_2S \rightarrow HgS + 2R_3MC(N_2)COOEt \quad ;$$

$R_3M = Me_3Si$, Me_3Sn, or Ph_3Sn.

$$Hg[C(N_2)COOEt]_2 + 2R_3SiI \rightarrow HgI_2 + 2R_3SiC(N_2)COOEt \quad .$$

However the method of synthesis of $LiC(N_2)COOEt$ examined in the previous section is preferable.

A general method of the synthesis of α-metallated diazocarbonyl compounds which are derivatives of Group IVB elements is based on radical exchange reactions between bis(triethylsilyl)mercury or its analogues and mercurated diazocarbonyl compounds. In this case the exchange reactions are accompanied by demercuration[60–63]:

$$(R_3M)_2Hg + Hg[C(N_2)C(O)R']_2 \rightarrow 2R_3M{-}Hg{-}C(N_2)C(O)R' \rightarrow$$

$$\rightarrow 2Hg + 2R_3MC(N_2)C(O)R' \quad ;$$

$R_3M = Et_3Si$, $MePh_2Si$, Et_3Ge, or $(Me_3CCH_2)_3Sn$; R′ = Me, Et, OMe, OEt, or Ph.

The esters of stannylated diazoacetic acids react exothermically with trialkylhalogenosilanes, forming the corresponding silyl derivatives (yields 75–90%):[52]

$$R_3SnC(N_2)COOMe + R_3'SiBr \rightarrow R_3'SiC(N_2)COOMe + R_3SnBr \quad ;$$

R = Et or n-Bu; R′ = Me or Et.

3. Other Methods of Synthesis

Trimethylsilyldiazomethane can be obtained by treating with alkali *N*-(trimethylsilylmethyl)-*N*-nitrosourea[64,65,66] (a procedure analogous to the synthesis of diazomethane[67]) and

methyl[68] or ethyl[65] *N*-(trimethylsilylmethyl)-*N*-nitrosocarbamates and also by the decomposition of *N*-(trimethylsilylmethyl)-*N*-nitrosoacetamide with β-phenylethylamine[13,55]:

$$Me_3SiCH_2N(NO)CONH_2 \xrightarrow{20\%\ KOH} Me_3SiCHN_2\ (53—70\%)\ ;$$

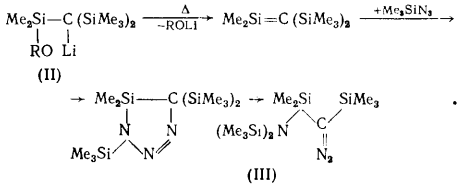
$$Me_3SiCH_2N(NO)COOR \xrightarrow[Et_2O,\ 20^\circ]{NaOH} Me_3SiCHN_2\ (\sim 25\%)\ ;$$

$$Me_3SiCH_2N(NO)COMe \xrightarrow{PhCH_2CH_2NH_2} Me_3SiCHN_2\ .$$

Like the usual diazoalkanes[69], their α-silylated analogues have been obtained by oxidising hydrazones by metal oxides[57,70] and by treating *N*-tosylhydrazines with alkali[71]:

$$Ph_3SiCOPh + N_2H_4 \rightarrow Ph_3SiC(Ph)=NNH_2 \xrightarrow[or\ HgO]{MnO_2} Ph_3SiC(N_2)Ph\ ;$$

$$Ph_3SiCOR + TsNHNH_2 \rightarrow Ph_3SiC(R)=NNHTs \xrightarrow[or\ MeONa]{n\text{-}BuLi} Ph_3SiC(N_2)R\ ;$$

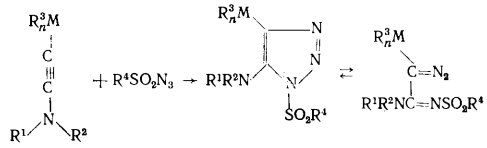


R=Me, Et, Ph, 4-FC_6H_4, 4-ClC_6H_4, 4-BrC_6H_4, or $PhCH_2$.

Phenyl(triphenylgermyl)diazomethane, phenyl(trimethylsilyl)-diazomethane[71], and phenyl(trimethylsilyl)diazomethane labelled with ^{13}C at the diazo carbon atom have also been obtained using tosylhydrazine[72-74].

γ-Triethylsilylacetyldiazomethane has been synthesised by treating triethylsilylacetyl chloride with diazomethane[1]:

$$Et_3SiCH_2COCl + CH_2N_2 \xrightarrow[-5—0^\circ]{Et_2O} Et_3SiCH_2\overset{\overset{O}{\|}}{C}CHN_2\ .$$



According to the data of Wiberg and coworkers[75], the thermolysis of compound (II) involves the intermediate formation of 1,1-dimethyl-2,2-bis(trimethylsilyl)-1-silaethylene. Its reaction with trimethylsilyl azide leads to a silicon-containing diazomethane (III) in a yield up to 50%:

(II) (III)

The second product of this unusual reaction is bis(trimethylsilyl)diazomethane.

It has been shown[76-78] that the reaction of sulphonyl azides with organometallic ynamines proceeds regiospecifically and leads to 5-amino-1,2,3-triazoles, which, depending on the nature of the substituents R^1, R^2, R^3, R^4, either wholly isomerise to α-metallated diazoacetamidines or are involved in a tautomeric equilibrium with the latter:

R^1, R^2, R^4 = alkyl, or aryl; $R^3_nM = R^1_2As$, R^1_2Sb, $Ph_2P(O)$—, $Ph_2P(S)$—, R^1_3Si, R^1_3Ge, or R^1_3Sn.

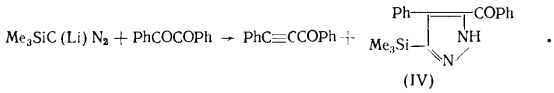
III. REACTIONS WITHOUT THE EVOLUTION OF NITROGEN

1. Reactions not Involving the Diazo-Group

Trimethylsilyldiazomethyl-lithium reacts with D_2O, forming Me_3SiCDN_2, which is of preparative interest[12]. Reactions with ketones in a mixture of tetrahydrofuran (THF) and pentane at −100 °C lead to 1-diazo-1-(trimethylsilyl)-2-alkanols—a new type of organosilicon bifunctional compound[13]:

$$Me_3SiC(Li)N_2 + RCOR' \xrightarrow[-100^\circ]{hydrolysis} Me_3SiC(N_2)C(OH)RR' \quad (65—85\%)\ ;$$

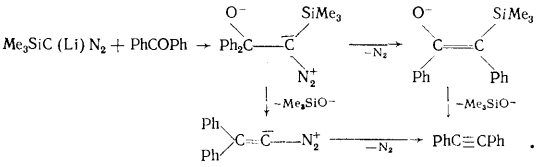
R=H, Me; R'=Me, Ph; or R, R'=$(CH_2)_5$.



Benzophenone, whose reaction with $Me_3SiC(Li)N_2$ leads to diphenylacetylene (yield up to 85%), is an exception[15,79].

The reactions of the lithio-derivative of diethyl diazomethylphosphonate with diaryl ketones and with 2-benzoylthiophen and 3-benzoylpyridine proceed analogously:

$$(EtO)_2P(O)C(Li)N_2 + 4\text{-}RC_6H_4COPh \xrightarrow[-78\rightarrow 20^\circ]{THF} \xrightarrow{H_2O} 4\text{-}RC_6H_4C{\equiv}CPh \quad (66—94\%)\ ;$$



R=H, Cl, or MeO .

One of the products of the reaction of trimethylsilyldiazomethyl-lithium with benzil is pyrazole (IV)†:

(IV)

It has been suggested[15] that in these reactions the nucleophilic addition of the anion [for example, $Me_3SiC(N_2)^-$] to the carbonyl group is accompanied by the Wolff rearrangement, which involves the evolution of nitrogen and the elimination of the Me_3SiO^- anion (the sequence of these stages has not been elucidated):

A series of diazo-esters have been obtained in reactions of ethoxycarbonyldiazomethyl-lithium with alkyl halides, benzoyl chloride, benzaldehyde, and certain ketenes in THF at −50 °C or lower temperatures[16-18], for example:

$$LiC(N_2)COOEt + PhCOCl \rightarrow LiCl + PhCOC(N_2)COOEt\ ;$$

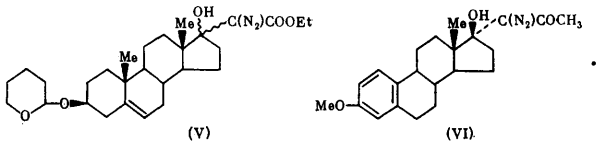
$$LiC(N_2)COOEt + RCOR' \rightarrow RR'C(OH)C(N_2)COOEt\ .$$

The yield of diazoesters $RR'C(OH)C(N_2)COOEt$ can be significantly increased when the reaction is carried out without the isolation of $LiC(N_2)COOEt$, by adding n-butyl-lithium to an equimolar mixture of diazoacetic ester and the carbonyl compound[17,19,20]:

$$HC(N_2)COOEt + RCOR' \xrightarrow[-60^\circ]{+BuLi} RR'C(OH)C(N_2)COOEt\ ;$$

R=H or Me, R'=Me or Ph; R, R'=$(CH_2)_4$, $(CH_2)_5$ or $(CH_2)_6$.

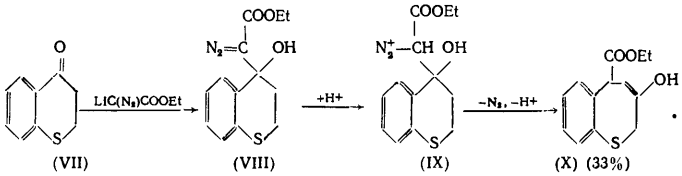
An analogous procedure has been proposed for the synthesis of β-hydroxy-α-diazoketones (yields up to 95%). In this case the lithio-derivative of the diazoketone is formed *in situ* on treatment with lithium diisopropylamide:



$$HC(N_2)\overset{\overset{O}{\|}}{C}R + R^1COR^2 \xrightarrow[-70^\circ]{iso\text{-}Pr_2NLi} R^1R^2C(OH)C(N_2)\overset{\overset{O}{\|}}{C}R$$

R=Me, Ph, 4-$MeOC_6H_4$, or t-Bu; R^1 = H or Me; R^2=Me, Ph, or PhCH=CH.

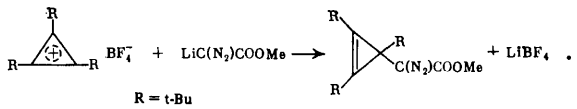
The diazoester (V) has been obtained in this way[17], i.e. by



† The structure of a silylated enol was erroneously attributed to this product in a preliminary communication[79].

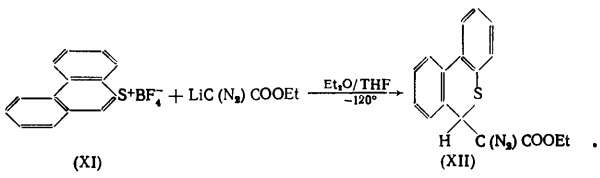
treating a mixture of 3β-(tetrahydro-2-pyranyloxy)-5(6)-androsten-17-one and diazoacetic ester with n-butyl-lithium, while treatment of a mixture of 3-methoxy-1,3,5,(10)-oestratrien-17-one and diazoacetone with lithium diisopropylamide leads to the diazoketones (VI):

(V) (VI)



It has been shown recently[19] that the nucleophilic addition to $LiC(N_2)COOEt$ to the carbonyl group of 4-thiochromanone (VII) leads to the diazoester (VIII). Its treatment with a methanol solution of HCl generates the diazonium ion (IX)#, which then eliminates a nitrogen molecule and a proton, being converted into ethyl 2,3-dihydro-4-hydroxy-1-benzothiepin-5-carboxylate (X):

(VII) (VIII) (IX) (X) (33%)



The ester of 1,3-dihydro-4-hydroxy-2-benzothiepine-5-carboxylic acid was synthesised similarly[19].

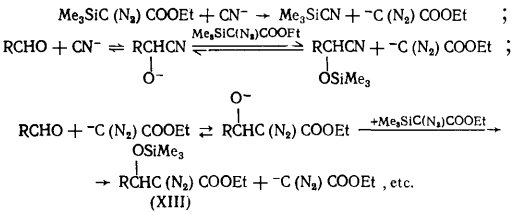
It is known[17] that the reactions of $LiC(N_2)COOEt$ with alkyl halides give low yields of compounds of the type $RC(N_2)COOEt$. On the other hand, tri-t-butylcylcopropenylium tetrafluoroborate reacts smoothly with methoxycarbonyldiazomethyllithium[81]:

R = t-Bu

A new synthesis of dienzo[*b*,*d*]thiepin[82,83], involving the reaction of dibenzothiopyrylium tetrafluoroborate (XI) with $LiC(N_2)COOEt$, has been described[82,83]; the diazo-compound (XII) is formed in 32% yield:

(XI) (XII)

The silver derivatives of diazoacetic ester[22,24], diazoketones[22], and diphenyl(diazomethyl)phosphorane[4] are readily alkylated by alkyl halides:



$$AgC(N_2)COOEt + BrCN \xrightarrow{Et_2O} BrC(N_2)COOEt + AgCN \quad .$$

The reactions of iodine or bromocyanogen with $AgC(N_2).COOEt$ and $AgC(N_2)P(O)(OMe)_2$ also do not involve the diazo-group[5,22], for example:

$$AgC(N_2)COR + R'X \rightarrow AgX + R'C(N_2)COR \quad .$$

Diazoesters of the $XC(N_2)COOEt$ (X = Cl, Br, or I) series have been obtained in addition by treating mercuribisdiazoacetic ester with thionyl chloride, bromine, or iodine[23,84]. However, the treatment of mercuribis(adamantoyldiazomethane) with a solution of ICl in chloroform (at ~10 °C) yielded adamantyl chlorodi-iodomethyl ketone as a result of the substitution of the diazo-group and the mercury atom by halogen atoms[85]. The reaction of $Hg[C(N_2)COOEt]_2$ with bromotriphenylmethane leads to the ethyl ester of 2-diazo-3,3,3-triphenylpropionic acid[22].

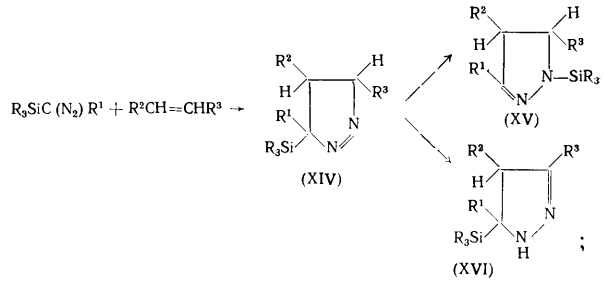
It has been shown recently[86] that ethyl α-(trimethylsilyl)-diazoacetate reacts exothermically with aliphatic and aromatic aldehydes, forming adducts (XIII) in nearly quantitative yields. The reaction is catalysed by the complex KCN.18-crown-6- and includes initiation and catalytic stages:

When trimethylsilyldiazoacetic acid ester interacts with ethyl chlorocarbonate at 100 °C, the Si–C bond is cleaved selectively[52]:

$$Me_3SiC(N_2)COOEt + ClCOOEt \rightarrow Me_3SiCl + N_2C(COOEt)_2 \quad .$$

The reaction of stannylated diazoketones with methanol results in the selective heterolysis of the Sn–C bond[52]:

$$Bu_3SnC(N_2)COR + MeOH \rightarrow Bu_3SnOMe + HC(N_2)COR \quad ;$$



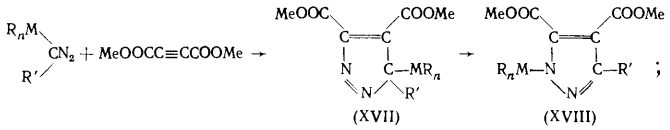
R = Me or Ph.

2. 1,3-Dipolar Cycloaddition Reactions

The formation of five-membered heterocycles in reactions with dipolarophiles is characteristic of the usual diazoalkanes[87,88] as well as their α-metallated analogues. In particular the cycloaddition of α-silyldiazoalkanes to diethyl fumarate, acrylonitrile, methyl acrylate, and analogous compounds with activated C=C bonds has been most thoroughly investigated[59,64,65,89–92]. It has been shown by ^1H NMR [89,92] that the primary products are 3-organosilyl-Δ^1-pyrazolines (XIV). The majority of Δ^1-pyrazolines are known to isomerise readily to Δ^2-pyrazolines[87,88,93]. The isomerisation of the heterocycles (XIV) leads to compounds (XV) as a result of the 1,3-migration of the R_3Si group or to their analogues (XVI) if the process is accompanied by the 1,3-transfer of a hydrogen atom. A rearrangement of the first type is characteristic of the diazoalkanes $R_3SiC(N_2)R^1$ with R^1 = Ph or COOEt, while that of the second type is characteristic of the

For details of the methods for the generation and reactions of aliphatic diazonium ions, see Kirmse's review[80].

diazoalkanes with $R^1 = H$ or Me:[65,89,92]

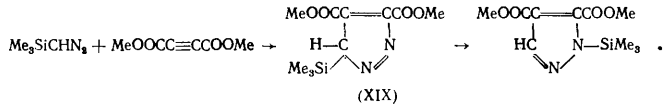


R = Me or Ph; R^1=Ph, COOEt, Me, or H;
R^2 = H or COOEt; R^3=CN, COMe, COOMe, or COOEt.

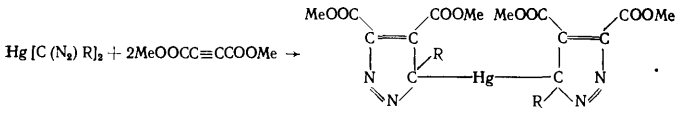
It has been shown for diethyl fumarate[92] that the relative rates of cycloaddition of diazoalkanes decrease in the sequence

$$\underset{1}{Me_3SiC(N_2)Me} > \underset{2\cdot10^{-2}}{Me_3SiC(N_2)Ph} > \underset{25\cdot10^{-4}}{Ph_3SiC(N_2)Me} > \underset{\sim2.5\cdot10^{-6}}{Ph_3SiC(N_2)Ph} > \underset{\sim2.5\cdot10^{-7}}{Me_3SiC(N_2)COOEt}.$$

The authors[92] believe that the rates of these reactions are determined by the degree of $(p \rightarrow d)_\pi$ interaction of the silicon and diazo-carbon atoms in the compound $R_3SiC(N_2)R^1$ (which was confirmed by CNDO/2 calculations) and also by the resonance-stabilising properties of R^1 and the steric conditions in the transition state of the cycloaddition reaction[92]. The rate of the isomerisation (XIV) → (XV) increases with enhancement of the electron-accepting properties of R^1: COOEt > Ph ≫ Me. The 1,3-migration of the hydrogen atom in the process (XIV) → (XVI) is accelerated under the influence of electron-accepting groups R^3 and in addition is catalysed by traces of water and amines[89,92].

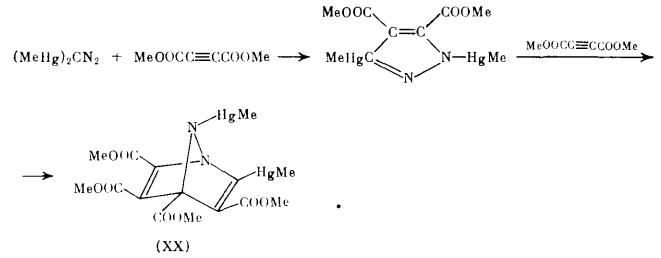


The reactions of ethyl triethylplumbyldiazoacetate with acrylonitrile, dimethyl maleate, tetracyanoethylene, and related compounds are analogous to those discussed above[94]. It has been shown[94,95] that the reactions of metallated diazoalkanes $R_nMC(N_2)R'$ with dimethyl acetylenedicarboxylate lead to isopyrazoles (XVIII) with 1,3-migration of the R_nM fragment:



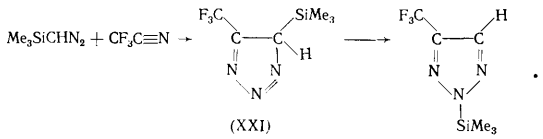
R_nM=Me_3Sn, Me_3Pb, Me_2Sb, Me_2Bi, MeHg.

HgC(N2)COOEt, or HgC (N2) COMe; R′=R_nM, COOEt, COMe, or COPh.



Me_2AsCHN_2, $(Me_2As)_2CN_2$, and $Me_2AsC(N_2)COOEt$ do not enter into this reaction, which can be explained by steric hindrance[95], nor does bis(dimethylthallium)diazomethane, which has an ionic structure[42]. Sigmatropic rearrangements of the type (XVII) → (XVIII) accompany also reactions involving the 1,3-dipolar cycloaddition of diazoalkanes $(Me_3Sn)_2CN_2$ and $Me_3SiC(N_2)R$ to MeOOCC≡CCOOMe, while the capacity of R for migration diminishes in the sequence[56,59] $Me_3Sn > Me_3Si > H > COOEt$. For example[14,91], in the isomerisation of isopyrazole (XIX) the Me_3Si group migrates and not the hydrogen atom as suggested previously[90]:

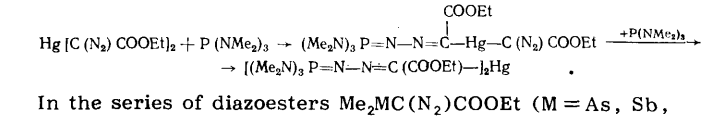
The reactions of mercuribis(diazoalkanes) of the type $Hg[C(N_2)R]_2$, where R = COOEtCOMe, with MeOOCC≡CCOOMe also proceed via the 1,3-cycloaddition mechanism[95]:



Bis(methylmercuri)diazomethane is converted in an analogous reaction into a mercurated pyrazole, which undergoes the Diels–Alder reaction with a second mole of MeOOCC≡CCOOMe, forming adduct (XX). On the basis of mass-spectrometric data, the structure of bis(methylmercuri)diazanorbornadiene was attributed to the latter[95]:

Dipolarophiles such as phenylacetylene, diphenylacetylene, sodium acetylenedicarboxylate[6,94], and bis(trimethylstannyl)-acetylene[95] do not react with α-metallated diazoalkanes or react sluggishly.

According to Crossman et al.[66], the reaction of trimethylsilyldiazomethane with trifluoroacetonitrile leads to adduct (XXI), which is converted into 4-trifluoromethyl-2-trimethylsilyl-1,2,3-triazole as a result of the migration of the Me_3Si group:



3. The Staudinger Reaction

It has been shown recently[44,46] that organometallic derivatives of diazo-compounds react with tris(dimethylamino)phosphine, which is highly basic, to form the corresponding phosphazines. In this reaction, discovered by Staudinger[96,97] for non-metallated analogues, the reactivity of the α-metallated diazoalkanes is determined by steric factors. Derivatives of diazomethane in the series Me_nMCHN_2 (M = Si, Ge, or As; $n = 3$ or 2) reacts spontaneously with $(Me_2N)_3P$; in the case of M = Si or As, a mixture of *cis*- and *trans*-phosphazines is formed:

$$Me_nMCHN_2 + (Me_2N)_3P \xrightarrow{Et_2O} Me_nMCH{=}N{-}N{=}P(NMe_2)_3 .$$

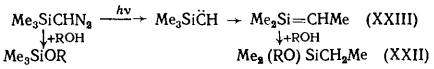
The analogous reaction with the compounds $MeHgC(N_2)R$, where R = COOEt, COMe, or COPh, takes place under mild conditions, while the interaction of mercuribisdiazoacetic ester can be carried out in stages:

In the series of diazoesters $Me_2MC(N_2)COOEt$ (M = As, Sb,

or Bi) phosphazines have been obtained only for the first two representatives. On the other hand, diazoalkanes with bulky substituents, for example compounds of the type $(Me_2M)_2CN_2$ (M = As or Sb), $(Me_3M)_2CN$, and $Me_3MC(N_2).COOEt$ (M = Si, Ge, Sn, or Pb) do not react with tris-(dimethylamino)phosphine[44,46]. Bis(dimethylthallium)diazomethane also does not react with $P(NMe_2)_3$, but this is due to the ionic structure of the diazoalkane[42].

We may note that 1-diazo-3-(trimethylsilyl)-2-propanone, in which the diazo-group is not shielded by the organometallic fragment, readily reacts with triphenylphosphine[1], like the usual diazo-compounds:

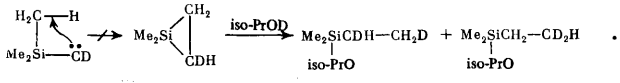
$$Et_3SiCH_2\overset{O}{\overset{\|}{C}}CHN_2 + Ph_3P \rightarrow Et_3SiCH_2\overset{O}{\overset{\|}{C}}CH{=}N{-}N{=}PPh_3 \quad (73\%)$$



It has been suggested that in the transition states of these reactions the phosphine attacks the electrophilic α-N atom with subsequent rearrangement to Staudinger's β-N-adduct[44].

IV. REACTIONS INVOLVING THE INTERMEDIATE FORMATION OF CARBENES AND CARBYNES

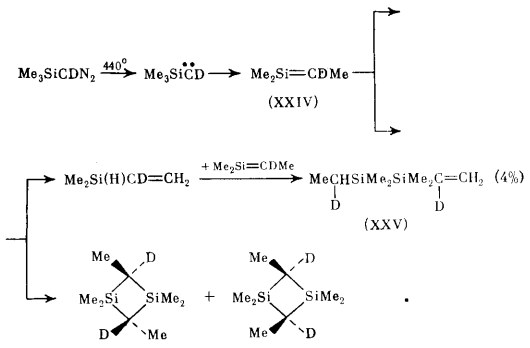
1. Intramolecular Rearrangement of Carbenes



Kinetic and chemical evidence was obtained in 1967 [98,99] for the existence of the short-lived sila-alkenes $R_2Si{=}CR'_2$, in which the silicon atom has a coordination number of 3. This stimulated an intense development of methods for the generation of sila-alkenes as well as the study of their structure and reactivity (see the relevant reviews[100-102]). In particular, it was found that α-silyated diazoalkanes are available as precursors of sila-alkenes.

Thus photolysis of trimethylsilyldiazomethane in alcohols leads to alkoxydimethylethylsilanes (XXII).[12,103,104] Me_3SiOR is formed via a side reaction (non-photochemically):

$$Me_3SiCHN_2 \xrightarrow{h\nu} Me_3Si\ddot{C}H \rightarrow Me_2Si{=}CHMe \quad (XXIII)$$
$$\downarrow +ROH \qquad\qquad \downarrow +ROH$$
$$Me_3SiOR \qquad\qquad Me_2(RO)SiCH_2Me \quad (XXII)$$



It has been suggested that the photolysis generates trimethylsilylcarbene, whose isomerisation leads to the sila-alkene (XXIII) as a result of the 1,2-shift of the methyl group to the carbene centre. The formation of the intermediate (XXIII) has been confirmed by the reaction with deuterated alcohols. For example, the photolysis of Me_3SiCDN_2 in iso-PrOD yielded isopropoxysilane $Me_2(iso\text{-}PrO)SiCD_2Me$, in which deuterium atoms are present only in the methylene group of the Et fragment[12]. This rules out the alternative mechanism—via the silacyclopropane intermediate:

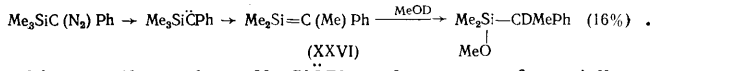
$$H_2C{-}H \quad CH_2$$
$$Me_2Si{-}\ddot{C}D \rightarrow Me_2Si \quad CDH \xrightarrow{iso\text{-}PrOD} Me_2SiCDH{-}CH_2D + Me_2SiCH_2{-}CD_2H$$
$$\text{iso-PrO} \qquad\qquad \text{iso-PrO}$$

It has also been shown[103] that the photolysis of $Me_2PhSiCHN_2$ and $Me_2(PhCH_2)SiCHN_2$ in methanol leads to the carbenes $Me_2PhSi\ddot{C}H$ and $Me_2(PhCH_2)Si\ddot{C}H$. They isomerise to sila-alkenes via the 1,2-shift of one of the groups from silicon to the carbene centre. The ease of migration varies in the sequence Me > Ph ≅ $PhCH_2$.

Judging from the composition of the products and their yield, the pyrolysis of Me_3SiCHN_2 (or Me_3SiCDN_2) in a flow system generates trimethylsilylcarbenes, which isomerise preferentially to a sila-alkene[12,104], for example:

$$Me_3SiCDN_2 \xrightarrow{440^\circ} Me_3Si\ddot{C}D \rightarrow Me_2Si{=}CDMe \quad (XXIV)$$

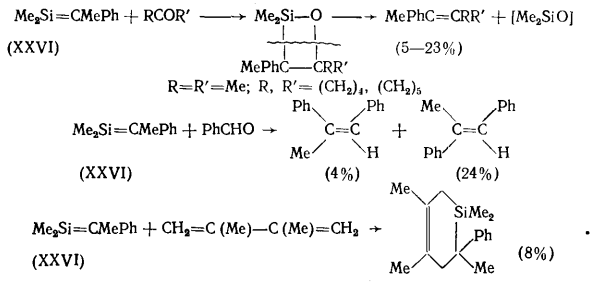
$$Me_2Si(H)CD{=}CH_2 \xrightarrow{+\,Me_2Si=CDMe} MeCHSiMe_2SiMe_2C{=}CH_2 \quad (4\%)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad D \qquad\qquad D$$
$$(XXV)$$



The sila-alkene (XXIV) dimerises to *cis*- and *trans*-disilacyclobutanes (overall yield >40%) and to a lesser extent rearranges to dimethylvinylsilane. The reaction of the latter with compound (XXIV) leads to adduct (XXV) in 4% yield. Furthermore, thermolysis gives rise to traces of ethylene and dimethylsilene as a result of a side reaction[104]:

$$Me_3Si\ddot{C}D \rightarrow Me_2Si\langle \rightarrow CHD{=}CH_2 + Me_2Si\,.$$

The intermediate formation of compound (XXIV) was confirmed by the pyrolysis of Me_3SiCHN_2 in the presence of 2-propanol. The latter traps sila-alkene with the formation of 2-propoxydimethylethylsilane (yield more than 67%).[12,104]

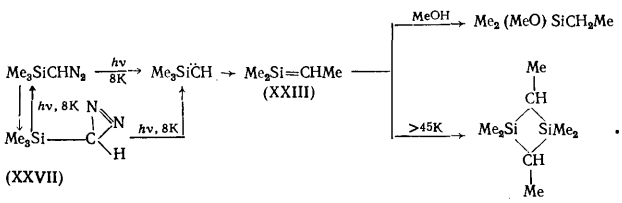


On the other hand, in the pyrolysis of phenyl(trimethylsilyl)diazomethane in the presence of alcohols the yield of sila-alkene (XXVI) was low[73]:

$$Me_3SiC(N_2)Ph \rightarrow Me_3Si\ddot{C}Ph \rightarrow Me_2Si{=}C(Me)Ph \xrightarrow{MeOD} Me_2Si{-}CDMePh \quad (16\%)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad (XXVI) \qquad\qquad\qquad\qquad\quad MeO$$

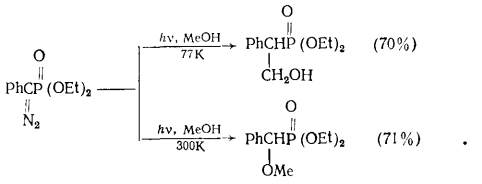
In this case the carbene $Me_3Si\ddot{C}Ph$ undergoes preferentially carbene–carbene rearrangement (see below).

The intermediate formation of sila-alkenes[105,106], including the intermediate (XXVI),[73,107] has been confirmed in addition by the reaction with ketones, which leads to olefins, by the reaction with aldehydes, in which mixtures of *cis*- and *trans*-alkenes are formed, and by the reaction with 2,3-dimethylbutadiene, which is known to trap sila-alkenes effectively[101] with formation of Diels–Alder adducts:



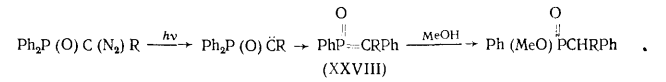
$$Me_2Si{=}CMePh + RCOR' \rightarrow Me_2Si{-}O \rightarrow MePhC{=}CRR' + [Me_2SiO]$$
$$(XXVI) \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (5\text{–}23\%)$$
$$MePhC{-}CRR'$$
$$R{=}R'{=}Me;\ R,\ R' = (CH_2)_4,\ (CH_2)_5$$

$$Me_2Si{=}CMePh + PhCHO \rightarrow \quad C{=}C \quad + \quad C{=}C$$
$$(XXVI) \qquad\qquad\qquad\qquad (4\%) \qquad\qquad (24\%)$$



$$Me_2Si{=}CMePh + CH_2{=}C(Me){-}C(Me){=}CH_2 \rightarrow$$
$$(XXVI) \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (8\%)$$

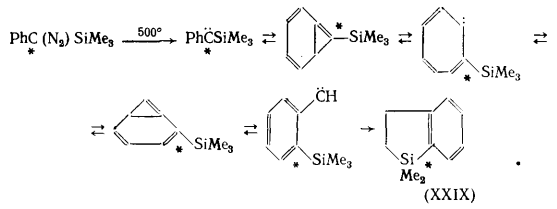
In 1967 two groups of investigators[104,108,109] obtained simultaneously data for the mechanism of the photolysis of trimethylsilyldiazomethane, isolated in an argon matrix at 8 K:



$$Me_3SiCHN_2 \xrightarrow[8K]{h\nu} Me_3Si\ddot{C}H \rightarrow Me_2Si{=}CHMe \quad (XXIII)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \xrightarrow{MeOH} Me_2(MeO)SiCH_2Me$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \xrightarrow{>45K} Me_2Si\langle CH(Me)$$
$$Me_3Si{-}C(N{=}N){-}H \quad h\nu, 8K$$
$$(XXVII)$$

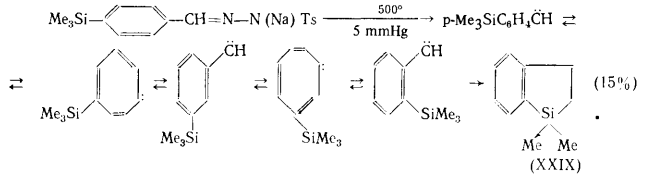
It was shown by ultraviolet, ^{1}H NMR, and infrared spectroscopy that the primary photolysis product is trimethylsilyldiazirine (XXVII), which is stable at room temperature. Further photolysis of the mixture of Me_3SiCHN_2 and compound (XXVII) proceeds via the carbene to the sila-alkene (XXIII). The infrared spectra of compound (XXIII) (not entirely identical) were also published in other communications[108,109]. Furthermore, compound (XXIII) was identified on the basis of the formation of a mixture of *cis*- and *trans*-disilacyclobutanes by the reaction with methanol. It has been found by EPR that trimethylsilylcarbene has a triplet ground state[108]. This was confirmed by the formation of triplet carbenes in the photolysis of Me_3SiCDN_2, $Me_2(H)SiCHN_2$, and $(Me_3Si)_2CN_2$ in argon matrices at 8 K. At the same time it has been suggested that thermolysis of Me_3SiCHN_2 at ~420 °C and its photolysis at 25 °C leads to singlet trimethylsilylcarbene[108]. Two recently published interesting examples of the dependence of the spin state of carbenes on the conditions of their generation are consistent with this finding. Thus the photolysis of α-diazobenzylphosphonate in a methanol matrix at 77 K leads to triplet carbene and its photochemical decomposition in alcohols at 300 K leads to singlet carbene[110]. In the former case the reaction with the alcohol yields preferentially the C–H insertion product, while in the latter case the O–H insertion product is formed, in agreement with Kirmse's data[111]:

Similarly[112] the photolysis of phenyldiazomethane in 2-propanol at 20 °C results in the formation of benzyl 2-propyl ether (77%) as a result of the insertion of singlet phenylcarbene in the O–H bond of the alcohol molecule. On the other hand, if the photolysis is carried out in a 2-propanol matrix at −196 °C, then triplet phenylcarbene is generated (cf. Refs. 113–115) and reacts with the alcohol preferentially via the C–H insertion mechanism.



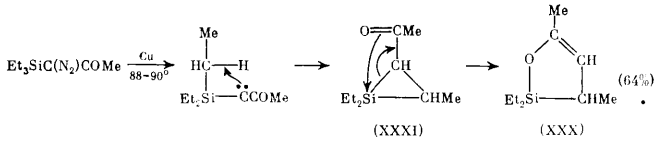
In conclusion of the discussion of the methods for the generation of sila-alkenes, we may note that the photolysis of the derivatives of diphenylphosphoryldiazomethane generates carbene which, like silylcarbenes, isomerise to unstable alkylideneoxophosphoranes (XXVIII) as a result of the 1,2-shift of the pH group from the hetero-element to the carbene centre[116,117]:

The intermediates (XXVIII) belong to a new class of heterocumulenes containing quinquevalent phosphorus having a coordination number of 3. They have been trapped successfully with methanol, aldehydes, and ketones[116,117].



The reactions of phosphorylcarbenes, including their intramolecular rearrangements, have been discussed in reviews[4,118].

In the pyrolysis of $Me_3SiC(N_2)Ph$ and $Me_3SiC(Ph)$=N–N(Li)Ts in the gas phase[72–74,107,119] one of the products is 1,1-dimethyl-1-silaindan (XXIX) (yield up to 37%). It is assumed that the carbene Me_3SiCPh formed is in equilibrium with trimethylsilylheptatrienylidene and *o*-trimethylsilylbenzylidene (carbene–carbene rearrangement). The pyrolysis of the labelled compounds $Me_3Si^{13}C(N_2)Ph$ and $Me_3Si^{13}C(Ph)$=N–N(Li)Ts leads to indan (XXIX) with the label in the benzene ring, which confirms the following mechanism[72,73]:

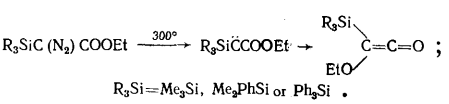


Side reactions lead to the isomerisation of the carbene $PhCSiMe_3$ to the sila-alkene (XXVI) (again see above) and to a lesser extent to 1,1-dimethyl-2-phenyl-1-silacyclopropane.

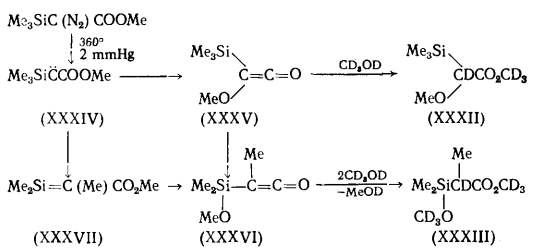
It is of interest that silaindan (XXIX) has also been obtained by the pyrolysis of the sodium salt of *p*-trimethylsilylbenzaldehyde tosylhydrazone[120], which generates the carbene p-$Me_3SiC_6H_4CH$, differing in structure from $PhCSiMe_3$. The reaction mechanism is analogous to that discussed above:

The copper-catalysed thermolysis of triethylsilyldiazoacetone in hexane leads to 1,1-diethyl-3,5-dimethyl-1-sila-2-oxa-3-cyclopentene (XXX). The carbenoid§ $Et_3SiCCOMe$ formed is probably inserted intramolecularly into the C–H bond of the Si–CH_2 fragment. This is followed by ring expansion[63,121,122] in the intermediate (XXXI):

The intermediate formation of silacyclopropanes in the rearrangements of carbenes has also been postulated in other studies[73,104]. On the other hand, the thermolysis of triethylgermyldiazoacetone and its analogues over copper generates the carbenoids $Et_3GeCCOR$, which undergo the Wolff rearrangement with formation of germylated ketens[63,123]:



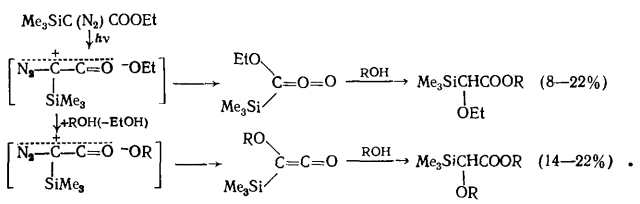
The thermolysis of the usual α-diazoketones over a copper catalyst is known to lead to ketocarbenoids which do not undergo the Wolff rearrangement[125], with a few exceptions[124].



---

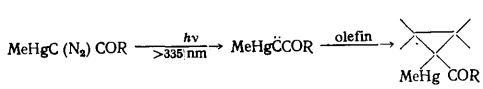
§ Following Marchand and MacBrockway[126], here and henceforth the term carbenoids is applied to the carbenes formed in the thermocatalytic decomposition of diazoalkanes on metals or their salts. There are data showing that the carbenoid is usually coordinated to the catalyst; as a result, the properties of the carbenoid can differ from those of the corresponding carbene.

We may note that the pyrolysis of α-silyldiazoacetates in a flow system leads to the Wolff rearrangement[127];



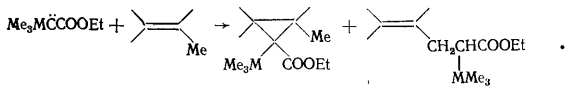
Ando and coworkers[128,129] showed that the esters (XXXII) and (XXXIII) are formed, together with other products, in the pyrolysis of methyl trimethylsilyldiazoacetate in a flow system in the presence of alcohols (for example, CD_3OD). They suggested that the pyrolysis leads to the carbene (XXXIV), which undergoes the Wolff rearrangement to the alkoxyketen(XXXV) and the latter can isomerise to the ketone (XXXVI). The reactions of (XXV) and (XXXVI) with the alcohol lead to esters:

Later the authors[129] suggested that the keten (XXXVI) is formed as a result of the rapid isomerisation of the silaalkene (XXXVII), which fails to react with the alcohol.



In its photochemical decomposition in alcohols[130,131] ethyl trimethylsilyldiazoacetate undergoes the Wolff rearrangement without the intermediate formation of carbenes (cf.Refs.132 and 133):

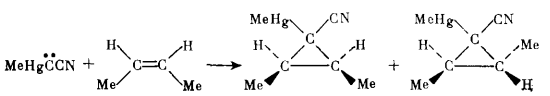
The photolysis of $MeHgC(N_2)COOMe$ [39] and $MeHgC(N_2)COMe$ [134] generates carbenes; the Wolff rearrangement is not typical for these compounds.



2. Addition to Multiple Bonds

The photolysis of α-metallated diazo-compounds under the usual conditions leads to carbenes in a singlet form. If the rate of their reaction with olefins is greater than the rate of their intercombination transition to the triplet state, stereospecific cycloaddition to the C=C bond and insertion in the C–H bond take place. The relative contributions of these reactions depend on many factors. For example[39,134], the yield of cyclopropanes is 70–90% in the photolysis of MeHgC.(N$_2$)COR (R = Me or OMe) in but-1-ene, 2-methylpropene, *cis*- or *trans*-but-2-ene, and buta-1,3-diene:

The reaction mixtures contain virtually no CH insertion products and the yield of products corresponding to the Wolff rearrangement is less than 4%.

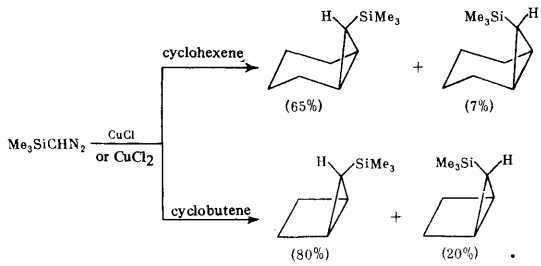


On the other hand, the photolysis of the diazoesters $Me_3MC(N_2)COOEt$ (M = Si, Ge, Sn, or Pb) leads to carbenes, which react with olefins less selectively: the formation of cyclopropanes is accompanied by the CH insertion[49,58,59,135]:

Steric factors have a considerable influence. Thus the interaction of the carbene $Me_3SiCCOOEt$ with isobutene entails the formation of only the cycloaddition product, while the reaction with the sterically hindered tetramethylethylene yields to the CH insertion product only[59]. The photolysis of Me_3SiCHN_2 generates trimethylsilylcarbene, whose reactions with ethylene and *trans*-but-2-ene give a low yield of cyclopropanes[136]. At the same time the carbene dimerises with formation of *trans*-1,2-bis(trimethylsilyl)ethylene. The latter reaction becomes the main one in the photolysis of Me_3SiCHN_2 in the presence of sterically hindered tetramethylethylene, tetrafluoroethylene, and perfluoropropene[136].

It has been shown by ^{1}H NMR that, on direct photochemical generation of the carbenes MeHgCCOMe, MeHgCCOOMe, Me_3SiCH, and $Me_3MCCOOEt$ (M = Si, Ge, Sn, or Pb),[49,59,134,136] their cycloaddition to *cis*- and *trans*-but-2-enes is mainly *cis*-stereospecific. This is evidence for the singlet state of the carbenes[111,137]. The contribution of the non-stereospecific cycloaddition of $Me_3SiCCOOEt$ is only 5%. The introduction of even small amounts of benzophenone into the reaction mixture[59] increases this contribution to 15% as a result of the sensitisation of the photolysis[111].

It has been shown recently[53] that the cyanocarbene HCCN, obtained by the direct photolysis of diazoacetonitrile, adds mainly *cis*-stereospecifically (to the extent of 94%) to *cis*-but-2-ene. Consequently, the contribution of triplet cyanocarbenes to this reaction is also low. On the other hand, both the direct benzophenone-sensitised photolysis of $MeHgC(N_2)CN$ in *cis*-but-2-ene leads to 1:1 mixtures of *cis*- and *trans*-dimethylcyclopropanes, which indicates the non-stereospecificity of the reaction

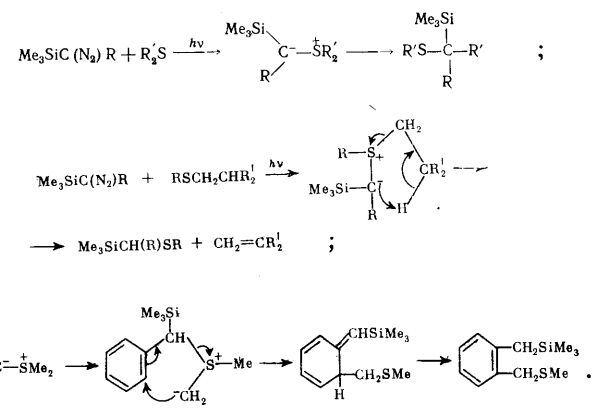


The difference between the properties of the carbenes HCCN and MeHgCCN has been explained[53] by the heavy atom effect. Both kinds of carbenes are generated in the singlet form, but, under the influence of the α-mercury atom, there is a rapid intercombination transition of MeHgCCN to the triplet state and the steady-state concentration of triplet carbenes increases.

The catalytic decomposition of trimethylsilyldiazomethane over copper salts in the presence of olefins leads to the carbenoid¶ Me_3SiCH. It is stabilised by cycloaddition to olefins and by dimerisation to *trans*- and *cis*-1,2-bis(trimethylsilyl)ethylenes[64,65,136,138]. The reaction with *trans*-but-2-ene takes place stereospecifically and leads to 1-trimethylsilyl-2,3-*trans*-dimethylcyclopropane (yield 13%).[136] The interaction with cyclohexene results in the formation of *anti*- and *syn*-7-trimethylsilylnorcarane[64,65]; the reaction with cyclobutene gives a mixture of *exo*- and *endo*-5-trimethylsilylbicyclo[2,1,0]pentanes[138], while the reaction with cyclohexa-1,3-diene leads to *exo*-7-trimethylsilylbicyclo[4,1,0]-hept-2-ene.[139] In the first two instances the cycloaddition

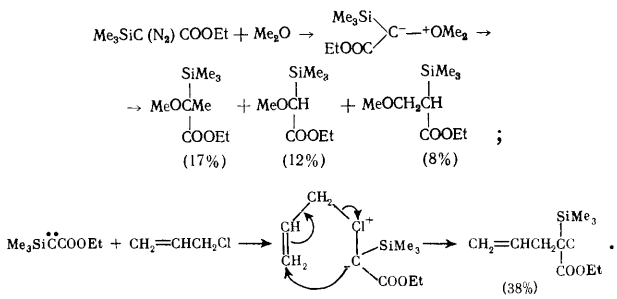
¶ For the role of the catalysts in the carbenoid decomposition of aliphatic diazo-compounds, see Mandel'shtam[140].

takes place with the preferential formation of the *exo*-isomers:



3. The Insertion of α-Metallated Carbenes in the O–H, C–H, C–O, C–S, C–Cl, Si–H, Si–Hg, and Ge–Hg σ-Bonds

Reactions of this type were investigated in relation to a large number of examples. It has been shown[39,59,71,119] that, in their reaction with alcohols, carbenes are usually selectively inserted in the O–H bonds, which makes it possible to use methanol and its deuterated derivatives for the identification of carbenes in the singlet state. For example, the photolysis of $MeHgC(N_2)COOMe$ in methanol leads to $MeHgCH(OMe)COOMe$ in 98% yield. The structure of the product was confirmed by its reduction (with $NaBH_4$ in ethanol) to $MeOCH_2COOEt$ and the photolysis of the initial diazoester in CD_3OD.[39]

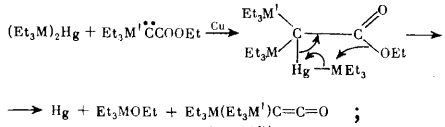


There is yet another reaction specific to singlet α-metallated carbenes—the insertion in the C–H bond[49,59,136]. Thus the photolysis ($\gamma > 300$ nm) of $Me_3SiC(N_2)COOEt$ in cyclohexane leads to ethyl cyclohexyltrimethylsilylacetate (yield 49%) while in n-butane at −30 °C a mixture of ethyl 2-trimethylsilylcaproate and ethyl 3-methyl-2-trimethylsilylvalerate is formed (overall yield 52%).[59] Furthermore, the rearrangements of certain carbenes, for example $Me_3SiC\ddot{P}h$ [72,119] and p-$Me_3SiC_6H_4$–$\ddot{C}H$ [120] include a stage involving the intramolecular insertion of the carbene group in the C–H bond (see Section IV).

It has been shown recently[131,141] that the photolysis of the diazoalkanes $Me_3SiC(N_2)R$ (R = COOEt or Ph) in dialkyl sulphides at ~20 °C leads to the carbenes $Me_3Si\ddot{C}R$, which react with R'_2S to form sulphonium ylids. This can be followed by stages involving insertion in the C–S bond, elimination, and the Sommelet–Hauser rearrangement (cf. Hauser et al.[142]):

The photolysis of $Me_3SiC(N_2)COOEt$ in dimethyl sulphide[141] at −78 °C leads to the stable ylid Me_2S^+–$^-C(COOEt)SiMe_3$ (m.p. 40 °C). Other evidence in support of the intermediate formation of ylids in such reactions has been presented in a review[143].

The reactions of α-silylated carbenes with ethers and alkyl halides also includes the ylid formation stage[131]:



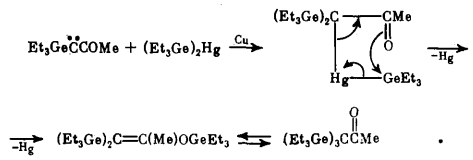
The insertion of the unusual carbenes[140,144,145] and their α-metallated analogues[136,147,148] in the Si–H bond is of synthetic interest. In the general case this bond is more carbenophilic than the C–H bond[136,146]. However, the yield of the Si–H insertion product can depend on the method of generation of the carbene. Thus the liquid-phase photolysis of a mixture of trimethylsilyldiazomethane and trimethylsilane leads to the Si–H insertion product $Me_3SiCH_2SiMe_3$ (yield 66%). On the other hand, this product is not formed in the liquid-phase thermolysis (in the photolysis of the same mixture in the gas phase)[136].

The catalytic decomposition of $Et_3GeC(N_2)COOEt$ over copper in benzene in the presence of triethylsilane or triethylgermane proceeds with the selective insertion of the resulting carbenoid in the Si–H or Ge–H bonds[147], for example:

$$Et_3Ge\ddot{C}COOEt + Et_3SiH \rightarrow Et_3Si(Et_3Ge)CHCOOEt\ .$$

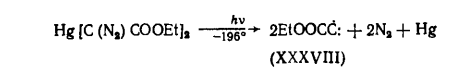
In the analogous reaction with $Me(C_6F_5)_2SiH$ the insertion of $Et_3Ge\ddot{C}COOEt$ in the more inert Si–H bond does not occur[148]. The reaction leads to the azene $Et_3Ge(EtOOC)C{=}N{-}N{=}C(COOEt)GeEt_3$ (yield ~90%), which is known to be formed[60] via the addition of carbenoid $Et_3Ge\ddot{C}COOEt$ to a molecule of the initial diazoester.

It has been shown[149,150] that dihalogenocarbenes react non-selectively with bis(trimethylsilyl)- and bis(trimethylgermyl)-mercury. Dihalogenocarbenes are inserted both in the mercury–Group IVB element bond and in the newly formed Hg–C bond. On the other hand, the carbenoid $Et_3MCCOOEt$, formed in the catalytic decomposition of α-metallated diazoesters of the $Et_3M'C(N_2)COOEt$ (M' = Si, Ge, or Sn) series over copper in hexane or toluene in the presence of bis(triethylsilyl)- or bis(triethylgermyl)-mercury, is inserted in the Si–Hg or Ge–Hg bond. Successive demercuration ketens[61–63]:



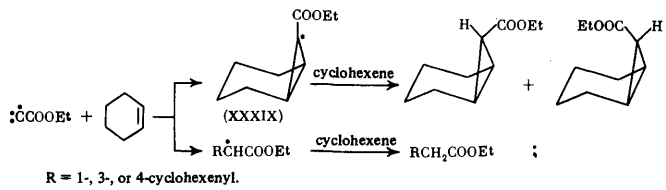
$$\rightarrow Hg + Et_3MOEt + Et_3M(Et_3M')C{=}C{=}O \quad ;$$

(58–92%)



M = Si or Ge; M' = Si, Ge, or Sn.

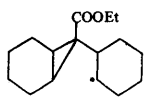
The acetyltriethylgermylcarbenoid, generated by the thermocatalytic decomposition of $Me_3GeC(N_2)COMe$, is inserted selectively in the Ge–Hg bond in the reaction with bis(triethylgermyl)mercury. The reaction is also accompanied by demercuration[147]:



4. Methods of Generation and Reactivities of Carbynes

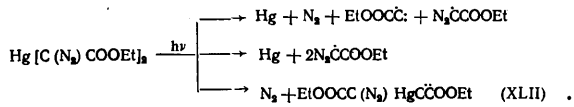
The chemistry of carbynes, which are derivatives of univalent carbon, has been developing vigorously in two directions. Studies have been made on the methods of synthesis and reactivities of transition metal complexes in which one of the ligands is a carbyne (see Fischer's review[111] review[151]). Methods for the generation of carbynes as kinetically independent species are being developed (see the short review of Strausz er al.[152]). In particular, ethoxycarbonylmethine (XXXVIII) is generated in the short-wavelength photolysis ($\lambda > 2100$ Å) of mercuribis(ethyl diazoacetate)[33,152] or alkylmercuridiazoacetates[39]:

(XXXVIII)



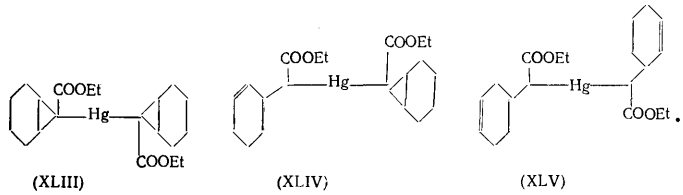
It was established that the carbyne (XXXVIII) is in the $^2\Pi$ ground state (↑↓↑ CCOOEt). Two parallel processes are characteristic of its reaction with cyclohexene: (1) addition to the double bond (concerted mechanism forbidden by orbital symmetry rules), leading to the formation of 7-ethoxycarbonyl-7-norcaranyl radicals (XXXIX); (2) insertion in the C–H bond (preferentially the allylic bond) with formation of alkyl radicals (XL):

(XXXIX)



R = 1-, 3-, or 4-cyclohexenyl.

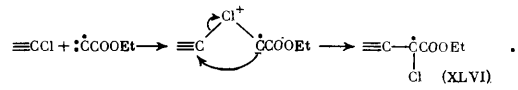
The radicals (XXXIX) and (XL) abstract hydrogen from cyclohexene. For (XXXIX), this process takes place stereospecifically with the preferential formation of the less stable ethyl *endo*-norcarane-7-carboxylate. Furthermore, the radicals (XXXIX) add to the double bond of cyclohexane and the resulting radicals (XLI) then disproportionate:



(XLI)

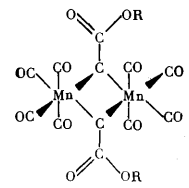
With increase of λ (for $\lambda > 2800$ Å), the yield of the carbyne (XXXVIII) falls owing to photolysis via competing pathways:

(XLII)



Under these conditions, the overall yield of the organomercury products (XLIII)–(XLV) increases to 38% with a simultaneous decrease of the yield of the non-mercurated products from 31 to 5%. Consequently the relative contribution of the mercury-containing carbenes [for example, (XLII)] in reactions with the solvent (cyclohexene) greatly increases:

(XLIII) (XLIV) (XLV)

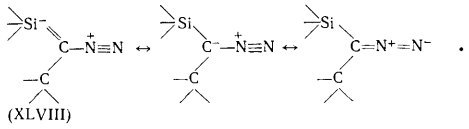


The regioselective insertion of the carbyne (XXXVIII) and the mercurated carbene (XLII) in the C–H bonds in the α-position with respect to the heteroatom has been observed in the photolysis of $Hg[C(N_2)COOEt]_2$ in heterocyclic compounds (tetrahydrofuran, tetrahydrothiophen, or pyrrolidine).[153] Judging from the proportions of the insertion products, the principal intermediate is the carbene (XLII), while the yield of the carbyne (XXXVIII) is 10–20%.

According to Patrick and Kovith[154], the photolysis of $Hg[C(N_2)COOEt]_2$ in the chloroalkanes $Me_{4-n}CCl_n$ ($n = 1$–4) at $\lambda < 2900$ Å leads to derivatives of ethyl chloroacetate and ethyl chloroacrylate. In this case the ethoxycarbonylmethine (XXXVIII) formed is inserted preferentially in the C–Cl bond with the intermediate formation of the chlorine-containing radical (XLVI). By analogy with the chemistry of the carbenes[126], it is suggested that the insertion step is preceded by the formation of an ylid radical:

(XLVI)

It is of interest to note that, in the reaction of $Mn(CO)_5Br$ with $Hg[C(N_2)COOR]_2$ (R = Et or t-Bu) in boiling ether, one of the products is the dimeric complex (XLVII) in which ethoxycarbonylmethine and t-butoxycarbonylmethine function is neutral three-electron bridge ligands[155,156].



(XLVII)

The analogous complex is not formed in the reaction with $AgC(N_2)COOEt$. So far no analogies for this reaction are known[156].

V. STRUCTURAL AND SPECTROSCOPIC STUDIES

According to X-ray diffraction data[157], the $Ph_3SiC(N_2)Ph$ molecule is monomeric. It contains the linear C–N–N group and the planar Si–C(N_2)C fragment. The C–N bond is somewhat shorter and the N–N bond somewhat longer than in diazomethane (cf. Cox et al.[158]). The Si–C bond in the fragment is single (1.88 Å), which has been explained by the low contribution of structure (XLVIII) to the resonance

hybrid:

(XLVIII)

According to the same data[157], phenyl(triphenylgermyl)diazomethane has the same structure as its silicon analogue.

It has been shown[159,160] that all seven atoms of the $HgC(N_2)CO_2$ fragment in the crystals of t-BuHgC(N_2)COOEt and $Hg[C(N_2)COOEt]_2$ lie in the same plane. In the t-butyl derivative the carbonyl group is in the *cis*-position with respect to the diazo-group. This conformation is in general more stable than the transoid conformation[161]. It is particularly characteristic of aliphatic α-diazoalkanes[162].

It has been shown by NMR and infrared (IR) and Raman spectroscopic methods that bis(dimethylthallium)diazomethane is an ionic compound and that the anion $[CN_2]^{2-}$ has a linear structure[42]. In other compounds of the type $(R_nM)_2CN_2$ the metal–diazo-carbon bonds are covalent. The diazo-group gives rise to a distinct band in the IR spectra of these compounds in the range 1950–2050 cm^{-1}, due to the asymmetric stretching vibrations of the N–N bond[40,47]. The diazo-group in the compounds $(R_3Sn)_2CN_2$ absorbs in the region of 2000 cm^{-1} regardless of the nature of R. However, in the $(Me_3M)_2CN_2$ series the frequency $\nu_{as}(CN_2)$ decrease on average by 50 cm^{-1} in the following sequence of M: Si > Ge > Sn > Pb, which reflects the inductive effect of the Me_3M groups[40]. An analogous shift of the absorption band in the region of low frequencies has been observed in the spectra of the following series of compounds: $Me_2As(Me_3Ge)CN_2$ (2020 cm^{-1}), $Me_2As(Me_3Sn)CN_2$ (2000 cm^{-1}), and $Me_2As.(Me_3Pb)CN_2$ (1985 cm^{-1}).[47]

The introduction of the Me_2M fragment (M = As, Sb, or Bi) at the α-carbon atom of ethyl diazoacetate reduces the frequency by 45–55 cm^{-1}. It has been suggested[43] that this effect is due to the mass of the substituent and to a lesser extent the nature of the metal. An analogous conclusion was reached in the analysis of the IR spectra of $Me_3MC(N_2)COOEt$ (M = Si, Ge, Sn, or Pb) and certain related compounds[40].

As regards the stretching vibrations of the carbonyl group, an appreciable bathochromic shift is observed only after the introduction of the Me_3Sn, Me_3Pb, MeHg, and EtHg fragments, whereupon, according to the authors[40,43], the carbonyl group is coordinated intramolecularly to the metal atom. On the other hand, if such coordination does not occur in the compounds $Me_nMC(N_2)COOEt$ (M = Si, Ge, As, Sb, or Bi), the band shifts only very slightly[40,43].

Analogous effects are characteristic also of α-metallated diazoketones. For example, the carbonyl absorption band in the spectra of the compounds $Hg[C(N_2)COR]_2$ (R = alkyl, adamantyl, or aryl)[33,35,38] undergoes a 25–45 cm^{-1} bathochromic shift relative to the non-mercurated analogues.

The ultraviolet spectra of mercuridiazoacetates $RHgC(N_2).COOR'$ (R and R' = alkyl) contain two absorption bands: at 374–377 nm ($\varepsilon \cong 44$–59) and at 268–274 nm ($\varepsilon \cong 8600$–10 000). The introduction of the alkylmercuri-group in $HC(N_2)COOR'$ causes a 20–25 nm shift of the short-wavelength maximum and reduces its intensity by 40%. The position of the long-wavelength maximum changes only slightly (by 2–3 nm), but its intensity increases by a factor of three[39]. Similar features are characteristic of α-mercurated diazoketones[33,35].

Organometallic derivatives of diazo-compounds are also widely investigated by pulse $^{13}C\{^1H\}$ Fourier transform NMR.[43,163] In particular, $^1J(H-C)$ and the chemical shifts $\delta(^{13}CN_2)$ of the diazo-carbon atom in the compounds Me_nMCHN_2, $(Me_nM)_2CN_2$, and $Me_nMC(N_2)COOEt$ (M = Hg, Si, Ge, Sn, Pb, As, Sb, or Bi; $n = 1$, 2, or 3) have been determined. It has been found[163] that the substitution of the hydrogen atom in diazomethane or ethyl diazoacetate by the Me_3M fragment entails a downfield shift of the $^{13}CN_2$ signal, the magnitude of the signal increasing in the sequence Si < Ge < Sn < Pb.

In their analysis of the $^{13}C\{H\}$ NMR spectra of compounds in the $(Me_3M)_2CN_2$ series (M is a silicon subgroup element), Lorberth and coworkers[43,163] established that the carbon atom linked to the diazo-group is shielded owing to the diamagnetic influence of the neighbouring Me_3M fragments. The atom is particularly strongly shielded in bis(trimethylstannyl)diazomethane [$\delta(^{13}CN_2) = 5.8$ p.p.m.] and bis(trimethylplumbyl)diazomethane [$\delta(^{13}CN_2) = 1.9$ p.p.m.]. To account for this effect, the compound $(Me_3Sn)_2CN_2$ was investigated in detail by photoelectron spectroscopy, ^1H, ^{13}C, ^{15}N, and ^{119}Sn NMR, as well as ^{119} ^{119}Sn-Mössbauer spectroscopy[164]. It was established that the Me_3Sn groups function in this case as very powerful electron donors, as a result of which the CN_2 fragment acquires an enhanced electron density, which is distributed fairly uniformly over all three atoms of this group. Analysis of the Mössbauer spectra of solid specimens of $(Me_3Sn)_2CN_2$ led to the conclusion that tetracoordinate tin atoms, deshielded by the CN_2 group, are present[164].

A similar effect of the Me_3M groups (M = Si, Ge, or Sn) had been observed previously by ^{13}C NMR in dimetallated ketens $(Me_3M)_2C{=}C{=}O$.[165] In the diazoesters $Me_3MC(N_2)COOEt$ the shielding of the α-carbon atom is less marked [$\delta(^{13}CN_2) = 37.8$–42.9 p.p.m.].[163,164]

The Synthesis of Active Metabolites and Analogues of Vitamin D_3

R.I.Yakhimovich

The literature data on the synthesis of the active metabolites and analogues of vitamin D_3 (cholecalciferol), which play an important role in regulating the homeostatis of calcium in the organism, are reviewed.
The bibliography includes 150 references.

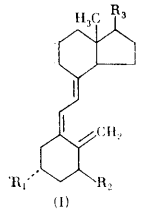
I. INTRODUCTION



A rigorously defined concentration of calcium in the blood is essential for the normal functioning of the living organism. The factors responsible for maintaining a constant level of calcium are the parathyroid hormone, which mobilises calcium cations from the bones when the calcium concentration falls, as well as calcitonin, which lowers the level of calcium, when its concentration increases, by the calcification of the bone tissue. Both of these hormones maintain a constant level of calcium in the blood by drawing on the internal reserves of the organism[1]. A possible regulator of the homeostasis of calcium entering the organism is vitamin D_3 (cholecalciferol) (Ia), which is a natural and the most active vitamin of the D group.

Vitamins of the D group control the entry of exogenic calcium into the organism by absorbing it from the food in the intestine; in addition, they participate in the mobilisation of calcium from the bones and promote the calcification of the bone tissue and an increase of the concentration of phosphate in the blood. These functions are impaired in rickets, a common disease of a growing organism, and vitamins D are virtually the only radical anti-rickets preparations.

It was believed for a long time that vitamin D_3 acts in the organism without undergoing any changes. The difficulty of studying the mechanism of the action and metabolism of vitamin D_3 is due to the fact that the amounts of the vitamin to which animals respond are vanishingly small and extremely sensitive methods are required for their detection. It was not until the end of the 1960's, after the synthesis of radioactive preparations of vitamin D_3 with a high specific activity, the development of new effective thin-layer and column chromatographic methods, and the application of high-resolution mass spectrometric and NMR methods, that it was possible to investigate the transformations of vitamin D_3 in the organism and to elucidate the mechanism of the action of its metabolites.

In 1966 American investigators[2,3] detected the first metabolite of vitamin D_3, which was isolated and identified as 25-hydroxycholecalciferol (25-OHD_3) (Ib).[4,5] DeLuca and coworkers[6] established that 25-hydroxylation of vitamin D_3 takes place in the liver and that this results in the formation of a metabolite 1.4 times more active than vitamin D_3 in the treatment of rickets and acting three times as fast[7,8].

The synthesis of radioactive 25-OHD_3 made it possible to follow the further transformations of this metabolite in the organism. In 1971 three groups of investigators, headed by Kodicek[9], DeLuca[10,11], and Norman[12], isolated almost simultaneously a new metabolite—1α, 25-dihydroxycholecalciferol [1α, 25-$(OH)_2D_3$] (Ic). It is biosynthesised in the kidneys[13] and is not formed in nephrectomised animals[14]:

(I)

(a) D_3: R_1 = OH; R_2 = H; R_3 =

(b) 25-OHD_3: R_1 = OH; R_2 = H; R_3 =

(c) 1α,25-$(OH)_2D_3$: R_1 = OH; R_2 = OH; R_3 =

(d) 1α-OHD_3: R_1 = OH; R_2 = OH; R_3 =

(e) 3-deoxy-1α-OHD_3: R_1 = H; R_2 = OH; R_3 =

(f) 24*R*, 25-$(OH)_2D_3$: R_1 = OH; R_2 = H; R_3 =

(g) 25, 26-$(OH)_2D_3$: R_1 = OH; R_2 = H; R_3 =

(h) 1α, 24*R*, 25-$(OH)_3D_3$: R_1 = OH; R_2 = OH; R_3 =

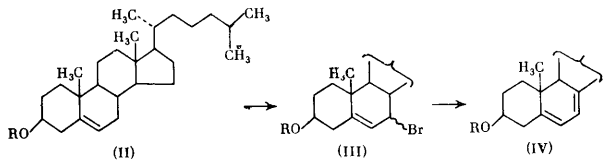
The metabolite 1α, 25-$(OH)_2D_3$ is the most active hormonal form of vitamin D_3, being 10–15 times more active than the latter[1,15]. It acts very rapdily on all known systems, which are acted upon by vitamin D_3, stimulating the absorption of calcium in the intestine, the mobilisation of calcium from the bone, and the calcification of the bone tissue; it also increases the concentration of phosphate in blood serum. A very important property of 1α, 25-$(OH)_2D_3$ is that it induces all these processes also in the case of kidney diseases, when neither vitamin D_3 nor its other metabolites have any activity. 1α, 25-$(OH)_2D_3$ has therefore been used successfully

in the treatment of various bone diseases associated with kidney affections, such as osteomalacia, osteoporosis, etc. However, the complexity of the synthesis of 1α, 25-$(OH)_2D_3$ makes it so far relatively unavailable for wide-scale application. The search for a synthetic analogue of 1α, 25-$(OH)_2D_3$ led DeLuca to the synthesis in 1973 [16] of 1α-hydroxycholecalciferol (1α-OHD_3) (Id) which was shown by extensive studies of its biological activity[16-20] to be capable of replacing 1α, 25-$(OH)_2D_3$ in therapeutic practice[21,22].

3-Deoxy-1α-hydroxycholecalciferol (3-deoxy-1α-OHD_3) (Ie), synthesised in 1974 in the laboratories of Norman[23] and DeLuca[24,25], also proved to be an analogue of 1α, 25-$(OH)_2D_3$ with a high biological activity. It stimulates the transport of calcium in the intestine almost as actively as 1α, 25-$(OH)_2D_3$,[23,24,26] but its effect on the bone system is less pronounced. This specific property makes this compound extremely important in the treatment of bone diseases in those cases where it is necessary to stimulate the transport of calcium in the intestine without causing its mobilisation from the bone.

Several other metabolites, in addition to 25-OHD_3, and 1α, 25-$(OH)_2D_3$, were isolated in the study of the metabolism of vitamin D_3. In 1970 DeLuca and coworkers[27,28] isolated 24, 25-dihydroxycholecalciferol [24, 25-$(OH)_2D_3$] (If), which is formed when animals are on a normal or a hypercalcemic diet[29]. The synthesis of two stereoisomers and the study of the biological activity of 24*R*- and 24*S*-25-$(OH)_2D_3$ showed that the 24*R*-isomer is formed in the organism and is almost as active as 25-OHD_3.[30,31]

25,26-Dihydroxycholecalciferol [25,26-$(OH)_2D_3$] (Ig) [32] and 1α, 24,25-trihydroxycholecalciferol [1α, 24,25-$(OH)_3D_3$] (Ih) [33] were isolated from the blood plasma of animals administered radioactive vitamin D_3. These metabolites are active in the transport of calcium in the intestine, but are relatively ineffective in the treatment of rickets and in the mobilisation of calcium from bone[33-37]. However, one cannot rule out the possibility that, on being formed in the organism, these metabolites play an important physiological role †.



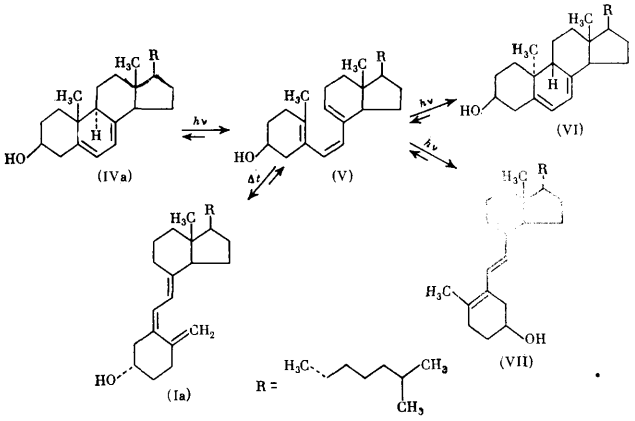
The high activity of vitamin D_3 metabolites not only in the treatment of rickets but also in other severe diseases associated with the breakdown of the homeostasis of calcium in the organism led chemists in many countries to join in the search for a solution to the problem of the chemical synthesis of these compounds. During the last few years, different versions of complex chemical syntheses of active metabolites of vitamin D_3 and some of its active analogues were therefore proposed.

The biochemical synthesis of the metabolites in the organism takes place with the aid of the corresponding enzyme system in the liver or in the kidneys and proceeds in such a way that direct transition from the molecule of vitamin D_3 to that of its hydroxy-derivative is acheived. Chemical syntheses of the active metabolites and analogues of vitamin D_3 involve complex multistage transformations of the entire structure of the steroid molecule of the initial substance and are therefore in most instances mainly of theoretical interest. Practical applications of these important biologically active compounds have unfortunately not been found so far.

† The relation between the structure and biological activity of vitamins D, their metabolites, and synthetic analogues was described in greater detail in a monograph by the author of the present review[38].

II. THE SYNTHESIS OF CHOLECALCIFEROL

The synthesis of vitamin D_3, achieved as early as 1936 by Windaus and coworkers[39,40], includes two main stages: the formation of the provitamin and its photochemical isomerisation. A distinctive feature of provitamins D is the presence of two conjugated double bonds at the ring $C_{(5)}-C_{(6)}-C_{(7)}-C_{(8)}$ atoms of the steroid molecule. 7-Dehydrochloesterol, which is a provitamin of cholecalciferol, is cholesterol (IIa) dehydrogenated at $C_{(7)}-C_{(8)}$. The introduction of an additional double bond into the cholesterol molecule is achieved by different methods: by the oxidisation of a cholesterol ester to the 7-oxo-derivative and then by reduction, benzoylation, and elimination of benzoic acid from 7-hydroxycholesterol 3,7-dibenzoate[41-42]; the formation of the tosylhydrazone from the 7-oxo-derivative by the Bamford–Stevens reaction has been described. It is subsequently converted into the provitamin on interaction with LiH.[43] The method involving the allylic bromination of the cholesterol ester (IIb) with subsequent dehydrobromination of the 7-bromo-derivative (III) and the hydrolysis of the 7-dehydrocholesterol ester (IVb) to 7-dehydrocholesterol (IVa) is most widely used[44]:

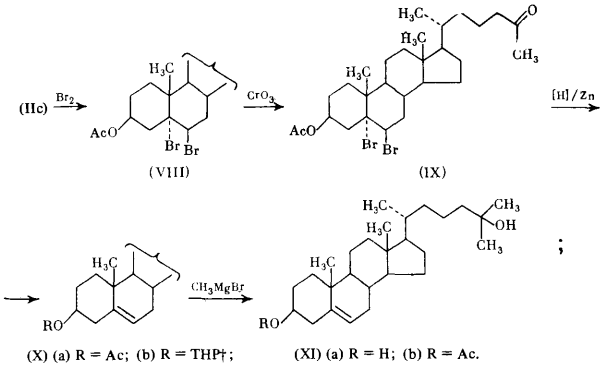


The allylic bromination of cholesterol esters (usually the benzoates) is carried out with 1,3-dibromo-5,5-dimethylhydantoin in a benzene-petroleum ether mixture[45] or in CCl_4 in the presence of radical initiators[46,47]. The yield of compound (III) reaches 92–94%.[47] Depending on the dehydrobrominating agents and the reaction conditions, the dehydrobromination of (III) can lead to the formation, apart from the required $\Delta^{5,7}$-diene (IVb), also of other cholestadienes (the $\Delta^{4,6}$-, $\Delta^{5,8(9)}$-, $\Delta^{6,8(14)}$-, and $\Delta^{8,14}$- derivatives) and cholestatrienes (the $\Delta^{2,4,6}$- and $\Delta^{4,6,8(14)}$- derivatives). The maximum yield of the $\Delta^{5,7}$-diene (up to 60%) was obtained on dehydrobromination in boiling xylene with various organophosphorus compounds (trialkyl phosphites and dioxaphospholans)[45,48-50] as well as $NaHCO_3$ in the presence of catalytic amounts of α-picoline[46,51]. The main side product under these conditions is the $\Delta^{4,6}$-diene.

Provitamins derived from cholecalciferol are usually synthesised in accordance with the above scheme, but in certain cases it is impossible to introduce the double bond at $C_{(7)}-C_{(8)}$ by the methods described or the yield of provitamins is very low[23,52,53]. Certain new methods for the introduction of conjugated double bonds into the B ring, which will be considered directly in connection with the synthesis of hydroxylated cholecalciferols, have therefore been proposed[54-56].

The photochemical isomerisation of provitamins D is accompanied by the dissociation of the $C_{(9)}-C_{(10)}$ bond and the opening of the B ring with the formation of the direct precursor of vitamins D—previtamin D (V). When the previtamin is irradiated with ultraviolet light, two photoisomers are formed—lumisterol (VI) and tachysterol (VII), while thermal isomerisation leads to the formation of vitamins D (I). The mechanism of these reversible transformations, which is nowadays generally accepted, was established by the studies of Velluz and coworkers[57] and Havinga and coworkers[58-60] over a period of many years.

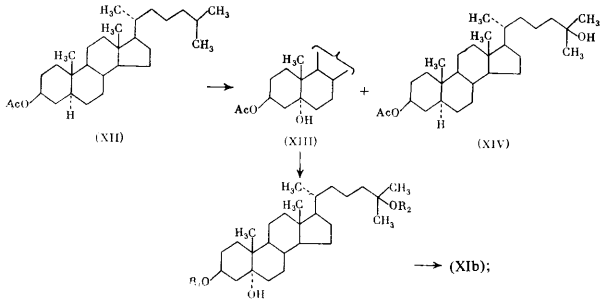
The photochemical isomerisation of provitamins D is usually carried out in solution in ethanol, ether, benzene, and other solvents up to not more than 50% conversion, in order to reduce the accumulation of side products—tachysterol and lumisterol. The yield of the previtamin is a maximum when unfiltered ultraviolet light at $\lambda = 295$ nm [61] or erythemal lamps E-3 phosphor (transmission maximum at 302–305 nm) [62] are used:



III. THE SYNTHESIS OF 25-HYDROXYCHOLECALCIFEROL

The chemical synthesis of 25-hydroxycholecalciferol was achieved by Blunt and DeLuca[63,64] to confirm the structure of the active vitamin D_3 metabolite isolated from blood plasma, and Haltes and van Vliet[65] obtained for the first time crystalline 25-OHD_3 in the form of the monohydrate.

The main difficulty in the synthesis of 25-OHD_3 is the formation of the key compound—25-hydroxycholesterol. Numerous studies on the synthesis of this compound, differing mainly in the starting material, have therefore been published in recent years. 25-Hydroxycholesterol is converted into 25-OHD_3 as described in Section II.

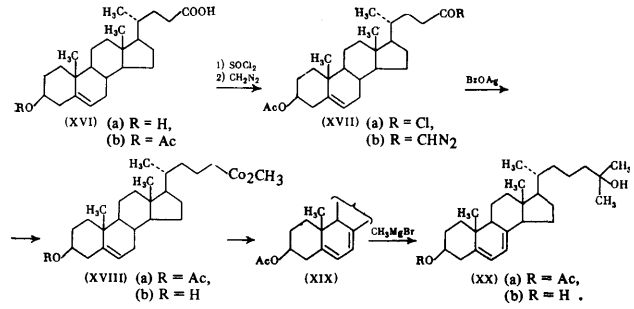


1. Synthesis from Cholesterol and Cholestanol

25-Hydroxycholesterol is formed in a small amount in the autoxidation or photolysis of cholesterol together with other hydroxylated derivatives[66,67]. DeLuca and coworkers[63,64] and Halkes and van Vliet[65] synthesised 25-hydroxycholesterol from cholesterol by the method described as early as 1950.[68–70] The bromination of cholesteryl acetate (IIc), the oxidation of the dibromide (VIII) with CrO_3 in acetic acid to the 27-nor-25-oxo-derivative (IX), and treatment of the latter with zinc dust in acetic acid lead to 25-oxo-27-norcholest-5-en-3β-yl acetate (Xa). The reaction with methylmagnesium bromide yields the 3β-acetate of 25-hydroxycholesterol (XIb). However, the yields of (Xa) and (XIb) are very insignificant.

(X) (a) R = Ac; (b) R = THP†; (XI) (a) R = H; (b) R = Ac.

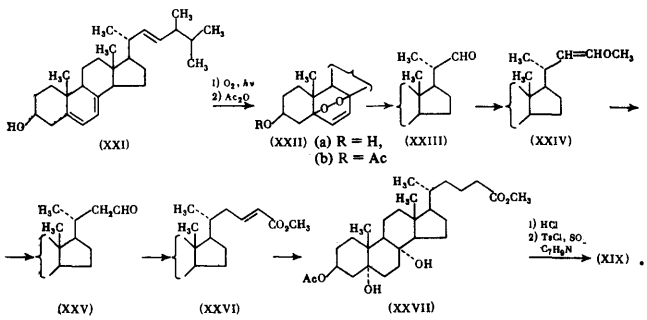
On irradiating cholestan-3β-yl acetate (XII) ultraviolet light at $\lambda = 300$ nm in acetic acid + hydrogen peroxide solution, Rotman and Mazur[71] obtained 37.5% yield of the 25-hydroxy-derivative (XIV) and a 30% yield of the 5α-hydroxy-derivative (XIII). On further irradiation of compound (XIII), the 3β-acetate of cholestane-3β, 5α, 25-triol (XVa) is formed, giving rise to the 3β-acetate (XIb) after acetylation and treatment of the diacetate (XVb) with a mixture of acetic acid and toluene-*p*-sulphonic acid and hydrolysis:



(XV) (a) R_1 = Ac, R_2 = OH; (b) $R_1 = R_2$ = Ac.

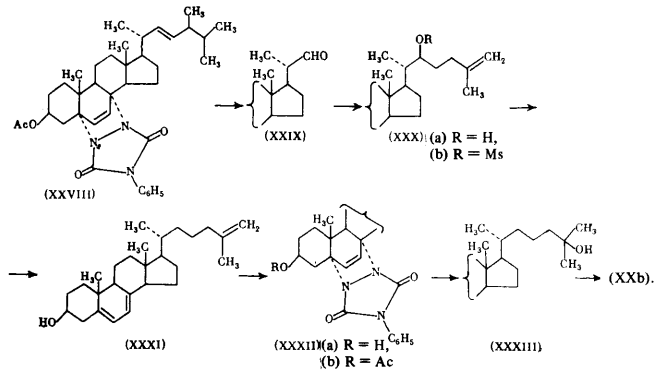
2. Synthesis from 3β-Hydroxychol-5-enoic Acid

3β-Hydroxychol-5-enoic acid (XVIa), which is a relatively readily available substance formed on oxidation of the cholesterol side chain, has been used[72,73] to synthesise the provitamin 25-OHD_3. The acid (XVIa) was converted via the 3β-acetate (XVIB) and the acid chloride (XVIIa) into the diazoketone (XVIIb) and then into the 25-homoester (XVIIIa) on interaction with silver benzoate. After these transformations in the side chain, the 5,7-diene (XIX) was obtained by the usual method involving allylic bromination and dehydrobromination. The synthesis of the provitamin–cholesta-5,7-diene-3β, 25-diol (XXb)—is completed by the reaction



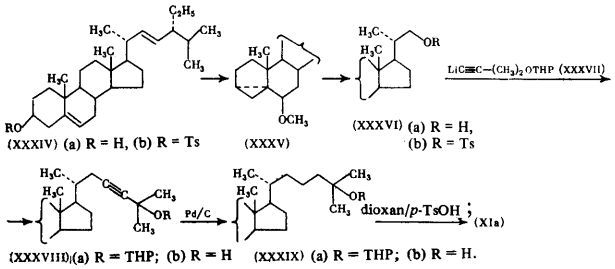
† THP = tetrahydropyranyl ether.

with methylmagnesium bromide and hydrolysis:

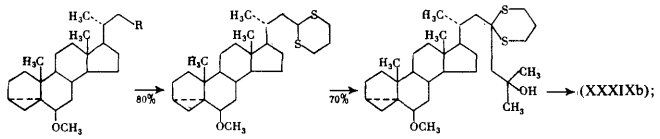


3. Synthesis from Ergosterol

The 5,7-diene (XIX) has been obtained[74-77] by the transformation of the ergosterol side chain. The photosensitised addition of oxygen to ergosterol (XXI) leads to the peroxide (XXIIa), while the cleavage of the double bond in the side chain by the ozonolysis of the acetate (XXIb) yields the aldehyde (XXIII). The growth of the side chain was achieved by condensation with triphenylmethoxymethylenephosphorane to the methyl ether (XXIV), which gives rise to the aldehyde (XXV) after hydrolysis with formic acid. On treatment with triphenylmethoxycarbonylmethylenephosphorane, the aldehyde is converted into a mixture of the *trans*- and *cis*-isomers of the methyl esters of 3β-acetoxy-5,8-epidihydroxyhomochola-6,23-diene-25-ioc acid (XXVI). The methyl ester of the *trans*-acid was hydrogenated in the presence of palladium and the dehydration leading to the formation of compound (XIX) was carried out without isolating the triol acetate (XXVII). The conversion of the ester (XIX) into 25-OHD_3 was described above[72,73]:

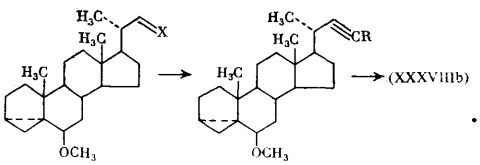


A more convenient pathway from ergosterol to the 25-hydroxy-provitamin (XXb) has been proposed by Eyley and Williams[56,78]. The adduct of the ergosteryl acetate and 4-phenyl-1,2,4-triazoline-3,5-dione (XXVIII) was obtained by the method of Barton et al.[79] and was converted into the aldehyde (XXIX) by ozonolysis. The reaction of compound (XXIX) with the Grignard reagent obtained from 4-chloro-2-methylbut-1-ene in tetrahydrofuran (THF) at 30 °C gave the alcohol (XXXa), which gave rise to the trienol (XXXI) after conversion into the methanesulphonate (XXXb) and reduction with $LiAlH_4$. The 5,7-double bonds were again protected via the adduct (XXXIIa) and the acetylation of the latter, the oxidation of the diene (XXXIIb) with $Hg(OAc)_2$ to the 25-hydroxy-derivative (XXXIII), and reduction with $LiAlH_4$ gave compound (XXb):



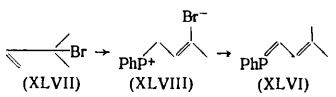
4. Synthesis from Stigmasterol

The synthesis of compound (XIa) from stigmasterol (XXXIVa), which is a fairly readily available plant sterol obtained from soya beans, is also based on the cleavage of the double bond in the side chain. Partridge and coworkers[80,81] achieved this cleavage in the following way. The 5,6-double bonds of stigmasterol were initially protected by the formation of the *i*-methyl ester (XXXV), which is achieved by treating the toluene-*p*-sulphonate (XXXIVb) with methanol and pyridine. The *i*-methyl ester (XXXV) was ozonised at -78 °C and then reduced with sodium bis-(2-methyoxyethoxy)aluminium hydride to the alcohol (XXXVIa), which was converted into the crystalline toluene-*p*-sulphonate (XXXVIb). Alkylation of the latter with lithium acetylide (XXXVII) (obtained from n-butyl-lithium and 3-methyl-1-but-3-ynyl tetrahydropyranyl ether) gave a 90% yield of compound (XXXVIIIa). The acetylenic bond in (XXXVIIIa) was hydrogenated over PtO_2 or Pd/C and compound (XXXIXa) was isolated in quantitative yield. The authors then propose several versions of the synthesis of compound (XIa). One of these involves the conversion of compound (XXXIXa) into the alcohol (XXXIXb), which, on treatment with aqueous dioxan in the presence of catalytic amounts of toluene-*p*-sulphonic acid, gave compound (XIa). The overall yield of compound (XIa) was 30% with respect to stigmasterol.



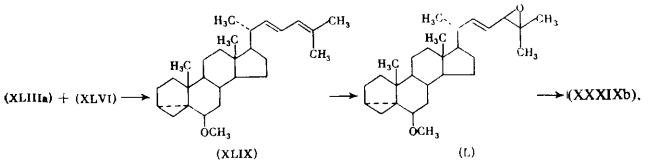
By the reaction of the bromide (XLa) or the iodide (XLb), obtained by Partridge et al.[80] from the alcohol (XXXVIa), with 2-lithiodithian, Salmond and Maisto[82] obtained the dithioacetal (XLI), which gives rise to the alcohol (XLII) after treatment with n-butyl-lithium and subsequent condensation with 1,2-epoxy-2-methylpropanol. When the alcohol (XLII) is refluxed with $LiAlH_4$ + $TiCl_4$ in THF, compound (XXXIXb)

is obtained:



(XL) (a) R = Br; (b) R = I. (XLI) (XLII)

Salmond et al.[83] also used the aldehyde (XLIIIa) [obtained by the ozonolysis of compound (XXXV)], which, on reaction with dibromomethylenetriphenylphosphorane, gives a high yield of 20*R*-dibromovinylpregnane (XLIIIb). Treatment of the dibromo-olefin with n-butyl-lithium at -68 °C leads to the lithio-derivative (XLIV), from which 20*R*-ethynylpregnane (XLV) was obtained by hydrolysis. Its interaction with 1,2-epoxy-2-propanol in the presence of hexamethylphosphoramide results in the formation of the alcohol (XXXVIIIb) in 70% yield. The hydrogenation of the acetylenic bond over PtO_2 results in the formation of the alcohol (XXXIXb):

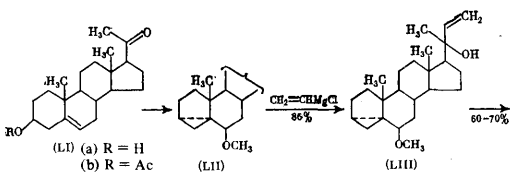


(XLIII) (a) X = O, (XLIV) R = Li
(b) X = CBr_2 (XLV) R = H

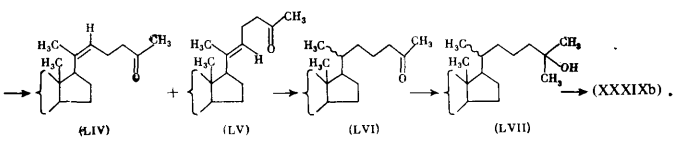
Salmond and Sobala[84] recently proposed a still simpler procedure for the formation of compound (XXXIXb) from stigmasterol with an overall yield in excess of 50%. Although the total number of stages was 7, as in the work of Partridge et al.[80], it was necessary to isolate and crystallise the reaction products only three times, which greatly simplifies the synthesis. The first three stages, namely the conversion of stigmasterol into the toluene-*p*-sulphonate (XXXIVb) and the *i*-methyl ester (XXXV) and ozonisation to the aldehyde (XLIIIa), were described above. In order to introduce the side chain, the diene (XLVI) was synthesised from the bromide (XLVII) via the salt (XLVIII):

(XLVII) (XLVIII) (XLVI)

The condensation of the aldehyde (XLIIIa) with (XLVI) yields the diene (XLIX):



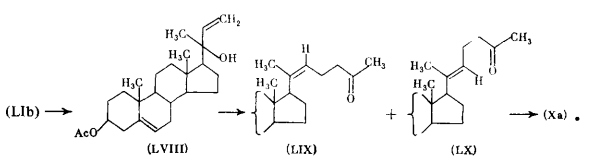
(XLIX) (L)



Next the Δ^{24}-double bond was selectively epoxidised with peracetic acid and the epoxide (L) was obtained; it was reduced over Pd/C to compound (XXXIXb) in 56% yield with respect to (XXXIVb). When the *i*-ester (XXXIXb) is refluxed in acetic acid, compound (XIb) is formed in 94% yield.

5. Synthesis from Pregnenolone

Narwid and coworkers[85,86] used a commercial product—pregnenolone (LIa)—and its acetate (LIb) to synthesise 25-hydroxycholesterol. As in the case of stigmasterol, the 5,6-double bonds in compound (LIa) were first protected by conversion into the *i*-steroid (LII), which gives rise to the allyl alcohol (LIII) after reaction with vinylmagnesium chloride. Next the side chain was lengthened to 7 carbon atoms by treating the alcohol (LIII) with an excess of diketen, giving a 1 : 2 mixture of the *cis*- and *trans*-oxo-isomers (LIV) and (LV), which was reduced over PtO_2 to a mixture of saturated ketones (LVI). After treating the latter with CH_3MgI, a mixture of alcohols (LVII) was obtained. The natural 20*R*-isomer (XXXIXb) was separated by crystallisation and obtained in 26% yield, from the alcohol (LIII). The overall yield of 25-hydroxycholesterol with respect to pregnenolone was 17%:

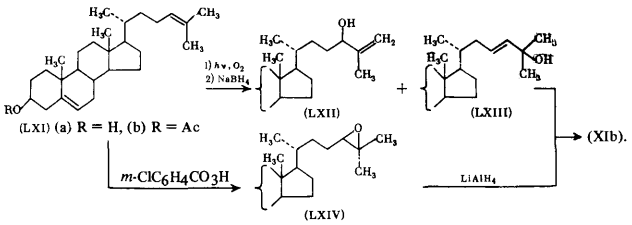


(LI) (a) R = H (LII) (LIII)
(b) R = Ac

(LIV) (LV) (LVI) (LVII)

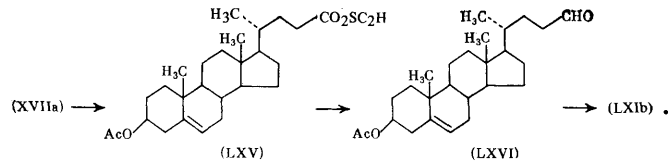
Compound (XIa) can be synthesised from the acetate of pregnenolone (LIb) without the preliminary protection of the 5,6-double bond. For this purpose, the alcohol (LVIII) was obtained from the acetate (LIb) and vinylmagnesium chloride[85]. The side chain was lengthened by interaction with diketen. A mixture of the *cis*- and *trans*-keto-olefins (LIX) and (LX) was obtained with an overall yield of 72%. Catalytic hydrogenation of this mixture over PtO_2 leads to the 20*R*-ketone (Xa). (Xa) was converted into (XIa) in 88% yield by the Grignard reaction with subsequent hydrolysis of the ester. The overall yield of compound (XI) with respect to compound (LIb) was 25–28%:

(LVIII) (LIX) (LX)



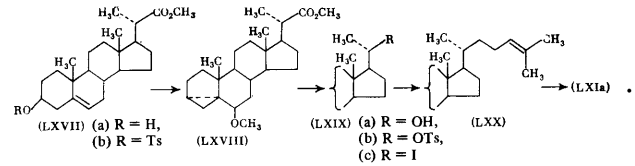
6. Synthesis from 3β-Hydroxyandrost-5-en-17-one

The stereospecific synthesis of 25-hydroxycholecalciferol from 3β-hydroxyandrost-5-en-17-one has been described[87]. Although the overall yield is 42%, the authors carried out more than 10 transformations in order to introduce the cholesterol side chain with the 25-hydroxy-group.



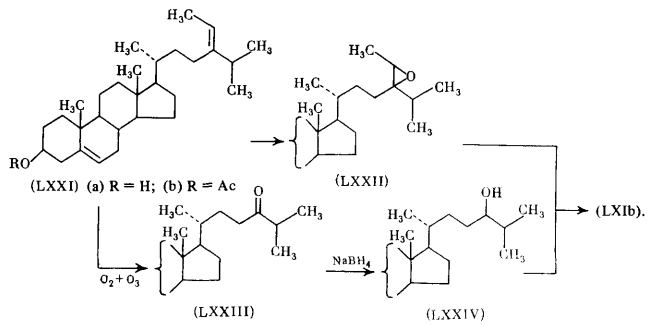
7. Synthesis from Desmosterol

A series of investigations by Japanese workers on the synthesis of active forms of vitamin D was published in 1973[88-92]. Desmosterol (LXIa), the structure of which is very convenient for the introduction of a hydroxy-group at $C_{(25)}$ by various methods, was chosen as the starting material.



When a solution of desmosteryl acetate (LXIb) [88] was irradiated with sunlight in isopropyl alcohol in the presence of a sensitiser and the unpurified product was reduced with $NaBH_4$, two substances were obtained—the 3β-acetates of cholesta-5, 25-diene-3β,24-diol (LXII) (25%) and cholesta-5,23-diene-3β, 25-diol (LXIII) (35%). The catalytic hydrogenation of the latter over Pd/C gives compound (XIb) in 60% yield. Another way of obtaining compound (XIb) from (LXIb) involves the selective epoxidation of the double bond at $C_{(24)}$–$C_{(25)}$ in *m*-chloroperbenzoic acid with formation of the 24,25-monoepoxide (LXIV), which is then reduced with $LiAlH_4$ to compound (XIb) with an overall yield of 50%. Finally, the third and most convenient method of synthesis of compound (XI) involves the treatment of compound (LXIb) with $Hg(OAc)_2$ or HgBr followed by reduction with $NaBH_4$. After chromatographic purification on silica gel, compound (XIb) is obtained in 85% yield. This is apparently the simplest and most effective method of synthesising 25-hydroxycholesterol among all those described.

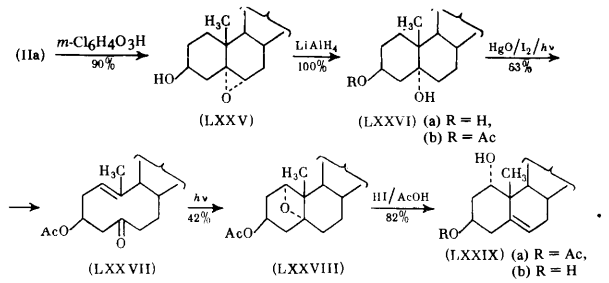
Since desmosterol proved to be a very convenient starting material for the synthesis not only of 25-OHD_3 but also of other active vitamin D_3 metabolites, numerous studies have now been carried out on its preparation[94–99]. The Wittig synthesis of desmosterol from the acetate of 3β-hydroxycholest-5-enoic acid (XVIb) has been described[100]. The acid was converted into the chloride (XVIIa), the condensation of which with ethanethiol gave ethyl thiocholenoate (LXV), which was converted into the aldehyde (LXVI) by treatment with Raney nickel, and finally the reaction with the Wittig reagent gave compound (LXIb):



3β-Hydroxybisnorchol-5-enoic and 3β-hydroxynorchol-5-enoic acids can also serve as the starting materials for the synthesis of compound (LXIa).[94] The methyl ester (LXVIIa) was converted into the toluene-*p*-sulphonate (LXVIIb) and then into the *i*-ester (LXVIII), which was reduced with $LiAlH_4$ and converted into the 22-toluene-*p*-sulphonate (LXIXb) without isolating the alcohol (LXIXa). The reaction of the toluene-*p*-sulphonate with NaI gave the corresponding iodide (LXIXc):

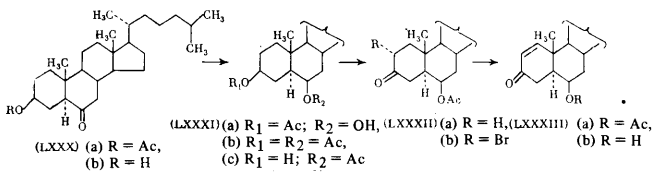
Next the iodide was converted by treatment with π-(dimethylallyl)nickel bromide into the desmosterol *i*-ester (LXX), whose treatment with $HClO_4$ gave desmosterol (LXIa) in an overall yield of 20%. Bergmann and Dusza[96] obtained demosterol from 25-oxocholesterol.

Japanese workers[97–99] developed several methods for the preparation of demosterol from fucosterol (LXXIa), the principal sterol in brown algae[101,102]. Fucosteryl acetate (LXXIb) was oxidised with *m*-chloroperbenzoic acid to the 24,28-epoxide (LXXII) and, after treatment of the latter with BF_3. .($SnCl_4$, $AlCl_3$), desmosteryl acetate was obtained in 30% yield. When the 24,28-epoxide was treated with silica gel, a zeolite, and other Lewis acids, the yield of compound (LXIb) was 40%.[99] Fucosteryl acetate was converted into compound (LXIb) via the ketone obtained by the ozonolysis of compound (LXXIb) with a $O_3 + O_2$ mixture in CH_2Cl_2 at -78 °C after its reduction to the alcohol (LXXIV) and dehydration of the latter latter by P_2O_5 in benzene:



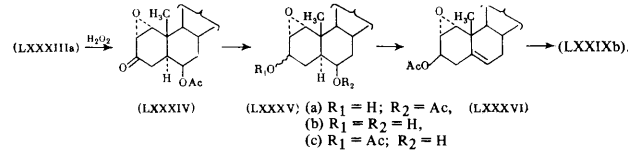
Other methods for the introduction of a hydroxy-group at $C_{(25)}$ are also known[103–105], but unfortunately they all involve many stages and give fairly low yields.

IV. THE SYNTHESIS OF 1α-HYDROXYCHOLECALCIFEROL

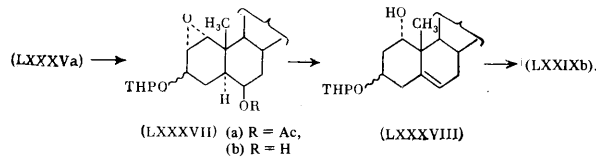


The high biological activity of 1α-hydroxycholecalciferol, comparable to that of 1α, 25-$(OH)_2D_3$,[16–22] and its simpler synthesis, involving the transformation of only the A ring, make this compound the most promising synthetic analogue of 1α, 25-$(OH)_2D_3$—the active hormonal form of vitamin D_3. During the last few years, numerous reports of the synthesis of 1α-OHD_3 have therefore been published.

As in the case of 25-OHD_3, the most complex feature of the synthesis of 1α-OHD_3 is the formation of the 1α-hydroxy-derivative of cholesterol, which is converted into 1α-OHD_3 by the usual methods. 1α-Hydroxycholesterol has been obtained[106] in a study of the photochemical cyclisation of 5,10-seco-steroids together with other products in a fairly low overall yield. At that time the authors' aim was not the development of a 1α-hydroxylation method, which is so necessary for the synthesis of 1α, 25-$(OH)_2D_3$ and 1α-OHD_3. In 1977 Mihailović et al.[107] improved the method of synthesis of 1α-hydroxycholesterol via the seco-derivative and proposed a fairly simple method with an overall yield of approximately 20%. Cholesterol (IIa) was oxidised with *m*-chloroperbenzoic acid to give a 90% yield of the 5α, 6α-epoxide (LXXV), which was reduced quantitatively with $LiAlH_4$ to the 3β, 5α-diol (LXXVIa) and the latter was converted into the 3β-acetate (LXXVIb). Treatment of the acetate with HgO, I_2, and ultraviolet light gave a 63% yield of the 3β-acetate of 5,10-seco-cholest-1(10)-en-5-one (LXXVI), whose photochemical cyclisation gives compound (LXXVIII)(42%). Treatment of compound (LXXVIII) with HI led to an 82% yield of the 3β-acetate of 1α-hydroxy-

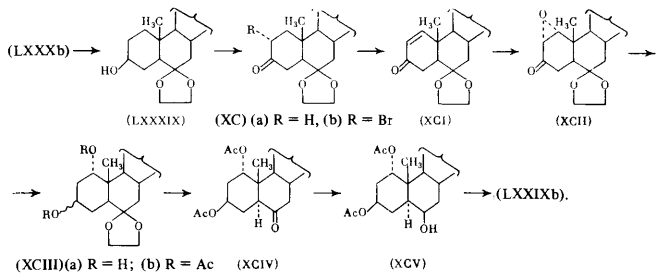


cholesterol (LXXIXa):

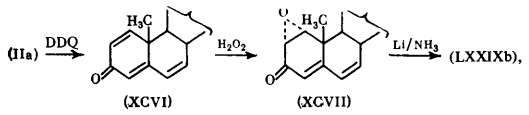


The first study on the specific synthesis of 1α-hydroxycholesterol (LXXIXb) was carried out in 1970 by Pelc and Kodicek[108], who detected, in the study of the metabolism of [1-^{3}H] vitamin D_3, a metabolite with a deficiency of radioactive hydrogen and more polar than 25-OHD_3, probably as a result of the incorporation of an additional oxygen atom at $C_{(1)}$;[109,110] an attempt was therefore made to synthesise the 1α-hydroxy-analogue of vitamin D_3. These workers began with 6-oxo-5α-cholestan-3β-yl acetate (LXXXa), which can be readily obtained from cholesteryl acetate by nitration and subsequent reduction of the nitro-compound and hydrolysis. The 6-oxo-derivative (LXXXa) was reduced with $NaBH_4$ to the 6β-hydroxy-derivative (LXXXIa) in a high yield and the latter was then acylated to the 3β,6β-diacetate (LXXXIb), which was converted by mild aklakine hydrolysis into the 6β-acetate (LXXXIc):

The oxidation of the 3β-hydroxy-group to the carbonyl group with sodium dichromate in acetic acid and then bromination of the ketone (LXXXIIa) with bromine and treatment of the 2α-bromo-derivative (LXXXIIb) with $CaCO_3$ in dimethylformamide (DMF) gave the 6β-acetate (LXXXIIIa). Hydrolysis of the 6β-acetate gave 6β-hydroxy-5α-cholest-1-en-3-one (LXXXIIIb). Pelc and Kodicek were unable to complete the synthesis of 1α-hydroxycholesterol[111], but the ketone (LXXXIIIb) which they synthesised was used by other investigators as the starting material for the preparation of compound (LXXIXb). By oxidising compound (LXXXIIIa) with 35% H_2O_2, Morisaki and coworkers[89,112] obtained in 1973 the 1α, 2α-epoxide (LXXXIV). The reduction of the keto-group with $NaBH_4$ led to a 4 : 1 mixture of the epimeric 3β- and 3α-alcohols (LXXXVa) and, after hydrolysis, a mixture of the epimeric diols (LXXXVb). Chromatographic separation and acetylation with half an equivalent of acetic anhydride led to the isolation of the 3β-acetate (LXXXVc) in an overall yield of 24% with respect to the initial compound (LXXXIIIa). The dehydration of the 3β-acetate (LXXXVc) with $POCl_3$ gives a 75% yield of the Δ^5-olefin (LXXXVI), whose reduction with $LiAlH_4$ leads to the formation of compound (LXXIXb):

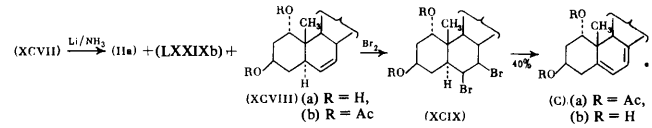


Furst et al.[113] carried out an analogous synthesis of compound (LXXIXb), but the starting material was the ketone (LXXXIIIb), the provitamin and 1α-OHD_3 being obtained in a crystalline form. The conversion of compound (LXXXVa) into (LXXIXb), without the isolation of intermediates and with an overall yield of 30% has been described[89]: compound (LXXXVa) was converted into the tetrahydropyranyl ether (LXXXVIIa), which was hydrolysed to compound (LXXXVIIb). Dehydration with $POCl_3$ and subsequent reduction with $LiAlH_4$ gave a mixture of the 3β- and 3α-tetrahydropyranyl ethers (LXXXVIII), whose hydrolysis led to compound (LXXIXb):

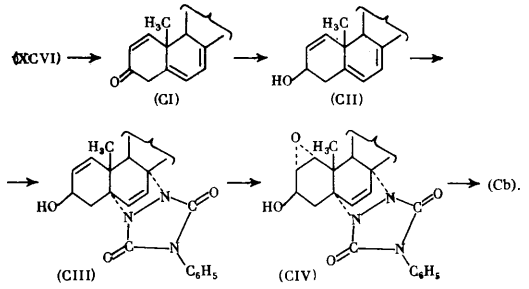


Yet another method of synthesis of 1α-OHD_3 was proposed by Morisaki et al.[114], but the overall yield of the final product was not more than 1%.

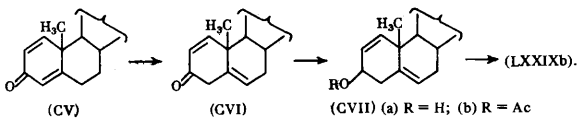
The method for the introduction of the 1α-hydroxy-group used by DeLuca and coworkers[16,115,116] in the synthesis of 1α-OHD_3 and 1α, 25-$(OH)_2D_3$ involves a fairly large number of transformations in the A and B rings and consists in the conversion of cholesterol into the 6-oxo-derivative (LXXXb), its treatment with diketen, and the formation of 6-ethylenedioxy-5α-cholestan-3β-ol (LXXXIX). The 3β-hydroxy-group is then oxidised to the carbonyl group [compound (XCa)] by CrO_3 in pyridine and the ketone is brominated with bromine to give the 2α-bromo-derivative (XCb). The dehydrobromination of the latter with *sym*-collidine gives the Δ^1-diene (XCI). The conversion of the diene (XCI) to the epoxide (XCII) and the reduction of the latter with $LiAlH_4$ lead to a mixture of the 3α- and 3β-epimers of the 1α, 3-diol (XCIIIa) and, after acetylation, to a mixture of the 1α, 3-diacetates (XCIIIb). Mild acid hydrolysis yields the ketone (XCIV), whose reduction with $NaBH_4$ gives rise to the 1α, 3-diacetate of the triol (XCV); the dehydration of the latter with $POCl_3$ and hydrolysis lead to 1α-hydroxycholesterol:



A fairly simple method of synthesis of 1α-OHD_3 has been proposed by Barton and coworkers[17,117]. By dehydrating cholesterol (IIa) with dichlorodicyanobenzoquinone (DDQ),[118] the authors obtained the trienone (XCVI),[119] which was converted by treatment with alkaline hydrogen peroxide[120] into 1α, 2α-epoxycholesta-4,6-diene-3-one (XCVII) with an overall yield of 45%. Treatment of the epoxide (XCVII) with a large excess of metallic lithium in a 1 : 1 NH_3–THF mixture or with sodium in ammonia[121] leads to 1α-hydroxycholesterol in 60% yield. The overall yield with respect to cholesterol is 27%.



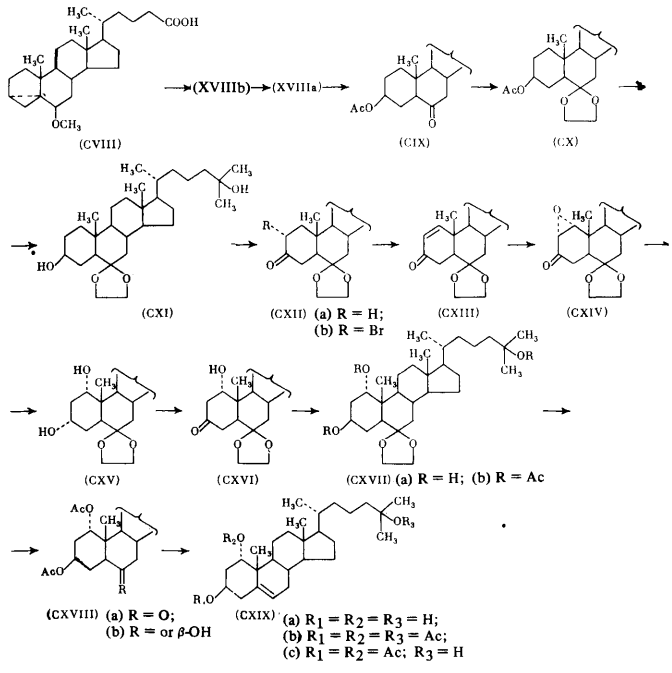
The conversion of 1α-hydroxycholesterol into the provitamin 1α-OHD_3,



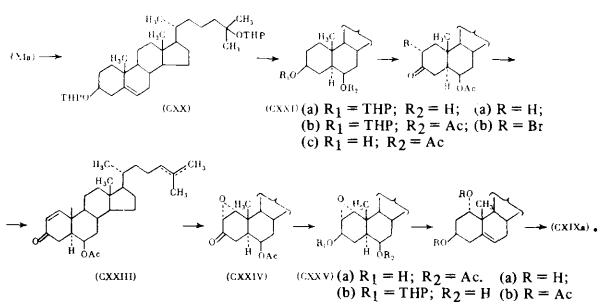
by the usual methods (bromination–dehydrobromination) involves low yields of the $\Delta^{5,7}$-diene. Methods have therefore been developed for the direct synthesis of the provitamin 1α-OHD_3. Mazur and coworkers[54] modified somewhat the method of Barton et al.,[17] in the reduction of the epoxydienone (XCVII) with lithium in liquid ammonia and obtained a mixture of three products: cholesterol (IIa) (15%), 1α-hydroxycholesterol (LXXIXb) (20%), and 5α-cholest-6-ene-1α, 3β-diol (XCVIIIa). The latter was acetylated to the diacetate (XCVIIIb), and brominated with bromine to the diaxial dibromide (XCIX), which was dehydrobrominated to the provitamin (Ca):

The provitamin (Cb) was obtained by Kaneko and coworkers[55,122,123], who used the familiar deconjugation reaction to isomerise the 1,4,6-trienone (XCVI), obtained by the method of Barton et al.[17], to the 1,5,7-trienone (CI) with potassium t-butoxide in dimethyl sulphoxide (DMSO) and then reduced it to the 3β-hydroxy-derivative (CII) with $Ca(BH_4)_2$. After protecting the 5,7-double bonds by forming the cyclic 1,4-adduct (CIII) with 4-phenyl-1,2,4-triazoline-3,5-dione[79], the epoxide (CIV) was obtained by oxidation with *m*-chloroperbenzoic acid. Its reduction with $LiAlH_4$ leads to compound (Cb):

Kaneko et al.[124] used the isomerisation reaction to convert cholesta-1,4-dien-3-one (CV) into the 1,5-dienone (CVI), which was then reduced with $NaBH_4$ or (better) with $Ca(BH_4)_2$ to the 3β-hydroxy-derivative (CVIIa). Hydroboration with B_2H_2 and oxidation with alkaline H_2O_2 give a low yield (10–15%) of compound (LXXIXb). A somewhat higher yield of this compound was obtained by treating the 3β-acetate (CVIIb) with HgO in the presence of trifluoroacetic acid and then reducing with $NaBH_4$:[125,126]

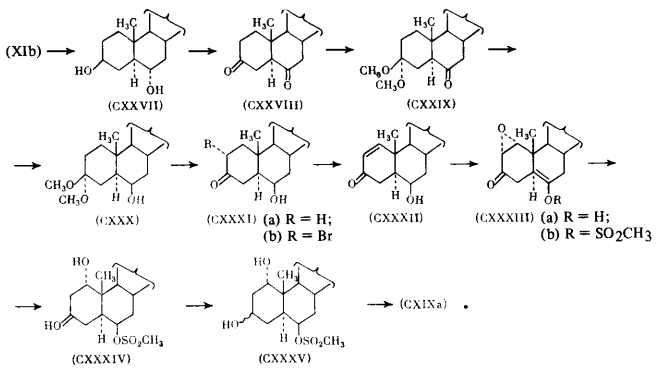


Harrison et al.[127,128] achieved the total synthesis of 1α-OHD_3 in 1973.

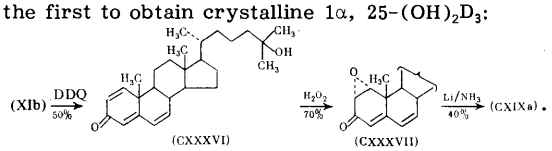


V. THE SYNTHESIS OF 1α,25-DIHYDROXYCHOLECALCIFEROL

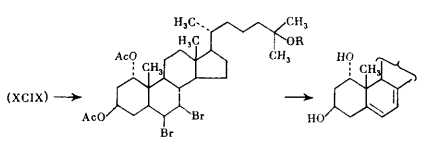
The synthesis of 1α, 25-$(OH)_2D_3$, the active hormonal form of vitamin D_3, which involves the introduction of two hydroxy-groups into the molecule of vitamin D_3, still remains fairly complex. All the methods for the introduction of the 1α- and 25-hydroxy-groups described above can be used in the synthesis of 1α, 25-$(OH)_2D_3$. However, the hydroxy-groups are not always introduced consecutively; this usually involves simultaneous transformations in the A and B rings and in the side chain, which leads to the synthesis of new and hitherto unknown intermediates.



The synthesis of 1α, 25-$(OH)_2D_3$ by DeLuca and coworkers[115], who were the first to obtain this metabolite in 1971, was based on the conversion of the methyl ester of isohomocholanoic acid (CVIII) into a derivative of cholenoic acid (XVIIIb) by esterification with diazomethane and subsequent acid hydrolysis. After nitration, reduction, and acid hydrolysis, the acetate (XVIIIa) was converted into the ketone (CIX) and after the protection of the keto-group, the 25-hydroxy-derivative (CXI) was obtained via the ketal (CX) by the Grignard reaction. The oxidation of the 25-hydroxy-derivative with CrO_3 gives the 3-oxo-derivative (CXIIa), which is converted via the 2α-bromo-derivative (CXIIb) into the Δ^1-compound (CXIII). Its treatment with H_2O_2 leads to the 1α, 2α-epoxide (CXIV), whose reduction with $LiAlH_4$ yields the 1α, 3α-diol (CXV). In order to obtain the required 1α, 3β-diol, compound (CXV) was subjected to selective oxidation with *N*-bromosuccinimide, which gave the 3-oxo-derivative (CXVI), whose reduction with $NaBH_4$ led to the 1α, 3β-isomer (CXVIIa), which was then converted into the triacetate (CXVIIb) and then by mild acid hydrolysis into the 6-oxo-derivative (CXVIIIa). The reduction by $NaBH_4$ to compound (CXVIIIb) and dehydration of the 6-hydroxy-derivative with $POCl_3$ led to the triacetate of 1α, 25-dihydroxycholesterol (CXIXb), which was converted into 1α, 25-$(OH)_2D_3$ in the usual way:



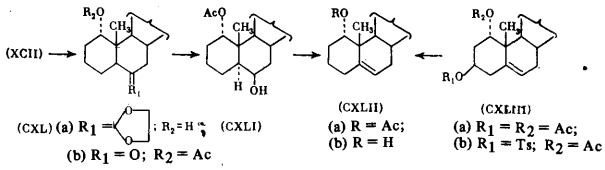
The syntheses of 1α, 25-dihydroxycholesterol described by Japanese workers are similar multistage processes[90,120,130]. One of them consists in the successive treatment of the dihydropyranyl ether (CXX), synthesised from 25-hydroxycholesterol (XIa), with B_2H_6 and H_2O_2 to form the 6-hydroxy-derivative (CXXIa) and then the acetate (CXXIb), whose hydrolysis led to the 3β, 25-diol (CXXIc). Its oxidation with CrO_3 gave the 6β-acetate of 6β, 25-dihydroxy-5α-cholestan-3-one (CXIIa) in an overall yield of 52% with respect to compound (XIa). The 1α-hydroxy group was introduced into compound (CXXIIa) by bromination to the 2α-bromo-derivative (CXXIIb) followed by dehydrobromination to give a mixture of the $\Delta^{1,24(25)}$- and $\Delta^{1,25(26)}$-dienes (CXXIII). The conversion into the 1α-hydroxy-derivative was achieved via the epoxykentone (CXXIV), the alcohol (CXXVa), and the tetrahydropyranyl ether (CXXVb). The dehydration of the latter and alkaline hydrolysis gave the 1α, 3β-diol (CXXVIa). The 25-hydroxy-group was introduced by treating the acetate (CXXVIb) with $Hg(OAc)_2$ and reducing with $NaBH_4$. The hydrolysis of the 1α, 3β-diacetate (CXIXc) gave 1α, 25-dihydroxycholesterol (CXIXa):



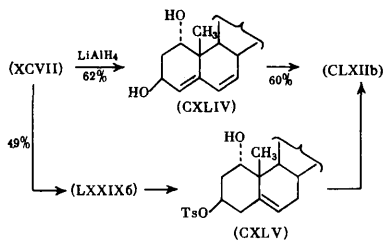
The synthesis of 1α, 25-dihydroxycholesterol from 25-hydroxycholesterol, involving transformations in the A and B rings only to give an 18% yield with respect to 25-hydroxycholesteryl acetate (XIb), has been achieved[131-133]. The hydroboration of (XIb) with diborane followed by treatment with alkaline H_2O_2 gives a mixture of alcohols, among which the main product is the triol (CXXVII). The unpurified mixture of alcohols was oxidised with the Jones reagent ($CrO_3 + H_2SO_4 + H_2O$) to the diketone (CXXVIII) with an overall yield of 74%. In order to convert the 6-oxo-group into the β-hydroxy-group, required for the subsequent introduction of the Δ^5-double bond, the 3-oxo-group in compound (CXXVIII) was converted into the dimethoxy-group in compound (CXXIX) and the latter was then reduced with $NaBH_4$ to the 6β-hydroxy-derivative (CXXX), whose hydrolysis gave the hydroxyketone (CXXXIa). The bromination of the latter to 2α-bromoketone (CXXXIb) followed by dehydrobromination led to the introduction of the Δ^1-double bond. Treatment of compound (CXXXII) with alkaline H_2O_2 gave the epoxyketone (CXXXIIIa). Next the 6β-hydroxy-group was protected by conversion into the methanesulphonate (CXXXIIIb) and the epoxy- compound was cleaved with aluminium amalgam to give the 1α-hydroxyketone (CXXXIV). Its reduction with $NaBH_4$ to a mixture of epimeric 3-hydroxy-derivatives (CXXXV), treatment of the mixture with $LiCO_3$ in DMF, and chromatographic separation of the epimers made it possible to isolate the pure compound (CXIXa):

Using the methods described above for the introduction of the 1α- and 25-hydroxy-groups, Japanese workers[91] achieved the synthesis of 1α, 25-$(OH)_2D_3$ from fucosterol. Fucosterol (LXXI) was converted into desmosterol (LXIb) via the ketone (LXXIII) in 45% yield. After treatment with $Hg(OAc)_2$ and then $NaBH_4$, the 3β-acetate of 25-hydroxycholesterol (XIb) was obtained from desmosterol in 85% yield; the overall yield of compound (XIb) with respect to (LXXI) was 38%. Next the synthesis was continued by the method of Barton and coworkers[17,134]. The dehydrogenation of compound (XIb) with the aid of DDQ leads to 25-hydroxy-1,4,6-trien-3-one (CXXXVI). The synthesis of 1α, 25-dihydroxycholesterol is completed by the conversion of the trienone into the triol (CXIXa) via the epoxide (CXXXVII). The overall yield with respect to fucosterol is not more than 5%. Barton et al.[134] were the first to obtain crystalline 1α, 25-$(OH)_2D_3$:

A relatively simple method of synthesising 1α, 25-$(OH)_2D_3$ has been developed by Mazur and coworkers[105]. The dibromide (XCIX) described above was adsorbed on silica gel and saturated with ozone at -78 °C and the mixture was then slowly heated to room temperature. Chromatographic separation of the mixture gave 51% of compound (CXXXVIIIa) for an 11% conversion of compound (XCIX). The hydroxy-group at $C_{(25)}$ was protected by the formation of the trifuloroacetate (CXXXVIIIb). Compound (CXXXVIIIb) was dehydrobrominated to the provitamin (CXXXIX), as described above[54]. The synthesis of 1α, 25-$(OH)_2D_3$ from cholesterol includes only seven stages:



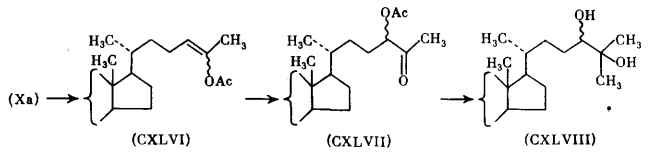
VI. THE SYNTHESIS OF 3-DEOXY-1α-HYDROXYCHOLECALCIFEROL



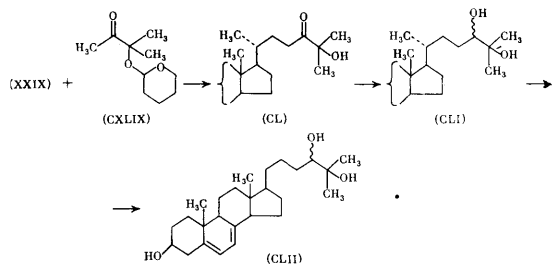
The presence of three hydroxy-groups, at $C_{(1)}$, $C_{(3)}$, and $C_{(25)}$, in the molecule of 1α, 25-$(OH)_2D_3$—the most active metabolite of vitamin D_3—stimulated attempts to elucidate the functional role of each of them. The synthesis of 1α-OHD_3 and the study of its biological activity showed that the absence of the hydroxy-group at $C_{(25)}$ hardly lowers the biological activity. The synthesis of 3-deoxy-1α-OHD_3 (Id) and its

high biological activity made it possible to demonstrate for the first time the exceptionally small role of the 3β-hydroxy-group in the manifestation of biological activity.

3-Deoxy-1α-OHD_3 was synthesised in 1974 by Norman and coworkers[22,135] and by DeLuca and coworkers[24,25]. DeLuca and coworkers synthesised this compound from the epoxy-ketone (XCII) obtained in the synthesis of 1α-OHD_3 [16,25]:



Treatment of the epoxyketone with hydrazine hydrate followed by catalytic hydrogenation led to the formation of the 1α-derivative (CXLa). Hydrolysis of the ketal under mild conditions with subsequent acetylation gave rise to the 6-oxo-derivative (CXLb), which was converted into the 6β-hydroxy-derivative (CXLI) after reduction with $NaBH_4$, while dehydration with $POCl_3$ gave cholest-5-en-1α-yl acetate (CXLIIa). A second method of synthesis of compound (CXLII), based on the diacetate of cholest-5-ene-1α, 3β-diol (CXLIIIa), is possible. Partial hydrolysis of the acetate group at $C_{(3)}$, the formation of the toluene-*p*-sulphonate (CXLIII), and reduction with $LiAlH_4$ lead to compound (CXLIIb). Norman and coworkers[23,135] obtained compound (CXLIIb) from cholesterol via the epoxyketone (XCVII) on reduction of compound (XCVII) with $LiAlH_4$ to the diol (CXLIV) and then with Li/NH_3 to compound (CXLIIb). If compound (XCVII) is reduced initially by the method of Barton et al.[17] to 1α-hydroxycholesterol (LXXIXb) with Li/NH_3, then subsequent treatment of its 3β-toluene-*p*-sulphonate (CXLV) with $LiAlH_4$ leads to the formation of compound (CXLIIb):

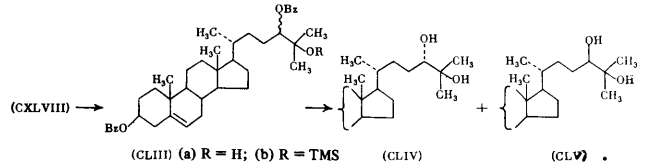


Successive bromination of compound (CXLIIa), dehydrobromination, and photochemical and thermal isomerisation lead to 3-deoxy-1α-OHD_3 with very low yields (8–10%) at each stage.

VII. THE SYNTHESIS OF 24*R*,25-DIHYDROXYCHOLECALCIFEROL

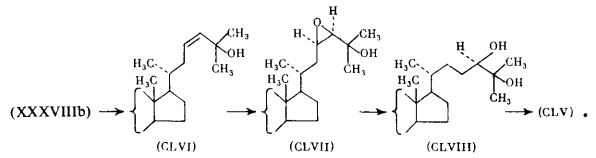
Synthetic 24,25-$(OH)_2D_3$ was obtained by DeLuca and coworkers[136,137] in 1973 from 25-oxo-27-norcholest-5-en-3β-yl acetate (Xa). Refluxing of compound (Xa) with acetic anhydride in the presence of toluene-*p*-sulphonic acid leads to a mixture of the *cis*- and *trans*-acetates of the Δ^{24}-enols (CXLVI). The 24-acetate of the 25-oxo-derivative (CXLVII) was obtained from this mixture via the intermediate bromo- and iodo-derivatives using the method of Moffett and Weisblat[138]. The reaction with a Grignard reagent leads to 24ξ, 25-dihydroxycholesterol (CXLVIII). The triacetate of the latter was converted into the provitamin and then into 24,25-$(OH)_2D_3$ by standard methods:

Eyley and Williams[56] obtained the provitamin 24,25-$(OH)_2D_3$ directly from ergosterol. The aldehyde (XXIX), obtained by the ozonolysis of the adduct of ergosterol with 4-phenyl-1,2,4-triazoline-3,5-dione, undergoes the aldol condensation with the enolate of 3-methyl-3-tetrahydropyranyloxybutan-2-one [which is formed when the ketone (CXLIX) is treated with lithium di-isopropylamide] to give the 24-oxo-derivative (CL):



The reduction of this ketone with $NaBH_4$ leads to the adduct of the 3β, 24ξ, 25-triol (CLI). Treatment of the adduct with $LiAlH_4$ yields the provitamin (CLII), the overall yield of which is 38% with respect to the aldehyde (XXIX).

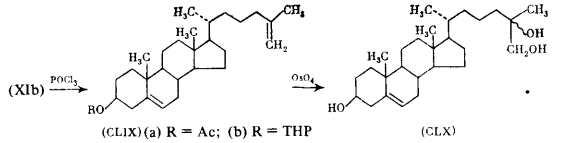
Japanese workers developed a simple method for the synthesis of 24,25-dihydroxycholesterol from desmosterol. Desmosteryl acetate (LXIb) was oxidised with *m*-chloroperbenzoic acid to the 24,25-epoxide (LXIV), whose treatment with H_2SO_4 gave compound (CXLVIII) [92]:



(LXIb) → (LXIV) → (CXLVIII).

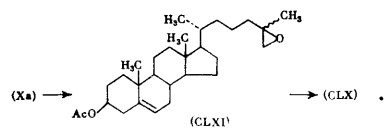
An even simpler method of synthesis of compound (CXLVIII) consists in the oxidation of compound (LXIb) with OsO_4 in anhydrous ether[130], the yield being almost quantitative. Kodicek and coworkers[140,141] established that the oxidation of compound (LXIb) with osmic acid in benzene gives rise to a mixture of epimers with respect to $C_{(24)}$ (*R* and *S*). Next the authors obtained a mixture of epimers of 24(*R*,*S*), 25-$(OH)_2D_3$, one of which was the active metabolite isolated by Suda et al.[27] from a living organism. In 1975 Japanese workers[142,143] separated a mixture of 24(*R*,*S*), 25-dihydroxycholesterols into epimers. For this purpose, the mixture (CXLVIII) was converted into the 3β, 24ξ-dibenzoate (CLIIIa), which gave rise to the 25-trimethylsilyl ether (CLIIIb). The latter was resolved on a silica gel column and after hydrolysis two epimers were obtained: 24*S*, 25- and 24*R*, 25-dihydroxycholesterols (CLIV) and (CLV):

Their conversion into 24*S*, 25-$(OH)_2D_3$ and 24*R*, 25-$(OH)_2D_3$ and the study of their biological activity showed that 24*R*, 25-$(OH)_2D_3$ is the natural and active product.



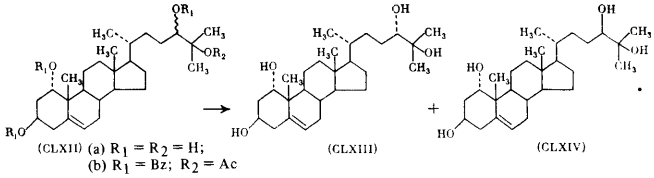
The sterospecific synthesis of 24*R*, 25-dihydroxycholesterol was achieved by Partridge and coworkers[144,145]. The hydrogenation of the unsaturated alcohol (XXXVIIIb) over the Lindlar catalyst gave a 90% yield of the *Z*-allyl alcohol (CLVI). Its oxidation with a peracid or better with t-butyl peroxide gives the 23*R*, 24*R*-epoxyalcohol (CLVII), whose reduction with $LiAlH_4$ results in the formation of the 24*R*, 25-diol (CLVIII). After treating the latter with acid dioxan, 24*R*, 25-dihydroxycholesterol (CLV) was obtained:

VIII. THE SYNTHESIS OF 25,26-DIHYDROXYCHOLECALCIFEROL



25,26-Dihydroxycholecalciferol was isolated and identified by DeLuca and coworkers in 1970,[32] The same investigators[146] patented a biochemical method of preparing this metabolite from the blood plasma of animals to which labelled vitamin D_3 had been administered. The configuration of the hydroxy-group at $C_{(25)}$ has not so far been established, but biological tests on a synthetic preparation showed that only one of the diastereoisomers with respect to $C_{(25)}$ is biologically active.

25,26-Dihydroxycholesterol was synthesised[92,139] from the acetate of 25-hydroxycholesterol (XIb), whose degradation with $POCl_3$ gave the $\Delta^{5,25}$-diene (CLIXa); the oxidation of the latter with OsO_4 gives a high yield of 25(*R*,*S*), 26-diol (CLX):



The chemical synthesis of 25,26-$(OH)_2D_3$ was carried out by Kodicek and coworkers[147,148] in 1973. The tetrahydropyranyl ether of 3β-hydroxy-27-norcholest-5-en-25-one (Xb) was converted by the Wittig reaction into the tetrahydropyranyl ether of the $\Delta^{5,25}$-diene (CLIXb). After hydrolysis (with HCl/MeOH) and acetylation, the acetate (CLIXa) was oxidised to compound (CLX) with OsO_4, as described above. The provitamin and 25,26-$(OH)_2D_3$ were obtained by the usual methods.

Lam et al.[34] developed another method for the conversion of compound (Xa) into 25,26-$(OH)_2D_3$. Treatment of compound (Xa) with a mixture of sodium hydride and trimethylsulphonium iodide in DMF yielded the 25,26-epoxide (CLXI), which was converted by treatment with alkali into the crystalline 3β, 25,26-triol (CLX):

IX. THE SYNTHESIS OF 1α, 24*R*, 25-TRIHYDROXYCHOLECALCIFEROL

Ikakawa et al.[149] synthesised the two epimers 24*R*- and 24*S*-1α, 24,25-$(OH)_2D_3$ in order to elucidate the configuration of the natural metabolite. 1α, 24,25-Trihydroxycholesterol was synthesised by the methods described above: 24,25-dihydroxycholesterol was obtained by the method of Seki et al.[92], after which the 1α-hydroxy-grlup was introduced by the method of Barton et al.[17] and a mixture of 1α, 24(*R*,*S*)25-trihydroxycholesterol (CLXIIa) epimers was obtained. They were then esterified and the mixture of tribenzoate acetates (CLXIIb) was separated chromatographically into two epimers. It was established by NMR that the more polar product (CLXIII) is the 24*R*-epimer, while the less polar product (CLXIV) is the 24*R*-epimer:

The conversion of these cholesterol derivatives into 1α, 24*R*, 25-$(OH)_3D_3$ and 1α, 24*R*, 25-$(OH)_3D_3$ [150] and the study of their biological properties showed that the natural metabolite is 1α, 24*R*, 25-$(OH)_3D_3$.

The Stabilisation of Enzymes—a Key Factor in the Practical Application of Biocatalysis

K.Martinek and I.B.Berezin

The present state of the problem of the practical application of biocatalysis is examined and physicochemical approaches whereby the denaturation of enzymes under the influence of elevated temperatures, extreme pH values, and organic solvents can be suppressed are analysed. The general principles of the stabilisation of enzymes are formulated.
The bibliography includes 225 references.

I. INTRODUCTION

1. Practical Application of Biocatalysis

Enzymes as biocatalysts differ from the usual chemical catalysts by their exceptionally high catalytic activity under mild conditions and their unique substrate specificity[1,2]. This leads to wide prospects for their use as catalytic and regulating elements in various branches of science and engineering. A number of factors have interfered hitherto with the realisation of these possibilities: the low availability (and hence relatively high cost) of enzymes, high lability, and the difficulty of their separation from the reaction products.

However, in recent years the situation has altered radically. Firstly, the development of methods for the preparation of enzymes from micro-organisms has virtually solved completely the first problem[3-5], and one can claim confidently that, after a further improvement of microbiological technology, the cost of enzymes will decrease. Secondly, a new field, involving the preparation and study of immobilised enzymes[5-9], has been established at the junction between a number of chemical and biological disciplines[6]. As a result of immobilisation (for example the covalent binding of enzymes to water-insoluble particles, the inclusion of enzymes in a gel or hollow fibres, and the adsorption of enzymes on various carriers), the first benefit has been the possibility to separate the heterogeneous catalyst thus obtained from soluble

products and the ability to use it again. In many instances the stability of the enzymes has also been significantly increased. Because of this, the practical applications of enzymes have increased sharply. We shall indicate certain examples.

(1) The use of enzymes has been firmly included among the methods of analytical chemistry[9-11] and medicine[9,11].

(2) Particularly notable advances have been achieved in the fine organic synthesis of medicinal preparations and important biochemical compounds. Certain enzymic processes of this kind have already been carried out on the laboratory scale. As an example, one may mention the separation of the racemates of synthetic aminoacids[12,13], the synthesis of aminoacids[13-15] and antibiotics[15-17], the transformation of steroids[18,19], the synthesis of *N*-oxides of medicinal preparations[20,21], the synthesis of pyrrole porphobilinogen[9,22], the synthesis of hydroxynitriles[23], the preparation of pharmaceutically pure labelled aminoacids[24], the synthesis of important biochemical substances such as ATP,[25] NAD,[26] and others[27], and the synthesis of homopolynucleotides[28,29]. There is no doubt that the application of enzymes in preparative organic synthesis will develop vigorously also in the future[9,30,31].

(3) The use of enzymes has served as a powerful stimulus in the development of new large-scale technologies, such as the preparation of glucose by the hydrolysis of starch[32] and the isomerisation of glucose to fructose[33], the synthesis of L-DOPA and L-methionine[34], and reduction of the lactose content in milk[35,36]. Research into the possibilities of the industrial preparation of glucose from cellulose with the aid of cellulase is being vigorously prosecuted[37].

(4) Approaches to the preparation of enzymic light-sensitive[38] and sound-sensitive[39] materials, which can serve as chemical amplifiers of weak signals (particularly for the creation of new photographic and sonographic processes), have been developed.

(5) Methods for the solution of energy problems of the future with the aid of enzymes have been outlined[5,7,40].

The above list of problems which have been already solved or merely formulated cannot be regarded as complete and it can be extended (see, for example, Refs.5–9 and 41); however, we shall concentrate attention on the discussion of the causes which for fundamental reasons still limit the application of enzymes as catalysts of chemical reactions of practical importance, namely the inactivation of enzymes under technological conditions.

2. The Causes of the Inactivation of Enzymes

The loss of observed catalytic activity by the system as a whole can be due, for example, to the elution of the immobilised enzyme from within the carrier or from its surface or the partial breakdown (or deformation) of the carrier itself by both mechanical and microbiological means[42,43]. These and similar technological aspects[43] are of only partial interest, because the observed inactivation of this kind can be readily prevented by choosing another carrier or by altering the method for the immobilisation of the enzyme.

The following inactivation processes, in which the enzyme itself (its active centre) is "destroyed" are more important.

A. The enzyme can be "poisoned" by inhibitors such as heavy metal cations: in order to avoid this, one can add a metal-chelating agent of the type of EDTA [44] either in a free form (this appears more promising) or in an immobilised form[45].

B. The catalytic activity can decrease as a result of the oxidation of the functional groups of the protein. In this case protective agents must be introduced into the system. In principle, one can employ for this purpose antioxidants [(inhibitors of free radical reactions, which have already proved useful in the solution of other applied problems in biochemistry and medicine (see, for example Emanuel'[46])]. Sulphydryl compounds are used to protect the SH groups[47]. The oxidative degradation of enzymes can be eliminated by employing anaerobic conditions (in principle, a very low oxygen concentration can be maintained in the system by absorbing oxygen via auxiliary autocatalytic oxidative processes or even with the aid of enzymic oxidative processes coupled with the main reaction.

C. The "eating" of the protein catalyst by micro-organisms (they are almost always present in the system as an impurity) can be avoided by immobilisation if the enzyme is incorporated in a carrier (for example a microporous carrier) which protects it as a result of steric hindrance[5,42,43].

D. Covalent immobilisation also prevents various kinds of polymolecular inactivating processes of the type of enzyme–enzyme interaction, such as aggregation[48] or autolysis in the case of proteolytic enzymes[5,7].

E. When used in flow reactors, the enzyme can be inactivated as a result of the elimination of the cofactor from the system. However, recently this problem has been solved in principle. There exist three most promising (from our point of view) approaches: (a) a membrane reactor is used and the cofactor is attached to a water soluble polymer[49]; (b) the enzyme (enzymes) and the cofactor are jointly subjected to covalent immobilisation[49]; (c) more complex enzyme systems are created in which the cofactor is regenerated[25,49,50].

F. Inactivation of enzymes caused by the denaturing activity of the external medium. Since methods for the suppression of inactivation via mechanisms (A)–(E), developed to a greater or smaller extent, already exist, in the present review we shall deal only with mechanism (F). There is naturally no special point in considering the problems of preventing the denaturation of enzymes under the influence of the carrier[51]—it is simplest to use another carrier. We shall have in mind primarily the following denaturing factors: increased temperature, unfavourable pH values, and the addition of organic solvents.

3. The Necessity to "Suppress" the Denaturation of Enzymes

The prevention of the denaturation of enzymes is an essential step towards their wide-scale practical application. We shall demonstrate this on the following examples.

1. When enzymes are extracted from their natural environment (*in vivo*), they become as a rule labile and in many instances their "lifetime" is measured in minutes[52-54]. For example, the stability of immobilised aspartase proved to be unsatisfactory for its use in industry[55].

2. It is desirable to carry out many processes at an elevated temperature. This is associated, in the first place, with the fact that the rates of the majority of chemical reactions, including enzymic reactions, increase with increasing temperature (in accordance with the Arrhenius equation). It is therefore natural that at elevated temperatures the specified degree of conversion of the substrate in the chemical reactor is attained after a shorter period or even in the presence of smaller amounts of the immobilised enzyme, and in many industrial processes the cost of the enzyme is an important economic factor, for example, in the case of glucoamylase[32]. In the second place, an increase of temperature ensures bactericidal conditions[43], which are very important, for example, for processes in the food industry[35, 56,57]. However, we may note that at elevated temperatures the denaturation of biocatalysts intensifies[52-54].

3. The equilibrium position in many processes of practical importance is such that the required products can be obtained when the reaction is carried out in a mixture of water and an organic solvent with a high content of the latter. On the other hand, enzymes as a rule lose their catalytic activity or specificity under these conditions[53,58] (see also the references in the paper of Klibanov et al.[59]).

4. In certain cases the pH optimum of the reaction and the pH range corresponding to the stability of the enzyme catalysing it are not the same. A typical example is in the synthesis of penicillin antiobiotics under the influence of penicillin amidase: the equilibrium position in the synthesis is displaced towards products in an acid medium, where the enzyme is fairly unstable[60].

5. Evidently in the practical employment of enzyme preparations their direct application takes place long (sometimes very long) after their preparation. This gives rise to the problem of the stabilisation of enzymes in relation to their inactivation on prolonged storage[61].

4. Methods for the Solution of the Problem of Undesirable Inactivation

In order to solve the problem of the undesirable inactivation of enzymes, a number of approaches have been proposed. Firstly, one can use whole (or only partly degraded) cells as the catalyst without extracting the enzyme from its natural environment[4-9]. For example, owing to the low stability of free aspartase, immobilised cells of *Escherichia coli* had to be used for the continuous synthesis of L-aspartic acid[55]. Partly degraded cells retain their catalytic properties even in organic solvents[62]. Secondly, the enzyme can be isolated from specially stable, for example, thermophilic, strains[54,63].

However both these approaches have their disadvantages. The use of whole cells creates the problem of the diffusion of the substrates or products through cell walls; furthermore, the choice of the method of immobilisation is in this case evidently limited. The use of enzymes from thermophilic microorganisms is limited by the fact that the search for strains suitable in the required catalytic reaction constitutes in each case a special (individual) problem, which is by no means simple.

In the present review, we shall therefore consider the third possible solution—the stabilisation of an enzyme molecule (globule) in relation to denaturing influences by artificial means.

The stabilisation of enzymes could not be achieved "at a stroke" by their immobilisation: the stability of enzymes in relation to inactivating influences in some cases increases on immobilisation, in others it decreases, while in instances of a third kind, it remains virtually unaltered[6]. Certain advances in the formation of enzyme preparations with an increased stability have therefore come to be regarded[7,42] as an exception rather than a rule. Furthermore a large text published in 1976 and devoted to immobilised enzymes[9] altogether failed to provide a genuine treatment of this problem.

II. THE STABILITY AND STABILISATION OF ENZYMES; DEFINITIONS AND GENERAL REMARKS

The stability of an enzyme *E* will be understood as its ability to retain its intrinsic catalytic activity under conditions where the inactivating mechanisms (A)–(E) are absent. The effective first-order rate constant, characterising the unimolecular inactivating process

$$k_{inact} = (d[E]/dt)/[E],$$

where [E] is the relative specific catalytic activity, will serve as a quantitative criterion of the stability of the given enzyme under the given conditions.

The decrease of k_{inact}, observed as a result of a particular treatment of the enzyme (modification, immobilisation, etc.), will serve as a measure of stabilisation.

In certain systems, an apparent stabilisation of the immobilised enzyme in relation to its native precursor is observed, being caused, for example, by diffusion-dependent obstacles to the enzymic reaction, which arise under the influence of the carrier[64]. We shall consider only studies where complications of this kind have been excluded; we shall make use of the kinetic criteria formulated by Berezin et al.[65] (see also Goldstein[66]).

The problem of the stabilisation of enzymes in relation to denaturing influences does not have only practical aspects of the kind discussed above. It is important also for the study of the mechanisms of the denaturation of enzymes. Furthermore, certain stabilised enzyme systems serve as models of systems functioning *in vivo*. All these aspects will be considered in the present review.

Below we shall analyse methods (mechanisms) of stabilisation, which, being to some extent general, in the first place do not reduce unduly the initial level of the catalytic activity of enzymes extracted from their natural environment (as a rule, not more than by a factor of 2–3) and, in the second place, ensure the continuing functioning of the enzyme under unfavourable conditions in the surrounding medium. We shall consider separately the preparation of water-insoluble (truly immobilised) heterogeneous catalysts with an increased stability and, on the other hand, stabilised water-soluble enzyme preparations. The need for soluble enzymes has been continuously increasing in recent years[5,67], primarily in medicine[5,9,11,68] and in chemical engineering, in processes involving the use of water-insoluble substrates[69]; the cellulase cleavage of cellulose to glucose is particularly promising in this connection[37].

However, we shall in no way endeavour to compile fully all the studies in which the enzyme stabilisation effect has been observed (a continuously increasing number of such studies apparently precludes this within the framework of a single article). We shall concentrate attention only on those investigations where the observed effects have been subjected to an experimentally tested physicochemical treatment; the number of such studies is relatively small. The main aim of this review is to formulate (and to illustrate by the most striking examples) the physicochemical principles of the solution of the problem of the stabilisation of enzymes. We shall begin with the fact that enzymes are inactivated via identical mechanisms (see above) under both technological conditions and on storage. We may note that the stability of enzymes is usually considered separately in the two cases; this is justified in view of the fact that, under particular conditions, the contribution of each inactivating mechanism can be signifcantly different. For example, at an elevated temperature (in technological processes) mechanisms involving the denaturation uncoiling of the protein or its oxidation largely operate, whereas during storage (usually at a reduced temperatue) one may expect mainly the degradation of the enzymes under the influence of micro-organisms and proteases (particularly in a moist state). For attempts to stabilise the enzyme to be well-founded, it was therefore necessary to begin in the first place with the causes of the inactivation; it is even better (although not essential) to know the mechanism of the inactivation.

III. THE STABILISATION OF ENZYMES IN RELATION TO THERMAL INACTIVATION (IN RELATION TO THE UNCOILING OF THE PROTEIN GLOBULE)

As a result of the modification of enzymes by chemical reagents (including water-soluble synthetic reagents or biopolymers) or their attachment to a water-soluble carrier, their thermal stability is frequently altered (both decreased and increased). This is usually explained (see, for example Refs.5–7, 42, and 70) by the following causes: (1) the change in the conformation of the enzyme molecule compared with its native structure on the assumption that the thermal stability of the protein globule depends on its conformational state; (2) the change in the microenvironment of the enzyme molecule, assuming that it influences the intramolecular links (factors) which maintain its native structure.

These views, however valid they may be, cannot serve as a basis for the development of general methods for the stabilisation of enzymes. The point is that we do not know in what way the stability of the enzyme is related to its conformation and microenvironment; furthermore, even if this relation actually exists†, it ought to be, in all probability, specific to each enzyme.

The fact that the overall fundamental mechanisms of the inactivation of enzymes still remain unelucidated[52] although vigorous research in this field has continued for many decades also hinders the development of rational ways of increasing enzyme stability. It is extremely likely that a single general mechanism of the denaturation of proteins does not exist al all[77]. However, there is no doubt that the inactivation of enzymes under the influence of, for example, heat or denaturing agents is accompanied by considerable conformational changes in protein molecules, i.e. their uncoiling[52–54,77]. It therefore appears evident that an increase of the thermal stability of enzymes can be achieved by yet another procedure, namely if (3) the native conformation of the protein globule is made more rigid (is fixed).

In fact, if it is recognised that a necessary stage in the inactivation of the enzyme is the uncoiling of its molecule, then, the more rigidly (firmly) is the protein globule of the enzyme fixed, the greatly the difficulty of uncoiling it and hence of inactivating its active centre. One should note that this approach (involving a variation of the rigidity of proteins) is widely used in nature in the adaptation of organisms to the conditions in the environment[54].

The fixation of the enzyme globule to prevent its uncoiling can be achieved in several ways: by the introduction of cross links (1), by covalent (2) or non-covalent (3) attachment to a carrier, and by mechanical inclusion (4) in the narrow pores of a carrier. We shall consider each of these approaches in greater detail.

1. Intramolecular Cross Links and Their Influence on the Thermal Stability of Enzymes

There is extensive information in the literature about methods for the chemical modification of enzymes and the properties of the resulting preparations. However, one can hardly predict in a single instance how the thermal stability of the enzyme will alter as a result of its chemical modification. This is associated with the exceptional complexity of the molecular structure of biocatalysts (which, in addition, are still unknown for many enzymes). As an example of the extremely complex dependence of the thermal stability of an enzyme on the degree of modification of its surface layer, we shall indicate the behaviour of α-chymotrypsin alkylated via its NH_2 groups[105]. The enzyme was modified by treating it with acroleine with subsequent reduction of the Schiff bases by sodium tetrahydroborate (using the methods indicated by Feeney et al.[106]); this entailed hardly any loss of catalytic activity by the enzyme. Fig.1 shows that the alkylation of the NH_2 groups, which are the first to be modified, also hardly affects the thermal stability of α-chymotrypsin. The modification of the least reactive NH_2 groups (apparently relatively inaccessible groups deep in the globule) plays a decisive role: the thermal stability of the enzyme increases sharply in the concluding state of its modification (by two orders of magnitude); on further alkylation, the thermal stability of the enzyme preparation falls (as a result of the complete modification of all the NH_2 groups titratable by trinitrobenzenesulphonic acid). Fig.1 shows that the observed effect (a sharp increase of thermal stability with a subsequent sharp fall) is manifested to the maximum extent when only two-thirds of the NH_2 groups, the total number of which is 17, are modified.

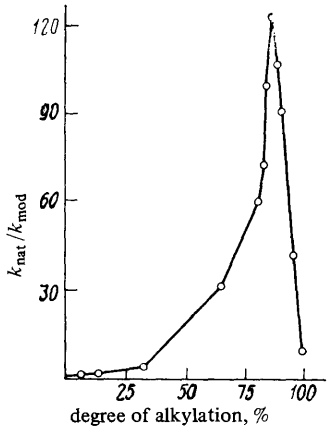

Figure 1. Dependence of the pseudo-first-order rate constant (k_{mod}) for the unimolecular thermal inactivation of α-chymotrypsin on the degree (based on titration data) of alkylation of the NH_2 groups by acroleine (with reduction of the Schiff bases by sodium tetrahydroborate); the value of k_{nat} obtained for the native (unmodified) enzyme was adopted by convention as unity. Conditions: 50 °C, pH 8 (5×10^{-3} M tris.HCl + 0.1 M KCl).[105]

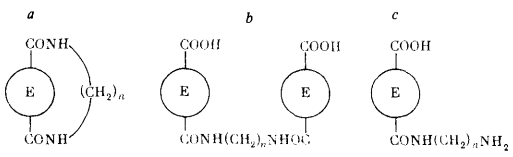
The situation is different when bifunctional reagents, capable of cross-linking covalently the protein globule, are used: here one may expect an increase of the conformational stability of the protein molecule[78]. This approach therefore leads to wide prospects for the preparation of water-soluble stabilised enzyme preparations, which may find practical applications (see Section I).

Intramolecular cross links in nature. Nature makes an extensive use of intramolecular cross links for increasing the rigidity (and hence the stabilisation) of protein molecules[54].

† Thus it has been shown in recent studies by direct physical methods that the attachment of proteins to carriers does not lead to any significant conformational changes in their macromolecules[71–76].



These cross links can be both covalent bonds (disulphide bonds[79-81]) and weaker linkages ("salt bridges"[82], or, for example, Ca^{2+} ions incorporated into the protein molecules[83], etc.).

The artificial introduction of cross links ("clamps") into protein molecules can be achieved by treating them with bifunctional reagents[11,84,85]. Dialdehydes, diimidoesters, diisocyanates, bisdiazonium salts, etc. are usually employed as reagents of this kind. Analysis of literature data[67,78,86-94] shows that in most cases the stabilisation effects are extremely small and sometimes are apparently in fact caused not by the cross links but by simple (single-point) chemical modification of the enzyme[67] as shown recently for glutaric dialdehyde[92]. In other cases the stabilisation effect proved to be more appreciable[78,91], an increase of stability being correlated with the increase of the rigidity of the protein molecule[78].

In all probability the success or failure of the attempt to increase the stability of the enzyme by treating it with bifunctional reagents, depends mainly on the extent to which the length of the bifunctional reagent corresponds to the distance between the possible centres of cross links in the protein globule. Evidently, for each given protein there is an optimum size of the intramolecular cross-linking agent. Studies directed to the selection of the optimum size of the bifunctional reagent are therefore of greatest interest.

Variation of the length of the intramolecular cross link. Studies of this kind are rarely performed, probably because the bifunctional reagents used directly to introduce cross links are commercially unavailable and their chemical synthesis is extremely laborious. It is therefore a very attractive propostion to employ bifunctional reagents which cannot be used directly to cross-link the enzymes intramolecularly but become suitable if the enzyme is subjected to an appropriate preliminary modification. A number of aliphatic diamines, which are commercially available, have a carbon chain comprising between 0 and 12 methylene groups, and are fairly cheap, proved useful for this purpose[95]; both factors are particularly important for possible practical applications. The diamines can be used to cross-link the carboxy-groups of enzymes (which are usually fairly numerous in proteins) provided that they are first activated with carbodiimide. This results in the formation of a strong amide linkage between the amino-group of the modifying agent (the diamine) and the carboxy-group of the protein[96]:

Scheme 1

Under conditions where there are no intermolecular cross links between the protein molecules (leading to the formation of enzyme oligomers—see Scheme 1*b*), it has been found that[95] there is a significant increase of the thermal stability of α-chymotrypsin intramolecularly cross-linked by this method (relative to the native preparation, the thermal inactivation rate constant decreases by a factor greater than 40). The observed stabilisation effect cannot be explained by simple (single-point) chemical modification of the enzyme (Scheme 1*c*), because the modification of chymotrypsin by a monoamine (provided the enzyme is subjected to preliminary activation with carbodiimide), namely 1-amino-3-propanol, actually reduces its thermal stability. The stabilisation effect depends on the number of methylene groups n in the molecule of the modifying agent $H_2N-(CH_2)_n-NH_2$. Fig. 2*a* shows that the dependence of the first-order reaction rate constant (observed for the thermal inactivation of chymotrypsins "cross-linked" by various diamines) has a minimum at $n = 4$, although the stabilisation of the enzyme is also observed for $n = 2$, 5, and 6.

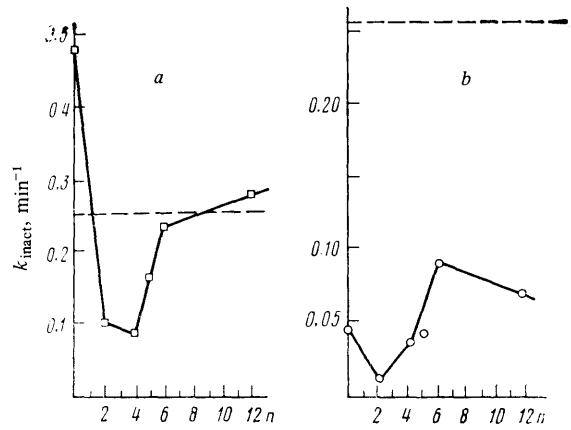


Figure 2. Dependence of the first-order rate constant (k_{inact}) for the unimolecular thermal inactivation of α-chymotrypsin (*a*) and succinylated α-chymotrypsin (*b*) cross-linked intramolecularly by diamines on the number of methylene groups in the molecule of the modifying agent $NH_2(CH_2)_nNH_2$.[95] The dashed line represents the level of the thermal stability of the native and succinylated enzymes. Conditions: pH 7 (0.02 M phosphate), 50 °C.

The fact that treatment with tetramethylenediamine leads to the maximum stabilisation of chymotrypsin is apparently due to the optimum correspondence between the length of the above cross-linking agent and the distance between the carboxy-groups of the protein molecule; this leads to the formation of a greater number of intramolecular cross links than for other diamines.

The grafting onto the enzyme of ability to interact with bifunctional (polyfunctional) reagents. Presumably the greater the number of clamps (cross links) applied to the protein molecule, the greater its stability in relation to uncoiling and hence inactivation. The possible number of cross links is determined in its turn by the number and relative positions of functional groups on the surfaces of the protein interacting with the cross-linking agent. Clearly their number (and hence the number of possible cross links) can be increased by the appropriate modification of the protein.

Reiner et al.[97] suggested that SH groups be introduced into the enzyme molecule for this purpose (by means of *N*-acetylhomocysteine thiolactone or other compounds)[98-100] with subsequent employment of the bisiodoacetamides derived from various aliphatic diamines as bifunctional reagents. For the system described above (Fig. 2*a*), it proved useful to subject the enzyme to a preliminary modification with succinic anhydride in order to increase the content of carboxy-groups in its surface layer[101]. The succinylated chymotrypsin was then treated (by the same method as the native

enzyme) with diamines of different lengths. Fig.2*b* illustrates the relation obtained under these conditions[95]. Evidently, firstly the maximum enzyme stabilisation effect has increased; secondly the maximum stabilising influence is shown by the shorter bifunctional reagent ethylenediamine and not tetramethylenediamine (cf. Fig.2*a*). The latter finding indicates a denser "population" of the surface of the succinylchymotrypsin globule (containing native chymotrypsin) by carboxy-groups.

The use of intramolecular cross links in fundamental biochemical research. Studies designed to select the optimum size of the cross-linking agent are not only important from the practical point of view (in order to obtain stabilised enzyme preparations) but can also yield new information about the tertiary structure (conformation) of proteins in solution[84] (for example, the distance between the functional groups in the surface layer of the protein globule can be estimated[102]), about the topography of the active centre (see the reference in the paper of Kennedy[85]), about the symmetry of the distribution of subunits in oligomeric proteins[85,102], about cooperative and allosteric effects[104], etc.

2. Multipoint Covalent Attachment of the Enzyme to the Complementary Surface of the Carrier

The methods for the covalent attachment of enzyme molecules to different carriers have been described fairly completely in numerous reviews (see, for example, Refs.5–9 and 11). This immobilisation procedure can promote, in principle, an increase of the conformational stability of the protein molecule and hence can prevent its uncoiling and inactivation. Thus the study of the conformational mobility of immobilised proteins (using various physical methods) showed that the attachment of the protein to the carrier makes the molecular structure of the former more rigid (it becomes "frozen")[71,72,74]. The same conclusion can be arrived at on the basis of many indirect data (obtained by both physical methods and by measuring the enzyme activity)[72,74,107–109]: after such proteins have been grafted to the carrier, the conformation transitions in them are greatly hindered. At the same time, Gabel showed in his pioneer investigation[110] that the greater the number of linkages attaching trypsin to Sephadex, the greater its resistance to inactivation by urea (under the influence of which the protein is known to become uncoiled[111]).

Thus the above findings suggest that the general principle governing the stabilisation of enzymes involves *multipoint* attachment of the catalyst molecule to the carrier. Such grafting should make the conformation of the catalyst molecule more rigid (incidentally it may not be otherwise altered in this process) and hence more resistant to uncoiling and inactivation. However, this principle is extremely difficult to apply methodologically because of steric factors: both the surface of the carrier and the surface of the protein have their individual reliefs which, generally speaking, are not complementary. Furthermore, it is evident that even in the case of multipoint interaction, when the enzyme is connected to the carrier solely by a small section of the surface, it is difficult to expect a significant increase of the rigidity of the entire molecule. Presumably this is why many attempts to stabilise enzymes failed[71,112,113]. The problem in fact reduces to creating a carrier surface which is rigorously complementary to the surface of the enzyme molecules. Only then is it possible to create a multipoint interaction between the protein and the carrier favourable for stabilisation.

The creation of a polymeric carrier complementary to the molecule of the immobilised enzyme. The essential feature of the approach permitting a solution of this problem[114–116] is as follows. The enzyme is modified by an analogue of the monomer and the resulting preparation is then copolymerised with the monomer itself (and in certain cases also with the cross-linking agent). Ultimately one obtains an enzyme which is chemically built into the three-dimensional network of the polymeric gel, the centres of the preliminary modification of the enzyme molecule serving as the points of attachment of the enzyme to the carrier. Evidently, by virtue of the very principle of the proposed method, the microsurface of the gel near the protein molecule built into it will be complementary to the surface of the protein.

A method for the preparation of enzymes immobilised by copolymerisation has been developed by Jaworek et al.[117], who endeavoured to prevent the elution of immobilised enzymes from gel carriers. The authors of the present review[114–116] developed this method independently in order to stabilise enzymes. It is very convenient to employ as monomer analogues acylating and alkylating agents containing a double bond capable of copolymerisation, for example, acryloyl chloride (which acylates the NH_2 and OH groups of the protein) or acroleine[114] (which interacts with the NH_2 groups; when the Schiff bases formed are reduced with sodium tetrahydroborate, the protein is found to be alkylated); a method has also been developed for the vinylation of the carboxyl-groups of the protein[118]. Acrylamide, sodium methacrylate, and ethylene methacrylate, which are frequently used to synthesise gels, can be used as the monomers and the cross-linking agent can be *N,N'*-methylenebisacrylamide. All these reagents are commercially available and cheap.

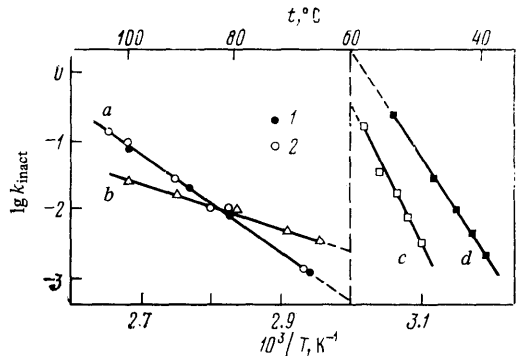

Figure 3. Temperature variation of the pseudo-first-order rate constant (k_{inact}, min^{-1}) for the unimolecular thermal inactivation of acryloylchymotrypsin incorporated in polymethacrylate (*a*) and polyacrylamide (*b*) gels [1) water-insoluble enzyme; 2) water-soluble enzyme], native α-chymotrypsin (*c*) and α-chymotrypsin modified by acryloyl chloride (*d*). Conditions: pH 8 (0.005 M tris.HCl+3 M KCl).[114]

The magnitude of the stabilisation effect. Fig.3 presents, as a striking example, data, expressed in terms of the Arrhenius coordinates, for the rate of thermal inactivation of α-chymotrypsin built into polymethacrylate and polyacrylamide gels (straight lines *a* and *b*)[114]. The resistance of the

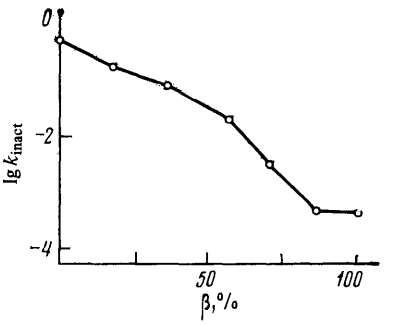
immobilised enzyme preparations to heating is so much greater than that of the native enzyme (line *c*) that a direct, i.e. at the same temperature, experimental comparison is impossible. It is therefore necessary to compare the thermal inactivation rate constants determined by extrapolation, for example, at 60 °C (the vertical dashed line in Fig.3). At 60 °C acryloylchymotrypsin built into polymethacrylate (line *a*) and polyacrylamide (line *b*) gels is respectively 1000 and 200 times more stable than the native enzyme (line *c*). Compared with free acryloylchymotrypsin (line *d*), an even more striking difference is observed.

Fig.3 shows that the activation energies for the thermal inactivation of acryloylchymotrypsin built into both polymethacrylate and polyacrylamide gels are much lower (35 and 15 kcal mol^{-1} respectively) than for the native enzyme (110 kcal mol^{-1}). From this it follows that, with increase of temperature, the degree of stabilisation of the immobilised chymotrypsin will increase compared with the native enzyme. Thus extrapolation of straight line *c* in Fig.3 shows that at 102 °C the enzyme built into the gels is more stable than the native enzyme by a factor greater than 10^8.

Dependence of the stabilisation effect on the number of links between the immobilised enzyme and the carrier. It is noteworthy that the stabilisation effect in systems discussed above (Fig.3) is independent of both the initial density of the gel carrier (i.e. of the polymer concentration or more correctly of the monomer concentration) in the polymerisation mixture in the range from 10–15 to 50 wt.% and of the degree of its swelling (which depends on the amount of cross-linking agent, namely *N,N'*-methylenebisacrylamide). Furthermore, if the acrylic derivatives of the enzyme are copolymerised with the comonomers altogether in the absence of a cross-linking agent, the resulting gel-like polymer can be fully dissolved in water and, what is most important, the enzyme preparation obtained has the same high thermal stability as the enzyme immobilised in an insoluble gel (Fig.3*a*)[114]. This phenomenon is apparently due to the fact that the polymeric structure of the gel in the vicinity of the enzyme molecule, being complementary to its surface, is specified by the number of cross links with the protein.

The degree of covalent binding of the copolymerised enzyme to the carrier exerts in its turn a decisive influence on the thermal stability of the enzyme, namely, with increase of the number of cross links between the immobilised enzyme and the carrier, there is an increase in the thermal stability of the catalytic activity in the system. Thus Fig.4 shows that the effective rate constant for the thermal inactivation of α-chymotrypsin (at 60 °C) falls by a factor greater than 1000 when the degree of binding of the enzyme to the polymethacrylate carrier increases (the number of residual free NH_2 groups after acryloylation was determined experimentally by titration)[114].

The stabilisation mechanism. The observed enzyme stabilisation effect cannot be explained by the possible change in the thermal stability of the enzyme as a result of chemical modification, because free acryloylchymotrypsin is thermally even less stable than the native enzyme (Fig.3). Nor can stabilisation be explained by the influence of the micromedium in the gel on the enzyme, because the thermal stability of chymotrypsin physically incorporated in the polymethacrylate gel at the same concentration is virtually the same as that of the free enzyme[119,120] (Fig.5). The nature of the gel is also not a decisive factor for the stabilisation of the enzyme—analogous effects have been obtained for both polyelectrolyte (polymethacrylate) and electrostatically neutral (polyacrylamide) gels (Fig.3). The stabilisation effect occurs when different methods are used for the preliminary modification of the enzyme: alkylation of the NH_2 groups by acroleine or acylation of the protein by acryloyl chloride (Fig.3)[114] or vinylation of the carboxy-groups[118]. Finally, stabilisation has been achieved for different enzymes: α-chymotrypsin, trypsin[114], and penicillin amidase[121]. Consequently the very fact that the enzyme molecule is built into the three-dimensional network of the gel and not the method of preliminary modification or the nature of the gel is of decisive importance. Evidently the stabilisation mechanism depends on the fact that the uncoiling of the globule on heating is difficult in a fixed state of the protein. Here one must emphasise that the native (catalytically active) conformation of the active centre can be preserved only if the enzyme is bound to the carrier via numerous points of attachment (Fig.4).



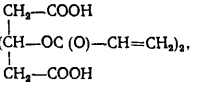


Figure 4. Dependence of the pseudo-first-order rate constant (k_{inact}) characterising the unimolecular thermal inactivation of α-chymotrypsin incorporated in a polymethacrylate gel on β (the degree of covalent binding of the enzyme to the carrier). Conditions: pH 8 (0.005 M tris.HCl + 3 M KCl), 60 °C.[114]

Further prospects. There is no doubt that the thermal stability of the copolymerised enzyme must depend (for the specified number of cross links between the protein and the carrier) on the rigidity (flexibility) of the polymer chains linked covalently to the protein globule and maintaining the native structure of the latter: for more rigid (less flexible) polymers (we have in mind this property at the molecular level), one should expect a greater stabilisation effect[115]. This principle must be tested experimentally in the future. Protein modifying agents and comonomers containing in their molecule at least two polymerisation centres and hence ensuring the formation of branched (completely cross-linked) polymeric gel structure may prove to be useful for this purpose. In order to ensure an adequate solubility, these compounds must be electrolytes, for example, the compound

which must be synthesised by acylating tartaric acid by acryloyl chloride. Furthermore, the polyelectrolyte nature of the resulting polymer might ensure an additional increase of the rigidity of its chains[122].

Gels suffer from a number of disadvantages as carriers[123], which include, in particular, low mechanical strength and a tendency of the gel grains to deteriorate on storage. However, these disadvantages can be avoided if the polymerisation is carried out within the pores of fairly stable carriers, for example, inorganic carriers, which have proved to be very useful[32,124,125]. The covalent attachment of the enzyme to elastic carriers (including gel-like carriers) leads to the possibility of regulating the catalytic activity by mechanical means[126]. In the case of polyelectrolyte carriers the catalytic activity of the immobilised enzyme can also be regulated by altering the ionic strength of the solution[127]. These aspects of the regulation can prove to be useful when enzymes are employed in organic synthesis (in chemical engineering).

The use of covalently immobilised enzymes in fundamental research has been very fully described by Mosbach[9].

3. The Multipoint Non-Covalent Interaction between the Enzyme and the Carrier

The multipoint interaction between the enzyme and the carrier can ensure, in principle, the stabilisation of the biocatalyst even when physical immobilisation methods are used. Physical immobilisation methods (for example, mechanical inclusion in gels[123], microencapsulation[128], adsorption on carriers[129,130], etc.) have been developed in fair detail[5,9,11], but the thermodynamic causes (mechanism) of the thermal stabilisation of enzymes in such systems have been discussed only recently and recommendations have been made for the formation of stabilised enzyme preparations[119,120]. As an example, we shall consider in greater detail the thermal stability of α-chymotrypsin incorporated mechanically in a polymethacrylate gel. In principle, the enzyme can form weak electrostatic or hydrogen bonds with this polyelectrolyte matrix.

The magnitude of the stabilisation effect. Fig.5 presents the variation of the logarithm of the effective rate constant for the thermal inactivation of α-chymotrypsin with the concentration of the polymethacrylate gel (up to the limit of the solubility of the monomer in water). Evidently, when the gel concentration is varied from 0 to 30 wt.%, the rate of thermal inactivation (at 60 °C) of the enzyme is almost constant, but, on further increase of the gel concentration, it falls very rapidly: in 50% gel the stabilisation effect reaches 10^5. Furthermore, extrapolation of the linear relation between $\lg k_{inact}$ against $1/T$ showed[119] that the lifetime of the enzyme immobilised in a polymethacrylate (45 wt.%) gel can amount to millions of years at room temperature.

The stabilisation mechanism depends on the interaction between the enzyme molecules and the polymer matrix. In principle, protein molecules can form electrostatic and hydrogen bonds with the carboxy-groups of the carrier, i.e. with polymethacrylic acid. However, these bonds are relatively weak; this is probably why they are hardly formed in a polymer solution or in dilute gels, where the formation of such a complex would entail considerable entropy losses in the "quenching" of the translational as well as rotational movements of the enzyme molecules.

The situation should be different in concentrated gels, where one may expect that the translational (possibly rotational) movement of protein molecules is significantly retarded (regardless of the formation of the complex) by virtue of steric hindrance introduced by the dense three-dimensional polymer network. Consequently in a concentrated gel the formation of a protein–matrix complex should be thermodynamically much more favourable, because there is no expenditure of free energy (or it is significantly reduced) caused by the loss of translational and rotational entropy by the enzyme globule when it is sorbed on the polymer matrix. One cannot rule out the possibility that in a concentrated gel the mobility of the polymer chains themselves is somewhat limited, so that the entropic losses of free energy, necessary for the local "freezing" of the matrix on formation of its complex with the enzyme, are therefore also significantly reduced compared with dilute gels (or a polymer solution).

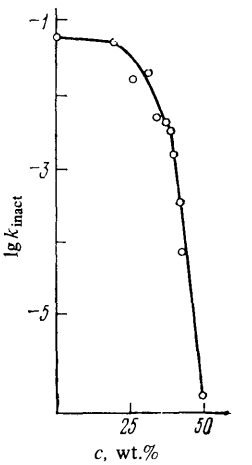

Figure 5. Dependence of the pseudo-first-order rate constant (k_{inact}, s^{-1}), characterising the unimolecular thermal inactivation of α-chymotrypsin incorporated mechanically in a polymethacrylate gel, on the concentration c of the polymethacrylate in the gel. Conditions: pH 8, 60 °C.[119]

Finally, under the conditions of a concentrated gel one may expect that the interaction of the enzyme with the matrix should be of the multipoint type for purely steric reasons, because polymer chains will approach the enzyme globule from all sides. Such multipoint interaction can lead to a sharp increase of the thermal stability of the immobilised enzyme (as already shown above for the covalent enzyme–carrier interaction).

All these postulates have been proved[119] as a result of a study of the thermal stability and the translational and rotational mobilities of enzyme molecules as a function of the gel concentration.

The proposed mechanism[120] operates also in other systems investigated previously. The specific protein–carrier interaction can also be of a type other than in the case discussed above, where electrostatic and hydrogen bonds are formed. We shall consider data[131,132] for the thermal stability of acetylcholinesterase, glucose oxidase, and peroxidase incorporated mechanically in the hydrophobic organosilicon gel silastic. While the thermal stability of the first enzyme increased sharply after incorporation in this gel, those of the remaining enzymes remained virtually unchanged when the enzymes were immobilised. In principle, all three enzymes could be stabilised in relation to uncoiling and hence thermal inactivation by forming multipoint hydrophobic contacts with the carrier. However, the enzyme–matrix interaction can be thermodynamically favourable, as shown by the examination of the above mechanism, only subject to the condition that the molecular mobility of the protein molecules

incorporated mechanically in the gel is reduced even in the initial stage. In the gel silastic at a given concentration the inhibition of translational diffusion (and hence stabilisation) is apparently achieved only for very large acetylcholinesterase molecules but not for the relatively small glucose oxidase and peroxidase molecules.

Further prospects. One can hardly give preference to any particular physical immobilisation method without knowing the purpose of the resulting enzyme preparation. If, however, one endeavours merely to increase the thermal stability of the enzyme as a result of immobilisation, then we believe that mechanical incorporation of the enzyme in a gel capable of specific interaction with the protein is most attractive. The advances achieved in this field (see above) can be enhanced still further if an attempt is made to optimise the gel structure using more than one monomer (not counting the cross-linking agent) and thus introducing various functional groups into the carrier[123,133].

On the other hand, one should recall that the stabilisation effect in such systems depends radically on the concentration (density) of the gel (Fig.5) and that only a concentrated gel exerts a stabilising influence (if such an influence occurs at all). Consequently the swelling of gel particles (grains) in water results in the reversible disappearance of the stabilisation effect[119]. It would seem that this limits the applicability of such systems in the formation of stabilised enzyme preparations. However, the swelling of the gel in water can be prevented (and the thermal stabilisation effect can thus be retained) by employing gels which are sufficently cross-linked (by carrying out the cross-linking either directly during polymerisation using comonomers of the type *N,N'*-methylenebisacrylamide or by an additional treatment of the gel particles—grains several microns in size—with bifunctional cross-linking agents)[134]

Thermally stabilised enzyme preparations based on gels have found applications also in the catalysis of reactions in organic solvents. However in this case the organic solvent should be immiscible with water and the gel will hardly swell (after a suitable choice of polymer); consequently the thermal stabilisation effect (of the kind illustrated in Fig.5) should be preserved; the enzymic reactions in water–organic solvent systems will be described in greater detail below.

Biological aspects (model of biological membranes). The mechanism of the stabilisation of enzymes incorporated mechanically in concentrated polymeric matrices (i.e. the forced arrest of the translational movement of the enzyme molecule followed by multipoint interaction between the protein and the relatively immobile matrix), proposed by Martinek et al.[119], can function *in vivo* in membrane enzyme systems[135,136], where, firstly, an extremely low mobility of the molecules in the membrane is observed (the translational and rotational movements are inhibited)[137] and, secondly, the enzyme molecules can interact with the constituent phospholipids and structural proteins in the membrane, forming a set of relatively weak bonds—hydrophobic, electrostatic, hydrogen, etc.[138] Furthermore, such formal similarity makes it possible to understand certain aspects of the functioning of biological membranes. Thus it is known that, in the adaptation of organisms to changes in the temperature of the environment, the thermal stability of membrane enzymes also changes[54]. The molecular mechanism of such regulation may consist in an alteration of the fraction of unsaturated lipids in membranes[54], which should influence the viscosity of the membrane phase and hence the molecular mobility of the enzyme molecules incorporated in it. The molecular mobility and the thermal stability of the enzymes incorporated mechanically in the matrix are in their turn interrelated; this has been shown[119] by the model system "α-chymotrypsin in a polymethacrylate gel" (see above).

4. Mechanical Incorporation of Enzymes in the "Narrow" Pores of the Carrier

The uncoiling of the protein globule on denaturation can also be prevented by accommodating the native enzyme molecule in a cell which does not react with it via either chemical or sorption mechanisms but is so "narrow" that the uncoiled conformation cannot be formed for steric reasons. In this case the native conformation of the protein globule can be maintained by purely mechanical means. This mechanism has been frequently proposed in the literature as a hypothesis (frequently in a very implicit form)[139–142], but experimental evidence has been obtained only recently[134,143,144] in studies of the properties of α-chymotrypsin and trypsin in a polyacrylamide gel or in (on) polysaccharide carriers.

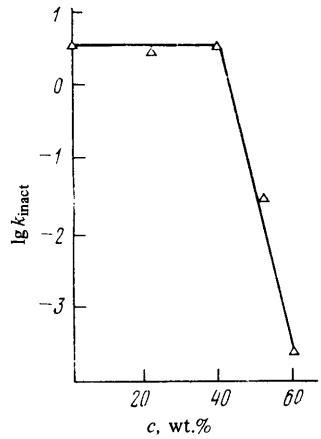

Figure 6. Dependence of the pseudo-first-order rate constant (k_{inact}, min^{-1}), characterising the unimolecular thermal inactivation of α-chymotrypsin incorporated mechanically in a polyacrylamide gel, on the concentration *c* of polyacrylamide in the gel. Conditions: pH 8, (0.02 M tris.HCl + 0.1 M KCl), 60 °C.[134,143]

The polyacrylamide gel is an extremely suitable carrier for research of this kind: firstly, this gel is chemically inert[145], secondly, the size of its pores can be readily varied by altering the monomer concentration[146], and, thirdly, at fairly high gel concentrations the size of its pores is comparable to the size of enzyme globules[147,148].

Two methods have been used for the mechanical incorporation of the enzyme in the gel: acrylamide at the required concentration is polymerised directly in the enzyme solution (as described by Martinek and coworkers[114,119]) or the gel particles (obtained in the absence of the enzyme and carefully washed free of low-molecular-weight impurities) are impregnated with the enzyme solution and are then lyophilised to give the required concentration of polyacrylamide[143,144]. The thermal stability of the enzyme is the same in both cases (Fig.6): whereas at a not unduly high gel concentration (less than 45 wt.%) there is no appreciable stabilisation of the enzyme in relation to irreversible unimolecular thermal

inactivation, in a denser carrier (more than 50 wt.% of polyacrylamide) the thermal stability of the enzyme increases sharply.

The magnitude of the stabilisation effect. The thermal stability of the enzyme incorporated mechanically in a very concentrated polyacrylamide gel (lyophilised powder) is so much higher than the thermal stability of the enzyme in solution that the two quantities cannot be measured at the same temperature. It is necessary to investigate the temperature variation of the rate of unimolecular thermal inactivation: linear extrapolation of the data presented in Fig.7 to the centre of the temperature range (120 °C, vertical dashed line) shows that the stabilisation effect in a fully dried gel reaches a value corresponding to an increase by a factor of 10^{13}. For less concentrated gels, the stabilisation effect is naturally smaller.

The stabilisation mechanism is not associated with the influence of the non-polymerised acrylamide[149] because it was completely washed out of the comminuted gel[143,144]. Nor can stabilisation be explained by the chemical grafting of the enzyme to the gel, because both chymotrypsin and trypsin could be completely eluted from the swollen gel[143,144]. The enzyme hardly interacts with the matrix via a sorption mechanism, because the protein globule retains a high rotational mobility up to a gel concentration of 50 wt.% (where appreciable thermal stabilisation is already observed)[119,143,144]. Consequently the pore size presumably diminishes with increasing gel concentration and ultimately the enzyme globule is "clamped" and cannot uncoil (be denatured) as a result of the "cage effect".

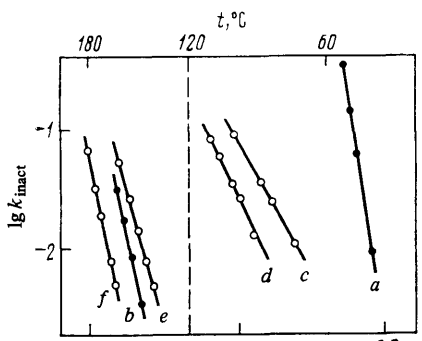

Figure 7. Temperature variation of the pseudo-first-order rate constant (k_{inact}, min^{-1}) characterising the unimolecular thermal inactivation of α-chymotrypsin: *a*) solution of native enzyme (pH 5–8); *b*) lyophilised enzyme; *c*)–*f*) enzyme incorporated mechanically in 48, 60, 80, and 100 wt.% polyacrylamide gel respectively (the polymer concentrations indicated are those in 60 μm gel grains washed after lyophilisation)[134,143].

It might have been supposed that a different stabilisation mechanism operates, namely that the dehydration of the protein can lead to a decrease of the mobility of the polypeptide chains, which would hinder the uncoiling of the globule. A choice between these alternative mechanisms cannot be made in a study of the thermal stability of a lyophilised preparation of the free enzyme. In this state the protein molecules are in all probability involved in a very close packing, where each globule can be incorporated (as in immobilisation in a gel) in a "narrow pore" formed by similar globules. The exceptionally high thermal stability of dry (lyophilised) enzyme preparations[139,141,142] (particularly that of chymotrypsin, see Fig.7), observed experimentally, can be caused both by the "dehydration of the polypeptide chains" and by the "cage effect". This problem was resolved, i.e. an unambiguous choice was made between these two mechanisms, by employing polysaccharide carriers.

Polysaccharide carriers are inert and hardly interact with proteins. This is indicated by the following fact: although the translational diffusion of protein molecules (lactoglobulins, ribonuclease, etc.) virtually disappears in a 40% dextran solution, their rotational diffusion is not significantly inhibited (compared with an aqueous solution without a polysaccharide)[150].

Pseudo-first-order rate constants (min^{-1}) for the irreversible unimolecular thermal inactivation (60 °C) of native and immobilised α-chymotrypsin[134,144].

Preparation	Free enzyme	Enzyme attached to the surface of cellulose	Enzyme incorporated in the pores of Sephadex
Solution or suspension at pH 8 (2×10^{-2} M tris-HCl + 0.1 M KCl)	3	0.1	0.08
Lyophilised state	*	0.05	*

*Thermal inactivation was not observed for 30 min even at a higher temperature (100 °C).

In order to obtain an answer to the above question, a study was made of the thermal stability of chymotrypsin attached covalently to two polysaccharide carriers—cryptocrystalline cellulose and Sephadex. Although these carriers are very similar in their chemical compositions, they are structurally fundamentally different: in contrast to cellulose, Sephadex has a porous structure. Consequently, whereas in the case of cellulose the enzyme is attached to the surface, in Sephadex the attached protein molecule is incorporated within a carrier pore. On lyophilising the carrier, the "cage effect" can therefore obtain in the latter case (and only in the latter case). The Table shows that covalent immobilisation has only a slight influence on the thermal stability of chymotrypsin on both polysaccharide carriers (in relation to the free enzyme). The additional lyophilisation of the enzyme attached to the surface of cryptocrystalline cellulose also does not alter significantly the thermal stability of the enzyme preparation. On the other hand, thermal inactivation of the enzyme attached to Sephadex G-150 could be observed neither under comparable conditions (see Table) nor even at 100 °C (incubation time 30 min).

Since the only significant difference between these two polysaccharide carriers is that in the Sephadex the enzyme was located in a narrow pore after drying, while in cellulose it remained on the surface of the particle, one may reach the following conclusion: the very high increase of the thermal stability of enzymes in concentrated porous carriers (Sephadex and polyacrylamide) is caused by the "cage effect" and not the dehydration of the protein.

Further prospects. Preparations with such high thermal stability can be used in practice if the swelling of the carrier in water is prevented. This can be achieved by employing sufficiently cross-linked polymeric materials or by carrying out enzymic reactions in organic solvents immiscible with water (for further details, see below).

The method involving the immobilisation of protein globules in the narrow pores of an inert carrier leads to new possibilities for the stabilisation (as a result of the "cage effect") of even extremely labile enzymes, which are usually inactivated as a result of immobilisation on interaction with carriers.

In nature a similar mechanism (based on the "cage effect") can stabilise proteins in spores in relation to unfavourable conditions in the environment.

5. Approaches Based on the pH Dependence of the Rate of Thermal Inactivation

The rate of thermal inactivation sometimes depends significantly on the pH (see, for example, Goldstein and coworkers[6,101]). In this case the denaturation of the enzymes can be suppressed by procedures based on the physicochemical principles described below in Sections IV.2 and IV.3.

IV. THE STABILISATION OF ENZYMES IN RELATION TO INACTIVATION UNDER THE INFLUENCE OF EXTREME pH VALUES

Many enzymes lose their catalytic activity rapidly and irreversibly under the influence of what for them are extreme pH values (i.e. at pH values of the medium remote from the natural pH range of their activity)[52]. The "alkaline" inactivation of pig pepsin (which begins already at pH 5) and the "acid" inactivation of chicken lactate dehydrogenase (which takes place effectively at pH 4) can be pointed out as thoroughly investigated examples.

In principle, when an enzyme is immobilised, its pH stability can change (as well as its thermal stability—see the previous Section). Indeed this phenomenon has been observed experimentally[5,6,42,151] for many enzymes. In order to account for it, one usually points (see, for example, Goldstein and coworkers[6]) to the change in the microenvironment of the enzyme when it is immobilised; another possible effective factor may be a change in the enzyme conformation on immobilisation (induced, for example, by its chemical modification or interaction with the carrier).

However, as in the consideration of the thermal stability of enzymes, we are forced to conclude that, despite the probable validity of these causes, they cannot be used in the development of general principles for increasing the pH stability of enzymes, since it is not known in what way the stability is related to the microenvironment of enzymes and their conformations. On the other hand, one can now already formulate several general principles (unrelated to those discussed above), which increase the pH stability of enzymes as a result of their immobilisation.

1. Prevention of the Uncoiling of Enzyme Molecules

The pH inactivation of enzymes, like thermal inactivation, apparently includes as a significant stage the uncoiling of protein molecules[53] caused by the change in the balance of electrostatic and hydrogen bonds when the ionised state of ionogenic protein groups is altered by the change of pH. In this case all the recommendations made in the discussion of the stabilisation of enzymes in relation to thermal inactivation are applicable (see above).

2. Immobilisation of the Enzyme on a Carrier with Buffer Properties

Suppose that the enzyme is immobilised on a carrier with ionogenic groups exhibiting buffer properties with a considerable capacity. It is then evident that, following a change in the pH of the solution, the change in "micro-pH" in the carrier (i.e. the pH values around the enzyme) will always be considerably smaller. This increases the observed pH stability of the immobilised enzyme compared with its native state.

A brilliant illustration of this postulate is apparently provided by the work of Kaplan and coworkers[152], who investigated the acid inactivation of native lactate dehydrogenase and the enzyme attached covalently to glass. Whereas the native enzyme is almost completely inactivated after 1 h at pH 3.2 (25 °C), the immobilised enzyme retains virtually 100% activity under these conditions even after incubation for 35 days (Fig.8). The buffer properties of the carrier surface are in this case confirmed by the fact that, in contrast to the native lactate dehydrogenase, the catalytic activity of the enzyme attached to glass is almost independent of the pH of the medium[152].

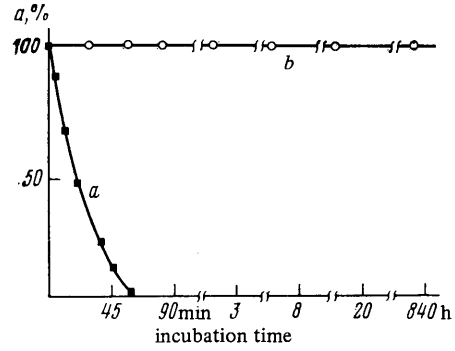

Figure 8. The pH stability of native lactate dehydrogenase (*a*) and the enzyme bound covalently to porous glass (*b*) (25 °C, pH 3.2).[152]

3. The Shift of the pH Profile for the pH Inactivation of the Enzyme

After the studies by Katchalski and coworkers[153,154], which have become classical, the shift of the pH profile of the catalytic activity of enzymes when they are attached to polyelectrolytes appears quite natural[65]. When enzymes are immobilised on polyanions, the pH profile of their activity shifts to the alkaline region (in consequence of the higher proton concentration in the carrier phase compared with the solution), and when they are immobilised on polycations there is a shift to the acid region (in consequence of the lower proton concentration in the carrier phase compared with the solution); see, for example, Fig.9*a*. The shift of the pH

profile of the catalytic activity of enzymes on immobilisation should also be observed, generally speaking, in the case of a non-electrolyte carrier owing to a specific distribution of protons between the latter and the medium[65].

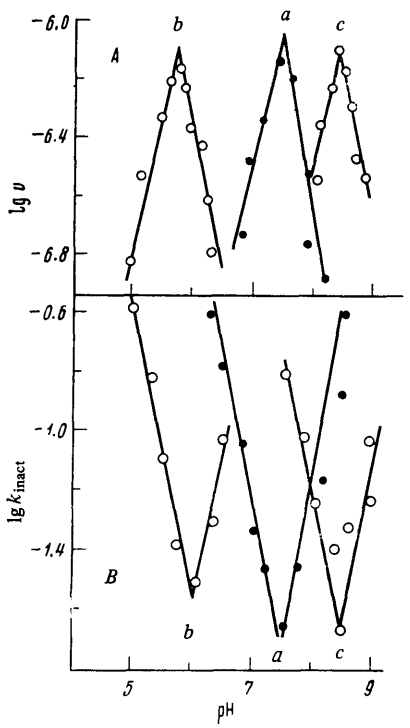

Figure 9. The pH variation of the maximum rate V (arb. units) of hydrolysis of benzylpenicillin catalysed by penicillin amidase (A) and of rate constant (min^{-1}) for the inactivation (at 50 °C) of penicillin amidase (B): a) native enzyme; b) enzyme–polycation complex; c) enzyme–polyanion complex[155].

Evidently analogous effect should obtain also in the pH inactivation of enzymes—the difference between the pH values of the solution and the carrier phase should lead to a shift of the observed pH profile for the pH inactivation process. Indeed, a series of studies by Katchalski and coworkers (see the references in a paper of Goldman et al.[6]) showed that, as was to be expected, the attachment of enzymes to a polyanionic carrier increases their stability at alkaline pH, while attachment to a polycationic carrier makes them more stable in acid solutions. This phenomenon is illustrated by the results of a study[155] (Fig. 9) in which the activity and stability of penicillin amidase immobilised on different carriers were investgiated. Evidently (Fig. 9*B*) the pH profiles of the rate constant for the pH-inactivation of the enzyme are displaced depending on the nature of the carrier, in full agreement with this theory.

V. ENZYMIC REACTIONS IN ORGANIC SOLVENTS WITH A LOW CONTENT OF WATER (OR IN ITS ABSENCE)

Many enzymes have been adapted by nature to function effectively primarily in aqueous solutions. This fact limits, in principle, the activation of enzymes as catalysts of reactions employed in practice. The point is that many chemical reactions are thermodynamically favourable only in specific organic solvents, which is due to specific solvation effects, the solubility of individual reactants, and the fact that, apart from the required product, water is sometimes formed, so that the equilibrium is strongly displaced towards the initial substances when the reactions are carried out in aqueous solutions. The last cause inhibits the use of biocatalysis in important processes such as the synthesis of esters or amides, the polymerisation of aminoacids or sugars, dehydation reactions, etc.

Evidently this difficulty can be overcome by replacing water as the reaction medium by a non-aqueous solvent. There have been fairly numerous studies in which attempts were made to carry out enzymic reactions in organic solvents or aqueous organic media with a high concentration of the non-aqueous component[58,156–181]. However, all valid studies of this kind, led to the conclusion that on passing from water to the organic solvent, the catalytic activity of the enzymes falls sharply and their substrate specificity disappears.

A partial solution to this problem can be found by selecting an organic component which denatures the enzyme to the smallest extent[181]. However, two other approaches are more promising: the use of two-phase aqueous organic systems (mixtures of water and organic solvents with which it is immiscible)[59,182] or inclusion of enzymes in "inverted" micelles of surfactants[183]. We shall consider in greater detail the physicochemical principles of these three approaches.

1. Criteria for the Selection of the Optimum Organic Solvent

In order to carry out enzymic processes in non-aqueous or aqueous organic media with a high content of the non-aqueous component, one uses as a rule organic solvents such as dimethyl sulphoxide[158–165], formamide[163,166], dimethylformamide[163,167–169], dioxan[170–174], ethylene glycol[172,175], glycerol[175,176], monohydric alcohols[165,172,177–180], and acetone[165,174]. The choice of a particular solvent is in most cases random and lacks theoretical foundations.

The criterion for the selection of the optimum solvent (from the standpoint of its influence on the enzyme) can be based on the general ideas of the relative role of the forces maintaining the native structure of protein molecules in aqueous solutions: hydrophobic interactions play a dominant role[79]. Consequently a non-aqueous solvent which is "satisfactory" for the protein should not disrupt such interactions.

In order to obtain an answer to the question which solvents have this property, we shall turn to data for the model process involving the formation of surfactant micelle in various solvents. Ray[184] concluded that hydrophobic interactions constitute merely a special case of solvophobic interactions. All solvents can be divided into three classes in terms of their ability to undergo solvophobic interactions: the first class includes water, glycerol, ethylene glycol, aminoethanol, formamide, and certain others; the second includes methyl, and dimethyl-formamides, and the third includes methanol, ethanol, and toluene. Solvophobic interactions occur to the greatest extents in solvents of the first class (thus it has been found that[184] detergent micelles are formed only in such solvents); they take place to a much lesser extent in solvents

of the second class and are virtually absent in solvents of the third class.

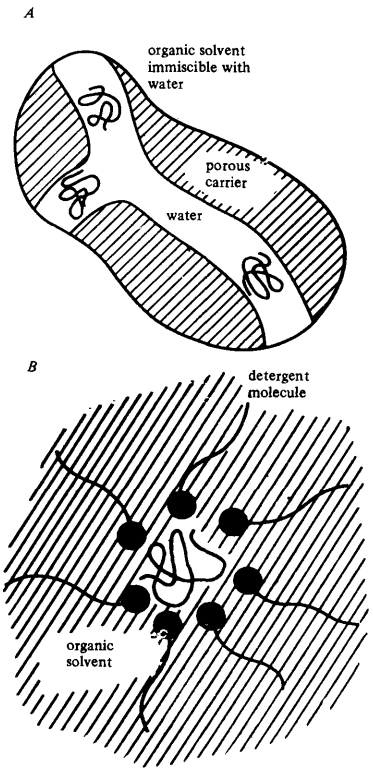
According to Ray[184], this difference is due to the fact that the molecules of solvents of the first class contain at least two or three fragments capable of forming hydrogen bonds. As a result of intermolecular interactions, hydrogen bonds form rigid (thermodynamically unfavourable) skeletal solvent structures around the solvophobic solute molecules. This leads to solvophobic (or in the special case hydrophobic interactions). In the series of solvents of the first class solvophobic interactions occur most effectively in water and glycerol (estimated from critical concentrations for micelle formation); in the remaining solvents this ability is significantly smaller.

The above data made it possible to formulate[181] a criterion for the choice of the optimum solvent. The criterion is extremely universal, because the efficiency of solvophobic (as well as hydrophobic[185]) interactions is determined primarily by the nature of the solvent and not the nature of the interacting molecules. Consequently if it is assumed that hydrophobic interactions play the main role in maintaining the structure of protein molecules[79], one must recognise that the best solvents for enzymic reactions should be those of the first class, including water (which is employed in nature) and glycerol.

We may note that the authors of the majority of studies used solvents belonging to the second or even third group (see above), i.e. the least successful solvents. However, in some investigations it was nevertheless found experimentally[172,180,186,187] that solvents belonging to the first class (particularly glycerol and to a lesser extent ethylene glycol) denature proteins much less than others. These empirical findings can be given a physicochemical explanation in the light of studies by Martinek and coworkers[181,184].

2. Enzymic Reactions in Two-Phase Systems Comprising Water and an Organic Solvent Immiscible with It

Following the development of research into immobilised enzymes, studies began to appear whose authors attempted to make enzymes function in organic solvents and aqueous organic media with a high concentration of the organic component having increased their stability in relation to the denaturing influence of the non-aqueous medium by attaching them to a carrier (see, for example, Refs.165, 168, 169, 173, 174, 176, 179, 180, and 189–191). However, even in the most successful systems, when the concentrations of the organic component are above 90%, the immobilised enzyme is nevertheless inactivated. Thus, from the standpoint of preparative enzymic synthesis, the problem formulated remains unsolved. It is extremely likely that in this form it is insoluble, in principle, because, on passing from water to a non-aqueous medium, there is bound to be a significant change in the conformation of enzymes[58,192] and a consequent sharp impairment of their catalytic function.



We found a fundamentally new solution[59,182]. In all the studies with which we are familiar, where the behaviour of enzymes was investigated in aqueous organic or organic media, solvents such as acetone, acetonitrile, dioxan, dimethyl sulphoxide, dimethylformamide, methanol, ethanol, and others (see above) were used as the non-aqueous component. A common feature of these solvents is that they are infinitely miscible with water. This is in fact why one has to solve the problem of the stabilisation of enzymes in relation to inactivation by the organic component.

The basic idea of our approach[59,182] is that the organic solvents added to the enzyme-containing aqueous phase should be virtually immiscible with water (for example, chloroform, ether, aliphatic alcohols, hydrocarbons, etc.). In this case the resulting system will consist of two phases—aqueous and organic. The enzyme will be contained solely in the aqueous phase, because, firstly, it can be immobilised there, and, secondly, even if immobilisation is impossible, proteins, which are satisfactorily soluble in water, are usually virtually insoluble in hydrophobic solvents[58]. The substrates, being soluble in the organic phase, can in their turn diffuse freely[193,194] from the latter to water, where they undergo a chemical transformation under the influence of the enzyme; the products diffuse from water back to the organic phase. Thus the thermodynamic equilibrium in the given chemical reaction is established throughout the aqueous organic system via water (with the aid of the enzyme catalyst present in water).

Such a two-phase system has a number of fundamentally important properties: (1) since the enzyme is not in contact with the non-aqueous component of the reaction medium, there is no need to solve the problem of its stabilisation[59,192]; (2) the volume fraction of the organic phase can be in principle as close to unity as required, so that equilibrium conditions in a two-phase system of this kind can be made as close to equilibrium in the pure organic medium as one wishes (see the theoretical aspects below[59,182]); (3) a high content of the non-aqueous component of the medium can ensure also a solubility of hydrophobic reactants, for example, steroids, sufficient for preparative synthesis[195,196].

Methodological aspects. The enzyme system comprising water and an organic solvent immiscible with it can be prepared as an emulsion of an aqueous solution of the enzyme in the organic medium or as a suspension in the organic medium of porous particles (for example, a porous glass or ceramic, a hydrophilic gel, etc.) impregnated by the aqueous enzyme solution[59,182] (see Scheme 2, *A*), the latter procedure being much more convenient both methodogically and tecnologically.

Scheme 2

The aqueous enzyme solution can also be enclosed in microcapsules or hollow fibres[9,11] or even in the microcracks of a polymeric carrier by mechanical deformation of the latter[197]. The enzyme can be used in both free and immobilised states.

It would seem that preparative enzymic synthesis in a two-phase system is inapplicable to reactions in which the reactants (and in the first place products) are ions, because ions cannot pass from water to the organic phase. However this difficulty can be overcome[182] by selecting hydrophobic counterions for ionic reactants (as suggested in the chemistry of nucleotides[198] and used widely in phase transfer catalysis—see, for example, Dehmlow[199]).

Examples. (a) The idea of carrying out enzymic organic synthesis in a two-phase aqueous organic medium with a high content of the non-aqueous component was tested[59,182] in relation to the chymotrypsin-catalysed synthesis of the methyl ester of *N*-acetyl-L-tryptophan from ethanol and *N*-acetyl-L-tryptophan. Since water is formed together with the ester in the synthesis, the equilibrium was strongly displaced towards the initial reactants when the reaction was carried out in water (see the references in the papers by Martinek et al.[200] and Carpenter[201]). Furthermore, at neutral pH (at which the enzyme employed is active) there is an additional shift of the equilibrium unfavourable for the synthesis of the ester and caused by the thermodynamically favourable ionisation of one of the initial components—the acid. Ultimately the yield of the ester is negligible, amounting to less than 0.01% even at a relatively high ethanol concentration (~10 M). In the "chloroform + 1 vol.% of water" two-phase system the equilibrium was completely displaced towards the ester[59,182] and the yield was virtually 100%.

The enzymic synthesis was carried out as follows. The porous glass was simply soaked in an aqueous buffer solution (1 M KH_2PO_4, pH 7) of chymotrypsin (5×10^{-4} M) and then 0.3 g of the resulting preparation was transferred to 30 ml of chloroform containing the substrates, i.e. 10^{-2} M *N*-acetyl-L-tryptophan and 1 M ethanol, and the system was stirred overnight. Analysis of the resulting mixtures showed that the entire *N*-acetyl-L-tryptophan was converted into the corresponding ethyl ester. The identity of the product with the commercial ethyl ester of *N*-acetyl-L-tryptophan was demonstrated by gas–liquid chromatography—the retention times agreed. In order to isolate the product, it was sufficient to separate the aqueous phase and to evaporate the chloroform on a rotating evaporator.

(b) The equilibrium could be shifted analogously in the synthesis of glycerophosphate from glycerol and inorganic phosphate catalysed by alkaline phosphatase[182]. In order to ensure the solubility of the ionic phosphate reactants in the two-phase "chloroform + 1 vol.% of water" system, tetrabutylammonium was used as the counterion. Whereas the yield of the ester in water[188] was neglibile (less than 0.1%), in the two-phase system it amounted to 30%.

Theoretical aspects and prospects. The observed shift of the equilibrium is common to chemical reactions. In order to demonstrate this, consider the reaction

$$A + B \overset{K}{\rightleftarrows} C + D, \qquad (1)$$

where K is the equilibrium constant. Suppose that the aim of the synthesis is, for example, the formation of product C. Its yield is evidently defined by the expression

$$[C] = K[A][B]/[D]. \qquad (2)$$

It is seen that there are two causes of the shift of the equilibrium (and of the increase of the yield of product C) on passing from water as the reaction medium to the two-phase aqueous organic system described. Firstly, if the product D of the reaction is water, a decrease of its concentration in the system leads to an increase of the yield of products in accordance with Eqn.(2). Thus in the syntheses described above a change from 100% water to an approximately 1% aqueous system resulted in an approximately 100-fold increase of the yield of the ester.

Secondly, the shift of the equilibrium in reaction (1) can occur due to a change in the effective equilibrium constant on passing from water to the two-phase system. Suppose that the equilibrium constant for reaction (1) in water is K_w. Then the effective equilibrium constant in the two-phase system K is defined (by analogy with the study of Martinek et al.[202]) by the expression

$$K = K_w \frac{(1+\alpha P_C)(1+\alpha P_D)}{(1+\alpha P_A)(1+\alpha P_B)}, \qquad (3)$$

where α is the ratio of the voumes of the non-aqueous and aqueous phases and P_A, P_B, P_C, and P_D are the partition coefficients of the reactants between the non-aqueous and aqueous phases. We shall assume that the initial reactants A and B are sparingly soluble in the organic phase, but are effectively soluble in water, i.e. have low partition coefficients—for example, $P_A \cong P_B \cong 10^{-2}$. In this case, even if only one of the products is sparingly soluble in water but effectively soluble in the organic phase, i.e. has a high partition coefficient, for example, $P_C \cong 100$, then it follows from Eqn.(3) that $K > 2500\ K_w$ for $\alpha = 100$.

Evidently the effective equilibrium constant in the two-phase system can in principle exceed that in water by many orders of magnitude. This constitutes an additional (in some cases the main one) cause of the shift of equilibrium (1).

In principle, by varying the nature of the non-aqueous phase (and hence by varying the partition coefficients of the reactants), it is possible to alter K as required and hence also the yield of the product. The partition coefficients of ionic reactants can be altered (and hence the reaction equilibrium can be displaced in the required direction) by selecting hydrophobic counterions (see the methodological aspects described above).

3. Catalysis by Water-Soluble Enzymes Incorporated in "Inverted" Surfactant Micelles in Organic Solvents

The molecules of many surfactants form in organic solvents associated species of the type of "inverted" micelles in which the polar (ionic) groups of the surfactant molecule constitute the nucleus of the associated species, while the hydrocarbon fragments make up the outer layer[203–205]. Such micelles are known to be capable of solubilising ions, polar organic substances, as well as considerable amounts of water (several tens of H_2O molecules per surfactant molecule). It has been shown recently[183] that relatively high concentrations of biopolymers (enzymes) can also be solubilised by micelle-forming surfactants in organic solvents, up to 1 mg ml^{-1}, which corresponds to $\geqslant 10^{-5}$ M active centres (for a molecular weight of the enzyme not more than 100 000) and greatly exceeds the required level of "catalytic concentrations" of the majority of enzymes[1,2]. The enzyme then retains almost completely its catalytic activity and substrate specificity.

When it is enclosed in the inverted micelle (see Scheme 2, *B*), the enzyme molecule is apparently protected against denaturation (against the uncoiling of its structure) by the fact that the "interface" between the protein globule (or its surface layer of water) and the organic solvent is stabilised by the surfactant molecules. Ultimately the biocatalyst may not in fact come into direct contact with the organic solvent unfavourable for it, being located in a kind of microreactor

containing only several hundredths of H_2O molecules per enzyme molecule (this corresponds to a total water content in the organic solvent–surfactant system less than 1 vol.%). Thus the relative catalytic activity of α-chymotrypsin solubilised in octane is retained for months at room temperature[183].

The systems investigated. All these postulates have been demonstrated[183] in relation to the proteolytic enzyme chymotrypsin (in the hydrolysis of the *p*-nitroanilide of *N*-glutaryl-L-phenylalanine) as well as peroxidase [in the oxidation of hexacyanoferrate(II) ions and pyrogallol]. The reactions of these enzymes with their specific substrates have been investigated in extremely hydrophobic (hydrocarbon) solvents, namely octane and benzene, using as the surfactant a product manufactured on a large scale—the di-(2-ethyl) ester of the sodium salt of sulphosuccinic acid (Aerosol OT), which was kindly supplied to us by Prof.Menger (USA). Data for the formation and properties of the micelles of this surfactant in organic solvents have been reviewed[206]. A typical experiment was as follows: 2 ml of 0.1 M solution of the surfactant in the hydrocarbon was treated with $\leqslant$0.01 ml of a concentrated (10^{-3} M or less) solution of the enzyme in an aqueous buffer, $\leqslant$0.01 ml of the substrate solution in water or acetonitrile was introduced, and the rate of enzymic reaction was measured spectrophotometrically in the resulting homogeneous (optically transparent) system.

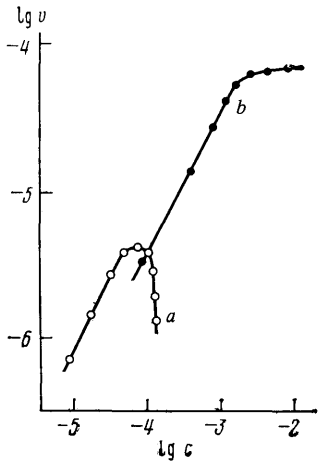


Figure 10. Dependence of the initial rate of the peroxidase oxidation of pyrogallol in water (*a*) and octane (*b*) on the molar pyrogallol concentration. Conditions: pH 7, 26 °C, 2.5×10^{-3} M H_2O_2, 3×10^{-9} M peroxidase, in octane containing 2 vol.% of water and 0.01 M Aerosol OT.[183]

As an example, Fig.10 presents data[183] for the peroxidase oxidation of pyrogallol. Evidently, when the reaction is transferred from water to a medium containing inverted micelles in octane, the kinetic mechanism of the catalysis changes. This is associated with the fact that in the latter case there is no substrate inhibition characteristic of the reaction in water.

Use in fundamental biochemical research. Enzymes solubilised by the method of Martinek et al.[183] in organic solvents (to which a surfactant forming inverted micelles has been added) will undoubtedly find applications as models of enzymes functioning *in vivo* in biological membranes and also in the study of the role of water in the structure of proteins and of the mechanisms of enzyme catalysis (particularly the catalysis of processes where water is a chemical reactant). The point is that the amount of water solubilised in the system and hence the amount surrounding the enzyme in the inverted surfactant micelle can be strictly controlled.

VI. CONCLUSION

1. Stabilisation of Enzymes under the Influence of Water-Soluble Additives

We endeavoured to describe as fully as possible the problem of the stabilisation of enzymes, but we deliberately disregarded an enzyme stabilisation phenomenon which is widespread and is frequently discussed in the literature; it takes place under the influence of effectors such as bivalent metal ions (in the first place Ca^{2+}, Mg^{2+}, Sr^{2+}, Zn^{2+}, Co^{2+}, and Mn^{2+} [207–210]) ammonium sulphate[211], various anions (in the first place phosphate and sulphate[212–215]), serum albumin[216,217], polyols (in the first place glycerol as well as ethylene glycol, sucrose, etc.)[218–220], detergents[221], and organic solvents[222,223].

In the present review we did not consider this type of stabilisation of enzymes for the following reasons. Firstly, the above effects are not general: the same effector can stabilise one enzyme and reduce the stability of another[211,224]. At the same time a given enzyme can be stabilised by one of the above effectors and labilised by others[225]. Secondly, in most cases the physicochemical mechanism of the stabilisation of enzymes by the effectors is obscure and in others is trivial—for example, sometimes when serum albumin is added as a stabilising additive. This protein is either effectively adsorbed on the interface (for example on the water/air interface) and thus prevents the surface inactivation of the enzyme itself, or it sorbs heavy metal cations and other admixtures which "poison" the enzyme. At the same time, one must emphasise the practical and theoretical importance of studies in this field, particularly those with the correct quantitative profile.

2. Two General Principles of the Stabilisation of Enzymes

In the present review we considered fairly extensively only the general physicochemical approaches, which are also of technological importance and which protect the enzyme from denaturing factors in the medium (elevated temperature, extreme pH values, and the addition of organic solvents). The entire wide variety of approaches discussed (see Sections III–V) can be divided into only two groups, corresponding to the following two general principles.

(1) An increase of the rigidity of the protein globule which prevents its uncoiling on denaturation and hence inactivation; this can be achieved both by cross-linking the protein (with formation of a water-soluble preparation) and as a result of the multipoint interaction of the protein (both covalent and physical) with a complementary carrier surface (for the preparation of an insoluble heterogeneous catalyst).

(2) The spatial separation of the enzyme and those factors in the medium which do not favour the retention of catalytic activity and specificity. The application of this principle depends on the nature of the inactivating influence. Thus, in order to prevent the pH inactivation, one can immobilise the enzyme on a carrier either having buffer properties or

ensuring a local shift of the pH in its surface layer. The influence of the organic solvent can also be avoided in two ways: either by carrying out the enzymic reaction in a two-phase system comprising water and an organic solvent immiscible with it or by enclosing the enzyme in the "inverted" micelles of a surfactant.

3. Stabilisation of Enzymes as a Problem with Optimum Solution

The methods for the stabilisation of enzymes developed at the present time (in relation to inactivation as a result of the uncoiling of protein globules) can lead in many instances to undesirable secondary effects, which hinders somewhat the practical application of biocatalysis.

Thus, firstly, when attempts are made to stabilise the enzyme, the increase in the rigidity of the protein globule should not be too extreme: otherwise a loss of catalytic activity may ensue. The point is that the functioning of the active centre presupposes as a rule the concerted action of several functional groups of the protein and therefore requires a definite mobility of the polypeptide chains[1,2]. Incidentally, the relation between the stability and catalytic activity of enzymes apparently plays an important role in the adaptation of the organism to changes in the environment (temperature, salt content in sea water)[54].

Secondly, when the enzyme is included in a carrier (particularly in a gel), there may be an increase of steric hindrance to the interaction of the enzyme with macromolecular substrates (see the references in the reviews by Berezin et al.[5,65]).

Thirdly, and finally, in unduly dense carriers, which ensure a high thermal stability of the immobilised enzyme, there may arise in their turn significant diffusion-dependent obstacles to the exchange of reactants between the catalyst and the medium (see the references in Refs.5 and 64–66).

Consequently, in many instances enzyme stabilisation involves a problem with an optimum solution, i.e. it is necessary to optimise the enzyme immobilisation process in such a way that the gain in thermal stability is achieved at the expense of only a slight loss of catalytic activity.

Naturally, approaches based on the principle of the spatial separation of the enzyme and those factors in the region which do not favour its functioning are largely or completely free from these disadvantages.

Problems in the Study of Supported Metal Catalysts

A.A.Slinkin

Our current understanding of catalysis on supported metals is reviewed, and the three most important problems still outstanding in this area of catalysts are discussed: 1) the sintering mechanism of the supported metals, 2) the structure and catalytic properties of small metallic crystals, and 3) catalysis by metal clusters. 96 references.

CONTENTS

I. Introduction 404
II. Sintering mechanism of supported metal catalysts 404
III. Structure and catalytic properties of small metallic crystals 406
IV. Catalysis by metal clusters 409

I. INTRODUCTION

Among the various problems encountered in the study of the structure and catalytic properties of supported metals the following appear to be the most important:

1) the sintering mechanism of supported metal catalysts

2) the structure of small metal crystals, and their catalytic properties

3) catalysis by metal clusters.

Without attempting a comprehensive treatment of these complex problems, we shall formulate the basic concepts and approaches which have been developed for their solution.

II. SINTERING MECHANISM OF SUPPORTED METAL CATALYSTS

The scope of theoretical and experimental studies of the sintering of supported metal catalysts has increased in recent years because of the great practical importance of this problem in the development of stable catalysts, and also because many of the theoretical problems to be solved are relevant to catalysis as a whole, i.e.: 1) the interaction and diffusion of metal atoms on the metal surface, 2) the interaction of metal microcrystals and atoms with the carrier, 3) the effect of various gases on the sintering process, 4) the effect of impurities in the metal and in the carrier on the sintering mechanism.

We shall briefly review the basic theoretical considerations and some of the most important experimental results in this field of research.

1. Model of Particle Growth Through the Migration, Collision, and Coalescence of Crystals

A phenomenological description of these processes was recently developed by Ruckenstein and Pulvermacher[1,2] (the RP model) and analysed by Wynblatt and Ahn[3]. Sintering is described in terms of binary collisions on a plane surface, and rate limitation is associated either with the migration or with the coalescence of the particles. In either case we can write

$$\left[\frac{S_0}{S}\right]^n = 1 + (\text{const})\,t \qquad (1)$$

or

$$\frac{dS}{dt} = -kS^n, \quad n = 3+m,$$

where n and m are integers, and m is related to the diffusion coefficient (D) and to the radius of the particle (R) by the expression

$$D = c(1/R)^m;$$

S_0 is the initial value of S (the aggregate surface area of particles per unit area of carrier surface).

This model can be used to calculate the distribution of particles for either migration or coalescence as the rate-limiting step of the growth process. However for $n = 3$ the model predicts a diffusion coefficient independent of particle size, which is difficult to accept. The formalism of the RP model was extended by Wynblatt and Jostein[3], who calculated the coalescence times (τ_C) and the migration times (τ_p) of the particles on the surface (see Table).

Calculated coalescence and migration times of particles on the surface*.

$2R$, Å	τ_c, s	D_p, $cm^2 s^{-1}$	τ_p, s
25	$3.5 \cdot 10^{-4}$	$1.3 \cdot 10^{-13}$	12
100	$8.9 \cdot 10^{-2}$	$5.0 \cdot 10^{-16}$	$3 \cdot 10^4$
250	3,5	$1.3 \cdot 10^{-17}$	$1.2 \cdot 10^7$
2500	$3.5 \cdot 10^4$	$1.3 \cdot 10^{-21}$	$1.2 \cdot 10^{13}$

* $T = 700$ °C; the migration path is $10 \times 2R$.

The coalescence time is seen to be much shorter than the time for migration of the particle over a significant distance, and therefore the rate-limiting step of the sintering process is migration rather than coalescence. From the tabulated results and their associated calculations we conclude that the growth of particles can be limited by migration only for particle sizes below 50 Å. The RP model has been criticised[4,5] on the following grounds:

1) it ignores the energetic and morphological non-uniformity of the surface;

2) it fails to explain the observed increase in the dispersion of the metal at high temperatures in an O_2 atmosphere;

3) there is no independent demonstration that the motion of the particles is sufficient to account for sintering.

2. Model of Particle Growth Through the Migration of Atoms or of Sub-atomic Molecular Units

This model, which was developed by various workers[6-8], is illustrated in Fig. 1. Particles grow as a result of matter transport by two mechanisms: diffusion through the gas phase and diffusion on the carrier surface.

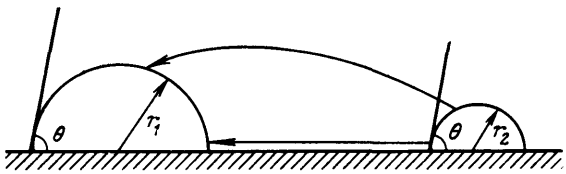

Figure 1. Transfer of matter between two particles on a plane surface[6].

The angle θ is given by the formula

$$\gamma_s = \gamma_{ms} + \gamma_m \cos\theta,$$

where γ_S and γ_m are the surface tensions of the carrier and of the particle respectively, and γ_{mS} is the interfacial tension. The chemical potential μ of the particle depends on the particle radius r according to the Gibbs–Thomson equation

$$\mu = \mu_0 + 2\gamma_m \Omega / r,$$

where Ω is the atomic volume.

Thus large particles will grow at the expense of the smaller particles, whose chemical potential is greater, leading to an overall decrease in the surface energy of the system. According to this model the atomic mechanism of the sintering process may involve three steps[7]: 1) removal of a metal atom (or molecular unit) from the crystal, and transfer to the carrier; 2) migration of the atomic (or molecular) particle on the carrier surface; 3) capture of the migrating atoms (or molecules) by the crystals during collisions.

In this model the sintering process can be described with allowance for specific physicochemical features of the system. For example, in a supported Pt system the diffusing species are Pt atoms in a reducing medium and PtO_2 or PtO particles in an oxidising medium. The rate of growth of the particles is small in a reducing atmosphere because the sublimation energy (which appears in the exponential term of the rate constant) is 135 kcal mole^{-1} for Pt. On the other hand since the activation energy for the removal of a Pt atom as PtO_2 is only ~ 42 kcal mole^{-1} we expect the rate of growth to be substantially higher in an oxidising atmosphere.

This sintering mechanism predicts the following phenomena[3]:

1) the sintering rate should increase with the partial pressure of O_2;

2) stronger wetting of the carrier surface by the particles (or an increased interaction between the diffusing atom and the defects in the carrier) should lower the sintering rate, and in this way it should be possible to control the sintering process by adding impurities to the carrier or metal crystal surface;

3) the growth of particles in an O_2 atmosphere should be strongly dependent on the enthalpy of the reaction

$$M(s) + xO_2(g) = MO_{2x}(g).$$

On this basis we can define the following stability series for supported metals in an oxidising atmosphere: Os < Ru < Ir < Pt < Pd, Rh;

4) the stability under reducing conditions is determined by the heat of sublimation, leading to the following stability sequence: Pd < Rh, Pt < Ru < Ir < Os.

Neither of these theories can at present be accepted with full confidence, though a recent experimental paper[9] has confirmed the stability sequences predicted for Rh, Pt, and Ir supported on Al_2O_3. The problem is still being actively discussed[10,11], and a model of the sintering process allowing for the transfer of atoms has recently been proposed by Ruckenstein[8].

We shall now examine some examples of sintering phenomena which fall outside the scope of existing theories and need new conceptual approaches.

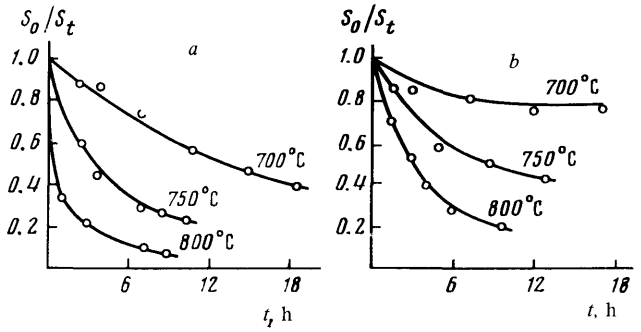

Figure 2. Sintering kinetics of Pt–Al_2O_3 catalysts: (*a*) in air and (*b*) in argon[12].

The sintering kinetics of a Pt–α-Al_2O_3 (0.036 wt.% Pt) catalyst[12] in air and in argon are shown in Figs. 2*a* and 2*b*. The sintering rate is much greater in air than in argon: the exponent n in Eqn. (1) takes the value 2 and 3 respectively, in keeping with the RP theory. However the sintering rate in N_2 quite unexpectedly goes through a maximum. This is ascribed[12] to chemical interaction between N_2 and Al_2O_3 at high temperatures (800 °C), leading to changes in the morphology of the carrier and in the sintering mechanism.

Electron microscopic studies[13] have confirmed that sintering is much faster in an oxygen atmosphere than in a vacuum. However the most fundamental result of this work was the first experimental observation of the motion of Pt crystals on the surface of graphite. The authors were able to monitor the tracks of particles moving on the graphite surface during combustion of the graphite in oxygen. Very surprisingly, particles of diameter ~ 1000 Å were found to move: this is theoretically impossible, but it can happen in this case because of the large decrease in interfacial energy resulting from the presence of O_2.

O_2 interactions on supported Pt crystals can lead to another effect not predicted by theory: dispersion of the crystals[14,15]. Pt crystals supported on Al_2O_3 whose diameter in air was initially 31 Å were found[14] to increase in size to 107 Å after a sintering treatment in air followed by slow cooling. However when the sample was re-heated in air to 500 °C and slowly cooled to 20 °C dispersion of the crystals was observed (to a diameter of 41 Å). This effect can be explained through the

formation of Pt(IV)–Al_2O_3 complexes, with a critical formation temperature of ~500 °C. This reaction at the interface between the metal and the carrier is accompanied by a large increase in the stresses applied to the metal, and these stresses are relieved by the cleaving of the crystals.

A different explanation of the same effect is given in Ref.15. It is pointed out that the PtO_2 molecules breaking away from the microcrystals can be stabilised on non-uniformities of the carrier surface and act as nuclei for new crystallites. Allowance for the inhomogeneity of the carrier surface is a significant refinement of the theoretical model, which is usually confined to a homogeneous surface. For example, the concept[16] of "trapping centres" from which microcrystallites can be released only by the expenditure of activation energy has been confirmed[17] by a demonstration that the disperseness of Pt on graphitised carbon increases (from a particle diameter of 68 Å to 19 Å) as the extent of burn-off is increased from 0 to 50%. In this case the dispersion effect arises from an increase in the energy non-uniformity of the carrier rather than from an increase in its surface area.

It is important to note that the re-dispersion of large metal crystals has been observed not only in supported platinum catalysts but also in metal–zeolite systems, in which cations are formed in an oxidising atmosphere and diffuse into the bulk of the zeolite[18,19].

Some of the most interesting publications discuss the chemical nature and the mechanism of action of the "trapping centres" which inhibit the sintering process. Thus it has been shown[20] that Pt microcrystals deposited on γ-Al_2O_3 by evaporation and decomposition of tetra-ammine complexes can be sintered in a N_2 or O_2 atmosphere, whereas crystals prepared from H_2PtCl_6 are stable up to 800 °C. It is suggested that sintering is inhibited by Cl^- ions. A similar inhibition effect by Mo^{2+} ions (added to the carrier) on the sintering of Pt and Pd was reported by Ermakov and coworkers[21].

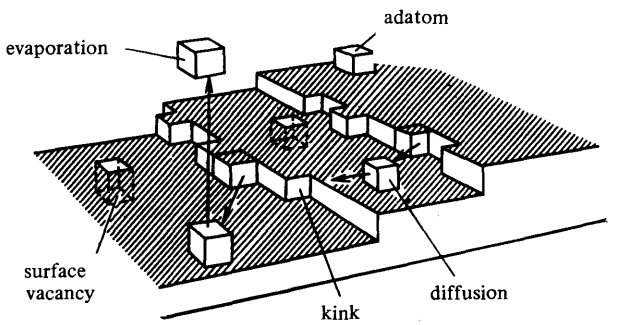

Figure 3. Elementary acts in diffusion on a crystal surface[24].

Takami and coworkers[22] made the important discovery that Rh–$MgWO_4$ catalysts have a high activity towards the reforming reaction of hydrocarbons with water vapour. Surprisingly, the surface area of the $MgWO_4$ sample was only 3–5 $m^2\ g^{-1}$, and most of the Rh was stabilised as large crystals. The high activity of these catalysts was explained by the formation of Rh^{3+} cations, which can replace Mg^{2+} in the tungstate lattice (isomorphous substitution). If tungstates of other metals (Be, Zn, Ca, Ba) are used as carriers the activity drops by a factor of 5–15. The possibility of dissolving atoms (or cations) of the metal in the lattice of the carrier was recently demonstrated (for Au atoms in MgO or Al_2O_3 lattices) by analysing the fine structure of the X-ray absorption spectra[23]. This possibility must be borne in mind when the structure and catalytic properties of supported catalysts are discussed.

The sintering processes discussed so far lead to a change in size of the metal crystals, and to a corresponding change in catalytic activity. However diffusion processes can occur not only between crystallites but also on the surface of a given crystallite[24]. The elementary steps in the diffusion of atoms on a crystal surface are shown in Fig. 3. Evidently, the "healing" of vacancies and the disappearance of kinks and steps can lower the activity without altering the size of the crystal. This process, termed "qualitative sintering", has been observed in Pd–Al_2O_3.SiO_2 catalysts[25], in which sintering is inhibited by the addition of Al^{3+}, La^{3+}, and Th^{4+} cations. The stabilisation mechanism associated with the presence of these cations is not fully understood, but one possible explanation is that the cations prevent "internal" sintering† by being adsorbed on defects contributed by surface centres.

III. STRUCTURE AND CATALYTIC PROPERTIES OF SMALL METALLIC CRYSTALS

For the last 20 years the key problem in the study of catalysis by supported metals has been to characterise the catalytic and structural properties of small metal crystals, and in more recent years this problem has attracted a great deal of attention[26–30]. We shall dwell on some aspects of this problem, i.e.: a) the structure of the crystals, and their catalytic and adsorption properties; b) interactions between the reaction system and the supported catalyst; c) the formation and properties of surface structures.

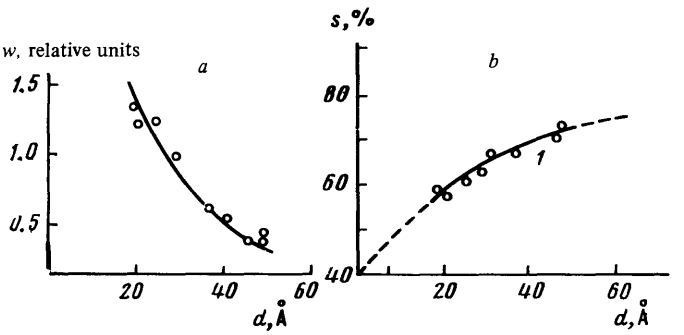

Figure 4. (a) velocity w and (b) selectivity s of the dehydrogenation of 2,3-dimethylbutane against disperseness of the Pt in a Pt–carbon catalyst[31] (curve *1*).

The number of publications on the effect of crystal size on catalytic activity and selectivity has continued to grow. It was shown[31] that the overall rate of dehydrogenation of 2,3-dimethylbutane by Pt–carbon catalysts decreases as the

† A process by which defects can be removed from the surface of microcrystals without sintering of the crystals.

average size of the Pt crystals increases, but the selectivity of the formation of 2,3-dimethylbut-1-ene increases (Fig. 4). This is ascribed to differences in the structure of intermediate complexes adsorbed on small and on large crystals, and is quoted as an example of a hindered reaction. Whether a reaction is hindered or unhindered is largely determined by the range of crystal size. The hydrogenation of benzene on $Pt-Al_2O_3$ is unhindered in the 10–50 Å crystal size range[32], whereas on Ni crystals ~5 Å in size the same reaction appears to be hindered[33]. A similar situation was observed in a study of the hydrogenolysis of ethane[34]: the specific activity was independent of the dispersion of the Ni catalyst in the range 15–70 Å, but it increased by a factor of 3 for a crystal size of ≤10 Å. The rate of oxidation of CO was found[12] to be extremely sensitive to the crystal size of the Pt catalyst.

This behaviour has been discussed both in terms of the structural features of small crystallites and by allowing for possible changes in electronic properties of the crystals (though these characteristics are often interrelated). For example, the decrease in specific activity of Ag crystals of increasing size, and the increase in their selectivity towards the formation of ethylene oxide or of CO_2 in the oxidation of ethylene, have been explained[35] by postulating two types of centre, corresponding to two forms of chemisorbed oxygen. Atomic oxygen, localised on atoms, occurs at the corners, edges, and growth steps of microcrystals: this form is very active, and leads to the formation of CO_2. Molecular oxygen, adsorbed on crystal faces, oxidises ethylene to ethylene oxide[35]. The 40-fold change in activity of Pt crystals towards the D_2 exchange with CH_4 on increasing the particle size from 9 to 100 Å is ascribed[36] to an increased proportion of the thermodynamically more stable (111) faces, which are not effective in catalysis. Thus the catalytic activity and selectivity of randomly oriented supported Ni crystals was found to be different from that of similar crystals in which the (111) and (110) faces were preferentially developed[37,38]. The oriented Ni crystals are more active towards the hydrogenation of ethylene, and they give a higher yield in the hydrogenolysis of n-heptane.

The concept of hindered and unhindered reactions is further developed in a study[39] of the isomerisation mechanism of 2-methylpentane and n-hexane on supported Pt crystals of different disperseness, allowing for the enhanced activity of atoms on corners or edges. The reaction mechanism (Fig. 5) includes the following steps:

1) weak adsorption on a Pt atom, localised on a crystal face (c_f);
2) surface diffusion to a reaction centre (edge atom, c_e);
3) formation of strongly dehydrogenated fragments on this centre;
4) rearrangement of the strongly adsorbed particles;
5) re-hydrogenation, surface diffusion, and desorption of the weakly adsorbed isomerised molecules.

A new classification of catalytic reactions has been proposed[39]. In reactions of type I all the surface atoms of the catalyst are equally active, and neither the rate nor the selectivity depends on the disperseness of the particles. In reactions of type II the number of reaction centres is greater than the number of weakly adsorbed molecules, and in this case the selectivity only is a function of disperseness. If the number of reaction centres is smaller than the number of weakly adsorbed molecules (type III) or if surface diffusion is very slow (type IV) both the selectivity and the specific reaction rate become a function of crystallite size.

Many workers have reported large differences in the adsorption and catalytic properties of metal atoms having different coordination. Thus it has been shown[40] that the n-heptane reforming reaction on supported rhodium catalysts involves atoms located on crystal faces, whereas the aromatisation reaction is due to edge atoms of Rh. Three types of centre have been defined[41] on a stepped metal surface: *A* centres (localised within a plane face), *B* centres (edge atoms), and *C* centres (corner atoms or atoms localised above the surface of a plane face). Each of these types of centre is thought to be responsible for a specific reaction involving olefins (*cis–trans*-isomerisation, migration of the double bond, hydrogenation). A similar explanation has been given[42] for the dependence of the rate of hydrogenation of cyclopropane, methylcyclopropane, and propylene on the disperseness of the Pt.

Calculations of the numbers of edge and corner Ni atoms in defect microcrystals have been used[43] to relate the amount of irreversible H_2 chemisorption to the disperseness of the Ni crystals.

Changes in catalytic activity and selectivity resulting from changes in crystal size may be due not only to structural differences between large and small crystals but also to a size dependence of the electronic properties of crystals. For example, the structure of the valence band of small crystals may be different from that of large crystals, since in small crystals: a) the potential may differ from the periodic lattice potential as a result of the presence of free valence electrons, b) the density of surface states may be greater than the density of electronic states, and c) the electronic state density may be affected by the presence of the carrier.

Thus in Pt crystals of 12–20 Å size supported on SiO_2 the edge of the valence band is shifted downwards by 1.5 eV relative to the Fermi level, and the valence band structure is quite different from that of a massive Pt crystal. On the other hand the electronic properties of Pt crystals 20 Å or more in diameter are identical to those of massive Pt.[44]

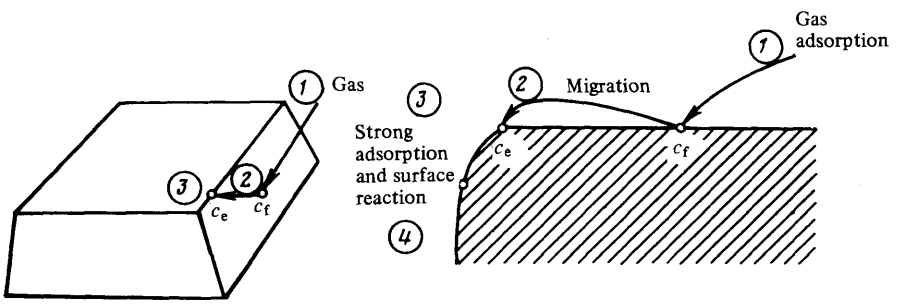

Figure 5. Mechanism of the isomerisation of 2-methylpentane and n-hexane[39].

Changes in crystal size have been shown[45] to influence the ratio of the ionisation potential to the electron affinity, and also the properties of the orbitals. Furthermore, the nature of the chemisorption bond may vary quite substantially under the influence of the carrier (and therefore as a function of the size of the crystals).[46] It is difficult at present to compare these theoretical calculations with experiment, but some workers have used calculated results to explain experimental findings. Thus the specific activity of Pt towards the methanation of CO increases by two orders of magnitude when the disperseness of the metal is increased 200-fold, an effect explained by the formation of the more weakly adsorbed, linear form of CO on the smaller crystals. On Pd, on the other hand, the activity is unaffected by the particle size of the metal though it is strongly dependent on the nature of the carrier (Al_2O_3, SiO_2), and this is ascribed to electronic interactions between the carrier and the metal microcrystals[47].

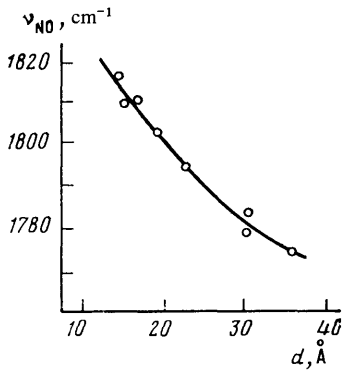

Figure 6. ν_{NO} against disperseness of the Pt.[48]

Changes in the nature of the chemisorption bond as a function of the disperseness of the metal must be allowed for when discussing catalytic systems, since this effect can influence both the rate and the selectivity of the process. As shown in Fig. 6, the frequency of stretching vibrations of NO irreversibly adsorbed on Pt crystals decreases as the crystal size increases, i.e. the energy of the N–O bond decreases[48]. The hydrogen bond strength and its charge also depend on the size of the Ni crystals[49]: these parameters can determine the reactivity of the adsorbed hydrogen. It has been shown that one form of ethylene adsorbed on Pd can be hydrated only by the negatively charged form of hydrogen, the positively charged form being completely inactive[50].

In this discussion of the structure and catalytic properties of supported metal microcrystals we have so far ignored changes induced by the reacting system. Yet very substantial effects of this type are possible: a) dispersion, or sintering, of the crystals, b) the development of facets which are more stable under the conditions of the catalytic reaction, c) internal reconstruction of the microcrystals without change in crystal size, and d) the formation of new phases on the catalyst surface.

Dispersion and sintering of supported metal crystals during a catalytic reaction are well known effects. Recently published data indicate a surprisingly fast reorganisation of a Ni surface under the influence of H_2 under conditions of hydrocarbon reforming with water vapour (due, no doubt, to the formation of different nickel hydrides[51,52]). It is interesting to note that the sintering of Ni in H_2 is much faster than the sintering of Pd.

A rearrangement of the surface facets of Pt [e.g. from (111) to (100)] under the influence of sulphur, leading to a decrease in surface free energy and in catalytic activity, has been demonstrated[53,54]. This effect may occur on other metals also.

The internal rearrangement of the microcrystals under the influence of the reacting species is particularly interesting. The main contribution to this work came from Boudart and coworkers[55–59], and it concerns the variations in the rate of the NH_3 synthesis on Fe crystals 15–300 Å in diameter stabilised on an MgO surface. The reaction rate increases as the particle size increases, but it also increases (for a constant crystal size of 15 or 40 Å) if the crystals are pre-treated in a mixture containing nitrogen. This pre-treatment causes a surface rearrangement (without changing the particle size) accompanied by a decrease in surface magnetic anisotropy and hence in the adsorption of CO. The underlying cause of these effects is shown to be the formation of C_7 centres#, which are active towards the NH_3 synthesis reaction.

The formation of a new phase on a catalyst surface during the reaction, and the structure of this phase, can influence the course of the reaction to a very large extent. This is clearly shown by studies of single-crystal faces[60,61]. For example, a disordered layer of carbonaceous products, which does not inhibit the reaction, is formed on the surface of stepped platinum faces during the hydrogenolysis of n-heptane. However the dehydrocyclisation reaction (with formation of toluene) occurs only on stepped crystal faces covered with an ordered carbon layer, and this layer is not formed on perfect (111) faces.

In addition to the oriented or non-oriented carbon structures formed by interactions with hydrocarbons on metal surfaces we can expect oxide, nitride, sulphide, and other structures to result from interactions with other compounds. A detailed analysis of the properties of these surface phases can be relevant to the identification of the mechanism of adsorption and catalytic processes. Experimental and theoretical studies of the interaction of oxygen with metal surfaces have been actively pursued in recent years[62–66]. By using monocrystal surfaces it has been possible to identify the various steps of surface and bulk reactions leading to the formation of two-dimensional and three-dimensional phases and to surface reconstruction.

Important results were obtained in studies of metal–oxygen structures formed by the action of O_2 on metal microcrystals. Fully disordered surface layers on Pt microcrystals following O_2 adsorption were observed[67] by the electron density radial distribution method. It was shown[68] that the deactivation of supported Pt microcrystals during the low-temperature oxidation of NH_3 is not due to a sintering process, but to the formation of an oxide layer several atoms thick or even to full oxidation of small crystals. These results force us to revise our views on the stability of the precious metals towards oxidation. Interactions with O_2 (under certain conditions) on Ni microcrystals stabilised by a carrier lead to the formation of surface nickel–oxygen structures of a quasi-metallic nature in which the oxygen shows a number of interesting properties[69], e.g.:

a) it acts as an additional centre for H_2 chemisorption, leading to a substantial increase in H_2 adsorption as compared with a clean Ni surface (Fig. 7);

b) it readily diffuses into the bulk of the crystal;

A surface centre with seven nearest-neighbour iron atoms.

c) the nickel–oxygen structure (unlike to NiO phase) is easily reduced by hydrogen.

We should note that the polarisation of the nickel atom is quite different in the nickel–oxygen structure and in NiO microcrystals, as shown by the large difference in adsorption capacity for ethylene (Fig. 8). This result suggests that the interaction of ethylene with the Ni^{2+} cation is much stronger than the interaction with the polarised nickel atom in the nickel–oxygen structure[70].

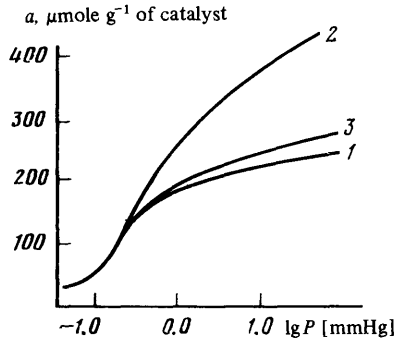

Figure 7. Adsorption of H_2 at 22 °C on supported Ni microcrystals[69]: *1*) clean surface, *2*) and *3*) surface covered with oxygen added at 150 and 300 °C respectively.

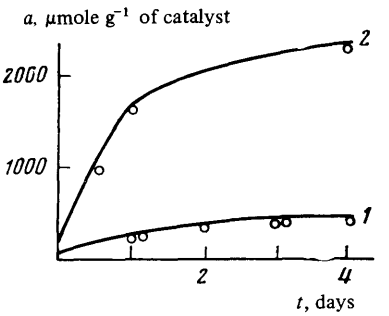

Figure 8. Kinetics of the adsorption of C_2H_4 at 22 °C: *1*) clean surface of supported Ni microcrystals and nickel–oxygen structure, *2*) supported NiO microcrystals[70].

IV. CATALYSIS BY METAL CLUSTERS

We shall now briefly consider the problems which arise in studies of catalysis by metal clusters (mainly, bimetallic clusters). These problems are attracting a great deal of attention because of their great theoretical and practical importance, and many recent results have already been critically reviewed[71–75].

There are several reasons for the current interest in this work: a) the prospects of a theoretical analysis of the interactions between atoms in a cluster and between the cluster and the carrier[76,77]; b) the large difference in selectivity between the bimetallic clusters and the component metals; c) the large difference in catalytic activity between the clusters and the component metals.

Theoretical analyses of the physical, adsorption, and catalytic properties of bimetallic clusters usually take account of two effects resulting from the addition of one metallic component to another:

1) the geometric factor (or "ensemble" effect),
2) the electronic factor (or ligand effect).

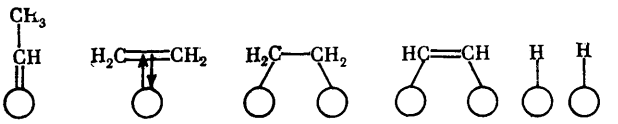

Figure 9. Adsorption forms of C_2H_4 on clusters of one, two, and four atoms respectively.

The geometric factor is clearly illustrated in Fig. 9, which shows various forms of ethylene adsorbed on nickel, requiring the presence of one-, two-, and four-atom ensembles on the surface respectively. Evidently, an increase in the amount of the second component (e.g. copper) on the surface lowers the probability of forming multi-atomic ensembles.

The electronic factor is far more complex. The "rigid band" model has long been used to discuss the physical and catalytic properties of alloys, and supported bimetallic clusters can be treated as a special case of alloy catalysts. Essentially the model states that an atom (for example, nickel) when introduced into the lattice of another component (for example, copper) loses its individuality, and its electronic levels are incorporated in the common *d*-band of the alloy. This model successfully describes the magnetic properties of alloys at relatively low concentrations of the additive, when the alloy remains ferromagnetic[78]. However there is evidence (experimental as well as theoretical) that the foreign atom can retain its individuality to a large extent[79,80].

The X-ray photo-emission spectra of the valence band of Ni–Cu alloys[81] are shown in Fig. 10. We note that the width and the shape of the Ni *d*-band are substantially unaffected by the addition of Cu. Characteristically, this *d*-band intersects the Fermi level at all compositions: the Ni atoms always have free *d*-levels and the electronic interaction with the Cu atoms is not very marked. This conclusion is confirmed by the failure to observe a shift in the frequency of the C–O bond vibration in the i.r. spectra of CO adsorbed on Ni–Cu alloys of increasing Cu content[82]: the only change was a decrease in the intensity of the band associated with the bridge form of CO adsorption. This decrease was ascribed to the geometric factor, i.e. to the decrease in the number of doublet centres on the alloy surface as the alloy is progressively diluted with copper.

However the existence of electronic interactions between the Ni and Cu atoms in this system has also been demonstrated[83]. As the alloy is made richer in copper both the intensity of the vibrations of the bridge form of adsorbed CO and the frequency of the vibrations of the CO bond in the

linear (*A*-band) as well as in the bridge (*B*-band) form decrease (Fig. 11), indicating an increase in the electron density on the nickel atoms. Magnetic data (Fig. 12) also show that an increase in the Cu content of the alloy is accompanied by a decrease in the number of bonds to the metal surface from 1.8 (for Ni) to 1.0 (for Cu), i.e. by a transition from the bridge to the linear adsorption form. It is interesting to note that Ni^{2+} ions in partially reduced $Ni-SiO_2$ catalysts lower the intensity of the band arising from the multi-centre form of CO adsorption, i.e. they act as diluents (like Cu atoms) by lowering the probability of finding clusters of several Ni atoms on the surface[84].

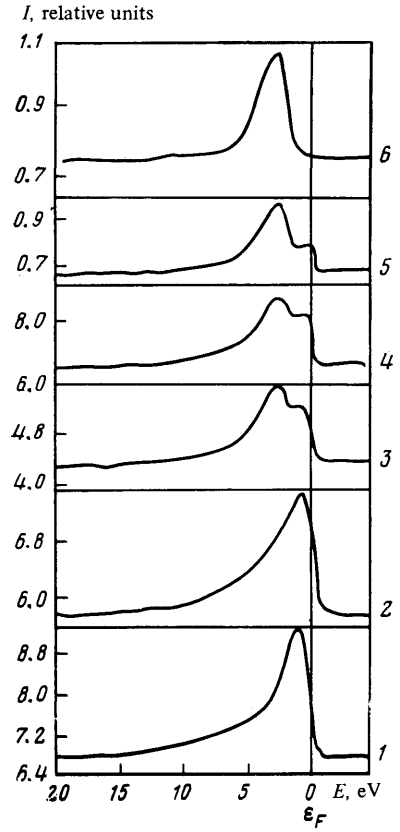

Figure 10. X-ray photo-emission spectra of the valence band of Ni–Cu alloys[81]: *1*) Ni, *2*) Cu(12%)–Ni(88%), *3*) Cu(44%)–Ni(56%), *4*) Cu(46%)–Ni(54%), *5*) Cu(74%)–Ni(26%), *6*) Cu.

In addition to demonstrating the presence of clusters in the Cu–Ni system recent work has shown that clusters can exist in other systems too. For example, Mössbauer spectral measurements have revealed the presence of Pd–Fe clusters in Pd and Fe supported on η-Al_2O_3.[85,86] The Mössbauer effect has proved very valuable in studies of electronic interactions in clusters. Thus iron in Pt–Fe clusters supported on γ-Al_2O_3 proved to be inactive (as compared to pure iron) towards the synthesis of hydrocarbons from CO and H_2.[87]

This effect may be related to the observed decrease in electron density on an Fe atom in a cluster due to interaction with the more electronegative Pt atom.

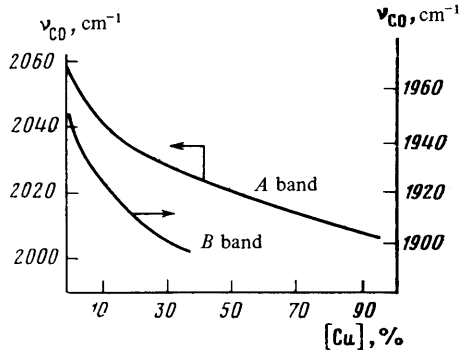

Figure 11. Variation of ν_{CO} for the *A* and *B* bands against Cu content of Ni–Cu alloys[83].

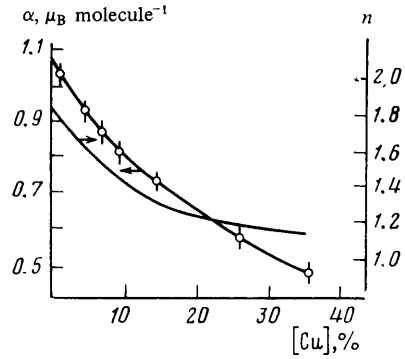

Figure 12. Effect of Cu concentration in a Ni–Cu alloy on the magnetisation (α) and number of bonds (n) per molecule of CO.[83]

Large electronic effects have been observed in clusters based on Pt and Sn as a result of electron transfer from Sn to Pt.[88] For example in the series $Pt < Pt_3Sn < PtSn < PtSn_2$ the surface is progressively enriched in Sn atoms, with a corresponding decrease in the strength of the bond between the surface and adsorbed CO, C_2H_4, and D_2 molecules. The downward shift of the ethylene desorption temperature on going from Pt_3Sn to PtSn is shown in Fig. 13. Typically, whereas the adsorption of ethylene on pure Pt is accompanied by a significant amount of self-hydrogenation the addition of Sn causes the adsorption of ethylene to be reversible. This is ascribed to the absence of Pt atomic ensembles on the surface of PtSn, but the effect could equally well be explained by an increase in electron density on the Pt atoms. Surprisingly, adsorbed CO molecules appear to "draw out" the Pt atoms from layers immediately below the surface and thus enrich the surface with Pt, but this effect is reversible and the initial state of the surface can be restored by pumping out the CO at room temperature.

Similar phenomena have been observed in the adsorption of O_2 on a Ni–Au alloy[89]. The alloy surface, initially consisting mainly of gold atoms, is found to be enriched in nickel atoms after O_2 adsorption: this effect is explained by the preferential attraction of Ni atoms towards the surface, resulting from the fact that the O–Ni bond energy is greater than the energy of the O–Au bond. These effects cannot be ignored when discussing the adsorption and catalytic properties of supported Bi- and polymetallic clusters.

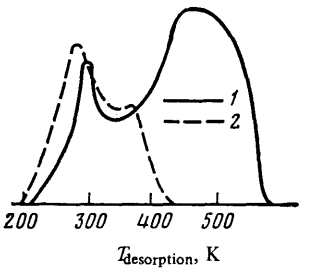

Figure 13. Desorption of ethylene from (*1*) Pt_3Sn and (*2*) PtSn surfaces.

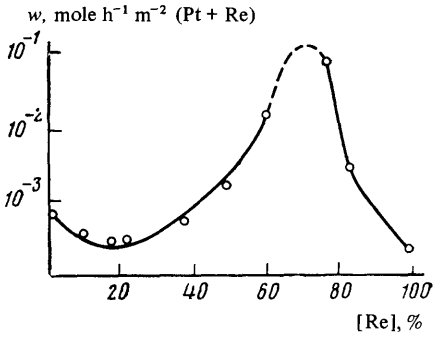

Figure 14. Specific catalytic activity *w* against concentration of Re in the hydrogenolysis of cyclopentane on $Pt–Re/Al_2O_3$ catalysts[93].

Thus in platinum–tin clusters the presence of the second component can have a powerful influence on the electronic state of the active centre[88], and hence on the type of interaction between the centre and adsorbed molecules. Similar effects were reported for additions of Sn to Pd or Ni supported on SiO_2.[90] The formation of carbonaceous deposits during the dehydrogenation of various compounds is suppressed if the Pd or Ni catalyst is alloyed with tin, suggesting a decrease in the energy of the bond between the reactants and the catalyst. According to measurements by X-ray photo-electron spectroscopy (XPES) the electronic structure of Pd and Ni is strongly affected by additions of Sn.

Another example of the decrease in bond energy between the reactant and the active centre is given in Ref. 91: the Pd–Au alloy (60 at.% Au) is approximately 50 times more active than Pd towards the oxidation of hydrogen by oxygen, showing that the energy of the bond between oxygen and a Pd atom is decreased by the presence of Au atoms on the surface.

Some of the most interesting Pt-containing clusters are the Pt–Re clusters supported on α- and γ-Al_2O_3. I.r. spectral data on CO adsorption have shown[92] that electron transfer from Re to Pt is responsible for the interactions in this alloy. The catalytic properties of this system towards the deuterium exchange and hydrogenation of benzene, the hydrogenolysis of cyclopentane and butane, and the dehydration of 1,1,3-trimethylcyclohexane suggest that in most cases the activity goes through a maximum (or several maxima): the maximum activity can be greater than the activity of the initial components, as shown by the change in specific activity as a function of composition of the cluster during the hydrogenolysis of cyclopentane (Fig. 14).[93] Within the framework of the "local" model these results can be explained[93] by the tendency of the cluster (depending on its composition) to acquire catalytic properties similar to those of Ir and Os as a result of electronic interactions between the components: these metals are known to be catalytically more active than Pt and Re towards the reactions under study.

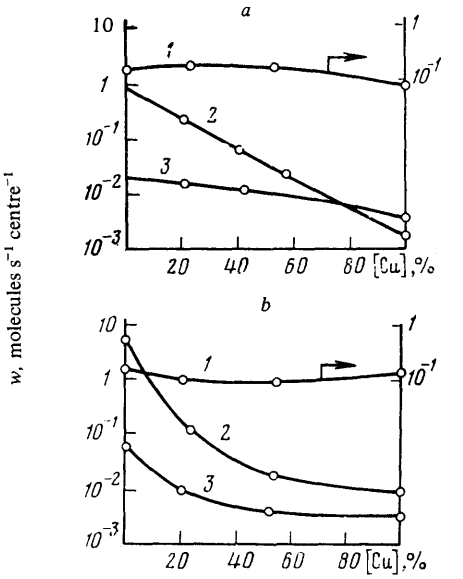

Figure 15. Specific catalytic activity *w* against composition of supported (on SiO_2) Cu–Ru (*a*) and Cu–Os (*b*) catalysts[94]: *1*) dehydrogenation of C_6H_{12}, *2*) hydrogenolysis of C_2H_6, *3*) hydrogenolysis of C_6H_{12}.

We shall close this review with a brief mention of the effect of composition on the selectivity and catalytic action of the cluster. This problem, as mentioned above, is currently one of the main areas of research on catalysis by clusters. The most important results obtained so far have already been critically reviewed[71–74]. Among the most interesting studies

in this area is Sinfelt's work[74] on the catalytic properties of Ni–Cu clusters towards the dehydrogenation of cyclohexane and the hydrogenolysis of ethane: a large increase in the amount of Cu in the alloy has practically no effect on the specific rate of dehydration of cyclohexane, whereas the rate of hydrogenolysis of ethane falls by about three orders of magnitude when as little as 5 at.% of Cu is added to the Ni. Similar results (Fig.15) were obtained for supported Ru–Cu and Os–Cu clusters in the same reactions[94]. Interactions in the Ru–Cu system have been studied by the XPES method[95]. It was shown that the Ru microcrystals are covered by Cu, and that heat treatment in H_2 produces a further increase in the surface concentration of Cu and a corresponding decrease in the rate of hydrogenolysis of ethane. No shifts of the absorption bands in the Cu and Ru XPE spectra were observed, but the conclusion[95] that electronic interactions between Cu and Ru are negligible does not seem justified.

A possible explanation of the reported effects is the following. Intermediate particles bound to several Ni atoms on the surface (i.e. bound to the cluster) are formed during the hydrogenolysis of C_2H_6. The addition of Cu lowers the probability of finding a cluster of several Ni (Ru,Os) atoms on the surface (geometric effect), and the rate of hydrogenolysis decreases. These intermediates are not formed during the dehydrogenation of cyclohexane, and therefore the rate of this reaction remains unaffected by the addition of copper over a wide range of composition.

This explanation is inconsistent with some of the considerations outlined above. Thus it has long been known that the adsorption of cyclohexane on Ni is accompanied by the formation of 8–12 bonds per molecule, i.e. it requires the presence of a much larger cluster of Ni atoms than does the conversion of a C_2H_6 molecule[96]. Hence the rate of dehydrogenation (or hydrogenolysis) of cyclohexane should be much more sensitive to the concentration of copper in the nickel than the rate of hydrogenolysis of ethane (if the geometric factor is predominant). In reality the situation is complicated by the possibility of changes in composition and in structure of the surface during the reaction, by the formation of carbonaceous surface structures, etc. Thus the problem of selectivity changes in the course of the reaction is still unsolved.

---o0o---

Though the problems presented by catalysis by supported metal crystals appear unrelated at first sight they have some important features in common, and progress in our understanding of any one of these problems can be expected to lead to progress in all directions.

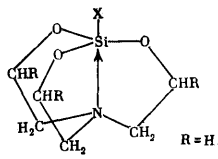
The Physical Chemistry of Silatranes

V.F.Sidorkin, V.A.Pestunovich, and M.G.Voronkov



The present state and evolution of the theoretical ideas concerning the steric and electronic structures of silatranes as well as certain characteristics of their reactivity are analysed critically. The decisive influence of the hypervalent X-Si ← N bond on the physicochemical and spectroscopic characteristics of silatranes is demonstrated.
The bibliography includes 109 references

III. C-substituted silatranes 423

I. INTRODUCTION

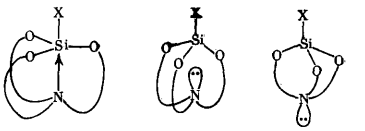
The considerable interest in the chemistry of silatranes arose primarily because they have been found to include a number of substances with high and specific biological activities[1-4].

R = H, CH_3, or CF_3.

The molecular structure of silatranes is of special interest, since they are the first representatives of stable inner-complex organic derivatives of pentacoordinate silicon and have been studied in very high detail by a wide variety of physical methods. The development of the theory of their structure is undoubtedly an important contribution to the creation of the theoretical foundations and practical chemistry of metalloatranes. The aim of this review is to describe the present state and evolution of the theoretical ideas about the steric and electronic structures of silatranes and to discuss certain features of their reactivity.

II. 1-SUBSTITUTED SILATRANES

The first mention of silatranes appeared in 1960–1961 in a patent[5] and in a letter to the Editor[6]. They reported the formation of silatranes by the reaction of organyltriethoxysilanes $XSi(OC_2H_5)_3$ with tris-(2-hydroxyethyl)amine $(HOCH_2CH_2)_3N$:



$$XSi(OC_2H_5)_3 + (HOCH_2CH_2)_3N \rightarrow XSi(OCH_2CH_2)_3N + 3C_2H_5OH .$$

The formation of silatranes in this reaction is unexpected, because the interaction of two trifunctional reagents as a rule results in the formation of polymers. Subsequent comparison of the chemical properties of silatranes and model compounds—organyltriethoxysilanes and triethanolamine—enabled the authors[6] to arrive at the following findings: (1) the nitrogen atom in silatranes is inert with respect to methyl iodide; (2) silatranes are more resistant to hydrolysis than the corresponding triethoxysilanes. On this basis, it was in fact suggested[6] that silatranes are the first representatives of organic compounds of pentacoordinate silicon containing the hitherto unknown intramolecular coordinate bond Si ← N.

Owing to the outward attractiveness and simplicity of this hypothesis, the absolute majority of the results of subsequent studies on silatranes were interpreted within its framework without further stipulations[1,2,7]. However, the above facts can be accounted for qualitatively without resorting to this hypothesis. For example, the reduced basicity of the nitrogen atom can be regarded as a consequence of the steric inaccessibility of its lone electron pair (LEP) in the *endo*-form of the silatrane molecule, stabilised by non-valence and electrostatic interaction. Below we shall attempt to analyse critically the results of physicochemical studies on silatranes from the standpoint of the choice of one of the two alternative hypotheses.

1. The Steric Structure

The classical theory of the structure of organic compounds permits three possible structures of silatranes[1]:

(Ia) (Ib) (Ic)

Structure (Ia) is planar-concave with a pentacoordinate silicon atom and a tetracoordinate nitrogen atom; structure (Ib) is convex-concave with a tetracoordinate silicon atom and a tervalent nitrogen atom; structure (Ic) (*exo*) is convex-convex and the heteroatoms are in the same valence state as in structure (Ib). Structure (Ic) can be rejected for silatranes on the grounds that the nitrogen atom in silatranes lacks basic properties[1,6,7]. Evidently the existence of silatranes in forms (Ia) and (Ib) would correspond to the first and second of the above hypotheses respectively.

It would seem that a decision can be reached concerning the alternative structures by resorting to X-ray diffraction. Table 1 presents the results of X-ray diffraction studies on a number of 1-substituted silatranes. In the molecules of the absolute majority of the compounds investigated the nitrogen atom is displaced from the plane of the neighbouring carbon atoms in the direction of the silicon atom (*endo*-orientation). The coordination polyhedron around the silicon atom consists of a distorted trigonal bipyramid, in the equatorial plane of which three oxygen atoms are accommodated, while the vertices contain the nitrogen atom and the α-atom of the substituent X. However, the deviations of the form of the coordination polyhedron from the ideal bipyramid are considerable. The average X–Si–O angles

(the values of which reflect to some extent the valence state of the silicon atom) are intermediate between the valence angles of compounds of tetravalent (109.5°) and pentacoordinate (90°) silicon atoms. On the basis of the valence angles, one cannot therefore decide reliably whether the steric structure of silatranes corresponds to distorted forms (Ia) or (Ib).

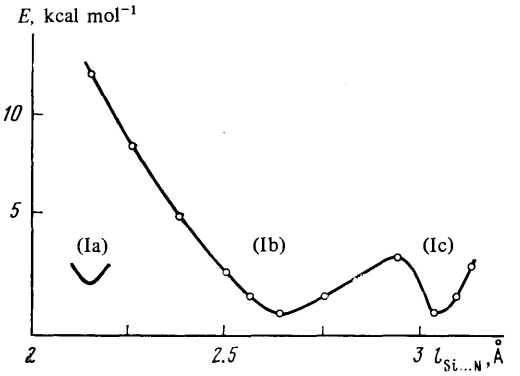


Table 1. The steric structures of 1-substituted silatranes.

X	Axial characteristics		Equatorial characteristics*		Refs.
	l_{X-Si}, Å	l_{Si-N}, Å	l_{Si-O}, Å	X-Si-O angle	
Cl	2.15	2.02	1.65	—	8
$ClCH_2$	1.91	2.12	1.67	97.4°	9
$Cl(CH_2)_3$	1.88	2.18	1.66	97.2°	10

*The average Si–O bond lengths and X–Si–O angles are quoted.

The Si...N internuclear distances in the molecules of silatranes (Table 1) are much greater than the sum of the covalent values (1.8 Å), but are smaller than the sum of the van der Waals radii (3.1 Å) of the silicon and nitrogen atoms. This permitted the assignment of the structure of silatranes to form (Ia) without any ambiguity. On the basis of a qualitative inspection of the Si...N internuclear distance, one can be certain that there is a definite interaction between the silicon and nitrogen atoms in silatrane molecules. However, without additional arguments it is impossible to identify such interaction with the Si←N coordinate bond. Indeed one can assume with just as much certainty that the real structure of silatranes corresponds to a minimum in the conformational energy of form (Ib), in which the internuclear distance depends on the degree of non-valence interactions, the latter being in many respects determined by the nature of the substituent X. This hypothesis seemingly received indirect support by the detection of the *trans*-{PtCl[$Si(OCH_2CH_2)_3N$].[$P(CH_3)_2C_6H_5$]} molecule in a kind of *endo*-form[16,17]. The silicon atom in this molecule has a tetrahedral structure and the nitrogen atom is only slightly displaced from the plane of the three carbon atoms linked to it (by 0.07 Å). It is believed[16] that the tetrahedral structure of the silicon atom in this silatrane is caused by the considerable steric hindrance due to the structure of the Si-substituent as well as the low electronegativity of the latter. The nearly planar disposition of the nitrogen atom was explained by the intense steric interactions of the three methylene groups surrounding it.

To elucidate the relative role of the conformational and electronic factors determining the structure of silatrane molecules, the dependence of the chain energy on the Si...N internuclear distance has been investigated for the 1-methyl silatrane molecule by the Westheimer–Kitaigorodskii method[18,19]. It was found that the real structure of the 1-methyl silatrane molecule corresponds to the minimum conformational energy in form (Ia) alone; the latter is more stable to the extent of 8.5 kcal mole^{-1} than structure (Ib) (for the same Si...N internuclear distance). It was thus possible to demonstrate that conformational factors play a major role in the formation of the steric structure of silatranes, tending to increase the coordination number of the silicon atom to five. At the same time, the conformational energy of the *endo*-form (Ia) proved to be fairly close to the value calculated for the *exo*-form (Ic), which does not really exist and the barrier to the (Ic)→(Ia) transition does not exceed 2 kcal mole^{-1} (see Figure). Consequently conformational factors cannot account for the experimentally observed stability of the *endo*-form (Ia). This leads to the conclusion that the main factor determining the high stability of form (Ia) is the considerable contribution of the Si←N valence interaction energy to the overall energy of silatrane molecules†. Subsequently this conclusion was confirmed by quantum-chemical calculations[21].

Dependence of the conformational energy E of the 1-methylsilatrane molecule on the distance between the silicon and nitrogen atoms ($l_{Si...N}$).

According to X-ray diffraction data[8–15,22], the three five-membered heterocycles in the molecules of 1-substituted silatranes are non-planar. They have the shape of an envelope bent as a rule along the N–Cβ line. The molecules of all the silatranes investigated are distributed in crystals at distances which are determined by the van der Waals interactions. The crystal structures of 1-methylsilatrane[23,24] and 1-phenylsilatrane[12–14] exhibit polymorphism. The existence of several crystalline modifications (α, β, and γ) of the last compound was explained by the different conformations of the silatrane skeleton.

The dipole moments of silatranes are extremely high (5–9 D);[25–27] they are several times greater than the values for the corresponding organyltriethoxysilanes (1.5–2 D). This was assessed[25] as evidence for the existence of silatranes in form (Ia). The dipole moment of the $Si(OCH_2CH_2)_3N$ fragment in both the *exo*-form (Ic) and the *endo*-form (Ia), calculated by an additive scheme[25] without taking account the moment of the Si←N bond, proved to be significantly smaller

†It has been possible to show recently[20] that the stabilisation of structure (Ib) by electrostatic interaction is possible only for unrealistically high dipole moments of the polar bonds (Si–O, O–C).

(by 4–5 D) than the experimental value. Since data for the molecular structure had not yet been obtained in our calculations[25] it was necessary to employ bond lengths and angles which proved to be far from realistic. Analysis of the results led the authors[25] to the conclusion that silatranes exist in form (Ia) and have a very high (up to 8 D) dipole moment of the Si←N bond; however, this conclusion cannot be regarded as reliable for the reason stated above.

According to ^{1}H NMR data[1,28,29], three five-membered atrane half-rings in silatrane molecules are independent and completely identical. The chemical equivalence of the geminal protons of the methylene groups shows that the non-planar half-rings Si–O–C–C–N are involved in rapid (in terms of the NMR scale) conformational transitions. Analysis of the constants for the spin–spin coupling between the protons of the substituted ring of 3-methyl derivatives of silatranes indicates the *endo*-orientation of the LEP of the nitrogen atom in their molecules[30]. However, an unambiguous choice between forms (Ia) and (Ib) of silatrane molecules cannot be made on this basis.

2. Electronic Structure of 1-Substituted Silatranes

The adoption of the hypothesis that silatranes contain the Si←N bond imposes a number of requirements on their electronic structure[31,32]. Firstly the formation of such a bond must be accompanied by a rearrangement of the electron cloud of the silicon and nitrogen atoms and to some extent also of their immediate environment. This type of rearrangement should be manifested in a comparative analysis of the physicochemical properties of silatranes and the corresponding model systems sensitive to changes in electron distribution. Secondly, the collective properties# of silatranes cannot be understood without taking into account the characteristics of the Si←N bond. Thirdly, the nature of the dependence of the physicochemical properties of silatranes on the nature of the substituent at the silicon atom is determined by the presence of the Si←N bond. On the other hand, the hypothesis of the stabilisation of the silatrane skeleton as a result of non-valence interaction does not require the fulfilment of these conditions.

At the very beginning of the development of the chemistry of silatranes it was already claimed intuitively[1] that the degree of interaction between the nitrogen and silicon atoms and the length of the Si←N bond in silatrane molecules must be determined by the nature of the substituent X. With increasing electronegativity of the latter, a strengthening of the Si←N bond is to be expected. This was indeed established experimentally by X-ray diffraction analysis of silatranes (Table 1). The dependence of the Si...N internuclear distance in silatrane molecules on the Taft inductive constant (σ^*) of the substituent X at the silicon atom is linear[8,33]: $l_{Si\leftarrow N} = 2.20 - 0.0636\sigma^*$.

In silatrane molecules the displacement Δ of the silicon atom from the equatorial plane containing the three oxygen atoms in the direction of the substituent X is linked to the Si←N bond length by the relation[22] $l_{Si\leftarrow N} - \Delta = d$, where d is the distance from the nitrogen atom to the equatorial plane of the trigonal bipyramid; the value of d in the series of 1-substituted silatranes is then approximately the same and amounts to 2.00 ± 0.05 Å. It has been suggested that this is due to the competition of the non-valence interactions between the substituent and oxygen atoms, on the one hand, and the strain forces in the heterocycles, on the other. Later[15], on the basis of the analysis of more extensive experimental data, it was found that both Δ and d vary linearly with the Si←N bond length: $\Delta = -1.052 + 0.576 l_{Si\leftarrow N}$ and $d = 1.055 + 0.422 l_{Si\leftarrow N}$. Comparison of these relations shows that the length of the transannular Si←N bond in the molecules of 1-substituted silatrane changes mainly owing to the displacement of the silicon (and not nitrogen) atom relative to the equatorial plane of the distorted trigonal bipyramid. It was assumed that this indicates a decisive influence of the electronic interactions on the structure of silatrane molecules[15].

Despite the fact that this claim is valid, it in no way follows from the considerations presented above. For a more correct analysis of the changes in the degree of interaction between the silicon and nitrogen atoms, it is necessary to compare the values of Δ with the distance between the nitrogen atoms and the plane formed by the three neighbouring carbon atoms (Δ') and not with the value of d.[33] $\Delta = 0.48$ Å and $\Delta' = 0.13$ Å correspond to the minimum conformational energy of the 1-methylsilatrane molecule in form (Ib).[18] On the other hand, owing to the valence interaction in real 1-alkylsilatrane molecules the values of Δ and Δ' are lower and higher respectively than those indicated above. With increase of the Si←N bond strength, Δ diminishes and Δ' increases[34], the extent of the changes in these quantities being virtually identical in the series of silatranes whose structures have been investigated[33]. Consequently, under the influence of the substituent X, identical changes take place in the valence states of the nitrogen and silicon atoms. This agrees well with the results of studies of silatranes by other physical methods[35].

The value of $l_{Si\leftarrow N} = 1.83$ Å corresponds to the intercept which the plot of Δ against l_{Si-N} makes on the abscissa axis[15]. On this basis, it has been concluded[15] that the "ideal" length of the transannular Si←N bond is equal to the covalent Si–N bond length. The linear dependence of $l_{Si\leftarrow N}$ on the Taft inductive constant σ^*_X shows[8] that in an "ideal" silatrane the substituent X should have $\sigma^* = 5.4$. This value is extremely close to that known for the $R_3\overset{+}{N}$- group. It is therefore logical to assume that the 1-azaniasilatrane structure $[R_3N\rightarrow Si(OCH_2CH_2)_3N]^+A^-$ corresponds to the concept of the "ideal" silatrane. Hence it follows that there is no complete electron transfer from the nitrogen atom to the silicon atom in the molecules of the silatranes investigated hitherto.

Structural studies on silatranes have shown[14,15,22] that the Si–O bond lengths in their molecules and in model triethoxysilanes are virtually the same. It has come to be believed that this is due to the compensation of the enhancement of σ-bonding by the weakening of the $d_\pi - p_\pi$ interaction between the oxygen and silicon atoms when the silicon atom passes to the pentacoordinate state. However, evidence has been adduced (which must be regarded as incorrect) also in support of the $p_\pi - p_\pi$ interaction between the same atom[36].

In a series of 1-organylsilatranes the Si–O bond length hardly changes[14,15,22] and the longest Si←N bonds correspond to the shortest C–Si bonds[14]. This shows that the *trans*-influence of the substituents is characteristic of silatranes.

The parallel variation of the energies of the 2p levels of the silicon atom and the 1s level of the nitrogen atom in 1-substituted silatranes has been demonstrated by the method of photoelectron spectroscopy for chemical analysis (ESCA).[37] This finding is consistent with the hypothesis that the Si←N bond exists in silatranes (i.e. that there is a charge transfer from the nitrogen atom to the silicon atom). According to

#Properties which are determined, to a first approximation, by the sum of the properties of the individual bonds.

photoelectron spectroscopic (PES) data[38], the ionisation potentials of the 2*p* level of the nitrogen atom in the molecules of 1-hydro-, 1-methyl-, and 1-ethoxy-silatranes are higher than in triethanolamine. The authors explained this by the σ-donation of the LED of the nitrogen atom to the 3*d* orbital of the silicon atom. The approximate constancy of the first ionisation potentials for silatranes with X = H and C_2H_5O was somewhat unexpected. However, one should note that the interpretation of the PES data for silatranes in the study of Cradock et al.[38] is not reliable. The levels were assigned on the basis of symmetry considerations, which is clearly insufficient in the analysis of the PES of such complex molecules.

X-Ray electronic spectra of silatranes have been studied[36,39,40]. The chemical shifts of the K_α lines of the silicon atoms, calculated by an additive scheme on the assumption of the tetravalent state of the silicon atom, proved to be greater than the experimental values. The difference is fundamental and supports the structure with a pentacoordinate silicon atom. It has been suggested[39] that the Si←N bond in silatrane molecules is responsible for the reduced effective charge on the silicon atom (i.e. for the increased electron density at this atom) and hence for the reduced chemical shift of the K_α line. This conclusion cannot be regarded as rigorously justified, because the formula $\Delta E_l = Kq_{eff}$, used to determine the effective charges, presupposes the equality of the constant *k* for compounds of tetra- and penta-coordinate silicon, which is extremely doubtful.

A hypsochromic shift of the absorption band of the $N(CH_2)_3$ group relative to the spectrum of triethanolamine, in which the LEP of the nitrogen atom is free, has been observed in the ultraviolet spectra of 1-substituted silatranes (X = C_2H_5, CH_3, or H).[41] This confirms the hypothesis that the Si←N bond is present in silatranes, since the higher binding energy of the lone electron pair in silatrane is in fact responsible for the hypsochromic shift. Analysis of the ultraviolet absorption spectra of 1-aryloxysilatranes leads to the conclusion[42] that the bands due to the aryloxy-groups (200–300 nm) are insensitive to the coordination interaction of the silicon and nitrogen atoms.

Absorption bands in the range 560–590 cm^{-1}, which are absent from the spectra of model compounds, are characteristic of the infrared spectra of silatranes[1,43–48]. These frequencies were assigned to the stretching vibrations of the Si←N bond on the grounds that the vibrations of the covalent Si–N bonds in aminosilanes are in the range 780–830 cm^{-1}, while the vibration frequency of the coordinate bond should be lower[1,43]. The integral intensity *A* of this band in the spectra of a series of 1-organoxysilatranes of the type $RO\overset{\downarrow}{S}i(OCH_2CH_2)_3\overset{\downarrow}{N}$ depends on the nature of the substituent[44,45]. There should be strong kinematic interactions between the vibrations of the collinear X–Si and Si←N fragments, as a result of which the stretching vibration frequency of the Si←N bond should be displaced towards lower values with increase of the atomic weight of the substituent at the silicon atom. Such a shift has indeed been observed[44,49] in the series of 1-substituted silatranes with X = H, F, Cl, or Br, which also confirms the validity of the assignment of the ν band to the Si←N vibration. The introduction of symmetry coordinates permitted the calculation of the force field of the 1-hydrosilatrane molecule[45]. The force constant of the Si←N bond proved to be 1.2×10^6 cm^{-2}, which is several times smaller than the force constants of covalent bonds.

Evidence has recently been presented[46] showing that the assignment of the 560–590 cm^{-1} band in the infrared spectra of silatranes to the Si←N bond vibrations is erroneous. According to some data[44,45], the integral intensities A_ν of this band are as a rule inversely proportional to its intensity at the maximum. On the other hand, according to Voronkov et al.[46] (although the latter do not in fact quote specific results for the compound investigated previously[44,45]), the half-widths of such bands are constant, which led them to the belief that the measurements of the values of A_ν in the earlier investigations[44,45] were methodologically incorrect. The integral intensity of this band, measured for the first time for the series of 1-alkyl- and *C*-substituted silatranes, proved to be independent of the nature of the substituent at the silicon atom[46]; this constitutes important evidence against the assignment of the band in the range 560–590 cm^{-1} to ν(Si→N). It is so far difficult to solve ultimately the problem of the assignment of this band. For example, despite the use of the same method for the determination of the integral intensities (the Iogansen method) in the studies described in Refs. 44 and 46, the values of A_{570} obtained for 1-ethoxysilatrane differ sharply (9250 and 1612 litre cm^{-2} mol^{-1} respectively). Yet another argument against the assignment of the 560–590 cm^{-1} band to the Si←N vibration is based on the hypothesis that such vibrations (symmetry A_1) should be inactive in Raman spectra§. Furthermore, the intensity ratio $A_{570}/A_{790} = 0.1$ in the infrared spectrum of 1-ethylthiomethyl-3-methylsilatrane, while in the Raman spectrum it increases to **0.3.**[46]

On the basis of the above considerations and the presence of a band in the region of 600 cm^{-1} in the infrared spectra of certain di- and tri-cyclic structures (including those of metalloatranes), the 560–590 cm^{-1} band in the infrared spectra of silatranes has been assigned[46] to the skeletal vibrations. If this hypothesis is adopted, it is not clear why, despite the significant deformation of the atrane molecular skeleton on substitution of the $O_{(2)}$ atom by the methylene group[7] or after the introduction of methyl groups in the 3-, 7-, and 10-positions[1,7,46], the frequency of the above vibration remains constant. At the same time the 560–590 cm^{-1} band has not been observed[16] in the infrared spectrum of the bicyclic *trans*-{PtCl[$Si(OCH_2CH_2)_3N$][$P(CH_3)_2C_6H_5$]} molecule, in which there is virtually no Si←N bond according to X-ray diffraction data[16,17]. We believe that this factor shows unambiguously that the presence of the Si←N bond is an essential condition for the manifestation of the band at 560–590 cm^{-1} in the infrared spectra of silatranes.

We may note that the 560–590 cm^{-1} band in the infrared spectra of Si- and C-substituted silatranes has been assigned to the fully symmetrical vibrations of the SiO_3 group[47]. It has also been suggested[48] that the moderately intense bands in the region of 300 cm^{-1} should be assigned to the Si←N bond vibrations. Thus one must admit that the problem of the direct manifestation of the Si←N bond vibrations in the infrared spectra of silatranes still remains essentially open.

At the same time, the bathochromic shift of the ν(H–Si) band in the spectrum of hydrosilatrane relative to triethoxysilane[1,6,43] as well as the appreciably lower ν_{as}(C–Si) and ν(Hal–Si) frequencies in the infrared spectra of 1-alkyl-[43] and 1-halogeno-silatranes[49,51] compared with the corresponding derivatives of triethoxysilane confirm indirectly the presence of the Si←N bond in silatranes.

A change in the nature of the substituent at the silicon atom has approximately the same influence on the degrees of electronic shielding of the protons of both OCH_2 and CH_2N groups in the ^1H NMR spectra of silatranes[1,28,29,38],

§This is a clear misunderstanding, since the A_1 vibrations are active in both Raman and infrared spectra[50].

[52–54]. This is responsible for the constancy of the difference between the chemical shifts of these protons (in a given solvent) for all 1-substituted silatranes (Table 2). The results show that the electronic influence of the substituent at the silicon atom is transmitted not only via the system of σ-bonds of the atrane half-rings (SiOCCN) but also via the Si←N bonds. The same feature can be seen also in the variation of the spin–spin coupling constants $^1J(^{13}C-^1H)$ for the OCH_2 and CH_2N groups[53]. It follows from statistical considerations that the Si←N bond transmits the influence of the substituent X more effectively than each of the Si–O bonds. Thus ^1H NMR data indicate one of the most significant features of silatranes—the *trans*-influence of the substituent at the silicon atom on the nitrogen atom.

Table 2. NMR parameters of 1-substituted silatranes.

X	^1H chemical shifts, p.p.m.*		^{29}Si chemical shifts, p.p.m.	
	δ_{OCH_2}	δ_{CH_2N}	δ_{Si}	$\Delta\delta_{Si}^{**}$
H	3.830	2.868	−83.6	17.6
CH_3	3.779	2.806	−65.7	21.7
CH_3CH_2	3.777	2.802	−67.1	21.2
$ClCH_2$	3.858	2.886	−77.2	21.1
$BrCH_2$	3.853	2.879	−77.7	21.5

*Values extrapolated to infinite dilution in $CHCl_3$.

**$\Delta\delta_{Si} = \delta_{Si}(X-Si(OCH_2CH_2)_3N) - \delta_{Si}(X-Si(OCH_2CH_3)_3)$.

When the nitrogen atom passes to the cationic state or its LEP is involved in a coordinate bond, the ^1H NMR absorption line of the protons of the methylene group linked to the nitrogen atom usually undergoes a paramagnetic shift of approximately 0.5–0.8 p.p.m. However, the chemical shifts of the CH_2N protons in the ^1H NMR spectra of silatranes are only slightly greater than in those of the acyclic and monocyclic analogues[29,52], where there is no Si←N bond. The observed difference between the chemical shifts of the CH_2N protons of silatranes and their analogues shows that the degree of transfer of the LEP of the nitrogen atom to the silicon atom is insignificant. This purely qualitative conclusion (which conflicts with the hypothesis put forward at one time[1,25] that the Si←N bond is highly polar) was later proved quantitatively[21,27,35,55].

The chemical shifts of the OCH_2 and CH_2N protons of 1-alkyl- and 1-alkenylsilatranes are correlated with the inductive substituent constant σ*.[29,52,56] However, 1-aryloxy- and 1-alkoxy-silatranes deviate from this relation. This has been explained[29,52] by the superposition of the effect due to the $d_\pi - p_\pi$ interaction of the silicon atom with the oxygen atom of the aryloxy- or alkoxy-group.

An equation for joint correlation of the σ_{CH_2N} and the field and resonance constants (F and R) of the substituent X has been found for a number of 1-alkyl or aryl- and 1-aryloxy- or alkoxy-silatranes[53]. ^1H NMR data also show that the distribution of electron density in silatranes depends also on the steric influence of the substituent at silicon atom[29,52]. The chemical shifts of the ^{13}C NMR signal of the atrane skeleton in silatrane molecules depend comparatively little on the nature of the substituent on the silicon atom [$\delta(C_N) = 51$ p.p.m. and $\delta(C_0) = 57$ p.p.m.].[53] This is probably caused by the damping effect of the readily polarisable C–H bonds in the silatrane molecules, which can compensate for the change in the charges on the α- and β-carbon atoms induced by the substituent X.

Despite the involvement of the nitrogen atom of silatranes in the Si←N coordinate bond, the ^{14}N NMR lines in their spectra are appreciably broadened (X = CH_3, $\Delta\nu = 2211$ Hz; X = H, $\Delta\nu = 638$ Hz).[57] The authors explain this by the local asymmetry of the nitrogen atom in the silatrane molecules and by the increase of the C–N–C valence angles. The isolation of the contribution of the Si←N bond to the ^{14}N shielding constant for silatranes is complicated by a number of factors. Among these, the main one is the cyclisation effect, which is of a distinctly diamagnetic type. At the same time, the change in the ^{14}N chemical shifts (by 9 p.p.m.) when the hydrogen atom in the 1-hydrosilatrane molecule ($\delta_N = -355$ p.p.m.) is replaced by the methyl group[57] is approximately equal to the downfield shift of the ^{14}N resonance of trialkylamines or their salts when the hydrogen atom at α-carbon atom is substituted by the methyl group. This kind of analogy in the behaviour of δ_N is caused by the formally similar mechanisms of the transmission of the effective substituent to the indicator centre (^{14}N) in the X–C–N and X–Si–N fragments.

In the NMR spectra of 1-substituted silatranes the ^{29}Si line is displaced upfield with increase of the electronegativity of the substituent X.[53,58,59] A similar dependence has been observed also for Si-substituted triethoxysilane $XSi(OCH_2H_5)_3$.[53,59] Consequently the presence of the Si←N bond in silatranes cannot be inferred from the nature of the change in the $\delta(^{29}Si)$ as the substituent X is varied. At the same time, the ^{29}Si signals in the NMR spectra of silatranes are appreciably displaced upfield compared with the signals observed in the NMR spectra of model Si-substituted triethoxysilanes (Table 2). This increase of the shielding cannot be accounted for either by the cyclisation effect (usually causing a downfield shift of the signals[60]) or by the influence of the high electronegativity of the nitrogen atom. The implication is that the factors which do not characterise directly the presence of the Si←N bond are unable to explain the upfield shift of the ^{29}Si NMR signal of silatranes relative to Si-substituted triethoxysilanes.

However, the increase of the shielding constants of the nuclei with increase of the coordination number of the atom, a fact which has not so far been accounted for theoretically, is widely known in ^{11}B, ^{29}Si, ^{119}Sn, ^{199}Hg, etc. NMR. On this basis one must conclude that the nature of the ^{29}Si NMR spectra of silatranes rigorously demonstrates the presence of the Si←N bond in their molecules. If one adopts the reasonable, at first sight, hypothesis that the presence of the Si←N bond is responsible for the increased electron density at the silicon atom (compared with model systems) and one takes into account the familiar[60,61] V-shaped relation between the chemical shift and the atomic charge, then one should expect a downfield shift of the ^{29}Si signal of silatranes. It was therefore necessary to assume[53,59] that, in contrast to Si-substituted triethoxysilanes, the ^{29}Si shifts of silatranes are determined not only by the effective charge of silicon atom but also by a certain positive coordination contribution δ_{coord}. The magnitude of the latter increases with increasing degree of the Si←N interaction.

The proposed interpretation explains why the absolute values of $|\Delta\delta Si = \delta Si(silatrane) - \delta Si(triethoxysilane)|$ decrease in parallel with increase of the degree of the Si←N interaction in silatrane molecules[53]. On the other hand, the hypothesis of the reduced electronic charge on the silicon atom in silatranes hinders the explanation of the observed relations, although it does provide a formal explanation of the upfield shift of the ^{29}Si signal in their NMR spectra. All these findings show that, like the majority of other spectroscopic characteristics of silatranes, their ^{29}Si NMR chemical shifts are not determined solely by the contribution of the charge on the central atom.

An increase of the degree of shielding (compared with the corresponding Si-substituted triethoxysilanes) of the nuclei of the atoms forming part of the composition of the substituent at the silicon is also characteristic of silatranes[1,29,52,53,58]. ^{13}C and ^{19}F linked directly to the silicon atom are the only exceptions[58]. The pentacoordinate state of the silicon atom in silatrane molecules is responsible for the increase of the spin–spin coupling constants $^1J(^{29}Si^{13}C)$ and $^2J(^{29}Si^1H)$ and for the decrease of $^1J(^{29}Si^1H)$ and $^1J(^{29}Si^{19}F)$ compared with the corresponding derivatives of tetravalent silicon[58]. The above properties are probably common to all derivatives of Group IVB elements containing a heteroatom with an increased coordination number.

Before silatranes were studied by ^1H NMR,[29,52] the hypothesis of the high polarity of the Si←N bond in their molecules aroused no doubts. This conviction was based on the determination and calculations of the dipole moments of silatranes[1,25]. The appearance of new data on the geometry of the silatrane molecules enabled one of the present authors and his coworkers[27,55] to recalculate their dipole moments on the basis of an additive scheme. It was found[55] that the Si←N bond dipole moment in 1-alkyl- and 1-aryl-silatranes does not exceed 2.20 D, which corresponds to the transfer of approximately 0.2*e* from the nitrogen to the silicon atom. At the same time the validity of the earlier conclusion[25] that the high dipole moments of silatranes cannot be explained without taking into account the contribution of the Si←N bond moment was demonstrated. Similar results were obtained in another study[27], where the dipole moment of the Si←N bond in 1-methylsilatrane was estimated as 1.38 D.

The dipole moments of silatranes depend not only on the electronic effect of the substituent X and hence also on the internuclear Si...X distance, as assumed before, but also on the conformational features of the heterocyclic skeleton of the molecules[55]. The revised values of μ(Si←N) are of fundamental importance for the theory of the structure of silatranes. In the study of 1-methylsilatrane solutions in dioxan measurements were made of the molar Kerr constants, the total polarisation, and the molecular anisotropy[62]. The determination of these molecular characteristics made it possible to establish, within the framework of the additive scheme for the calculation of bond polarisabilities, that the Si←N bond in silatranes is characterised by an appreciable anisotropy of its polarisability. The conformations of a number of silatranes containing a carbofunctional substituent were established by the same methods[63].

The molecular ions $(M-X)^+$ in the mass-spectra of silatranes[64,65] exhibit a high intensity (from 48.5 to 33.9%). This indicates the stability of the silatrane ring on electron impact, which can be accounted for by the presence of the Si←N coordinate bond. When the substituent X is extracted, the latter is converted into the "covalent" Si–$\overset{+}{N}$ bond, where the nitrogen atom is in the ammonium state.

The influence of the silatrane skeleton on the properties of the Si-substituent have been frequently considered. The ^{35}Cl NQR frequencies for 1-chloroalkyl- and 1-chlorovinyl-silatranes are somewhat lower than for the corresponding acylic analogues[54]. This is consistent with the hypothesis that there is a coordination interaction in silatranes between the silicon and nitrogen atoms, which increases the +*I* effect of the silatranyl group. The inductive constant of the silatranyl group has been determined as −1.2 by employing familiar[66,67] linear relations between the ^{35}Cl NQR frequencies and the σ_X^* constants for the $H_2C{=}CClX$ and $XX'CCl_2$ series. This value indicates a distinctly σ-donor character of the $-\overset{\downarrow}{Si}(OCH_2CH_2)_3N$ group. The high σ-donor capacity of the silatranyl group has also been confirmed by ^1H, ^{13}C, and ^{19}F NMR.[28,29,52,53,58,68–70]

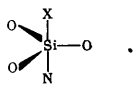
The quantitative estimate of the inductive effect of the silatranyl group, obtained[70] on the basis of ^{13}C NMR data for 1-phenyl silatrane ($\sigma^* = -0.9$) is lower in absolute magnitude than that determined[54] by ^{35}Cl NQR. This discrepancy is most probably independent of the difference between the reliabilities of the correlation equations employed, based on data found by different methods (^{35}Cl NQR and ^{13}C NMR). It can probably be explained by the fact that the σ-donor properties of the silatranyl group are not constant and depend on the nature of the substituent at the silicon atom. The latter in fact determines the degree of transannular interaction in silatrane molecules and hence the increased, compared with $Si(OR)_3$ groups, electron-donating capacity of the silatranyl fragment $-\overset{\downarrow}{Si}(OCH_2CH_2)_3N$ (see below). The quantitative estimate of the inductive effect of the silatranylmethyl group $-CH_2-\overset{\downarrow}{Si}(OCH_2CH_2)_3N$ ($\sigma^* = 0.8$) [69] is consistent with the value of $\sigma^*[-\overset{\downarrow}{Si}(OCH_2CH_2)_3N]$ obtained from ^{35}Cl NQR data.

It has been suggested[54] that there may be a coordination interaction between the chlorine and silicon (oxygen) atoms in the 1-(γ-chloropropyl)silatrane molecule. However, this was subsequently disproved experimentally[10].

Thus, despite the fact that, in the majority of the studies examined the isolation of the contribution of the Si←N bond to the properties of silatranes investigated has been achieved only at a qualitative level (and frequently very artificially), the results obtained convincingly demonstrate a significant change in the electron clouds of the silicon and nitrogen atoms as well as their immediate environment in silatrane molecules. Together with the characteristic influence of the nature of the substituent at the silicon atom on the properties of silatranes this indicates unambiguously the presence of the Si←N bond in their molecules. The existing experimental data cannot be accounted for within the framework of the alternative model (the stabilisation of the silatrane skeleton by non-valence and electrostatic interactions). At the same time, in view of the lack of experimental and theoretical estimates of the Si←N bond energy, the problem of the causes of the stability of silatranes, which is crucial for the theory of their structure, remained in fact open for a long time.

To solve this problem, the total energies of the 1-hydrosilatrane molecules and the most significant points on the potential function for the *endo–exo* transition were calculated[21] by the CNDO/2 method in terms of a novel parametrisation. It was shown that the *endo*-form is energetically more favourable than the *exo*-form (by 60 kcal mol^{-1}). The high value of the calculated barrier to the transition of the *endo*-form (Ia) into the *exo*-form (Ic) (~64 kcal mol^{-1}) and its low value (~4 kcal mol^{-1}) for the reverse transition demonstrated that the *exo*-form does not exist.

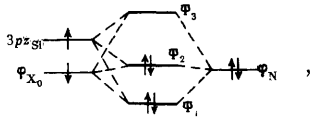
The energies of the skeletal bonds of the silatrane molecule do not actually change on transition from the *endo*- to



the *exo*-form (more precisely the changes in them are negligible compared with their absolute values). The decrease of the Si←N bond energy by more than an order of magnitude is unique and extremely symptomatic. Hence we may conclude that the main factor stabilising the *endo*-form of the silatrane molecule is the bonding interaction between the silicon and nitrogen atoms. The energy of the Si←N bond in the *endo*-form (Ia) of the 1-hydrosilatrane molecule can be regarded as close to 24–25 kcal mol^{-1}¶.

Analysis of the populations of the hybrid orbitals of the nitrogen atom indicates unambiguously the involvement of its LEP in the formation of the Si←N bond. The calculated degree of transfer of electron density from the nitrogen to the silicon atom in the hydrosilatrane molecule (~0.2*e*) agrees well with the earlier estimate obtained by analysing the dipole moments of silatranes[55].

The results of conformational[18,19] and quantum-chemical[21] analyses suggest[35,72] that the cause of the existence of the intramolecular Si←N bond in silatranes and the virtual absence of the formation of a similar intermolecular bond when organyltriethoxysilanes react with amines consists in the fundamental difference between the free energy profiles for the formation of the intra- and intermolecular hypervalent X–Si–N linkages. The energetically favourable transition of the silatrane molecule from the *exo*- to the *endo*-form occurs with retention of the conformational entropy. This follows from the existence, as the reaction coordinate r_{Si-N} is altered, of only two stable states and the dissociation of the intermolecular complex is characterised by a monotonic increase of the entropy.



The problem of the nature of the interaction between the silicon and nitrogen atoms in silatranes is particularly significant. Only one mechanism of their mutual binding was in essence considered in previous studies: the donor–acceptor interaction of the LEP of the nitrogen atom with the vacant 3*d* orbitals of the silicon atom having a suitable symmetry[1,28,38,73]. However, as shown above, this mechanism cannot explain logically certain results of physicochemical studies on silatranes. Futhermore, the concept of hybridisation involving 3*d* orbitals, particularly in the case of non-transition elements, has been recently subjected to serious and constructive criticism[74]. The problem of both the nature of the Si←N bond in silatranes and of the influence of the substituents at the silicon atom on the energetics of the molecule and the steric structure of the silatrane skeleton therefore clearly had to be reconsidered.

An attempt has been made[75] to treat the electronic and steric structures of silatranes within the framework of the model of hypervalent linkages[76]. A significant factor in the consideration of the electronic structure of silatranes is the isolation of the molecular fragment of greatest structural and chemical importance. This is the silicon atom and its immediate environment, which has approximately the symmetry of a trigonal bipyramid:

For a more logical determination of the influence of the substituent X on the equilibrium properties of silatranes, one can assume that, for a "standard" substituent X_0, the geometry of the local environment of the silicon atom corresponds rigorously to the ideal trigonal bipyramid†. Three sp^2-hybridised orbitals can be constructed from the four valence orbitals of the silicon atom (3*s*, $3p_x$, $3p_y$, and $3p_z$). The hybrid orbitals are involved in the formation of three "normal" equivalent equatorial Si–O bonds. The orbitals of the axial atoms (one from each atom) can then interact with the single $3p_z$ orbital of the central silicon atom common to all of them. According to the molecular orbital (MO) theory, this should lead to the formation of three three-orbital, three-centre MO.

In the case where the central atom is less electronegative than the axial atoms, this can be represented schematically as follows:

where ϕ_{X_0} and ϕ_N are the hybrid or the pure orbitals of the axial atoms used to construct the MO, ψ_1 is a bonding MO, ψ_2 a weakly bonding MO with a node in the region of the weaker bond (for the X–A–X fragment, the ψ_2 orbital becomes non-bonding), and ψ_3 an antibonding MO. The filling of ψ_2 with electrons corresponds to the model of hypervalent linkages and distinguishes such linkages from the "normal" bonds for which only bonding MO are filled with electrons. It can be readily shown that the filling of the ψ_1 orbital with electrons in the model of hypervalent linkages ensures the required energy gain in the interaction of three atomic orbitals.

The first evident consequence arising from the model is that the influence of the σ-linked substituent can be transmitted only via the $3p_z$ orbital of the central atom. This explains the *trans*-influence of the substituent characteristic of silatranes. The expression defining the effect of the bonding between the Si and N atoms can be formulated as follows for a three-level system:

$$\Delta E_{SiN} = \beta^2_{Si^0N} \Big/ \left(\alpha^0_{Si} + \frac{\beta^2_{Si^0X^0}}{\alpha^0_{Si} - \alpha^0_X} - \alpha^0_N \right),$$

where α and β are the Coulombic and resonance integrals, subscript 0 refers to the initial atomic levels, and the ratio $\beta^2_{Si^0N}/(\alpha_{Si^0N} - \alpha_{X^0})$ characterises the decrease of the effect of the bonding between the Si and N levels as a result of the X_0–Si interaction.

It follows from this expression that, with increase of the X–Si bond strength, the Si–N interaction in silatranes is weakened. Furthermore, the change in the Si←N bond energy depends significantly also on the electronegativities of the silicon and nitrogen atom (the Coulombic integrals α_{Si} and α_N). The conclusion that the silicon atom is displaced from the equatorial plane formed by the three oxygen atoms on transition from X_0 to X_i is natural. Indeed, the strengthening of one part of the X–Si–N fragment and the weakening of the other constitutes in essence the "expulsion" of the silicon atom from the equatorial plane. The greater the effect of the strengthening (and weakening) of one of the components of the fragment compared with the standard value, the greater should be the displacement Δ from this plane#.

¶The presence of the Si←N bond in the 1-methylsilatrane molecule was also confirmed by the 4NDO method[71].

†Such a "standard" substituent is the $R_3\ddot{N}$ group.

#The sign of Δ depends on the relative values of α_{X_0} and α_{X_i}.

When the contribution of the 3*s* orbital is neglected and for $|\alpha_{X_i}| > |\alpha_{Si}|$, an increase of the electronegativity of the substituent X should weaken the X–Si bond and enhance the Si←N interaction. If $|\alpha_X| < |\alpha_{Si}|$, variation of the substituent X leads to a parallel variation of the X–Si and Si←N bond strengths. Analysis of the experimental data for the steric structure of silatranes[14] fully confirmed the conclusions of Voronkov and coworkers[75]. In agreement with the theory, the weakest Si←N interaction is observed for a silatrane in which the silicon atom is linked to the atom of a transition metal (Pt: $|\alpha_{Pt}| \ll |\alpha_{Si}|$).[16,17] In this molecule the non-valence interactions make the dominant contribution to the stabilisation of the silatrane skeleton. Indeed, the optimum geometry of the silatrane ring in relation to the non-valence interactions, corresponding to a structure without bonding[18], is fairly close to the experimental structure[16,17].

The proposed model readily explains the destabilising resonance§ influence of the *p*- or π-donor Si-substituents in silatrane molecules, which is caused by the filling with electrons of the antibonding level of the hypervalent X–Si–N linkage as a result of which the degree of Si→N bonding diminishes.

The X–Si bond in silatranes is known[8,14,22,64] to be weakened¶, i.e. its length is increased, compared with the corresponding $X-Si_{sp^3}$ bond. This can apparently be accounted for by the fact that the hypervalent linkages are always weaker than the normal covalent bonds. The disposition and filling with electrons of the atomic levels corresponding to the experimental and theoretical results[21], which is illustrated in the diagram, clearly show that the degree of charge transfer from the donor orbital ϕ_N to the $3p_z$ orbital of the silicon atom is less than unity. The Si←N bond strength should increase with increase of the polarity of the bond. As the ionisation potential of the central atom increases, the energy of the bonding orbital falls, i.e. the hypervalent structure in fact becomes less stable (other conditions being equal). Comparison of the ionisation potentials of the carbon and silicon atoms (11.25 and 8.15 eV) explains why it is difficult to obtain carba-atrane†. On this basis, one may expect an increase of the bonding effect when the silicon atom in silatranes is replaced by a germanium or tin atom and also when the nitrogen atom is replaced by a phosphorus atom.

Thus the above investigation shows that the interaction between the silicon and nitrogen atoms in silatranes is due to the hypervalent bonding between these atoms and the substituent at the silicon atom. Despite a number of assumptions, the hypervalent bond model describes more realistically, in our view, the electronic and steric structures of silatranes than the widely held hypothesis of the sp_3d hybridisation of the silicon atom.

---

§This influence has not been established experimentally quite so convincingly as the inductive effect. It has been observed in the analysis of the ^1H NMR and ESCA spectra as well as the kinetics of the hydrolysis of silatranes.

¶In the limiting case which obtains under electron impact, the hypervalent X–Si–N linkage is converted into the usual covalent linkage in the substituted ammonium ion $[\overbrace{Si(OCH_2CH_2)_3N}]^+$ formed.

†A recent analysis[77] demonstrated the possibility of the existence of the stable hypervalent linkage X–C←P.

3. Donor–Acceptor Properties of Silatranes

The study of the mechanism of the hydrolysis of silatranes provided definite ideas about their donor–acceptor properties. The influence of the substituent at the silicon atom on the rate of hydrolysis of silatranes has been studied in both neutral[7,78,79] and in acid media[79–81]. The hydrolysis in a neutral medium is described satisfactorily by a first-order equation. The silatranes investigated can be divided into two reaction series. The first includes 1-alkylsilatranes and the second 1-alkoxy-derivatives. Linear relations between the logarithms of the rate constants for the hydrolytic reactions ($\lg k$) and the inductive constants of the substituent at the nitrogen atom (σ^*) have been observed for both series.

In the reaction series of 1-alkylsilatranes an increase of the inductive constant of the substituent X accelerates the hydrolysis. The high reaction constant $\rho = +4.76$ indicates a high degree of polarity of the transition state in which the silicon atom acquires a considerable negative charge.

The values of $\lg k$ for 1-vinyl- and 1-phenyl-silatranes deviate significantly from the linear correlation plot for 1-alkyl derivatives. This can be explained by the $p\pi-d\pi$ interaction of the above substituents at the silicon atom, which reduces the electron-accepting effect of X. A better explanation, from modern standpoints, consists in π-donation to the antibonding orbital of the hypervalent X–Si←N linkage. The same causes are probably responsible also for the lower than expected (in view of the high electronegativity of the alkoxy-groups) rate constants for the hydrolysis of 1-alkoxysilatranes. The reaction constant $\rho = 2.60$ for these compounds is smaller than for 1-alkylsilatranes. The results led to the conclusion that the rate-limiting stage in hydrolysis in a neutral medium is nucleophilic attack by a water molecule or an OH^- ion on the silicon atom.

The rate of hydrolysis of silatranes in an acid medium[79–81] is considerably higher than in a neutral medium. The influence of the substituent at the silicon atom is also different. With increase of the electronegativity of the latter, the rate constants for the hydrolysis of silatranes decrease appreciably, which made it necessary to assume[79,80] that the rate-limiting stage in the acid hydrolysis of silatranes is electrophilic attack by a hydronium ion on the oxygen atom with simultaneous transfer of the hydration shell to the silicon atom. The subsequent stages of the hydrolysis (in the first place the rupture of the Si–O) bond are probably very fast.

A somewhat different mechanism[82] has been proposed for the acid hydrolysis of the Si-substituted derivatives of tribenzosilatrane $X-\overbrace{Si(OC_6H_4)_3N}$. The protonation of the oxygen atom is fast; on the other hand, the slow stage of the reaction is the dissociation of the Si–O bond in the protonated molecule. In both cases the possibility of the protonation of the nitrogen atom (as the initial and slowest step of the hydrolytic reaction in an acid medium) is rejected owing to its weak nucleophilic properties due to the steric inaccessibility of the LEP. On the other hand, evidence has been obtained[81] showing that the slowest stage of the hydrolytic reaction is the *endo–exo* transition of the silatrane molecule accompanied by the cleavage of the Si←N bond, which is followed by the protonation of the nitrogen atom in the transition state. This evidence is based on the analysis of the kinetic isotope effect observed in the hydrolysis. The proposed mechanism explains naturally the influence of the nature of the substituent at the silicon atom on the rate of the process.

The experimental activation energy for the hydrolysis of 1-phenylsilatrane (22 kcal mol^{-1}) [81] agrees satisfactorily with the Si←N bond energy in 1-hydrosilatrane estimated by the CNDO/2 method[21].

One of the most important pieces of chemical evidence for the involvement of the nitrogen atom in the transannular interaction with the silicon atom and hence for the pentacoordinate state of the latter in silatrane molecules is their inability to form methiodides as well as the low rate of their interaction with perchloric acid[1,6,7,73]. It is therefore not surprising that a number of studies have been made on the possibility of the formation of complexes of silatranes with other electron-accepting reagents. 1:1 complexes with certain Lewis acids ($TiCl_4$, $AlCl_3$) have been obtained for a series of 1-substituted silatranes; the structure of these complexes has been studied by infrared spectroscopy[83]; after the interaction of 1-ethoxysilatrane with $TiCl_4$, it was possible to isolate a 2:1 complex. In the infrared spectra of these complexes the bands assigned previously[1,7,43] to the Si←N coordinate bond persist, while the ν(Si–O) bands undergo a regular displacement. This led to the hypothesis[83] that the nitrogen atom in the silatrane molecule is not involved in the donor–acceptor interaction with Lewis acids. One of the oxygen atoms functions as the nucleophilic centre of the silatrane molecules in the complexes.

The isolation of the pure 1:1 hydrochloride of 1,3,7,10-tetramethylsilatrane, which is unstable in air, and analysis of its infrared spectrum led to the assertion[84] that the nitrogen atom is the centre of coordination with the HCl molecule. Evidence for this has been based on the fact that the infrared spectrum of the hydrochloride contains absorption bands of the stretching vibrations of the hydroxy-groups, which usually appear in the region of 3200–3300 cm^{-1}. This indicates the retention of the Si–O–C bonds in the complex-formation process. A group of bands characteristic of trialkylamine hydrochlorides was observed in the range 2500–2800 cm^{-1}. It was found that in the infrared spectrum of the hydrochloride of 1,3,7,10-tetramethylsilatrane all the absorption bands characteristic of the silatrane itself, including the 560–590 cm^{-1} band, are retained. Since this band has been assigned to the vibrations of the silatrane skeleton[46], its presence in the spectrum has been interpreted[84] as evidence for the retention of this skeleton in the complex. In this connection we may note that there is no absorption at 560–590 cm^{-1} in the infrared spectrum of the platinum derivative, which contains no transannular Si←N bond[16]. It is correct to assume[83] that the presence of the 560–590 cm^{-1} band in the infrared spectra of the complexes of silatranes with Lewis acids is evidence for the retention of the Si←N bond in these compounds. One cannot rule out the possibility that the hydrochloride of 1,3,7,10-tetramethylsilatrane is an oxonium derivative or a clathrate compound.

The ability of the nitrogen atom in certain 1-substituted silatranes to participate in complex formation with tetracyanoethylene (TCE) has been reported[84]. However, later convincing evidence was obtained[81] showing that the nitrogen atoms in silatrane molecules do not interact with TCE. The application of the EPR method and analysis of data published previously[84] established[85] that the absorption bands in the range 20000–25000 cm^{-1}, assigned[84] to the silatrane–TCE complex, are in fact due to the TCE radical-anion (and its conversion product). The formation of the TEC radical-anions is due to the electron transfer from the nitrogen atoms of impurity molecules present in the test substances in very small amounts. Carefully purified 1-alkylsilatranes do not give rise to a colour and EPR signals in systems with TCE.[85]

At the same time, it has been shown by ultraviolet spectroscopy[69] that 1-phenyl- and 1-benzyl-silatranes form charge-transfer complexes with TCE. However, in these two cases the donor centre is the aromatic substituent at the silicon atom. Analysis of the absorption bands in the spectra of these complexes shows convincingly that the silatranyl substituent is a better electron donor than the $Si(OC_2H_5)_3$ group. Silatranes are able to form hydrogen bonds with chloroform[26,52]. The composition of some of these associated species has been established by measuring the dielectric losses[86]; the proton acceptors in these compounds are oxygen atoms.

1-Methylsilatrane is capable of forming complexes with lanthanide shift reagents[87]. The interpretation of the paramagnetic shifts in the ^1H NMR spectrum of 1-methylsilatrane induced by europium trisdipivaloylmethanate [Eu(DPM)$_3$] (a lanthanide shift reagent) was based[88] on a comparison of the relative observed chemical shifts with the values calculated from McConnell's formula[89]. The best agreement (in terms of the *R*-factor) with experiment is obtained on the hypothesis that 90% of the 1-methylsilatrane molecules are involved in coordination with the acceptor via the oxygen atoms, while the remaining 10% are coordinated via the nitrogen atom. The 1-methylsilatrane molecule assumed to be coordinated with the shift reagent via the nitrogen atom should exist in the *endo*-form according to the calculation. However, the electron pair of the nitrogen atom in such a structure is known to be inaccessible to electrophilic attack. We believe that the results of the calculation[88] cannot be regarded as convincing demonstration of the involvement of the nitrogen atom in silatrane molecules in complex formation with Eu(DPM)$_3$. This is due to a number of fundamental difficulties which arise when the method of shift reagents is used in structural chemistry[90,91].

The conclusion that the nitrogen atom in silatranes is able to participate in complex formation was reached also on the basis of the study of the ^1H NMR of certain representatives of this class (X = CH_3, $ClCH_2$, or Cl) in the presence of paramagnetic complexes of $NiCl_2$ or $CoCl_2$ with 1-ethylimidazole[92]. In the systems investigated the induced shifts could be recorded reliably only in the presence of an excess of the paramagnetic complex by a factor of 1.5–2, which indicates an exceptionally low capacity of silatranes for coordination (the addition of individual $NiCl_2$ or $CoCl_2$ salts does not cause any changes in the ^1H NMR spectra of silatranes). It was found that there is a significant upfield shift of the signals due to the CH_2N protons, and not OCH_2 protons, in the ^1H NMR spectra of silatranes under the influence of these paramagnetic complexes. This served as the basis for the assumption that the nitrogen atom is a centre of coordination. However, the shifts induced by the Ni^{2+} and Co^{2+} complexes are largely of the contact type. Consequently, their values depend not only on the geometrical factor but also on the nature of the distribution of spin density in the adducts.

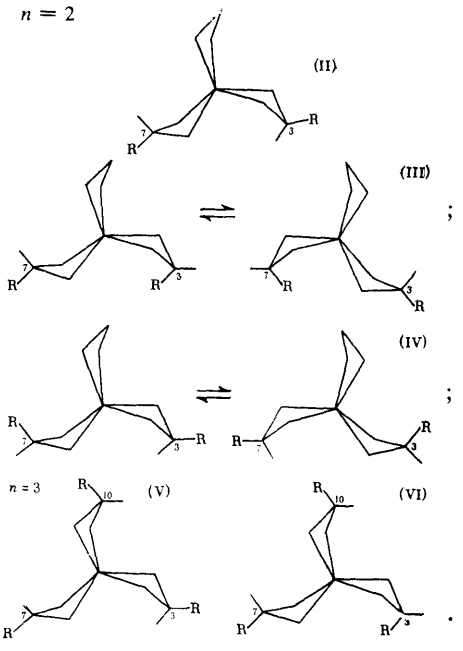
Thus there are at present no convincing grounds for the assertion that the lone electron pair of the nitrogen atom can be involved in the formation of complexes by silatranes with weak Lewis acids.

By virtue of the high dipole moments of silatranes, many of their properties should depend significantly on the polarity of the medium. The mechanism of the influence of the polar solvent reduces to non-specific interactions which induce the formation of solvates and the dissociation of the self-associated silatrane species, which leads ultimately to the perturbation of the most readily polarisable hypervalent X–Si←N linkage.

The phenomenon is illustrated by the recently observed dependence of the stretching vibration frequencies of the Si–H bonds in 1-hydrosilatrane (but not trialkoxysilane) on the solvent polarity and temperature[93]. With increase of the dielectric constant of the medium, the frequencies ν(Si–H) diminish, which corresponds to a weakening of the H–Si bond owing to the enhancement of the interaction between the silicon and nitrogen atoms. A significant influence of the medium on the properties of silatranes has also been observed in the study of the ^{1}H NMR spectra[53].

Further investigation of the interaction in silatrane–solvent systems may throw light also on the hitherto completely obscure problem of the mechanism of the formation of complexes by silatranes.

III. *C*-SUBSTITUTED SILATRANES



The study of the influence of the substituents R at the carbon atoms of the silatrane skeleton yields interesting information about the steric and electronic structures of silatranes. Successive substitution of the hydrogen atoms in the 3-, 7-, and 10-positions in chloroalkylsilatranes by methyl groups (i.e. R=CH_3) leads to an increase of the dipole moments[27]. It has been suggested that this is due to the conformational distortions of the atrane skeleton induced by the introduction of the methyl groups or by changes in its electronic structure.

At the same time the dipole moment of 1-phenyl-2-homosilatrane $C_6H_5Si(OCH_2CH_2CH_2)(OCH_2)_2N$ hardly changes when methyl groups are introduced into the 8- and 11-positions[94]. The intensity of the $(M-X)^+$ ions in the mass-spectra of 3-mono-, 3,7-di-, and 3,7,10-trimethyl derivatives of 1-chloroalkylsilatranes decreases linearly with increase of the number of methyl groups in the molecule[64]. The authors explained this by the increased strength of the Si–C bond, since, owing to the inductive influence of the *C*-methyl substituents, there is an increase of the electron density at the silicon atom and a weakening of the degree of the transannular interaction of the latter with the nitrogen atom. The ^{35}Cl NQR frequencies for 1-chloroalkyl-3,7-10-trimethylsilatranes are higher than for their *C*-unsubstituted analogues[54]. These data are consistent with the decrease following the introduction of the *C*-methyl group in the electron-donating capacity of the silatrane skeleton, which is caused by the weakening of the Si←N bond. Previously[54] this decrease was attributed to the distortion of the geometry of the silatrane skeleton arising when methyl groups are introduced.

The introduction of methyl groups in the 3-, 7-, and 10-positions in the silatrane skeleton reduces the hydrolysis rate constant[79,81]. This has been explained[79] by the increased order and hence strength of the Si–O bond. Within the framework of the proposed mechanism of the hydrolytic process (with the protonation of oxygen atoms as the rate-limiting stage), this hypothesis appears likely. In terms of the alternative concept (where protonation of the nitrogen atom is the primary step), the observed behaviour cannot be explained[81]. However, on the basis of the proposed mechanism for the hydrolytic reaction[81], one can assume that the introduction of *C*-methyl groups into the silatrane skeleton reduces its conformational mobility, hindering thereby the *endo–exo* isomerisation of the molecule.

As methyl groups accumulate, the intensity of the band in the range 560–590 cm^{-1} increases in the infrared spectra of 3-mono-, 3,7-di-, and 3,7,10-trimethylsilatranes[46]. However, without a correct identification of the band under discussion, it is so far impossible to explain the effect.

According to ^{1}H NMR data, Si-substituted 3-methylsilatranes exist as a single diastereoisomer with a pseudoequatorrial orientation of the substituent[30,52]; Si-substituted 3,7-dimethylsilatranes and 3,7,10-trimethylsilatranes consist of mixtures of the following diastereoisomers[53,95]:

Judging from the spin–spin coupling constants between the protons of the substituted atrane half-rings, all the methyl groups of isomer (V) as well as the 7- and 10-groups of isomer (VI) are oriented pseudoequatorially, while the 3-CH_3 group of isomer (VI) is disposed pseudoaxially. In diastereoisomer (II) both methyl groups are pseudoequatorial, but the substituted atrane half-rings are non-equivalent. On the other hand, in diastereoisomers (III) and (IV) the substituted half-rings are equivalent in pairs owing to the high conformational mobility of these isomers, the conformational changes being accompanied by a rapid *ae–ea* reorientation of the *C*-substituents.

A change in the temperature of solutions of 3,7-dimethyl-, and 3,7,10-trimethylsilatranes in various solvents from −80° to +200 °C does not alter the relative positions of their ^{1}H NMR lines[95]. This shows that the height of the barrier to the conversion of the *C*-substituted rings in silatrane molecules is very small (<2 kcal mol^{-1}). However, the differences between the strain energies of the rings substituted pseudoequatorially and pseudoaxially are fairly large. These two factors fully explain the existence of molecules of 3-methyl-substituted silatranes as well as diastereoisomers (V) and (VI) in a single energetically favourable conformation. The same causes are responsible for the ease of the conformational transitions between the two states (III) and (IV) which are degenerate with respect to energy. Furthermore, the equatorial–axial and not equatorial–equatorial orientation of the 3,7-substituents in isomers (III) and (IV) shows that the non-concerted conversion of the three five-membered rings is forbidden by virtue of the high strain energies of the asymmetric structure. This is confirmed by the results of conformational calculations[20]. Thus the conformational transitions of the silatrane skeleton are collective and take place with retention of C_3 symmetry.

Analogous conclusions were reached[96] in a ^{19}F NMR study of the stereochemistry of the *C*-(trifluoromethyl)silatranes# ($R = CF_3$). Naturally, the strain arising in the axial orientation should influence the extent of the transannular Si←N interaction. The shielding constants for the protons of the substituent at the silicon atom and the ^{29}Si nuclei in the case of *C*-substituted silatranes are greater for the less strained diastereoisomers[53].

The sum total of the data presented above requires a reconsideration of the problem of the influence of *C*-substituents on the spectroscopic and physicochemical properties of silatranes substituted in the 3-, 7-, 10-positions and the formulation of a series of new experimental approaches to its solution. The point is that all the characteristics of 3,7-di- and 3,7,10-tri-substituted silatranes obtained hitherto must be regarded as integral characteristics referring to a mixture of stereoisomers. This constitutes one of the causes of the evident conflict between the conclusions based on the change in the properties of silatranes following their successive *C*-substitution. Hence it is necessary to separate the above mixtures into individual components and to study in detail the physicochemical and spectroscopic properties of the latter. In analysing the results, particular attention must be paid to the stereodynamic characteristics of each isomer§. The solution of the problem formulated here can play a significant role in the practical applications of the silatranes. Data indicating the biological activity of *C*-substituted silatranes already exist[97]. One must assume that their optically active isomers will be still more effective.

---o0o---

The structural studies on silatranes make a fundamental contribution to the development of a general theory of the structure of organic compounds containing the atoms of pentacoordinate silicon and its neighbours in the Periodic System.

Analysis of the results of physicochemical studies on silatranes indicates a significant influence of the hypervalent—Si←N linkage on their steric and electronic structures and in many instances also on their reactivity. At the same time, the extensive experimental data accumulated point to an urgent need for the solution of a number of new vital problems in the structural chemistry of silatranes. These involve in the first place a theoretical study of the structure and spectroscopic characteristics, an experimental determination of the thermodynamic parameters, and a systematic study of the reactivity and of the influence of the medium on the physical and chemical properties of silatranes.

The solution of all these problems will not only prove to be extremely useful for the theory of chemical structure and reactivity but will also permit a deeper understanding of the nature of the biological activity of silatranes.

During the preparation of the manuscript for the press, a number of new studies, extending the available ideas about silatranes, were published. A monograph[97] and a brief review[98] devoted to silatranes appeared. The concept of the hypervalent nature of the bonding in the axial fragments of silatrane molecules has been confirmed[99] by the CNDO/2 method (in terms of two parametrisations) in relation to 1-hydro- and 1-fluoro-silatranes. The constancy of the hypervalent X–Si←N bond order when the nature of the substituent X is varied has been demonstrated[33]. An increase of the degree of Si←N interaction in silatrane molecules with increasing proton-donating capacity, polarity, and polarisability of the medium has been observed by infrared spectroscopy[100] and ^{15}N and ^{29}Si NMR.[101,102] The solvent effects diminish with increasing strength of the Si←N bond under the influence of the 1-substituent[102]. According to ^{29}Si NMR data for the solid state[103], the influence of the crystal field on the state of the Si←N bond in silatrane molecules does not exceed the effect of a highly polar solvent. The influence of the nature of the 1-substituent in silatranes on the ^{15}N NMR chemical shifts has been studied[104,105]. The spin–spin interaction between the ^{15}N and ^{29}Si nuclei has been observed[104] in relation to 1-chloromethylsilatrane. The relaxation times of the ^{29}Si and ^{13}C nuclei have been studied by NMR.[106] The pathways leading to the dissociative ionisation of 1-substituted silatranes on electron impact have been examined[107]. Arguments supporting the manifestation of the ν(Si←N) stretching vibration band in the infrared spectra at frequencies below 400 cm^{-1} have been obtained[108]. It has been shown by EPR [109] that unstable silatranyl radicals are formed in the oxidation-reduction reactions of 1-hydrosilatrane.

#For these diastereoisomers, a further spin–spin interaction between the fluorine nuclei separated by eight valence bonds was observed for the first time.

§This must be taken in account also in a more detailed analysis of the known properties of *C*-unsubstituted and 3-substituted silatranes.

Advances in the Chemistry of Azaindoles

L.N.Yakhontov and A.A.Prokopov

The results of research into the chemistry of azaindoles during the last ten years are examined and the advances in the development of new methods for the synthesis and the study of the chemical and physicochemical characteristics of the behaviour of azaindole systems containing condensed rings with an excess and a deficiency of π-electrons are discussed. The studies on the nature of the biological activity of various derivatives of isomeric azaindoles are summarised.
The bibliography includes 267 references.

CONTENTS

I. Introduction 428
II. Methods of synthesis of azaindole structures 428
III. Physicochemical studies on azaindoles 433
IV. Synthetic studies based on azaindoles 435
V. Biological properties of azaindole derivatives 439

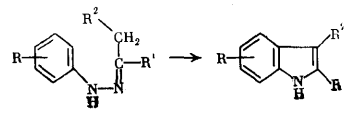
I. INTRODUCTION

As a result of vigorous research by Soviet and foreign investigators, new significant results have been obtained in the chemistry of azaindoles during the ten years which have elapsed since the publication of two previous reviews on this field[1,2]. The methodological possibilities of the synthesis of azaindole structure have greatly expanded and the study of the characteristics of the structure of azaindoles compared with indoles revealed new chemical transformations (the cleavage of the N-N bond in hydrazones with simultaneous alkylation of the nitrogen atom[3-5], etc), which are outside the framework of the problem under consideration.

Azaindoles proved to be convenient models for the study of the mutual influence in condensed systems of *N*-heteroaromatic rings with opposite shifts of the π-electron density within each ring—a problem which is of general interest for the chemistry of heterocyclic compounds and theoretical organic chemistry.

Studies on the tautomerism of hydroxy-, amino-, and acylamino-azaindoles[6] served as the starting point of the investigation of a number of general problems of tautomeric equilibria involving *N*-heteroaromatic compounds[7-10], while consideration of the protonation of azaindoles showed that these compounds are effective models for a more detailed study of the mechanisms of protolytic equilibria[11-13].

Studies on the interrelations between tryptophan, heteroauxin, and other biologically important indole compounds, on the one hand, and their 7-aza-analogues on the other, in biochemical processes have been greatly expanded and carried out in greater depth. The observation of a high activity of new antibiotics—tubercidin, toyocamycin, and sangivamycin—which are *N*-glycosylated derivatives of diazaindoles[14], stimulated research into the synthesis and activities of *N*-glycosylated indoles as the antimetabolites in the metabolism of nucleic acids[15,16].



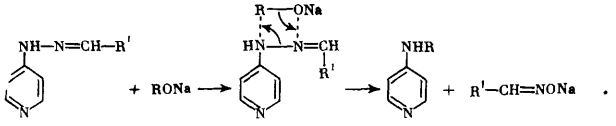
The above factors as well as the psychotropic and cardiovascular activities of a wide variety of synthetic azaindole derivatives, discovered in recent years, led to an extensive development of synthetic research into this series of compounds. Chemical and biochemical investigations in the field of porphobilinogens—derivatives of azaindoles linked to porphyrins, protoporphyrins, and their analogues, have been prosecuted vigorously[17-19].

Within the framework of a single review, it is difficult to cover the entire wide range of problems associated with azaindoles and we therefore decided to disregard in the present review studies on condensed azaindole systems (a small section dealing with the formation of new condensed heterocyclic systems based on 7-azaindole derivatives is an exception) as well as studies on fully or partly hydrogenated azaindoles (with the exception of azaindolines and systems in which aromaticity breaks down as a result of tautomerism). The studies on the chemistry and biology of azaindoles published up to 1967 and discussed in earlier reviews[1,2] are quoted in exceptional instances where it is necessary to describe the general characteristics of the state of the problem.

II. METHODS OF SYNTHESIS OF AZAINDOLE STRUCTURES

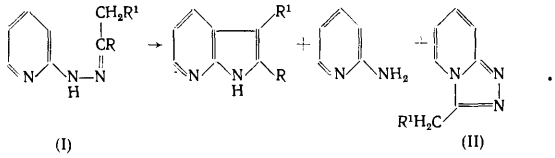
1. Syntheses Based on Pyridylhydrazines

The attempts to apply to the series of azoindoles the Fischer reaction, on which one of the main methods for the synthesis of indole derivatives is based[20], yielded few positive results under the usual conditions of acid catalysis:



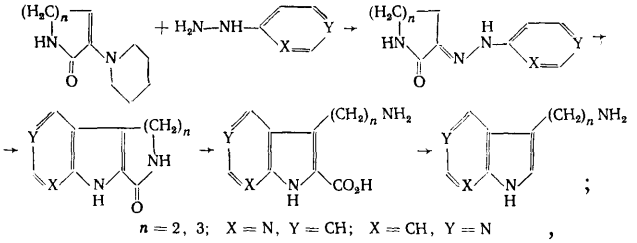
azaindole derivatives were isolated in low yields or were not obtained at all, owing to the relative inertness of the pyridine ring with respect to electrophilic attack on the carbon atoms and the ease of such attack on the pyridine nitrogen atom[21]. Modification of the reaction conditions, involving a transition to "non-catalytic" thermal cyclisation, extended somewhat the possibilities of the method[22]. Thus the 4-pyridylhydrazones of isobutyraldehyde and ethyl methyl ketone were converted into 2,3-dimethyl-5-azaindole on being refluxed in diethylene glycol, while the 4-pyridylhydrazones of propionaldehyde and 2-methylbutyraldehyde were converted into 3-methyl- and 2-ethyl-3-methyl-5-azaindoles[23-25].

1,2-Dialkyl (or-diaryl)-4-methyl-7-azaindoles have been obtained from 4-methyl-2-pyridylhydrazones of propionaldehyde, phenylacetaldehyde, acetophenone, and deoxybenzoin[26], while the analogous 4-azaindole derivatives have been synthesised from 3-pyridylhydrazones of propionaldehyde, ethyl methyl ketone, acetophenone, and certain others[25]. 4-Substituted 5-azaindoles have been synthesised on the basis of 2-hydroxy-6-methyl-4-pyridylhydrazine[27].



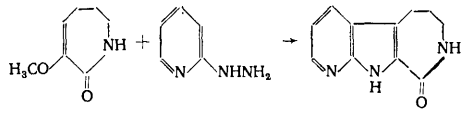
Studies designed to optimise the conditions of the "normal" Fischer reaction in the synthesis of azaindoles have not ceased either. It has been established[28-35] that the yields of the "normal" products of the conversion of 2- 4-pyridylhydrazines by the Fischer reaction vary within wide limits, depending on the nature of the initial hydrazine and that of the substituents in the hydrazine component, as well as the structure of the carbonyl component and the catalyst employed. The introduction of electron-donating substituents into the pyridine ring facilitates the "normal" Fischer cyclisation; on the other hand, electron-accepting groups hinder this process and promote an "anomalous" course of the reaction with formation of aminopyridines of products of cyclisation via the pyridine nitrogen atom.

It has been possible to carry out the Fischer reaction in the presence of not only acid but also alkaline catalysts[34,35]. In the course of this research a new type of cleavage of the N-N bond in isomeric 2-, 3-, and 4-pyridylhydrazones under the influence of alkali alkoxides was discovered; it results in the formation of monoalkylaminopyridines and *syn*-oximes of the carbonyl components of the hydrazones[4,35]:



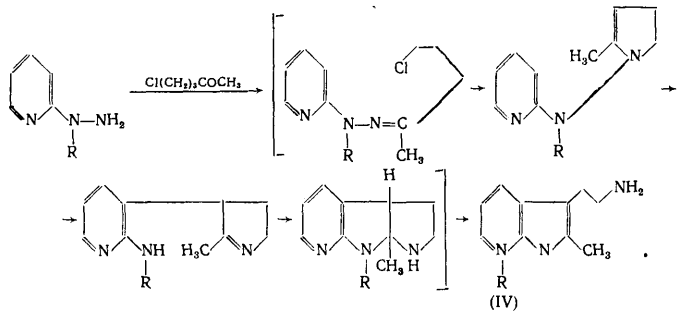
The use of aromatic aldehydes as the carbonyl component in those cases where the "normal" course of the Fischer reaction becomes impossible led to the development of a new preparative method of synthesis of *N*-monoalkylaminopyridines[4,36].

Azaindole structures are formed also in the Fischer cyclisation under the conditions of high-temperature heterogeneous catalysis[37,38]. 7-Azaindole and its 2-methyl- and 2,3-dimethyl-derivatives have been obtained from the 2-pyridylhydrazones of acetaldehyde, acetone, and ethyl methyl ketone (I) by the above method in the presence of alumina. The reaction was accompanied by the formation of 2-aminopyridine and the product of the cyclisation via the pyridine nitrogen—3-methyl-*s*-triazolo[4,3-*a*]pyridine (II).



(I) (II)

The synthesis of 5- and 7-azatryptamines and 5- and 7-azahomotryptamines from α- or γ-pyridylhydrazines and lactam α-enamines[39] via the mechanism

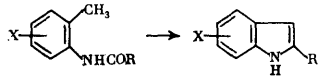


$n = 2, 3$; X = N, Y = CH; X = CH, Y = N

has been described. The use of pyridylhydrazine and 3-methoxy-2-oxo-2*H*,1,5,6,7-tetrahydroazepine (III) in the Fischer reaction yielded the new system of 1-oxo-9-aza-1*H*,2,3,4,5-tetrahydrazepine[3,4,-*b*]indole[40]:

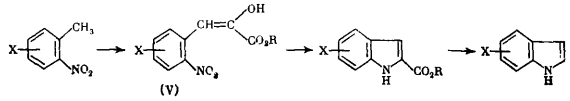
(III)

The synthesis of 2-methyl-7-azatryptamine (IV, R = H) and 1,2-dimethyl-7-azatryptamine (IV, R = CH_3) has been achieved[41,42] by the reaction of 2-pyridylhydrazine with γ-chloropropyl methyl kentone:



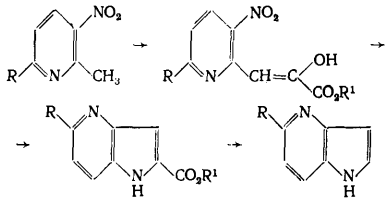
(IV)

2. Syntheses Based on *o*-Nitro- or *o*-Acylamino-picolines and Their Derivatives



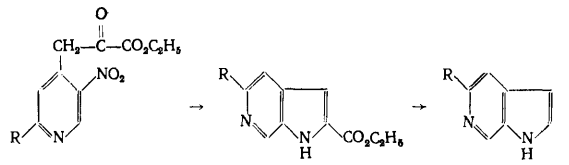
This group of methods includes primarily the Madelung and Reissert reactions which are widely used in the chemistry of indoles.

The Madelung synthesis, which consists in the cyclisation of *o*-acylaminomethyl derivatives of aromatic compounds, was of the greatest importance in the synthesis of azaindole compounds until the last decade:



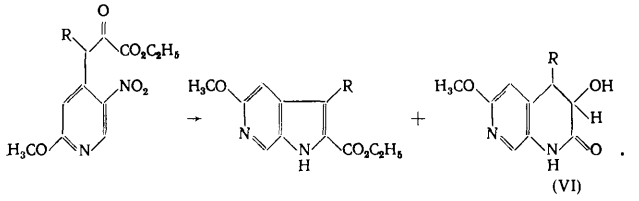
Unsubstituted 4-, 5-, and 7-azaindoles and some of their alkyl derivatives have been synthesised with the aid of this reaction[1]. However, during the last 10 years the Madelung method has not been specially developed for the synthesis of azaindoles owing to inadequate yields and the limited range of substituents which can be introduced into the azaindole system. Among the studies carried out in this field mention should be made of the confirmation[26] of the superiority of sodium *N*-methylanilide over sodium ethoxide as the catalyst in the synthesis of 2-methyl, 2-phenyl-, and 2-pyridyl-7-azaindoles, which agrees well with the hypothesis[43] concerning the roles of amidines as intermediates in the Madelung reaction. The 2-phenyl derivatives of 4-, 5-, 6-, and 7-azaindoles have been synthesised in low yields by the cyclisation of *o*-benzamidopicolines under the conditions of alkaline catalysis[44].

The Reissert method, which consists in the condensation of *o*-nitromethyl derivatives of aromatic compounds with diethyl oxalate, further reductive cyclisation of the intermediates (V) followed by the hydrolysis of indole-2-carboxylic acid esters, and decarboxylation has found extremely limited applications in the series of azaindoles[2]:



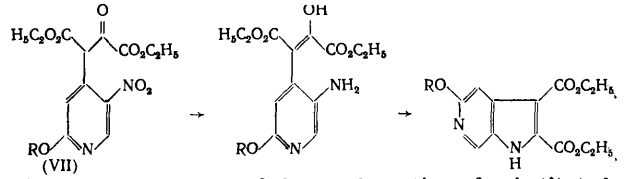
(V)

It was not until 1968 that the Reissert method began to be used successfully[45-48] in preparative synthesis of 4-azaindole and 5-alkoxy-derivatives:



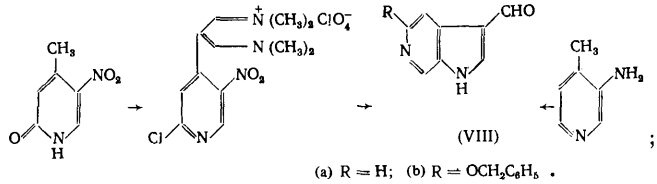
The greatest difficulty in this synthesis was the decarboxylation of 4-azaindole-2-carboxylic acids, for which satisfactory conditions could not be found initially[46]. Later a convenient method was developed[45,47,48] for the direct elimination of the carboxy-group by refluxing the acids in biphenyl in the presence of copper bronze.

The Reissert method has been used widely also in the synthesis of 6-azaindole derivatives[17,18,46,49,50]:



The presence of substituents in the α-methylene group of the side chain complicates the process: together with 6-azaindole derivatives, partly hydrogenated 1,7-naphthyridines (VI) are produced[51]:

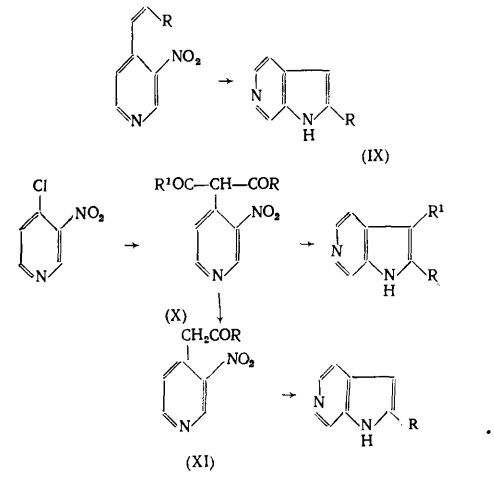
(VI)



The reduction of the diethyl esters (VII) leads to the preferential formation of 3-aminopyridine derivatives, which are converted into 2,3-diethoxycarbonyl-6-azaindoles in the presence of phosphoryl chloride[51]:

(VII)

Among the products of the condensation of substituted 2-chloro-3-nitropyridine with malonic[52] or cyanoacetic[53,54] esters, 4-azaoxindole and its derivatives were synthesised.

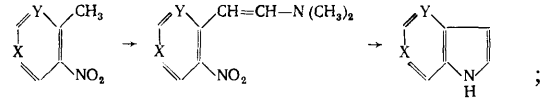


The synthesis of 3-formyl-6-azaindole (VIIIa) [55] and its 5-benzyloxy-derivative (VIIIb) [9] has been achieved in low yields under the conditions of the Wilsmeyer reaction:

(VIII)

(a) R = H; (b) R = $OCH_2C_6H_5$.

2-Substituted 6-azaindoles (IX), R = alkyl or heteroaryl, have been synthesised in yields of 12–22% by the reductive cyclisation of 3-nitro-4-vinylpyridines with triethyl phosphite[44]:

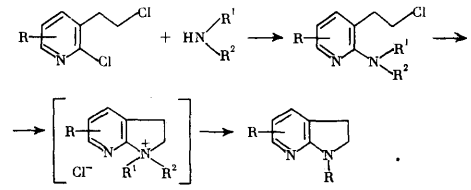


(IX)

(XI)

Various 2-substituted and 2,3-disubstituted 6-azaindoles have been synthesised by the reaction of 4-chloro-3-nitropyridine with β-dicarbonyl compounds (malonic, acetoacetic, and benzoylacetic ester, etc) or with cyanoacetic ester followed by reductive cyclisation of compounds (X) obtained or their reaction products (XI).[52,56-58]

The use of condensation of *o*-nitropicolines (XII) with the dimethylformamide (DMF) acetal followed by the reductive cyclisation of nitroenamines (XIII) proved to be fruitful in the synthesis of isomeric 4- and 6-azaindoles[59,60]. The yields of the azaindoles (XIV) (with respect to the readily available *o*-nitropicolines) are nearly quantitative when this method is used:

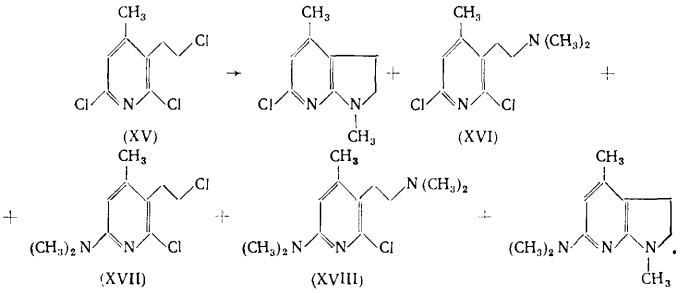


(XII) (XIII) (XIV)

X = CH, Y = N; X = N, Y = CH .

The employment of 3-bromo-5-nitro-γ-picoline as the starting compound yielded 4-bromo-6-azaindole[61], while the introduction of (3-nitro-4-pyridyl)acetone or ethyl (3-nitro-4-pyridyl)acetate instead of *o*-nitropicolines led to 3-substituted 6-azaindoles[62].

3. Syntheses from Halogeno-Derivatives of 3-(β-Chloroethyl)Pyridines via the Corresponding Azaindolines

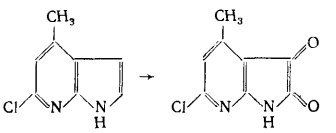


A general method of synthesis of a wide variety of derivatives of 5- and 7-azaindoles had been developed previously[1] on the basis of the reaction of 3-(β-chloroethyl)pyridines, containing halogen atoms in the 2- or 4-positions, with ammonia and primary or secondary amines:

During the last ten years, the study of this method was continued in relation to the reaction of 2,6-dichloro-3-(β-chloroethyl)-4-methylpyridine (trichlorocollidine) (XV) with

asymmetric secondary amines[63]. It was established that the ease of elimination of the substituent at the pyrroline nitrogen atom in the intermediate quaternary azaindoline salt increases in the sequence aryl < alkyl < benzyl, while for alkyl substituents the sequence is hexyl < ethyl < methyl[64].

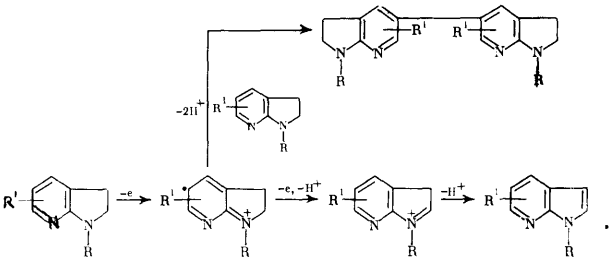
Detailed study of the side reactions occurring when compound (XV) interacts with dimethylamine[65] established the possibility of controlling the process by altering the reactant ratio, temperature, the reaction time, the polarity of the medium, and the catalytic effect of metal salts. It was shown that side processes leading to the monocyclic products (XVI)–(XVIII) can be suppressed by increasing the polarity of the medium:



(XV) (XVI) (XVII) (XVIII)

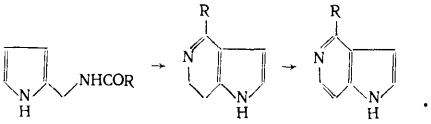
Trichlorocollidine (XV) reacts with sterically hindered primary amines of the type of β-phenylisopropylamine as well as *N*-substituted anilines to form 6-chloro-7-azaindolines and not the 6-amino-derivatives[66]. On passing to t-butylamine, the nucleophilic attack on the α,α′ positions in the pyridine ring becomes sterically impossible and the main reaction pathway becomes the dehydrohalogenation of compound (XV) to 2,6-dichloro-4-methyl-3-vinylpyridine.

5-Azaindolines have been obtained in analogous processes from 4,6-dichloro-3-(β-chloroethyl)pyridine[47,67], while 4-chloro-(5-chloroethyl)pyrimidines gave rise to derivatives of 5,7-diazaindoles[68].



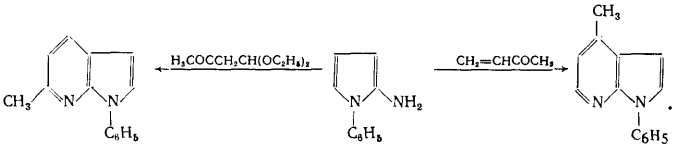
The hydrogenation of azaindolines, i.e. conversion into aromatic azaindole systems, has been achieved successfully by reaction with chloranil and dichlorodicyanoquinone and catalytically in the presence of palladium[47,63,66,69–71]. The dehydrogenation reaction involves *N*-debenzylation[63] and even *C*-dealkoxylation[69].

Studies on the polarographic dehydrogenation of azaindolines and the mechanism of this process have been published[72–77]. It has been shown that azaindolines with an oxidation potential $E_{1/2}$ < 1.1 V are capable of being dehydrogenated by chloranil, those with $E_{1/2}$ up to 1.2 V can be dehydrogenated by dichlorodicyanoquinone, and those with a potential up to 1.4 V can be dehydrogenated by activated manganese dioxide[78]. Azaindoles are oxidised by chromium trioxide to azaisatins[79]:

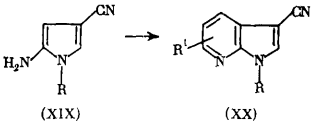


The conversion of 7-azaindolines into indolines without electron-accepting pyridine nitrogen is facilitated by dehydrogenation[72–74], while the conversion to 5-azaindolines and 5,7-diazaindolines gives rise to a successively enhanced hindrance to this process[75].

A mechanism has been proposed for the polarographic oxidation of 7-azaindolines via the formation of intermediate radicals of the semiquinonoid type with further aromatisation to give7-azaindoles or dimerisation to give the corresponding 5,5-bis-7-azaindolines, which have been isolated on a preparative scale[76]:

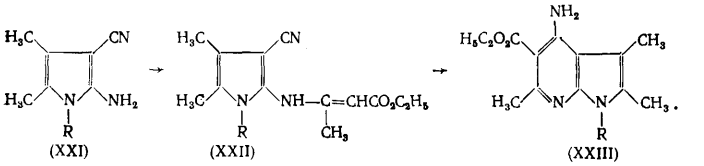


4. Syntheses Based on Pyrrole Derivatives



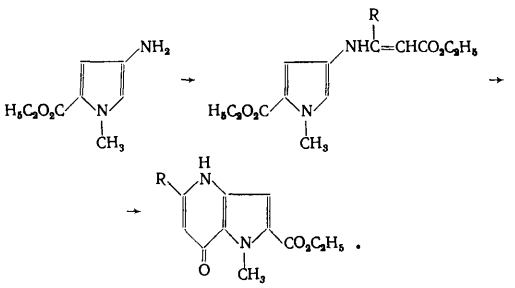
Up to 1968 there were only isolated publications concerning the syntheses azaindole systems based on pyrrole derivatives which dealt[1] with the preparation of 5-azaindoles from acylated 1-(β-aminoethyl)pyrroles by the Bischler–Napieralski reaction:

The synthesis (with a yield of 18–23%) of 4-methyl- and 6-methyl-1-phenyl-7-azaindoles by the reaction of 2-amino-1-phenylpyrrole with methyl vinyl ketone and the acetal of acetoacetaldehyde in the presence of zinc and iron chlorides was reported in 1973 [80]:



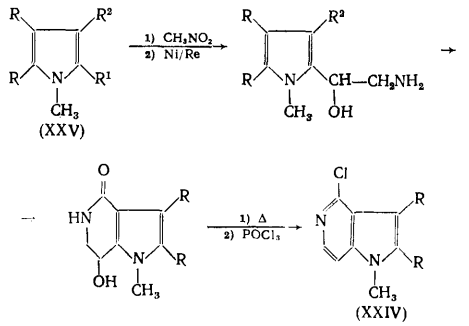
The use of cyanaminopyrroles as the starting materials for the extension of the range of dicarbonyl compounds employed led to the synthesis of a wide variety of 7-azaindole derivatives[81,82]. Thus 1-alkyl(or aryl)-2-amino-4-cyanopyrroles (XIX) undergo cyclocondensation with 1,3-dicarbonyl compounds and their acetals to form unsubstituted 1-alkyl(or aryl)-3-cyano-7-azaindoles (XX) or derivatives substituted in the pyridine ring[81]:

(XIX) (XX)



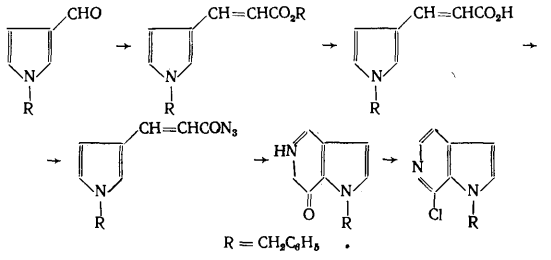
R′ = H or alkyl.

When 1,4,5-trisubstituted 2-amino-3-cyanopyrroles (XXI, R = aryl or cyclohexyl) were allowed to react with acetoacetic ester, the products were propenylaminopyrroles (XXII), which were converted by reductive cyclisation into bifunctional polysubstituted 7-azaindoles (XXIII) [82]:



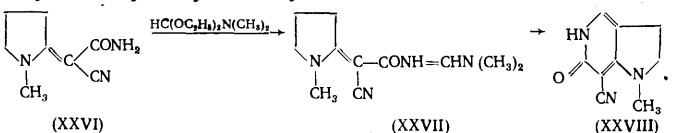
(XXI) (XXII) (XXIII)

The successful use of the 2-ethoxycarbonyl derivative of the isomeric 4-amino-pyrrole in syntheses of substituted 4-azaindoles has been reported[83]. The reaction with β-dicarbonyl compounds proceeds in this case also via propenylaminopyrroles, whose cyclisation can yield 2-ethoxycarbonyl-1-methyl-4-azaindoles with substituents in the pyrridine ring:



The method of synthesis of 4-chloro-1-methyl(or benzyl)-5-azaindole (XXIV, R = H) and its 2,3-dichloro-derivative (XXI, R = Cl) from 3-ethoxycarbonyl-2-formyl-*N*-methyl(or benzyl)pyrrole and its 4,5-dichloro-derivative (XXV, R = Cl, R^1 = CHO, $R^2 = CO_2C_2H_5$) [84,85] via the mechanism

is of interest.

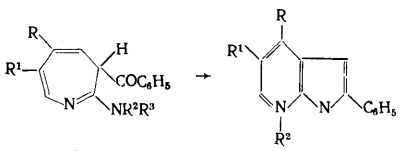


Compound (XXIV, R = H) has also been obtained[86,87] by the reaction of 2-formyl-*N*-methylpyrrole (XXV, $R = R^2 = H$, R^1 = CHO) with malonic acid and by the cyclisation of the azide of the resulting substituted acrylic acid derivative (XXV, $R = R^2 = H$, $R^1 = CHCHCO_2H$) followed by treatment with phosphoryl chloride[88].

1-Benzyl-7-chloro-6-azaindole has been synthesised using an analogous scheme[87] from 1-benzylpyrrole-3-aldehyde via 1-benzyl-3-pyrrolylacrylic acid:

The synthesis of 4,6-dihydroxy-5-azaindole (3,7-didesazaxanthine) has been achieved recently by the alkaline cyclisation of 3-ethoxycarbonyl-2-pyrrolylacetamide[89].

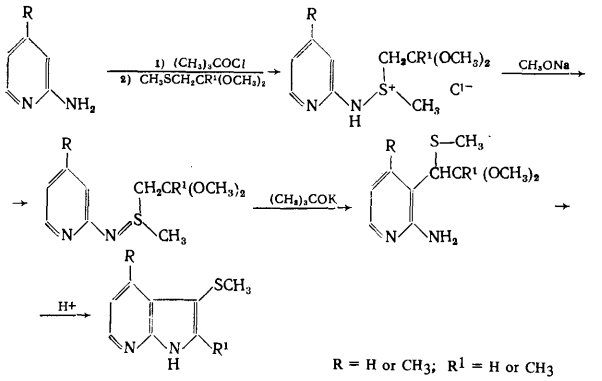
In the reaction of 2-(2′-cyano-2′-carbamoylmethylene)-1-methylpyrrolidinone (XXVI) with the DMF acetal the condensation involves the amide NH_2 group and the resulting substituted acylformamidine (XXVII) readily cyclises to the 7-cyano-6-hydroxy-1-methyl-5-azaindoline (XXVIII) [90,91]:



(XXVI) (XXVII) (XXVIII)

An analogous synthesis based on the *N*-benzyl derivative of pyrrolidinone makes it possible to obtain 1-benzyl-7-cyano-6-hydroxy-5-azaindoline, which splits off the cyano- and benzyl groups simultaneously on being refluxed with hydrobromic acid and gives rise to a high yield of 6-hydroxy-5-azaindoline[92].

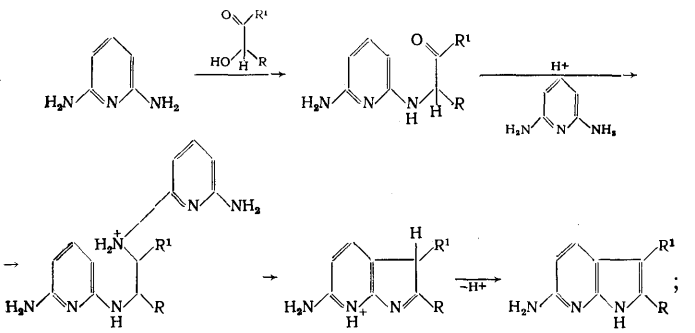
5. Other Syntheses



Certain syntheses of azaindolines by specific methods have been described in the literature. An example is provided by the thermal rearrangement of 3-acyl-2-amino-3*H*-azepines (XXIX) to 7-azaindoles (XXX) [93]:

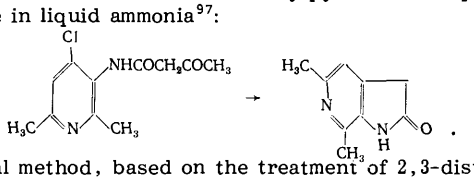
(XXIX) (XXX)

R, R^1 = H, Cl; R^2 = H, C_6H_5, or n-C4H9.



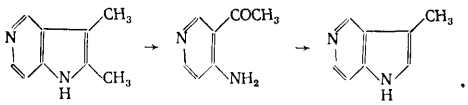
The synthesis of 3-methylthio-7-azaindoles from 2-aminopyridines via the mechanism

R = H or CH_3; R^1 = H or CH_3



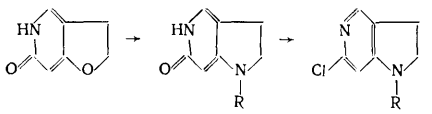
has been reported.

The use of the Bischler reaction, which involves the interaction of α-hydroxy-ketones with 2,6-diaminopyridine, for the synthesis of 7-azaindoles has also proved to be successful[96]:

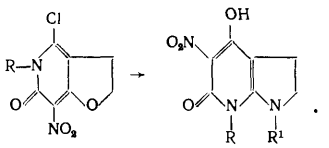


R, R^1 = H, alkyl, or aryl.

5,7-Dimethyl-6-azaoxindole has been obtained by cyclising 3-acetoacetamido-4-chloro-2,6-dimethylpyridine with potassium amide in liquid ammonia[97]:

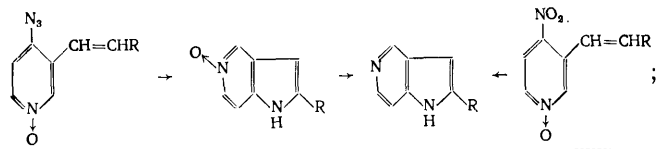


An unusual method, based on the treatment of 2,3-disubstituted 5-azaindoles or 6,7,8,9-tetrahydro-γ-carbolines with hydrogen peroxide in acetic acid, has been proposed[98] for the synthesis of 3-substituted 5-azaindoles. The process takes place with the opening of the pyrrole ring and further cyclisation of the resulting *o*-aminopyridyl ketones or *o*-aminopyridinecarboxylic acids with dimethylsulphonium methyid:



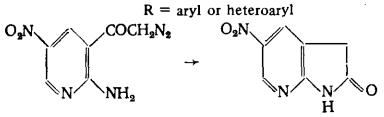
An analogous closure of the pyrrole ring is believed[98] to be possible also for 7-azaindoles. However, the yields in both stages of the process are low so that the method is of no practical value.

Satisfactory results have been obtained in the synthesis of 1-phenyl and 1-benzyl-5-azaindolines[47,70,99,100] by the reaction of 6-oxo-2,3-dihydro-5-azabenzofuran (XXXI) with primary amines:



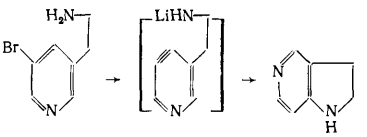
(XXXI)

The interaction of 4-chloro-7-nitro-6-oxo-2,3-dihydro-5-azabenzofurans (XXII) with primary and secondary amines involves the substitution of the chlorine atoms by amine residues and recyclisation of the compounds to 7-azaindoline derivatives[101]:



(XXXII)

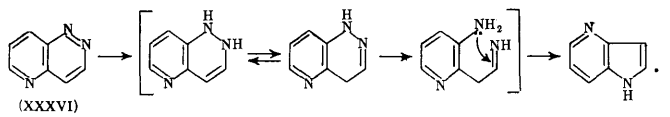
The synthesis of azaindoles by the thermal cleavage of 4-azido-3-styrylpyridine 1-oxide (XXXIII) with subsequent *N*-deoxidation of the resulting 2-phenyl-5-azaindole 5-oxide[44] as well as the synthesis of 5-nitro-7-azaoxindole by the thermal decomposition of 2-amino-3-diazoacetyl-5-nitropyridine[102] have been described:



(XXXIII) (XXXIV)

R = aryl or heteroaryl

2,3-substituted 5-azaindoles have been obtained[44] by the reduction of the *N*-oxides of 4-nitro-3-styrylpyridines (XXXIV).



The reaction of 3-(2-aminoethyl)5-bromopyridines with lithium diethylamide proceeds via the hetaryne (XXXV) and gives rise to 5-azaindoline[103] in 56% yield:

(XXXV)

We may note that the above reaction is the first example of the intramolecular addition of a base in the series of hetarynes.

A novel synthesis of unsubstituted 4-azaindoles has been achieved by the reduction of 5-azacinnoline (XXXVI) [104] via the mechanism

(XXXVI)

III. PHYSICOCHEMICAL STUDIES ON AZAINDOLES

1. Ionisation Constants and Electronic Structures of Azaindoles and Their Protonated Forms. The Study of Azaindole Bases and Their Cations by Spectroscopic Methods

As mentioned previously[1,2], the properties of azaindoles are determined by the involvement in their condensed bicyclic system of two *N*-heteraromatic rings with opposite shifts of π-electron density within each ring: pyridine with a deficiency of π-electrons and pyrrole with an excess of π-electrons. During the last decade a number of theoretical and experimental studies have been carried out on the interaction of π-electron systems of this kind. The study of the ionisation constants of a large group of derivatives of 4- and 5-azaindoles using correlation methods made it possible to generalise the relations governing the transmission of the influence of such substituents and to calculate the transmission factors for isomeric 4-, 5-, 7-azaindoles and 5- and 7-azaindolines[105].

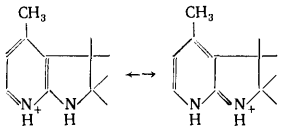
In order to estimate the ability of isomeric azaindoles to undergo electrophilic substitution reactions, a study was made of the kinetics of deuterium exchange involving 4-, 5-, and 7-azaindoles[106]. The penetration integrals have been determined[107] for isomeric azaindoles and indole by the Pariser–Parr method, the calculated π–π* transition energies agreeing satisfactorily with experimental data.

Calculations have been made for the molecules of isomeric azaindole and indole by the Hückel and Pariser–Parr–Pople methods, the nature of the mutual influence of the five- and six-membered rings has been examined within the framework for the π-electron approximation, and the energies of the lowest excited states have been calculated by the method of limited interaction of the configurations[108,109]. The results indicate a relatively large π-electron charge on $C_{(3)}$ in all azaindoles and indole. The distribution of π-electron density in the $C_{(1)}$–$C_{(2)}$–$C_{(3)}$ atomic group changes little from molecule to molecule, i.e. the rotation of the pyridine ring has little effect on the electronic structure of the five-membered ring. The π-electronic charges in the six-membered ring are as it were rotated when the position of the pyridine nitrogen atom is altered, without undergoing significant distortions in this process[109].

Calculations for the cations of isomeric azaindoles indicate a relatively high charge on the $C_{(3)}$ atom, which enables the protonated azaindoles to react via an electrophilic mechanism.

The shielding of the positive charge of the cation as a result of solvation enhances this possibility[110]. It has been found that the electron affinity increases in the sequence indole < 5- < 6- < 7- < 4-azaindoles. The ionisation potentials increase in the sequence indole < 5- < 7- < 6- < 4-azaindoles[109].

On the other hand, the experimental basicities of azaindoles are correlated neither with the charge on the nitrogen atom of the six-membered ring nor with the analogous value for the protonated molecules. The discrepancy between the experimental and theoretical data has been attributed[110] to the characteristic features of the structure of the σ-skeleton of azaindoles, as a result of which the basicity of azaindoles can be influenced by the relatively positively charged nitrogen atom of the pyrrole ring.



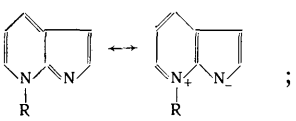
Attempts have been made[111,112] to estimate experimentally the electron distribution in the 7-azaindole system. This was done taking into account the measured chemical shifts (with a correction for the shielding influence of the ring), the magnetic anisotropy of the neighbouring atoms, and the electric field of the free electron pair of the heteroatom dipole. However, in this case too the agreement between the experimental and calculated data was not very satisfactory. In particular the positive charge on the carbon atoms of the rings proved to be greater than the calculated value, experiment revealing an excess negative charge on the heteroatoms and on the bridging carbon atoms. The authors[111,112] do not rule out the possibility that the contradictory data are due to insufficient allowance for the mutual influence on the five-and six-membered rings in the condensed azaindole systems.

^{1}H NMR has been used to investigate the protonation of 5-azaindoles and 5-azaindolines in media with different dielectric constants[11-13]. It has been shown that the structures of the monocations of 5-azaindole, 5-azaindoline, and their 1-substituted derivatives indicate an appreciable contribution of quinonoid structures with transfer of the positive charge to the nitrogen atom of the pyrrole or pyrroline fragment.

The dependence of the chemical shifts of the proton signals of 1-substituted 5-azaindoles or 5-azaindolines on the concentration of trifluoroacetic acid in methylene chloride, acetonitrile, and deuteroacetone led[11,12] to a protonation mechanism in which the proton transfer from the donor to the acceptor in media of low polarity takes place via the formation of a hydrogen-bonded molecular complex of the base and the acid, which is followed by conversion into an ion pair and dissociated ions.

The relative equilibrium position in reactions involving proton transfer via a hydrogen bond and dissociation of hydrogen-bonded complexes with formation of solvated ions has been determined as a function of the concentration of acids on the basis of a model of the amine—acid system in which the amine component is 4-methyl-7-azaindoline[113]. Near the equimolar reactant ratio in the amine—trifluoroacetic acid system, the protolytic equilibrium is fully displaced towards hydrogen-bonded complexes of the ion pair type. The interaction with acetic acid under the same conditions involves a molecular complex ⇌ ion pair equilibrium. The enthalpy and entropy of the proton transfer reaction have been determined.

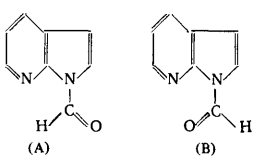
In a neutral molecule the greatest sensitivity to the effects of the medium and to the formation of hydrogen bonds is shown by the proton in the α-position with respect to the nitrogen atom of the pyridine ring ($H_{(6)}$). On passing from the neutral molecule to the cation, the changes in the ^{1}H NMR spectrum, particularly the upfield shift of the $H_{(6)}$ signal, correspond to the addition of a proton to the pyridine nitrogen with formation of a conjugated ion of the amidinium type (XXXVII)[113]:



(XXXVII)

A detailed study[114] of the ^{1}H NMR spectra of 5-azaindole and its 1- and 3-methyl derivatives showed that the protons in the 3- and 7-positions interact, while the $H_{(1)}$—$H_{(3)}$—$H_{(2)}$—$H_{(6)}$ and $H_{(4)}$—$H_{(6)}$ interactions were not observed in any one spectrum.

Mass-spectrometric studies on 7-azaindole and a large number of its derivatives established[115] that, on fragmentation on electron impact, the common intermediates for many compounds are naphthyridines and pyrido[2,3d]pyrimidines.

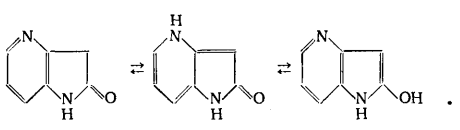


The structure of anhydro-salts of the (XXXVIII) series was determined with the aid of absorption spectroscopy[116] and the contribution of each resonance structure, which varies as a function of the type of solvent, was estimated:

(XXXVIII)

R = alkyl or aryl.

The rotation of the acyl groups about the N—C bond has been studied by ^{1}H NMR for a set of *N*-acylindoles[117] and it has been shown that, in contrast to other *N*-acyl derivatives, 1-formyl-7-azaindole exists predominantly in form A:

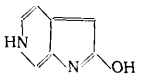


(A) (B)

The chromatographic mobilities of azaindole derivatives have been investigated[118] by thin-layer chromatography.

2. Problems of the Tautomerism of Azaindole Systems

Studies in recent years on tautomeric transformations of isomeric azaindoles have dealt mainly with problems of the lactam—lactim tautomerism of hydroxy-derivatives. It has been established[52,54] that 4-azaoxindole exists in the lactam form (a) in the crystalline state; in protic solvents it has been possible to detect by ultraviolet spectroscopy all three tautomeric forms (a, b, and c) [54]:

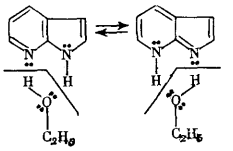


a b c

A change of solvent or the introduction of substituents into the molecule influences significantly the position of the tautomeric equilibrium.

6-Azaoxindole exists as a mixture of comparable amounts of the tautomeric lactam and lactim forms in solution in dimethyl sulphoxide and in the crystalline state[52,56,119], although the possibility of the presence of form (XXXIX) as

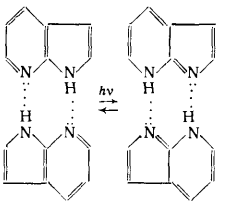
well is not ruled out:



(XXXIX)

In the crystalline state 3-ethoxycarbonyl-6-azaoxindole exists as a mixture of two tautomeric forms, the equilibrium being strongly displaced towards the lactam, in contrast to 3-ethoxycarbonyl-4-azaoxindole, which exists in the lactim form in the crystalline state[52,56].

The lactam—lactim tautomerism of 7-azaindole and 7-azaindoline systems containing the oxo-group in the α-position with respect to the pyridine hydrogen atom had been studied fairly completely previously[1]. It was noted that, in contrast to other analogous *N*-heteroaromatic systems, a complete shift of equilibrium towards lactams is not observed in 6-hydroxy-7-azaindolines and 6-hydroxy-7-azaindoles. This is due to the inductive effect of the nitrogen atom of the pyrrole ring on the α-hydroxy-*N*-heteroaromatic system which exhibits a tendency towards tautomerism. On passing from 7-aza-compounds to the analogous 5-aza-derivatives, the inductive effect on the nitrogen atom of the five-membered ring is greatly weakened, which is responsible, in particular, for the shift of the lactam—lactim tautomeric equilibrium involving 6-hydroxy-5-azaindolines[120] and 4-hydroxy-5-azaindoles[84] almost completely towards the lactam forms. The tautomeric lactam form predominates also in derivatives of 2-ethoxycarbonyl-7-hydroxy-1-methyl-4-azaindole containing a methyl or phenyl group in the 5-position[83].



A study of the temperature dependence and the thermodynamic characteristics of the lactam—lactim tautomeric equilibrium of 1-substituted 6-hydroxy-4-methyl-7-azaindoles established[121] that the conversion of the lactim into the lactam is an exothermic process in most of the forms investigated. On passing to less polar solvents, the process becomes less exothermic and in dioxan, where the lactim form predominates to a large extent, the process becomes endothermic. An increase of temperature in more polar solvents promotes a decrease of the content of the lactam forms; the opposite behaviour is observed in less polar solvents.

Examination of the optical, absorption, and luminescence spectra of 7-azaindole in ethanol revealed a two-proton phototautomerism[122]. The influence of the tunnel effect and of the migration of the excited proton cannot explain the changes in the luminescence but does show that the excited state of the molecule is the cause of the ready two-sided migration of the two combined protons:

The spectra of solutions of 7-azaindole in aprotic solvents have two fluorescence maxima, the relative intensities of which depend on the concentration of the solution, temperature, pH, wavelength, and irradiation intensity. The second maximum is apparently caused by the tautomeric form produced as a result of the rapid intramolecular migration of the proton doublet in the excited state, and constitutes a doubly hydrogen-bonded dimer[122-128].

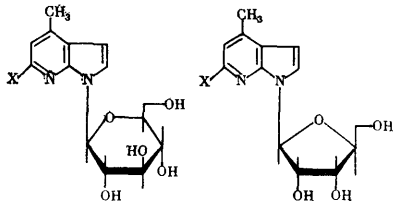
A study of the cleavage of the 7-azaindole dimer in 3-ethylpentane by investigating its fluorescence at 77 and 4.2 K led to the determination[127] of the potential energy barrier to the double prototropic intermolecular reaction. The rate of deuterium exchange involving the excited 7-azaindole molecule and the rate of migration of the proton in the excited non-deuterated 7-azaindole molecule have been determined[127]:

IV. SYNTHETIC STUDIES BASED ON AZAINDOLES

The characteristic features of the chemical behaviour of condensed pyrrolopyridines (azaindoles), associated with the nature of the electron density distribution in their molecules, have been examined in fair detail in earlier reviews[1,2]. Further studies did not alter the fundamental ideas concerning the chemical properties of compounds of this class but greatly extended the synthetic possibilities in the series of azaindole derivatives and led to the discovery of new ways of constructing condensed heterocyclic systems on the basis of 7-azaindole derivatives.

1. Reactions of Azaindoles Involving Nitrogen Atoms

One of the commonest reactions of isomeric azaindoles is alkylation at the pyrrole nitrogen atom[24,114,129-131]. This process takes place fairly readily in the presence of strong bases (sodium amide, sodium hydride, etc.) which convert azaindole compounds into the corresponding anions[1]. In the absence of strong bases the reaction usually takes place via several pathways and leads to a mixture of products of alkylation at the pyrrole and pyridine nitrogen atoms[132-135]. In some instances the alkylation of 7-azaindole derivatives in the presence of alkali involves the expansion of the pyrrole ring with formation of 1,8-naphthyridine derivatives[26].

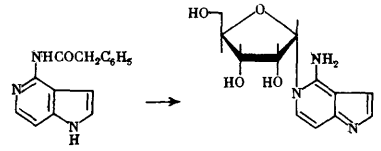


7-Azaindole reacts with ethylmagnesium iodide to form a Grignard compound, which is converted into the 1-acetyl and 1-ethoxycarbonyl derivatives on treatment with acetyl chloride and ethyl chloroformate respectively[26].

Oxidation of 5- and 7-azaindoles with *m*-chloroperbenzoic acid converts them into the *N*-oxides[52,136], which like the *N*-oxides of other six-membered *N*-heteroaromatic compounds, are capable of rearrangement under the influence of acetic anhydride, phosphoryl chloride, and other analogous reagents.

Certain mercury derivatives of 7-azaindole substituted at the pyrrole nitrogen atom[137] as well as cobalt[138] and copper[139] complexes of 7-azaindole, which exhibit antiferromagnetic properties of practical interest, have been synthesised.

The synthesis of *N*-glycosylated azaindoles by fusing 7-azaindole with 1,2,3,5-tetra-*O*-acetyl-β-*D*-ribofuranose did not give positive results[140]. The use of the indoline—indole method[15,16], which consists in the glycosylation of 7-azaindoline derivatives by *D*-glucose or 5-*O*-trityl-*D*-ribofuranose residues with subsequent dehydrogenation to 1-β-*D*-glucopyranosyl-7-azaindole (XL) and 1-β-*D*-ribofuranosyl-7-



azaindole (XLI), was more successful:

(XL) X = H or Cl. (XLI)

1-Glycosyl derivatives of 5-azaindole have been obtained by the glycosylation of the chloromercury salt of 5-azaindole by acetylated bromosugars[141].

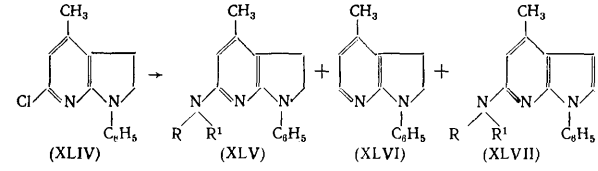
Direct glycosylation of 4-benzamido-5-azaindole (XLII) by 2,3,3-tri-*O*-benzoyl-*D*-ribofuranosyl bromide takes place at the nitrogen atom of the pyridine ring, subsequent debenzoylation yielding 4-amino-5-β-*D*-ribofuranosyl-5-azaindole (XLIII) [87,142]:

(XLII) (XLIII)

2. Electrophilic Substitution Reactions in the Series of Isomeric Azaindoles and Azaindolines

The influence of the π-electron-deficient pyridine ring is responsible for certain characteristic features in the behaviour of azaindole molecules under the conditions of the electrophilic substitution reaction in relation to indoles[1,2]. The earlier investigations of the Mannich, Vilsmeier, cyanomethylation, halogenation, and nitration reactions of 7-azaindoles have been extended during the last decade to 4-, 5-, and 6-azaindoles[26,62,71,133,134,143-148], which exhibited the same features as 7-azaindoles. It is of interest to note that 7-azagramine has been used as a model of a polymer oxidation inhibitor[149]. New literature data[145] disproved earlier conclusions[1,2,150] that 5-azaindole is incapable of undergoing electrophilic substitution reactions.

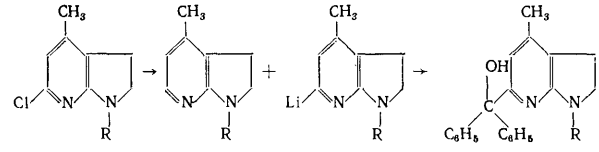
A quantitative study of the comparative reactivities in the electrophilic substitution reactions of isomeric azaindoles has been carried out in relation to the acid-catalysed deuterium exchange involving the 3-position[106].



Electrophilic substitution reactions of azaindolines have been studied in relation to 6-chloro-7-azaindolines[151,152], which, in contrast to 7-azaindolines, lacking a halogen atom in the α-position with respect to the pyridine nitrogen, are readily brominated, chlorinated, and nitrated with formation of 5-substituted 6-chloro-7-azaindolines. In the absence of an *N*-acyl protecting group, nitration yields the 1-nitro-isomer in addition to the 5-nitro-isomer.

3. Nucleophilic Substitution Reactions in the Series of Isomeric Azaindoles and Azaindolines

Nucleophilic substitution reactions of azaindole and azaindoline compounds are difficult[1,2]. Thus 4-methyl-7-azaindoline and its 1-phenyl derivative are not aminated under the conditions of the Chichibabin reaction[153]. The pyrrole ring in 1-phenyl-5-azaindole is opened under the influence of sodium amide and 4-phenylamino-3-vinylpyridine is formed. Nor was it possible to achieve the Chichibabin amination of 4-azaindole[153]. These results can be accounted for by the enhanced electron density, compared with pyridine, in the pyridine ring of azaindoles.

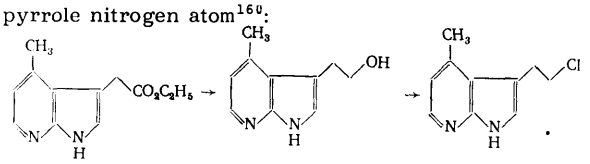


Substitution of the chlorine atom in the 6-position by hydrogen in derivatives of 7-azaindoline[63,66,71] and 5-azaindoline[67,70] as well as the chlorine atom in the 4-position in 5-azaindole[87] proceeds smoothly in the presence of a palladium catalyst. Nucleophilic substitution of chlorine by alkoxy-groups[67] by reaction with alkali metal alkoxides requires severe conditions. Even more severe conditions are necessary for the substitution of chlorine atoms in the pyridine component of the molecules of 5- and 7-azaindoles by nucleophiles such as primary or secondary amines[84,85,87,154-158]. A kinetic study of the nucleophilic substitution of chlorine in 4-chloro-1-methyl-5-azaindole by the piperidine residue revealed an autocatalytic effect[156].

In the reactions of primary and secondary amines with 6-chloro-4-methyl-1-phenyl-7-azaindolines (XLIV), which take place under severe conditions, the normal nucleophilic substitution process is accompanied by the reduction of the hitherto unreacted compound (XLIV) by the *N*-substituted 6-amino-4-methyl-1-phenyl-7-azaindole (XLV) formed to 4-methyl-1-phenyl-7-azaindoline (XLVI) with simultaneous oxidation of compound (XLV) to *N*-substituted 6-amino-4-methyl-1-phenyl-7-azaindole (XLVII) [154,155]:

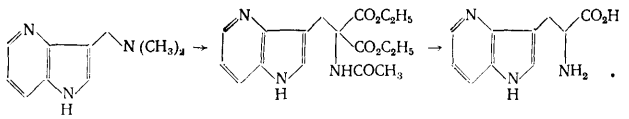
(XLIV) (XLV) (XLVI) (XLVII)

The interaction of 6-chloro-7-azaindolines with lithionaphthalene at temperatures between -35° and -40 °C in tetrahydrofuran followed by treatment with benzophenone yielded substituted 7-azaindoline-6-yldiphenylmethanols together with 6-unsubstituted 7-azaindolines[159]:



4. Transformations of Azaindole Compounds Associated with Reactions Involving the Carbon Side Chain

The characteristics of the distribution of electron density in azaindole systems do not interfere with a number of classical reactions involving their side chains. Thus 3-formyl-1-phenyl-7-azaindole has been reduced to the alcohol, the hydroxy-group of which is readily acetylated and substituted by chlorine; the latter can in its turn be substituted by various acyloxy-groups[146].

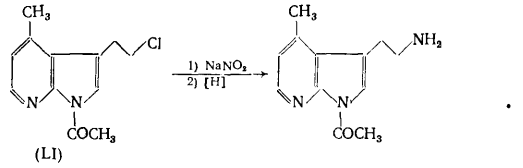


The reduction of the ethyl ester of 4-methyl-7-azaindole-3-acetic acid led to the synthesis of the alcohol (XLVIII), the hydroxy-group of which is also readily substituted by chlorine; the resulting compound is fairly readily acetylated at

the pyrrole nitrogen atom[160]:

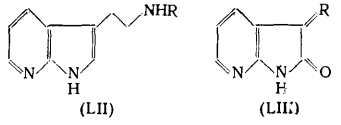
(XLVIII)

During the last decade considerable interest has been shown in azaindoles containing nitrogen in the side chain[39,41,42,144,147]. 4-Azatryptamine has been obtained by the reduction of 4-azaindole-3-acetamide and 4-azatryptophan (XLIX) has been synthesised[161] by the reaction of 4-azagramine (L) with acetamidomalonic ester followed by hydrolysis or partial decarboxylation:



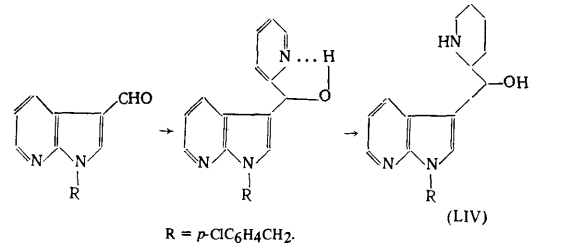
(L) (XLIX)

The method of synthesis of 3-aminoalkyl-7-azaindoles[1,2], consisting of the condensation of 3-formyl-7-azaindoles with nitroalkanes and subsequent reduction of the intermediates, has been developed further[71,143,147,162]. In particular, 7-azatryptamines, substituted at the pyrrole nitrogen atom by aliphatic or aliphatic-aromatic residues[71], have been synthesised by this procedure; 3-aminomethyl derivatives of 7-azaindole have been obtained by reducing the oximes of the corresponding 3-aldehydes[143,147].



It has been shown that the oxime of 6-chloro-3-formyl-4-methyl-7-azaindole consists of *syn*- and *anti*-isomers in the crystalline state[163], while the crystalline oxime of 3-formylindole exists as the *anti*-isomer.

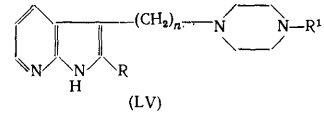
The synthesis of 1-acetyl-4-methyl-7-azatryptamine from 1-acetyl-3-(β-chloroethyl)-4-methyl-azaindole (LI), based on the substitution of a chlorine atom in the side chain by the nitro-group with subsequent reduction, has been investigated[160]. The interaction of compound (LI) with ammonia, potassium bis(dimethoxysilyl)amide, and potassium phthalimide (with subsequent removal of the phthalimide protecting group) involves the elimination of the *N*-acetyl group:



(LI)

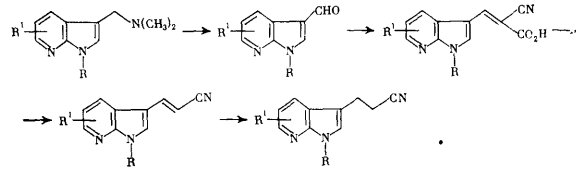
Derivatives (LII) of 7-azatryptamine substituted in the amino-group have been synthesised from 7-azatryptamine itself[164]. The interaction of 7-azaoxindole with nitrosoketones yielded the oximes (LIII, R = CCH_3CH = NOH or CC_6. .H_5CH = NOH), which were then reduced to 2-(7-azaoxindol-3-yl)propylamines (LIII, R = $CCH_3CH_2NH_2$) [164]:

(LII) (LIII)



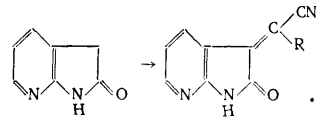
1-(*p*-Chlorobenzyl)-7-azaindol-3-yl-α-piperidinylmethanol (LIV) has been synthesised[133,134] by the interaction of 3-formyl-7-azaindole with 3-pyridyl-lithium and selective reduction of the product to a mixture of diastereoisomers:

(LIV)



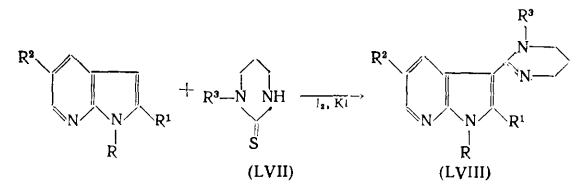
R = *p*-$ClC_6H_4CH_2$.

A large group of compounds of the type (LV, R = H or CH_3; n = 1–3; R^1 = alkyl, aryl, or heteroaryl) have been synthesised from 7-azaindole-3-ylalkanecarboxylic acids via the corresponding piperazides with reduction of the amide group by lithium tetrahydroaluminate[148,165]:



(LV)

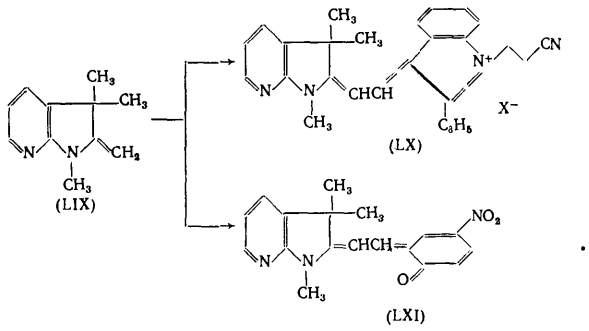
3-Cyanoethyl derivatives of 7-azaindoles have been obtained from 7-azagramines, which were converted into 3-formyl-7-azaindoles under the conditions of the Duff reaction (with urotropine in aqueous acetic acid solutions) and were then condensed with cyanoacetic acid. The subsequent decarboxylation of the substance and catalytic reduction of the double bond leads to the required products[131]:



3-[β-(2-Imidazoline-2-yl)ethyl]-7-azaindoles have been synthesised from 3-cyanoethyl-7-azaindoles[131].

On reaction with compounds of the type RCOCN (R = CH_3, C_2H_5, or C_6H_5), 7-azaoxindole is converted into acetonitriles (LVI) [164]:

(LVI)

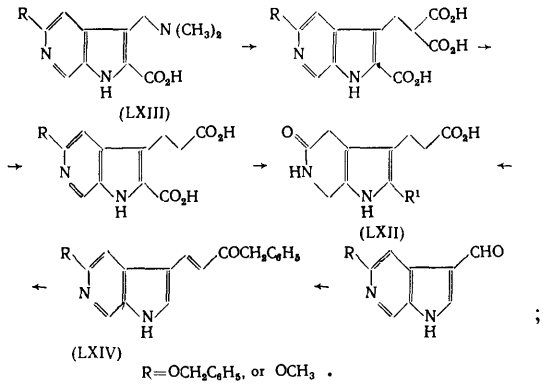


Compounds (LVIII), containing tetrahydropyrimidine residues in the 3-position in 7-azaindoles, have been obtained on condensing 7-azaindoles with tetrahydropyrimidinethione (LVII) in the presence of iodine[166,167]:

(LVII) (LVIII)

The interaction of 2,3-dihydro-1,3,3-trimethyl-2-methylene-7-azaindole (LIX) with 1-(2-cyanoethyl)-3-formyl-2-phenylindole leads to the cyanine (LX, X = *p*-$CH_3C_6H_4SO_3^-$ or

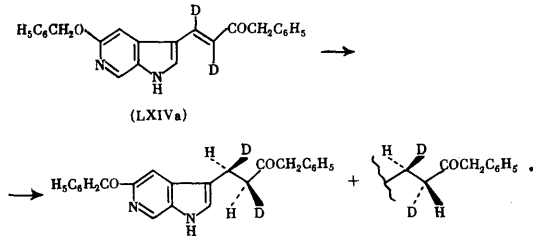
ClO_4^-) [168], while the reaction of compound (LIX) with nitrosalicylaldehyde makes it possible to obtain compound (LXI) [169]:



(LIX) (LX) (LXI)

Compounds of this type are of practical interest—as photosensitisers in colour photography[168-173].

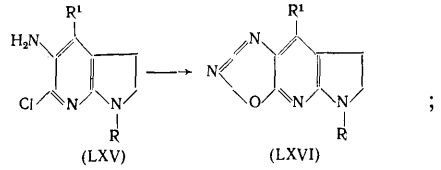
A number of compounds have been synthesised from 3-formyl-6-azaindole[169], in particular its oxime, as well as 3-cyano-, 3-methyl-, 3-aminomethyl-, and 3-dimethylamino-6-azaindoles.



The lactams of porphobilinogen-2-carboxylic acids (LXII, R^1 = COOH) have been synthesised via the Mannich bases (LXIII) [17,18], introduced into the malonic ester synthesis and then subjected to familiar transformations in accordance with the scheme

(LXIII) (LXII) (LXIV)

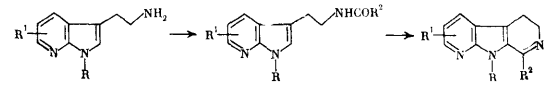
R=$OCH_2C_6H_5$, or OCH_3 .



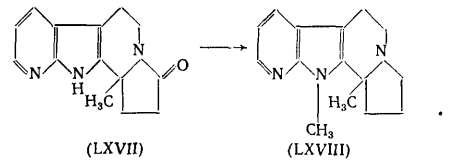
The reduction of the deuterated product (LXIVa) over a palladium catalyst gives rise to the racemate[19]. The separation of the optical isomers and their use in further synthesis yielded optically active lactams of porphobilinogens:

(LXIVa)

5. Synthesis of Condensed Heterocyclic Systems from 7-Azaindole Derivatives



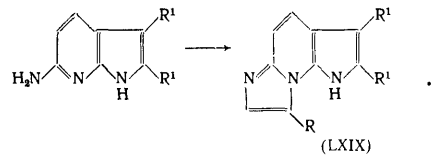
Derivatives of 7-azaindole have been used successfully in recent years to synthesise new more complex condensed systems. Thus the closure of the 1,2,3-oxadiazole ring has been achieved by the diazotisation of 5-amino-6-chloro-7-azaindoline (LXV) with formation of the 1,2,3-oxadiazolo[4,5-g]7-azaindoline system (LXVI) [151,174,175]:



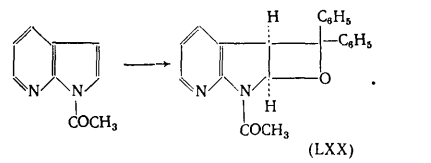
(LXV) (LXVI)

R and R^1 = H or alkyl.

The application of the Bischler–Napieralski and Pictet–Spengler reactions to 7-azatryptamines permitted the synthesis of derivatives of the new tricyclic system of 12-aza-β-carboline[176]:



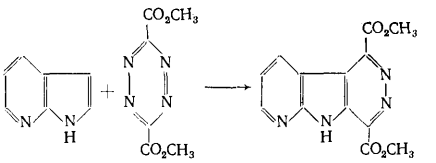
Cyclisation of 7-azatryptamine with laevulinic acid gave rise to the lactam (LXVII), which was converted into pyridopyrroloindolizine (LXVIII) by reduction and subsequent methylation[177,178]:



(LXVII) (LXVIII)

Derivatives of 1*H*-imidazo[1,2-*a*]pyrido[3,2-*e*]pyrrole (LXIX) have been obtained by condensing 6-amino-7-azaindoles with α-halogenocarbonyl compounds[179]:

(LXIX)



In contrast to furans and 2,3-dimethylthiophens, which interact with benzophenone under irradiation to form condensed oxetans, unsubstituted 7-azaindole, pyrrole, and imidazole do not react with benzophenone under these conditions[180]. This has been explained[180] by the quenching influence of the free electron pair of the pyrrole nitrogen atom on the excited ketone. Indeed, when a mixture of 1-acetyl-7-azaindole and benzophenone is irradiated, cycloaddition to the double bond of 7-azaindole and the formation of oxetano-7-azaindoline (LXX) in 4% yield are observed:

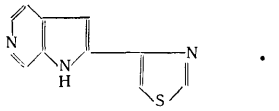
(LXX)

Condensed pyridazinoazaindoles (LXXI) have been obtained by the cycloaddition (of the type of the Diels–Alder reaction) of the tetrazine (LXXII) to the unsubstituted 7-azaindole, acting as the dienophile, with subsequent elimination of a

nitrogen molecule[181]:

(LXXII) (LXXI)

V. THE BIOLOGICAL PROPERTIES OF AZAINDOLE DERIVATIVES



The range of studies of the biological activity of azaindole derivatives has significantly expanded in recent years, although the main information still concerns 7-azaindoles.

The high and varied biological activities of a wide variety of azaindole derivatives have been reported in the patent literature. It has been established[182] that 2,3-dimethyl-5-azaindole and its 1-glucopyranoside suppress the growth of the tumour cells of sarcoma-37 to the extent of 60–67% in experiments *in vivo* and at the same time exhibit a low toxicity. In experiments on sea urchins 4-methyl-1-phenyl-7-azatryptophan exhibited a cytotoxic activity[183].

(7-Azaindol-3-yl)alkylpiperazines showed a considerable psychotropic and cardiovascular effect[148,165]. Antidepressant properties have been found in a series of derivatives of azaindoles and their analogues[132,184,185]; 7-methyl-7-azaindole[132], which blocks certain effects of reserpine in experiments on mice, proved to be most active. Tryptamine-like properties have been found in 3-amino-methyl-4-methyl-1-phenyl-7-azaindole[147,186]; when 3-hydroxymethyl-4-methyl-1-phenyl-7-azaindole is administered to various animal species both internally and parenterally, it induces a state resembling narcosis[146].

A series of 7-azaindole derivatives, particularly 7-azaindole-3-acetoxime, exhibit a hypotensive activity[166,167,187,188]. There have also been reports of the vasoconstrictor activity of imidazolinylalkyl-7-azaindoles[131], the anti-inflammatory activity of 4-aminophenyl-5-azaindoles[86,157], the gonadotropic effect of 7-azatryptophan[189], the antiserotonine activity of 4-methyl-1-phenyl-7-azatryptamine[190,191], etc.

Chemotherapeutic research on laboratory animals revealed an activity of the 4-,5-,6, and 7-aza-analogous of thiabendazole, for example compound (LXXIII), as well as 2-phenyl-5-azaindole and 2-phenyl-6-azaindole against trichostrongylids[44]:

(LXXIII)

It has been shown that 7-azatryptophan does not exhibit a significant inhibiting activity on the development of *Heterodera trifolii*[192], while 7-azaindole to a large extent suppresses the formation of *Meloidogyne javanica* galls[193] and inhibits the stimulating effect of indole-2-carboxylic acid on the multiplication of *Aphelenchoides ritzema-bozi*[194].

One of the diastereoisomers of (1-*p*-chlorobenzyl-7-azaindol-3-yl)-2-piperidinylmethanol proved to be an effective antimalerial agent[133,134]. A study of the antifungal activity of coal tar led to the isolation of 2-isopropyl- and 2-isobutyl-7-azaindoles as active components[195]. 7-Azaindole and its condensed systems have been detected in tobacco smoke and tobacco[196]. The antimicrobial properties of 2-alkyl- and 2-alkenyl-7-azaindoles have been the cause of the incorporation of these compounds in the composition of cosmetics for the skin[197].

Numerous studies have been devoted to the involvement of 7-aza-analogues of tryptophan and its metabolites in biochemical processes in the cell[198–216]. The bacteriological synthesis[217–219] of *L*-7-azatryptophan by a whole series of bacterial and fungal strains from 7-azaindole has been reported. The similarity of the biological activities of 7-azaindole-3-acetic acid and indole-3-acetic acid (heteroauxin) has been confirmed[220]. A number of studies on the interrelations of 7-azatryptophan with plant objects have been carried out[221–225].

During the preparation of this review for the press, new data on the syntheses of isomeric azaindoles were published; substituted 4-azaindoles have been obtained from isoxazolylpyrrole[226] and enaminonitriles[227], derivatives of 5-azaindole (of the type of 3,7-dididesazaxanthine) have been obtained from pyrrole-2,3-dicarboxylic acid esters[228] and 2,3-disubstituted 6-azaindoles have been synthesised by the reduction of (3-nitro-4-pyridyl)dicarbonyl compounds[229]. A series of studies[230–236], which throw light on the "anomalous" course of the Fischer reaction, observed in the formation of azaindoles and associated with the homolytic dissociation of the N–N bond in hydrazones, have been carried out.

Physicochemical investigations of azaindoles dealt with the spectroscopic characteristics of substances of this class[237–239], the phototautomerism of 7-azaindole and its derivatives[240–242], the kinetics of deuterium exchange[243] and the nitration of isomeric azaindoles[244], etc[245]. The π- and σ-electron densities of the carbon atoms of isomeric azaindoles have been calculated, the results being used to estimate their capacities for electrophilic substitution reactions[246].

New data have been published on the behaviour of azaindoles under the conditions of electrophilic[247,248] and nucleophilic[249,250] attack. Studies have been continued on the synthesis of *N*-glycosylated azaindoles[251], and a cobalt complex of 7-azaindole has been obtained[252]; a series of compounds containing azaindole fragments proved to be of interest for photography[253–257].

The publication of studies on the biochemical and chemotherapeutic activities of azaindole derivatives has been continued[228,258–265]. Certain derivatives of 7-azaindoles exhibited an antiulcer activity[266] and inhibited the secretion of the gastric juice and the growth of malignant neoplasms[267].

Structure and Properties of Networks in Heat-resistant Polymers

A.A.Askadskii and Yu.S.Kochergin

Methods are discussed for obtaining networks in heat-resistant polymers, including cross-linking at terminal groups, the use of reactive oligomers together with heat-resistant polymers capable of interacting with them, polycyclotrimerisation, etc. The influence of the chemical structure of the network and the frequency of branch points has been traced on the dynamic mechanical properties of the polymers and also on the stress relaxation and creep under static conditions. Network parameters and strength properties are compared, and methods of controlling the mechanical properties of network systems possessing enhanced heat-resistance are discussed. A list of 75 references is included.

I. INTRODUCTION

The preparation and properties of heat-resistant polymers based on network systems have been the object of persistent attention by research workers. This is due to the great difficulties often encountered in producing articles from linear heat-resistant polymers, as a consequence of the high temperatures and pressures in their processing by the usual methods (hot extrusion, injection moulding) necessitated by the high softening points and great viscosities of the systems. However, the initial compounds for the preparation of network systems (oligomers of aromatic structure, mixtures of linear thermostable polymers with reactive oligomers) can easily be converted into a plastic state, and the required materials obtained from them by heat-treatment or other methods.

Several processes are now available for obtaining network systems based on heat-resistant polymers: oligomers containing aromatic rings and reactive terminal groups can be cross-linked; heat-resistant linear polymers containing reactive groups in the chain can be mixed with reactive oligomers, and the mixture then heat-treated; and oligomers containing aromatic units between reactive groups can undergo cyclotrimerisation. The chemical structure of the chain segments between branch points, of course, has a substantial influence on the properties of the heat-resistant network system; formation of a supermolecular structure at different stages of network formation is also important.

A vast amount of research work, summarised in a monograph[1], has been devoted to traditional network systems. The present Review is concerned with the structure and properties of network heat-resistant polymers. Such systems have the characteristic methods of preparation enumerated above (which, however, have much in common with methods for obtaining traditional networks) and exhibit specific effects of network structure on polymer properties. In the case of networks constructured of flexible macromolecules forming the internodal segments heat-resistance can be enhanced only by substantial increase in the density of cross-linking. However, the polymer material then loses its valuable qualities: brittleness, cracking, etc. appear. A high degree of cross-linking is not necessary to obtain heat-resistant materials based on rigid macromolecules, for the chemical structure of the internodal segments then has the greatest influence on properties. Furthermore, a feature of networks based on aromatic compounds is their capacity of order, evident in signs of crystallinity at high degrees of conversion.

II. INFLUENCE OF CHEMICAL STRUCTURE ON MOLECULAR MOBILITY OF NETWORKS

Heat-resistant polymers are extremely interesting materials for the investigation of relaxation transitions, since they exist in a vitreous state over wide temperature ranges, within which many transitions can be detected. Completely aromatic polymers provide unique opportunities for the study of molecular motions, in particular those responsible for transition ranges and relaxation effects. In ordinary linear aromatic polymers relaxation processes arise from rotational movements of chain segments and also of various polar radicals. In completely aromatic polymers the rotational mobility of the molecules is considerably restricted by resonance and steric effects (e.g. barriers to rotation due to *ortho*-substitution), so that mobilities other than rotational must be expected.

Great attention has recently been paid to the study of relaxation transitions in heat-resistant polymers[2-13]. Fundamental research on transitions in heat-resistant aromatic polymers[2] has involved study of the relaxation properties of poly(phenylquinoxalines) over the wide temperature range from −200 to 500 °C. Far less study has been made of the dynamic mechanical properties of network systems based on heat-resistant polymers. Most heat-resistant aromatic polymers can be cross-linked simply by holding isothermally at high temperatures. The density of cross-linking and hence the dynamic mechanical characteristics can be varied within wide limits by controlling the time and/or temperature of cross-linking.

Investigation of the influence of the previous thermal history on the dynamic characteristics of polyquinoxaline and poly(phenylene oxide) films has shown[2,5] that heating in helium at 400 °C gradually displaces the temperature dependence of the modulus of elasticity E' to higher temperatures, and shorter times of heating in air yield similar results. This change in modulus is explained[2,5] by pyrolytic cross-linking during heating in an inert atmosphere, which in air is accompanied by oxidation.

Linear poly-(2,2'-*p*-phenylene-6,6'-bis-3-phenylquinoxaline) has been cross-linked[14] by isothermal heating at 425–490 °C, with the kinetics monitored by the variation in the glass point T_{gl}. The influence of the molecular mass and nature of terminal groups on dynamic properties was examined in three specimens differing only in these characteristics. The apparent activation energy of cross-linking is independent of them and has the same value (60 kcal mole^{-1}) as the activation energy of thermal breakdown of the polymer (which was determined from measurements of the isothermal weight losses). However, the rate of change of the glass point resulting from heating at these temperatures is a function of both molecular mass and type of terminal groups. It was also observed that the isothermally cross-linked polymer undergoes a sharp decrease in mass at a higher temperature than its linear analogue, and leaves a larger carbon residue at 800 °C.

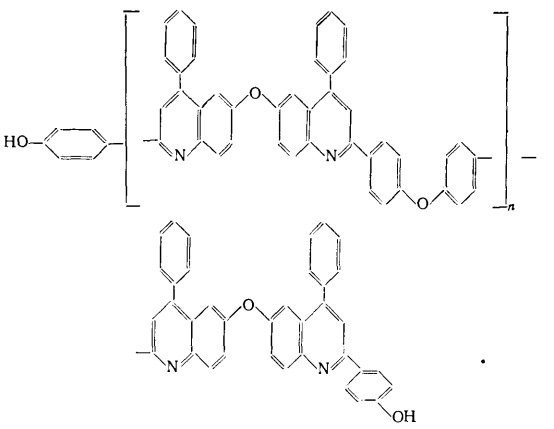
The same workers have investigated[15] the thermomechanical properties of poly(phenylimide-quinoxaline), which differs from the polyphenylenephenylquinoxaline only in the presence of an imide group in the chain. In the present case, unlike the former, no difference between rates of change of glass point is observed after specimens containing different terminal groups have been heated. Comparison of such rates in specimens of the two types of polymer showed that, despite the identical activation energies, formation of cross-links is far more intense in the polymeric imide derivatives. This implies an additional mechanism of formation of cross-links, probably involving opening of the imide ring.

The density of cross-linking can be varied also by introducing reactive side-groups. An investigation[16] of the mechanism of the hardening of linear poly(phenylenequinoxalines) containing and not containing such groups led to the conclusion that their presence promotes more rapid change in glass point. An accompanying kinetic examination of cross-linking in poly(phenylamide-quinoxalines) of high molecular mass showed that isothermal holding in nitrogen at temperatures from 380 to 420 °C produced an initial lowering of the glass point followed by a rise with increasing duration of heating. In some polymers of this type the fall in glass point during the initial stage of heating reached 16 deg. Such behaviour was attributed[16] to the superposition of two effects—random chain rupture and cross-linking—the former of which leads initially to a sharp decrease in mean molecular mass with a corresponding fall in glass point, whereas thermal cross-linking produces an almost linear rise in glass temperature. In polymers of low molecular mass random chain rupture has little effect on the glass point, change in which is due mainly to cross-linking. Therefore such polymers do not exhibit a minimum in the isothermal variation of glass point with time. It must be stressed that such minima have never been observed with poly (phenylenequinoxalines) or poly (phenylimide-quinoxalines), which possess greater resistance to chain rupture, so that cross-linking is dominant.

When isothermal heating is conducted above the glass point the time variation of the loss coefficient passes through a maximum. In all cases (heating below and above the glass point) an equilibrium state is established within a time depending on the hardening temperature. However, the resulting glass points do not remain the same, but rise significantly[16].

Comparison of the dynamic mechanical properties of hardened phenolic resins with those of poly(phenylenequinoxalines) showed[17] that not only the speed but also the absorption of sound is greater in the former, which is unexpected, since materials with a higher velocity of sound usually have lower absorption. It was therefore assumed[17] that some additional loss mechanism operates in phenolic resins. The absorption of sound depends significantly on the degree of hardening, and may serve for determination of the degree of cross-linking.

Oligo(phenylquinoxalines) containing vinyl terminal groups undergo thermal cross-linking far more readily than does the standard poly(phenylenequinoxaline) and form structures with a high frequency of cross-linking and high glass points[18]. On heat-treatment (in nitrogen at 350 °C) the glass point rises rapidly during the first 15 min, after which it remains almost unchanged.



Oligo(phenylquinoxalines) containing acetylenic terminal groups are also used to form network heat-resistant polymers[19,20]. The oligomers dissolve well in organic solvents and have comparatively low softening temperatures. When such systems are heated at 200–300 °C they undergo cross-linking owing to polymerisation of the acetylenic groups; the process of cross-linking is extremely complicated and takes place by various mechanisms. Analysis of the influence of temperature and duration of hardening of oligo(phenylquinoxalines) on their properties must take into account the sharp rise in glass point on hardening, which slows down cross-linking. Thermogravimetric and mass-spectrometric examination of hardening of the oligomers and degradation of the hardened systems has shown[20] no evolution of volatile components in the temperature range of hardening (200–300 °C), and vacuum degradation beginning at 465 °C.

The cross-linking of poly(phenylene sulphide) when heated is assumed[21] to be accompanied by oligomerisation with increase in chain length. In air cross-linking is thought to be effected by oxygen bridges, but in an inert atmosphere through benzene rings and sulphide bridges. The cross-linking of poly(phenylene sulphide) by sulphur leads to a decrease in thermal stability, although the heat-resistance increases[22].

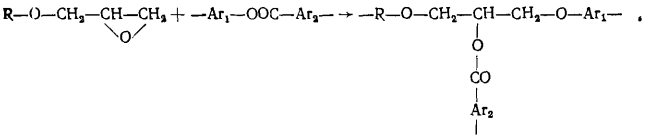
Several studies have been made[23–26] on the properties of thermostable polymers already cross-linked in course of preparation. Biphenylene units introduced into the macromolecular chain have been used[23] as hardening agents for polyquinolines. Cross-linking takes place without evolution of volatile products, but the resulting compounds possess enhanced heat-resistance. Hardening can be effected either thermally or in the presence of a rhodium catalyst, which appreciably lowers the temperature of cross-linking. Cross-linked poly(phenylquinoxalines) have been obtained[24] by introducing trisbenzyl into the reaction mixture. They have been used in the production of multicomponent materials containing graphite fibres.

Cross-linked polymers have been obtained[25] by the polycondensation of tetracarboxylic dianhydrides with polyfunctional amines. Under thermomechanical constraint these polymers behave similarly to other cross-linked systems that exhibit a rise in glass point with increase in concentration of the cross-linking agent.

Cross-linked polyphenylenes and poly(phenylquinolines) have been obtained[26] by the cyclotrimerisation of aryl cyanates. An example of the former is the condensation of di-*p*-acetylphenyl ether with di-*p*-amino-*m*-benzoylphenyl ether and *p*-hydroxyacetophenone to give the structure This prepolymer containing terminal hydroxyls was treated with excess of cyanogen bromide to convert it into the aromatic dicyanate, which was then transformed by heat-treatment into a cross-linked product. The temperature required for cross-linking rises with increase in the length of the segment between the cyanato-groups. Cross-linking raises significantly the glass point of the polymer (in relation to those of the prepolymers), although leaving it lower than for linear analogues (e.g. polyphenylene).

(I)

However, chemical cross-linking in heat-resistant polymers, which can be effected at relatively low temperatures (200–300 °C), yields materials having lower glass points (and hence lower operating temperatures) than have materials that have been thermally cross-linked at high temperatures[23, 24, 26]. Even with 100% content [sic] of cross-linking agent the materials exhibit thermoplasticity[24], but this is eliminated by additional heating at high temperatures (482–510 °C). Similar results have been obtained by the high-temperature afterhardening of compositions with lower contents (30–60%) of cross-linking agent.



Calculated and experimental glass points for poly(phenylquinoxaline) have been compared[27, 28]. Formation of cross-links in this polymer by heat-treatment raises the glass point by 50–80 deg.

Investigation of the dynamic mechanical properties of polyamides has shown[29] that formation of a polymer network by irradiation[30] or chemical reaction[31] diminishes the mobility of the amorphous regions. As a consequence there is a loss of mechanical properties due to large amounts of the α-form. The glass transition of the polyamide is displaced to higher temperatures. The influence of density of cross-linking on local and segmental mobility of networks has been discussed in detail in the monograph[1].

The effect of isothermal heat-treatment of a polyimide on its dynamic mechanical properties has been studied[32, 33]. Heating at 500 °C raises the glass point from 350 to ~500 °C, whereas the relaxation transition in the vitreous state (with a maximum at ~150 °C) actually remains unchanged after heat-treatment. This suggests that here the density of cross-linking is sufficient to have an appreciable influence on the motion of the large chain segments involved in the glass transition but insufficient to affect the small-scale movements responsible for relaxation in the vitreous state.

An important achievement of the dynamic mechanical method for investigating relaxation transitions is to permit study not only of the properties of the final reaction products but also of the variation in such properties during the actual reaction. Recently several workers[34–39] have used measurements of dynamic mechanical properties to study the kinetics of hardening. Usually the phenomenon is investigated by estimating the degree of conversion of reactive groups by chemical analysis, infrared spectroscopy, or calorimetry. However, the sensitivity of these methods drops abruptly in the final stages of hardening (at high degrees of conversion) that generally are largely responsible for the optimum properties of cross-linked polymers.

The dynamic mechanical method has been used[39] to investigate the kinetics of the hardening of epoxy-polymers of heat-resistant aromatic systems. Such hardening is due to reaction of the epoxy-rings with ester links[40]. When a polyarylate serves as chemically active heat-resistant polymer, for example, its reaction with an epoxy-oligomer can be represented[41]:

The temperature at which reaction begins and the rate are significantly influenced by the chemical structure both of the epoxy-polymer and of the polyester. Reaction takes place also in the hardening of compositions containing traditional hardeners together with polyesters. The result is a polymer network possessing several interesting mechanical properties, as will be shown below.

A study has been made[39] of the influence of the composition of polymer networks on the temperature dependence of the modulus of eleasticity E' and tan δ. Fig. 1*a* illustrates the measured temperature dependence for a composition based on the polyarylate F-2 (a polyester of terephthalic acid and phenolphthalein)[42] and the cycloaliphatic epoxy-resin UP-612 (epoxide number 26–28) and containing various quantities of the hardener UP-607 (a polyanhydride of sebacic acid). Increase in the hardener concentration is accompanied by increase in the maximum values of tan δ, but a fall in the glass point, evidence of the plasticising effect of the aliphatic hardener. A sharp rise in tan δ, corresponding to softening of the system as a whole, occurs with all compositions in a similar temperature range. Fig. 1*a* shows also that introducing a larger quantity of hardener leads to formation of a more elastic network with a smaller modulus of elasticity. In order to assess the effect of the concentration of the epoxy-polymer on the temperature dependences, various quantities of UP-612 were introduced into a composition containing 50 parts by weight of UP-607 per 100 of F-2. Fig. 1*b* shows that tan δ_{max} increases with the concentration of the epoxy-polymer and that the corresponding temperature T_{max} rises. The slight increase can be attributed to the accompanying decrease in the proportion of the plasticising low-molecular hardener.

A characteristic feature of a polymer network formed by reaction between a polyarylate and an epoxy-polymer is a well defined difference in rigidity between cross-linked chains (polyarylate) and cross-linking bridges (epoxy-polymer). The network itself can be constructed in several ways—by formation of (i) an ordinary three-component network, (ii) so called interpenetrating networks as a consequence of the difference in reactivity between two macromolecular hardeners, and (iii) an intermediate system by partial interpenetration of networks accompanied by formation of chemical branch points—of which process (iii) is the most interesting. Interpenetrating networks form a complicated system[43–47] comprising two or more three-dimensional network polymers, not combined chemically but inseparable owing to the mechanical intertwining of chains consequent on the conditions of preparation. In the opinion of some workers[45] such systems must be regarded as a particular case of graft copolymers, in which the number of cross-links between macromolecules of each component far exceeds the number of grafts of one component on the other.

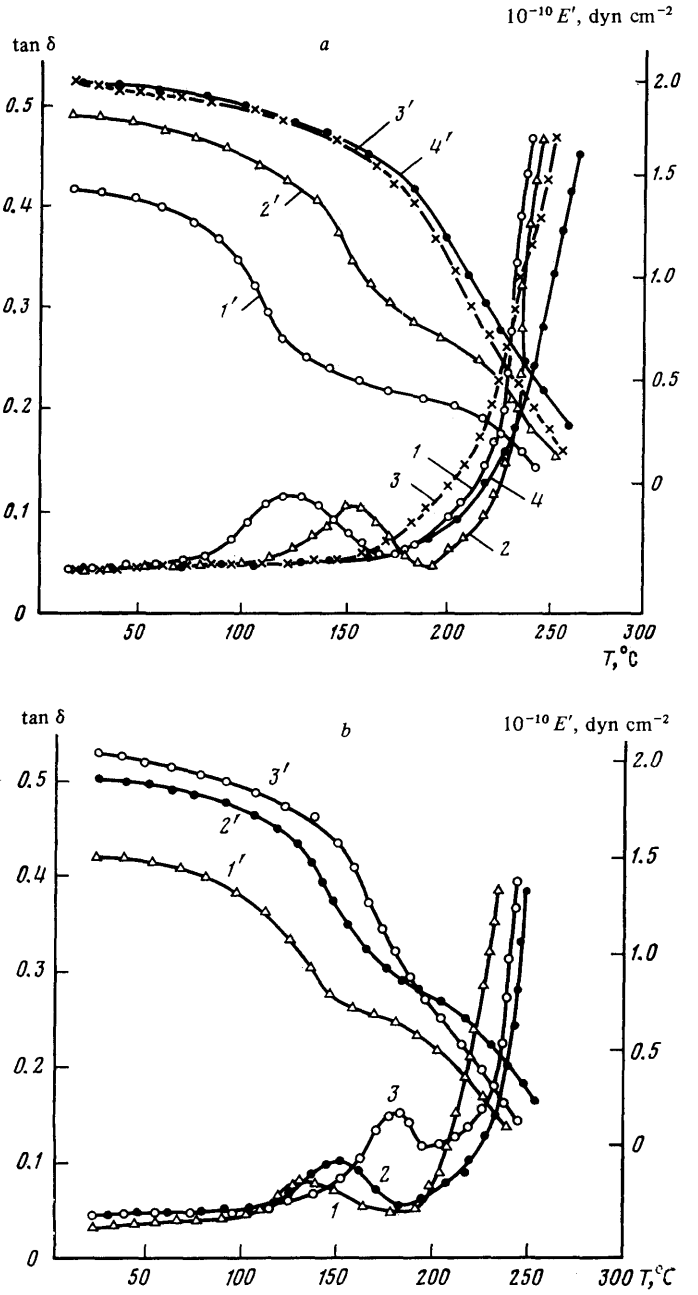


Figure 1. Temperature dependence of tan δ (unprimed curves) and E' (primed) for materials based on (parts by weight) 100 F-2: (*a*) with 100 UP-612 and different quantities of UP-607 hardener: 1,1′) 100; 2,2′) 50; 3,3′) 25; 4,4′) 0; (*b*) with 50 UP-607 and various quantities of UP-612: 1,1′) 50; 2,2′) 100; 3,3′) 150.

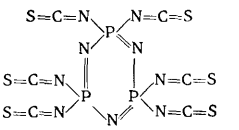
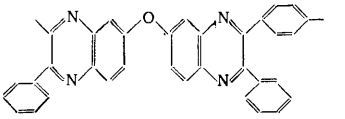


The synthesis of interpenetrating networks represents a new method for controlling the size and structure of different phase regions by varying the degree of cross-linking. Whereas many mechanical mixtures of polymers exhibit a tendency to form large (1–10 μm) phase regions, interpenetrating networks give a more uniform phase structure with smaller inhomogeneities. When the phase regions are very small (~100 Å), the classic concept of a sharp boundary separating two phases is inapplicable. A composite material having regions of ~100 Å is non-classical and varies continuously from point to point. In this case every local volume element makes its contribution to the glass point according to its composition and structure.

Materials comprising normally incompatible polymers forced into a single network possess a fairly broad region of high damping, which may cover the temperature range between the glass points of the individual components. Several vibration-absorbing materials having a wide (and controllable) useful temperature range for the damping of vibrations have been obtained[48–51] by preparing special compositions of interpenetrating networks, but they cannot be applied above ~100 °C. The temperature range of effective damping can be extended by the use of heat-resistant systems. In particular, a high-temperature vibration-absorbing material, exhibiting great absorption of mechanical energy over the range 160–220 °C, has been developed from networks of a polyarylate and epoxy-polymers[52,53].



III. DYNAMIC MECHANICAL INVESTIGATION OF CHEMICAL CROSS-LINKING PROCESSES

Since hardening is a chemical reaction accompanied by conformational rearrangements of the polymer molecules, the dynamic mechanical method might be used to investigate not only the kinetics of hardening but also any solid-phase reaction in general. In this case, too, highly heat-resistant polymers provide unique opportunities for research. Indeed, owing to the degeneration of the relaxation transitions that are due to rotational mobility, and because of the high softening temperatures, heat-resistant polymers may have wide temperature ranges within which their intrinsic relaxation does not develop. This enables them to be used as matrices for the investigation of chemical changes in reactive substances introduced into them.

Chemical reactions of the relatively simple compound—hexaisothiocyanatocyclotriphosphazene

have been investigated[39] in a matrix of the poly(phenylquinoxaline)

Diffractograms obtained for the initial hexaisothiocyanate powder and for a film of the polymer modified with the former show that the crystalline hexaisothiocyanate undergoes complete amorphisation on introduction into the poly (phenylquinoxaline) matrix, which indicates excellent compatibility of the two compounds.

Application of the dynamic mechanical method to films containing different quantities of the hexaisothiocyanate shows (Fig.2) a sharp increase in tan δ with rise in temperature, to reach a maximum at ~150 °C. Such behaviour of the films on heating is due to softening of the system followed by chemical formation of a network by polymerisation

of the hexaisothiocyanate. A higher content of the latter corresponds, of course, to a more intense maximum in tan δ observed at the given temperature. With decrease in the hexaisothiocyanate content the maximum gradually degenerates, and is not observed at all for the initial poly (phenylquinoxaline).

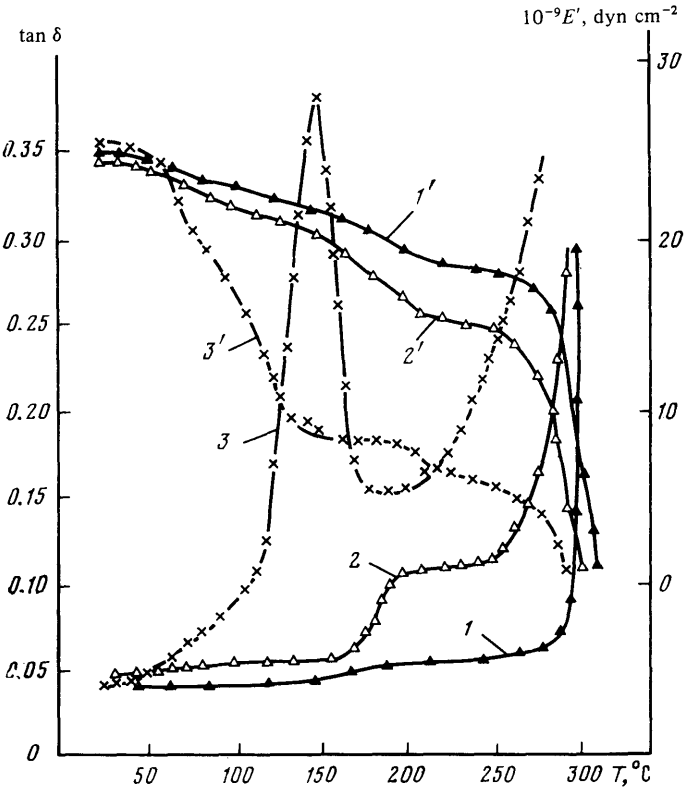


Figure 2. Temperature dependence of tan δ (unprimed curves) and E' (primed) for films obtained from mixtures of 100 parts by weight of poly(phenylquinoxaline) with different quantities of hexaisothiocyanatocyclotriphosphazene: 1,1') 1; 2,2') 10; 3,3') 50.

The characteristic temperature dependence of tan δ suggests[54] that by the dynamic mechanical method it is comparatively easy to study chemical processes occurring in the solid phase on heating: the sharp increase corresponds to the temperature range in which chemical reaction takes place; and the temperatures at which reaction begins, has its maximum rate, and in effect terminates can easily be determined (from respectively the start of the rise in tan δ, its maximum value, and the end of its decrease). The modulus of elasticity falls fairly sharply (which is to be expected of a system with great molecular mobility) in the temperature range in which the hexaisothiocyanate softens and formation of a network is only beginning. After reaction has proceeded sufficiently on heating to temperatures above that of maximum tan δ, the decrease in modulus of elasticity slows down. In this respect these systems differ in behaviour fundamentally from the usual linear and network polymers, which when heated pass from the solid (vitreous or crystalline) state to a hyperelastic or plastic state. In this case, too, a maximum is observed in the temperature dependence of tan δ, but the modulus of elasticity falls by a few orders of magnitude.

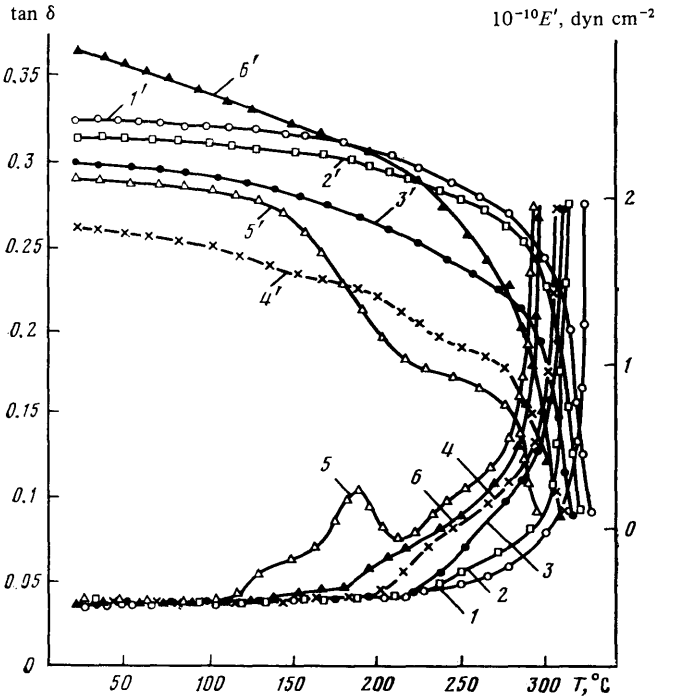

Figure 3. Temperature dependence of tan δ (unprimed curves) and E' (primed) for films, preheated at 180 °C for 30 h, of 100 parts by weight of poly(phenylquinoxaline) with different quantities of hexaisothiocyanatocyclotriphosphazene: 1,1') 1; 2,2') 10; 3,3') 25; 4,4') 50; 5,5') 100; 6,6') 100 additionally preheated at 280 °C for 4 h.

The dynamic mechanical results have been confirmed[54] by direct infrared-spectroscopic monitoring of the polymerisation of hexaisothiocyanatocyclotriphosphazene in a film of the poly(phenylquinoxaline). The variation in the characteristic absorption bands indicated both polymerisation of the hexaisothiocyanate with ring cleavage and reaction of isothiocyanato-groups with terminal amino-groups in the poly (phenylquinoxaline) to form thiourea links. The result is cross-linking of the polymer with a loss in solubility and a change in physicomechanical properties. This appears entirely probable, since ordinary poly(phenylquinoxalines) obtained from stoichiometric proportions of the reactants usually contain terminal amino-groups[55]. The hexaisothiocyanate is distinguished by great reactivity and readily interacts with compounds containing active hydrogen (amines, alcohols)[56].

Comparison of the results of infrared and thermomechanical spectroscopy on specimens that have been heated to different temperatures shows that heating lowers tan δ_{max} and shifts it slightly to higher temperatures. Heating at a relatively low temperature (120 °C) leads to some diminution in tan δ_{max}

in comparison with the initial specimen, but even when the temperature is raised only slightly (to 130–150 °C) the value decreases significantly, and at higher temperatures the maximum degnerates completely[54]. All this is consistent with the infrared results, and indicates a vigorous irreversible chemical reaction occurring in the range 140–160 °C. With rise in the temperature of preheating the sharp increase in tan δ following the maximum, which corresponds to softening of the specimens as a whole, takes place at increasingly high temperatures. This is evidence of the formation of a single network on opening of the phosphazotrien ring and interaction with the poly(phenylquinoxaline.)

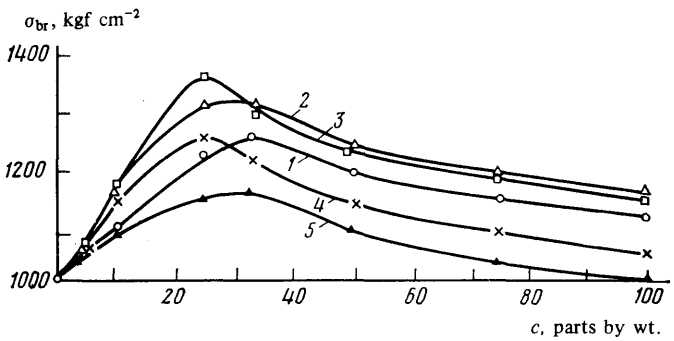

Figure 4. Effect of content c (parts by weight) of UP-612 on breaking strength σ_{br} of compositions, preheated at 200 °C for 20 h, of 100 F-2 with different quantities of UP-607: 1) 0; 2) 5; 3) 10; 4) 20; 5) 30.

Investigation of the effect of the hexaisothiocyanate concentration on the temperature dependence of tan δ for films heated at 180 °C for 30 h has shown (Fig.3) that, under otherwise similar conditions, the completeness of network formation depends on the quantity of hexaisothiocyanate added. When the latter is large (100 parts by weight) a well defined maximum is observed in tan δ with a peak at 180 °C; when the content is lowered (to 50 and below) the maximum degenerates almost completely, and the sharp rise in the temperature dependence occurs at ever higher temperatures. The presence of a clear maximum at 100 parts by weight indicates that under the above conditions (180 °C for 30 h) network formation is incomplete. Further heating of the specimen at 280 °C for 4 h results in complete disappearance of the maximum (Fig.3, curve *6*). This again confirms that the dynamic mechanical method permits the study even of extremely delicate chemical changes in the solid phase and reliable assessment of their completeness.

IV. STRENGTH PROPERTIES OF NETWORKS

Here we consider the changes in the strength and deformation properties of heat-resistant polymers accompanying formation of network systems and the influence of composition on the mechanical properties. It has been shown above that a network system can be obtained from an epoxy-polymer by the simultaneous introduction into the resin of a chemically active heat-resistant polymer of high molecular weight and traditional hardeners such as a polyanhydride of sebacic acid (UP-607) and tetrahydromethylphthalic anhydride. As a consequence of the presence of excess of the reactive polymer the portion thereof not involved in network formation remains as a free powder and serves as a filler. Such a chemically active macromolecular filler lowers significantly the specific gravity of the material, and produces sharp increases in thermal shock resistance and mechanical indices relative to a material containing an ordinary mineral filler[57]. Several compositions[58–61] have a density of 1.1 g cm^{-3}.

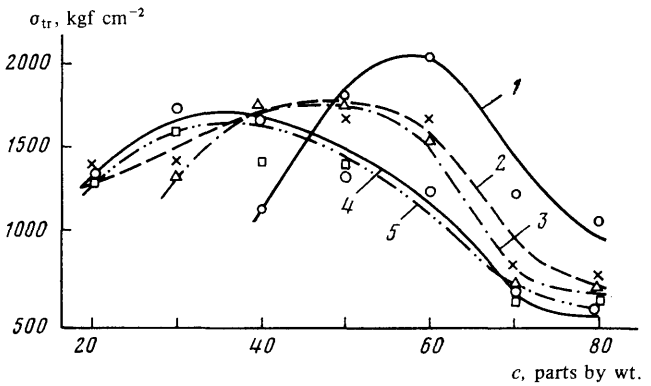

Figure 5. Dependence of transverse strength σ_{tr} on content c of UP-607 hardener for different contents of F-2 polyarylate: 1) 10; 2) 20; 3) 30; 4) 40; 5) 50.

Fig.4 shows the dependence[39] of the breaking stress σ_{br} of F-2 polyarylate network compositions containing various quantities of UP-607 hardener on the content of UP-612 polymer. All the curves pass through a maximum at a content of 25–33 parts by weight of the epoxy-polymer per 100 of the polyarylate. If the strenght of the polyarylate is 1020 kg cm^{-2}, the introduction of 33 parts by weight of UP-612 increases the breaking strength to 1260 kg cm^{-2} (curve *1*). Addition of a small quantity of the hardener (5–10 per 100 parts by weight of UP-612) produces a further improvement in strength properties (curves *2* and *3*). When the hardener content is increased to 20 parts by weight and above, the strength properties of the materials deteriorate (curves *4* and *5*). These compositions exhibit maximum specific elastic modulus at a UP-607 content of 40–60 parts by weight. Fig. 5 illustrates the variation in the transverse strength σ_{tr} for monolithic specimens of the same compositions[58]. The dependence of this property on the UP-607 content with various contents of F-2 polyarylate also passes through a maximum, at approximately 50% of UP-607.

It is noteworthy that the strength characteristics of the network systems exceed those of the polyarylate over very wide ranges of contents both of UP-607 and of F-2 polyarylate; this permits wide variation in the composition of the systems to obtain materials with other optimum mechanical properites, without fear of lowering the tensile strength[39,58]. In contrast to the above variation in breaking and transverse strengths, the compressive strength σ_c and the modulus of elasticity E' usually decrease monotonically with increase in the content of UP-607 hardener (Fig.6). Compositions containing a minimum quantity of UP-607 exhibit the highest values of these two properties, which is fully explicable,

since network formation by cross-linking with a more rigid system (F-2 polyarylate) will produce more rigid networks possessing a higher modulus of elasticity and greater static compressive strength. Introduction of a larger quantity of a flexible-chain oligomeric hardener will yield a more elastic network with a smaller modulus of elasticity and lower compressive strength. On the whole the mechanical properties on compression of networks based on heat-resistant polymers are quite high (Fig.6).

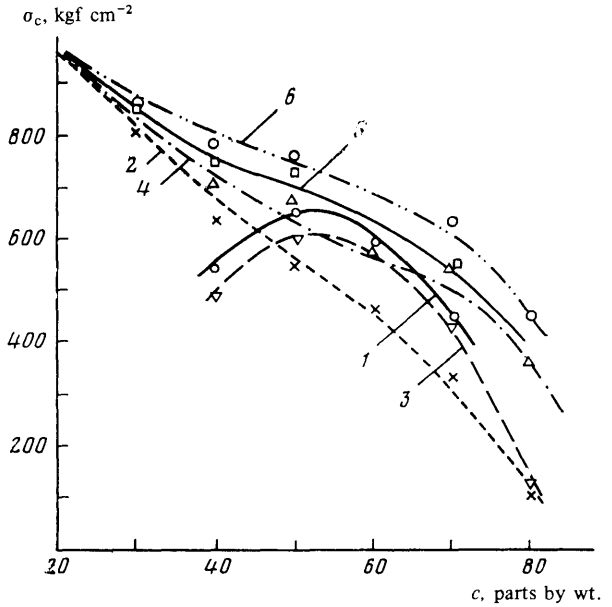

Figure 6. Dependence of compressive strength σ_c on content c of UP-607 hardener for different contents of F-2 polyarylate: 1) 10; 2) 20; 3) 0; 4) 30; 5) 40; 6) 50.

Data on mechanical properties have been obtained for other compostions based on UP-612 cycloaliphatic epoxy-polymer with UP-607 and tetrahydromethylphthalic anhydride as traditional hardeners and F-2 polyarylate, a polyimide of benzophenonetetracarboxylic acid and anilinephthalein, or an aromatic polyamide of terephthalic acid and anilinefluorene as chemically active macromolecular hardener–filler[61]. The results are essentially similar to those illustrated in Figs.5 and 6. Thus the introduction into compositions based on epoxy-polymers of chemically active aromatic polymers of high molecular weight, which act both as hardeners and as fillers, yields strong and light materials, capable of functioning over wide ranges of temperature and mechanical loadings.

Interesting results have been obtained[39] for the strength and deformation properties of a poly(phenylquinoxaline) alone and modified with a small quantity (20 parts by weight) of hexaisothiocyanatocyclotriphosphazene. Fig.7 shows that at low temperatures the modified polymer is slightly the stronger, but with rise in temperature loses strength more rapidly. At 150 °C, however, the decrease in breaking strength ceases owing to network formation, and at high temperatures (when this can be completed within the duration of the experiment) there may even be some increase in strength, with the modified specimen becoming stronger than the unmodified. At comparatively low temperatures the former breaks down at smaller deformations, but with rise in temperature to 220–230 °C the pattern reverses abruptly: at high temperatures the modified poly(phenylquinoxaline) exhibits extremely large (up to 200%) elongations at rupture, which is not usually characteristic of heat-resistant polymers. Hence the modification of poly(phenylquinoxaline) by the addition of a small quantity of hexaisothiocyanatocyclotriphosphazene tends to improve the deformability of the system at high temperatures.

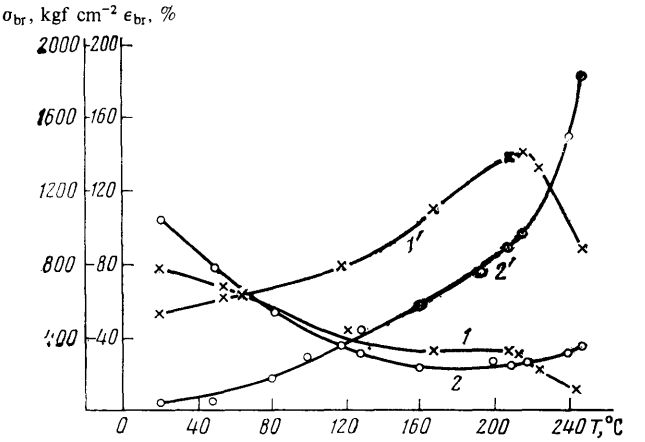

Figure 7. Effect of modification with hexaisothiocyanatocyclotriphosphazene temperature dependence of breaking strength σ_{br} and elongation at break ε_{br} for poly(phenylquinoxaline): 1) unmodified σ_{br}; 1') unmodified ε_{br}; 2) modified σ_{br}; 2') modified ε_{br}.

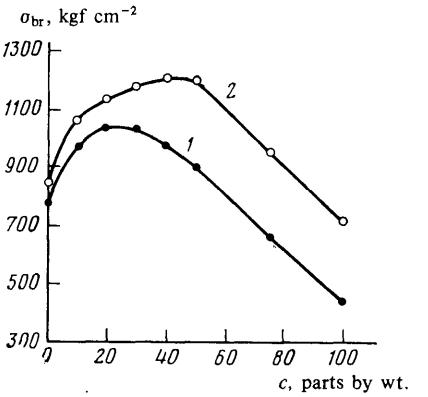

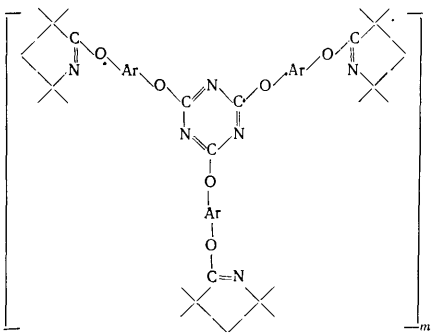

Figure 8. Dependence of breaking strength σ_{br} on content c of hexaisothiocyanatocyclotriphosphazene in modified poly(phenylquinoxaline) films: 1) initial; 2) after heating.

An increase in strength is produced[39] also by heating at 150 °C for 2 h poly(phenylquinoxaline) films modified with different quantities of hexaisothiocyanatocyclotriphosphazene (Fig.8). As already noted, this is due to the polymerisation of the hexaisothiocyanate occurring under these conditions, with formation of a network system. With such heat-treatment the strength of the initial poly(phenylquinoxaline) changes little (from 780 to 830 kg cm^{-2}), but an appreciable increase in breaking strength (to 1200 kg cm^{-2}) is produced at a higher temperature (280 °C for 10 h). The probable cause is formation of a network system by thermal cross-linking of the polymer molecules, but this is accompanied by a sharp decrease in deformability.

An interesting recent development in heat-resistant systems is investigation of the preparation and properties of networks formed by the polycyclotrimerisation of various arylene dicyanates[62,63] to give network aromatic polycyanates having the structure

This process is characterised by great selectivity and a quantitative yield of a highly cross-linked polycyanate. Hence the resulting network is very regular, and monolithic specimens are distinguished by improved properties in comparison with ordinary network polymers.

It is of interest to examine in greater detail the influence of the chemical structure of the initial dicyanic esters on the properties of the network polycyanates[64]. In the case of dinuclear aromatic dicyanates the nature of substituents attached to the central carbon atom has a significant effect on the properties of the networks. Table 1 shows the structure of the initial esters together with several parameters for the corresponding polycyanates. Since mechanical and other properties depdend also on the crystallinity of the specimens, Table 1 includes appropriate characteristics.

The first striking fact is that polymers of dicyanates containing identical small substituents attached to the central carbon atom (I–III in Table 1) have abnormally high resilience (23–25 kgf cm cm^{-2}). However, the presence of identical aromatic substituents attached to this atom (IV–VI), and also large planar groups (VII–IX), produces an appreciable diminution in resilience for moulded specimens of the polycyanates. In the latter cases, however, the transverse strength of the polycyanates is increased appreciably.

In the absence of a bonding sp^3 carbon atom between the benzene rings, as in the polycyanate (XII) from *pp'*-biphenylylene dicyanate, the resulting material has comparatively low specific resilience (6 kgf cm cm^{-2}). Diminishing the distance between branch points to single phenylene groups (polycyanates from *m*- and *p*-phenylene dicyanates) again produces a considerable improvement in resilience and transverse strength.

X-Ray examination indicates that most of the polycyanates obtained are amorphous polymers. In several cases, however, when identical small substituents (hydrogen, methyl) are attached to the central carbon atom, and also in polycyanates formed from dicyanic esters of resorcinol, quinol, and biphenyl-*pp'*-diol, slightly and moderately ordered structures are formed. Thus the presence of a rigid three-dimensional network in these polymers is not an obstacle to the appearance of ordered structures. A slightly ordered crystalline structure is observed also in the polycyanate from 10,10-diphenylanthr-9-one *pp'*-dicyanate, which contains large planar groups attached to the central carbon atom.

V. RELAXATION PROPERTIES OF NETWORKS UNDER CONDITIONS OF STATIC CONSTRAINT (STRESS RELAXATION AND CREEP)

Investigation of stress relaxation in heat-resistant aromatic polymers under both isothermal and non-isothermal conditions and study of the mechanical applicability of the systems under conditions of stress relaxation over wide ranges of temperature and deformation have been conducted for a relatively long time and have been quite widely discussed[65–68]. In the present Review, therefore, attention will be concentrated mainly on the most recent studies of static relaxation properties.

A detailed investigation of the relaxation properties of networks based on epoxy-oligomers and heat-resistant aromatic polymers[58–60] has enabled the influence of the chemical structure of the network on the heat-resistance to be identified and the boundaries of possible application of the materials to be determined. Both binary systems (epoxy-resin–aromatic polymer) and ternary systems (with addition of a hardener) have been studied. Relaxation properties have been examined under non-isothermal conditions with uniaxial compression by a method[68,69] permitting determination of the ranges of stress and temperature within which the polymer retains distinct hardness and can function as a structural material. The boundary of the operable region is drawn through the maxima of relaxation curves obtained with a linear temperature rise at a specified rate for compressed specimens whose deformation remains constant during an experiment.

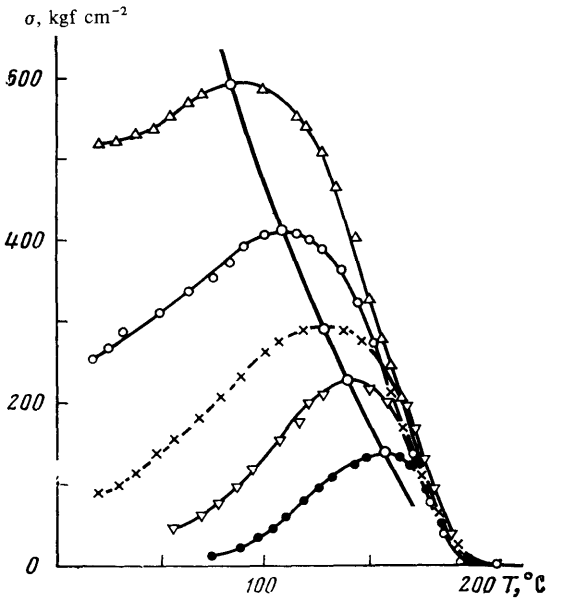

Figure 9. Region of applicability of composition containing (parts by weight) 100 UP-612 + 60 F-2.

Hardening an epoxy-oligomer with a chemically active aromatic polymer leads to a significant broadening of the region of mechanical applicability, with respect both to stress and especially to temperature. For example, the solid material formed by reaction between an epoxide and a polyarylate possesses far greater heat-resistance than do the usual hardened epoxy-resins. Such a material can be used at significantly higher temperatures than can an ordinary composition hardened with a traditional hardener.

A similar result has been obtained[58] for binary compositions containing UP-612 cycloaliphatic resin and F-2 polyarylate. The composition for which results are illustrated in Fig. 9 possesses the largest range of application, with respect to both temperature and stress, among all the solid compositions studied.

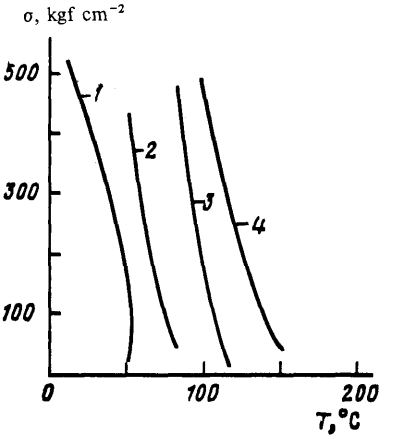

Figure 10. Curves bounding regions of applicability of various compositions (parts by weight): 1) 100 Ed-16 + 60 UP-607; 2) 100 ED-16 + 40 F-2; 3) 100 Ed-16 + 50 F-2; 4) 100 ED-16 + 60 F-2.

In order to trace the effect of the quantity of polyarylate on heat-resistance curves bounding the region of applicability have been obtained for a composition based on ED-16 epoxy-resin hardened with a polyanhydride of sebacic acid. With increase in the quantity of polyarylate these curves (Fig. 10) are regularly displaced to higher temperatures, and are situated substantially to the right of the curve for an ordinary solid composition. Thus introduction of a polyarylate into an epoxy-resin increases the heat-resistance of the composition, which may function at higher temperatures under greater loads.

As has already been noted, the introduction of a heat-resistant aromatic polymer into an epoxy-resin with the aim of obtaining a network does not prevent simultaneous use of a traditional hardener. Networks formed by the interaction of three components have special features. As example Fig. 11 shows the region of applicability of a solid composition comprising a polyarylate, ED-16 epoxy-oligomer, and a polyanhydride of sebacic acid as the traditional hardener. Introduction of a polyarylate into a ternary composition appears to give two regions of applicability, characterised respectively by (i) comparatively low temperatures and high stresses and (ii) high temperatures and low stresses. The region corresponding to high stresses remains approximately the same whether or not the heat-resistant polymer (polyarylate) is present: there is merely a slight

rise in the temperature limits. However, in the presence of the polyarylate the composition based on the epoxy-resin can withstand at high temperatures far larger loads than can the usual compositions. The height of the "loop" (i.e. the stress) then increases with the quantity of polyarylate added[58].

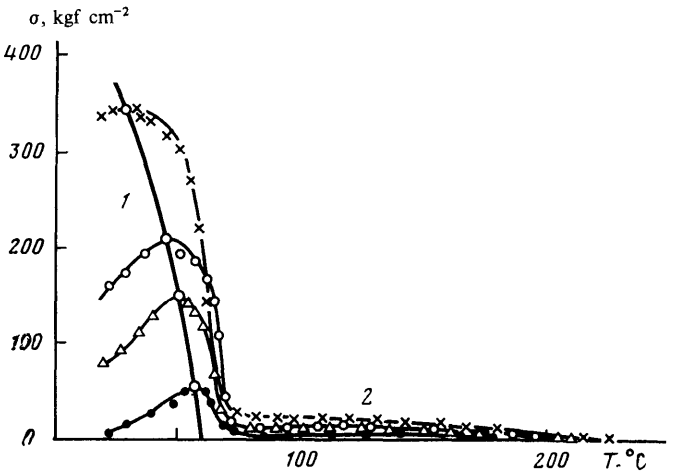

Figure 11. Region of applicability of composition comprising (parts by weight) 100 ED-16 + 40 UP-607 + 50 F-2.

These results have been attributed[58] to differences in flexibility among the chain segments between branch points in the network formed by hardening of an epoxy-resin with a mixture of a traditional hardener and a polyarylate. When such a network is heated in a stressed state for determination of the region of applicability, stress relaxation will occur primarily by the appearance of molecular mobility in the flexible chain segments of the epoxy-resin. Since these are present in every composition, acceleration of relaxation processes will develop, of course, at approximately the same temperatures in composite materials differing in composition. At high temperatures, however, at which stress relaxation is complete in the usual compositions, the presence of polyarylate fragments in the present case prevents complete relaxation right up to 220 °C: slight stress is retained in the material.

A similar result is obtained when other heat-resistant aromatic polymers are introduced into compositions based on epoxy-resins of diverse structure. Two regions of applicability are evident: the high-temperature region may extend to 300 °C; the low-temperature region (at high stresses) remains almost the same as in the absence of heat-resistant aromatic polymers[61].

Thus the investigation[58-61] has shown that solid compositions based on epoxy-resins can be obtained without the use of traditional hardeners by introducing into the resin chemically active heat-resistant polymers (polyarylates, aromatic polyamides, polyimides, etc.). Such a process produces a significant extension to higher temperatures of the region of mechanical applicability of the composition. Introduction of aromatic polymers into an epoxy-resin does not prevent use of ordinary hardeners, and the properties of the material can be controlled by varying the composition of such a ternary system[61].

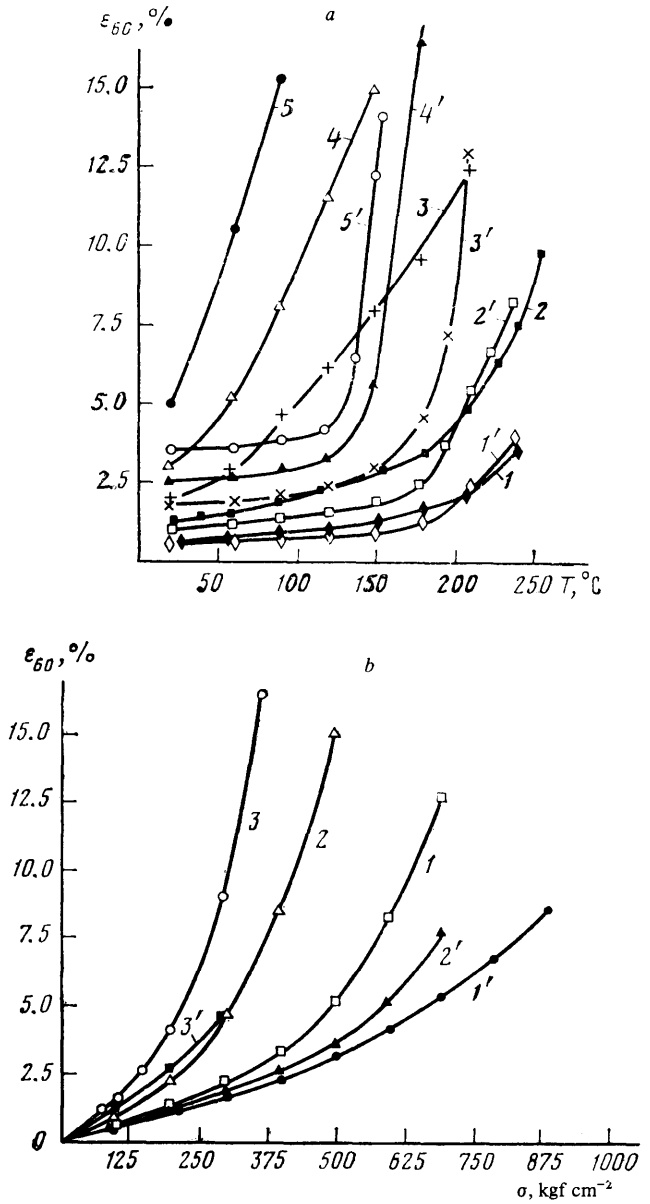

Figure 12. Dependence for initial and preheated polyarylate (respectively unprimed and primed curves) of deformation ε_{60} developed during 60 min of creep: (*a*) on temperature under stresses σ (kgf cm^{-2}): 1,1′) 100; 2,2′) 200; 3,3′) 300; 4,4′) 400; 5,5′) 500; (*b*) on stress at various temperatures *T* (°C): 1,1′) 20; 2,2′) 90; 3,3′) 150.

A considerable number of studies has been made on creep in network systems based on heat-resistant polymers. Such investigation is of fundamental interest, since it helps to reveal the limits of stress, temperature, and duration within

which deformation in the polymer material does not exceed a specified value. It may even be claimed that the study of creep is more importanat than the investigation of stress relaxation for assessing the mechanical applicability of polymer materials, since in most cases their working conditions tend to develop creep (with variable or constant loading and temperature). Measurements of creep must be made over all temperature and stress ranges possible for a given specimen in order completely to characterise the region of its applicability. The possible range of stresses is determined by the ability of the polymeric material to creep without disintegration; the possible temperature range is determined in the case of heat-resistant solid plastics by the glass point.

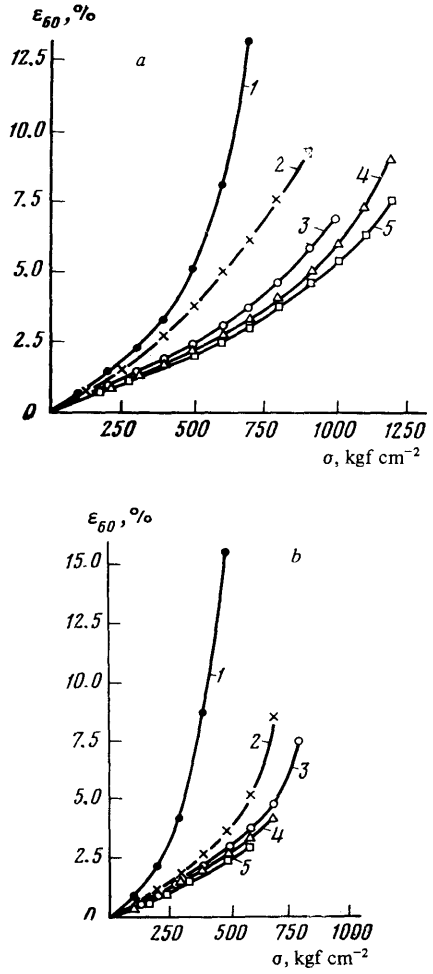

Figure 13. Dependence of ε_{60} on σ at (*a*) 20 °C and (*b*) 90 °C for 100 parts by weight of a polyarylate alone and in network systems containing various quantities of an epoxy-polymer: 1) 0; 2) 0 (preheated); 3) 10; 4) 20; 5) 33.

Detailed investigation of creep in the initial heat-resistant polymers and derived network systems[39,54,70] has shown that such polymers are characterised by very slight dependence of deformation on temperature over a very wide range. This experimental finding is illustrated by Fig.12, which shows the creep deformation ε_{60} developed during the process lasting 60 min for initial and heated polyarylates and for network systems. With various constant stresses the variation in ε_{60} is small over a fairly wide temperature range (depending on the stress), and only near the softening point does the creep begin to increase rapidly. This is especially characteristic of the heated polyarylate, which exhibits a far smaller tendency to creep than does the original specimen. Diffractograms[70] show that the reason for such behaviour is that the specimen becomes more ordered as a result of heating.

The influence of stress on creep is readily seen from Fig.12, in which is plotted the dependence of ε_{60} on mechanical stress at various constant temperatures. These curves show that the deformation increases appreciably with stress throughout its range, and here, too, a heated specimen exhibits far less tendency to creep than does the initial specimen.

Investigation[39,70] of the creep of film specimens containing various quantities of UP-612 epoxy-polymer and heated to form a cross-linked network of chemical bonds has revealed a generally smaller tendency of the network specimens to creep. In several cases the curves for the latter are almost horizontal lines: i.e. deformation does not develop with time. This result has considerable practical value, since undeformable materials, which do not change their shape with time under the influence of quite large stresses, can be obtained on the basis of networks of a polyarylate with an epoxy-polymer. A similar conclusion can be reached from a series of creep curves for initial and network specimens obtained under different mechanical stresses at a constant temperature[70].

To summarise the results and present them more vividly Fig.13*a* illustrates the stress dependence of ε_{60} (at 20 °C) for initial and heated polyarylate and for derived network specimens containing various quantities of UP-612. The network specimens exhibit a far smaller tendency to creep even than the heated polyarylate at the same stress throughout the range investigated. The best results are obtained with specimens containing 20–50 parts by weight of UP-612 per 100 of the polyarylate. The above tendency is maintained with rise in temperature, but the curves representing the stress dependence of ε_{60} are closer together (Fig.13*b*). This is entirely reasonable, since with rise in temperature the presence of a less heat-resistant material in the network should tend to increase creep, although, as noted above, network specimens undergo less deformation in all cases.

Thus the investigation of creep in an initial polyarylate and in network polymers based on the polyarylate and epoxy-polymers has shown that, as a consequence of the formation of a network of chemical bonds, heating diminishes substantially both the magnitude and the rate of creep. Almost complete cessation of the development of deformation with time under the influence of very large stresses can be achieved by varying the composition.

Fig.14 shows correlated logarithmic pliability curves plotted on the principle of temperature–time equivalence by displacement along time axis with $T_0 = 20$ °C selected as reference temperature. Three series of curves are included, representing respectively the behaviour under creep conditions of initial and heated polyarylate and of a network formed by interaction with UP-612 epoxy-polymer. Curves obtained at different constant stresses for initial and heated polyarylate specimens are evidently not superposable. The greater the applied stress, the greater the pliability. All this clearly indicates non-linear mechanical behaviour of

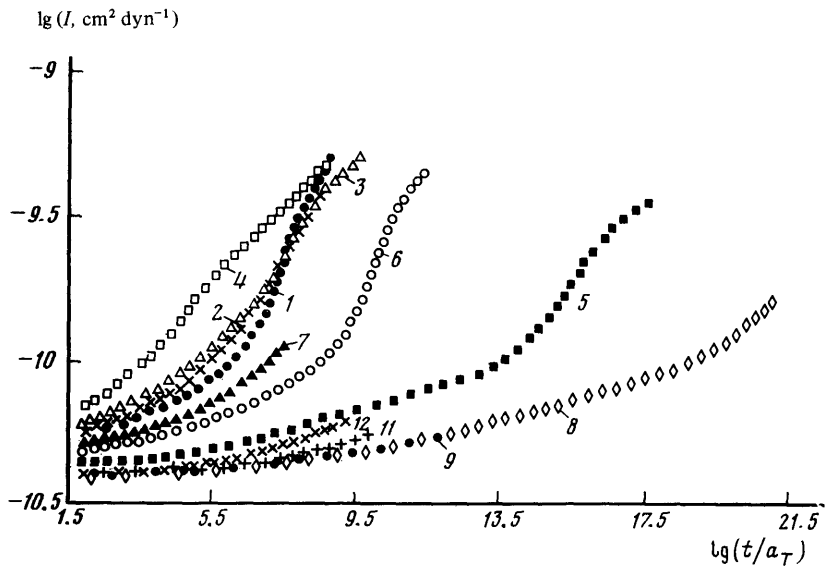

Figure 14. Correlated pliability curves (reference temperature $T_0 = 20$ °C) for initial and preheated polyarylates and a network polymer containing 33 parts by weight of an epoxy-polymer per 100 of the polyarylate, obtained under different stresses (kgf cm^{-2}): 1) polyarylate 200; 2) polyarylate 300; 3) polyarylate 400; 4) polyarylate 500; 5) preheated 200; 6) preheated 300; 7) preheated 400; 8) network 200; 9) network 300; 10) network 500; 11) network 600; 12) network 900.

polyarylates over wide ranges of stress and temperature. However, the network system exhibits quite different behaviour: the correlated curves practically coincide over a wide stress range, especially for short durations. Only at high stresses (600–900 kg cm^{-2}) do the curves begin to diverge towards an increase in pliability (at comparatively short durations). Another feature of the network system is lower pliability than for initial and heated polyarylate throughout the correlated curve.

Another feature of Fig.14 is that plots of $\lg I$ against $\lg (t/a_T)$ obtained for relatively small stresses, where I is the pliability, t the time, and a_T the displacement factor, consist of two segments having different slopes. The first is gently sloping, which indicates a low rate of creep within the given range of $\lg (t/a_T)$ values, corresponding to a definite range of comparatively low temperatures. The second segment has a greater slope, indicating compartively rapid creep. The principle of temperature–time equivalence can be used to determine the temperature range of the transition between these two sections of relatively slow and rapid creep. As has been established for a polyarylate, this temperature range, in which creep undergoes abrupt acceleration, coincides precisely with that in which stress relaxation is sharply accelerated.

Thus investigation of the creep of heat-resistant systems has yet again confirmed the advisability of subdividing the temperature range of the vitreous state into two subranges with different rates of relaxation. When polymeric materials are used under non-isothermal conditions, it must be borne in mind that a rapid increase in the rate of creep will be observed on passing from one subrange to the other, which may lead to an unacceptable change in shape of the material.

The course of the creep curves for the polymeric systems studied is well reproduced by the quantitative relation[71]

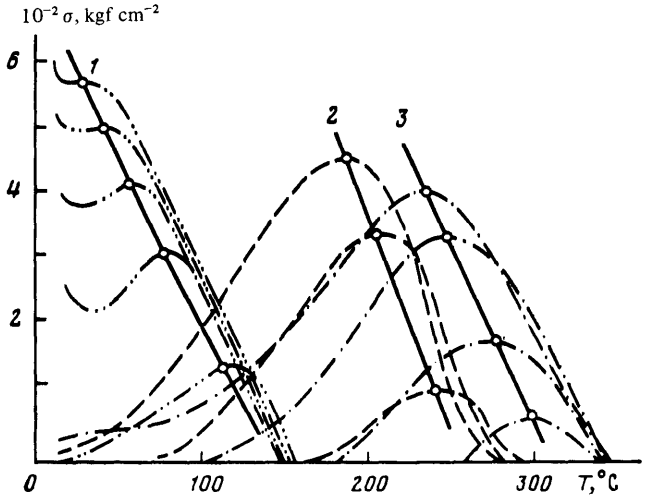
$$\varepsilon(t) = \sigma_0 I_\infty [1 - e^{-(t/\theta)^m}] + \frac{\sigma_0}{\eta} t,$$

where the product of the applied constant stress σ_0 and the equilibrium pliability I_∞ gives the equilibrium deformation $\varepsilon_0 = \sigma_0 I_\infty$, while θ is the time lag, m a constant characteristic of the material, and η the viscosity coefficient of the system. All the creep curves obtained for the initial F-2 polyarylate and its derived network systems have been calculated[70] by means of this equation from statistical least-squares processing of experimental results. The calculations show that the parameters m, θ, and η have a strong scatter, so that a regular temperature and stress dependence cannot be established. Only for the equilibrium pliability I_∞ is a smooth dependence observed.

A detailed investigation has been made[64] of the heat resistance of highly cross-linked polycyanates prepared from dicyanic esters of various aromatic diols. Fig.15 shows as example the temperature limits of the heat-resistance of several polycyanates as a function of the mechanical stress. A striking feature is the similarity between the non-isothermal stress-relaxation curves (broken) and curves bounding the region of applicability for highly cross-linked systems—polycyanates and linear heterochain polymers (with a polycarbonate as example).

Replacing an isopropylene by a fluorene group in the chain segments between branch points increases the heat-resistance of the polymer throughout the temperature and stress ranges investigated. An appreciable shift is also observed in the maximum temperature of applicability, at

which the stress in the specimen relaxes completely to zero. Replacing a *para*-substituted dinuclear dicyanate residue by a mononuclear *meta*-radical between the branch points in the polymer network lowers the heat-resistance of the polycyanate with respect both to temperature and to stress[64]. Introduction of a 1,2-carborane instead of a 9,9-fluorene bridge between the phenylene groups of the cyanate also lowers the heat-resistance of the polycyanates (Fig.15).



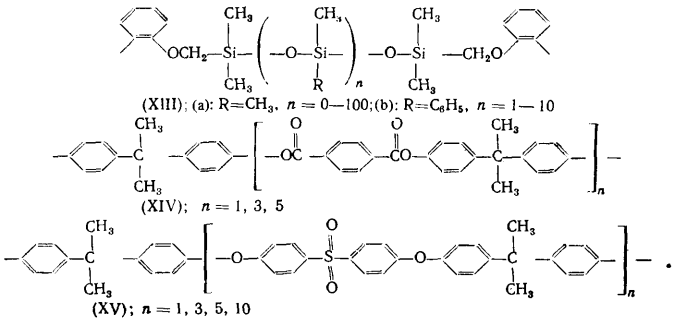


Figure 15. Regions of applicability of 1) a polycarbonate from 2,2-diphenylpropane-*pp'*-diol; 2) polycyanate (II); 3) polycyanate (VIII).

Thus the structure of the initial aromatic cyanate exerts a significant influence on the properties of the resulting polycyanates, although the latter are dense networks. Even small changes in the structure of the segments between branch points in such a dense network lead to appreciable changes in the properties of monolithic specimens of the polycyanates.

Still greater variation in properties can be achieved by varying the chemical nature of the segments between branch points in the dicyanates. Dicyanic esters of oligosiloxanes, oligo(arylene sulphoxides), and oligoarylates of various lengths have been used[72] as initial compounds for network formation. It is interesting that linear macromolecular analogues of these segments find wide application. The segments between the branch points[72] had the structures

Depending on the chemical structure and also on the number n of repeating units monolithic specimens of the network polycyanates had properties varying from rubberlike with large reversible deformation and a low modulus of elasticity to vitreous with a high modulus. Analysis of the equilibrium modulus in the rubberlike state showed that the distance between network branch points in the polycyanates corresponded almost exactly to the chain lengths in the initial oligocyanates, evidence of a process with high selectivity and a network with few defects. It is therefore possible to analyse the effect of the chemical structure of the internodal segments on the properties of the network polycyanates.

Table 2. Parameters in the Kohlrausch equation for network polymers.

n	Gel fraction, %	ε, %	E_∞ (kgf cm^{-2})	E_0 (kgf cm^{-2})	τ_p, min	k	$10^{-7}\eta$, P
Polymer (XIIIa)							
5	96	20	16.0	5.50	23	0.70	6.3
25	95	50	2.3	0.12	18	0.52	1.88
50	95	50	1.7	0.12	14	0.42	0.51
70	92	50	1.0	0.08	8	0.33	0.41
Polymer (XIV)							
1	96	30	19.3	9.17	32	0.83	$5.11\cdot10^9$
3	95	30	13.2	3.84	28	0.17	$6.03\cdot10^{10}$

The investigation[72] has shown that stress relaxation in the polycyanates is well described by the Kohlrausch equation with parameters depending very characteristically on the chemical structure of the network. Comparison of polycyanates based on oligosiloxanes and on oligoarylates with small values of n shows that such parameters as E_∞, E_0 and τ_p have closely similar values (Table 2). The main difference between these polymers lies in the fractional power of the time ($k = 0.70$ and 0.17) and in the viscosity ($\eta = 6.3 \times 10^7$ and 6.03×10^{10} P respectively). Such a substantial difference in the viscosities of the polymers is attributed to the chemical structure of the internodal segments. In the region of the hyperelastic state polymers with oligoarylate segments probably exhibit considerably greater intermolecular interaction and rigidity than do network polydimethylsiloxanes[72].

Comparison of the relaxation properties of polycyantes based on oligo(arylene sulphoxides) and on oligoarylates does not reveal such an important difference (at equal values of n). However, a network polycyanate based on the former type of oligomer has the larger relaxation modulus.

Great selectivity of the polycyclotrimerisation of arylene dicyanates, which governs many physical and chemical properties of the resulting polycyanates, distinguishes it favourably from that of other groups having multiple bonds (–N:C:O, –C:CH), which is accompanied by numerous side-reactions such as dimerisation, polymerisation in the chain, etc.[73,74]. As a consequence of the great selectivity of cyclotrimerisation of –O.C:N groups in arylene dicyanates and its nearly quantitative completion the resulting highly cross-linked polymers possess several properties marking them off from well known cross-linked polymers, e.g. greater specific resilience, which is not typical of highly cross-linked systems.

Under certain conditions several polycyanates form partly crystalline structures[72], which is probably also related to the regularity of their chemical structure, confirmed by calculations of the density of packing of macromolecules in the final monolithic polycyanates. The density of packing of the chain was assessed from the molecular packing coefficient defined by the formula

$$K = \frac{N_A \sum_i \Delta V_i}{M/d},$$

in which ΔV_i is the van der Waals volume of the ith atom in the repeating unit, M the molecular mass of the unit, d the density, and N_A Avogadro's number.

Calculations have shown[64] that packing coefficients for network polycyanates differing in aromatic structure lie in the range 0.673–0.697 (Table 1). The mean packing coefficient for monolithic specimens of linear polymers is 0.681. Hence network systems based on aromatic polycyanates exhibit as high a density of packing of macromolecules as do linear systems. When polysiloxane segments are introduced between network branch points, the packing coefficient decreases rapidly, especially with increase in chain length between these points[72]. This is a feature also of linear polydimethylsiloxanes.

The process of formation of the supermolecular structure of polycyanates at various stages of synthesis—from the initial monomer to a regular network with almost 100% conversion of functional groups—has been examined[75] in order to find the reasons for the improved mechanical indices (especially on impact). In the early stages the specimens were liquids, which were frozen down to −150 °C to fix the structure instantaneously after which relicas were sputtered at −190 °C. The initial monomer comprised finely crystalline structures, which on heating underwent changes as a consequence of polycyclotrimerisation. In the early stages of this reaction sharply bounded regions of globular structure, with globules of mean size 500 Å, appeared on the background of the characteristic structure of the monomer. With further polycyclotrimerisation the whole surface consisted of globules, whose size gradually diminished with increase in the degree of conversion of cyanato-groups. In the very last stage of polycyclotrimerisation fibrillar structures appeared. This may be the reason for the characteristic mechanical properties of aromatic polycyanates.

The relaxation properties also change with the degree of conversion (and hence the supermolecular structure). In the comparatively early stages the stress-relaxation curves shift to higher stress values (the modulus of eleasticity and the equilibrium modulus increase). In the later stages, however, these moduli begin to decrease (i.e. the rigidity of the specimen diminishes under otherwise similar geometrical conditions). Thus there exists a definite relation between the chemical structure of a polycyanate (its degree of conversion), the supermolecular structure, and its mechanical properties.

* * *

From our discussion of the structure and properties of networks based on heat-resistant polymers we may conclude that the most promising trends in this field are the synthesis of network systems from reactive oligomers of aromatic structure, including polycyclotrimerisation, and the production of networks by chemical reaction between oligomers such as epoxy-resins and heat-resistant aromatic polymers containing in the main chain groups capable of interacting with reactive groups in the oligomers. The properties of the resulting network systems can be controlled within wide limits by varying the chemical structure of the segments between and also the density of branch points in the network. In the Reviewers' opinion the greatest interest attaches to densely cross-linked polymers based on polycyanates, in which the networks are almost completely free from defects; the formation of these systems is accompanied by substantial change in the supermolecular structure at various stages of conversion, resulting in extremely ordered structures with clear signs of crystallinity at high conversions. In the future it may be of great interest to obtain highly crystalline network systems with interesting sets of properties.

It is also necessary to seek quantitative relations between the chemical structure, the topology of the network, and the set of mechanical properties. It is important to calculate the number of branch points in a network formed of aromatic segments. Since the mechanical (relaxation) behaviour of network systems having aliphatic and aromatic segments differs greatly, only a few values of the equilibrium modulus of elasticity may prove insufficient for such calculation.

There thus remains several unresolved questions in the recent study of the preparation and properties of network systems based on heat-resistant polymers, associated with controlling their properties by varying both chemical and network structures. In view of the rapid development of this field, interesting new results may be expected in the future.

Chemospecific (Covalent) Chromatography of Biopolymers

V.I.Lozinskii and S.V.Rogozhin

The literature on the applications of one of the modern methods for the isolation and thorough purification of biopolymers —chemospecific (covalent) chromatography based on the chemical interaction of substances in solution and the chromatographic carrier—is reviewed.
The bibliography includes 164 references.

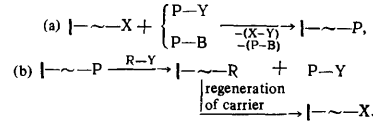
VI. Certain methodological problems of the chromatographic process 468

I. INTRODUCTION

Modern biochemical methods make it possible to isolate in a pure state from a wide variety of sources and to investigate the structure, properties, and the mechanism of action of virtually all classes of biopolymers present in the tissue and liquids of organisms even in extremely low amounts. However, the schemes developed for the isolation and purification of the required substance are sometimes too cumbersome and laborious. The success of new not unduly laborious but much more effective methods such as biospecific (affinity) chromatography, affinity electrophoresis, etc. is not therefore surprising. They have significantly simplified and reduced the cost (which is also important) of the processes involving the isolation and purification of peptides, proteins, enzymes, nucleic acids, etc.



As will be shown below, there exist at the same time a number of problems which are difficult and sometimes simply impossible to solve on the basis of the physical properties of the substances alone or the principles of biological activity, since they require the "chemical involvement" of particular functional groups of the biomolecules. The processes in the isolation and purification of natural products, based on reversible chemical reactions between an insoluble carrier and the substances to be isolated, have come to be referred to as "covalent chromatography".

This review describes the main achievements of this method for the separation of substances and its applications and discusses some of its specific problems.

II. GENERAL SCHEME FOR THE PROCESS. TERMINOLOGY

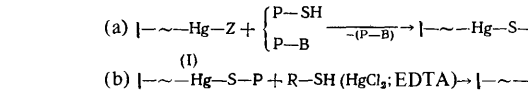
"Covalent chromatography" is a comparatively new method for the isolation and purification of biopolymers. The first publication in this field refers to 1963 [1] and in the subsequent ten years only a few studies appeared[2-8]; subsequently, starting from 1973, interest in this method increased appreciably and the main bulk of the publications took place in the last five years. It is noteworthy that there are virtually no reviews of the method in the literature.

The general scheme for covalent chromatography includes the following sequence of operations†:

A mixture of biopolymers, one or several components of which are the required products of the separation (indicated by P–Y in the scheme above), is brought into contact with an insoluble carrier having a chemically active "anchor" group X capable of reacting selectively solely with group Y; this results in the immobilisaton of material carrying accessible Y residues and the products which have not been bound covalently (P–B) are washed off. The carrier–biomolecule covalent bond (hence the name of the method—covalent chromatography) is stable in the absence of a specific reagent (R–Y), but readily decomposes when such a reagent is introduced into the system in the next, deimmobilisation stage (b), as a result of which the required product of the separation passes to the solution. The carrier is regenerated as far as possible and is used again.

Several names have been proposed for the scheme given above: "covalent affinity chromatography"[7,8], "covalent chromatography"[9], and "reversible immobilisation"[10]. A more exact name for the method would probably be "chemospecific chromatography", which reflects the main ideas of the process—specific reversible chemical interaction of substances with an insoluble carrier. In the description below we shall therefore adhere to the terminology proposed here.

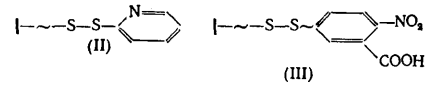
† Here and henceforth the symbol | denotes the matrix of the chemospecific carrier and the symbol ~ denotes an intermediate group ("spacer").



III. CHEMICAL PRINCIPLES OF THE METHOD

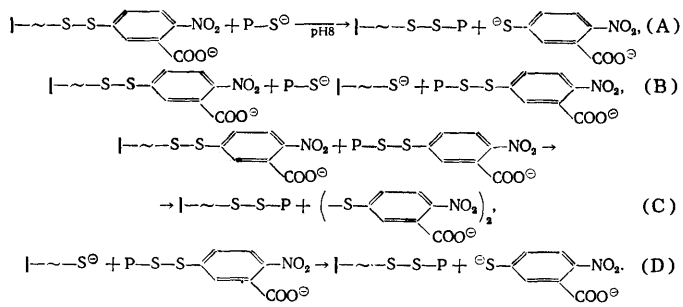
Since the main bulk of the publications in this field refer to studies on proteins and peptides, it is necessary to examine at the beginning the problem of which functional groups of protein molecules and which reversible chemical reactions involving them are used in the chemospecific chromatography (CSC) of proteins.

In the first place such groups must include the sulphydryl groups of the cysteine residues which form part of the composition of particular proteins. Whereas other groups (amino-, hydroxy-, phenoxy-, carboxy-, etc.) are present in other biopolymers (nucleic acids, polysaccharides) as well as proteins, the mercapto- and disulphide groups are almost exclusively a specific chemical feature of proteins as a class of biological macromolecules[11]. Numerous proteins with accessible SH groups are now known and the involvement of cysteine residues in enzyme catalysis by many enzymes (for example thiol proteases, creatine kinases, 3-phosphoglyceraldehyde dehydrogenases, etc.[12]) has been demonstrated. Reversible modifying agents for the mercapto-groups of proteins have also been thoroughly investigated[13]. It is not therefore surprising that reversible immobilisation via the SH groups of proteins was first used[1] for CSC and the majority of the publications on this method are in fact devoted to the isolation and purification of thiol-containing proteins and peptides on various carriers.

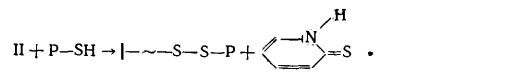


However, reactions other than those with SH groups can be used in the CSC of biopolymers. This has been demonstrated in a number of instances which will be discussed in detail below. Here one must emphasise that, in principle, it is possible to use the reversible reactions of any accessible groups in biomolecules subject to the only stipulation that the reactions must be highly specific and must occur under fairly mild conditions which do not decompose the biomolecules themselves or the carriers. Preliminary information concerning the effect of the low-molecular-weight reagent, whose insoluble analogue is to be employed, is therefore always necessary, i.e. CSC is based on data obtained in studies on the chemical modification of biopolymers. Thus this type of chromatography can also be regarded as the reversible modification of the functional groups of biological macromolecules by insoluble reagents.

As regards chemical processes involving SH groups, the formation reactions of either mercaptide (Hg—S), or disulphide (S—S), or thioester (CO—S) bonds have been used for CSC. The covalent bond between the mercury atom of the insoluble carrier and the mercapto-group of the protein or the peptide can be ruptured under mild conditions by low-molecular-weight thiols, soluble mercury salts, or complexones such as ethylenediaminetetra-acetic acid (EDTA):[1]

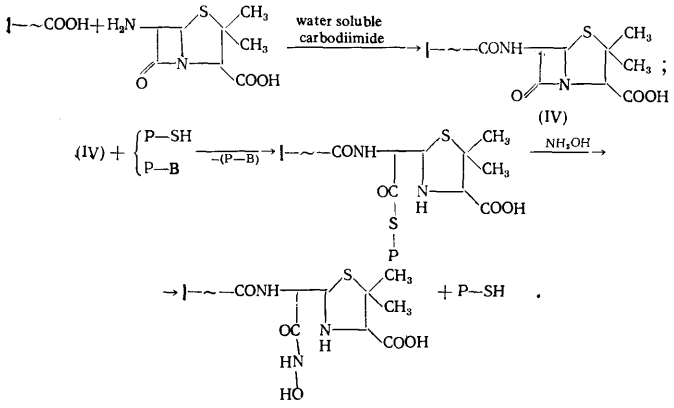


However, one should bear in mind that mercury-containing carriers must be used with a fair amount of caution, since the slow elution of the metal (partial decomposition of the carrier during manipulations and gradual hydrolysis of the carrier–ligand bonds), which always occurs, contaminates the protein, which is particularly undesirable if the biopolymer being isolated is to be introduced into some kind of organism. Furthermore, mercury carriers can retain also non-thiol proteins if the latter have intensely complex-forming groups capable of being incorporated in the coordination sphere around the mercury atom, which interferes with the isolation of the SH-products.



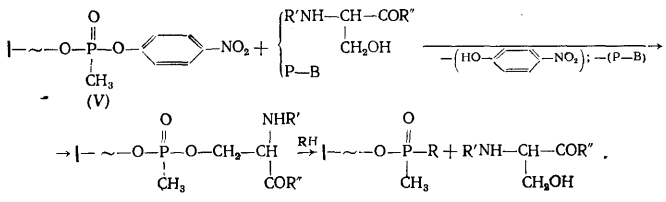
For CSC based on thiol–disulphide exchange reactions, insoluble analogues of reagents for SH groups have been used as the anchor groups of the carriers: di-(2-pyridyl)-disulphide (II) [14] and 5,5′-dithiobis-(2-nitrobenzoic acid) (III):[15]

The disulphide linkages of such carriers are activated by the electron-accepting effect of the aromatic system and readily enter into thiol–disulphide exchange reactions with the sulphydryl groups of the proteins. It has been noted[16] that, for carriers of type (III), the main reaction (A) via the CSC mechanism may be accompanied by other processes—(B), (C), and (D):



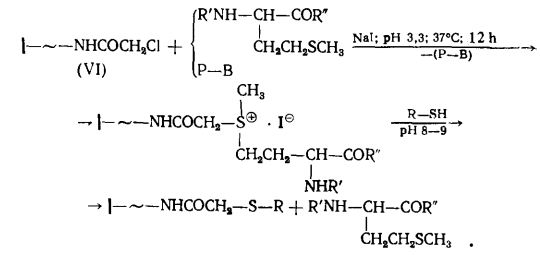
Such multiplicity of thiol–disulphide exchange reactions is missing in studies with carriers of type (II) containing dipyridyl disulphide active groups, since the 2-mercaptopyridine isolated immediately isomerises to 2-thiopyridone, which no longer takes part in the exchange processes and the reaction equilibrium is almost wholly displaced to the right[9,17,18]:

The deimmobilisation of the SH-protein occurs in the presence of an excess of a low-molecular-weight thiol (cysteine, 2-mercaptoethanol, and dithiothreitol).



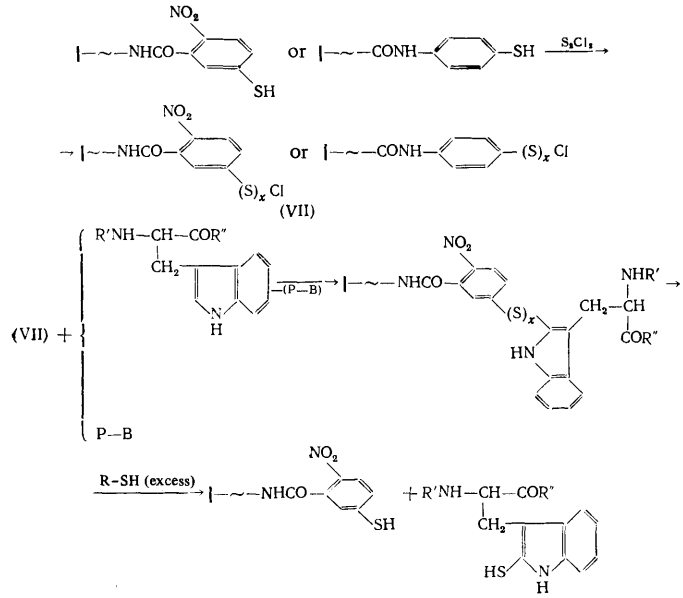
An interesting version of CSC has been achieved in the study of the penicillin-binding components of the membranes of *B. subtilis*[8,19,20]. As shown previously[21], these protein components are acylated by penicillin via the SH groups of the cysteine residues and the resulting thioester linkages can be ruptured either by hydroxylamine, or thiols, or hydrogen peroxide. A chromatographic process, carried out on carrier (IV) with immobilised 6-aminopennicillanic acid

(6-APA), has been developed on the basis of these data:



The above scheme is to some extent tentative, since the conditions governing the condensation of 6-APA with the COOH-carrier, quoted by the authors[8], do not exclude the formation in succession of several 6-APA molecules, linked by amide bonds, on the insoluble phase. It is therefore difficult to say which particular type of carrier is truly involved in the process—with monomeric or oligomeric penicillin. Another factor is important—this type of chemochromatographic approach can apparently prove useful in the study of the mechanism of the interaction of various medicinal drugs with cell components, since the formation of stable covalent ligand–protein bonds makes it possible to wash off thoroughly all the remaining substances and then to isolate the ligand receptors alone and to investigate them separately.

As already mentioned above, the CSC scheme need not be applied solely to SH-proteins. The reversible phosphorylation of the OH group of the serine residues has been used[7,22] in the isolation of enzymes containing this aminoacid at the active centre (acetylcholinesterase, α-chymotrypsin):



Here RH = 2-(hydroxyiminomethyl)-1-methylpyridinium iodide, 1,1′-trimethylenebis-(4-hydroxyiminomethyl)pyridinium dibromide, or hydroxylamine and R′ and R″ are polypeptide chains. The presence of serine in an activated form is apparently an essential condition for reaction with a carrier of type (V), since a protein not belonging to the class of serine enzymes but containing serine in its composition (serum albumin) is not retained by the carrier.

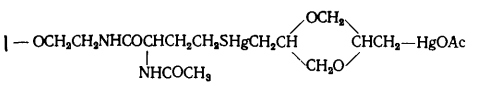
The formation of sulphonium derivatives on interaction of the thioester group of the methionine residue with α-halogeno-acids in an acid medium and their subsequent decomposition with low-molecular-weight thiols has been used recently[23] in CSC involving methionine residues:

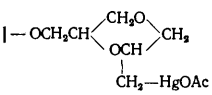
It is necessary that the methionine residue is not a C-terminal aminoacid, since otherwise it is converted into a homoserine residue and the protein or peptide is not fixed on the carrier. One should note that the fairly severe conditions required for the immobilisation of methionine-containing substances probably limit the applicability of this scheme to relatively stable proteins. For peptides, it is apparently not so significant if they do not contain labile linkages of the type Asp–pro.[24] There are also some doubts about the stability of the material of the carrier under the fixation conditions. Furthermore, the above scheme does not provide for the regeneration of the carrier.

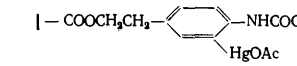
The ability of sulphenyl chloride[25] and sulphur monochloride[26] to modify the tryptophan residues at the 2-position of the indole ring has been used[27] for the chemospecific isolation of tryptophan-containing compounds:

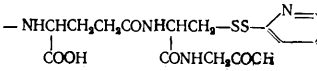
Ultimately the tryptophan residue is modified—an SH group appears in the indole ring. The introduction of this group, which is convenient for further modification, will apparently prove useful also in the study of the role of Trp residues in enzyme molecules. Since carriers of type (VII) bind covalently also mercapto-groups, it follows that, when it is necessary to carry out the process via the tryptophan residues alone, one must block appropriately the SH groups of the cysteine.

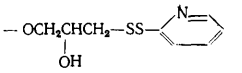
Table 1. Carriers for the chemospecific chromatography of biopolymers.

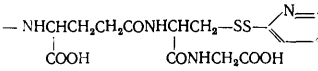


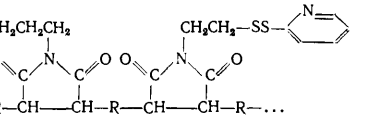


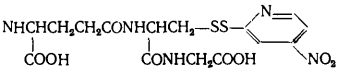


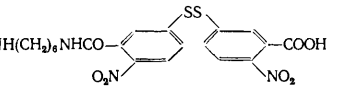


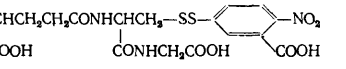


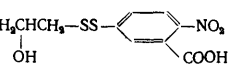


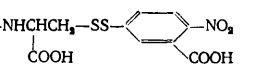


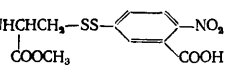


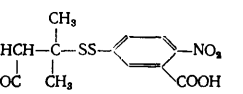


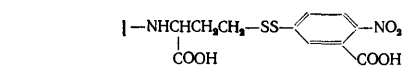


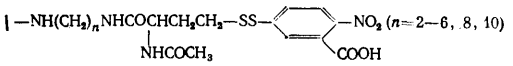


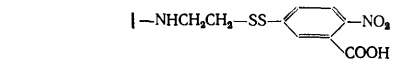


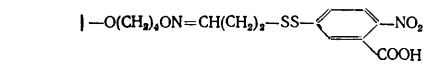


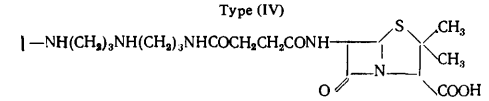


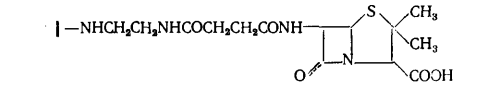


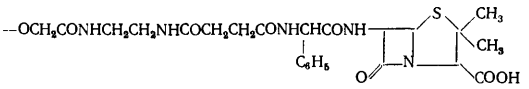


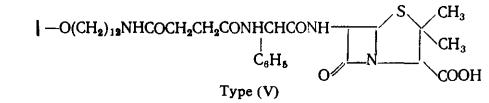


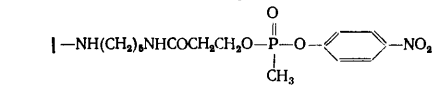


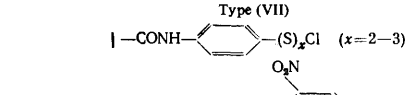


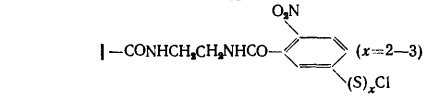












No.	Matrix	Chemospecific group with spacer	Capacity with respect to active groups	Refs.
		Type (I)		
1	Sephadex G-25		0.15 mmole g^{-1}	1

*Carrier exhibits an appreciable non-specific sorption with respect to the main proteins.
**The substituent R = *N*-vinylpyrrolidinone, ethyl vinyl ether, styrene, or ethylene.
***The capacity is quoted with respect to the dry weight of the carrier.
****The protein consists of the light κ-type immunoglobulin chain.

There have also been studies where a modified version of CSC, in which the anchor groups X were introduced into the biopolymer while the Y groups were contained in the carrier, has been used. For example, an SH-protein was treated with dipyridyl disulphide, the excess reagent was removed by gel filtration, the protein was hydrolysed by a proteolytic enzyme, and the solution of the resulting peptides was passed through a column with a carrier containing mercapto-groups[28]. In studies with polynucleotides both isolation of the mercapto-derivatives of nucleic acids on an Hg-carrier[29] and, conversely, the isolation of mercurated RNA and DNA on an SH-carrier have been used[30-32].

The choice of a chemical pathway for a chromatographic process is largely dictated by the specific conditions of each concrete problem. It is of course impossible to reach an unambiguous conclusion as to which version is best (with the anchor group on the carrier or on the biopolymer). One can only note that, from the standpoint of the stability of the carrier (in the case of insoluble thiol phases), preference should be given to chemosorbents with a protected SH group—in this form it is subject to much less risk of oxidation. The lower effectiveness of the fixation of the dithio-2-nitrobenzoate derivative of the protein on an SH-carrier compared with the reaction of an SH-protein and a type (III) carrier has also been demonstrated[33].

IV. CARRIERS FOR THE CHROMATOGRAPHIC PROCESS

Like any chromatographic process, chemospecific chromatography imposes requirements on the carrier: (1) chemical, physical, mechanical, and biological stabilities; (2) sufficient permeability to macromolecules ensuring their free approach to the active groups of the carrier; (3) hydrophilic properties of the carrier, permitting experiments in an aqueous medium; (4) homogeneity of shape—preferred use of

carriers in the form of spherical beads of identical size; (5) commercial availability of the material of the carrier matrix and as far as possible its low cost.

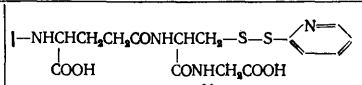
Apart from these properties of the matrices, which are generally speaking the same for all chromatographic processes involving biopolymers and which have been discussed in fair detail in specialist literature (see, for example, Klyashchitskii and Shapot[34] and Berezin et al.[35]), carriers with functional groups capable of undergoing readily reactions for the addition of anchor groups are necessary in CSC.

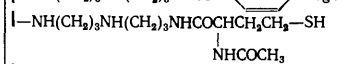
Table 1, which summarises the literature data for the carriers used in CSC, shows that chemosorbents based on agarose gels, which have proved useful for affinity chromatography and the immobilisation of biopolymers, have been used in most cases. Agarose matrices are available commercially, exhibit a non-specific sorption, and methods for the introduction of various groups into such carriers have been thoroughly developed[36–38]. However, such carriers are not free from a number of disadvantages either: namely their mechanical strength is low, the structure of the polysaccharide matrix breaks down under the influence of organic solvents and temperatures above 50–60 °C, and the rate of flow of the liquids through the column containing the gel is rather low even when a small excess pressure is applied, the carrier is subject to microbial infection, and, finally, it is fairly expensive. Cross-linked agarose gels of the type of Sepharose-CL,[39,40] which have improved physicomechanical properties, will probably prove very useful in this process, as shown[41] by the application of a chemosorbent based on this Sepharose derivative (No.10, Table 1). A similar cross-linked agarose carrier (Nos.9 and 18, Table 1) has been obtained[42] by treating a polysaccharide matrix with epichlorohydrin (for the introduction of epoxy-groups). However, since the degree of cross-linking was not controlled and the formation of cross-links in the gel was a concomitant process in the formation of the active groups on the carrier, it is not clear to what extent such cross linking took place.

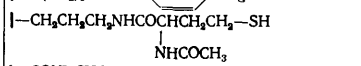
Carriers based on cross-linked polyacrylamide gels have also been used in CSC (Nos.31–33, Table 1). They have been employed in studies with proteins of low molecular weight and peptides. Here the very matrix imposes limitations—biopolymers with high molecular weights (in excess of 100 000 for Bio-Gel P-100 and above 300 000 for Bio-Gel P-200, on the basis of which chemosorbents have been prepared[23,27]) cannot penetrate[43] into the particles of the swollen gel. Furthermore, the mechanical strength of weakly cross-linked polyacrylamide matrices is likewise low.

In recent years carriers on an inorganic base have been used increasingly in the immobilisation of various biologically active compounds[44,45] and also for the specific isolation of enzymes[46] and gene fragments[47] with the aid of affinity chromatography. Materials such as porous glass, macroporous silicas, metals, metal oxides, ceramics, etc. have a high mechanical strength and standardised characteristics, are resistant to microbial infection, and are readily available; any chaotropic agents, high salt concentrations, and organic solvents can be used in experiments with them.

We obtained[48–51] a number of carriers for the CSC of proteins and peptides (Nos.11–13, Table 1) on the basis of a macroporous silica—silochrome[52]. Carriers containing a polymer grafted to an inorganic surface (No.13, Table 1) (R = ethyl vinyl ether, *N*-vinylpyrrolidinone, etc.) are characterised by a non-specific sorption of proteins and an improved stability of the matrix in alkaline media, in addition to an ehanced capacity with respect to dipyridyl disulphide groups. We believe that inorganic carriers whose surface is coated by a hydrophilic polymer are promising for studies on biopolymeric phases, since they combine the useful physicomechanical properties of inorganic matrices with adsorption passivity (when a collect choice is made) of the polymer coating. The preparation and use of combined carriers of this type have been described in a number of publications on the immobilisation[53,54] and affinity chromatography[55–57] of enzymes.







In the study of the properties of the carriers used, much attention has been devoted recently to the investigation of the influence of the distance of the immobilised affine ligand from the matrix on the efficiency of the chromatographic process and on the possibility of non-specific interactions. Such interactions (hydrophobic, electrostatic, sorption, etc.) usually interfere with the main procedure and its is therefore always desirable to eliminate them as far as possible. Summarising the results of these studies, one may conclude that the lengthening groups—the so called spacers—should undoubtedly by hydrophilic, simply because long polymethylene systems interact appreciably with the hydrophobic sections of protein molecules, as shown clearly, for example, by O'Carra et al.[58] Or, at least under the conditions employed (ionic strength of the solution, pH of the medium, and temperature), hydrophobic interactions should be minimal, which, however, must always be demonstrated in preliminary control experiments. It is also better if the spacer contains no ionogenic groups. Otherwise, there is, firstly, a superposition of ion exchange and, secondly, carriers of the gel type, containing charged groups, undergo an appreciable change in their volume and hence also there is a change in the size of the gel pores as the composition of the buffer is altered.

Although ionogenic groups do not in fact enter into the composition of the proposed spacer, the chosen chain of the chemical transformations for the immobilisation of the ligand frequently permits side reactions, which may "unexpectedly" give rise to an undesirable effect. For example, if the very popular method involving the attachment of amines to BrCN-activated agarose[37] is used, reactions via both NH_2 and SH groups can occur in the case of aminothiols[17]. This entails a decrease of the capacity of the carrier with respect to the mercapto-groups and introduces unnecessary ionogenic amino-groups. As regards the size of the spacer, the literature data are fairly contradictory. It is most likely that the optimum length is determined by the substance to be isolated and purified and by its structure and properties. It has been noted[34] that an unduly long spacer is relatively ineffective owing to its conformational bending, conversion into a helix, etc.

In CSC the influence of the length and structure of the spacer have so far been studied inadequately, although there are certain interesting data. Thus investigation of the kinetics of the deimmobilisation of lipoamide dehydrogenase with type (III) carriers (No.23, Table 1) established[59] that the enzyme dissolves under the influence of a reducing agent faster the longer the spacer, i.e. the approach of the cleaving agent to the covalent carrier–enzyme linkage is sterically facilitated. The chemical structure of the spacer near the active group is also important. It has been shown[33] that a carrier with the dithio-2-nitrobenzoate group at a quaternary carbon atom (No.21, Table 1) reacts to a very insignificant extent with SH-proteins—the shielding influence of the substituents has an effect, whereas branching at the next carbon atom of the main chain (Nos.17–20, Table 1) virtually no longer hinders the fixation of the protein. Thus, in the synthesis of active groups on carriers, it is necessary to take into account all the factors discussed above.

A number of carriers for CSC are now manufactured by certain companies. Table 2 presents the characteristics of

Table 2. Commercial carriers for chemospecific chromatography.

No.	Manufacturing company	Name of product	Matrix	Chemispecific group with spacer	Capacity with respect to active groups
1	Pharmacia Fine Chemicals (Sweden)	Activated Thiol-Sepharose	Sepharose 4B		1.0 μmole ml^{-1}
2	Ditto	Thiopropyl-Sepharose	Sepharose 6B		20 μmole ml^{-1}
3	Serva (Western Germany)	Servachrom-A-Hg	agarose		—
4	Ditto	Servachrom-A-SH	"		—
5	Bio-Rad Laboratories (USA)	Affi-Gel 401	"		6.0 μmole ml^{-1}
6	Ditto	Affi-Gel 501	"		3.0 μmole ml^{-1}
7	Pierce (USA)	Thiol/CPG	porous glass (d_{pore} = 550 A)		30 μmole g^{-1}
8	Koch-Light Ltd. (England)	Enzacryl-Polythiol	cross-linked polyacrylamide		—
9	Sigma (USA)	Cysteamine-agarose	agarose		0.1 μmole ml^{-1}
10	Ditto	*L*-Cysteine-agarose	"		2-10 μmole ml^{-1}

these chemosorbents based on the data supplied by the manufacturing companies (according to the 1977–1978 catalogues). Also included is information about certain commercially available SH-carriers, since they can be converted into derivatives with activated thiol functions by familiar reactions. However, one should note that all these carriers are fairly expensive, so that the development and practical employment of cheaper chemosorbents is an urgent problem whose solution will greatly extend the application of the CSC method not only in the laboratory but possibly also in biotechnology.

V. APPLICATIONS OF CHEMOSPECIFIC CHROMATOGRAPHY

The trends in studies on the CSC of biopolymers and the applications of this interesting highly selective method for the thorough purification of substances have now become clearly established. As already mentioned, most of the published data refer to studies with proteins or peptides. The use of CSC for the isolation of polynucleotides[30], gene fragments[29, 31,32], and low-molecular-weight cofactors[60] has been reported. Problems involving the isolation and purification of biopolymers, which have been solved with the aid of CSC, can be classified as follows.

1. Separation into fractions based on the chemical composition (for example, the separation of proteins with accessible SH groups from all the remaining mixture components).
2. Isolation of individual proteins and enzymes and isolation of isoenzymes.
3. Separation of chemically non-identical sub-units of oligomeric proteins.
4. Chemospecific isolation of peptides containing aminoacids with reactive side chains.
5. Purification of synthetic peptides.
6. Elimination of non-protein substances from proteins.
7. Isolation of modified nucleic acids and gene fragments.

Reversible immobilisation has also been used in the chemical modification of an enzyme temporarily fixed on an insoluble carrier followed by its dissolution[41,61]. This approach[41] makes it possible to avoid intermolecular cross-links if it is necessary to modify groups in the protein molecule in an isolated form by means of a bifunctional reagent.

Table 3 present a compilation of data on specific substances whose isolation or purification have been achieved with the aid of CSC. One should bear in mind that the chemospecific purification stage is hardly ever used in isolation. If there are simple methods for the preliminary fractionation and concentration of the desired product, then it is undoubtedly desirable to use them; this applies particularly to the removal of low-molecular-weight components, since they may contain substances which either interfere with the chemical fixation of the biopolymer on the carrier or are capable of cleaving the covalent carrier–biopolymer bond formed.

Table 3. Isolation and purification of biopolymers with the aid of CSC.

Substance isolated and purified	Source of biopolymer	Carrier		Refs.

Mercurated RNA (chemical mercuration)	SH–	–	30,138,143
8. Isolation of cofactors			
Flavin-adenine dinucleotide	(I)	4	60
Coenzyme A from *Sarcina lutea*	(I)	4	60

*The number refers to Table 2.

The combination of CSC with other selective methods yields satisfactory results when it is necessary to obtain, for example, a particularly pure and active enzyme preparation. Thus, in the isolation of phospholipase A_2 from human blood serum[62], several preliminary purification stages were followed by the consecutive application of three affinity columns: chromatography on concanavaline A-Sepharose—for the isolation of glycoproteins, which included also the required phospholipase; chromatography on a column with immobilised antiserum and γ-immunoglobulin (in the fraction of which activity was detected) for the separation of immunoglobulin; and finally CSC on an activated thiol-Sepharose (No.1, Table 2). This yielded an enzyme with more than a 10 000-fold

degree of purification. The above example refers to the isolation of a protein present in the initial material in extremely low amounts. On the other hand, when the required product is one of the main components (for example, papain in dried papain latex[9]), it can be isolated with the aid of CSC fairly simply and rapidly using a minimum number of stages. This is particularly convenient for the thorough purification of commercial protein preparations. For example, the isolation of mercaptopapain from a commercial papain[9,17] or the isolation of highly active urease from a commercial preparation of this enzyme[63] have been achieved rapidly and effectively on chemospecific carriers, while the isolation of the SH-components alone of the above proteins by the usual methods is laborious and leads to considerable losses of valuable enzyme material.

It has been shown that it is possible to separate rapidly non-identical subunits of oligomeric proteins with the aid of chemospecific sorbents, when some subunits contain and others do not contain reactive aminoacid residues. The SH-subunit of lombricine kinase[64], the α-subunit of yeast phenylalanyl-tRNA synthetase[65], κ-casein and αS-casein from whole casein[66], the β-chain of bovine haemoglobin[49], and the *a*-subunit of factor XIII of the blood clotting system[67] have been isolated in this way. In the last case the SH-*a*-subunit, immobilised reversibly on an Hg-carrier (No.6, Table 2), was used also to investigate its non-covalent interactions with the *b*-subunit.

In the study of the properties of "unusual" proteolytic enzymes—thiolsubtilisin[68] and thioltrypsin[69], obtained by the chemical transformation of the serine residue of the active centre into a cysteine residue by the method of Photaki and Bardakos[70]—CSC made it possible to isolate in a single stage the active modified protein.

The chemospecific isolation of substances in the determination of the primary sequence in proteins and particularly high-molecular-weight proteins, where the separation of complex peptide mixtures based on the differences between the charges, molecular sizes, hydrophobic properties, etc. frequently becomes relatively ineffective, gives rise to interesting prospects. There exist two versions of the chemospecific extraction of peptides for further structural studies. The first involves the interaction of the active carrier with the mixture of peptides obtained enzymatically or by chemical hydrolysis. Depending on the type of carrier and the amino-acid composition of the protein fragments, the reaction with the corresponding side groups of the peptides can proceed: the mercapto-group of cysteine[4,16,64,71-73], the thioester group of methionine[23], and the indole ring system of tryptophan[27]. After washing away the unreacted material, the peptides fixed covalently on the chemosorbent are dissolved by treatment with an appropriate cleaving agent.

The second method involves the fragmentation (enzymatic or chemical) of the reversibly immobilised protein directly on the carrier[49,74-78]. The carriers on an inorganic base (No.11, Table 1), which we proposed[48], proved useful in this instance[49], because the matrix consisting of macroporous silicon dioxide (silochrome) is stable under the conditions of different types of treatment of immobilised polypeptide chains such as pepsinolysis, trypsinolysis, cleavage with bromocyanogen, rupture of aspartyl–proline bonds (pH 2.2, 37 °C, 36 h), as well as the solid-state version of the determination of the peptide sequence by the Edman method. The fragmentation of the reversibly immobilised enzyme simplifies the isolation and identification of the peptides containing functionally important (essential) chemical groups in the active centres, provided that it is possible to select conditions ensuring the covalent fixation of only such groups of the active centre on the chemosorbent.

Generally speaking, it is not difficult to envisage the chemical separation of peptides on a series of carriers which selectively extract from the mixture the peptide (or peptides) containing a specific trifunctional aminoacid.

One of the problems in the solid-phase peptide synthesis is the elimination from a peptide with a specified sequence of the so-called "false" peptides, which are formed in the course of the synthesis mainly in consequence of the failure of the reactions to reach completion at various stages of the multi-stage process. A procedure has been proposed[79] for the isolation of the desired peptide by CSC. The essential feature of the method is that, after the completion of the synthesis of the required sequence, the peptide is augmented by the Cys–Met fragment (either consecutively, one residue at a time, or by adding the dipeptide at once) and then all the peptides obtained are separated from the insoluble support with simultaneous removal of the protective groups (for example, by treatment with HF). The treatment of this sum total of peptides by a sorbent chemospecific in relation to the SH groups removes the Cys–Met peptides from solution. All the remaining products are washed off. Peptides are removed from the chemosorbent by a low-molecular-weight thiol, the excess reductant being eliminated by gel filtration. Next follows the cleavage of the N-terminal dipeptide with bromocyanogen and repeated gel filtration. As a result, it is possible to separate many "false" peptides, particularly those whose chain growth was arrested during the synthesis for various reasons (*N*-acylation, the formation of a pyroglutamic derivative, the inaccessibility of the growing chain to the reactants in consequence of steric hindrance, etc.). Synthetic peptides on an Hg-containing carrier[79] and on a dipyridyl disulphide carrier[73] have been purified in this way. Clearly peptides containing methionine residues in the main sequence cannot be isolated in this way; in this case it is necessary to employ another selectively cleaved terminal fragment.

It has been shown recently[80,81] that CSC can be used for the elimination of non-protein substances from proteins and peptides. A carrier on an inorganic base has been used, which made it possible to use solvents and concentrated urea solutions to wash surfactants and lipid-like compounds out of the temporarily immobilised protein[81].

VI. CERTAIN METHODOLOGICAL PROBLEMS OF THE CHROMATOGRAPHIC PROCESS

When the two main stages of CSC, namely (a) covalent fixation of substances from solution on the carrier followed by (b) their deimmobilisation are carried out, it is necessary to remember that chemical reactions, at least those on the carriers known hitherto, do not take place instantaneously—a certain amount of time is required to complete the reactions. The stream of liquid through the material of the packing in the column must not therefore be very rapid, particularly in the column version of the process; the use of recirculation gives rise to satisfactory results in stage (a). There are few literature data for the gradient supply of the cleaving agent for the removal of the immobilised biomolecules from carriers. Nevertheless this deimmobilisation procedure apparently greatly improves the resolving capacity of the method as a whole.

Elution with stepwise changes in the strength of the cleaving agent has been used already in the first studies on CSC.[1,2] A model mixture of SH-proteins (mercaptoalbumin, glyceraldehyde-3-phosphate dehydrogenase, haemoglobin, and aldolase) have been separated by this method on a mercury-containing carrier (No.1, Table 1).[1] In order to rupture the mercaptide carrier–protein bonds, a reducing

agent (mercaptoethanol or dithiothreitol) was applied to the column, ensuring a linear concentration gradient, which made it possible to separate the required SH compound (factor XIII in the blood clotting system) from other thiol proteins linked to the chemosorbent, "by virtue of their different reactivities with respect to the cleaving agent"[67]. Strictly speaking, this version of the process actually constitutes a chromatographic separation of the substances and not simply a sequence of two operations: chemospecific sorption and desorption. It may be hoped that the separation of biopolymers by CSC using a cleaving agent gradient will be employed on an increasing scale.

Our data[80] show that the presence of a reductant concentration gradient in experiments with carriers of type (II) makes it possible to wash the protein off the insoluble phase with the minimum amount of the low-molecular-weight thiol required for this purpose, which greatly diminishes the risk of the intramolecular disulphide bonds of the protein itself being affected.

One should note a disadvantage which is encountered when carriers of types (II) and (II) are used. When the SH-containing product, initially fixed on the insoluble phase, is removed with a thiol, it is difficult to detect the biopolymer at the outlet from the column, since the residual "unused" active groups of the carrier are also cleaved by the reductant and are washed off together with the required products, which makes the ultraviolet detection of the eluted protein or peptide with the aid of the usual flow-type photometers virtually impossible owing to the intense absorption by 2-thiopyridone or 2-nitro-5-thiobenzoate. It is therefore necessary to analyse the material by some other method (for example by the gel electrophoresis of the fractions, by measuring, whenever possible, the enzyme activity, by chromatography—for peptides, etc.). It is thought that, at least for proteins and polypeptides, this disadvantage can be eliminated by employing a membrane eluate concentrator (model CEC1, Amicon, Holland) beyond the column, which cuts off the low-molecular-weight substances in the stream. The only important factor is that the change in the salt composition of the buffer occurring under these conditions does not cause a sharp impairment of the solubility of the biopolymers.

Finally we come to the last remark concerning experiments with SH-biopolymers or sulphur-containing carriers; it is always necessary to use deaerated buffer solutions; likewise it is extremely undesirable that even traces of heavy metal ions should be present. In order to bind such ions, EDTA is therefore usually introduced into the solution. These precautions guarantee the stability of the mercapto- and disulphide groups in the test compounds.

---o0o---

In conclusion one should note that chemospecific chromatography has now found an honourable place among other highly selective methods for the isolation and purification of biologically active compounds; it is developing vigorously, is being improved, and is being applied on an increasing scale to a wide variety of test objects.

During the preparation of the review for publication, reports have been published, describing the syntheses of certain chemosorbents[144-148] belonging to types (I)–(IV) described above and the isolation by the CSC method of peptides[149], proteins[144,145,148-161], nucleic acids[147,162], and fragments of membranes[163], as well as studies of certain methodological problems of the process[157,164].

Reproducibility of Retention and Identification Data in Gas-Liquid Chromatography

A.N.Korol'

The elementary sorption processes taking place in a chromatographic column are discussed. The reasons for the lack of reproducibility of retention data in GLC are analysed. The basic requirements for a chromatographic apparatus capable of giving high-precision retention data are formulated, and conditions suitable for the measurement of retention quantities for identification are recommended. 243 references.

I. INTRODUCTION

Gas chromatography was developed as a method of quantitative microanalysis of complex mixtures. In the early stages of its development the retention volume V_g was used[1-3] as the basic parameter for identifying the components of complex mixtures. However it was found that discrepancies in the measured values of V_g between different laboratories could be as high as 10–15%, and this led Adlard and coworkers[4] to recommend the use of the more reproducible Kovats retention indices for identification. Even this recommendation failed to solve the identification problem, because retention indices (I) measured in different laboratories were found to vary by 0.7 to 7.9 units, corresponding to an error of 1.6–12% in the measurement of retention volume. These discrepancies have focussed attention on the reasons for the unsatisfactory reproducibility of retention data obtained in different laboratories.

Careful studies of the sorption mechanism under GLC conditions have shown[5,6] that the retention data are affected not only by the gas–liquid separation coefficient K_l, but also by adsorption at interfaces and by the extent of curvature of the sorption isotherms: as a result, the retention data are a function of the amount of stationary phase deposited on the carrier (w_l) and of the sample size (q_S), i.e. of parameters which do not appear explicitly in the classical expression for calculating retention data. These conclusions raised doubts on the validity of retention data as a source of qualitative GLC information: in particular, it was stressed[7] that only in the most favourable circumstances can retention data be used to specify the order in which components will emerge from a column.

Yet the increasing precision of the measurement of retention data and the simplicity of the procedure are very attractive features of the use of these quantities for identification. The basic reasons for the lack of reproducibility of retention data measured in different laboratories have been investigated fairly fully, but the results have not yet been critically discussed in review articles, and therefore it is difficult at present to standardise methods of determining retention data †. This review aims to analyse the reasons underlying the lack of reproducibility of retention quantities, to assist the standardisation of experimental conditions, and to examine possible ways of presenting retention data for identification.

The general equation relating to net retention volume V_N to the parameters of the sorbent is[8]

$$V_N = \sum_i^k \frac{\partial V_N}{\partial V_i} V_i + \sum_j^m \frac{\partial V_N}{\partial S_j} S_j, \qquad (1)$$

where V_i is the volume of the i-th type (or state) of stationary phase, and S_j is the surface area of the j-th type of interface of the sorbent. Usually, with $w_l > 0{,}5\%$, the stationary phase on the surface of the solid carrier is present as a capillary liquid (index "c") or as an adsorbed layer (index "a")[9]. The following types of interface can be identified on the sorbent: solid carrier–stationary phase (index sl), capillary liquid–gas (index clg), and adsorbed liquid layer–gas (index alg). If all the distribution coefficients are constant Eqn.(1) can be written

$$V_N = K_{cl}V_{cl} + K_{al}V_{al} + K_{sl}S_{sl} + K_{clg}S_{clg} + K_{alg}S_{alg}, \qquad (2)$$

† The use of retention data for identification is discussed in the following recently published books: M.S.Vigdergauz, L.V.Semenchenko, V.A.Ezrets, and Yu.N.Bogoslovskii, "Kachestvennyi Gazokhromatograficheskii Analiz" (Qualitative Gas-chromatographic Analysis), Izd.Nauka, Moscow, 1978; Yu.N.Bogoslovskii, B.I.Anvaer, and M.S.Vigdergauz, "Spravochnik Khromatograficheskikh Velichin Uderzhivaniya" (Handbook of Chromatographic Retention Quantities), Izd.Standarty, Moscow, 1978; M.S.Vigdergauz, "Raschety v Gazovoi Khromatografii" (Calculations in Gas Chromatography), Izd.Khimiya, Moscow, 1978.

where K are the distribution coefficients of the sorbate between phases. With most of the sorbents commonly used in GLC ($w_l = 10-15\%$) over 90% of the stationary phase is in the form of a capillary liquid[9]: the contribution of the other four terms on the right-hand side of Eqn.(2) varies with the amount of stationary phase and with the nature of the carrier, and this is one of the main reasons for the lack of reproducibility of retention data between laboratories.

II. SOLUBILITY IN THE STATIONARY PHASE

When the stationary phase is first added to the carrier an adsorbed layer of liquid is formed: in the case of white diatomaceous carriers the formation of this layer is complete at $w_l = 0.3\%$, as shown by the existence of an optimum amount of modifier on the surface of the carrier[10-12]. Further additions of liquid phase produce two simultaneous effects: an increase in the thickness of the adsorbed layer, and the filling of the pores of the carrier by the "capillary liquid". The properties of the adsorbed layer of liquid are affected by the presence of the carrier surface, and they differ from those of the pure (or of the capillary) liquid, as shown by a decrease in the vapour pressure of the liquid[13,14]. There are reports[15] of differences in properties between the capillary and the pure liquid, though the theoretical analysis[16] suggests that substantial differences can be expected only for high-molecular stationary phases. The phase equilibrium constants for the pure and the capillary liquid (sorbates and sorbents of different polarity) have been found to be the same within experimental error (~1%).[4,17-20].

The effect of the carrier surface on the properties of the adsorbed liquid layer is discussed in Refs.21–26. It is found[27] that 5 monolayers of water and 10 monolayers of nitrogen are adsorbed on titanium dioxide. The effect of the solid surface on the properties of the adsorbed liquid can be detected at distances of up to 100 Å.[24] The upper temperature limit for the use of an adsorbed layer of stationary phase is found[28-31] to be higher in capillary columns than in packed columns. The thermodynamic properties of adsorbed and capillary liquids were found to be different[32,33], and an increase in density of a liquid in the adsorbed layer has been demonstrated by direct measurements[34]. Detailed studies[35-41] of the properties of layers of stationary phase adsorbed on diatomaceous carriers, silica gel, and graphite have established that the melting point of the compound increases by 4– K upon adsorption.

The retention volume (referred to the stability in the stationary phase, V_{Nl}) can be expressed as

$$V_{Nl} = K_{al}V_{al} + K_{cl}V_{cl};$$

and therefore, since $V_l = V_{al} + V_{cl}$, we can write

$$V_{Nl} = K_{cl}(V_l - V_{al}) + K_{al}V_{al}.$$

If the measurement is carried out at a sufficiently large value of w_l (such that only V_{Cl} is affected in changes in w_l) we can extrapolate the plot of V_{Nl} against V_l to $V_l = 0$ and obtain the extrapolated value V_N^{ext}:

$$V_N^{ext} = V_{al}(K_{al} - K_{cl}).$$

Evidently, $V_N^{ext} = 0$ for $K_{al} = K_{cl}$. It has been found experimentally[25] that $V_N^{ext} < 0$, i.e. $K_{cl} > K_{al}$.

Let us examine the case of a sorbate whose solubility depends on its concentration in solution. Liquid solutions usually have isotherms of the anti-Langmuir type[42-44], the only exceptions being solutions in which the activity coefficient is much less than unity[45]. The concentration dependence of the activity coefficient γ for non-electrolyte solutions is given by the Margules equation[46]

$$\ln\gamma = (1-x^2)\ln\gamma^{\infty},$$

where γ^{∞} is the activity coefficient of the solution at infinite dilution, and x is the mole fraction of solute. We can also use the Krichevskii equation[47], which is expressed in terms of the distribution coefficients $\tilde{K} = p/x$:

$$RT\ln\tilde{K} = RT\ln\tilde{K}^{\infty} - A_1x(2-x),$$

where A_1 is the concentration solubility coefficient and p is the vapour pressure in Torr. Replacing the parameter $\tilde{K}$ by the chromatographic distribution coefficient K_l, which characterises the ratio of the bulk concentrations, we obtain the equation

$$RT\ln K_l = RT\ln K_l^{\infty} + A_2x(2-x),$$

from which it follows that K_l increases with the concentration of the solution. A_2 is also a concentration coefficient. The concentration coefficients increase with the difference in polarity between the stationary phase and the sorbate[48]. It has been shown[20,49] that K_l varies with the concentration of the solution even if the solution obeys Henry's law: concentration-independent K_l values are found only in some solutions showing negative deviations from Raoult's law.

Thus, with a few exceptions, K_l is a function of the concentration of the solution, and therefore V_N also varies accordingly. Concentration effects are particularly strong in the chromatography of polar substances on non-polar stationary phases, as shown also by the molar heats of dissolution[20,50].

Differences in properties between the adsorbed and the capillary liquid are most conveniently revealed by comparing V_N values measured in capillary and in packed column (note that the adsorbed layer of liquid is more substantial in a capillary column than in a packed column). This type of comparison has shown[51-53] that the Kovats indices for hydrocarbons, their chloro-substituted derivatives, ketones, esters, alcohols, nitro compounds, and nitriles in squalane are identical for the two types of column, though the reproducibility of the retention data is unsatisfactory in the case of polar sorbates[52]. When polar stationary phases are used some differences between the retention data in capillary and in packed columns are observed[53].

III. THE SOLID CARRIER–STATIONARY PHASE INTERFACE

Though inertness towards adsorption is one of the main requirements for a chromatographic carrier, this requirement is never fully satisfied because all surfaces have an adsorption potential. Quantitative allowance for the effect of the carrier on the retention data was first made by Keller and Stewart[54], and the effect is discussed in detail in Refs.55–57. If adsorption at the *sl* interface is predominant the parameter V_N is given by the equation[58]

$$V_N/V_l = K_l\frac{K_{sl}S_{sl}}{V_l}. \qquad (3)$$

Extrapolation of plots of V_N/V_l against $1/V_l$ to $1/V_l = 0$ gives the constant K_l and the contribution of interfacial adsorption to V_N. A reference point method had been proposed[8] for calculating the adsorption contribution to V_N, but its precision is not high[59].

The effect of adsorption on V_N is especially marked when non-polar stationary phases are used to separate polar sorbates, and in this case it is very important to choose the carrier correctly. White and pink diatomaceous carriers have

different adsorption activities. Replacement of a pink carrier by a white carrier was found[60] to lower the adsorption contribution to V_N 2.5–3-fold. The lowest adsorption activity towards polar compounds is found in silanised white diatomites, which yield the most inert carriers (HP type) after heat treatment. A good example of such a carrier is Chromation N Super. The adsorption activity of diatomaceous carriers decreases in the following sequence of sorbates: amines > n-alcohols > iso-alcohols > carbonyl compounds > nitriles > nitro compounds > ethers > chloro-hyrocarbons > aromatic hydrocarbons > olefins > saturated hydrocarbons.

V_N for polar sorbates in non-polar sorbents is significantly affected by the nature of the carrier surface, and therefore the reproducibility of retention data in these systems can be problematic, since neither adsorbents nor carriers have fully reproducible properties. Evans and Smith[61] prepared a squalane and dinonyl phthalate sorbent with three different batches of silanised Chromosorb G: the retention indices for polar sorbates on these sorbents failed to show any differences arising from the different adsorption activities of the solid carriers. The effect of differences in the carrier on the retention data has been studied also by other workers[62–67].

Teflon has been recommended[68–70] as the ideal inert carrier, with the smallest possible adsorption effects: however, later work[61,71,72] revealed a high adsorption activity in Teflon towards low-polarity compounds, and Conder[73] showed that with the optimum amount (8%) of stationary phase on this carrier the contribution from adsorption to V_N is significant for all classes of sorbate.

Diatomaceous carriers have been found[74] to have a smaller contribution from adsorption to V_N than glass micro-spheres coated with n-octadecane.

Because of the adsorption effects at the *sl* interface fixed values of w_l must be used to ensure reproducible retention data from different laboratories. However the poor reproducibility of retention data for diatomaceous carriers arises from the curvature of the adsorption isotherm[54] as well as from adsorption. A typical manifestation of this effect is the "tailing" of peaks, and also the observed dependence of V_N on the size of the sample[75–78]. Obviously, this dependence may completely invalidate V_N as a source of information for qualitative analysis, and therefore the achievement of reproducible retention data in non-linear GLC has become a very important problem.

The effect of non-linearity in the adsorption isotherm for the *sl* interface is most marked in the separation of polar sorbates on non-polar or weakly polar stationary phases. In this case the molecules of the stationary phase are competing with those of the sorbate for adsorption on the carrier surface. Since diatomaceous carriers are polar, the molecules of the polar sorbate (in spite of their lower molecular weight) can penetrate close to the carrier surface and be adsorbed, the inhomogeneity of the carrier surface resulting in a non-linear adsorption isotherm[79–82]. When a polar stationary phase is used the sorbate molecules cannot penetrate the layer of adsorbed stationary phase, and the adsorption isotherm of the sorbate molecules on the energetically uniform adsorbed layer of stationary phase is approximately linear. With other (non-diatomaceous) types of carrier the general behaviour is very similar. Thus the adsorption isotherm of alcohols on Teflon coated with squalane is found to be curved[75].

The strong effect of sample size on V_N in polar sorbate–non-polar stationary phase systems can be ascribed to the curvature of the isotherm describing the adsorption at the *sl* interface (since the effect disappears when polar stationary phases are used). This prompted a search for methods of modifying the carrier surface to make it homogeneous towards interfacial adsorption. The first attempts were made in the early days of GLC [1,83] by adding a polar modifier (a fatty acid) to a weakly polar stationary phase used to separate a mixture of fatty acids. However the modifier did not prove to be universally effective. More recent attempts at modifying the carrier surface include the use of an inert polymer[84], silver[85], and copper[86], but even these were not fully successful in screening the active surface of the carrier.

The first successful results were obtained by chemically modifying the surface of the carrier (silanation[87,88] and polymerisation on the carrier[10,12,89]). Convincing results were obtained also by physical modification of the carrier with polar substances[31,90–92]. It was shown that not all polar liquids are suitable for physical modification: for example, poly(vinyl alcohol) is less successful than diglycerol as a modifier[11], and polyglycols (of different molecular weight) are now the most commonly used physical modifiers. When the carrier surface is coated with a thin layer of physical modifier the polar sorbate molecules are unable to reach the carrier surface, and adsorption is confined to the interface between the adsorbed layer of modifier and the capillary liquid.

"Self-modification" of the carrier surface under the influence of the polar sorbate can be important in the separation of polar sorbates on non-polar sorbents. In this case the sorbate peak has a highly extended trailing edge, and the carrier surface remains exposed to the modifying effect of the polar component (which influences its sorption properties) until that component has been completely eluted from the column. Therefore if the next sample is added to the column before complete elution of the previous polar sample grossly erroneous retention data may be obtained: thus in the case of ethyl methyl ketone on a squalane column the discrepancy can be as high as 50% in the retention volume and 1 kcal mole^{-1} in the relative molar heat of dissolution. Hence the retention data of these systems should be measured only by injecting pure compounds into the column, and the possibility of mutual effects of the sorbates on the individual retention volumes should be borne in mind when mixtures of polar substances are analysed.

Chemical modification by grafted polymers offers a useful increase in the maximum working temperature of sorbents. Thus sorbents modified with grafted Carbowax 20 M have been used (in conjunction with a flame-ionisation detector) at temperatures up to ~260 °C, i.e. well above the maximum working temperature of Carbowax 20 M.

The effect of adsorption at the *sl* interface on the retention indices can be observed also in capillary columns[93]. Thus it is found that the effect of the surface of a stainless steel capillary on the adsorption of the substances to be separated depends on the method of production of the capillary and on the treatment applied to its surface before deposition of the stationary phase: for example, thorough washing of the capillary surface with various solvents can increase its adsorption properties very markedly[94], though the optimum amount of solvent has to be used for the greatest effect. For this reason workers have turned their attention to glass capillaries[95], but the adsorption activity of glass was found to depend on the presence of sodium, boron, and hydroxyl groups[96,97]. The presence of OH groups causes irreversible adsorption of several polar compounds as well as introducing curvature into the adsorption isotherm[10,96,98–101]. Silanation[102,103], etching with hydrogen fluoride, and physical or chemical modification have been used to lower the adsorption activity of the surface of glass capillaries. One of the best methods is the glass surface deactivation procedure described in Refs. 10 and 12 and applied to capillary columns[104,105] in conjunction with etching with hydrogen fluoride[106]. After

being etched the capillary is coated with Carbowax 20 M, its ends are sealed, and the column is heated in a nitrogen atmosphere for 24 h at 280 °C. The physisorbed Carbowax 20 M is then washed out of the column with dichloromethane and methanol. However there is at least one report[102] of unsatisfactory reproducibility of the retention data after this treatment.

The extent of adsorption on the *sl* interface of capillary columns depends also on the purity of the stationary phase. For example it was shown[104] that "tailing" of the peaks of polar components occurs with SF-96 silicone oil but not with a high-purity grade of silicone oil (OV-101).

Thus the results discussed in this Section lead to the following recommendations for improving the reproducibility of retention data: a) only glass columns modified by Carbowax 20 M (or silanised) should be used in capillary chromatography; b) in packed columns, high-grade carriers of the Chromaton N Super type should be used, and non-silanised carriers should be chemically modified with Carbowax 20 M (amines and alkalis for the separation of amines, phosphoric acid for the analysis of acids); c) stationary phases of the highest possible purity should be used. These precautions should minimise the effects of adsorption at the *sl* interface (especially those associated with the curvature of the adsorption isotherm) on the effective value of V_N.

IV. ADSORPTION AT THE LIQUID-GAS INTERFACE

Adsorption of the compounds to be separated at the free surface of the stationary phase is possible[107]. A combination of static and chromatographic experiments[108,109] has shown that the value of V_N for the benzene–thiodipropionitrile and cyclohexane–thiodipropionitrile systems is significantly affected by adsorption at the *gl* interface.

Since the surface tension of non-polar stationary phases is relatively low we cannot expect large adsorption effects at the *gl* interface with non-polar or weakly polar stationary phases. Thus effects of adsorption at the *gl* interface on V_N were not detected in studies[110] of the retention of isooctane, cyclohexane, benzene, toluene, acetone, ethyl methyl ketone, and methanol on squalane and tricresyl phosphate: this result is consistent with other similar work[60,111,112]. However some workers consider[113–116] that V_N is affected by adsorption at the *gl* interface for polar sorbates in non-polar stationary phases, though their conclusions seem to be based on an incorrect treatment of the experimental results. Thus the change in $\ln\gamma$ brought about by an increase in the mole fraction of sorbate is treated[115] as a manifestation of interfacial adsorption, in spite of the anti-Langmuir shape of the adsorption isotherm (which suggests a concentration effect). Similarly erroneous conclusions are drawn from measurements[116] of sorption in dinonyl phthalate at high solution concentrations.

Polar stationary phases have a high surface tension, and adsorption at the *gl* interface is very marked on sorbents coated with stationary phases of this type, especially in the separation of hydrocarbons. For example, the adsorption contribution to V_N in the separation of hydrocarbons with thiodipropionitrile varies from 10 to 70%.[60] Similar effects were observed[117] for poly(ethylene glycol succinate).

A detailed study[118] of interfacial adsorption on a Carbowax 20 M column was based on the equation

$$V_g = V_g^{\infty} + k_1/w_l + k_2(1/w_l - 1/10);$$

where k_1 and k_2 are constants describing the contribution of adsorption at the *gl* and *sl* interfaces respectively. The coefficient 1/10 is introduced to allow for the authors' assumption[118] that when $w_l \geq 10\%$ adsorption at the *sl* interface is negligible.

The results of that study[118] lead to the following conclusions: a) the parameter k_1 increases along a homologous series, i.e. the contribution of adsorpton to V_N increases with the length of the alkyl radical, and it is negligibly small in the case of cyclic molecules; b) the k_2 values for isomeric ketones differ by ~10–15%, and this can affect the selectivity of stationary phases towards ketones (as compared to the solubility of ketones in the pure stationary phase).

The dependence of adsorption at the surface of the stationary phase upon the number of methylene groups in the alkyl radical of the sorbate can be expressed at[119]

$$K_{gl}^{p}/K_{gl}^{x} \approx (K_{gl})^{\Delta C},$$

where ΔC is the difference between the numbers of carbon atoms in the molecules of two compounds with the same retention volume, one of which is a n-paraffin (superscript *p*); the subscript *gl* denotes the gas-liquid interface.

Since the effect of adsorption at the surface of the stationary phase on V_N is usually smaller than the effect of adsorption at the *sl* interface it is useful to distinguish the systems in which the contribution to V_N of interfacial adsorption on the stationary phase surface is less than 1% by using the criterion[120]

$$K_{gl}/K_l < V_l/100S_{gl}.$$

As a rule the contribution to V_N of adsorption at the surface of the stationary phase can be ignored in systems with $\gamma < 5$, i.e. in the chromatography of substances of comparable polarity.

Liquid surfaces are energetically far more uniform than solid surfaces: for this reason the curvature of the adsorption isotherm is detectable only after completion of the first monolayer in the case of adsorption at the *gl* interface. Indeed, effects arising from non-linearity of the adsorption isotherm are observed[48] only at very low vapour pressures (~10^{-3} mmHg).

In GLC the stationary phase can be in two different energy states on the carrier, as was pointed out above. Hence it is correct to consider two types of adsorption at the stationary phase–gas interface: capillary liquid–gas adsorption and adsorbed liquid–gas adsorption. The properties of the two liquid surfaces are different, and as w_l is increased the area of the adsorbed liquid layer decreases while the area of the capillary liquid correspondingly increases. These differences can give rise to discrepancies between the retention data for polar stationary phases obtained with capillary and with packed columns.

V. EFFECT OF CHANGES IN EXPERIMENTAL CONDITIONS ON THE RETENTION VOLUME

Allowing for all possible sorption mechanisms we can write the following equation for real GLC situations (i.e. assuming normal analytical values of w_l):

$$V_N = \int_0^{V_{cl}} \left(\frac{\partial c_{cl}}{\partial c_g}\right) \mathrm{d}V_{cl} + \int_0^{V_{al}} \left(\frac{\partial c_{al}}{\partial c_g}\right) \mathrm{d}V_{al} + \\ + \int_0^{S_{sl}} \left(\frac{\partial q_{sl}}{\partial c_g'}\right) \mathrm{d}S_{sl} + \int_0^{S_{alg}} \left(\frac{\partial q_{alg}}{\partial c_g'}\right) \mathrm{d}S_{alg} + \int_0^{S_{clg}} \left(\frac{\partial q_{clg}}{\partial c_g'}\right) \mathrm{d}S_{clg},$$

where c_g is the volume concentration of sorbate in the gas phase, c_g' is the weight concentration of sorbate in the gas

phase (g ml^{-1}), c_l is the volume concentration of sorbate in the liquid, and q is the amount of adsorbed material (g cm^{-2}).

To a first approximation the terms of this equation can be evaluated separately as follows.

1) The distribution coefficient K_{cl} is the parameter which most directly determines the value of V_N: the smaller the activity coefficient, the greater is the contribution of solubility in the capillary liquid to V_N. If the system contains an average amount of stationary phase, and $\gamma \leq 1$, we can ignore adsorption effects on the retention volume (to a precision of 1%). This behaviour is observed in non-popar and weakly polar systems.

2) The distribution coefficient K_{al} has a substantial effect on V_N for low values of w_l. The contribution of this term to the relative retention quantities is small for $w_l > 10\%$.

3) The distribution coefficient K_{sl} can have a powerful influence on the retention, especially in systems consisting of a non-polar or weakly polar stationary phase and a polar sorbate. The numerical value of this distribution coefficient is significantly influenced by the size of the sample.

4) The distribution coefficients K_{alg} and K_{clg} can affect V_N when the stationary phase is polar and the sorbate is weakly polar or non-polar. These effects can be ignored (to a precision of 1%) for $\gamma < 5$ and normal values of w_l.

Since in a real chromatographic system the relative contributions of these sorption mechanisms depend on the experimental conditions it is interesting to consider the way in which the basic solubility characteristic (V_g) varies as w_l increases. As the stationary phase is first added to the carrier a film of adsorbed liquid is formed on the solid surface, but further additions of stationary phase cause a shrinkage of the *gl* interface due to the filling of capillaries and pores. The increased amount of capillary liquid on the carrier lowers the adsorption contributions to V_N: the combined result of all these effects is to lower V_g to ~10–15% as stationary phase is added to the carrier. Still further additions of stationary phase to the sorbent has practically no effect on the surface area of the *gl* interface, and the amount of adsorbed liquid also remains constant. Only the amount of capillary liquid on the carrier increases. Since the components of the mixture are more soluble in the capillary liquid than in the adsorbed layer, a small (~3–8%) increase in V_g is observed[25,121] as w_l increases beyond 15%, but V_g becomes independent of w_l when $w_l > 30\%$. As a result, reproducible inter-laboratory comparisons are obtained only with sorbents for which $w_l \cong 12$ to 15% (i.e. sorbents for which the dependence of V_g on w_l is a minimum).

There are various recommendations[18,122] on methods for obtaining invariant qualitative retention data by extrapolating plots of V_N/w_l against $1/w_l$ to $1/w_l = 0$ [see Eqn.(3)], and the K_l values obtained by this method are affected only by the solubility in the capillary liquid. However the method is laborious and the measurement of w_l has a low precision, and therefore the results are of doubtful value. Furthermore the non-linear dependence of V_g on w_l at fairly high values of w_l limits the validity of extrapolations from experimental data. However if we wish to identify the components of a complex mixture we are unlikely to achieve satisfactory separation over a wide range of w_l values. Therefore it is preferable to adopt a fixed value of w_l (~12–15%) in order to achieve reproducible measurements of retention data.

1. Size of Sample

The effect of sample size on V_N is usually caused by the non-linearity of the adsorption isotherm. The concentration of sorbate at the maximum of the chromatographic band c_g (in the gas phase) falls as the band travels along the column [Eqn.(49)]. The parameters of this equation are the effective diffusion coefficient D, the column length L, the velocity of the carrier gas u, and the sorption coefficient per unit length of column K' [123]:

$$c_g = \frac{q_s}{3.54K'\sqrt{DL/u}}. \qquad (4)$$

The steepest fall of c_g occurs near the inlet of the chromatographic column, where deviations from Henry's law can be expected; at large enough values of L the retention is affected more markedly by the curvature of the isotherm which describes the adsorption at the interface. Allowing for both dissolution and adsorption gives a complex picture of the dependence of V_g on L: as the column length is increased V_g initially decreases, before going through a shallow minimum. This minimum occurs at a column length of ~1 m, and therefore it is desirable to use columns with $L \geq 1$ m when the aim is identification of the components[48].

For a constant column length the variation of V_N with q_s also goes through an extremum, with a much sharper minimum in the region of mutual compensation of the dissolution and the adsorption isotherm, which creates an apparent independence of V_N on q_s.[48] This region can be very narrow (as in the alcohol–squalane system) or relatively broad (five orders of magnitude of q_s for the benzene–squalane system). For practical reasons it is preferable to measure retention data in the region of the minimum of the V_N–q_s relationship.

However in a real GLC apparatus it may be impossible (for a number of reasons) to measure retention data in the region of the minimum. This is the case, for example, in the analysis of trace impurities (especially, in the atmosphere) when the size of the sample is insufficient to bring the measurement to the region of the minimum and the retention volume is affected by the curvature of the adsorption isotherm. In these circumstances we can resort to one of the following procedures: a) measure V_N at a fixed value of q_s or at a fixed peak height h, or b) extrapolate V_N to infinite dilution of the solution. The latter variant implies adsorption and dissolution in the Henry's law region: it is very attractive, but in the majority of non-linear systems it has to be operated at the limit of sensitivity of the detector, with signals not much above noise level, and therefore it may be impossible in practice to work with sufficiently low sorbate vapour pressures. However for theoretical work the second variant is undoubtedly very important.

The first variant is by far the more important in practical work. In order to use it we must know the dependence of V_N on q_s or on h: the V_N values for fixed values of h or q_s are found by interpolation from experimental data. Retention data obtained at a fixed value of q_s lack physicochemical meaning, because (at different column temperatures) they correspond to different vapour pressures of sorbate and different degrees of column loading (or solution concentration), i.e. these data are neither isobaric nor isosteric[58]. Values referred to a fixed value of h are more useful, because they correspond to isobaric experimental conditions[45].

Various ways of obtaining invariant retention data in non-linear GLC have been proposed. One method[74] involves extrapolation of the concentration-dependent part of the dependence of V_N on q_s to infinite dilution. Thus it was shown experimentally[74] that the V_g values for n-propanol and diethylamine in heptadecane and dioctyl ether are identical for 10 and 15% concentrations of the stationary phase on the carrier when referred to infinitely dilute solutions. Other workers[124] allowed for adsorption effects by correcting the retention data extrapolated to infinite dilution for the amount of stationary phase in the column, as recommended in Ref.45.

Though the data were processed on a computer, there is some uncertainty in the extrapolation of the non-linear relationships, leading to an error of at least 1–1.5%. The method is laborious, and it gives a low precision in the measurement of w_l.

The measurement of retention data under isosteric conditions is described in Ref.45: the value of h at which V_N is measured is chosen by using the expression

$$h_j/h_0 = V_{Nj}/V_{N0} = V_{lj}/V_{l0}. \quad (5)$$

The measurements are made by using a set of columns [from zero to j, see subscripts in Eqn.(5)] containing different amounts of stationary phase. Since fairly high concentrations of solution are permitted, a significant proportion of the sorbate may be in the gas phase. We allow for this effect by introducing the concentration of sorbate in the gas phase (y) and the Martin compressibility factor (J). Isosteric solubility data are obtained by extrapolating the plot of $V_N/V_l(1-Jy)$ against $1/V_l$ to $1/V_l = 0$. The value of V_N at the given value of h is obtained from the trailing, diffuse edge of the peak, but this procedure causes substantial errors arising from the diffusion processes in the column. On the whole the method can be very useful in physicochemical research but it is difficult to exploit in practical analytical GLC.

Reproducible retention data in the adsorption region of the dependence of V_N on q_S (i.e. for sample sizes more typical of analytical GLC) can be obtained by using the equation[125,126]

$$V_N = A_3/\lg h + B, \quad (6)$$

where A_3 and B are constant. The region over which this equation is valid is limited to 2–5 orders of magnitude of h, but within this region we can evaluate V_N at any value of h by interpolation of plots of V_N against $1/\lg h$. Eqn.(6) was derived on the assumption that the interfacial adsorption in GLC (which makes the greatest contribution to adsorption at the sl boundary) is described by the Temkin isotherm equation: its validity has been demonstrated with a large number of systems, including a polar sorbate in a non-polar (or weakly polar) stationary phase.

Eqn.(6) can be used to obtain isobaric or isosteric retention data under given column operating conditions. For example, isobaric data could be obtained for $1/\lg h = 0.3$ (flame-ionisation detector; full-scale deflection 10^{-11} A; all values of h recalculated for this sensitivity and expressed in mm; specified column length, amount of stationary phase on the carrier, and velocity of carrier gas). In this way the experimental conditions can be standardised sufficiently to give reproducible retention data in different laboratories for non-linear GLC.

Isosteric retention quantities are often useful for calculating thermodynamic values: these can be calculated by inserting into Eqn.(5) the V_N values for given values of h obtained by interpolation from Eqn.(6).

2. Time-changes of the Sorption Properties of Columns

At high column temperatures the low-molecular fractions of the stationary phase can evaporate from the first parts of the column[21,127–130], causing a change in the selectivity of the column with time. Data on the separation of alcohols on a poly(ethylene glycol) column have shown[21] that the slope of the $\ln V_g - 1/T$ plot is not affected by evaporation of the stationary phase from the first part of the column, though the straight lines are shifted along the ordinate axis: this suggests a constant molar heat of sorption and a varying molar entropy of sorption, which is typical of an adsorbed liquid layer[48]. Thus the adsorbed layer has a greater temperature stability than the capillary layer, and initially only the capillary liquid evaporates from the first part of the column while the adsorbed layer remains on the carrier. The evaporation of some of the stationary phase from the first part of the column causes a local increase in concentration of the solution and a significant influence of interfacial adsorption on the retention data, which increases the dependence of V_N on q_S. This phenomenon sets a limit to the range of column temperatures consistent with reproducible retention results: the highest temperature at which a stationary phase is used should be 30–60 K below the usually recommended value. The use of large samples can also contribute to the loss of stationary phase from the first part of the column[130].

The time-changes in the properties of the column due to evaporation of the stationary phase are relatively slight. Far more serious obstacles to the acquisition of reproducible retention data arise from changes in the chemical composition of the stationary phase. Thus prolonged heating of squalane at 80 °C is found[131] to increase the concentration of lower hydrocarons from 6.1 to 14.7%: this effect is accompanied by changes in the relative retention volume of n-pentane, n-hexane, and benzene by 1.0, 2.5, and 1.5% respectively.

The most serious problems in the acheivement of reproducible retention data arise from the formation of polar compounds, which modify the surface of the carrier. These reactions usually occur at high temperatures in the presence of traces of oxygen (introduced by the carrier gas). Thus the passage of oxygen through a squalane column at 100 °C has been shown[132] to lower the retention index of polar compounds by more than 40 units, and similar effects have been observed in columns containing octadecanol. This behaviour is consistent with the formation of polar compounds as a result of the oxidation of squalane. The retention of polar (or readily polarisable) compounds is very sensitive to the concentration of impurities belonging to other classes in the squalane[133]: for example, in the presence of 0.1% of squalene the Kovats index for aromatic hydrocarbons is altered by 0.15 units.

Many commercial stationary phases consist of a mixture of polymers of different molecular weight (for example, polyglycols). The influence of molecular weight distribution on the selectivity of the stationary phase has been studied[134,135] in the poly(ethylene glycol) system (PEG). A comparison of three different PEG of average molecular weight 400 but prepared from individual PEGs taken in different proportions revealed an arithmetic mean deviation of the Kovats indices on these sorbents varying from 1.4 to 4 units. Alcohols are especially sensitive to changes in composition of the PEG, because of the change in the number of free hydroxyl groups in the stationary phase. However after prolonged operation at the highest permissible working temperatures, which cause partial evaporation of the lower fractions from the column, the spread of retention indices of PEG columns operated with different sorbents was only 0.4–0.8 units (i.e. of the same order as the experimental error).

The selectivity of the stationary phase is affected not only by the number of polar (active) functional end-groups per unit volume, but also by the molecular weight. The latter effect is observed also in stationary phases of the paraffin type, which do not contain functional groups[136–138]. It is stressed[136] that the polarity of the paraffin stationary phase increases with its molecular weight. These observations underline the importance of careful purification of the stationary phase when reproducible retention data are required, and the disadvantages of using stationary phases consisting of mixtures of polymers.

The water content of the sorbent can also influence the retention of polar compounds on non-polar stationary phases[81], and also of all classes of sorbate on polar stationary phases[134]. When non-polar stationary phases are used the *sl* interface is modified by the presence of water in the sense of decreasing the retention of polar compounds. Moisture in PEG produces a sharp fall in V_g for all sorbates, but the original properties of the sorbent can be recovered by drying.

The column history (i.e. its length of service, and the nature of the mixtures which have been analysed on the column) can have a significant effect on the retention properties, especially in columns with non-polar or weakly polar stationary phases. It has been pointed out[139] that in stainless steel capillary columns the retention index for hydrocarbons changes after prolonged operation, and adsorption effects increase at the same time. Thus after 1200 h operation of the column using Apiezon L the Kovats indices for cyclic and aromatic hydrocarbons increased by 2–3 units, an effect ascribed[139] to the catalytic activity of stainless steel towards the oxidation of Apiezon oil. No such effects were observed on glass capillaries.

After 3 years' operation between 50 and 70 °C with hydrocarbon mixtures the Kovats index for aromatic hydrocarbons of a stainless steel capillary column containing squalane changed by less than 0.1 unit[140], but when the same column was operated between 80 and 95 °C for several weeks the Kovats index for aromatic hydrocarbons rose by 0.2 units. The highest permissible operating temperature of stainless steel columns containing squalane can be inferred from these results. Operation of the same column for 6 years at temperatures between 86 and 130 °C produced a 10 unit change in the Kovats indices for aromatic hydrocarbons, and a 2 unit change in the indices for alkenes.

If polar stationary phases are used the retention data are unaffected by adsorption at the *sl* interface, but the role of adsorption at the *gl* interface becomes much more marked (depending on the concentration of impurities in the stationary phase, since these impurities become concentrated at interfaces). The impurity content can vary during the operation of the column: thus after three months' operation of a column containing acetyl tributyrate the relative retention of paraffins varied by 0.5%, whereas that of aromatic hydrocarbons (which are less sensitive to this type of adsorption) varied by only 0.1%.[140] On a highly polar stationary phase (1,2,3-*tris*-(2-cyanoethoxy)propane) at 94 °C the retention indices of aromatic hydrocarbons vary by 0.3 units per day as a result of differences in the adsorption of n-paraffins (introduced as standards) on the stationary phase[140].

Some interesting observations on the ageing of sorbents in packed columns have been reported[81]. After treatment of a squalane sorbent for 35 h at 110 °C in a stream of nitrogen the V_g value for n-propanol falls off sharply, and similar effects are observed after prolonged heating in vacuum or refluxing of the sorbent under hexane[141,142].

Thus the basic reason for the lack of reproducibility of retention data in analytical GLC is interfacial adsorption, coupled with the non-linearity of the isotherm describing this adsorption. We must stress that interfacial adsorption effects are most marked in systems consisting of molecules of different polarity, which form non-ideal solutions (with $\gamma > 5$). Under these conditions it is most important to choose and standardise the experimental conditions carefully in order to optimise the reproducibility of the retention data. In other types of system these requirements are less stringent unless the highest precision is required (errors of less than 0.1% in the relative retention and 0.05 units in the retention indices).

VI. METHODS OF PRESENTING RETENTION DATA FOR IDENTIFICATION

In this Section we shall discuss the "apparatus" errors in the measurement of retention parameters and we shall propose rational methods of calculating retention quantities for later use in inter-laboratory identifications and comparisons.

1. Specific Retention Volumes

Theoretically the parameter V_g is independent of the amount of stationary phase in the column, but it is influenced by variations in the velocity of the carrier gas and the temperature of the column. Both temperature fluctuations and temperature gradients can affect V_g. In commercial apparatus the temperature of the column thermostat is controlled to give fluctuations of less than 0.1 K and local temperature differences of less than 0.5 K along the column. In many of the currently available models the flow rate of the carrier gas is automatically controlled, but nevertheless some modifications to the gas control part of the apparatus are usually needed for the highest precision in the measurement of V_g.

The first high-precision chromatograph for the measurement of retention is described in Ref.143. Subsequently several papers on high-precision chromatography were published, with emphasis on achieving a constant flow rate of the carrier gas and a constant column temperature, and on accurate measurement of the main parameters of the chromatographic experiment. The most successful development was an apparatus with manual (semi-automatic) control[131], in which the input pressure was measured with a standard deviation of 0.24 mmHg, the output pressure with a standard deviation of 0.1 mmHg, and the column temperature to ±0.05 K. An *a-priori* calculation of the possible standard deviation s^0 in the measurement of V_g gave a value of 0.19%.

According to error theory, the overall error of the experiment is determined mainly by the two or three experimental parameters which introduce the largest errors. In the measurement of V_g the precision is limited by the error in w_l: in packed columns the standard deviation of this parameter is $s^0 = 0.16–0.32\%$, and in capillary column $s^0 = 0.24–0.42\%$.[131] An additional error in the measurement of V_g in capillary columns arises from the difficulty of measuring small gas-flow rates accurately.

We can measure w_l by weighing the sorbent before and after filling the column, and extracting the stationary phase from the sorbent after removing it from the column[131], but it is important to allow for the loss of stationary phase during activation of the column. The "burning off" and extraction of the stationary phase from the sorbent could be incomplete if some of the stationary phase becomes chemically bound to the surface of the carrier by the high-temperature activation[10]. The error of the measurement of w_l in the column determines the overall error of the measurement of V_g (0.15%), even if the chromatographic apparatus is ideal in all respects. These problems explain the large scatter of V_g values reported from different laboratories[144]. Thus we cannot recommend the use of V_g as a reliable criterion for identifying the components of a mixture from retention data.

2. Absolute Retention Volume

This parameter does not require measurement of w_l, and therefore its measurement error is lower than that of V_g. For qualitative analysis the parameter has a serious drawback: its dependence on w_l. Hence it cannot be recommended for

identification in GLC. However it is useful to analyse the sources of error in the determination of V_N, because they explain the shortcomings of various methods of measuring relative retention characteristics widely used in qualitative analysis.

The errors in the measurement of V_N with a soap-bubble gas flow-meter are discussed in detail in Ref.145. Before analysing these errors we should stress the requirement for high efficiency of the chromatographic column used to measure the retention data, since this parameter does not appear in the classical equations for calculating the errors of the measurement of V_N. The efficiency of the column affects the precision of the measurement of retention quantities through two parameters: a) it is essential to work with a sharp, narrow, steep-fronted peak in order to obtain an accurate measurement of the time of emergence of the peak from the column, and b) in the measurement of retention data for mixtures it is important to achieve separation of the components as early as possible in order to avoid mutual interactions. In order to locate the peak maximum with a precision of 0.1% the efficiency of the column should be at least 500 theoretical plates[145]. However it has been suggested[146] that a column efficiency an order higher is needed to achieve this level of precision, but the arguments used are not convincing.

When retention data are determined simultaneously for several components displacement effects and interactions between incompletely resolved bands are possible. The displacement effect consists in the replacement of the less strongly sorbed by the more strongly sorbed components, which decreases the retention time of the less strongly sorbed components. It has been shown[145] that in the case of two poorly resolved bands the appearance time of the first peak is shorter, and that of the second peak is longer, than the corresponding times for the pure components, but this phenomenon does not appear to involve the mutual solubility of the components[147]. In general the separation criterion should not be less than 3 to ensure that the mutual effect of the components on their measured retention is less than 0.1%.[145]

a) Measurement of the retention time of a non-sorbed gas (t_0). The method of measuring this quantity depends mainly on the type of detector used. With a katharometer it is convenient to measure t_0 by the appearance time of helium or other inert gas. However inorganic gases are not detected by a flame-ionisation detector, and therefore in this case it is convenient to use methane: at a column temperature of 100 °C the appearance times of air and methane are indistinguishable, but at lower temperatures the sorption of methane can cause a systematic error in the measurement of t_0.[148]

A more correct method of measuring t_0 with a flame-ionisation detector is to determine the retention time of helium against a background provided by the diffuse trailing edge of any other peak (vacancy chromatography method) at a high setting of the detector sensitivity, or by injecting a sample of helium into the column with nitrogen containing a trace of methane as the carrier gas (the function of the methane being to provide a steady base-line detector current[149]). A base-line detector current can also be produced by raising the column temperature until the vapour of the stationary phase or of its decomposition products appears at the column outlet. In every case the helium sample is detected as a negative peak.

Many of the recommended methods of calculating t_0 [150-153] rely on linear approximations of the retention data for n-paraffins. However a comparison[117] of calculated and experimental values of t_0 clearly shows the greater precision of the values obtained experimentally.

b) Measurement of the retention time of the component under study. The appearance time of the peak maximum of a component can be measured as the distance (on the chromatogram) between the sample injection and the appearance of the peak, or it can be measured directly with a stop-watch. If the former method is used the measurement error can be considerable[154]: a 2 s error in the sample injection marker, a 30 s error due to variations in chart speed, an additional error of 2% due to the effect of mains frequency fluctuations on the chart speed, and a 10 s error in locating the peak maximum. It is usually easier to measure the retention time with a stop-watch, when the error is less than 0.02% for retention times of >10 min. In this method the overall error is at least four times smaller than in the determination of retention times from measurements of length on the chromatogram[155]. However the latter method is convenient because it does not require the presence of the experimenter at the appearance time of the peak: it is often used, therefore, in approximate measurements.

Electronic chronometers offer a high precision for the measurement of the appearance time of individual peaks, but this precision cannot be exploited to the full because of the limitations of the experimenter's reaction times (0.1–0.3 s). By using a computer to detect the injection of the sample and to measure the appearance time of the peak we can reduce the error of the measurement of retention time 5–7-fold in the case of a non-polar stationary phase, but if the sorbent is coated with a polar stationary phase the precision is not significantly improved by using a computer[94].

The absolute error of the measurement of retention time is proportional to the retention time, and for very long retention times the relative error of the measurement is constant[156].

In addition to the errors associated with the measurement of retention time, which can be minimised, we need to consider errors in the determination of retention time arising from instability of the experimental parameters. These errors are mainly responsible for the overall experimental error of measured retention times[157-167].

Stable conditions for the measurement of retention times are most easily obtained by using a computer-controlled chromatograph, especially in the separation of complex mixtures of many components[22,160-164]. Conventional electronic proportional temperature controllers can stabilise the temperature of the column thermostat to within 0.05 K, and this uncertainty can be lowered to 0.02 K by using computer control[165,166]. The fluctuations in the flow rate of the carrier gas can be less than 0.1 ml min^{-1} with computer control. Some workers recommend the use of liquid-filled thermostats[167], which offer a temperature stability ranging from 0.0025 to 0.01 K, but these thermostats also have a number of shortcomings (corrosion of the apparatus, high thermal inertia, and large temperature gradients along the column). Air thermostats can give temperature differences as low as 0.02 K in the vertical direction and 0.2 K in the radial direction[168].

The use of computer control of the operating parameters of the column can greatly reduce the lack of reproducibility of the experimental conditions but it cannot eliminate it completely. Therefore allowance for the residual fluctuations of the experimental parameters, and appropriate corrections to the measured quantities, are as important as control[163,169,170]. All the experimental parameters were measured at intervals varying from 0.05 s to several seconds and the retention volume was obtained as the sum of micro-elementary volumes corresponding to the measured column temperatures and carrier gas flow rates[171]. The detectors were thermo-anemometers, manometers, and resistance thermometers: for a column temperature stability of 0.01 K and a pressure measurement precision of 0.05 mmHg the standard deviation of

the measurement of retention volume of n-heptane in octadecane at 60 °C was 0.43% with manual processing of the data and 0.02% with computer processing[171].

Thus by using commercial apparatus with appropriate modifications to the gas handling system the standard deviation of the measurement of V_N is 0.1–0.2%: an order of magnitude improvement in precision is possible by using computer control and data processing methods.

3. Relative Retention Volume

This parameter was first proposed for the identification of components in 1952 [172]: its value is independent of the amount of stationary phase (if interfacial adsorption is negligible), but it is affected by changes in the flow rate of the carrier gas and by changes in column temperature.

The precision of the measurement of relative retention volume (r) can be raised by correctly choosing the reference standard. With high-grade apparatus the method of introducing the standard does not affect the error of the measurement of r: it can be introduced with the components of the mixture to be analysed, or after each analysis, or even after several analyses[156]. A 20–50% improvement in precision in the measurement of r by introducing the standard as part of the unknown mixture (rather than separately) has been reported[139]. However adding the standard as part of the mixture is legitimate only when the peak of the standard is completely resolved from those of the unknown components, and therefore the retention times of the components are unaffected by the presence of the standard. The best compromise is to add the standard to the column once every 2–4 h, depending on the stability of the control of experimental conditions.

The standard substance should appear at the outlet of the column in 5–15 min, its adsorption at the interfaces should be negligibly small, and it should be readily available. For these reasons aromatic hydrocarbons are often used as standards, since their adsorption at the *sl* and *gl* interfaces makes a negligible contribution to V_N, and the compounds are easily obtained. For example, at low temperatures (up to 100 °C) benzene can be used as a standard, naphthalene at temperatures up to 200 °C, and anthracene or phenanthrene at still higher temperatures.

In general r can be measured with any arbitrarily chosen standard, but if the results are to be published and used in other laboratories for qualitative analysis they should be recalculated on the basis of one of the above standards. This involves determining the r value of the arbitrary standard with respect to one of the aromatic hydrocarbons. In the R_{x9} system of r values with a single standard[101,173,174] n-nonane is used as the standard compound: the reproducibility of the measurement of retention indices in this system is given as 10. An important disadvantage of the use of a n-paraffin as the standard is the large contribution to V_N from adsorption at the surface of the stationary phase when polar liquids are used.

In the early experiments[175] the error in the measurement of r was 0.5%, but the use of computers has lowered this error to 0.02% [168,176–180]. With manual processing of the data the error of the measurement of r in glass capillary columns was 0.16–0.19% for OV-17 silicone oil, 0.26–0.28% for Carbowax 20M, and 0.38–0.55% for SF-96 silicone oil[181]; the increase in error caused by the last two stationary phases is probably due to poor wetting of the capillary surface by the liquid and hence to adsorption at the glass–gas interface[182]. In stainless steel capillary columns the error in the measurement of r is slightly higher[183].

4. Systems of Retention Indices

A detailed mathematical analysis of the errors in the calculation of retention indices has been published[156,184–186]. The first report of high reproducibility in the measurement of retention indices was made in 1970 [187], and it was shown that the error in the measurement of retention indices can be decreased by an order of magnitude by using a computer. The conditions for precise measurement of the retention indices are formulated in Refs. 131, 188, and 189, and an error of 0.03 units was claimed[94]. Sojak and Rijks[140] describe the conditions which allow the retention indices of hydrocarbons on squalane to be measured with an error of 0.02 units. Attempts to calculate retention from the centre of gravity rather than from the apex of the peak[190,191] failed to reduce the error below 0.05 units.

The reliability of the determination of retention indices on capillary columns is discussed in detail in Ref. 140. Changes in the input pressure of the carrier gas from 2.5 to 4 atm produced changes of 0.08–0.13 units in the retention indices of hydrocarbons when hydrogen was used as the carrier gas, whereas with nitrogen as the carrier gas the retention indices varied by 0.27–0.33 units when the pressure at the column inlet was varied from 1 to 4 atm. Within the limits of experimental error (0.05 units is the retention index) there was no effect from changes in helium pressure. The response to changes in carrier gas pressure increases in the sequence paraffins < alkenes < cycloparaffins < aromatic hydrocarbons[140].

In Kovats' conventional system of retention indices the standard components are n-paraffins, for which the retention data on polar stationary phases are strongly affected by interfacial adsorption (leading to poor reproducibility). It was pointed out[119] that the error in the calculation of the retention indices increases with the polarity of the stationary phase. According to Bonastre and coworkers[118] a change from 10 to 30% in the w_l value of Carbowax 20M on a sorbent increases the retention indices from 14 to 22 units because of the decreased retention of n-paraffins. In order to overcome this difficulty the use of a homologous series of n-alcohols as standards is proposed[192] when polar stationary phases are used. This suggestion is not incompatible with the concept of a system of retention indices, based on the assumption of direct proportionality between $\lg V_N$ and C (where C is the number of carbon atoms in the molecule) for a homologous series[193,194].

The desirability of choosing polar standard substances when polar stationary phases are used has been stressed by many workers[122,133,195–203], with a tendency to use as standard the homologous series whose members are being studied. However there are objections to the use of a homologous series as standard on polar sorbents, because interfacial adsorption increases sharply with the length of the alkyl radical and this lowers the reliability of the results. Another important shortcoming of the retention index system is the assumed linear dependence of $\lg V_N$ on C, which does not apply in a number of systems[193,204–206]. Deviations from linearity arise from the parity rule[206], and from the interaction of methyl groups[207], which led to the principle of non-calculability of the indices (according to which the linear dependence of $\lg V_N$ on C is only approximate, with a confidence interval of two units). When the molecules of the stationary phase contain aromatic rings the relationship is no longer linear[204].

The consistency of retention indices obtained in different laboratories has been analysed in several papers. The error in the measurement of the retention index from data reported by different laboratories is stated[140] to be 0.2 unit, but we should note that recalculation of the quoted results[140] gives

an error varying from 0.6 to 1.5 unit. The discrepancies between retention indices obtained in different laboratories may be due to effects from the material of the capillary column or to changes in composition or in concentration of the stationary phase during operation of the column. Thus it has been shown[208] that after high-temperature activation of a non-polar capillary column the retention index of aromatic hydrocarbons varies by 8 units. Standardisation of the capillary surface is said[94] to lower inter-laboratory discrepancies (to 0.2 unit of index). The work of Schomburg (quoted in Ref.155) has shown that if the capillary columns are prepared in one laboratory and distributed to other laboratories the discrepancy between the results is less than 0.05 unit, whereas if the columns are prepared in the different laboratories the reproducibility falls to 1 unit.

A careful comparison of the retention data for n-paraffins on squalane obtained in different laboratories under a satisfactorily controlled experimental conditions is given in Ref.209: the error varies from 0.09 to 0.28 unit whereas the reproducibility within each laboratory is 0.025 unit. For an internal reproducibility of 0.2 unit[19,95] an inter-laboratory comparison gave a discrepancy of 1 unit[95,205-213]. Hence the consistency of the retention quantities between laboratories is 4–5 times worse, on average, than the measurement error within one laboratory, though we should note that all these results apply to systems in which the retention of the components is almost unaffected by adsorption effects. When the influence of interfacial adsorption is not negligible the above recommendations for achieving reproducible retention data must be strictly observed.

In conclusion we shall briefly dwell on some systems of retention indices which have been developed to remedy the shortcomings of the Kovats system. In view of the non-linearity of the dependence of $\lg V_N$ or C Matukuma[214] proposed a new form of index in which three successive homologues of the n-paraffin series are used as standards:

$$I_w = 100C + \frac{\lg(1 + i/a - i/b)}{\lg(b/a)} 100,$$

where $i = t_{Nx} - t_{Nc}$, $a = t_{Nc} - t_{N(c-1)}$, $b = t_{N(c+1)} - t_{Nc}$, t_{Nx} is the appearance time of the unknown component, and t_{Nc}, $t_{N(c+1)}$, $t_{N(c-1)}$ are the appearance times of the n-paraffins with the same number of carbon atoms as the unknown, one carbon atom fewer, and one carbon atom more respectively. Though this system of indices yields more accurate results it suffers from a loss of generality in comparison with the Kovats system.

The arithmetical indices proposed by Vigdergauz[215] are the simplest form of indices:

$$I_a = \frac{t_{Rx} - t_{Rc}}{t_{R(c+1)} - t_{Rc}},$$

where t_R are the appearance times of the components uncorrected for the dead volume of the column (the unknown components and the n-paraffins with the same number of carbon atoms). Expressions relating the arithmetic indices to the Kovats indices have been obtained[216-218], and some applications of the arithmetic indices have been described[219,220]. Though the calculation of the arithmetic indices is extremely simple the indices are not particularly useful because they contain no physicochemical information and they lack the generality of the Kovats indices for identification.

The differences between different systems of retention indices are not fundamental in principle, and the choice of a particular type of index is usually dictated by tradition or by convenience. Evidently, the Kovats index was historically the first and it will continue to be widely used in analytical practice.

5. Comparison of Different Methods of Presenting Retention Data

The basic characteristics of the four most widely used retention parameters are compared in the Table. The specific retention volume V_g has some important advantages over the other parameters because it contains physicochemical information, but it cannot be recommended as an identification parameter because the precision of its measurement is low.

The relative retention volume r and the Kovats index I are similar in many ways, and the choice between them is often a matter of convenience or tradition. The parameter I lends itself particularly well to calculations by the additivity principle: any n-paraffin with an appearance time comparable to that of the unknown component can be used as standard for the calculation of this parameter. However with polar stationary phases we must use homologous series of polar compounds as standards, and even this procedure does not exclude interfacial adsorption effects on the retention parameters of the standards. Another shortcoming of the Kovats indices is the need to assume a linear dependence of $\lg V_N$ on C, which is often not appropriate. Furthermore the error in the measurement of I is almost twice as great as the error in the measurement of r.

Characteristics of the retention parameters.

Parameter	Reproducibility, %		Advantages	Disadvantages
	within laboratory	between laboratories		
Specific retention volume V_g	0.2	4.5	A thermodynamic parameter, describing the gas–liquid equilibrium; can be used to calculate all the thermodynamic characteristics of the phase equilibrium; independent of the amount of stationary phase in the column	Laborious measurement of the amount of stationary phase in the column, and associated errors
Net retention volume V_N	0.1 (0.02)	–	–	**
Relative retention volume r	0.1 (0.02)	0.8	Simple to calculate, consistent with the order of appearance of the peaks, few parameters to be measured. No assumptions needed	The need to recalculate the results to a single standard from secondary standards
Kovats index I	0.2 (0.05)	2.3	Rational presentation of the results as a sum of increments associated with the atomic groups in the sorbate molecule; any member of the homologous series can be used as standard	The need to postulate linearity of the logarithm of the retention volume as a function of number of carbon atoms in the molecule for members of a homologous series; the need to use at least two standards

*The errors obtained in computer-controlled experiments are shown in brackets.

**Not recommended for identification, not reproducible between laboratories.

Though the equivalence of I and r as identification parameters has been convincingly demonstrated[184] the r values are more convenient to use because they are simpler. They are also more accurate because no assumptions are made in their derivation. Since the choice between I and r does not raise

any fundamental questions, it is desirable to standardise on one of these quantities: the choice of r (with aromatic hydrocarbons as standards) appears to be the best overall approach to a standard identification procedure in GLC.

Because of the complexity of sorption processes in chromatographic columns the following experimental parameters should be stated in publications to ensure reproducibility of the retention data in other laboratories: 1) the column temperature (to the nearest 0.1 K), 2) a full description of the stationary phase (purity, origin, amount of liquid phase on the carrier, details of the activation process), 3) a full description of the carrier, 4) length, diameter, and material of the column, and (in the case of capillary columns) pretreatment conditions, 5) size of injected sample and dependence of the appearance time on sample size, 6) method of measuring the dead time of the system, 7) nature, input pressure, and flow rate of the carrier gas, 8) sensitivity of the detector and chart recorder, 9) type and model of the chromatograph, 10) errors in the determination of retention data.

It is also desirable to state the operating life of the column, and to point out any changes in retention behaviour observed after lengthy operation of the column, as well as the role of adsorption effects. Lastly, the results being reported should be compared with published data if possible.

6. Choice of Parameters for Identification in GLC

Reliable identification of a component requires the coincidence of two independent retention parameters for the unkown peak and for the peak of the standard. We shall discuss two variants of the method of identification from retention data, though non-retention methods (spectral, chemical, etc.) are also widely used.

a) Chromatographic spectra. Coincidence of the retention parameters for the unknown and the standard component on two or three different stationary phases is a good criterion of identify of the substances being compared. Stationary phases of very different polarity and chemical nature are often used for comparison. The following can be recommended for identifications: squalane (up to 100 °C), the C_{87} hydrocarbon[221] (up to 250 °C), oxydipropionitrile (up to 80 °C), *hexakis*(2-cyanoethoxy)hexane (up to 180 °C), polyphenyl ether from 6 rings (up to 250 °C).

The separation of not very complex mixtures on two or three columns with different stationary phases yields "chromatographic spectra" which can be used to identify the components[222-228]. Analogous to the chromatographic spectrum is the parameter ΔI, calculated as the difference between the Kovats indices for the unknown component on two stationary phases. Both these methods are useful for the identification of the components in mixtures of 5–10 substances present at different concentrations. The main difficulty in identification from chromatographic spectra is the "recognition" of the peaks of a particular component when the mixture is separated on different columns, since the peaks appear in different order at the column outlet and they can only be recognised by their relative height. Another drawback of the chromatographic spectra is the difficulty of obtaining an acceptably complete resolution of all the peaks for a complex mixture on a number of stationary phases. Often only one stationary phase is available for identifying the components of a complex mixture. In this case we need another independent parameter determined on the same stationary phase—the temperature dependence of the retention quantities—in addition to the indices r or ΔI for reliable identification.

b) Temperature dependence of the relative retention volume and of the Kovats index. These temperature dependences are determined directly by the enthalpic selectivity of the stationary phase (the relative molar heat of dissolution ΔH_S°, whose value can be calculated relatively simply by using the additivity principle). The quantity ΔH_S° can be used directly for identification[229,230], because it is much less sensitive to experimental conditions (such as interfacial adsorption) than the parameter r. It can be evaluated very simply from experimental data by using the expression

$$\Delta H_s^0 = \frac{4.58\,(\lg r_1 - \lg r_2)}{1/T_1 - 1/T_2},$$

where the subscripts 1 and 2 refer to different column temperatures.

The temperature dependence of the retention can be described also by indirect parameters (e.g. the constants of an equation of the Antoine type[231,232]) or by the temperature dependence of the Kovats index δI. The latter type of dependence is widely used to identify substances of different classes[24,233-243,209-212], but we should note that δI can vary with temperature as a result of non-linearity of the relationship between I and the column temperature, and this effect must be allowed for when δI is used for identification. Since neither the constants of the Antoine equation nor δI contain as much physicochemical information as ΔH_S° we recommend the two quantities r and ΔH_S° as the basic independent parameters to be used for identification.

Gas-chromatographic Analysis of Nucleic Acids

V.V.Tets

Problems of the gas-chromatographic analysis of the components of nucleic acids are examined and data for the conditions governing such studies are presented. Since the investigation of the composition of nucleic acids involves, apart from gas chromatography, their isolation from natural sources and the preparation of volatile derivatives, particular attention is devoted to the problem of the preparation of samples for analysis. The fundamental trends in the practical applications of the method are discussed.
The bibliography includes 120 references.

I. INTRODUCTION

The unflagging interest in nucleic acids (NA) is due to their relation to such most important problems of vital activity as heredity and the development and regulation of various functions. One of the most important aspects of the study of NA involves the investigation of their composition, i.e. the separation, identification, and quantitative determination of purine and pyrimidine NA derivatives. For this purpose, studies have been made of a wide variety of fractionation methods, including ion-exchange chromatography[1-4], paper chromatography[5-8], paper electrophoresis[9-12], and thin-layer chromatography[13-15]. With their aid, most of the studies on the composition of NA have been carried out. The characteristics of the above methods have been widely discussed in a series of detailed reviews[16-21].

The majority of the methods employed require milligrams of material for investigation if a radioactive tracer is not employed. Since biological samples are frequently very small (micrograms of material), there was a need for methods which would yield satisfactory quantitative results under these conditions also. The attention of investigators was therefore attracted to liquid and gas–liquid chromatography. Gas–liquid chromatography (GLC), which ensures rapid separation of the test systems, selectivity, and sensitivity of the analysis, is becoming increasingly popular in the study of various biological substances. A GLC technique for numerous biological components has now been developed: aliphatic acids, cyclic compounds, alcohols, aldehydes, ketones, essential oils, steroids, lipopolysaccharides, amino-acids, and others[22-24].

The first attempt to use the GLC analysis in the study of NA was undertaken in 1962.[25] Since the NA components are inert and involatile in the temperature range used in gas chromatography, the authors used their acetyl, methyl, and isopropylidene derivatives. In 1964 MacGee[26] investigated *N*-methyl derivatives of purine and pyrimidine bases. However, the data presented were unsuitable for quantitative analysis, because numerous derivatives were obtained for each NA component after esterification (thus, four such derivatives obtained for adenine alone). Despite the fact that MacGee[27] was able to obtain certain quantitative data in 1966, this method for the analysis of NA has not been widely used. Progress in the application of GLC in the analysis NA became possible when silylating agents began to be used to prepare their volatile derivatives.

The majority of the studies on NA by gas chromatography have now been carried out using their trimethylsilyl (TMS) esters, their acetylation and methylation being used only in a few investigations[28-33]. Silylated NA derivatives were first obtained by Hancock and Coleman[34] who used for this purpose hexamethyldisilazane (I) and chlorotrimethylsilane (II) in pyridine. They authors obtained numerous derivatives of the constituents and asymmetric peaks were recorded on the chromatogram. In the same year Hancock[35] reported a successful separation of various adenosine derivatives and showed that, after silylation, they can be used for quantitative analysis.

In 1966–1968 Hashizume and Sasaki[36-38] published studies devoted to the separation and quantitative determination of TMS derivatives of the bases, nucleosides, and nucleotides obtained using compounds (I) and (II) as silylating agents. The possibility of using this method for the analysis of bases forming part of the composition of TNA and RNA was also demonstrated in these investigations. Gehrke and Ruyle[39] proposed a quantitative method for the GLC analysis of TMS derivatives of NA obtained in the reaction with *N*,*O*-bis(trimethylsilyl)acetamide(III) and *N*,*O*-bis(trimethylsilyl)trifluoroacetamide(IV), which had been used earlier to modify aminoacids[40]. Subsequently *N*-trimethylsilylimidazole, *N*-diethyl-*N*-trimethylsilylamine, *N*-methyl-*N*-trimethylsilylacetamide and their various combinations were used to silylate NA derivatives[41-44]. All the reagents enumerated above are used nowadays to prepare TMS derivatives of NA. Silylation of the NA components made it possible to obtain quantitative data by the gas chromatography of microamounts of the test material, which permits a wide scale application of the method.

The present review deals with problems of the preparation of NA samples for GLC analysis, the experimental technique, and aspects of its practical applications.

II. PREPARATION OF SAMPLES FOR THE GAS-CHROMATOGRAPHIC ANALYSIS OF NUCLEIC ACIDS

1. Hydrolysis of Nucleic Acids

For the GLC analysis of NA, it is necessary in the first place to hydrolyse the polymer to various monomers: purines, pyrimidines, nucleosides, or nucleotides (depending on the

method of depolymerisation). The characteristics of the silylation method show that the best procedure involves decomposition to the bases or nucleosides carried out with the aid of various acids and enzymes[45-47]. The method of hydrolysis of NA by $HClO_4$ has come to be widely used. This method, followed by purification of the product by ion-exchange chromatography, has been employed in the preparation of samples for GLC.[36,37] However, the method of hydrolysis of NA by trifluoroacetic acid or a mixture of trifluoroacetic and formic acids must be regarded as more useful, since the two acids can be separated from the sample by simple evaporation and there is therefore no need for an additional purification of the sample. The depolymerisation of the NA in this way greatly simplifies the procedure involving the preparation of the sample and increases the overall reliability and sensitivity of the method. Purines and pyrimidines, prepared in this way, have been studied successfully by GLC.[48,49]

2. Silylation of Nucleic Acids

Detailed information about the properties of the silylating agents and about the nature of their interaction with the NA component has been published in a number of reviews[50-52]. According to Muni and Altschuler's data[53], the formation of the TMS esters of NA derivatives involves the substitution of an active proton by a trimethylsilyl group. This phenomenon decreases the possibility of the formation of hydrogen bonds and increases the stability of the mixture. The silylated derivatives of purines and pyrimidines are less strongly bound and are more volatile compared with their unmodified analogues.

The conversion of NA into volatile components can be regarded as ideal when it proceeds in accordance with the "one base (nucleoside, nucleotide)–one derivative" principle. However, such a ratio cannot always be maintained for each component of the test mixture. In certain cases purines and pyrimidines containing a functional amino-group each form two derivatives[52,54]. The cause of this is a whole series of factors: the nature of the silylating agent, the solvent, the reaction temperature, and certain others[55]. At the same time the presence of two peaks corresponding to a single base (nucleoside, nucleotide) on the chromatogram does not interfere with the quantitative analysis and is fully reproducible[39,56,57]. Cytosine and the corresponding nucleoside and nucleotide most frequently give rise to two such compounds[48,56]. According to the results of the mass-spectrometric analysis of TMS-cytosine, the two peaks of its derivatives correspond to di-TMS-cytosine and tri-TMS-cytosine[58].

The available information about the proposed structures of various TMS-nucleosides and TMS-nucleotides as well as the isomers has been published in a number of communications[44,59-63]. According to the data obtained, cytidine forms tetra-TMS-cytidine and penta-TMS-cytidine. The reactions of minor derivatives of cytosine (5-methylcytosine) and adenine (6-methylaniline) with compound (III) or (IV) also each gave rise to two TMS-derivatives[56,64,65]. It is noteworthy that, when other silylating agents or other modification conditions are used, it is possible to obtain only one derivative of the base[49,66,67].

Much attention is devoted nowadays to the selection of both the best silylating agent and of the optimum esterification method. The data for the silylation conditions and the agents employed are compiled in Table 1. Among the substances enumerated which are used to prepare the TMS esters of NA, compounds (III) and (IV) are the most popular in view of their high modifying activity in relation to NA compared with other silylating agents[44,54,68,69].

It has been suggested that the optimum conditions for the interaction of bases and nucleotides with compound (III) involve heating of the reaction mixture for 45 min at 150 °C in the presence of 100 moles of the above agent in excess[39]. It has also been suggested that, in the treatment of nucleosides with compound (III), the latter be present in excess (225 moles) and that the mixture be heated for 2 h at 120 °C.[44] In the optimisation of the conditions in the modification of bases and nucleosides using compound (IV) best results were obtained on heating the mixture for 15 min at 150 °C in the presence of 225 moles of the silylating agent in excess[57,70]. The same amount of compound (IV) was chosen as optimal also in the silylation of nucleotides. An increase of the volume of the silylating agent led in this case to the appearance in the mixture of the corresponding TMS-bases. Deoxycytosine gave rise to a TMS-cytosine peak on the chromatogram also under all other silylation conditions using both compound (III) and compound (IV).[44]

The optimum conditions in the esterification of nucleotides and dinucleotides using compound (IV) as the silylating agent have been studied by Patel and Gehrke[71], who concluded that, for a more successful modification and chromatography, mono- and di-nucleotides from biological samples must be converted into the corresponding nucleosides or bases. According to the data of Miller et al.[54] optimum silylation using compound (IV) is attained in the case of bases by heating at 150 °C in the presence of 100 moles of compound (IV) in excess for 15 min, while in the case of nucleosides the heat treatment should last 30 min. It is noteworthy that NA are silylated also at room temperature but less efficiently[42,44,49]. The silylation of NA has been studied quantitatively by Řehák and Pacáková[72], who established, using spectrophotometric and radioisotope methods to follow the process, that if the latter takes place at 150 °C over a period of 45 min in the presence of 50 moles of compound (IV) in excess, then at least 95% of the initial amount of the bases investigated are converted into TMS-derivatives.

Dichloroethane, hexane, benzene, acetonitrile, pyridine, dimethylformamide, toluene, and certain other substances have been used as solvents for the preparation of volatile NA derivatives. Pyridine and acetonitrile are most widely used nowadays. Comparative data for the solvents employed are listed in Table 1. According to the available information about the influence of various solvents on the silylation process, acetonitrile must be regarded as the best[44,65]. Data on the efficiency of the silylation of nucleosides using various solvents are presented in Table 2.

Apart from all the factors enumerated, the preparation of TMS ethers of purines and pyrimidines and the results of their subsequent GLC analysis can be influenced by various salts in water, which sometimes remain in the NA sample after its isolation or hydrolysis. The studies carried out to elucidate this problem have shown that the NA components respond in different ways in the presence of particular salts. When compounds such as Na_2SO_4 and $CaSO_4$ were added to the reaction mixture, the results of the GLC analysis remained unchanged, while the presence of added $CaCl_2$ caused some decrease of the guanine peak[57]. The Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cu^{2+} cations added to the reaction mixture in the silylation of guanine and hypoxanthine had a negative influence on the esterification process, apparently owing to the decrease of the volatility of TMS-derivatives[43]. The presence of NH_4^+ cations did not affect this process.

In their study of the influence of salts such as NaCl, KCl, NH_4Cl, $(NH_4)_2SO_4$, $MgCl_2$ $CaSO_4$, $CaCl_2$, and Na_2SO_4 and the silylation and chromatography of nucleosides, Patel and

Table 1. Experimental conditions in the silylation and gas-chromatographic analysis of purines and pyrimidines*.

Components investigated	Silylating agent	Solvent	Silylating conditions		Carrier	Liquid phase, %	Type of detector	Carrier gas	Refs.

**Different values for different silylating agents.

Gehrke established that thymidine is most sensitive to them on modification with compound (IV). If a mixture of the above salts was involved in the reaction, an appreciable decrease of the relative weight sensitivity coefficients of all the nucleosides was observed. According to the authors[71], these solvents can decrease the degree of silylation of nucleosides by reducing their solubility and the molar excess of compound (IV) as a result of the formation of derivatives of TMS anions such as TMS-SO_4 and TMS-PO_4 and the decomposition of the TMS-nucleosides in the sample. A similar response to the presence of these salts apparently occurs also in the silylation of the bases.

Various workers obtained data according to which the maintenance of anhydrous conditions is obligatory for the successful GLC analysis of NA derivatives. After the silylation of guanine and hypoxanthine by compound (III), the peaks of these substances were not observed on the chromatograms when 100 μl of water had been added to a sample containing 5 mg of each substance[43]. According to the data of Gehrke and Lakings[57], the presence of 5 μl of water in a 200 μl sample of the bases reduced the second peak corresponding to cytosine on the chromatograph up to its complete disappearance. On further increase of the concentration of water, the first peak also diminished as well as the peak corresponding to guanine. In the reaction of nucleosides with compounds (III), (IV), and trimethylsilylimidazole a negative influence of water on the silylation process was observed. The necessity to maintain anhydrous conditions in the GLC analysis of NA has also been reported by other workers[53].

The retention of the TMS derivatives of NA from the instant of their preparation until the gas-chromatographic

investigation is of practical importance. Thus the TMS derivatives of bases stored at room temperature for five days yielded a clearly reproducible result in their GLC analysis[57]. TMS derivatives of nucleosides stored under the same conditions remained stable for 48 h. After more prolonged storage of the samples, numerous peaks, corresponding to the TMS-bases of the initial nucleosides and other products of the decomposition of the TMS-derivatives of nucleosides, appeared on their chromatogram[70]. At the same time there are data[53] according to which the majority of the silylated purines and pyrimidines are chromatographically stable for a year and more when stored in a tightly closed vessel in the presence of an excess of the silylating agent at 3–5 °C.

Thus reliable methods have now been developed for the quantitative preparation of volatile derivatives of bases and nucleosides suitable for GLC analysis.

Table 2. The effect of various solvents (relative weight sensitivity coefficient) on the silylation of nucleosides by compound (IV).[70]

Compound	Aceto-nitrile	Pyri-dine	Dimethyl-formamide	Methylene chloride	Chloroform	Benzene	Toluene	Hexane

*The peak was not obtained.

III. ANALYTICAL CONDITIONS

1. Liquid Phases

Non-polar and moderately polar liquid phases have been used successfully for the separation of TMS derivatives of NA. With their aid, it is possible to separate TMS derivatives of the bases, nucleosides, and the phosphates (Table 1). Among non-polar liquids, phases such as SE-30, OV-1, OV-101, DC-430, and certain others are employed. Among moderately polar phases, those containing phenyl groups have been used: OV-3, OV-17, XE-60, OV-7, and others. The characteristics of these phases are quoted in a handbook[81]. The non-polar liquid phase SE-30, which is a methylsiloxane polymer, has been most frequently used for the separation of NA derivatives.

The concentration of the liquid vary within fairly wide limits—from 0.2 to 10%.[39,65,72] Universally prescibed concentrations are lacking for each phase. In choosing the concentration of the liquid phase, one must bear in mind that the presence of a large amount of the latter entails an increase of the separation time, while the phase present in a small amount cannot fully compensate for the inertness of the carrier, which impairs the quality of the separation and decreases the sensitivity of the method. The selection of the liquid phases and their concentrations is related to the nature of the mixtures separated and the purposes of the investigation. Thus in the separation of ribonucleosides, best results were obtained using phases such as 4% of OV-11 and 3% of OV-17.[70] The best separation of the minor bases was achieved on 0.5% of OV-3.[65] The separation of 5-methylcytosine from cytosine in preparation of bases obtained from calf thymus DNA and bacteriophages was observed on the following liquid phases: 3% of SE-30 and 2% of OV-225.[49] According to Muni and Altschuler[53], a satisfactory separation of the TMS derivatives of purines and pyrimidines was attained using 3–5% of the SE-30 and OV-17 phases.

Substances lacking catalytic activity, exhibiting a minimal adsorption capacity, and having highly homogeneous surfaces, dimensions, and shapes are used as carriers for the liquid phase. Such substances are in the first place diatomaceous carriers of the type of Chromosorb W, Supelcoport, Anachrome, Gas Chrom Q, etc. (Table 1). Silylated carriers are frequently used[54,56].

2. Conditions of the GLC Analysis of NA

A relatively wide set of GLC analytical conditions can be used in the study of NA. After the liquid phase, the carrier, and the column length have been chosen, the temperature and the flow rate of the gas are usually regulated in such a way that the required separation can be achieved during a satisfactory time. The GLC analysis of NA can be carried out under both isothermal conditions and with temperature programming. The choice of the conditions in the investigation depends in many respects on its aim. Multicomponent systems are mainly separated using temperature programming[38,64,65,67,75]. The separation of the TMS derivatives of the bases, nucleosides, and nucleotides is as a rule carried out in the temperature range from 80° to 325 °C.[38,65,67,75,78]

The chromatographic columns are in most instances 1–2 m long and have an internal diameter of 2–4 mm. Both glass and metallic columns are used for the chromatography of the TMS derivatives of NA. However, it is believed[82] that the entire GLC analysis should be carried out in glass apparatus, since the TMS derivatives decompose on contact with heated metallic components. An analogous behaviour has been observed also in the gas chromatography of aminoacids[23].

A flame ionisation detector and more rarely thermal conductivity, argon ionisation, and electron capture detectors are used in most studies. The carrier gas is chosen depending on the type of detector employed: nitrogen, argon, and helium (Table 1). Since the TMS derivatives of purines and pyrimidines are highly sensitive to moisture, thorough drying of the gas supplied is necessary.

3. Quantitative Analysis

The quantitative determination of the bases, nucleosides, and nucleotides in the GLC analysis is carried out by an internal standardisation method. The internal standards employed are phenanthrene, pyrene, purene, acenaphthene, n-octacosane, n-tetratriacontane, n-nonadecane, and others[42,43,76,83,84]. Among these, phenanthene and pyrene are most widely used. The internal standard is added to the initial mixture and undergoes all the stages in the preparation of the TMS derivatives. The amount of test substance is calculated using the "relative molar sensitivity coefficient" or the "relative weight sensitivity coefficient"[65,66].

The reproducibility of the data obtained in the GLC analysis of NA has been estimated with the aid of the relative standard deviation calculated from the results of several measurements. Thus the standard deviation for the TMS

derivatives of the minor components, determined in biological liquids, is on average 3.8% according to the results of four measurements[65]. The results of the determination of the relative molar sensitivity coefficients as well as the standard deviations for various nucleosides are presented in Table 3.

The introduction of comparatively large concentrations of the test substance is undesirable if quantitatively reproducible data are to be obtained. Thus, when a flame ionisation detector was used, the introduction of more than 25 μg of the TMS derivative led to the appearance of an additional peak on the elution curve, which may be associated with the moderate cooling of the flame as a result of the combustion of the organosilicon substance[85]. The minimum amount of the TMS derivatives of purines and pyrimidines which can be determined by GLC using a flame ionisation detector is $(3-5)\times10^{-9}$ g, which corresponds to 3×10^{-11} moles of each of the bases introduced[39].

Qualitative investigation of the composition of the DNA bases of salmon sperm and calf thymus and the RNA bases of yeast and tobacco mosaic virus by GLC at a macrolevel (1 mg), semimicrolevel (100 μg), and microlevel (5 μg) yielded data identical with those obtained earlier for the same systems when the latter were studied with the aid of other fractionation methods[48,75].

Table 3. The reproducibility of the results of etherification and the GLC of the TMS derivatives of the methylated bases.

Compound	Retention time, min	Relative molar sensitivity coefficient	Standard deviations*
6-Methyladenine	13.2	0.58	0.024
6-Dimethyladenine	13.0	0.64	0.029
6-Isoadenine	18.4	0.86	0.025
2-Methyladenine	16.4	0.57	0.008
2-Methylguanine	17.2	0.58	0.017
2,2-Dimethylguanine	18.0	0.83	0.020
7-Methylguanine	19.6	0.39	0.320
5-Methylcytosine	9.6—12.0	0.73**	0.024
Thymine	6.8	0.63	0.025

*The standard deviation was determined from the results of four independent experiments.

**Two peaks were obtained, each being independently integrated, and were then added to determine the overall area and to calculate the relative molar sensitivity coefficient.

4. Qualitative Analysis

The gas-chromatographic analysis of the composition of NA is extremely sensitive; it ensures a high degree of resolution and detection of the components present at very low concentrations. The identification of the unknown TMS components of the mixture by GLC in a pure form is in most cases carried out by comparing their retention times with those of known standards. Another procedure involves the comparison of the behaviour of the TMS derivatives on different phases. In order to obtain data permitting the identification of the unknown components and in the first place those for which comparison standards are not already available, it is necessary to employ an additional technique. The possibility of employing spectrometric methods such as ultraviolet and infrared scanning, NMR, mass spectrometry, and certain others for the identification of the TMS derivatives of NA has therefore been investigated[64,66,86-88]. The combination of modern GLC with the above methods[64,72] greatly extends the scope of the analysis of NA.

The absorption by purines and pyrimidines in the ultraviolet and infrared is highly specific and is widely used for their identification and quantitative determination[89-94]. The study of the spectroscopic properties of the TMS derivatives of NA obtained by GLC showed that, although the ultraviolet absorption differs to a considerable extent from that observed for the intact purines and pyrimidines, it is nevertheless specific[53,64]. The ratios of the absorption at 260 and 280 nm and at 250 and 280 nm have been used as characteristics of the TMS derivatives of NA and of their unmodified precursors. The absorption of TMS derivatives of NA in the infrared is also fairly characteristic[64,66].

The specificity of the properties of the TMS-bases has been demonstrated also in their study by NMR.[64,66] However, one should note that the application of this method is limited, because a comparatively large amount of the starting material is required for the investigation.

One of the most promising procedures for the study of mixtures of TMS derivatives of NA components is the combined GLC–mass-spectrometric method. The possibility of using it for this purpose was first demonstrated by McCloskey et al.[88] The mass spectra of the bases, nucleosides, and nucleotides, obtained on silylation with compounds (III) and (IV) as well as trimethylsilylimidazole, proved to be simple to interpret. Derivatives obtained from NA components by methylation, acetylation, trifluoroacetylation, trimethylsilylation, and the synthesis of 2′,3′-*O*-isopropylidene and 2′,3′-*O*-phenylborate ethers and esters have been investigated by this method[33,58,60,88,95]. The above combined method has been used successfully to investigate bacterial RNA and rare NA components[79,87,96,97]. Together with gas chromatography, a new mass-spectrometric method—mass-fragmentography has been employed in the analysis of TMS derivatives of NA. The application of other methods for the qualitative analysis of NA together with GLC greatly increases the accuracy of the latter.

It follows from the data presented that the purine and pyrimidine components of NA can be separated successfully by GLC. Various conditions for the GLC of nucleic acids, whereby they can be studied both quantitatively and qualitatively, have been developed. Bearing in mind the flexibility of the method, in view of the possibility of employing various liquid phases and conditions for the GLC itself, one may claim that virtually any NA component can be separated and identified with its aid.

IV. EXAMPLES OF THE APPLICATIONS OF THE GAS-CHROMATOGRAPHIC ANALYSIS OF NUCLEIC ACIDS

Gas–liquid chromatography has already found extensive applications and is arousing increasing interest, as shown, in particular, by the increase of the number of studies, carried out with its aid, which have been published in the last few years. The composition of the RNA of microorganisms, which are of theoretical and practical importance in agriculture, medicine, and industrial microbiology, has been studied by the above method[38,39,48,75,79,87,96,98,99]. Preparations of DNA from animal and bacterial cells have been investigated, particular attention being devoted to its minor components[38,48,49,74]. The biological importance of these compounds is now being vigorously investigated.

GLC has been employed in pharmacology for monitoring the chemical composition and purity of preparations and for the investigation of their distribution in the organism. The

applications of the method in this field are associated with the use of derivatives of the bases and nucleosides as therapeutic agents in the treatment of various diseases (hypertension, sugar diabetes, malignant neoplasts, etc.). In the study of therapeutic chemical preparations—standard and in biological liquids—with the aid of GLC their various volatile derivatives have been used[28-31,54,77,100-102]. The substances 6-mercaptopurine-nucleoside, 5-fluoro-2-deoxyuridine, ftorafur, investigated in these studies include 5-fluorouracil, 6-azauridine, allopurinol, β-phenylethylbiguanidine, and certain others.

The GLC analysis of NA has acquired major importance for clinical laboratory diagnosis. A method for the detection of minor NA components in biological liquids has now been developed in greater detail. It is known that the quantity of these compounds in such liquids increases in certain diseases as a result of the degradation of transport RNA.[103,104]. An increase of the content of these bases has also been observed in diseases such as accute leukaemia, psoriasis, melanoma, etc.[105,110]. The possibility of obtaining TMS derivatives of the purines and pyrimidines encountered in urine and of their analysis by GLC has been demonstrated[67,78]. Comparative GLC study of the minor derivatives of NA present in the urine of healthy and ill humans revealed diagnostically significant differences between them. Such studies have been carried out in instances of leukaemia, various malignant neoplasts, and other diseases[65,76,80,83,111,112].

The information presented in this review justifies the claim that GLC ensures a highly effective separation and identification of minimal amounts of the test substance combined with a high degree of reproducibility. The extensive possibilities of the employment of GLC in the manufacture of preparations containing NA components and in clinical laboratory diagnosis are due to the fact that, apart from the advantages already mentioned, the method can be fully automated.

---o0o---

During the preparation of the manuscript for the press, certain studies of fundamental importance on the GLC of NA were published. Conditions were proposed for the GLC investigation of DNA bases under isothermal conditions[113,114] and the first successful attempt was made to separate the TMS derivatives of NA components using capillary columns[115]. The possibility of investigating certain pyrimidines by GLC without their preliminary conversion into volatile derivatives was demonstrated[116]. It is noteworthy that the method of pyrolytic GLC study of NA, which had been used earlier[117-119] but had not found extensive applications, is nowdays used successfully for the comparative analysis of biological samples containing NA.[120]

The Use of Mass Spectrometry to Study the Structure of Flames and Combustion Processes

O.P.Korobeinichev

The general characteristic methods of the mass-spectrometric study of flames and combustion processes, and the latest achievements in experimental technique in the molecular-beam diagnostics of flames have been examined. The problems associated with the use of probe methods—the effects of freezing the chemical reactions, translational-vibrational relaxation, and perturbations introduced by the probe in the combustion process—have been analysed. The possibilities provided by the technique have been demonstrated for various examples in the study of the combustion of gaseous, liquid, and solid fuels, including that in various technical arrangements—internal combustion engines and liquid rocket motors. Questions related to the use of mass-spectrometric probes for the study of the mechanism and kinetics of chemical reactions in flames and for the determination of the rate constants of the elementary stages have been discussed. The bibliography contains 53 references.

I. INTRODUCTION

Mass spectrometry provides one of the most popular and effective methods of studying flames and combustion processes[1,2]. One reason for this is the universal character of the method, by means of which it is possible: 1) to identify the components present in flames, 2) to determine their quantitative composition (concentrations), and 3) to measure the distribution of these components in the combustion zones (to study the structure of flames) and on this basis to calculate the component fluxes and reaction rates.

Flames involve high-velocity fluxes of reactive gases with high temperature gradients and concentrations of the original components and final and intermediate reaction products. The gaseous components in flames can be classified as stable or highly active—atoms, radicals, ions, and excited species. Their typical maximum concentrations in flames are given below.

Species	N, mole fraction
Stable (CH_4, O_2, H_2O)	0.1—1
Atoms and free radicals (H, O, OH)	10^{-1}—10^{-2}
Ions (CHO^+, H_3O^+)	10^{-7}—10^{-12}
Excited (HF^*)	10^{-6}

The first important problem in the mass spectrometry of flames is the removal of the particles from the combustion zone and their introduction into the ion source of the mass spectrometer. The maximum temperatures in flames lie in the range 1000–3000 °C, and the characteristic times of chemical reactions under these conditions are 10^{-4}–10^{-7} s. To ensure preservation of the particles, the times taken to remove them from the combustion zone must be much shorter than their lifetimes. In the process of probe sampling, it is necessary to lower the temperature rapidly. With "quenching" in this way, it is easiest to preserve stable particles, and most difficult to preserve active species.

Comparison of the mass-spectrometric probe method with non-contact spectroscopic methods reveals two advantages of the former for probing flames: 1) the possibility of recording all species (this is particularly important for such complex systems as flames); and 2) the greater spatial resolving power. For example, in the latest method of laser Raman spectroscopy, the limiting sensitivity of the measurement amounts to 10^{11} particles[3], which for a pressure of 25 mmHg, $T = 2000$ K, and an accuracy of recording of 1% corresponds to a zone with characteristic dimensions of 2 mm. The spatial resolving power of infrared spectroscopy under the same conditions is not better than 0.1 mm.[4] Moreover, in the last case the probing is not local, but is carried out along a straight line, so that the method is applicable only to uniform one-dimensional systems with rigorously parallel fronts—lines of equal concentration (with deviations from the parallel arrangement $\ll 0.1$ mm).

Because of the complexity of the spectrum, the spectroscopic method cannot detect many of the particles existing in flames. At the same time, the spectroscopic method has the important advantage over mass spectrometry that it is a non-contact method, and does not perturb the process being studied. Thus the two methods supplement one another, and to achieve best results in the study of flames and combustion processes it is necessary to use both methods.

Mass spectrometry has for several decades been used successfully to study flames and combustion processes. The monograph by Fristrom and Westenberg[1] described the results of studies in this field obtained up to 1965. In recent years, as a result of the rapid development of experimental technique, new achievements and promising possibilities have appeared in the mass-spectrometric study of flames and combustion processes, but these developments have not yet been adequately reflected in the literature.

II. ANALYSIS OF PROBLEMS ASSOCIATED WITH THE USE OF THE MASS-SPECTROMETRIC METHOD OF PROBING FLAMES FOR THE STUDY OF THE STRUCTURE OF FLAMES AND COMBUSTION PROCESSES

1. Technique for Removing the Specimen

Probe sampling is an extremely simple process. Two types of apparatus are used as probes. The first are the so-called "isokinetic" micro-probes—cones with a small aperture angle (10–20°), which remove a specimen of gas with the velocity of the advancing flux; the aperture in the apex of the probe being ~10–100 μm. The advantages of samplers of this type are the small aerodynamic and thermal perturbations of the flame; their disadvantages are the poor conditions for quenching the chemical reactions and preserving active species. Samplers of this type are used to study systems which react slowly. Probes of the second type are sonic probes, at the inlet to which the velocity of the gas is equal to the velocity of sound; they consist of cones having an aperture angle of 30–40° or more. As a result of the expansion of the flow at the inlet into the cone, a supersonic stream is formed. The decrease in temperature and the quenching of the chemical reactions take place at a distance of several times the diameter of the opening in the probe. After the sample has been removed, it is necessary to introduce it without distortions into the ion source of the mass spectrometer. The input systems are of two types. In the first, the gas being analysed is introduced into the ion source in the form of a molecular beam, and in the second it is introduced in the form of a supersonic stream, from which the molecular beam may subsequently be formed.

2. Application of the Molecular-beam System for Specimen Removal

Molecular beams represent the most effective system for transporting the particles removed from the flame to the ion source of the mass spectrometer, since the absence of collisions of the particles of the beam with one another and with the walls of the sampling and input system ensures the best conditions for preserving the particles. There are two types of source of molecular beams: effusion and gas-dynamic (supersonic). The molecular beam is formed as a result of the flow of the gas into a vacuum through a small opening of diameter d. Depending on the value of the Knudsen number $\mathrm{Kn} = \lambda/d$ (where λ is the mean free path of the gas molecules in the source), it is possible to have two flow conditions: effusive for $\mathrm{Kn} \gg 1$, and supersonic for $\mathrm{Kn} \ll 1$.[5]

The most important advantage of the gas-dynamic source compared with the effusion source is that it can be used to obtain beams which are two orders of magnitude more intense than those obtained using the effusion source.

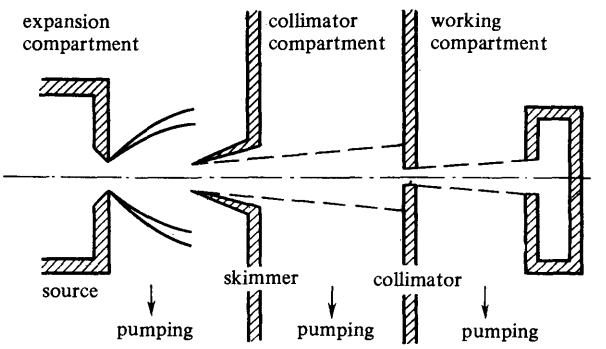

Figure 1. Basic elements of the beam created by a gas-dynamic source.

The principal elements of the beam created by a gas-dynamic source are represented in Fig. 1. The flux expands, flowing through the opening, and forms usually a hypersonic free stream in the expansion compartment, which is evacuated to 10^{-2}–10^{-4} mmHg.[5,6] The purpose of the conical separator (skimmer) is to pass the main body of the free stream without perturbations and with a highly ordered motion into the collimator compartment, in which a high vacuum (typically ~10^{-6}–10^{-7} mmHg) to exclude scattering, is created. The collimator

is designed to separate the working beam, which passes into the working compartment of the mass spectrometer.

The general idealised characteristics of the system have been determined[7], with the following assumptions: 1) the expansion is isentropic as far as the skimmer; 2) the flux passes unperturbed through the skimmer; and 3) collisions between the molecules do not take place after the skimmer. For Mach numbers greater than 3, these assumptions lead to the following basic equations defining the characteristics of the beam[5].

The flow rate through the skimmer N_S (molecule s^{-1}) is

$$N_s = \frac{1}{4}\pi d_s^2 n_s a_0 M_s \{1 + [(\gamma - 1)/2] M_s^2\}^{-1/2},$$

where a_0 is the velocity of sound in the gas at rest, γ the ratio of the specific heats, d_S the diameter of the opening in the skimmer, and M_S and n_S the Mach number and density of the molecules at the inlet to the skimmer, related isentropically to the parameters in the source. These quantities can be calculated, and are functions of the distance between the sonic opening and the skimmer. The rate of flow of gas through the collimator N_C is

$$N_c = \frac{1}{2} n_s a_0 \left(\frac{\pi}{4} d_c^2\right)\left(\frac{\pi}{4} d_s^2\right) \frac{M_s (3 + \gamma M_s^2)}{\pi L_s^2 \{1 + [(\gamma - 1)/2] M_s^2\}},$$

where d_C is the diameter of the collimator, and L_S the distance from the collimator to the skimmer.

The picture of the flow given above relates to the ideal case where the scattering of the molecules of the beam is negligible. These conditions can be established only in an assembly in which a high degree of evacuation of the background and scattered gases is ensured by the use of: a) highly efficient pumps and the required geometry of vacuum compartments having a high transmitting capacity at all stages of the evacuation; b) sufficiently large openings in the skimmer and aperture angles of the cone of the skimmer; and c) sufficiently sharp edges of the opening in the skimmer and a high degree of cleanliness in the mechanical treatment of its surface. Otherwise, the formation of shock waves, the penetration of the background gas into the beam, can occur, leading to scattering of the molecules of the beam, etc.

According to calculated data, the intensity of the molecular beam should increase continuously with decrease in the distance between the openings of the jet and the skimmer. In practice, however, decrease in this distance is accompanied by an increase in the pressure between the jet and the skimmer, as a consequence of the decrease in the transmitting capacity of the gap between the jet and the skimmer (particularly in the case where a cone having a small aperture angle is used as jet–sampler). This in turn leads to decreased intensity of the beam due to scattering.

3. Effects of Freezing the Chemical Reactions

To obtain a representative sample, it is necessary that effective freezing of the chemical reactions and the internal state of the particles takes place during their removal. In a typical case, the expansion takes place in several microseconds and involves several thousand bimolecular collisions. Relaxation of the translational temperature is achieved; at the end of the expansion, the rotational temperatures are considerably higher than the translational temperatures; the vibrational relaxation is much less complete than the rotational relaxation. In molecules frozen as a result of the expansion, unimolecular reactions may take place along the path of their track in the detector compartment. The disappearance of active species, atoms, radicals, and ions may take place during the expansion of the gas, as a result of bimolecular reactions. Calculations have been carried out[8], which make it possible to estimate the probability of the disappearance of particular species during the expansion of the flux in the removal of a sample, if the rate constants of the reactions taking place are known. These calculations give encouraging results, which make it possible to neglect the above effect in many cases of interest.

It should be borne in mind that the above applies fully only to the molecular-beam method of removing the specimen using samplers in the form of a cone having an aperture angle of 30° and with a sufficiently large opening at the apex. In this case the main body of the stream from which the molecular beam is subsequently formed is unperturbed. This is due to the small dimensions (compared with the diameter of the stream) of the width of the boundary layer, which is formed on the inner walls of the probe during the expansion of the specimen and in which chemical reactions may take place with a high probability (including heterogeneous catalytic reactions on the walls of the probe). When capillary micro-probes having cones with small aperture angles (10°) are used, freezing of the chemical reactions does not take place effectively.

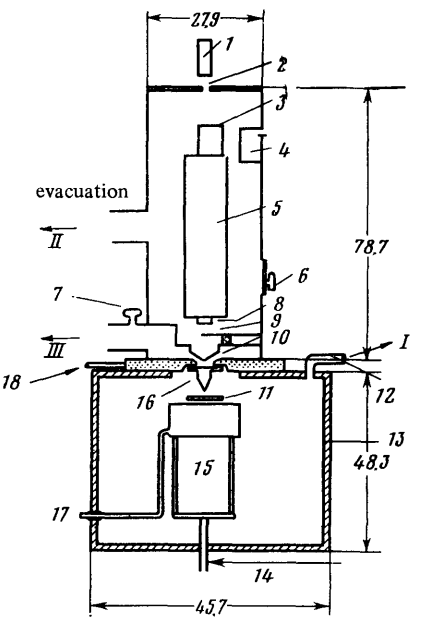

Figure 2. Apparatus of Biordi and coworkers[10]: *1*) laser, *2*) window, *3*) detector, *4*) cold trap, *5*) detector of the mass spectrometer, *6,7*) ionisation lamps, *8*) ion source, *9*) beam modulator, *10*) skimmer, *11*) flame, *12*) copper flange, *13*) combustion chamber, *14*) device for moving the burner in the combustion chamber, *15*) planar burner, *16*) probe, *17*) inlet for the gaseous components of the fuel, *18*) cooling water; *I*) to booster pump. *II,III*) to diffusion pump.

4. Apparatus with Molecular-beam Removal of Specimens from the Flames and Mass-spectrometric Detection

In recent years, with the development of experimental technique in various laboratories throughout the world (the National Bureau of Standards[9], the Bureau of Mines[10,11], the

Institute of Gas Technology[12], etc.[13] in the USA, the Rocket Propulsion Establishment[14] in England, in Belgium[15], etc.), assemblies have been produced with molecular-beam removal of the sample and subsequent mass-spectrometric analysis of the flames, making it possible to record atoms and radicals in the flames.

In the USSR there are assemblies for studying the kinetics of the reactions of atoms and radicals under isothermal conditions in the stream (the "diffusion cloud in the flux" method[16]). An important contribution to the molecular-beam mass spectrometry of flames (particularly atmospheric flames) was made by Greene and Milne[17], whose review systematised work carried out in this field up to 1968.

Fig. 2 represents a typical assembly (that of Biordi and coworkers[10,11]) used to study the structure of gaseous flames and the mechanism of their inhibition. It includes a combustion chamber with a stationary planar burner, capable of moving relative to the probe, which consists of a quartz cone. The assembly also includes a system for forming and detecting the molecular beam (skimmer, modulator, etc.). A quadrupole mass spectrometer was used as detector.

Similar assemblies have been used to study the distribution of the concentrations of atoms, molecules, and radicals in flames. Quadrupole and time-of-flight mass spectrometers are mainly used as detectors. The choice of quadrupole mass spectrometers is related to their very high sensitivity (reaching 10^{-15} mmHg). Time-of-flight mass spectrometers, which have a lower sensitivity than quadrupole instruments, have a much higher speed of operation, which makes it possible to use them to study fast processes. To separate the signal of the beam against the background of the molecules scattered by the walls of the compartment, mechanical modulation of the beam (by chopping it) and subsequent synchronous detection are used; the frequency of the modulation varies from several tens to several hundred Hertz. When modulation of the beam is used, the signal : noise ratio increases by a factor of 10^2–10^4. When this technique is used, the sensitivity of the detecting apparatus also increases considerably. A tendency to use computer control with mass spectrometers can be observed.

An important problem is to increase the heat resistance of the material of the probe. The maximum temperatures in the combustion zone amount to 1000–3000 °C, and are often higher than the melting point of the material used as sampler. The material of the sampler should satisfy the following requirements: 1) it should have a high melting point, and 2) it should be inert, and should not be broken down in the high-temperature active gaseous medium. The materials most frequently used for samplers are quartz, corundum, and refractory metals (platinum, tantalum, and a tantalum–hafnium alloy). Probes consisting of metals having a much higher coefficient of thermal conductivity than quartz and corundum, however, remove heat from the combustion zone much more rapidly than probes of quartz and corundum, and hence introduce greater thermal distortions into the flame. High-temperature ceramics can be recommended as probe materials. Difficulties arise in the construction of microprobes, however, when ceramics are used. The opening at the apex of the probe should be small and have a small wall thickness, and the length of the channel should be less than the diameter of the opening in the probe. The skimmer should have sharp edges, and the walls a small roughness factor, to prevent the production of reflected shock waves.

To select the optimum parameters for the assembly (in particular the distance between the sampler and the skimmer L), a number of authors have studied the dependence of the intensity of the beam I on L/d (for a fixed pressure p in the source; d is the diameter of the opening in the sampler) or the relationship $I = f(p)$ for different L/d. The data obtained by different authors do not show satisfactory agreement. According to some workers[18,19], the $I = f_1(L/d)$ curve has a maximum at $L/d = 30$–100, whereas according to others[12], the intensity increases continuously with decrease in L/d to 2–3. In the apparatus of Greene and Milne[18], the intensity of the molecular beam reached 10^{17} molecule cm^{-2} s^{-1} at a pressure of 1 atm in the source. The authors cited carried out detailed studies with individual gases and their mixtures, and showed that the intensity of the peak I_i of a component in a mixture is proportional to its partial pressure in the source p_i and its molecular mass M_i:

$$I_i = kp_iM_i.$$

5. Perturbations Introduced by the Probe

This question is one of the basic factors determining the quantitative aspect of the mass-spectrometric probing of flames. It is therefore not surprising that a large number of experimental and theoretical studies have been devoted to its examination. The most important perturbations introduced by the probe in the combustion process are aerodynamic and thermal. The probe acts as a material and heat sink, and this leads to the distortion, close to the probe, of the lines of equal concentrations and temperature in the flow. Since the component of the gas velocity along the axis of the probe is, close to it, greater than the gas velocity in the advancing flux, the lines of equal concentrations will be displaced in the direction of the probe (bent towards it) by an amount proportional to the diameter of the opening in the probe. This feature must be taken into account when matching the temperature (generally measured without the probe) and concentration profiles.

It should also be noted that with change in the temperature distribution in a flame without a probe as a result of the flow around the thermocouple, an aerodynamic track is formed; this produces a displacement of the lines of equal concentrations and temperatures by an amount proportional to several times the diameter of the thermocouple junction; an analogous effect is observed when the flux flows around the probe. These displacements must also be taken into account when matching the temperature and concentration profiles. It should be noted, however, that up to the present there has been insufficient quantitative study of these questions. A method for matching temperature and concentration profiles has been proposed[20], but it requires a more rigorous quantitative basis.

The aerodynamic perturbations introduced by a point sink into an advancing plane-parallel flux were calculated by Rosen[21], who found the velocity field close to the sink and calculated the dependence of the distance z (in units of the radius of the sink r) at which the vertical component of the velocity v_y/v_∞ is 5% on the sample removal factor $\alpha = Q/\pi r^2 v_\infty$ (where Q is the bulk velocity of the sink). For example, for $\alpha = 2$ (determined experimentally[22]), $z/r = 2$, that is breakdown takes place at a distance from the probe smaller than the diameter of its opening. A real probe, however, consists not only of a sink but also of an obstacle in the form of the walls of the probe, the thickness of which may be many times the diameter of the opening. Allowance for this feature in the quantitative examination of sampling problems may lead to results different from those obtained by Rosen[21].

In calculations of the isentropic flow of a gas close to and inside a probe[13], it was found that cooling as a result of the expansion of the gas specimen being analysed takes place even before the aperture of the probe (where the gas velocity is equal to the velocity of sound) at a distance of

~(1–1.5)d. Thus the gas temperature decreases by 5% at a distance d from the aperture upstream along the flux, and by 20% in the cross-section of the aperture. Thus the freezing of the chemical reactions in the gas specimen being removed begins even before its entry into the probe; the result of the analysis therefore refers to a point separated from the probe by a distance equal to its diameter.

A more important effect than that examined above is the cooling of the gas in front of the probe by the removal of heat by the latter. This question has been examined theoretically[23]; it was shown that the decrease in temperature may reach 8.5% under typical experimental conditions. The question has also been studied experimentally[24]. The experiments were carried out as follows: a thermocouple was placed at a definite point in the flame front, and the probe was placed at different distances from the thermocouple. When the probe was situated at a considerable distance from the thermocouple (greater than the width of the combustion zone), it had no influence on the thermocouple readings. As the probe approached the thermocouple, the temperature decreased; the maximum effect was ~150 K. The distribution of the temperature of the flame of the planar burner was measured by the thermocouple without the probe and with the probe placed at a distance of 2d from the thermocouple (the aperture angle of the probe was varied). The experimental results (Fig. 3) show that a probe with a cone aperture angle smaller than 40° does not distort the temperature profile in the flame zone (except for temperatures close to the flame temperature), but displaces it as described above. In the case given, this displacement amounted to 0.5 mm, which is one tenth of the width of the combustion zone, and was much greater than the diameter of the opening in the probe (which was equal to 0.1–0.14 mm).

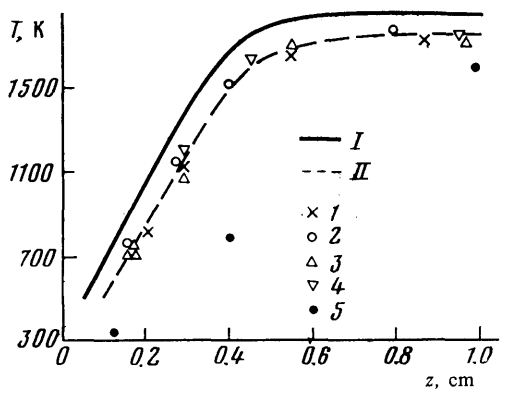

Figure 3. Temperature distribution in the flame of a planar burner (z is the distance from the burner surface) without a probe (I) and with probes (II) having different hole dimensions d and aperture angles α' of the cone. The distance between the thermocouple and the probe was equal to twice the diameter of the opening in the probe; α': 1, 2) 10–15°; 3) 40°; 4) 64°; 5) 78°; d, μm: 1) 137.5; 2) 51; 3) 114; 4) 100; 5) 87.5.

In the experiments described above, the aperture angle of the cone of the probe was varied. When the aperture angle of the cone is greater than 40°, it influences the concentration and temperature distributions[24]. Increase in the aperture angle of the cone apparently increases the heat losses into the probe, and the flame front is no longer one-dimensional. On the other hand, decrease in the aperture angle of the cone of the probe below 40° leads to an increase in the thickness of the boundary layer inside the probe near the inlet hole. This leads to an increase in the probability of the disappearance of the active species (particularly atoms, radicals, and ions) on the walls of the probe. Thus the optimum aperture angle of the cone of the probe is 30–40°.

The distortions of the concentration gradient during sampling with a probe under isothermal conditions have been studied theoretically and experimentally[22]. It was concluded that the effect of distortion of the concentration gradient can be neglected if the ratio of the dimensions of the opening in the probe to the width of the reaction zone is much less than unity. Thus to decrease the distortions it is possible to recommend a reduction in the size of the opening in the probe. Decrease in the size of the opening in the probe, however, leads to an increase in the proportion of the boundary layer and hence to an increase in the distortion of the composition of the gas in the specimen (chiefly the concentrations of the active species, for which the probability of disappearance increases in the boundary layer as a result of homogeneous and heterogeneous-catalytic reactions).

To estimate how the composition and concentration profiles of the specimen are distorted during its removal, a number of authors have carried out independent measurements of various parameters by other non-contact methods. For example, the distributions of the concentrations of hydrogen in an H_2–O_2–N_2 flame have been determined by mass-spectrometric and optical methods (Fig. 4).[9] The concentrations of OH radicals in the flame for 10.3% CH_4–21.6% O_2–68.1% Ar ($p = 0.042$ atm, $T = 1835$ K), measured optically (from the absorption), by mass spectrometry, and by the method of balanced reactions (from the data in Ref. 9) at a point 3 cm above the surface of the burner were 7.8×10^{14}, 15.5×10^{14}, and 16.9×10^{14} particles cm^{-3} respectively.

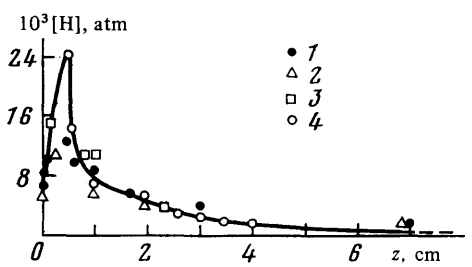

Figure 4. Concentration profiles of hydrogen atoms in an H_2–O_2–N_2 flame, measured by the mass-spectrometric method using ceramic (1) and metallic (2, 3) probes and by an optical method (4).

As shown below, the constants for a number of elementary chemical reactions, found by the treatment of data obtained by mass-spectrometric probe methods, show satisfactory agreement with published data[25] and data obtained independently by other methods. Thus in spite of the perturbations introduced by the probe method, it can be used to determine with sufficient accuracy the chemical structure of the flame front, the concentrations of the reacting components, and the kinetics of chemical reactions in flames.

III. STUDIES OF THE MICROSTRUCTURE OF FLAMES AND THE MECHANISM AND KINETICS OF CHEMICAL REACTIONS IN GASEOUS FLAMES

1. Equations Describing a Planar Laminar Flame

The equations defining the behaviour of a one-dimensional (planar) laminar flame are given below[1].

1. Equation for the conservation of mass:

$$\rho v = \rho_0 v_0 = \text{const},$$

where v is the velocity of the flux, and ρ the density.

2. Equation for the conservation of the fluxes of the individual compounds:

$$\frac{d}{dz}[N_i(v + V_i)] = \sum_{j,k=1}^{N'} k_{jk} N_k N_j;$$

Thus the derivative of the flux of a compound at any point in the flame should be equal to the rate of the appearance or disappearance of this compound as a result of the chemical reaction; k_{jk} is the rate constant for the reaction of the two compounds j and k; the sign of k_{jk} depends on whether the compound i appears or disappears in this reaction; N_i is the concentration of the ith component; V_i the diffusive flux of the ith component; N' the total number of components; and z the coordinate in the direction of which all the characteristics change.

3. The equation of state:

$$p = NRT; \quad N = \sum_{i=1}^{N'} N_i .$$

The velocity of the diffusive flux of the ith component is defined as

$$V_i = \frac{N^2}{N_i \rho} \sum_{j=1}^{N'} M_j D_{ij}^* \frac{d}{dz}\left(\frac{N_j}{N}\right) - \frac{D_i^{*T}}{N_i M_i} \frac{d}{dz} \ln T .$$

Here, D_{ij}^* and D_i^{*T} are the coefficients of binary diffusion and thermal diffusion, and M_i is the molecular mass of the ith component. This is the equation of Fick's law, applied to multi-component systems, with an additional term (the last) which takes account of thermal diffusion.

These equations are the basic equations describing the change in the characteristics in a laminar planar flame. In the analysis of data on the structure of flames, it is sometimes convenient to use an additional variable. This is the fraction of the flux of the mass of the ith component G_i, defined as

$$G_i = \frac{N_i M_i}{\rho v}(v + V_i).$$

It characterises that fraction of the total mass flux through unit area due to the diffusion and convection of the compound i.

The basic equations of a one-dimensional flame can be written in a more compact form using the variable G_i. For a planar flame, the equations for the conservation of the compounds can be written in the form:

$$\frac{\rho_0 v_0}{M_i} \frac{dG_i}{dz} = \sum_{j,k=1}^{N'} k_{jk} N_j N_k = R_i. \qquad (1)$$

If the concentration and temperature distributions are measured experimentally, the differential equations (1) can be used to find the rates of formation or disappearance of the compounds, and then the velocities and rate constants of the elementary reactions in flames for different experimental conditions.

2. Microstructure of Flames and Determination of the Rate Constants of the Elementary Stages

Figs. 5 and 6 give as examples the results of the mass-spectrometric study of the microstructure of the flame CH_4 (9.62%)–O_2 (21.4%)–Ar (68.97%) at a pressure of 32 mmHg.[10] Fig. 7 gives the rates of the reaction of the principal stable compounds in the zone of the flame, obtained by computer treatment of the data in Fig. 5 using the equations given above and specially developed programs[26]. Subsequent treatment of the data on the reaction rates of the stable components in the flame makes it possible to determine the rate constants of the elementary reactions if their mechanisms are known.

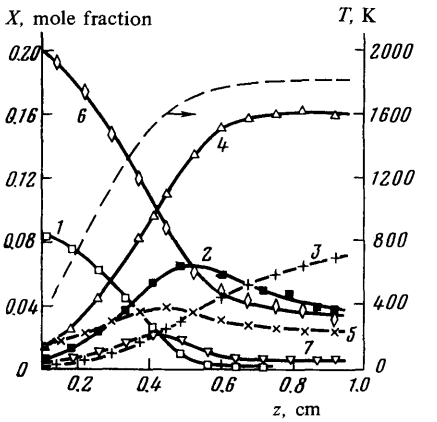

Figure 5. Temperature and concentration profiles for the principal stable components of the flame: *1*) CH_4; *2*) CO; *3*) CO_2; *4*) H_2O; *5*) H_2; *6*) O_2; *7*) CH_2O (× 20).

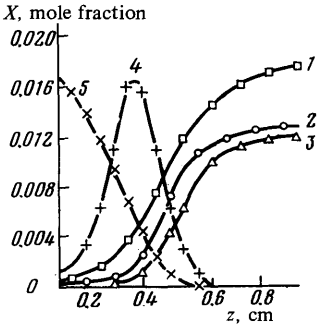

Figure 6. Concentration profiles for the principal intermediate products of the flame: *1*) H (× 0.8); *2*) OH; *3*) O; *4*) CH_3 (× 5); *5*) CH_4 (× 0.2).

Baulch and coworkers[26] give as an example the determination of the rate constant of the forward reaction

$$H + O_2 \underset{k_r}{\overset{k_f}{\rightleftarrows}} OH + O$$

from the data obtained by probing a CH_4–O_2 flame. The rate of the reaction of molecular oxygen in the flame, found from the concentration profile of O_2, is defined by the equation:

$$R_{O_2}=k_f[H]\cdot[O_2]-k_r[OH]\cdot[O].$$

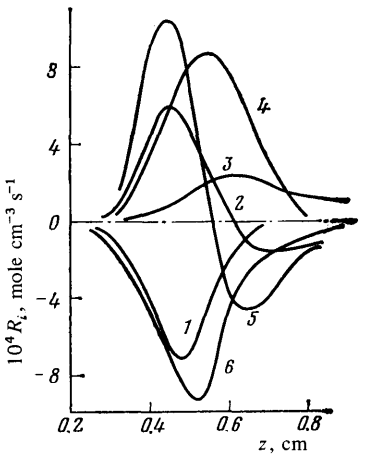

Figure 7. Profiles of the velocities of the reactions of the principal stable components in the flame: *1–6*) see Fig.5.

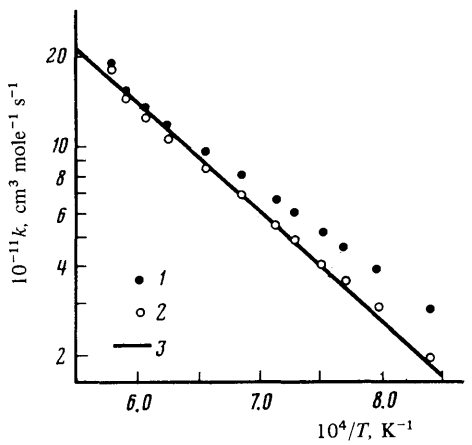

Figure 8. Arrhenius relationship for the rate constant of the reaction $H+O_2\rightarrow OH+O$; *1*) calculation from Eqn.(2) using experimental data; *2*) calculation using a more complex equation, taking account of the consumption of O_2 in its reaction with the radical HCO; *3*) straight line obtained from a critical analysis of published experimental data.

The square brackets denote the concentrations of the corresponding compounds. From the equilibrium constant of the above reaction K_{equil}, the quantity R_{O_2} can be expressed in terms of the mole fractions of oxygen and the radicals X_{OH}, X_{O_2}, X_H, and X_O, the profiles of which are known:

$$R_{O_2}=(p/RT)^2k_f(X_{OH}X_O/K_{equil}-X_HX_{O_2}). \qquad (2)$$

Fig.8 gives in Arrhenius coordinates the results of the calculation of k_f from this equation using experimental data[26], the results of a calculation using a more complicated equation taking account of the consumption of O_2 in the reaction with the radical HCO (using the published values of the rate constant of this reaction), and also the results of a critical analysis of published experimental data obtained independently over a wide range of temperatures using other experimental methods. It can be seen that the agreement is satisfactory.

Table 1. Magnitudes of the errors in the determination of the rate constants of the elementary reactions from mass-spectrometric studies of the microstructure of flames[25].

No.	Reaction	Temp. range, K	Smoothing, %	Matching of the temperature and concentration profiles, %	Temp. dependence of the intensities of the peaks of the fragment ions, %
1	$H+O_2\rightarrow OH+O$	1300—1500	20	35	—
	»	1500—1700	5	20	—
2	$H+CH_4\rightarrow CH_3+H_2$	1325—1500	30	35	20
	»	1500—1700	40	25	10
3	$CO+OH\rightarrow CO_2+H$	1425—1575	20	30	3
	»	1575—1725	10	30	3
4	$CH_3+O\rightarrow H_2CO+H$	1550—1650	20	25	5
	»	1650—1750	30	25	15

	»	1300—1600	20	20	—

Table 2. Comparison of reaction rate constants determined from mass-spectrometric studies of the microstructure of flames[25] and found by other methods (see Table 1 for the numbering of the reactions).

Reaction No.	T, K	Rate constant (Ref.25)	Data obtained by other methods	Refs.
1	1300—1700	$7.5\cdot10^{13}\exp(-13500/RT)$	$2.2\cdot10^{14}\exp(-16900/RT)$; 700—2000K	26
2	1325	$7\cdot10^{11}$	$3.1\cdot10^{13}\exp(-8200/RT)$; 1200—1800K	27
2	1540	$2\cdot10^{12}$		
2	1665	$4.7\cdot10^{12}$	$(3.2\pm0.6)\cdot10^{12}$; 1600 K	15
2	1700	$7.5\cdot10^{12}$		
3	1425—1725	$4.6\cdot10^{11}$	$k=10.83\pm3.9\cdot10^{-4}\ T$	28
4	1550—1750	$8.2\cdot10^{13}$	$2.6\cdot10^{14}\exp(-2000/RT)$; 1000—2000K	29
4	—	—	$7.4\cdot10^{13}$, 297K	30
5	1000—1600	$2.3\cdot10^{14}\exp(-9200/RT)$	$4.36\cdot10^{15}\exp(-17450/RT)$	31

The problems arising in the determination of the rate constants of elementary reactions from data obtained by probing flames have been listed and analysed[25]: 1) the problem of smoothing the curves drawn through the experimental points, arising from the need for double differentiation of the concentration profiles; 2) the matching of the concentration and temperature profiles; 3) the temperature dependence of the intensities of the peaks of the fragment ions; and 4) the problem of calibrating the mass spectrometer with respect to radicals and atoms. Table 1 gives the magnitudes of the errors arising in the determination of the rate constants of elementary reactions from the results of mass-spectrometric studies of the microstructure of a flame (with the exception of the errors associated with the determination of the absolute concentrations of atoms and radicals in the calibration, which amount to 100%). Table 2 gives the rate constants of elementary reactions, determined from the results of mass-spectrometric studies of the microstructure of flames using probe

removal of samples, and also calculated from experimental data obtained using other methods. It can be seen that the agreement is satisfactory; thus the mass-spectrometric method can ensure the determination of the rate constants of elementary reactions with an accuracy which at the present time is not less than the accuracy of the measurement of the rate constants by other methods (particularly in the high-temperature range).

3. Vibrational–translational Non-equilibrium in Flames

It is necessary to deal particularly with the question of translational–vibrational non-equilibrium in the reaction zone of a methane–oxygen flame[25] and its study by molecular-beam mass spectrometry. The existence of vibrational disequilibrium for certain diatomic radicals in the reaction zone of a flame has been proved directly by spectroscopic methods[32]. The mass-spectrometric probing of flames makes an additional contribution to the study of this question. The translational–vibrational disequilibrium of molecules is revealed in a change (compared with the equilibrium case) in the ratio of the intensities of the mass peaks of the "parent" and fragment ions, since the rate of fragmentation of a complex molecule depends on the degree of vibrational excitation.

In the molecular-beam mass-spectrometric probing of flames and the analysis of the data obtained, three questions are closely related: 1) the above-mentioned temperature dependence of the intensities of the peaks of the fragment ions; 2) vibrational–translational relaxation in the flame; and 3) vibrational–translational relaxation in the expansion of the gas during the removal of the specimen from the flame.

These questions have been analysed[25] for CO_2 and CH_4 molecules in a CH_4–O_2–Ar flame. Account was taken of data on the temperature dependence of the peaks of the fragment ions in the mass spectra of CO_2 and CH_4, obtained using effusion and gas-dynamic molecular beams. From the analysis of the experimental data, it was concluded[25] that translational–vibrational disequilibrium exists for the methane molecule both in the flame and in the process of gas expansion during the removal of the specimen from the flame. For CO_2, in both cases, vibrational–translational equilibrium can be established.

To explain this, the following estimates are given[25]. Under the conditions of the flame, the molecules undergo 10^8 collisions per second. The vibrational–translational relaxation times in a CH_4–Ar mixture were measured, and are equal to 3×10^{-5} s under flame conditions, which corresponds to an average of 3000 collisions. With allowance for diffusion, the flow velocity of methane in the flame is 2500 cm s^{-1}, which corresponds to a delay in the establishment of vibrational–translational equilibrium at a distance of 0.07 cm, comparable with the width of the chemical reaction zone and the high spatial resolving power of the probe. For the CO_2 molecules, however, the velocity of the flux under the same conditions is smaller by an order of magnitude than that for the CH_4 molecules (since the diffusion flux of CO_2, unlike that of CH_4, takes place in the opposite direction to the overall flux) and amounts to 300 cm s^{-1}. Thus the spatial lag of the vibrational relaxation for CO_2 is smaller by an order of magnitude and amounts to ~0.007 cm.

4. Mechanism of Inhibition in Flames

The flame probe method also makes it possible to study the mechanism of the action of additives introduced into a flame, for example to inhibit them. The results of studies of the microstructure of a methane–oxygen flame containing the added inhibitor CF_3Br have been used[26] to calculate the rates of consumption of the inhibitor in the chemical reaction zone of the flame.

The possible reactions involving the consumption of the inhibitor, and their contribution to the total rate of consumption of the inhibitor (CF_3Br) in the flame, as percentages of the experimentally observed maximum rate, are given below:

$CF_3Br \rightarrow CF_3 + Br$	8
$CF_3Br + CH_3 \rightarrow CH_3Br + CF_3$	2
$CF_3Br + O \rightarrow BrO + CF_3$	0.1
$CF_3Br + Br \rightarrow Br_2 + CF_3$	0.1
$CF_3Br + H \rightarrow HBr + CF_3$ + 25 kcal $mole^{-1}$	100

The rate of consumption of the inhibitor at a given point in the combustion zone by each of the possible reactions was determined by multiplying the corresponding rate constant, taken from published data, by the experimentally measured[25] concentration of the inhibitor and the radical at this point. The contribution of the reaction to the total maximum rate of consumption of the inhibitor was determined at the point of maximum rate by dividing the rate of consumption, calculated as described above, by the rate of consumption obtained by mathematical treatment of the concentration and temperature profiles in the flame. The data given show that the principal path in the consumption of the inhibitor is its reaction with hydrogen atoms, which are the main chain carriers in the branched chain reaction of methane oxidation. As a result of this reaction, there is a decrease in the concentration of hydrogen atoms; this leads to a decrease in the rate of the oxidation process and hence in the rate of propagation of the flame.

A cycle of studies has been carried out[33] to investigate the structure of the front of hydrocarbon flames (chiefly propane) and the mechanism of their inhibition. A knowledge of the mechanism of chemical reactions in the flame zone and the mechanism of inhibition makes it possible to develop methods for calculating flame propagation velocities and to establish methods for finding effective combustion inhibitors, which are of considerable importance for preventing fires and explosions.

The technique described above has been used to study the structure of the rarefied flames CH_4–O_2,[10,11] $HClO_4$–CH_4,[14] N_2O–H_2,[34] and C_2H_4–O_2[15] and the atmospheric flames CH_4–O_2 and H_2–O_2.[9,12,13] As a result of these studies, it has been possible in a number of cases not only to establish the mechanisms of the chemical reactions in the flames but also to find various previously unknown rate constants of elementary reactions.

IV. NON-STATIONARY PROCESSES

Dynamic mass spectrometry has found extensive application in the study of non-stationary processes in gaseous and condensed systems: in the study of the propagation of flames and shock waves, the kinetics of fast decomposition reactions, processes in internal combustion engines, etc. The propagation of atmospheric cold flames of butane in a tube (at a velocity of 4 cm s^{-1}) has been studied[35]; the products passed directly into the ion source of a time-of-flight mass spectrometer through a hole made in the wall of the tube by means of a laser.

The rarefied flame in mixtures of chlorine azide and hydrogen, being propagated along a tube at a velocity of 6 m s^{-1} has been studied[36]. The mixture was ignited at one end of the tube, and the probe placed at the other end. A Bendix Aviation Corporation time-of-flight mass spectrometer was used to record the change with time in the intensity of the mass peaks as the combustion wave passed the point where the specimen was consumed (the transit time amounted to

several milliseconds). Considerable concentrations of intermediate products—radicals and atoms—were detected.

The formation of nitric oxide in air in a spark discharge, which is important for investigating the mechanism of spark ignition, has been studied in a flow reactor[37]. The molecular-beam removal of specimens from the working compartment of an internal combustion engine during its operation is also of considerable interest[38]. The dependence of the concentration of propane on the angle of rotation of the crankshaft was measured experimentally. The results make it possible to understand the processes of combustion of the fuel in the engine, and this is important for developing measures to improve its operation.

The chemical structure of the turbulent track produced during the flight of a projectile at supersonic velocity has been studied[39]. A sphere of diameter 16 mm was projected in air at a pressure of 60 mmHg and a velocity of 6 km s^{-1} close to a probe having a molecular-beam system for extracting the sample. The formation of NO in the track was detected, and the time dependence of the concentration of nitric oxide in the track was measured: the decrease in [NO] was recorded over a period of several milliseconds after the flight of the sphere.

One of the most striking examples of the application of time-of-flight mass spectrometry to the study of high-temperature chemical processes is the study of the kinetics of reactions in shock waves[40] and in pulse flash photolysis[41-43] (the reaction times amount to tenths or hundredths of a microsecond).

In spite of the efficiency of the method, however, the time-of-flight mass spectrometer does not yet ensure the accuracy of recording required for carrying out kinetic studies of processes lasting for hundredths of a microsecond. Recently, therefore, new systems have appeared for the mass-spectrometric study of fast processes[44], in which the separation of the ions according to mass is carried out in a magnetic field, and each type of ion is recorded by means of its own collector. The dynamic mass spectrometer has also found extensive application in the study of the kinetics of the fast reactions involved in the decomposition of solid fuels (S.F.) as one of the stages of the combustion process. Work carried out in this field up to 1969 has been reviewed in detail[45].

Mass-spectrometric methods for studying the fast processes involved in the decomposition of solid fuels have continued to develop in recent years. Fig. 9 shows an assembly[46] used to study the fast processes involved in the decomposition of specimens of solid fuels at a pressure of 1 atm under isothermal (time ~ 1 s) and non-isothermal conditions (rate of heating 100–1000 K s^{-1}, close to the rate of heating in the combustion wave of the solid fuel). The assembly contains a heating system, a flow reaction vessel, a pumping system, a time-of-flight mass spectrometer (TFMS), and an automatic recording system, which includes a specially developed device, "Strob", which converts the mass-spectrometric information into digital form, and a PL-150 punch machine.

Examples have been given[46,47] of the study of the decomposition of catalyst-containing mixtures, based on ammonium perchlorate, under conditions of rapid heating, close to the rate of heating in the combustion wave. Correlations have been found between the decomposition and combustion processes.

The use of an automatic system for recording mass-spectrometric information has made it possible to reduce by an order of magnitude the time taken to process the results of measurements and to increase by an order of magnitude the accuracy of the measurement.

V. COMBUSTION OF CONDENSED AND HETEROGENEOUS SYSTEMS

The mass-spectrometric method can be used successfully to study the combustion of solid fuels and the flame structures and kinetics of the chemical reactions in solid fuel flames[48-50].

In the probing of solid fuel flames, additional difficulties arise (compared with gaseous flames); one of these is the difficulty of stabilising the combustion surface relative to the probe. The measurement process should therefore be rapid (several seconds) and have a low inertia. These difficulties have been overcome[48-50].

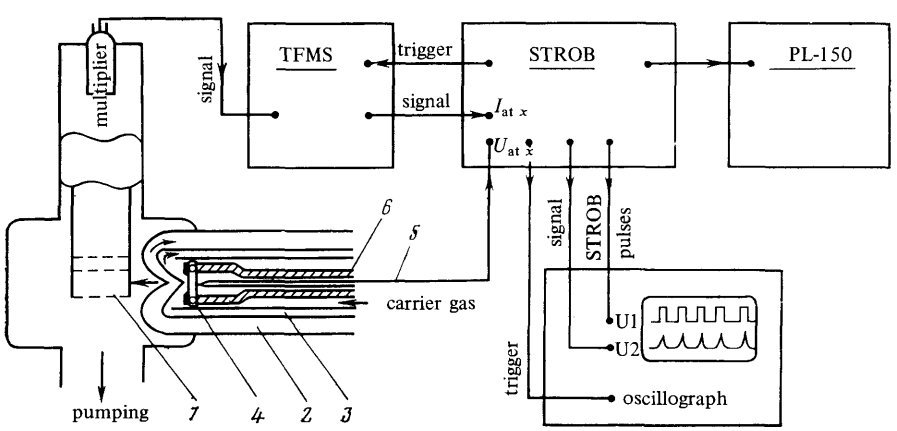

Figure 9. Diagram of the apparatus for studying the fast processes involved in the decomposition of solid fuels: *1*) ion source of the time-of-flight mass spectrometer; *2*) low-pressure compartment; *3*) high-pressure compartment (1 atm); *4*) cell for heating the specimen rapidly; *5*) thermocouple; *6*) current-carrying leads.

As an example, Fig. 10 gives the results of a study of the distribution of the concentration of the reacting components in the flame of a model solid fuel mixture based on ammonium perchlorate (84%) and polymethyl methacrylate (16%) at a pressure of 50 mmHg and an initial temperature of 180 °C.[50] The burning solid fuel specimen was moved in the direction of the stationary probe at a velocity greater than the velocity of combustion. As a result, the probe passed through all the combustion zones, including the reaction layer of the *K*-phase. As the combustion surface approached the probe, in the zone of the flame there was a decrease in the concentrations of the combustion products HCl ($m/e = 36$), $CO_2 + N_2O$ (44), and NO + N_2O (30), and also CO + N_2 (28) and H_2O (18), not shown in Fig. 10, and an increase in the concentrations of the products of the gasification of the oxidant, $HClO_4$, ClO_2 (67), O_2 (32), and NH_3 (16), and the fuel, methyl methacrylate (41).

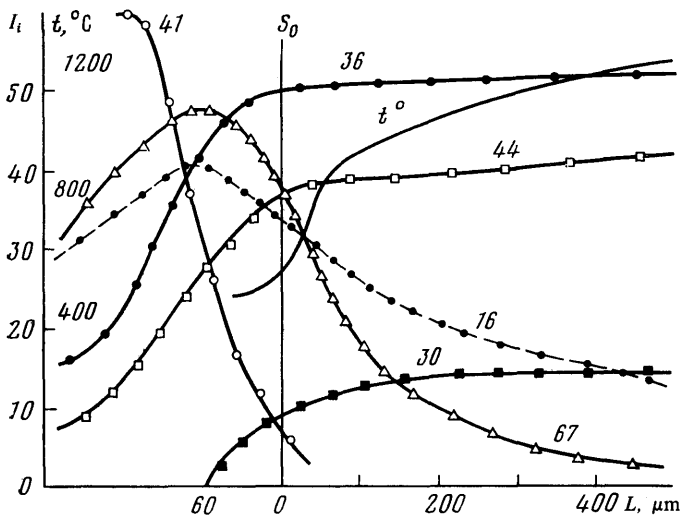

Figure 10. Profiles of the intensities of the peaks of the reacting components I_i in the combustion zone of a solid fuel mixture; S_0 is the combustion surface, $t°$ the temperature, L the distance to the combustion surface, and the figures next to the curve give the values of m/e.

On further movement of the specimen, the probe enters the reaction layer of the condensed phase, making it possible to record (qualitatively at least) the concentrations of gaseous components in the reaction layer of the solid fuel; this cannot yet be done by any other method. As the probe moves into the reaction layer away from the combustion surface, the concentration of oxidant increases, reaches a maximum, and then decreases, whereas the concentration of the products of the gasification of the fuel continue to increase, indicating that the decomposition takes place by a stepwise mechanism. The chemical structure of the combustion wave has also been studied[49,50] for ammonium perchlorate, ballistic powder, and mixtures containing added combustion catalysts.

The results obtained make it possible to deepen and broaden existing ideas regarding the mechanism of the combustion of solid fuels and to obtain data on the kinetics of chemical reactions in solid fuel flames, which can be used to develop mathematical models of their combustion.

There has recently been an increase in interest in the study of the mechanism of the combustion of polymers in connection with the search for polymer combustion inhibitors and methods for decreasing the combustibility of polymers. Mass spectrometry has been used[51] to determine the concentration profiles of the components in the combustion zone of polymethyl methacrylate in air (Fig. 11). The first results have been published[52] on the probing of the diffusion flame of an epoxide resin; the results show the variety of the chemical reactions accompanying the combustion of polymers. Further studies should assist in the investigation of the mechanism of the combustion of polymers.

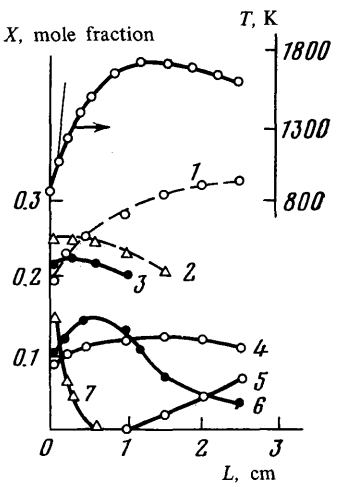

Figure 11. Dependence of the temperature and concentration of the products of the combustion of polymethyl methacrylate in air on the distance L (cm) from the combustion surface of the polymer: *1*) Ar (× 0.5); *2*) H_2 (+0.2); *3*) hydrocarbons (+0.2); *4*) CO_2; *5*) O_2; *6*) CO; *7*) methyl methacrylate.

VI. LIQUID ROCKET MOTORS

The possibilities provided by dynamic mass spectrometry for the study of the processes involved in the mixing of the components and their combustion in liquid rocket motors (LRM) have been demonstrated[53]. An assembly has been developed[53] which makes it possible to study the processes involved in the mixing and combustion of the oxidant (N_2O_4) and the fuel (N_2H_4) in the combustion compartment of a small LRM. Since the final aim of the studies was to analyse the combustion of a system containing the extremely aggressive components F_2–N_2H_4, an attempt was made to create a molecular-beam sampling system. In spite of the fact that a molecular beam was not established in the specimen-removal system, because of the insufficient rate of pumping of the skimmer compartment, it was possible to obtain a number of experimental facts of importance for understanding the processes taking place in the motor.

Fig. 12 shows the experimental assembly, which includes the combustion chamber of the LRM and the sampling system. To study the local concentrations of the components in the combustion compartment of the motor, the jet was replaced by a plate having 29 holes of diameter 0.21 cm, with centres

separated by 1.14 cm. The sampler could be placed at the centre of any of the holes, with a high accuracy. The pressure in the space in which the flow of the combustion products took place was 1 atm.

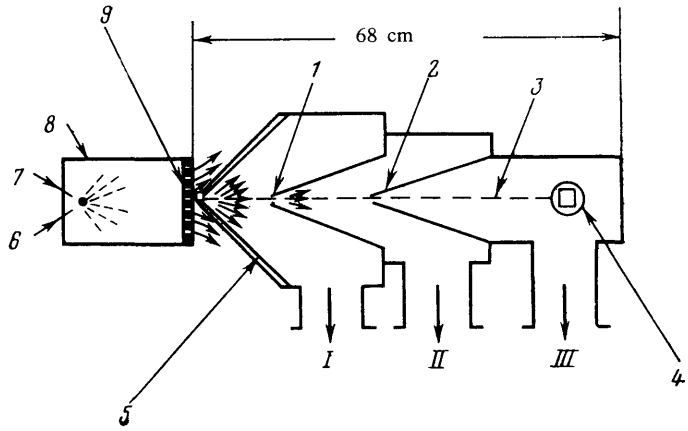

Figure 12. Removal of a specimen from the gases flowing from the combustion chamber of a liquid rocket motor: *1*) skimmer, *2*) collimator, *3*) supersonic molecular beam, *4*) quadrupole mass spectrometer, *5*) water-cooled heat shield, *6*) oxidant, *7*) fuel, *8*) combustion chamber, *9*) water-cooled multi-jet end plate; *I*, *II*, and *III*—evacuation stages.

Preliminary experiments established that the hole in the sampler was closed by fusion when the motor was operated for 6 s, but remained undamaged for a duration of operation of 3–3.5 s, which was found to be sufficient to obtain and record the required experimental results. Treatment of the results of the mass-spectrometric studies established significant non-uniformity of the oxidant/fuel ratio over the cross-section of the combustion chamber of the motor. It was shown that the phenomenon of so-called "stream penetration", previously detected in experiments with cold components, also takes place in the hot working motor. The large quantities of nitric oxide (compared with equilibrium) detected in the mass spectra indicate inadequate efficiency of the combustion in the motor. The results obtained indicate the need to improve the sampling system. The authors cited[53] subsequently intend to increase the rate of pumping the skimmer compartment and to obtain a molecular beam at a pressure at the point of sampling up to 6 atm.

Thus the mass-spectrometric method provides a powerful instrument for studying combustion processes. The possibilities provided by the method have not yet been fully revealed, and are far from exhausted. Mass spectrometry occupies an important position among other methods for studying flames and combustion processes, such as optical, radiospectroscopic, calorimetric, chromatographic, and other methods, each of which has its own advantages and disadvantages. Best results can undoubtedly be achieved by the simultaneous use of the above methods.

Theoretical Calculation of the Spatial Distribution of Molecules in Crystals

T.V.Timofeeva, N.Yu.Chernikova, and P.M.Zorkii

The fundamental energetic and geometric framework of the interpretation and prediction of molecular packing is discussed on the basis of results published between 1960 and 1977. The atom-atom potential method is described, and the methods of selecting the parameters of these potentials are examined. An extended tabulation of theoretically determined molecular packing arrangements is presented, listing the form of the chosen potential function, the structure parameters which are treated as adjustable in the minimisation of the energy, and other aspects of the method of calculation. 271 references.

I. INTRODUCTION

The *a-priori* determination of the distribution of molecules in a crystal structure without resorting to experimental data (or with a minimal use of such data) offers many attractive possibilities. Firstly, the very fact that prediction is possible confirms the validity of our views on the fundamental aspects of crystal structure. Secondly, there is now considerable practical interest in the theoretical calculation of structures in cases (e.g. polymers, layered polytypes) where X-ray diffraction cannot give full structural information but it can confirm *a-priori* calculations. Thirdly, these calculations can be useful in computations of approximate, model structures which can then be made more precise by using X-ray diffraction data. Therefore it is not surprising that the early theoretical calculations of the spatial arrangements of molecules in crystals were followed by a large number of publications on the same theme during the past 25–30 years.

The aim of this review is to analyse the results of that work and to assess the prospects of this field of science. We shall examine very recent results, which were not available to previous reviewers[1–4]. Furthermore previous writers[3–5] have tended to ignore work other than their own.

II. GEOMETRIC AND ENERGY INTERPRETATION OF MOLECULAR PACKING

The problem of determining the optimum structure reduces to finding the spatial distribution with a minimum energy. There are at present two ways of formulating the problem. One consists in finding the closest packing of particles, using van der Waals radii. In the absence of directionally specific interactions the tendency to give a close-packed structure is a good guide to finding the arrangement with minimum energy. The second (and stricter) approach is to calculate the arrangement corresponding to a minimum in the intermolecular interaction energy.

In general the calculation of the closest packing of bodies of arbitrary shape presents enormous mathematical difficulties. However in many crystal-chemical problems we can introduce substantial simplifications which allow us to reach a definite solution.

One of these simplifications is to assume that the elementary cell parameters are known. This variant of the problem was solved by Kitaigorodskii[6] for 2,6-dimethylnaphthalene by using a special apparatus (the "structure seeker"), and also for several other crystals[7–9] by computation. The combination of the principle of closest packing with experimentally measured lattice parameters forms the basis of the X-ray method of determining crystal structures developed by Gel'fand, Neigauz, and others[10,11] (the "gully" method).

Another simplification is possible in the case of polymeric molecules. Since the axes of these molecules must be parallel, one degree of freedom is lost. By virtue of this approximation the principle of closest packing allows us not only to predict the arrangement of chains in the cell but also to identify a very limited number of possible elementary cells. Studies of polyethylene by this method were reported by Kitaigorodskii[12,13] and by Segerman[14].

Zorkii and Porai-Koshits[15–17] combine the principle of closest packing with a quantitative calculation of the distribution of objects of arbitrary shape in a plane with the highest reticular density (the streamline trajectory method). This allows them to calculate the most compact type of packing of long-chain molecule (or planar molecules) in a layer whose plane coincides with the plane of the molecule. The crystal structures of $PdCl_2$,[18] $BeCl_2$,[19] Ni dimethylglyoxime[20], and Cu salicylalmethyliminate[21] have been successfully determined by the trajectory method.

The geometric approach continues to be an effective method of interpreting molecular crystal structures. Its value has been enhanced by the publication of an accurate set of van der Waals radii[22,23], obtained by a statistical analysis of a large amount of structural information. However, though it remains a simple and useful tool for qualitative and semi-quantitative estimates, the geometric model is not a serious contender for the quantitative *a-priori* prediction of molecular packing, i.e. the problem to which this review is devoted. The geometric approach is inferior to the energy approach (in that its postulates are less strict and well founded) without in any way making the calculation of the optimum structure (using a computer) more straightforward. Hence it is better to seek a solution of the molecular packing problem directly from calculations of the intermolecular interaction energy. The atom–atom approximation, which is discussed in detail in the next Section, offers a concrete method of calculating this energy.

The energy of a crystal structure consisting of rigid molecules can be expressed as a function of a series of structure parameters:

$$U(a, b, c, \alpha, \beta, \gamma, X_i, Y_i, Z_i, \varphi_i, \theta_i, \psi_i),$$

where a, b, c, α, β, γ are the lattice parameters, X_i, Y_i, Z_i are the coordinates of the centres of gravity of the symmetrical, independent molecules, and ϕ_i, θ_i, ψ_i are the Euler angles which characterise the orientation of these molecules. In special cases the number of independent parameters can be less: thus the energy of rhombic benzene is a function of six parameters only ($U(a,b,c,\phi,\theta,\psi)$). On the other hand the angles which characterise the conformation must be included among the parameters if the molecule cannot be treated as rigid.

By minimising the energy U we can find the structure parameters which offer the optimum molecular packing: in principle this should correspond to the crystal structure experimentally observed. Minimisation is usually applied to the potential energy of the structure. Thus we are in fact examining the structure of the crystal at a temperature close to the absolute zero. However we know experimentally that the vast majority of molecular crystals do not suffer phase transformations over a wide range of temperature (up to room temperature), and their geometric characteristics change very little. Hence the optimum structure for the absolute zero is often also the optimum for room temperature. However a strict formulation of the problem requires calculation of the free energy F of the crystal structure.

Consideration of the simplest model structure, consisting of an assembly of independent oscillators located at lattice sites, shows[24] that the free energy can be expressed as the sum of the following terms:

$$F=U_0+E_0+E_T-TS,$$

where U_0 is the potential energy of the structure at 0 K, and E_0 and E_T are the zero-point vibration and the thermal vibration energy respectively. The free energy of all molecular crystals is usually assumed to consist of these terms.

Molecular crystals are distinguished by a very large difference between the energies of their intramolecular and intermolecular interactions. For this reason Kitaigorodskii suggested[25] expressing the thermodynamic functions of molecular crystals as the sum of two terms: a "molecular" term and a "crystalline" term. The former is related to the structure of the molecules and to their internal vibrations, the latter to the relative position of the molecules and to their external vibrations:

$$U = U^{\text{intra}} + U^{\text{inter}},$$
$$S = S^{\text{mol}} + S^{\text{cryst}},$$
$$E_T = E^{\text{intra}} + E^{\text{ext}}.$$

Using these expressions the free energy of a molecular crystal can be written

$$F = E_0 + (U^{\text{intra}} + E_T^{\text{intra}} - TS^{\text{mol}}) + (U^{\text{inter}} + E_T^{\text{ext}} - TS^{\text{cryst}}) = E_0 + F^{\text{mol}} + F^{\text{cryst}}.$$

Our main interest lies in the evaluation of the term F^{cryst}. In the case of rigid molecules the minimum of the function F^{cryst} coincides with the minimum of the full free energy function.

Two specific ways of calculating F are known at present. The first, described in detail in Ref.26, includes a calculation of the full set of frequencies from the differentials of the potential energy with respect to the structure parameters (expressing the energy U in the atom–atom approximation). The standard free expressions in terms of the frequency distribution function (or density of states function) are then applied. Typical of this approach is a calculation[27] of the equilibrium parameters of the elementary cells of three hydrocarbons at different temperatures.

The second method of calculating the energy F is based on statistical mechanics, and involves a calculation[28] of the configurational integral

$$Q=\frac{1}{N!}\int_{\Omega}\cdots\int_{\Omega}\exp\left\{-\frac{U(q_1,\ldots,q_N)}{kT}\right\}\mathrm{d}q_1\ldots\mathrm{d}q_N,$$

where N is the number of molecules in the system, $U(q_1,\ldots,q_N)$ is the potential energy, and Ω is the volume in configurational phase space occupied by the system. In the calculation the configurations $q_1^{(i)},\ldots,q_N^{(i)}$ are randomly generated in phase space (Monte Carlo method) and the corresponding values of the integrand are averaged. Concrete calculations of this type have been reported for crystals of the intert gases[29,30], N_2,[31] and CO_2.[32] However this approach is too cumbersome for large (or even moderately large) molecules.

Excessive use of computer time can be avoided by using the cell model[33], whose application to the calculation of the thermodynamic functions of molecular crystals is discussed by Holt and coworkers[34]. According to this model the volume occupied by the system is divided into N cells whose centres form the lattice. Each cell contains one molecule whose position and orientation are described by the six-dimensional vector q (which includes three translational and three rotational components). The motion of each molecule is assumed to be independent of the motion of molecules in neighbouring cells. The quantity $U(q)$ is the interaction energy of a given molecule with its neighbours at the centres of their respective cells. If the equilibrium positions of the molecules in the crystal are taken as the centres of the cells, and denoted by $\bar{q}$, then the quantity $U(\bar{q})/2$ is the energy of the crystal structure.

The use of the cell model simplifies the calculation of the configurational integral, which in this case is written

$$Q=\left[\exp\left\{-\frac{U(\bar{q})}{2kT}\right\}\cdot V_t\right]^N.$$

In this expression V_t is the "free volume":

$$V_t=\int_{\Delta}\exp\left\{-\frac{U(q)-U(\bar{q})}{kT}\right\}\mathrm{d}q,$$

where Δ is the cell volume.

This approach, together with the atom–atom potential method[35,36], was used by Pertsin and Kitaigorodskii to calculated the optimum structure and to interpret the polymorphic transitions in benzene[37] and adamantane[38]. We shall discuss this work more fully in a later Section of this review.

The identification of the deepest minima in a multidimensional energy surface constructed from the structure parameters involves calculations as cumbersome as those required by the search for the closest packing. Hence various simplifying assumptions are usually made, and in particular the structure class (the symmetry space group and the type of equivalent positions available to the molecule) is assumed to be known. Thus the reported calculations of molecular structure cannot be claimed to be fully *a-priori*.

The latter difficulty can be largely overcome by the potential function symmetry method developed in Refs.17, 39, and 40. This method allows us to find the structure class most likely to apply to molecules or polymer chains of a given symmetry, and to evaluate the relative probabilities of alternative classes[41,42]. In the calculation of the chain structures of $PdCl_2$ and $BeCl_2$ crystals[18,19] the potential function symmetry method allowed the optimum configuration of the chains to be identified without using an experimental information on the packing of the chains.

III. THE ATOM–ATOM APPROXIMATION AS A METHOD OF CALCULATING THE ENERGY OF ZERO-VALENT INTERACTIONS

Van der Waals (zero-valent) interaction is a quantum effect: in principle it can be described by the standard methods of quantum mechanics. However the difficulties encountered in attempting to solve the Schroedinger equation for systems containing a large number of atoms and molecules are still unsurmountable. Therefore empirical and semi-empirical approaches are almost universally used in concrete calculations of zero-valent interaction energies.

It is usually assumed that the van der Waals interaction consists of several, qualitatively different contributions. Though a strict quantum-mechanical interpretation does not support this assumption, in most cases good agreement between calculation and experiment is obtained by treating the van der Waals forces as consisting of the following terms: 1) an attraction due to dispersion interaction, 2) a repulsion resulting from the close approach of the electron clouds of atoms not bound by valency forces, 3) the electrostatic interaction of the fixed charge distributions, and 4) specific intermolecular interactions such as hydrogen bonds.

Numerous and varied investigations during the last 30 years have shown that all these contributions can be described with adequate precision by assuming additivity of the interaction energy of multi-atomic molecules with respect to the interaction energies of their constituent atoms. This approximation allows us to express the interaction energy of two molecules (in the absence of specific bonding forces) as the sum

$$U = \frac{1}{2}\sum_{ij}(\varphi_{ij} + \psi_{ij}),$$

where ϕ_{ij} are the atom–atom potentials describing the first two of the above contributions, and ψ_{ij} are terms allowing for the interaction of the effective charges on the atoms (the atoms i and j being part of different molecules).

The van der Waals interaction energy within a single molecule can be described in a similar way. If the method of evaluating ϕ_{ij} and ψ_{ij} is known, the conformation of the molecules can be calculated (including the orientation of groups able to rotate round an ordinary bond, and perturbations caused by steric hindrance). Indeed, the first successful application of the atom–atom approximation was in the solution of conformational problems. This approach was pioneered by Hill[43,44] and Barton[45], who worked with compounds in which the effective charges on the atoms were so small that only the repulsion energy and the attraction from dispersion interaction needed to be considered. A detailed description of the many conformational calculations made by the atom–atom approximation is given in Dashevskii's monograph[46].

Summation over the molecules in pairs (i.e. calculation of the energy of interaction of one molecule, taken as the central molecule, with the whole of its surroundings) allows us to express the potential energy of the molecular crystal (U_Σ) in the atom–atom approximation. This quantity is approximately equal to the heat of sublimation extrapolated to the absolute zero (assuming that sublimation does not produce significant changes in the conformation of the molecules or in the energy of intramolecular vibrations). By minimising the quantity U_Σ, treated as a function of the parameters which characterise the relative position of the molecules, the structure of a molecular crystal can (in principle) be calculated theoretically, as stated above.

The ϕ_{ij} potentials are usually approximated by the Lennard-Jones "6–12" potential[47] or by the modified Buckingham "6–exp" potential[48]:

$$\varphi_{ij} = -A_{mn}r_{ij}^{-6} + B_{mn}r_{ij}^{-12},$$
$$\varphi_{ij} = -A_{mn}r_{ij}^{-6} + B_{mn}\exp(-\alpha_{mn}r_{ij}),$$

where the first term describes the attraction and the second the repulsion, the subscripts m and n refer to the types of atom, A, B, and α are empirical parameters, and r_{ij} is the interatomic distance.

In Ref. 49 the atom–atom potentials are expressed in a more general form (as "6–exp, D" potentials):

$$\varphi_{ij} = A\exp(-Br_{ij})/r_{ij}^{D} - C/r_{ij}^{6}.$$

If $D = 0$ this reduces to the "6–exp" potential, and if $B = 0$ and $D = 12$ it reduces to the "6–12" potential.

Recent papers often refer to a "repulsion potential", which we shall denote by "d–d_0". This potential, first proposed by Williams[50], is defined as

$$V_{ij} = \omega(d_0 - d_{ij})^2 \text{ for } d_{ij} < d_0;\ V = 0 \text{ for } d_{ij} > d_0.$$

Here d_{ij} is the interatomic distance, and d and ω are parameters depending on the nature of the interacting atoms. The use of this potential greatly simplifies the minimisation procedure by allowing the method of least squares to be used. The main shortcoming of the "d–d_0" potential is that the quantity $\sum_{ij} V_{ij}$ is not the energy of the structure: it cannot be compared with real physical quantities such as the heat of sublimation. Calculations by the "d–d_0" potential occupy a position intermediate between the geometric and the energy approach.

The method of selecting the appropriate parameters is very important in the application of atom–atom potentials. The usual selection criterion is good agreement between calculation and experiment for several model compounds and several quantities (various thermodynamic functions such as heats of sublimation, compressibility coefficients, components of the elasticity tensor, etc.). The chosen values of the parameters are then applied to other substances, not too different from the model substances. One of the most reliable and widely used methods of choosing the parameters relies on fitting the calculated crystal structure to the experimentally observed structure. This method is discussed in the next Section. The frequencies of intramolecular and intermolecular vibrations in crystals[26] have been used in recent work for optimising the parameters of atom–atom potentials.

Approximate quantum-mechanical formulae are occasionally used in parallel with the purely empirical approach. This is specially true of the parameters A, which can be calculated by the London formula[51] or by the Slater–Kirkwood formula[52], as in Refs. 53–55. In that work the repulsion parameters were found by minimising the potential at the equilibrium distance, which was selected empirically.

The first systematic selection of the parameters of the "6–exp" atom–atom potential in crystal chemistry is due to Kitaigorodskii and Mirskaya[56,57]. Since the parameters A, B, and α have no clear physical significance, these workers used formulae including characteristics of the potential curve such as r_0 (the equilibrium distance), ε (the depth of the potential well), and D (the second differential at the minimum). The advantage of this aproach is that the quantities r_0, ε, and D vary only within narrow limits, and they are sensitive to several specific properties (r_0 to the geometric parameters of the structure, ε to the heat of sublimation, and D to the vibration frequencies and to the elasticity tensor).

A unique feature of Kitaigorodskii's and Mirskaya's approach is their use of the "universal" curve

$$\varphi_{ij} = -0.119\,(r/r_0)^6 + 4.2\cdot 10^4 \exp(-13.6\,r/r_0),$$

obtained by assuming identical potential wells of −0.067 kcal mole^{-1} for the three main types of atom–atom interaction in organic crystals (C...C, C...H, and H...H). The expression also assumes that $r_0\alpha = 13.6$. If the equilibrium distances are known (and they are taken to be 3.8, 3.3, and 2.8 Å for C...C, C...H, and H...H respectively) the parameters A and α can easily be calculated. The parameter B is found to be constant for the three types of interaction.

Table 1. Parameters of the "6–exp" potential used by Kitaigorodskii et al.

Type of interaction	A, $\frac{\text{kcal}}{\text{mole}}\cdot$ Å^6	10^3B, kcal mole^{-1}	α, Å^{-1}	References
C...C	358	42.0	3.58	59
C...O	313.2	57.1	3.85	59
O...O	259.4	77.7	4.18	59
S...S	2346	235.0	3.49	60
S...C	847	99.4	3.54	60
N...N	259	42.0	3.78	61
N...O	256	57.0	3.98	61
C...C	421	71.6	3.68	90
C...H	118	18.6	3.94	90
H...H	29	4.9	4.29	90

Even these "universal" parameters gave an acceptable level of agreement between the calculated energy of the structure and the measured heat of sublimation. However subsequent work led the authors[58] to conclude that the best agreement with experiment is obtained by using atom–atom potential curves with minima of different depth (−0.067, −0.057, and −0.048 kcal mole^{-1} for C...C, C...H, and H...H respectively). The final values of the parameters obtained by Kitaigorodskii and coworkers for these three types of interaction are listed in Table 1 together with their later results[59–61] for interactions involving N, O, and S atoms.

Various combination rules are used to obtain the parameters of interactions between unlike atoms. Thus Scott and Scheraga[54], Hendrickson[62], and Kitaigorodskii and coworkers[59] obtained the parameter α_{mn} by the formula $\alpha_{mn} = (\alpha_m\alpha_n)^{1/2}$. Dashevskii and coworkers[63] relied on another empirical expression: $\alpha_{mn} = 2\alpha_m\alpha_n/(\alpha_m + \alpha_n)$. Similar combination rules were used by these workers for the parameters A_{mn} and B_{mn} in the equation for the "6–exp" potential. Theoretical justifications of the combination rules are given in Refs. 64–66.

Whereas early workers tended to ignore electrostatic interactions in crystals, arguing that their contribution to the energy of the structure was negligibly small[67–69], in more recent work this term is almost invariably included (albeit in different forms).

In principle there are two possible ways of calculating U_{el}, which characterises the electrostatic interaction of two molecules. The first consist in expanding the energy U_{el} in a series with respect to multipoles:

$$U_{el} = U^{(q,q)} + U^{(q,\mu)} + U^{(q,Q)} + \ldots U^{(\mu,\mu)} + U^{(\mu,Q)} + \ldots,$$

where q is the net charge of the molecules, μ is the dipole moment, and Q is the quadrupole moment. The quantity q is finite in charge-transfer molecular complexes, whereas for homomolecular crystals (i.e. crystals composed of identical molecules) $q = 0$ and the corresponding terms in the formula also vanish. For practical purposes the multipole expansion is used relatively rarely: on the one hand, the values of the higher-order multipoles are usually unknown, and on the other hand it is not easy to ascribe to point multipoles (and in particular dipoles) a definite position and orientation with respect to a molecule.

The second method of calculating U_{el} relies on the atom–atom approximation. The continuous distribution of electron density is replaced by a discrete distribution, and an effective point charge (localised near the nucleus) is assigned to each atom in the molecule. Then we can write

$$U_{el} = \sum_{ij} q_i q_j / r_{ij}.$$

The effective charges can be calculated by various quantum-mechanical methods. Some workers[70–72] use the simplest computational scheme, in which the effective atomic charge is treated as the sum of the π- and σ-charges (the former calculated by the simple Hückel method, the latter by the Del Re method[74]). Other workers have used more complex quantum-mechanical approximations[55,75]. As an alternative, the charges (as well as other parameters of the intermolecular interaction potentials) can be evaluated by fitting the optimum structure to the experimentally determined structure[76,77].

The components of the intermolecular interaction listed above contribute (though to varying extents) to the structure of all molecular crystals. In addition, we sometime meet specific intermolecular forces, which are always associated with the presence in the molecule of some particular atoms or atomic groups. These forces include hydrogen bonds, bonds of the metal–metal and metal–oxygen type, and other bonds found in crystals of some inner complex compounds. The energy of these interactions is quite difficult to calculate: a successful method of calculation has been developed (so far) only for the hydrogen bond.

Various procedures have been described for evaluating the hydrogen bond energy. Some workers[55,78,79] have used the "6–exp", "10–12", and "6–12" atom–atom potentials, assigning specially chosen parameters to the atoms taking part in the hydrogen bond, and allowing for the part of the hydrogen bond energy which appears as interaction between effective atomic charges. Other workers have used special empirical and semi-empirical functions: Stockmayer potentials[80–81], and Lippincott–Shroeder[82,83] or Morse[84] potentials.

Afonina and coworkers[85] have used all the above methods of allowing for the energy of the hydrogen bond in their calculation of the heats of sublimation of various organic compounds. The best agreement with experimental data was obtained by using the last two potentials.

One of the most interesting approaches in the current development of the atom–atom potential method is the work of Scheraga and coworkers[86–88], who treat the interaction between electrons and nuclei by assigning positive charges (located in the nucleus) of 1, 4, 5, and 6e to the H, C, N, and O atom respectively, while the electrons are placed in the bonds or in the directions occupied by unshared pairs. The distances between electrons and nuclei are used as the parameters of the model. The potential energy consists of coulombic terms of the q_iq_j/r_{ij} type, describing the interactions between electrons and nuclei, and terms which allow for the attraction and repulsion between electrons in terms of the "6–exp" potential. The parameters of these potential functions are chosen by least squares from a large fund of experimental data on various properties of the molecules and of the molecular crystals (dipole moments,

barriers to internal rotation, difference in energy of conformational isomers, lattice energies and lattice constants, etc.). The main advantage of this model is that special potentials are not needed to allow for H-bonds, and the barriers to internal rotation can be described without introducing torsional potentials[46].

IV. SELECTION OF THE ATOM–ATOM POTENTIAL PARAMETERS FROM CRYSTALLOGRAPHIC DATA

The parameters of the atom–atom interaction potentials can be determined from data on the molecular packing in the crystal by two methods. The first consists in finding the optimum packing for different values of the parameters (i.e. the packing corresponding to minimum energy). The best choice of parameters is taken to be the set which gives a calculated structure as nearly as possible identical to the experimentally observed structure. The second method relies on the following considerations. The experimental structure is assumed to be identical to the equilibrium structure. Hence the differentials of the energy at the experimental point should vanish, and therefore the parameters of the potential are chosen so as to keep the differentials of the potential equal to zero. This method of selection avoids the repetitive calculation of lattice sums† and thus offers a substantial saving in computer time.

The first of these approaches is used by Kitaigorodskii and coworkers, and also by Giglio, Liquori, and others.

As was mentioned in the previous Section, Kitaigorodskii uses a universal potential curve for C...C, C...H, and H...H interactions[56]. The parameters of this curve have been progressively modified in successive papers[58,89,90]. One-dimensional and multi-dimensional sections of the energy surface (U) were drawn for different values of the parameters of the potential curve for methane[56], adamantane[57], benzene[58], etc., and the best values of the parameters (for which the position of the energy minimum corresponds to the real structure) were identified in this way. The depth of the minimum was corrected in accordance with the known heat of sublimation. The set of parameters ultimately chosen gave excellent results in the calculation of the optimum packing in crystals of coronene[91], biphenyl[92], dibenzyl[92], and others.

The parameters of the potential functions describing interactions with oxygen[59], sulphur[60], and nitrogen[61] atoms were established in a similar way from data on the structure and heat of sublimation of CO_2, S_8, and N_2O. Numerical values of all the parameters recommended by Kitaigorodskii's team are listed in Table 1.

Giglio, Liquori, and others[93–97] used a different approach: they did not vary the parameters of the potential to search for the optimum packing, but they adopted sets of parameters previously suggested by various workers (in particular, for conformational analysis). The best values of the parameters for the "6–exp,D" potential are given in Table 2.

In the course of this work it was shown that the position of the minimum of the atom–atom potential curve plays an essential role in the search for the optimum packing: the other characteristics of the potential are relatively unimportant. However this conclusion cannot be extended uncritically to other physicochemical properties.

†The lattice sums are expressions of the type $\sum_{ij} 1/r_{ij}^{6}$, $\sum_{ij} 1/r_{ij}^{12}$, $\sum_{ij} 1/r_{ij}$, etc., in which the summation is taken over all the atoms in the structure.

The second of the above methods of selecting the parameters of C...C, C...H, and H...H interactions was first applied by Williams in the case of the "6–exp" potential. The experimental data used as a basis for the optimisation were the structures, heats of sublimation, and other constants of nine aromatic[69] and nine aliphatic and condensed hydrocarbons[68]. Using these data he wrote approximately 100 expressions equating the U_Σ values to heats of sublimation, the first differentials of energy to zero, and the second differentials to the elastic constants.

By using least squares Willams selected several sets of the A and B parameters most consistent with these equations. For convenience in the minimisation procedure the α parameters were not varied in the calculation of the lattice sums. The parameter α_{CC} was taken to be 3.60 Å^{-1} from calculations of the compressibility of graphite[98], and the parameter α_{HH} was taken to be 3.74 Å^{-1} from a quantum-chemical calculation of the repulsion between two hydrogen molecules[99]. The sets of parameters were obtained independently for the aromatic and the non-aromatic hydrocarbons: four for each of these two series of compounds. The difference between the sets was that the parameters A_{CH} and B_{CH} (either singly or jointly) were either treated as independent or calculated by the combination rules. The best of these sets was chosen by calculating lattice constants and molecular packing arrangements for different sets of parameters in several aromatic or aliphatic hydrocarbons. It was found that all the hydrocarbon crystals examined could be described satisfactorily by a single set of parameters (listed in Table 3).

In his more recent work Williams has selected and tested a new set of parameters for the "6–exp" potential which allows for the electrostatic component[76,100] (following Warshel and Lifson[77], who first demonstrated the need to allow for

electrostatic interaction in hydrocarbons). The charges on the atoms were treated as parameters of the potential function, and were evaluated by the above method together with other parameters of the same series of compounds. The numerical values obtained are shown in Table 3. The contribution of the electrostatic component in the different hydrocarbons varies from 0 (for n-pentane) to 29% (for benzene). Only by allowing for the U_{el} term was Williams able to account for the polymorphic transition in benzene[100]. This suggests that even in hydrocarbons electrostatic forces are far from negligible. On the other hand the contribution of the electrostatic component to the energy of the benzene structure seems too high to be acceptable.

Table 3. Parameters of the "6–exp" potential used by Williams.

Notes: in Ref. 76 the parameters are given in kJ mole^{-1}; $q_H = q_C = 0.179$ e.s.u. [76]

Scheraga and coworkers used both the first and the second approach in their search for the parameters of the potential functions. They found a set of parameters describing the interaction of hydrocarbon molecules by the method of Williams, using as their experimental basis the heats of sublimation and structures of benzene measured at three temperatures[101].

More recently Scheraga and coworkers[55] used a wide range of compounds (including hydrocarbons, carboxylic acids, amines, and amides) to select and test a system of parameters to be used in calculations of the conformation of polypeptides and proteins. The energy of zero-valent interactions was calculated by using the "6–12" potential, the hydrogen bond energy by the "10–12" potential, and the U_{el} energy by Coulomb's law. The A coefficient, which characterises the attraction forces, was calculated by the Kirkwood–Müller formula in the "6–12" potential and by a quantum-mechanical formula in the "10–12" potential. The charges were calculated by the CNDO/2 method. Thus only the B parameter was varied, i.e. the parameter describing the repulsion between atoms not joined by valence bonds, and in particular between atoms taking part in hydrogen bonds.

The criterion for the validity of the parameters was the quantity σ, defined as

$$\sigma = \left[(1/N)\sum_{i=1}^{N}(l_i^{\text{calc}} - l_i^{\text{exper}})^2\right]^{1/2},$$

where $l_i = a, b, c, \alpha, \beta, \gamma$ are the lattice parameters and N is the number of these parameters. The search procedure included two independent (but interrelated) minimisations: 1) minimising the energy by varying the lattice parameters, and 2) minimising the σ value obtained in the previous calculation by varying the B coefficients, using the formula

$$\frac{\partial}{\partial B}\{[a^{\text{exper}} - a^{\text{calc}}]^2 + \ldots + [\gamma^{\text{exper}} - \gamma^{\text{calc}}]^2\} = 0.$$

Different parameters were selected for different types of nearest-neighbour environment: thus, H atoms bound to an aromatic ring, to an aliphatic chain, to the nitrogen of an amino group, to the oxygen of a hydroxyl group, etc. were considered to be different.

Table 4. Parameters of the "6–12" potential used by Momany, Scheraga, et al.[55]

The parameters thus obtained (Table 4) were tested by calculating the packing and the energy of the structure for crystals of monomeric[102] and of polymeric amino-acids[103,104]. The authors stress that the results given by these parameters are satisfactory only if the charges on the atoms are calculated in the CNDO/2 approximation.

The two possible approaches to the selection of the atom–atom potential parameters are compared in a paper by Hagler and Lifson[105]. A serious drawback of the second approach is shown to be the non-equivalence of the optimisation of the potential parameters from the differentials of the energy and from the experimentally observed structure. Thus in the case of points on gently sloping regions of the potential energy surface the differentials can be small, and yet the distance from the minimum may still be large. For this reason these workers proposed a method[105] in which the exact values of the parameters are obtained directly from the structure whilst avoiding the need for repetitive calculations of lattice sums.

The authors[105] explain their method by defining the vector $\boldsymbol{a}$ whose components are the structure parameters. The special feature of the method is that the quantity $\Delta\boldsymbol{a} = \boldsymbol{a}_{\text{calc}} - \boldsymbol{a}_{\text{exper}}$ is obtained directly, by the Newton–Raphson method, of calculating $\boldsymbol{a}_{\text{calc}}$: $\Delta\boldsymbol{a} = -F(\boldsymbol{a}_{\text{exper}})^{-1}\nabla_{\boldsymbol{a}}U(\boldsymbol{a}_{\text{exper}})$, where F is the matrix of the second differentials $F_{\alpha\beta} = \partial^2 U/\partial a_\alpha \partial a_\beta$, $\nabla_{\boldsymbol{a}}U$ is a vector whose components are the differentials $\partial U/\partial a_\alpha$, and the numerical values of the differentials correspond to the experimentally determined structure.

The parameters of the potential, represented by the vector $\boldsymbol{p}$, are obtained by solving the equation

$$\delta\boldsymbol{p}^i = \boldsymbol{p}^i - \boldsymbol{p}^{i-1} = [(Z'Z)^{-1}Z'\Delta\boldsymbol{y}]^{i-1}$$

iteratively by least squares. In this equation $Z = \partial(F^{-1}\nabla U)/\partial\boldsymbol{p}$ is a matrix of the differentials of the deviations of the structure parameters (with respect to the parameters of the potential), and $\Delta\boldsymbol{y}$ is a vector of the deviation of the calculated from the experimental structure parameters.

In the first variant of the calculation the energy of the structure was described[106] by the formula

$$2U_{\Sigma}=-\Sigma A/r^6+\Sigma B/r^m+\Sigma qq'/r+2U_{H},$$

where m was taken to be 9 or 12. This formula includes a contribution from the hydrogen bonds (U_H), which was expressed by the Morse potential. However it was later shown that the hydrogen bond is adequately accounted for by the first three terms if the parameters of the potential and the charges are chosen for atoms taking part in hydrogen bond formation. The experimental material used in this calculation was a selection of structure data for eight amides, but heats of sublimation and dipole moments were also used in the minimisation procedure.

The parameters of the potential functions selected in Ref.106 are listed in Table 5: we note that the "6–9" and the "6–12" potentials give equally good results in the calculation of equilibrium structures. The charges on the atoms obtained as parameters of the intermolecular interaction function were compared[106] with the charges found by quantum-mechanical calculations (*ab initio*, CNDO/2, and the Del Re method). The best agreement was obtained with the charges given by *ab initio* calculation.

The validity of the parameters thus obtained was tested by calculating the packing of molecules in ten crystalline amides[107]. For three of these the energy minimum was sought by varying every possible geometric parameter: only the number of molecules in the elementary cell was treated as known. The authors stress that this is the first reported calculation of this type.

Mirskaya and coworkers[90] compared the parameters of the potentials recommended by different authors for calculating the properties of crystalline hydrocarbons. Only those parameters having a clear physical significance were compared: the equilibrium distance r_0, the depth of the potential well ε, and the quantity $\lambda = r_0\alpha$ which characterises the steepness of the slopes towards the minimum for the "6-exp" potential. The authors point out[90] that the failure to ensure physical significance of the atom–atom potentials often leads to unrealistic potential curves. Thus the parameter $r_0^{HH} = 3.37$ obtained by Williams[68,69] is too high (when compared with the sum of the van der Waals radii). The values of ε^{CC} and r_0^{CH} obtained in Ref.77 are clearly too high. Momany and coworkers[101] obtained a curve for the C...C interaction without a minimum, and curves for the C...H and H...H interaction with excessively deep minima.

*No minimum.

Subsequently[55,106] these same workers[77,101] reconsidered their recommended potential parameters and compared r_0 and ε values (Tables 7 and 8) as had been done in Ref.90. We see from these Tables that the discrepancy between the r_0 values for the curves proposed by different authors is much smaller than the discrepancy between the ε values. One reason for the large differences between the ε values is that the overall energy of the intermolecular interaction (which alone can be compared directly with experiment) depends not only on ε but also on the effective charges on the atoms, which vary quite markedly according to the method of calculation and are even ignored altogether in some cases. It follows that the methods of calculating the component of the energy which is determined by the "6–exp", "6–12", etc. potentials, and the method of calculating the electrostatic component, should be mutually consistent.

V. TABULATION OF THEORETICAL CALCULATIONS OF MOLECULAR PACKING

In this Section we shall try to present as fully as possible, in tabular form (Tables 9–16), all the results obtained in theoretical calculations of crystal structures using atom–atom potentials. These investigations began in 1961, when

Kitaigorodskii proposed this method of identifying the energy minimum in a crystal. Since then, and up to 1977, the number of papers published on this topic has risen to 180.

Table 8. Comparison of the characteristics of the potential curves proposed by various authors (ε in kcal mole^{-1}, r_0 in Å).

ε	r_0	Refs.	ε	r_0	Refs.	ε	r_0	Refs.

*The "6–12" potential was used in this calculation, the "6–exp" in all the others. New parameters used for: (a) C, H, (b) O, (c) S, (d) Si, Sn, Pb, (e) N.

The most important contributions to this area of research came from the teams of Kitaigorodskii, Williams, Giglio, Simonetti, Scheraga, Lifson, Sarko, and Zugenmaier. The work of these groups accounts for more than 50% of the published material, and is presented in Tables 9–15. Publications from other laboratories are listed in chronological order in Table 16.

It is clear from the Tables that the number of papers dealing with this topic has risen steeply in recent years: approximately 60 papers between 1961 and 1970, as compared with over 100 papers between 1971 and 1977. The greatest number of publications appeared in 1974–1975. Whereas the early papers dealt with crystals consisting of molecules containing a small number of atoms (halogens, methane, benzene), and a limited number (one or two) of types of atom, the scope of the more recent papers has become much wider.

Table 10. Publications by Williams and coworkers on molecular packing calculations.

Year	Compound	Adjustable parameters	Refs.	Remarks

1974	Coumarin*	ψ, X	137	Xsa
1977	Benzene, naphthalene, anthracene, phenanthrene[a]	a, ψ, X	138	ΔH

*The "6–exp, D" potential was used, **"6–12" potential (in all other calculations the "6–exp" potential was used). New parameters used for: (a) C, H, (b) S, (c) C, N, Cl, (d) Br, I.

At present most of the workers in this field are concerned with amides, mono- and poly(amino-acids), and other compounds of relevance to developing methods of calculation for complex, biologically important substances such as polypeptides and proteins. At the same time metal–organic and inorganic substances are beginning to be studied by the atom–atom potential method.

As the range of compounds being studied becomes wider, suitable parameters of the potentials have to be chosen. Papers dealing with this problem are mentioned in the Notes of the Tables.

*The "6–exp" potential was used in the approximation of the electron–nucleus interaction model; in all other calculations the "6–12" potential was used.
New parameters for the potentials of: (a) C, H, (b) C, H, N, O, S, (c) C, H, N, O.

It is clear from Tables 9–16 that the "6–exp" and "6–12" potentials have been used most frequently. The "6–exp, *D*" potential often appears in the papers from Giglio's laboratory. More recently some workers have successfully used the "d–d_0" potential proposed by Williams. All these types of potential are described in Section III. Special potentials of a non-standard type are only rarely used.

The complexity of the calculations reported can be judged by the column headed "Adjustable Parameters" in the Tables. Most of the authors have treated the space group, the number of molecules in the cell, and the type of position taken up by the molecules in the cell as known (from experimental data) when seeking to optimise the packing of the structure: in other words, they have assumed a given structure class. However some workers have considered different structure classes: this is indicated by the abbreviation SC in the Adjustable Parameters column. The following abbreviations are also used in that column to indicate the structure parameters which were varied during the optimisation procedure: *a*—the parameters of the elementary cell, ψ—the Euler angles which characterise the orientation of the molecules, *X*—the coordinates of the centres of gravity of the molecules, and ϕ—parameters describing the conformation of the molecules (usually the angular rotations about single bonds).

Table 14. Publications by Lifson and coworkers on molecular packing calculations.

Year	Substance	Potential	Adjustable parameters	Ref.	Remarks
1969	α-N_2	6-12	ψ, *X*	153	ν

1976	*N*-Methylamide, amides, peptides	6-9, 6-12	SC, *a*, ψ, *X*, φ	162	—

New parameters for the potentials of (a) N, (b) CH, (c) C, H, N, O.

Table 15. Publications by Sarko, Zugenmaier, and coworkers on molecular packing calculations.

Year	Compound	Adjustable parameters	Refs.	Remarks
1972	6-monosaccharides (α and β glucose, etc.)	ψ, *X*	163	H-b
1973	B-Amylose.H_2O	SC *a*, ψ, *X*, φ	164	H-b, Xsa
1974	Cellulose I	SC *a*, ψ, *X*, φ	165	H-b
1974	Mannan	ψ, *X*, φ	166	—
1974	Dimethylsulphoxide–amylose complex	ψ, *X*	167	Xsa
1976	Cellulose II	*a*, ψ, *X*, φ	168	H-b, Xsa
1976	Cellulose III_1	*a*, ψ, φ	169	H-b
1976	V-Amylose	ψ, *X*	170	H-b, Xsa, φfree
1977	β-*D*-Glucone acetate	ψ, *X*	171	Xsa, φfree

*New parameters for the potentials of C, H, O. The "d–d_0" potential was used in all calculations.

In the early work the number of adjustable parameters was usually small, but as computer techniques become more generally available the complexity of the calculations increased. The record for the number of parameters varied in the calculations is held by Scheraga's group, who treated

all the parameters listed above as adjustable and took only the number of molecules in the cell as given.

Notes. The following potentials were used: (I) "6–12", (II) "6–exp,*D*", (III) "*d*–d_0", (IV) a specially defined potential, (V) "6–exp" and "*d*–d_0", (VI) "6–exp" and "6–12" (in all other cases the "6–exp" potential was used). New parameters for the potentials of: (a) C, H, (b) C, H, O, (c) C, O, (d) C, H, Cl, (e) N, (f) C, H,N.

The column headed "Remarks" gives some additional information on the method of calculation or on the purpose of the investigation. The following abbreviations are used: *q*, μ, and *Q* denote allowance for the electrostatic interactions in the monopole, dipole–dipole, and quadrupole–quadrupole approximation respectively, ε denotes allowance for the dielectric constant in the calculation of the electrostatic component, H-b shows that the energy of the hydrogen bond has been allowed for, Δ*H* that the calculated results have been compared with the experimental heat of sublimation, el.const. that the results have been compared with the experimental elastic constants of the crystal, reorient. that the reorientation of molecules in the crystals has been considered, Xsa that the optimum structure was calculated in the course of an X-ray structural analysis, polymorph. that the work was aimed at interpreting a polymorphic transformation, ϕ_{free} that the conformation of the molecule in the crystal has been compared with the calculated conformation of the free molecules, *a*(t°) that the temperature dependence of the lattice parameters has been calculated, *A* that the thermodynamic functions have been calculated, ν that the vibration frequencies in the crystals have been calculated, and ν(t°) that the temperature dependence of the frequency has been calculated.

We note that a discussion of calculated frequencies of internal and external molecular vibrations lies outside the scope of this review. Special review articles have appeared on this topic[26,266]. Work on the calculation of frequencies

is included in the Tables only in so far as it involves minimisation of the intermolecular interaction energy by varying the structure parameters.

In most of the work listed in Tables 9–16 the structure class of the crystals under study is taken from X-ray diffraction data, i.e. the problem of optimising the packing of the molecules is solved for a given structure class. However some workers have formulated the problem more widely, and have treated the structure class as a variable. A brief outline of publications in which packing arrangements for different structure classes are compared is given below.

Brock and Ibers[253,254] tried to account for the square-pyramidal coordination of antimony in $Sb(C_6H_5)_5$ (structure class $P\bar{1}$, $Z = 2(1)$) as compared with the trigonal-bipyramid coordination found in $P(C_6H_5)_5$ and $As(C_6H_5)_5$ (structure class Cc, $Z = 4(1)$). For each of the three compounds the potential energy of the crystal structure was minimised for a coordination polyhedron taken either as a tetragonal pyramid in the class $P\bar{1}$, $Z = 2(1)$, or as a trigonal bipyramid in the class Cc, $Z = 4(1)$. The calculation was satisfactorily consistent with experiment, but only after allowing for the electrostatic component.

Kitaigorodskii and coworkers[120] studied acenaphthene (structure class $Pcm2_1$, $Z = 4(m,m)$), biphenylene ($P2_2/a$, $Z = 6(1,\bar{1})$), and tolane ($P2_1/a$, $Z = 4(1,1)$) to explain the existence of quasi-heteromolecular crystal structures, in which identical molecules can occupy more than one system of equivalent positions. To this end they calculated the optimum packing of acenaphthene molecules in the $P2_1/a$, $Z = 4(1)$ structure class, and of biphenylene and tolane in the $P2_1/a$, $Z = 2(\bar{1})$ structure class, i.e. they examined the normal packing arrangements in which all the molecules are symmetrically equivalent. Only in the case of acenaphthene was the potential energy of the real structure lower than the energy of the hypothetical packing arrangement. For biphenylene and tolane the energies of the real and the hypothetical packing were found to be almost identical.

The aim of Derissen and Smit[256] was to explain the specific behaviour of acetic acid during crystallisation. Unlike most of the other carboxylic acids, acetic acid forms a structure (structure class $Pna2_1$, $Z = 4(1)$) in which the molecules are connected by hydrogen bonds in infinite chains (rather than in dimers). The most likely alternative to the real structure of acetic acid was taken to be that of fluoroacetic acid ($P2_1/c$, $Z = 4(1)$). Minimisation of the potential energy for this structure class gave two minima of similar depth. Their energy was practically identical to that of the real structure. Thus the authors[256] could not reach any firm conclusion on the reasons for the anomalous structure of crystalline acetic acid. However they correctly point out[256], like other workers[120], that this type of problem cannot be finally resolved without calculating the free energy. In all probability the lack of success of a number of investigations[172,174,177,183] of the crystal structure of chlorine is also due to the use of the potential energy (instead of the free energy) of the structure in the minimisation procedure.

We shall now turn to a more detailed discussion of some special aspects of the calculation of the energy of molecular packing, noted in the "Remarks" column of Tables 9–16.

1. Comparison of the Conformation of the Free Molecule and the Conformation of the Molecule in the Crystal

If the molecule contains atomic groups able to rotate about an ordinary bond the crystal field may be sufficient to affect the conformation when such a molecule is introduced into a crystal. This effect has along been recognised in comparisons of X-ray diffraction results with the results of analytical methods sensitive to the geometry of "free" molecules (electron diffraction of vapours, and microwave spectroscopy).

Minimisation of the energy of zero-valent interactions in the atom–atom approximation allows us to interpret and to predict the influence of a crystal field on molecular conformation. The classical work in this area was contributed by various authors[92,141,125], who calculated the conformation of biphenyl molecules in the vapour and in the crystalline phase. In complete agreement with experiment, the calculations indicated a planar structure for the molecule in the crystal and a non-planar conformation (with an angle between the phenyl rings between 30° and 42° according to different authors) in the free state.

In a more recent paper of this type[250] the energy of the free molecule and the energy of the crystal structure are calculated as a function of the angle of rotation of the phenyl rings about the ordinary bond for hexaphenylbenzene, 1,3,5-triphenylbenzene, and 1,3,5-triphenyltriazine. The result of the calculation is that the isolated molecule has a higher symmetry, and that the rotation angles of the phenyl rings are slightly altered (by less than 10°) when the molecules are introduced into a crystal.

Calculations of molecular conformation in a crystal can be used to establish the location of atoms or atomic groups not detected with sufficient precision by X-ray diffraction. The calculation of the coordinates of hydrogen atoms in methyl groups is an example of this type of work[162,267].

2. Application of Optimum Packing Calculations in X-ray Diffraction Analysis

In this work an initial model of the molecule is usually assumed, based on standard bond lengths and bond angles, and supplemented if necessary by conformational analysis. Data on the structure class and on the elementary cell parameters are obtained from X-ray diffraction. The distribution of the molecules within the cell corresponding to a minimum energy is obtained from that information. If more than one distribution is found to be possible the R-factor is calculated in each case, and the structure corresponding to the lowest R-factor is identified by the standard methods of X-ray analysis. This method has been used, for example, in Williams' calculations of the structure of organic compounds containing nitrogen heterocyclic rings[124,126]. Simonetta and coworkers[145–147], having calculated the conformation of several derivatives of annulene, established their packing in the crystal to within $R \cong 5–8\%$. Similarly, Giglio and coworkers identified the structures of N,N'-dicyclohexylurea[132], 5α-androstan-3,17-dione[108], coumarin[137], and other compounds. The second structure in this list could not be determined by conventional methods of X-ray analysis.

The search for optimum packing as a means of determining structure is particularly valuable in the case of polymers. Perfect crystals, suitable for X-ray structural analysis, are seldom formed by polymers. By minimising the energy of the crystal structure we can build a model of the polymer which is then modified or confirmed by X-ray diffraction results.

A good example of this method of evaluating polymer crystal structures is given by the work of Sarko, Zugenmaier, and others (Table 15) on the crystal structure of carbohydrates and polysaccharides. These workers used the "$d–d_0$" potential (see above), with parameters chosen on the basis of six model monosaccharides[163]. This potential allowed them to calculate the effect of hydrogen bonds as well as ordinary intermolecular interactions. The packing of two model chains was considered in the work on the structure of

mannans[166]: these models gave very similar energy terms, and only by interpreting i.r. spectral data could one of them be chosen as the more likely.

The structure of different modifications of a material as important as cellulose could not be established until calculations of packing were applied to the problem. The first step in this type of work is a conformational analysis of the free molecule. Choosing the most probable conformations, and using experimental data on the space group and on the parameters of the elementary cell, 185 initial models were assembled. Minimisation of the energy reduced this number to 24 variants, from which the packing arrangements with the largest number of hydrogen bonds were chosen. The model was further refined by using experimental values of the structure amplitudes. It was shown that cellulose I consists of parallel chains and has a triclinic (and not monoclinic, as previously thought) unit cell. The *R*-factor of this structure was 29%. The modification known as cellulose II was characterised to an *R* value of 15.1%: it consists of antiparallel chains and contains a greater number of hydrogen bonds, which explains is greater stability. For the cellulose III modification the *R*-factor was 20.3%: in this modification the chains are parallel, as in modification I. Thus the polymorphic transformations in cellulose are now fully characterised.

3. Calculation of Thermodynamic Functions and Interpretation of Polymorphism

Methods of identifying the optimum packing by minimising the free energy were described in Section II. The problem of evaluating the thermodynamic functions is often encountered in various aspects of this type of work (not only in the calculation of the optimum structure). Several workers have calculated thermodynamic quantities through the frequency distribution functions. Thus in a study of crystalline benzene[190] the zero-point vibration energy and the specific heat for the range 60–220 K are calculated; the heat of sublimation at 0 K has also been obtained[77] from calculations of the optimum crystal structure, of the vibration frequencies, and of the molecular conformation in the gas and the crystalline phase.

Thermodynamic functions have also been calculated[35,36] through the configuration integral on the basis of the cell model. Thus the free energy, the specific heat, and the entropy at different temperatures have been obtained for naphthalene, benzene, and anthracene crystals.

One of the most important and interesting applications of the calculation of thermodynamic quantities is the explanation and prediction of polymorphism in molecular crystals. The simplest way of interpreting polymorphism is to demonstrate the presence of two minima, of similar depth, in the potential energy surface. Various attempts have been made[207,224] to account for polymorphism in this way, often successfully. Nevertheless the method is not universal because several minima of comparable depth can be found on the potential surface, and not all of these correspond to real modifications.

A strict interpretation of polymorphism requires calculation of the free energy. Pertsin and Kitaigorodskii[37,38] used the atom–atom potential method and the cell model to calculate the entropy and the free energy of benzene and adamantane as a function of temperature and pressure. At each point the free energy was minimised with respect to the structure parameters. The calculation was carried out for two modifications of each compound (treating the structure class as known): the intersection of the two free energy curves thus obtained gave the polymorphic transformation. In this way the phase transition temperature of adamantane was obtained, in excellent agreement with experiment. In the case of benzene the free energy isotherms intersected in the negative pressure region: the authors point out that the change in free energy with pressure is small, and comparable with the error of the calculation. However it is important to note that even in this case it was possible to obtain at least a qualitative prediction of the polymorphic transformation induced by changes in pressure.

4. Molecular Reorientation and Orientational Disorder

The symmetry or pseudo-symmetry present in some molecules can produce minima of identical (or similar) depth in the potential energy surface of the crystal for different values of the Euler angles. If the barriers separating these minima are low, reorientation is possible in the crystal (a sudden rotation of the molecule with a negligibly small effect on the position of the centre of gravity). On the other hand if the barrier is fairly high, and the molecule lies in substantially different positions before and after the change in orientation, orientational disorder can occur with molecules of suitable shape.

Reorientation can be observed experimentally through the NMR spectra, from which the height of the barrier can also be calculated. Orientational disorder is detected from X-ray diffraction data. However it should be noted that dynamic reorientation and static orientational disorder are almost impossible to distinguish by X-ray diffraction. Therefore published reports of orientational disorder should be accepted with caution.

This uncertainty can often be avoided by calculating the height of the reorientation barrier. In the case of planar molecules the simplest method of calculating the barrier height is the following. The molecule is rotated about an axis passing through its centre of gravity and normal to the plane of the molecule. The other molecules are considered to be rigidly fixed in the positions indicated by X-ray structural analysis. The plot of intermolecular interaction energy against angle of rotation gives the most favourable orientations and the height of the barrier opposing the orientational transitions.

Calculations of this type have been reported for benzene[67], for polycyclic aromatic molecules (naphthalene, coronene, pyrene, etc.)[228], and for a group of planar molecules including derivatives of benzene and naphthalene and some heterocycles[150]. The authors[150] point out the difference between: 1) crystals in which reorientation is easy (benzene, hexamethylbenzene, thiophen), 2) crystals in which reorientation is hindered (hexachlorobenzene), and 3) crystals in which reorientation is impossible (2-bromonaphthalene). This classification correctly reflects the qualitative conclusions obtained from NMR spectra. However not all the calculated reorientation barriers agree quantitatively with the experimental values.

Similar calculations have been carried out for organic molecular complexes[223,257], but unfortunately no allowance was made for the electrostatic component, which in this case can be expected to play an important role.

Calculations[226] on the TCE–naphthalene and TCE-paracyclophane complexes (where TCE is tetracyanoethylene) have shown the existence of the TCE molecule in two positions of similar energy differing by a 90° rotation of the molecule in its own plane. The barrier between these positions is unsurmountable in practice. This suggests the possibility of orientational disorder in these complexes, a conclusion which is consistent with X-ray diffraction data for the latter

complex[268], in whose crystals 25% of the molecules occupy one of the possible positions and 75% the other. However in the case of the TCE–naphthalene complex X-ray diffraction gives no evidence of orientational disorder[269].

The energy curve describing the rotation of the naphthalene molecule (in its own plane) in the naphthalene–TCE and naphthalene–TCB complexes (where TCB is tetracyanobenzene) has two minima separated by an angle of ~35° and by a barrier whose height (~3 kcal mole^{-1}) is much lower than the corresponding barrier for the TCE molecule. X-ray diffraction studies[269–271] have indicated the presence of disorder in these crystals, corresponding exactly to the calculated disorder, but with a lower barrier, which therefore does not exclude the possibility of dynamic reorientation.

The plots of energy against rotation angle for anthracene molecules in complexes with TCB and tetracyanoquinonedimethane show only one minimum. However this minimum is quite broad, and the molecules can perform large-amplitude librations in their own plane. This conclusion is consistent with X-ray results.

A calculation[244] of the reorientation barriers in crystals of adamantane (α and β modifications) and of hexamethylenetetramine was complicated by the absence of a direction which could be identified with the axis of rotation of the molecule. The authors considered two possible directions as the axis of rotation, corresponding to the diad and triad symmetry axes of the molecule, and two possible positions of the neighbouring molecules. The reorientation barrier of the molecules in the β modification was found to be higher than in the high-temperature (α) modification. Molecular rotation in hexamethylenetetramine crystals is strongly hindered by the intermolecular hydrogen bonds.

I. INTRODUCTION

Interest in organic sulphur compounds has increased in recent years, mainly because of the increased importance of the extraction and treatment of sulphur- and high-sulphur-bearing petroleum and natural gas, of the extensive use of hydro- and thermocatalytic processes, and of the more stringent requirements for high-purity petroleum products produced by our increasing awareness of the need to combat atmospheric pollution.

At present the chemistry of natural organo-sulphur compounds (and in particular those associated with petroleum deposits) is being developed in two main directions: 1) improvements and developments in the methods of decomposing organo-sulphur compounds in order to produce high-quality fuels and oils[1,2], and 2) developments in the separation[3,4] and in the practical exploitation[5-7] of organic sulphur compounds. The latter activities offer the greatest interest in the chemistry of organic sulphur compounds, because they relate directly to the most basic problems of petroleum refining: to obtain high-quality products, to protect the environment from contamination, and to optimise our usage of natural resources. In recent years this work has become even more important because of the wide use of organic sulphur compounds isolated from petroleum products as special solvents, as very efficient media for the extraction of precious metals, as flotation reagents, as physiologically active materials, etc.[5,6]. In some cases[7] the prospect of replacing currently used, expensive synthetic products by naturally occurring organic sulphur compounds has been convincingly demonstrated.

Organic sulphur compounds found in petroleum include sulphides, disulphides, mercaptans, and thiophens[3]. The separation of these compounds, dissolved in multi-component mixtures of petroleum hydrocarbons, is laborious and difficult. Therefore much of the current research is aimed at effective methods of concentrating and separating organic sulphur compounds. Adsorption chromatography is one of the most promising methods of separating complex mixtures, and is widely used in this work[8,9].

Methods of controlling the surface properties of adsorbents by chemical modification have attracted a great deal of attention[8,9], and the theory of intermolecular interactions has been further developed[10]. However still further developments are needed in the chemistry of organic sulphur compounds. The main achievements in the past few years have been the development of new methods of separating complex mixtures on pure and on mixed oxides with variously modified surfaces. This review aims to discuss recent publications on the separation of natural and model systems on oxide adsorbents and on zeolites (including organic sulphur compounds). Studies of the mechanism of adsorption of sulphur-containing organic molecules by thermodynamic, spectral, and quantum-chemical methods will be specially considered.

II. ADSORPTION METHODS OF SEPARATION AND PURIFICATION

Both synthetic (zeolites, silica gels) and naturally occurring sorbents (fuller's earths, bauxites, other ores) are used in adsorption methods for the industrial production of oils, purification of gases from sulphur compounds, and separation of aromatic hydrocarbons from the products of the dehydrogenation of light petroleum fractions[11-13]. However these adsorbents have insufficient selectivity. Aromatic hydrocarbons, which are valuable constituents of fuels, are removed from the distillates together with the organic sulphur compounds. Hence one of the most important current problems is to develop adsorbents able to separate aromatic hydrocarbons selectively from organic sulphur compounds.

In the purification of fuels it is important not only to remove the sulphur compounds but also to desorb them without decomposition, in order to exploit any possible practical application. Recently discovered possibilities in the application of sulphur compounds from petroleum have shifted the problem into the area of very fine differentiations. It is essential to be able to identify the organic sulphur compounds, and to establish their structure, both by classifying them into groups (sulphides, disulphides, thiophens, mercaptans) and by identifying the individual members of a homologous series. The ideal solution is to use adsorbents with an activity related to the functional properties of the sulphur atom in different compounds. On the whole, oxide adsorbents offer most of the features needed for the separation of organic sulphur compounds, while zeolites have a number of advantages for more complete separation and purification[14-17].

The selectivity of adsorbents has been studied on synthetic mixtures of hydrocarbons and organic sulphur compounds, and also on various petroleum fractions. It has been shown that organic sulphur compounds are adsorbed on silica gel less strongly than nitrogen and oxygen compounds of analogous structure[18,19], but more strongly than paraffin–naphthene hydrocarbons or aromatic hydrocarbons[20]. The adsorbability of compounds in these classes decreases in the sequence:

nitrogen-containing, oxygen-containing, sulphur-containing compounds, aromatic hydrocarbons, paraffin–naphthene hydrocarbons. Within the organic sulphur compounds class the adsorption affinity increases in the sequence thiophens, aliphatic thiols, aliphatic disulphides, aromatic and cyclic thiols, aliphatic and cyclic sulphides[20,21]. Within each homologous series the adsorption affinity of the organic sulphur compounds decreases as the molecular weight increases.

Synthetic sorbents (silica gels, alumina gels, alumina-silicas, Mg, Fe, Cr, Al, Mo silicates) have been used successfully in the separation of the paraffin–naphthene part of petroleum fractions[22]. However the aromatic hydrocarbons are eluted together with the organic sulphur compounds. Extensive work[22-24] on the choice of adsorbents, eluents, and conditions for the separation of aromatic hydrocarbons from organic sulphur compounds has resulted in a modest enrichment of the chromatographic fractions in organic sulphur compounds, though the proportion of aromatic hydrocarbons in these fractions remains as high as 40–70%.[25] The difficulty of separating organic sulphur compounds from aromatic hydrocarbons is due partly to the similarity in the adsorption affinities of the two classes[21,24] and partly to the possibility of interactions between molecules in these classes[26,27]. Furthermore it has been shown that the conjugation of π-electrons with the unshared electron pairs of the hetero-atom can assist the separation (by adsorption) of a mixture of organic sulphides and sulphur-containing compounds of the aromatic type with a sulphur atom in the ring (thiophens). It is reported[21,28] that these mixtures can be separated fairly cleanly into sulphides and thiophens by repeated chromatography on silica gel.

Some success has been reported also in the separation of sulphides with normal and iso structures[29].

The influence of the surface chemistry of silica gel on the adsorption of organic sulphur compounds has been studied by several workers[30-38]. It has been shown that an increase in the concentration of water from 6 to 10 wt.% produces an almost total loss of the adsorption capacity of silica gel for organic sulphur compounds. Finely porous silica gels are more selective towards organic sulphur compounds than silica gels with larger pores[30]. Because of their greater selectivity, and of their greater surface area, finely porous silica gels offer a greater concentration and a higher yield of sulphur in the chromatographic fractions.

In spite of their greater surface area, silica gels and alumina gels have been found[33-38] to be inferior to alumina-silicas and to natural sorbents in their specific desulphurisation value. The adsorption capacity of silica gel towards organic sulphur compounds is markedly increased by deposition on the silica gel surface of iron[39] or nickel[33] oxides, nickel sulphide and phenyltrichlorosilane[32], or mercury acetate[40].

A comparative study of the adsorption capacity of metal silicates (Mg, Fe, Hg, Cr, Al, Mo) with different metal oxide to silica ratios towards organic sulphur compounds has shown that the most effective adsorbent is chromium silicate[32]. Up to 99.6% of the organic sulphur compounds from an oil fraction can be adsorbed on chromium silicate. Unfortunately the surface compounds undergo catalytic changes on the chromium silicate surface. Catalytic changes in the organic sulphur compounds have been observed also in the desulphurisation of fuels on alumina–silica catalysts[35,36,41-47]. Furthermore hydrogen bond formation between the SH group of mercaptans and the surface hydroxyl groups has been suggested[34].

On changing from adsorption on silica gel to adsorption on alumina an inversion of the relative adsorption affinities of organic sulphur compounds and aromatic hydrocarbons has been observed[48]. Unlike the selectivity of silica gel[49-52] towards organic sulphur compounds, that of alumina increases steeply with the temperature of the preliminary heat treatment[53]. With alumina baked at 700 °C up to 93% of the organic sulphur compounds could be removed from an oil fraction. Sulphides[54] and thiophens[55] can be separated more fully from petroleum fractions by successive chromatographic treatments on silica gel and on alumina.

Naturally occurring sorbents and alumina–silicas are used mainly for desulphurising petroleum products and natural gases[13,32-35]. The desulphurising power of bauxite can be increased by working at a higher adsorption temperature, which assists the chemisorption and the catalytic changes of the organic sulphur compounds. It has been shown[34] that sulphides and disulphides are fully desorbed from the bauxite surface, whereas mercaptans are oxidised to disulphides. The latter reaction is observed also on zeolites[13].

The use of manganese and iron ores[56] and of tripoli earth[18] for desulphurising petroleum products in the liquid and the vapour phase has shown that the adsorption capacity of these materials towards organic sulphur compounds is relatively low. In some cases the effectiveness of the natural sorbent tripoli earth has been improved by acid–alkali activation.

Zeolites can be used to purify petroleum products from sulphur-containing constituents and to separate these impurities[57,58]. However this method of sulphur removal is most widely used for gaseous media[13,59,60]. Natural gas can be purified from hydrogen sulphide and other sulphur gases on zeolites.

Several variants of analytical and preparative gas–liquid chromatography[3,23,24,61] are used for identifying and classifying into groups the organic sulphur compounds obtained from petroleum products. The method offers effective separation into groups in the case of the low-molecular-weight organic sulphur compounds obtained from benzine and kerosine distillates[62-64]. However the results are directly applicable to the analysis of heavier fractions, because of the volatility of the liquid phase at the relatively high temperatures used in the chromatographic analysis. In this context the correct choice of adsorbent for analysis and preparative separation by liquid–adsorption chromatography is most important[65,66].

The method of chromatography in a thin layer of adsorbent has been widely used to monitor rate and extent of reaction in the synthesis of sulphides[67] and in studies of the reactions and transformations of sulphides[67,68].

III. ISOTHERMS AND HEATS OF ADSORPTION

The isotherms and the heats of adsorption provide important information on the mechanism of the interaction of organic sulphur compounds with the adsorbent surface. Adsorption isotherms have been measured mainly for low-molecular aliphatic sulphides[35,50-52,69], some aromatic (diphenyl and dibenzyl) sulphides[36], and thiophen[70-72] on silica gels, on mixed oxides, and on zeolites and naturally occurring sorbents.

A detailed study has been made[70-72] of the isotherm for the adsorption of thiophen from solutions in heptane and in benzene. As shown in Fig.1, in the low-coverage region the adsorption of thiophen by 13X zeolite is an order of magnitude greater than adsorption by silica gel or alumina. The difference on the adsorption of thiophen on silica gel and on alumina is relatively small.

A study of the adsorption isotherms of thiophen and of benzene on silica gel, alumina gel, and alumina[70] showed that the adsorption of thiophen (for the same relative pressure) is greater (by ~10%). The difference in adsorption is ascribed to the smaller size of the thiophen molecule (38 Å^2, as compared with 41 Å^2 for the benzene molecule). However the difference between the specific interaction energies of thiophen

(2.3 kcal mole^{-1}) and benzene (1.7 kcal mole^{-1}) with the silica surface suggests that the adsorption may be affected also by the interaction of the hydroxyl groups with the sulphur atom.

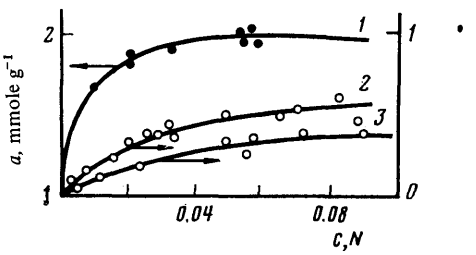

Figure 1. Isotherms for the adsorption of thiophen from hepaten on: *1*) 13X zeolite, *2*) silica gel, and *3*) aluminium oxide (*c* is the equilibrium concentration, *a* is the adsorption).

The influence of the chemistry of the adsorbent surface on the type of interaction can be studied by comparing the heats of adsorption of thiophen on mixed oxides, on silica gel, and on naturally occurring sorbents[49,74,75]. The cobalt–molybdenum oxide catalyst gives the highest interaction energy for thiophen molecules (15.5 kcal mole^{-1}, as compared with 8.4 kcal mole^{-1} on silica gel). Changes in the chemistry of the catalyst surface (by sulphidation) and of the silica gel (by dehydroxylation) are always accompanied by changes in heat of adsorption. However the largest effect is observed after sulphidation of the cobalt–molybdenum oxide catalyst: the heat of adsorption of thiophen on a sulphidised sample (6.6 kcal mole^{-1}) is close to the value obtained for a dehydroxylated sample of silica (6.1 kcal mole^{-1}).[49]

The effect of dehydroxylation of Aerosil[49] and silica gel surfaces[50–52] on the interaction energy of adsorbed molecules has been observed also for other classes of sulphur compounds. Progressive dehydroxylation of an Aerosil surface (by heating the sample at 300, 500, and 900 °C) lowers the heats of adsorption of sulphides, disulphides, and thiophens. By increasing the level of dehydroxylation of the surface we can decrease the sensitivity of the heat of adsorption to the chemical properties of the adsorbed molecules, confirming the important contribution of the sulphur atom to the specific interaction energy with the hydroxyl groups.

The nature of the interaction of organic sulphur compounds with the OH groups of the silica surface is reflected by the specific component of the heat of adsorption ΔQ.[49] Relatively low values of ΔQ (2.3–4.8 kcal mole^{-1}) suggest interaction through a hydrogen bond. Saturated aliphatic hydrocarbons have almost identical specific interaction energies (3.9–4.4 kcal mole^{-1}), somewhat lower than the specific interaction energy of cyclic sulphides (4.8 kcal mole^{-1}). It is interesting to note that disulphides have a specific interaction energy (3.0–3.2 kcal mole^{-1}) 1.5 times lower than that of sulphides. Even lower ΔQ values (2.6–2.2 kcal mole^{-1}) are reported[76] for compounds of the thiophen series, suggesting that the contribution of the sulphur atom to the interaction is weakened by the conjugation of its unshared electron pairs with the π-electrons of the thiophen ring.

The effect of dehydroxylation of the silica gel surface (by baking the sample at 200 and 500 °C) on the adsorption of low-molecular sulphur compounds has been studied by Ross and coworkers[50–52]. The fast desorption of hydrogen sulphide from the surface confirms that adsorption is physical, as reported also in Refs.69 and 77. The adsorption of methyl and ethyl mercaptan, and of dimethyl sulphide, is also reversible[50]. The energy of the specific interaction of methyl mercaptan with the hydroxyl groups of silica gel is ~2.2 kcal mole^{-1}.[50]

It has been suggested that the difference in the nature of the interactions of SO_2,[50] H_2S, CH_3SH, C_2H_5SH, and $(CH_3)_2S$[51,52] with the silica gel surface is determined by the symmetry and the character of the spatial localisation of the orbits occupied by the unshared electron pairs. This explanation is consistent with the formation of complexes of methyl mercaptan and dimethyl sulphide with diborane [$CH_3SH.BH_3$; $(CH_3)_2S.BH_3$]. This type of complex is not formed by hydrogen sulphide[78].

When organic sulphur compounds are adsorbed on silica gel at 150 °C the initial heat of adsorption is fairly high[51] (>30 kcal mole^{-1}): this is probably due to the presence of impurities, undergoing surface reactions.

The adsorption of methyl mercaptan, ethyl mercaptan, dimethyl sulphide, and hydrogen sulphide on γ-Al_2O_3 baked at 700 °C has been studied[79] at 150 °C. Hydrogen sulphide is adsorbed less readily than the other compounds. Unlike the adsorption of methyl and ethyl mercaptan and dimethyl sulphide, the adsorption of hydrogen sulphide leaves a residue of elemental sulphur on the γ-Al_2O_3 surface, which proves the reality of surface decomposition reactions.

The heat of adsorption of hydrogen sulphide falls from 31.5 to 16.3 kcal mole^{-1} as the surface coverage is increased from 0.05 to 0.34 mmole m^{-2}. Similar variations were observed for the adsorption of hydrogen sulphide on γ-Al_2O_3 at 300 and 464 °C, when the heat of adsorption was 25 and 38 kcal mole^{-1} for surface loadings of 0.17 and 0.114 mmole m^{-2} respectively[80]. The heats of adsorption (Q, kcal mole^{-1}) of organic sulphur compounds on silica gel[52] and alumina[79] surfaces dehydroxylated at different temperatures are listed below (for a surface coverage of 1.4 mmole m^{-2}):

t, °C	Silica gel			γ-Al_2O_3
	240	550	700	700
Hydrogen sulphide	9.8	7.3	5.8	16.8
Methyl mercaptan	11.5	10.5	6.5	16.5
Ethyl mercaptan	12.3	11.7	9.7	18.4
Dimethyl sulphide	17.5	14.7	12.3	20.7

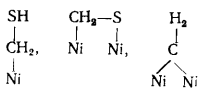
The higher heats of adsorption on γ-Al_2O_3 than on silica gel (at the same coverage) are ascribed to the interaction of the organic sulphur compounds with both the surface hydroxyl groups and the Lewis-acid centres of γ-Al_2O_3.

Gal'pern and coworkers[32] describe a comparative study of the adsorption of dibenzyl sulphide, diisopentyl sulphide, and biphenyl from solutions in iso-octane on a magnesium silicate adsorbent and on coarsely porous silica gel modified by nickel sulphide and phenyltrichlorosilane. The largest difference in the adsorptions of the sulphides and of biphenyl was observed on silica gel coated with a layer of nickel sulphide[32]. The largest increase in the adsorption capacity of tripoli earth[18] for dibutyl sulphide was achieved by acid–base activation (with a mixture of 12% NaOH and 20% HCl) of the surface of the naturally occurring sorbent.

Studies of the adsorption isotherms of organic sulphur compounds on zeolites have shown that the nature of the interaction is determined by the geometric and by the chemical structure of both the adsorbed molecules and the zeolite surface. It is reported[13,81] that hydrogen sulphide and mercaptans can be removed by CaA zeolites, and cyclic organo-sulphur compounds by type X zeolites: the difference is due mainly to steric hindrance during adsorption. The largest effect on the amount of adsorption is produced by the

type and extent of cation exchange. Thus it is shown[17] that the adsorption of sulphur compounds is more extensive on zeolites containing alkaline-earth metal cations than on NaY zeolite. However the adsorption does not increase regularly as the Na^+ cations are replaced by univalent and bivalent metal cations[82-86]. The amount of exchange giving optimum adsorption depends on the type of molecule being adsorbed, and for organic sulphur compounds (ethyl propyl sulphide, di-n-butyl sulphide, thiophen, alkyl mercaptan, thiophenol) the optimum varies between 25 and 70%.

The increased adsorption capacity of zeolites as a result of ion exchange is due to the creation on the zeolite surface of a distribution of cations with different charges which is favourable to adsorption. The adsorption capacity of NaA and NaX zeolites and their magnesium-substituted samples can be increased also by pre-adsorption of a controlled amount (between 1 and 3.5 wt.%) of H_2O, NH_3, or CH_3NH_2.[15,87] The exchangeable cations are located in different sites of the zeolite network, and site exchange is possible during adsorption[88,89].



The activity of zeolites towards organic sulphur compounds is substantially increased by decationation of the zeolite[90]. In this case the activity increases monotonically with the extent of decationation. By using this type of sample thiophen can be extracted almost quantitatively from dilute solutions in benzene.

IV. SPECTROSCOPIC STUDY OF ADSORPTION

The optical method most widely used to study the hydroxyl covering of oxide surfaces and its role in adsorption interactions is infrared spectroscopy[91-93]. It was first applied to studies of the adsorption mechanism of organic sulphur compounds by Eyring and Wadsworth[94], who explained the spectra of n-hexyl mercaptan on zinc oxide, sulphide, and silicate, and also on willemite ($ZnSiO_4$), by postulating the surface reaction

$$-Zn-OH + HSR \rightarrow -Zn-SR + H_2O.$$

From the spectra of hydrogen sulphide, methyl mercaptan, ethyl mercaptan, and diethyl sulphide adsorbed on nickel (20%) supported on silica gel it was concluded[95] that surface compounds of the following types are formed:

Analogous structures were proposed for chemisorbed ethyl mercaptan and diethyl sulphide.

The interaction of sulphides, disulphides, mercaptans, and thiophens with the surface hydroxyl groups of silica samples baked at 200 and 500 °C has been investigated by infrared spectroscopy[96-99]. It was found that the organic sulphur compounds interact with the hydroxyl groups of the silica surface, as shown by the decreased intensity and the shift of the absorption band at 3750 cm^{-1} (which characterises the stretching vibrations of the free OH groups). For the sulphides the absorption band of the perturbed OH groups lies at 3320–3390 cm^{-1}, for the mercaptans at 3310–3475 cm^{-1}, for the disulphides at 3340–3530 cm^{-1}, and for the thiophens at 3600–3630 cm^{-1}.

The smallest shifts in the absorption band for the stretching vibrations of the surface hydroxyl groups are observed after adsorption of compounds of the thiophen series (thiophen, 3-propylthiophen, 2,5-diethylthiophen, which give shifts of 116, 140, and 150 cm^{-1} respectively). These small values suggest a weak participation in adsorption interaction by the sulphur atom, due to the conjugation of its unshared electron pairs with the π-electrons of the thiophen ring.

It has also been shown that organic sulphur compounds of the aromatic type can interact with hydroxyl groups both through the unshared electron pairs of the sulphur and through the π-electron system. The absorption band at 3640 cm^{-1} characterises the interaction of the OH groups with the benzene ring, and the absorption band at 3550 cm^{-1} their interaction with the sulphur atom of thiophenol (Fig. 2). The shift of the absorption band of the surface hydroxyl groups increases in the same sequence as the specific interaction energy[49]. In homologous series of organic sulphur compounds the quantity $\Delta\nu_{OH}$ varies in direct proportion to the ionisation potential. The observed spectral[97-99] and energy parameters[49] of the adsorption process lead to the conclusion that organic sulphur compounds can be arranged in the following series as regards their affinity towards hydrogen bond formation with surface hydroxyl groups: sulphides > mercaptans > disulphides > thiophens.

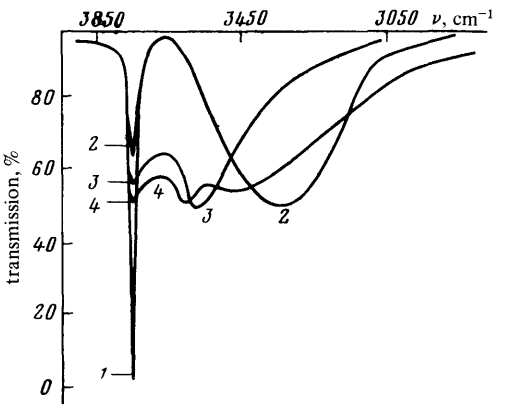


Figure 2. Changes in the spectrum of the surface hydroxyl groups of Aerosil (*1*) caused by the adsorption of organic sulphur compounds: *2*) dipropyl sulphide, *3*) thiophen, *4*) thiophenol (spectrum *1* was obtained after vacuum baking the sample for 5 h at 500 °C).

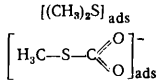
We should note that organic sulphur compounds behave as weaker donors than oxygen compounds of the same structure when forming hydrogen bonds with surface hydroxyl groups. This effect can be ascribed (as in the formation of hydrogen bonds with proton-donating solvents[100,101]) to the difference in electronic structure between the sulphur and the oxygen atom.

The i.r. spectra of sulphides, disulphides, mercaptans, and thiophens adsorbed on alumina[96,102-106] or on mixed oxides (Al_2O_3, NiO, MoO_3)[95,106-108] show that surface reactions can occur in parallel with the physisorption of organic sulphur compounds as a result of the formation of co-ordination bonds with the electronically unsaturated surface centres through the sulphur atom.

It has been shown also[97,105] that organic sulphur compounds adsorbed on alumina can interact with the hydroxyl groups of the surface through the formation of a hydrogen bond. The changes in frequency of the OH absorption bands ($\Delta\nu_{OH}$,

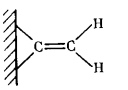
cm^{-1}) caused by adsorption on silica and on alumina are listed below:



Compound	Thiophan	Dimethyl sulphide	Dimethyl disulphide	Thiophenol	Thiophen
SiO_2[49]	415	369	215	200	116
γ-Al_2O_3[66]	180	130	120	130	100

The shifts in the absorption bands of the structural hydroxyl groups produced by the adsorption of aliphatic and cyclic sulphides and disulphides and of aliphatic mercaptans on alumina are less substantial than the shifts produced in silica. We note that the shift $\Delta\nu_{Al-OH}$ is less sensitive to the state of the sulphur atom in the molecule. Thus on changing from thiophan to thiophen the shift changes by ~3.6 for adsorption on silica and only by 1.8 for adsorption on alumina, which may be explained, as in the case of the adsorption of ethers[91], by the amphoteric nature of the groups in aluminium oxide. However, in contrast to adsorption on pure silica, we observe the formation of surface compounds containing CH_2 and CH_3 groups (with absorption bands at 2890, 2950, and 2988 cm^{-1}).

Analogous spectral changes in the region 2700–3200 cm^{-1} are observed during the interaction of thiophen with the surface of nickel[95], montmorillonite[76], cobalt molybdate, and molybdenum or germanium sulphide[107,108], and also zeolites of type HY,[109] NaX, CaX,[110] NaY, CaY, and CuNaY.[111,112]



The spectra of sulphides, mercaptans, disulphides, and thiophens adsorbed on alumina[102-106,112,113] and on the oxides of molybdenum, manganese, vanadium, and chromium[114,115] show absorption bands in the region of 1290–1600 cm^{-1} (with maxima at 1290, 1470, 1495, and 1600 cm^{-1}) even at 20 °C. The appearance of these bands is believed to result from the formation of thiocarbonate and thiocarboxylic acid groups on the surface[93,116,117], and of groups with an oxidised sulphur atom (see Table). The absorption bands at 1290, 1495, and 1600 cm^{-1} persist in the spectrum at high desorption temperatures (400–500 °C), demonstrating the high thermal stability of these surface compounds.

Structures formed by the adsorption of dimethyl sulphide on metal oxides (Si, Al, Mo, Cr, Mn, V).[114]

Structure No.	Structure	Formation temp., °C	Decomposition temp., °C
(I)	$[(CH_3)_2S]_{ads}$	20	100–150
(II)		20	450
(III)	$[(CH_3)_2SO]_{ads}$	20	150–200
(IV)	$[(CH_3)_2SO_2]_{ads}$	20	150–200
(V)	$[CH_3SO_3]^-_{ads}$	20–150	450
(VI)	$[HCOO]^-_{ads}$	20–250	450
(VII)	$(SO_4)^{2-}$	150	400–500

The breakdown of the surface structures produced by chemisorbed organic sulphur compounds yields hydrogen sulphide and unsaturated hydrocarbons. Thus on raising the desorption temperature of thiophen adsorbed on ultramarine[119] we observe the appearance of a new spectral band at 2630 cm^{-1} (for desorption at 100 °C), which splits into two bands (2500 and 2650 cm^{-1}) for desorption at 200 °C, accompanied by a new absorption band at 2690 cm^{-1}, characteristic of adsorbed hydrogen sulphide (2679 cm^{-1}). All three absorption bands disappear at 300 °C. Similar adsorption bands were observed[108] during the desorption of thiophen, water, and hydrogen adsorbed on MoS_2 and GeS. It is suggested[108,119] that the absorption bands at 2500–2700 cm^{-1} correspond to the vibrations of the S–H bonds of surface compounds. The appearance of absorption bands at 2850, 2960, and 3045 cm^{-1} is ascribed to the formation of but-1-ene or but-2-ene.

The absorption bands at 3050, 3140, and 3150 in the spectrum are assigned to HC ≡ CH surface groups, or to the structure

Davydova and coworkers[114,115] observed the oxidation of dimethyl sulphide on molybdenum, manganese, vanadium and chromium oxides in the presence of surface oxygen. The evidence was the appearance in the spectrum (Fig. 3) of absorption bands at 1045, 1145, and 1320 cm^{-1}, typical of the stretching vibrations of the SO group in adsorbed dimethyl sulphoxide[120] and dimethyl sulphone[121] [structures (III) and (IV)]. Raising the adsorption temperature (to 150 °C) caused the formation of surface structures [(V) and (VII)] with a sulphur atom in a higher state of oxidation, as shown by the appearance of absorption bands at 1045, 1145, and 1275 cm^{-1}, characteristic of the vibrations of the S–O bond in sulphites, sulphates, and sulphonates[122] [structure (VII)]. The formation of absorption bands at 1360 and 1380 cm^{-1} (stable up to 450–500 °C) in the spectrum of dimethyl sulphide adsorbed on chromium oxide at 250 °C is ascribed to formate ions on the surface [structure (VI)].

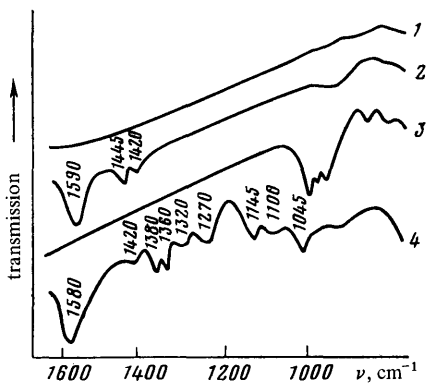


Figure 3. I.r. absorption spectra of chromium oxide: *1*) activated in vacuum at 250 °C, *2*) after adsorption of dimethyl sulphide at 250 °C, *3*) activated in oxygen at 250 °C, *4*) adsorption of dimethyl sulphide at 250 °C on a sample activated in oxygen.

Thiocarboxylate and thiocarbonate groups, and groups with an oxidised sulphur atom, are formed also during the adsorption of sulphur compounds on alumina, and on NaY, CaY, NaCay, and CuNaY zeolites[110-112,123,124]. The adsorption of thiophen on zeolites with exchanged cations of the transition metals produces complex compounds[110]. More

extensive decomposition of the sulphur-containing molecules occurs when the univalent cation is replaced by a bivalent cation. It is found[109,123] that the adsorption mechanism is strongly influenced by the protonic acidity of the zeolite. Thus on HY zeolite[109,123] (but not on NaY zeolite) thiophen undergoes chemical reactions involving the breaking of C–S bonds and the formation of surface compounds containing S–H bonds (2380 cm^{-1}) and unsaturated (3100 cm^{-1}) or saturated (2800–3000 cm^{-1}) C–H bonds. These results are relevant to our understanding of the mechanism of catalytic hydrodesulphurisation processes for organic sulphur compounds.

In recent years adsorption and spectra methods have been combined to demonstrate the important role of impurity centres during adsorption on silicas[91,125,126]. These results help us to understand the mechanism of adsorption, because technical grades of siliceous adsorbents always contain impurities of aluminium, iron, and other oxides. The effect of aluminium, boron, cadmium, titanium, and iron oxides on the interaction of organic sulphur compounds with silica has been studied in detail[96,127,128]: it was found that the sulphur compounds interact by the hydrogen bond mechanism with the silanol hydroxyl groups and with OH groups bound to impurity metal atoms. Furthermore the presence of impurity centres leads to chemisorption and to the formation of surface complexes, with partial decomposition of the sulphur compound.

U.v. spectroscopy has been used[129,130] for the analysis of charged forms of adsorbed molecules such as carbonium ions. We have studied[131] the u.v. spectra of thiopehn, thiophan, thiophenol, benzothiophen, 2- and 3-methylbenzothiophens, and 2-methyl-2,3-dihydrobenzothiophen adsorbed on alumina and on alumina-silica. Adsorption of these molecules on alumina does not produce any charged forms up to 300 °C, but charged forms are produced by adsorption on alumina–silica at temperatures above 100 °C.

V. QUANTUM-CHEMICAL CALCULATIONS OF ADSORPTION COMPLEXES

The methods of quantum chemistry are being used increasingly in the study of adsorption mechanisms[132–134]. In this approach the conventional semi-empirical procedures of quantum chemistry are applied to calculations on models which include an adsorbed molecule and an atom from the adsorbent surface (cluster).

Relying on the simple Hückel method, Stodoiski and coworkers[135] used the interaction between organic sulphur compounds and a transition metal surface to calculate adsorption models, allowing for the possible formation of surface structures without dissociation of the adsorbed molecules and also for the formation of sulphide layers by the reactions

$$R{-}S + M \rightarrow M \ldots S{-}R, \quad (1)$$

$$R{-}S + M \rightarrow R + MS, \quad (2)$$

where R is a hydrocarbon radical and M is a metal atom.

It was found that the stability of the S–M bond decreases as the electronegativity of the metal increases. The reaction between the organic sulphur compound and metals was shown to weaken the C–S bond and to strengthen the adjacent C–C bond. A significantly large decrease in the population of the C–S bond indicates the possibility of dissociation of the adsorbed molecules. By calculating the energy of reaction (2) it was shown that dissociation is most likely with thiophenol, hexamethylene sulphide, and vinyl mercaptan.

We have also used[136] the extended Hückel method in calculations on adsorption complexes containing hydroxyl groups, modelling the interaction of thiophen and dimethyl sulphide with oxide surfaces. The change in the properties of the hydroxyl group on different oxide surfaces was modelled by assigning a predetermined charge to the hydroxyl group. The CNDO/2 method was used[137] to show that the charge on the proton can be correlated with the acidic properties of the hydroxyl groups. Recent calculations[136] have shown that better agreement with experimental data[49,96,97] can be expected for models including uncharged hydroxyl groups.

The substantial stabilisation and strong change in the charge on the sulphur atom in the complexes produced by thiophen and dimethyl sulphide with a positively charged hydroxyl group are ascribed to the formation of bonds with charge transfer from the sulphur atom towards the hydroxyl group. In the model complexes between dimethyl sulphide and the hydroxyl group the weakening of the O–H bond is more marked than in the corresponding thiophen complexes. These results are consistent with the more substantial shift of the surface hydroxyl absorption band at 3750 cm^{-1} [96,97] and with the greater specific interaction energy for the adsorption of dimethyl sulphide on silica (360 cm^{-1} and 3.2 kcal $mole^{-1}$ respectively) as compared with the adsorption of thiophen (120 cm^{-1} and 2.3 kcal $mole^{-1}$ respectively). The calculations suggest that interaction of the organic sulphur compounds with two surface hydroxyl groups may be preferred on energy grounds. Hence a planar orientation of the molecules on the silica surface is probably the most favourable.

---oOo---

Thus adsorption-chromatographic methods will be used increasingly for the separation of naturally occurring organic sulphur compounds without changing their structure, and also for developing new methods of classifying these compounds by group (sulphides, disulphides, mercaptans, thiophens) and according to structural features within a homologous series.

The solution of important problems in the chemistry of the sulphur compounds occurring in petroleum depends on a correct understanding of the mechanism by which organic sulphur compounds interact with adsorbents of different types: this understanding is needed in the search for new modifying additives for inorganic sorbents, aimed at increasing their efficiency and at extending the practical utilisation of sulphur compounds from petroleum in the national economy.

This review has shown that the application of thermodynamic and spectral methods (together with quantum-chemical calculations) to adsorption studies can assist our understanding of the interactions taking place on the surface.

The Electrochemistry of Hydroxide Melts

O.G.Zarubitskii

The results of the study of electrode potentials and processes in molten alkalis have been analysed. The influence of acid-base equilibrium on the mechanism and kinetics of the reactions which take place at indifferent electrodes in hydroxide melts between 200 and 500 °C has been demonstrated. The results of the study of the decomposition voltage and the electrochemical transformations at the cathode and anode when direct current is passed through these electrolytes have been examined. The bibliography contains 85 references.

I. INTRODUCTION

Hydroxide melts exhibit specific physicochemical properties, which distinguish these media as a special class of high-temperature electrolytes. The electrolysis of molten alkalis is distinguished by a number of characteristic features. It was in the study of the electrolysis of hydroxide melts that the phenomenon of metal transport from the cathode to the anode was first observed[1]. Review articles and widely known monographs[2-4] devoted to ionic melts, however, contain practically no information on the chemistry and electrochemistry of molten alkali metal hydroxides. The study of the electrochemistry of alkali melts has been particularly intensive over the last 10–15 years in connection with the promising possibilities provided by their application in various branches of the new technology. The present review is devoted chiefly to an analysis and generalisation of work carried out in recent years, and the electrochemical properties of "pure" alkalis are examined.

II. EQUILIBRIA IN HYDROXIDE MELTS

In the molten state, alkalis are dissociated[5] to give the cations Li^+, Na^+, K^+, Rb^+, and Cs^+, and hydroxide ions OH^-. Recent work[5-16] has established that in molten alkalis there exist a number of oxygen-containing ions (O^{2-}, O_2^{2-}, O_2^-) and molecules (O_2, H_2O). The solubility of molecular oxygen is low[7]. At the same time, it reacts with the melt according to the scheme

$$2NaOH + 0.5O_2 \rightleftarrows Na_2O_2 + H_2O \cdot$$

Rahmel and Krueger[17] were able to determine the solubility of oxygen in NaOH by a gravimetric method. At an oxygen pressure of 1 atm, the equilibrium concentration of O_2 in the melt increases with temperature, and amounts to 0.8 cm^3 and 4.2 cm^3 per cm^3 NaOH at 350 °C and 500 °C respectively. The same authors[17] obtained experimental isotherms giving the change in the concentration of water in a sodium hydroxide melt at different pressures of H_2O in the atmosphere above the electrolyte. There is a linear relationship between the increase in the water vapour pressure above the melt and the increase in the mass of the melt Δm, that is Henry's law is obeyed.

$$\Delta m = k p_{H_2O}.$$

The constant k changes with temperature according to the Van't Hoff equation

$$\lg(k/k_0) = A/T,$$

where k_0 and A are constants, equal to 2.88×10^{-7} mg g^{-1} $mmHg^{-1}$ and 3.21×10^{-3} K respectively. This equilibrium is established in 2–3 h.

The principal chemical reactions taking place with the participation of oxygen-containing species are described[6] by the following equations

$$O^{2-} + 0.5O_2 \rightleftarrows O_2^{2-}, \quad (1)$$

$$O_2^{2-} + H_2O \rightleftarrows 2OH^- + 0.5O_2, \quad (2)$$

$$2O_2^- + H_2O \rightleftarrows 2OH^- + 1.5O_2, \quad (3)$$

$$O_2 + O_2^{2-} \rightleftarrows 2O_2^-, \quad (4)$$

$$3O_2 + 2O^{2-} \rightleftarrows 4O_2^-. \quad (5)$$

Of the three simple oxygen anions (O^{2-}, O_2^{2-}, O_2^-), the O^{2-} ion is the most highly reduced species[7]. It cannot coexist with water. The peroxide ion O_2^{2-} is an ampholyte; it is reduced to O^{2-} or oxidised to O_2. The superoxide ion O_2^- also exhibits amphoteric properties; it is an oxidising agent with respect to O_2^{2-}, and a reducing agent with respect to O_2. Sodium oxide and peroxide, and also gaseous oxygen, are relatively sparingly soluble in the NaOH–KOH eutectic at 227°.[7] According to the data of Lux and coworkers[18], however, the action of dry oxygen (1 atm, 410 °C) for 5–16 h (as far as complete equilibration) leads to the formation, in the melt, of 3 mass % Na_2O_2 in NaOH, 54 mass % K_2O_2 (or 22 mass % KO_2) in KOH, 137 mass % Rb_2O_2 (or 57 mass % RbO_2) in RbOH, and 165 mass % Cs_2O_2 (or 64 mass % CsO_2) in CsOH. In LiOH, the formation of Li_2O_2 and LiO_2 was not detected. The equilibria for the formation of peroxides and superoxides, for example Eqns.(2) and (3), indicates that the concentrations of O_2^{2-} and O_2^- should show a definite dependence on the partial pressures of oxygen and water vapour above the melt. This was confirmed experimentally by Lux and coworkers[18], and it was shown that NaOH contains the peroxide Na_2O_2 in solution, whereas in KOH, RbOH, and CsOH the superoxides KO_2, RbO_2, and CsO_2 predominate.

Appropriate experiments[18] established that in molten NaOH the reaction with oxygen takes place according to Eqn.(2), since the following relationships derived from it are obeyed:

$$c_{O_2^{2-}} = k' p_{O_2}^{1/4} \text{ for } p_{H_2O}/c_{OH^-}^2 = \text{const}$$

$$c_{O_2^{2-}} = k'' c_{OH^-}^2 / p_{H_2O} \text{ for } p_{O_2} = \text{const.}$$

Oxygen reacts with KOH, RbOH, and CsOH according to Eqn.(3), as indicated by the fact that the following relationships are obeyed:

$$c_{O_2^-} = k_1 p_{O_2}^{3/4} \text{ for } p_{H_2O}/c_{OH^-}^2 = \text{const}$$

and

$$c_{O_2^-} = k c_{OH^-} / p_{H_2O}^{1/2} \text{ for } p_{O_2} = \text{const.}$$

With increase in temperature, the concentration of higher oxygen compounds of the alkali metals increases[18] ($p_{O_2} = 0.94$ atm, $p_{H_2O} = 0$ mmHg, $\tau = 4$–5 h):

t, °C	360	410	460	510
Concentration of Na_2O_2 in NaOH, mass %	1.70	2.19	2.60	3.65
Concentration of KO_2 in KOH, mass %	—	21.97	26.49	31.88

The efficiency of the formation of peroxides and superoxides in the reaction of hydroxides with atomic oxygen, generated in a glow discharge:

Alkali	Concentration, mass %		
	peroxide	superoxide	hydroxide
NaOH	31.4	11.4	57.2
KOH	нет	80.5	19.2

is considerably greater than that in the O_2–molten NaOH or KOH systems.

The chemical properties of molten alkalis, used as solvents, are related chiefly to the properties of the OH^- ions, which dissociate according to the equation[5–9]:

$$2OH^- \rightleftarrows H_2O + O^{2-} . \qquad (6)$$

The constant for this equilibrium is equal to the product of the activities of H_2O and O^{2-}, and corresponds to the product of the concentrations of the components in the given dilute solution:

$$K_i = [H_2O][O^{2-}]. \qquad (7)$$

The concentration of OH^- ions is taken as constant, since the degree of dissociation according to Eqn.(6) is small. The ionic product (7) has a definite value for a given mixture of alkalis and a given temperature. For the NaOH–KOH eutectic at 227 °C, it is given by[7] $pK = -\lg K = 11.5 \pm 0.7$.

Eqn.(7) can be used to determine[5] the acid–base properties of molten alkalis. Just as in aqueous solution the H_3O^+ ion is a complex proton, solvated by a molecule of the solvent H_2O, so in molten hydroxides it is also possible to regard H_2O as a complex, that is a compound of the proton H^+ with the ions of the solvent OH^-. Thus in hydroxide melts, H_2O is the most "acidic" species, and O^{2-} the most "basic".

By analogy with the pH scale in water, it is possible[5] to introduce for molten alkalis an analogous scale, which Goret called the pH_2O scale ($pH_2O = -\lg [H_2O]$). The value of the ionic product $pK_i = -\lg K_i$ determines the range of pH_2O values which can be achieved in a given medium. If $[H_2O] = 1$, then $pH_2O = 0$, and the concentration of O^{2-} ions is very low, since

$$pH_2O = pK_i + \lg[O^{2-}],$$
$$pO^{2-} = 11.5 - pH_2O.$$

Neutrality of the medium corresponds to the pure anhydrous eutectic mixture KOH–NaOH at 227 °C, where $pH_2O = pO^{2-} = 1/2\ pK_i = 5.75$. Molten alkalis rich in water correspond to "acidic" media, and those rich in O^{2-} ions correspond to "basic" media. It is possible to change the acidity of a medium by introducing non-dried alkalis or alkali metal oxides (Na_2O, KO_2, etc.). In the examination of acid–base equilibria in hydroxide melts, it is assumed[5] that in these media, all compounds (ions) which facilitate the appearance of water behave as "acids". The examination of the behaviour of metal cations is of particular interest in this connection. For these, the following phenomena may be observed, depending on the magnitude of pH_2O.

1) In a very acidic medium (rich in water), strong acceptors of O^{2-} ions form complex oxides, for example the cations Ni^{2+}, Pt^{2+}, and Al^{3+} give the sparingly soluble oxides NiO, PtO, and Al_2O_3. Oxygen-containing species such as CO_2 and PO_3^- behave as acids and form CO_3^{2-} and PO_4^{3-} ions:

$$CO_2 + 2OH^- \rightarrow CO_3^{2-} + H_2O ,$$

$$PO_3^- + 2OH^- \rightarrow PO_4^{3-} + H_2O .$$

On going to more basic media (with the removal of water), higher complex compounds may be formed. Thus alumina is more soluble in a dehydrated medium and is transferred to the melt in the presence of the O^{2-} ion by the reaction

$$Al_2O_3 + O^{2-} \rightarrow 2AlO_2^- .$$

In molten alkalis, in addition to equilibria (1)–(5), dissociation according to the equation[14,19,20]

$$2MOH \rightleftarrows M_2O + H_2O \qquad (8)$$

is observed. Since M_2O is a strong O^{2-} donor, reactions (8) and (6) are displaced to the left.

Table 1. Calculated dissociation constants K^* of molten alkalis at different temperatures[14] (the hypothetical values corresponding to temperatures below the solidification temperature are given in brackets).

t, °C	LiOH	NaOH	KOH	RbOH	CsOH
227	(7.0)	(13.1)	(17.7)	(18.6)	(18.9)
350	(4.3)	9.7	13.1	13.7	14
400	(3.5)	8.5	11.8	12.3	12.5
477	2.5	7.4	10.3	10.5	10.8
577	1.8	6.2	8.8	8.7	9.0
723	1.1	5.0	7.1	6.8	7.0

By applying the law of mass action to equilibria of type (8), it is possible to obtain different values of the dissociation constants, depending on the method of expressing the activities of the components[14]. If the standard states of MOH, M_2O, and H_2O are taken as the liquid hydroxide, the pure solid oxide, and water dissolved at a vapour pressure of 1 atm respectively, then

$$a_{M_2O} p_{H_2O} / a_{MOH}^2 = K^* .$$

If $a_{MOH} = 1$, then

$$p a_{M_2O} - \lg p_{H_2O} = -\lg K^* = p K^* .$$

The values of pK^* for different alkalis have been calculated[14]

from thermochemical data using the equation

$$2.3RT\,\mathrm{p}K^{\bullet} = \mu^{\bullet}_{M_2O} + \mu^{\bullet}_{H_2O} - 2\mu^{\bullet}_{MOH}$$

and are given in Table 1.

The degree of dissociation of alkalis at a given temperature increases with decrease in the radius of the cation: LiOH dissociates when the alkali is melted; KOH, RbOH, and CsOH are less extensively dissociated, and NaOH occupies an intermediate position.

For analytical calculations, the preferred definition of the constant pK is

$$\mathrm{p}K = \mathrm{pO^{2-}} + \mathrm{pH_2O},$$

when the standard state is taken as the solution having O^{2-} and H_2O concentrations equal to unity. The experimental determination of pK presents considerable difficulty, however. Its value has been determined only for the KOH–NaOH eutectic mixture[7]. The values of pK for NaOH at different temperatures have been calculated[14] using published data[17,21–23] on equilibrium in the NaOH–Na_2O and NaOH–H_2O systems:

t, °C	360	420	500	600	700
pK	8.75	7.50	6.25	5.00	4.0

These calculated data have been confirmed[15] by potentiometric measurements.

III. ELECTRODE POTENTIALS IN ALKALI MELTS

As described above, various oxygen-containing ions may be present in hydroxide melts when the atmosphere above them contains O_2 and H_2O. These ions are involved in the electrode equilibria, which are characterised by definite potentials and influence the characteristics of technical electrolysis or the operation of a galvanic cell.

Antropov and Tkalenko[24,25] compiled nine equations (Table 2) corresponding to possible redox systems involving oxygen-containing anions. Using thermochemical data, they calculated the standard potentials of the reactions represented in Table 2 in NaOH, KOH, and LiOH melts relative to the reference electrode M/M^+, where M is the corresponding alkali metal. These calculations were used to construct the plots of the potential against the acidity of the medium, analysis of which showed that in these hydroxide melts ($c_{H_2O} > 0.01\%$), the potential-determining system is system 1 (Table 2). In particular, in an NaOH melt, the potential of the oxygen electrode is determined by system 1 at values of $pH_2O < 4.75$, and by system 5 at values of $pH_2O > 4.75$; in a KOH melt, the potential-determining system is system 1 at values of $pH_2O < 2.2$, and system 4 at values of $pH_2O > 2.2$. The E–pH_2O diagram for LiOH does not show regions corresponding to the preferential formation of the peroxide or superoxide. The calculated values[25] of the concentrations of active oxygen in mole litre^{-1} in NaOH and KOH melts at $p_{H_2O} = 1$, $p_{O_2} = 0.2$, and $T = 700$ K are given below:

Melt	Peroxide	Superoxide
NaOH	$1.5 \cdot 10^{-4}$	$7.6 \cdot 10^{-2}$
KOH	$1.78 \cdot 10^{-5}$	$4.52 \cdot 10^{-4}$

At an oxygen partial pressure of ~1 atm and $pH_2O = 2$ in an LiOH melt at 750 K, concentrations of peroxide and superoxide equal to 6.3×10^{-7} M and 2.5×10^{-5} respectively are established. Thus under identical conditions, the concentration of active oxygen in a KOH melt is 160 times that in an NaOH melt. When an LiOH melt is in contact with oxygen, O_2^{2-} and O_2^- ions may also be present in this medium, but in extremely small quantities. These data are confirmed by the results of direct measurements of the concentrations of peroxide and superoxide in hydroxide melts[18,26].

Using electrochemical data, Ogryz'ko-Zhukovskaya[27] represented the reactions involved in the formation of higher oxgyen compounds in molten alkalis by the equations:

$$2OH^- + 1.5\,O_2 \rightleftarrows 2O_3^- + H_2O\,,$$

$$2OH^- + 0.5\,O_2 \rightleftarrows O_2^{2-} + H_2O\,.$$

The equilibrium constants for these equations

$$K_1 = [O_3^-]^2\,[H_2O]/[p_{O_2}]^{3/2},$$

$$K_2 = [O_2^{2-}]\,[H_2O]/[p_{O_2}]^{1/2}$$

in KOH at 200 °C are 6×10^{-4} and 2.5×10^{-6} respectively. In this melt at $c_{H_2O} = 10\%$, $p_{O_2} = 1$ atm, and $T = 200$ °C, the concentration of O_3^- is 7.75×10^{-3}M, and that of O_2^{2-}, 2.5×10^{-7} M. The concentration of KO_2, determined experimentally for these conditons, is 7.2×10^{-3} M.[27]

Table 2. Standard potentials of the redox systems.

No.	System	ΔG, kcal mole^{-1}	$E°$, V	ΔG, kcal mole^{-1}	$E°$, V	ΔG, kcal mole^{-1}	$E°$, V
		KOH, 700 K		NaOH, 700 K		LiOH, 750 K	
1	$O_2 + 2H_2O + 4e \rightleftarrows 4OH^-$	187	2.03	202	2.2	262	2.85
2	$O_3^- + 2H_2O + 3e \rightleftarrows 4OH^-$	144	2.09	164	2.37	225	3.26
3	$O_2^{2-} + 2H_2O + 2e \rightleftarrows 4OH^-$	104.5	2.27	116	2.52	160	3.47
4	$O_2 + e \rightleftarrows O_2^-$	42.7	1.85	39	1.69	36.8	1.60
5	$O_2 + 2e \rightleftarrows O_2^{2-}$	82.5	1.79	85.9	1.86	102.5	2.23
6	$O_2 + 4e \rightleftarrows 2O^{2-}$	122.8	1.33	152.2	1.65	218	2.37
7	$O_3^- + e \rightleftarrows O_2^{2-}$	—	1.73	—	2.03	65.8	2.86
8	$O_3^- + 3e \rightleftarrows 2O^{2-}$	—	1.16	—	1.63	183	2.63
9	$O_2^{2-} + 2e \rightleftarrows 2O^{2-}$	—	0.87	—	1.44	115.5	2.51

A number of papers have been published on the potentiometric study of redox systems involving oxygen-containing ions in hydroxide melts. Thus a study of the $Pt(O_2)$ electrode by measuring the e.m.f. of the following concentration cell at 500 °C and at 350–600 °C[15]

$$Pt(O_2/H_2O)\,|\,NaOH,\ O^{2-}\ \text{or}\ O_2^{2-}\,\|\,NaOH,\ O^{2-}\ \text{or}\ O_2^{2-}\,|\,Pt(O_2/H_2O)$$

showed that the dependence of its potential on the partial pressures of oxygen and water vapour is described by the following equation:

$$E = E^{\bullet} + \frac{RT}{4F}\ln p_{O_2} + \frac{RT}{2F}\ln p_{H_2O}. \qquad (9)$$

The concentration of the species taking part in reactions (1)–(5) are inter-related, so that the potential E in Eqn.(9) is a function of four different combinations of variables, ($a_{O^{2-}}$, p_{O_2}), ($a_{O_2^{2-}}$, p_{O_2}), ($a_{O_2^{2-}}$, p_{H_2O}), and ($a_{O_2^{2-}}$, a_{O_2}). Using Eqn.(9), Kureger and coworkers[6] took as reference potential the potential established at platinum in NaOH at $p_{O_2} = 0.98$ atm and $p_{H_2O} = 0.02$ atm. The results of the measurements show that the values of the prelogarithmic (Nernst) coefficients $\Delta E/\Delta \lg p_{O_2} = 38.3$ mV and $\Delta E/\Delta \lg p_{H_2O} = 76.5$ mV correspond to the theoretical values, that is $2.3RT/4F$ and $2.3RT/2F$ respectively.

Afanas'ev and Gamazov[28,29] were the first to measure the e.m.f. of gas concentration cells of the type

$$(p'_{O_2})\,M\,|\,NaOH\,|\,alundum\,|\,NaOH\,|\,(p''_{O_2})\,M$$
$$M = Pt, Ni, Au$$

and concluded that platinum, nickel, and gold behave as reversible oxygen electrodes, and that $\Delta E = 0.0383 \lg (p'_{O_2}/p''_{O_2})$ at 500 °C.

Using the dependence of the potential of the platinum–oxygen electrode on the concentration of oxygen ions in the sodium hydroxide melt, Krueger and coworkers[6] established that the addition of Na_2O and NaOH produces practically no change in the e.m.f. of the cell. From this it was concluded that the reaction

$$O_2 + 4\,e \rightleftarrows 2\,O^{2-}. \qquad (10)$$

is not potential-determining. Moreover, contrary to widespread opinion, Krueger and coworkers[6] concluded that the electrode reaction which corresponds to Eqn.(9) and as a result of the combination of Eqns.(6) and (10) gives the relationship

$$O_2 + 2H_2O + 4\,e = 4OH^- \qquad (11)$$

similarly cannot be potential-determining. Here it is assumed that reaction (6) takes place fairly rapidly, and that Na_2O is dissociated to Na^+ and O^{2-} ions.

At the same time it has been established[6,28] that the dependence of the potential of the platinum electrode on the concentration of sodium peroxide in NaOH is given by the equation

$$E = E^0 + \frac{RT}{2F} \ln c,$$

where c is the concentration of O_2^{2-} ions. It follows from these data that the electrode reaction

$$O_2 + 2e = O_2^{2-}, \qquad (12)$$

which is the reduction of oxygen to the peroxide ion, takes place rapidly and is potential-determining. The corresponding Nernst equation

$$E = E^0 - \frac{RT}{2F} \ln \frac{a_{O_2^{2-}}}{p_{O_2}}$$

shows good agreement with the experimental data.

On the other hand, according to the data of Krueger and coworkers[6], the electrode reaction

$$O_2^{2-} + 2e = 2O^{2-} \qquad (13)$$

cannot be potential-determining. From the experimental data given by Kruger and coworkers[6], it follows that the potential of an indifferent (platinum) electrode depends chiefly on the formation of peroxide and its decomposition according to Eqn.(2). This result agrees with the conclusion[18] that the establishment of equilibria (2) and (3) takes place more rapidly in a moist atmosphere than in an atmosphere of dry oxygen. In an atmosphere of O_2, the removal of the water produced is decisive. Thus with increase in the rate of flow of oxygen there is an increase in the intensity of peroxide formation, as confirmed[6] by the experimental data.

It follows from Eqns.(2), (3), and (11) that the redox potentials of the corresponding systems are influenced by the concentration of OH^- ions in the hydroxide melt. This has been demonstrated experimentally[19,28–30]. The studies reduced to the measurement of the e.m.f. of concentration cells of the type

$$M\,|\,NaOH\,|\,alundum\,|\,NaOH—NaNO_3\,(N)\,|\,M$$
$$(M = Pt, Ni, Au)$$

at 500 °C[28,29] and 340 °C.[30] The potential difference between the electrodes is a linear function of the logarithm of the mole fraction of sodium hydroxide in the melt. The slopes of the straight lines obtained by plotting E against $\lg [OH]$[28,29] are practically identical (0.156–0.160), and for a number of electrons n equal to 4 they correspond to the theoretical value in the equation

$$E = -\frac{2,3RT}{nF} \lg [OH^-]^4,$$

describing the change in the potential associates with the electrode process (11). With change in the concentration of LiOH from 2 mole % to 18 mole % in a eutectic melt of lithium, sodium, and potassium carbonates at 600 °C, the potential of a gold electrode is also described by the semi-empirical equation[19]

$$E = a - b \lg [OH^-].$$

In this expression, the value of the prelogarithmic coefficient is $b = 2.3RT/F = 0.194$. Thus the experimental data described above indicate that at 350–600 °C, platinum, nickel, and gold electrodes, like iron and silver electrodes[31,32], behave as reversible oxygen electrodes.

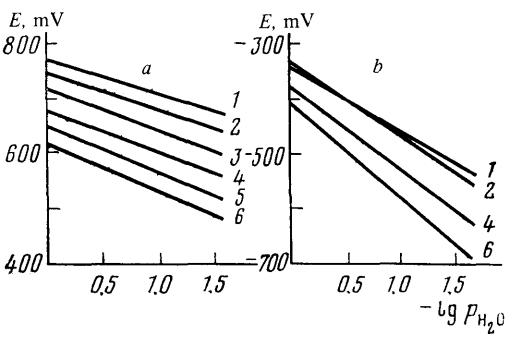

Figure 1. Isotherms giving the dependence of the potentials of oxygen (*a*) and hydrogen (*b*) electrodes in NaOH on the acidity of the electrolyte: *1*) 350, *2*) 400, *3*) 450, *4*) 500, *5*) 550, *6*) 600 °C.

The electrode processes described by Eqns.(2), (3), and (11) are not the only ones in which the hydroxide anion OH^- may take part. For example, Doisneau and Tremillon[15], who established an atmosphere of H_2 and H_2O above NaOH and used Pt and Ni electrodes at 350–600 °C, showed experimentally (Fig.1) that the electrode reaction taking place

$$4OH^- + 2H_2 \rightleftarrows 4H_2O + 4\,e$$

is described by the equation

$$E_{H_2} = E^*_{H_2} + \frac{2.3RT}{F} \lg p_{H_2O} - \frac{2.3RT}{2F} \lg p_{H_2}.$$

The calculated values of $E^*_{H_2}$ and $E^*_{O_2}$ show good agreement with the values obtained by extrapolating the straight lines (Fig.1) for $p_{H_2} = 1$ atm and $p_{O_2} = 1$ atm. The difference in

the standard potential $E^*_{O_2} - E^*_{H_2}$ corresponds to the e.m.f. of a cell of the form

$$Pt(H_2)\,|H_2O,\ NaOH|\,|NaOH,\ H_2O|\,(O_2)Pt,$$

in which the reaction

$$1/2O_2 + H_2 = H_2O \qquad (14)$$

takes place. The results of the calculation of this potential difference from the values of the Gibbs free energy show good agreement with experimental data[15].

IV. ELECTRODE PROCESSES

In recent years, original studies have been made of the electrode processes taking place at indifferent electrodes in alkali melts, involving alkali metal ions, water, and the anions OH^-, O^{2-}, and O_2^-. The concentrations of these ions and water can be varied by creating different atmospheres above the melt (p_{H_2O}, p_{O_2}) and by adding the oxides H_2O, Na_2O, and Na_2O_2 to the electrolyte. The products liberated at the electrodes may be the alkali metal, hydrogen, and hydride at the cathode, and water, oxygen, peroxide, and superoxide at the anode.

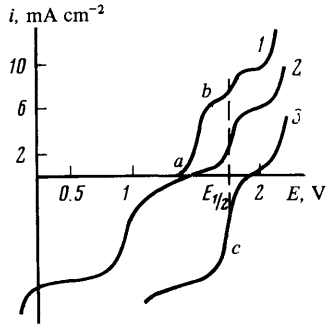

Figure 2. Polarisation curves characterising the electrochemical reaction $O_2^{2-} = 2O^{2-} - 2e$; *1*) Na_2O concentration in the melt 10^{-2} M, *2*) with oxygen bubbled through, *3*) the same after a long time interval; $2O^{2-} - 2e \rightarrow O_2^{2-}$ (*a*), $O_2^{2-} - e \rightarrow O_2^-$ (*b*), $O_2^{2-} + e + O_2^-$.

The behaviour of oxygen-containing anions in KOH–NaOH and NaOH melts has been studied in detail[5,7,15]. First of all, the behaviour of the O_2^{2-} and O_2^- ions at platinum and nickel electrodes was studied in a eutectic melt of sodium and potassium hydroxides at 220–270 °C and in sodium hydroxide at 350 °C. In particular, the electrode reaction (12) was studied at a rotating platinum electrode and at a nickel oxide electrode. A weighed specimen of sodium oxide was added to the melt, and the polarisation curves were recorded potentiodynamically. Two successive waves were observed (Fig.2), the height of the first being twice that of the second. The O^{2-} ion can be oxidised to peroxide and then to superoxide by the reactions

$$2O^{2-} - 2e \rightarrow O_2^{2-}, \qquad (15)$$

$$O_2^{2-} - e \rightarrow O_2^-. \qquad (16)$$

The O_2^{2-} ion is stable only in a basic medium; it exhibits amphoteric properties, and can be reduced to the oxide ion O^{2-} or oxidised to superoxide O_2^-. Oxidation according to the equation

$$O_2^- - e \rightarrow O_2$$

is not observed, since the hydroxide ions OH^- of the solvent are oxidised earlier: $E^0_{O_2-/O_2} = 2.33$ V.[10]

The half-wave potential of the first wave is not constant, and changes with change in the Na_2O concentration, but the potential $E_{1/2}$ of the second wave (Fig.2) remains unchanged. The limiting current of the first wave is proportional to the concentration of Na_2O in the melt[15]. The potentiodynamic studies[15] showed that the solubility of sodium oxide in NaOH at 350 °C is 2.3 mole kg^{-1} which is close to the value obtained (2.4 mole kg^{-1}) by measurements using a different method[21].

The existence of intermediate degrees of oxidation between O^{2-} and O_2 is confirmed by the disappearance of the wave for the oxidation of O^{2-} when dry oxygen is bubbled through the melt. When its passage is continued through a dilute solution of sodium oxide in an NaOH–KOH melt, a decrease in the height of the first wave and an increase in the height of the second is observed at first (Fig.2) as far as the appearance of curve *2*. When the bubbling is continued, the second oxidation wave also disappears[7] (curve *3* in Fig.2). Curve *3* shows only the wave corresponding to the reduction of O_2^- ions.

Under the conditions of this experiment, the oxide ion O^{2-} is oxidised by oxygen, first to peroxide according to Eqn.(1). Curve *2* (Fig.2) corresponds to the case where all the O^{2-} ions in the solution are converted into O_2^{2-} ions. This curve is characterised by a wave corresponding to the oxidation (16) and a wave corresponding to the reduction (13), the height of the latter being twice that of the former. The limiting current density for the cathodic reduction of Na_2O_2 in NaOH at 500 °C is also proportional to the concentration of peroxide in the melt[6]. The peroxide ions are then oxidised by oxygen according to Eqn.(4).

Curve *3* (Fig.2) corresponds to the case where the solution contains O_2^- ions, but O_2^{2-} ions are not present, since they have been oxidised by oxygen to superoxide. To some extent, these reactions "in solution" are analogous to the action of oxygen on solid K_2O, which forms K_2O_2 and then KO_2.

The experimental results indicate that the electrode reaction (16) is rapid, and its kinetics are determined by stationary diffusion[7]

$$E = E^0_{O_2^{2-}/O_2^-} + \frac{RT}{F} \ln \frac{[O_2^-]}{[O_2^{2-}]},$$

$$E = E_{1/2} + \frac{RT}{F} \ln \frac{i - i_1}{i_2 - i},$$

where i_1 and i_2 are the limiting currents of the reduction and oxidation respectively. They are proportional to the concentrations of O_2^- and O_2^{2-} in the solution:

$$i_1 = -k_1[O_2^-],$$

$$i_2 = k_2[O_2^{2-}].$$

$E_{1/2} = 1.75$ V relative to the sodium reference electrode.

It should be noted that at a platinum electrode, the wave corresponding to the oxidation (15) is observed from $E > 1.4$ V, but the wave corresponding to the reduction (13) appears only below 0.95 V ($\Delta E_{1/2} \cong 0.55$ V). This redox system is slow (like the H_2O_2/OH^- system in aqueous solution). These differences in the kinetics of the two systems (15) and (16)

being considered can be explained[7] from the structure of the species taking part in the reactions. Between peroxide and superoxide, only simple electron transfer involving two diatomic species takes place, whereas between peroxide and oxide the exchange of electrons is accompained by the rupture or formation of a covalent bond (oxide is monatomic, and peroxide diatomic). The authors cited[7] point out that the kinetics in the superoxide/oxide system, if they could be observed, would also be rapid, since they involve only two diatomic species.

It is possible to explain from this viewpoint the experimental fact[6] that at 500 °C in an NaOH melt, reaction (12) is rapid, whereas the electrode reaction (10) is slow.

A characteristic feature[7] is that the electrochemical reaction (15) ($E^0 = 1.4 \pm 0.05$ V) is rapid and reversible at a nickel oxide electrode, which catalyses the O^{2-}/O_2^{2-} system. This phenomenon is not new: in aqueous medium the decomposition of H_2O_2 is catalysed by nickel or cobalt oxides. It was also established[7] that when water is gradually added to an anhydrous dilute solution of O_2^{2-} ions, the height of the wave corresponding to the oxidation of these ions decreases, until it disappears completely. At the same time, O_2^- ions appear, and their reduction is reflected on the polarisation curves. This phenomenon is attributed[7] to the reaction taking place in the melt

$$3O_2^{2-} + 2H_2O \rightarrow 2O_2^- + 4OH^-$$

which corresponds to the dismutation equilibrium:

$$3O_2^{2-} \rightleftarrows 2O_2^- + 2O^{2-}. \qquad (17)$$

Like peroxide, superoxide may undergo dismutation, as follows:

$$4O_2^- \rightleftarrows 3O_2 + 2O^{2-}.$$

In the absence of water (strong O^{2-} acceptor), this reaction, like reaction (17), goes from right to left. It may be assumed that in the presence of H_2O, reaction (3) proceeds to the right, but the removal of the superoxide ion is difficult to achieve in practice. Prolonged bubbling of nitrogen leads to the gradual disappearance of superoxide (and also peroxide) as a result of dismutation, brought about by the removal of gaseous oxygen from the system. From an examination of the reactions of anionic oxidation in alkali melts, it was concluded[7] that the electrochemical oxidation of OH^- ions is probably accompanied by the formation of superoxide O_2^- by the reaction

$$4OH^- - 3e \rightarrow O_2^- + 2H_2O.$$

When a high current density is reached, however, the very high concentration of O_2^- ions and water may bring about partial dismutation of superoxide at the electrode according to Eqn.(3), and this is responsible for the familiar phenomenon of oxygen liberation in the electrolysis of molten NaOH. On the other hand, water does not react with superoxide, but facilitates its reduction.

These characteristic features of the course of reactions involving oxygen-containing species and the ranges of their existence can be represented graphically in the form of a E–pH_2O diagram (Fig.3): the method for constructing this diagram has been described in detail[7]. This diagram is similar to that for aqueous solutions on coordinates E–pH, which characterises the familiar redox equilibrium of water. The redox systems of oxygen differ (Fig.3), depending on whether water is present or absent, that is their ranges of existence are functions of pH_2O.

The above examination dealt chiefly with processes of oxidation at the anode. To obtain a complete picture of the electrochemical behaviour of molten alkalis, it is necessary to have information on the reactions of cathodic reduction. As already noted, the cathode products may be hydrogen, sodium, and sodium hydride. First of all, the values of the standard potentials of these electrode processes are of interest. Taking, as is usually done, as standard state the state of the electrochemical system in which all its components are in the state of pure substances, Doisneau and Tremillon[15] used thermochemical data to calculate E^* for the corresponding electrode reactions. These results, obtained with the condition $E^*_{M/M^+} = 0$, are given in Table 3.

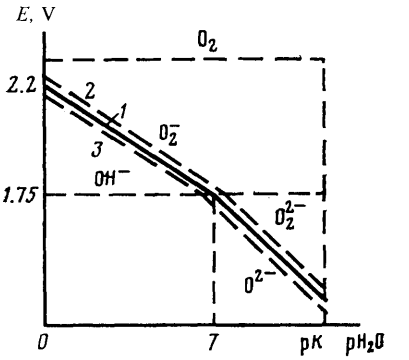

Figure 3. E–pH_2O diagram for oxygen redox systems at 227 °C; concentration of O_2^{2-} and O_2^- ions equal to: 10^{-2} M (*1*), 10^{-1} M (*2*), and 10^{-3} M (*3*).

The calculations were carried out with the assumption that the reactions taking place in the cell are

$$H_2O+M\rightarrow 1/2H_2+MOH,$$
$$H_2O+2M\rightarrow MH+MOH,$$

for which the standard e.m.f.'s are

$$E^*_{H_2}=\frac{\Delta G^*}{F}=\frac{1}{F}\left(\mu^*_{H_2O}-\frac{1}{2}\mu^*_{H_2}-\mu^*_{MOH}+\mu^*_M\right),$$
$$E^*_{MH}=\frac{\Delta G^*}{2F}=\frac{1}{2F}(\mu^*_{H_2O}-\mu^*_{MH}-\mu^*_{MOH}+2\mu^*_M).$$

Similar methods were used to calculate the standard potentials of the oxidation reactions accompanied by the formation of oxygen, peroxide, and superoxide:

$$4MOH\rightleftarrows O_2+2H_2O+4M\ ,$$
$$4MOH\rightleftarrows MO_2+2H_2O+3M\ ,$$
$$4MOH\rightleftarrows M_2O_2+2H_2O+2M\ .$$

The data obtained are given in Table 3.

It can be seen that the electrode potentials of the reactions (relative to the M/M^+ reference electrode) depend on the acidity of the melt, as follows

$$E_{H_2}=E^*_{H_2}+\frac{2.3RT}{F}\lg p_{H_2O}-\frac{2.3RT}{2F}\lg p_{H_2},$$
$$E_{MH}=E^*_{MH}+\frac{2.3RT}{2F}\lg p_{H_2O}-\frac{2.3RT}{2F}a_{MH},$$
$$E_{O_2}=E^*_{O_2}+\frac{2.3RT}{4F}\lg p_{O_2}+\frac{2.3RT}{2F}\lg p_{H_2O},$$
$$E_{MO_2}=E^*_{MO_2}+\frac{2.3RT}{3F}\lg a_{MO_2}+\frac{2\cdot 2.3RT}{3F}\lg p_{H_2O},$$
$$E_{M_2O_2}=E^*_{M_2O_2}+\frac{2.3RT}{2F}\lg a_{M_2O_2}+\frac{2.3RT}{F}\lg p_{H_2O}.$$

The electrode reactions are described by the equations:

$$H_2O+e\rightarrow 1/2H_2+OH^-\ ,$$
$$H_2O+M^++2e\rightarrow MH+OH^-\ ,$$
$$4MOH\rightarrow O_2+2H_2O+4M^++4e\ ,$$
$$4MOH\rightarrow MO_2+2H_2O+3M^++3e\ ,$$
$$4MOH\rightarrow M_2O_2+2H_2O+2M^++2e\ . \qquad (18)$$

The potentials of the cathode processes make it possible to characterise the conditions, for example the acidity of the medium, under which H_2, MH, and M are formed. An equilibrium is usually established between these products and MOH, but one of them predominates. Reduction leads to the formation of H_2 in an acidic medium, MH in a neutral medium, and M in a basic medium. Three cases can be distinguished, depending on the nature of the alkalis[15]. In LiOH, the acid–base dissociation, characterised by the quantity pK*, is not extensive, so that the reduction product is hydrogen, irrespective of the acidity. The second case corresponds to hydroxide having a high value of pK* (KOH, RbOH, CsOH). Since there are no data for Rb and Cs hydrides, it has been possible to carry out the calculations only for KOH. In this case, hydrogen is liberated in an acidic medium, and ptoassium in a basic medium. There is practically no range of acidity in which the solid hydride can exist. The third case corresponds to NaOH: close to the melting point, NaOH is reduced to hydrogen in an acidic medium and to the hydride in a basic medium, and at a higher temperature, the behaviour of NaOH is identical to that observed for KOH at the melting point. The conclusions reached agree with experimental data on reaction in the M–MOH system[33–43].

As in the case of the reduction reactions, different oxidation reactions are realised by creating a definite acidity of the medium: the coefficients of $\lg p_{H_2O}$ are also different. Oxidation takes place to oxygen in strongly acidic media, and to peroxide in the most basic media; in the intermediate acidity range, hydroxide is oxidised to superoxide. As far as the nature of the hydroxides themselves are concerned, examination of the oxidation reactions makes it possible to distinguish three cases. The first category corresponds to hydroxides having a low degree of dissociation (high value of pK*)—KOH, RbOH, and CsOH. In a neutral medium, the formation of superoxide takes place in an acidity range whose extent increases with the size of the cation of the solvent (Cs > Rb > K). Here, the CsOH represents an exceptional case, since it is oxidised to CsO_2 throughout the entire range of acidity at 350 °C, whereas KOH and RbOH are oxidised to O_2 in a strongly acidic medium and to peroxide in a strongly basic medium; LiOH is oxidised only to oxygen, irrespective of the acidity. As before, NaOH represents an intermediate case: there is no acidity range in which oxidation to superoxide could take place; oxidation leads to the liberation of oxygen in an acidic medium, and to peroxide formation in a basic medium. Thus oxygen acts on all molten hydroxides in a basic medium, with the exception of LiOH.

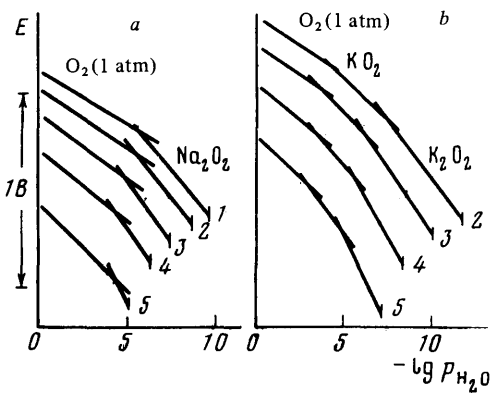

Figure 4. Isotherms giving the dependence of the equilibrium potentials in NaOH (*a*) and KOH (*b*) melts on the acidity of the medium in the presence of a strong oxidising agent at identical activities; *1*) 350, *2*) 400, *3*) 477, *4*) 577, *5*) 727 °C.

Fig. 4 shows the influence of the acidity of the medium on the electrode potential at different temperatures and equal activities (unity) of the oxidising agent. The results given for molten NaOH and KOH reveal the thermal instability of peroxides and superoxides, the range of formation of which decreases with increase in temperature. These data show good agreement with the results of thermochemical calculations[24] for the reactions involved in the oxidation of NaOH and KOH at 350 °C.

To some extent, the regular features described above can be represented by plotting the potential against the acidity of the medium, as shown in Fig.5. The difference in potentials between the upper and lower lines represents the "electro-activity region", that is the range of potentials lying between reduction and oxidation of the medium. In this case, for activities of the oxidising agent and reducing agent equal to unity, the extent and form of the "electro-activity range" (Fig.5) depends on temperature and, to a large extent, the nature of the cation. These ranges have been determined theoretically and confirmed experimentally[15]. At the same time it should be noted that the difference in the potentials $E^*_{O_2} - E^*_{H_2}$ is independent of the cation of the solvent, and is equal to the e.m.f. of the cell $Pt(H_2)\,|H_2O\,||\,H_2O\,|(O_2)Pt$. The current-producing process in the latter is reaction (14), which does not depend to a significant extent on the nature of the hydroxide. The potentials of the cathode and anode in this case are given by the following equations:

$$E_{H_2} = E^*_{H_2} - \frac{2,3RT}{2F}\lg p_{H_2} + \frac{2,3RT}{F}\lg p_{H_2O} - \frac{2,3RT}{F}\lg a_{NaOH},$$

$$E_{O_2} = E^*_{O_2} + \frac{2,3RT}{4F}\lg p_{H_2O} - \frac{2,3RT}{F}\lg a_{NaOH}.$$

Here, $E^*_{H_2}$ and $E^*_{O_2}$ are calculated from the data for the hypothetical cell in which the activities (partial pressures) of O_2, H_2, H_2O, and NaOH are equal to unity.

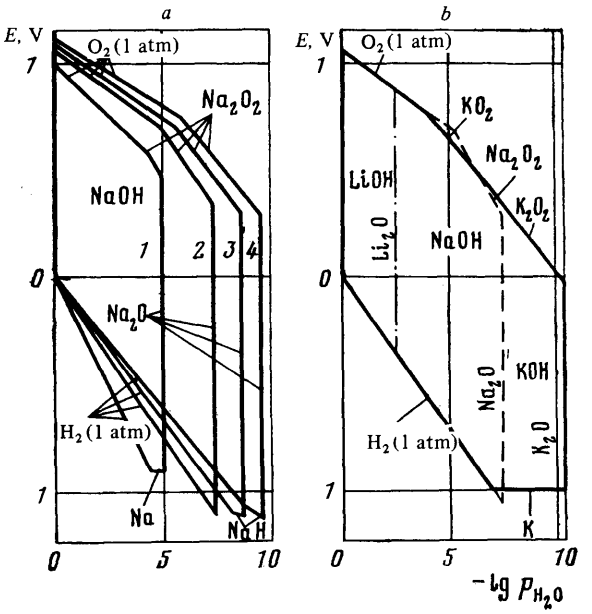

Figure 5. Dependence of the electro-activity ranges on the acidity of the medium; *a*) molten NaOH at different temperatures: *1*) 723, *2*) 477, *3*) 400, *4*) 350 °C; *b*) molten LiOH, NaOH, KOH at 477 °C.

As far as the stability of the products of the anodic oxidation are concerned, the following regular features may be noted[15]. In the solid state, the stability of peroxides increases with decrease in the radius of the alkali metal cation in the order $Cs_2O_2 < Rb_2O_2 < K_2O_2 < Na_2O_2 < Li_2O_2$, whereas the stability of the superoxides changes in the opposite order. In a molten alkali, a large radius for the cation facilitates the formation of superoxide and does not lead to the formation of peroxide.

The experimental study of the electrochemical behaviour of the ions O_2^{2-} and O_2^- in alkali melts was described above. It is of no less interest to examine the regular features of the liberation and consumption of the "visible" products of the electrode reactions, for example gaseous hydrogen and oxygen, and the alkali metals. This information is also important for the technical electrolysis of molten hydroxides.

The part played by the study of the electrolytic reduction of hydrogen ions from aqueous solutions is well known. A large number of studies have been devoted to this question. This problem is also of interest for the electrochemistry of ionic melts, since according to experimental data, hydrogen ions may be present in salt mixtures and molten slags at high temperatures. Water is also present in alkali melts, and in these electrolytes it is a product of an anode reaction[44-51]. Moreover, as noted above, the solution of H_2O in NaOH obeys Henry's law. In this connection, the processes involved in the discharge and ionisation of hydrogen in molten alkalis will be examined first.

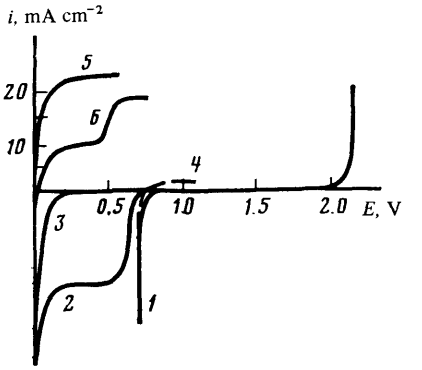

Figure 6. Polarisation curves obtained at a polished platinum electrode in an NaOH–KOH melt at 200 °C: *1* and *2*) reduction of H_2O from concentrated and dilute solutions respectively; *3*) decomposition of an anhydrous NaOH–KOH melt; *4*) oxidation of hydrogen, H_2O atmosphere; *5*) oxidation of sodium dissolved in an anhydrous melt; *6*) oxidation of sodium dissolved in an acidic melt.

The cathodic reduction of hydrogen ions in an NaOH–KOH eutectic melt at 220 °C was studied by Goret[5]. At a platinum electrode, when a potentiostatic method is used, the electroactivity range (decomposition voltage) of H_2O is 1.45 V. Reaction (18) takes place at the cathode.

In an NaOH–KOH melt not subjected to dehydration, and containing a high concentration of H_2O, the limiting current for the recduction of hydrogen is not observed (Fig.6). After drying (450 °C in a stream of dry nitrogen), a limiting current is observed on the *I–V* curve. The height of the corresponding wave (Fig.6) is proportional to the concentration of water in the melt. This wave is not observed in an anhydrous medium (curve *3* in Fig.6).

The oxidation of hydrogen in NaOH–KOH [5,52] and KOH (70–90 mass %)–H_2O (10–30 mass %) [52] melts has also been studied. A hydrated melt was used[5], and an atmosphere of hydrogen established ($p_{H_2} = 1$ atm). Since the solubility of hydrogen is low, the oxidation wave (curve *4* in Fig.6) shows a small limiting current. Its magnitude increases when a platinised platinum electrode is used[5].

Vasilistov and coworkers[52] used a palladium anode of the membrance type. With increase in temperature and the hydrogen pressure (from 0.2 atm to 1.5 atm), the activity of the process of H_2 ionisation increases sharply even in the initial polarisation range, and reaches 160 mA cm^{-2} at $E = 0.3$ V and $p_{H_2} = 1.5$ atm. In a hydrated KOH melt, this process takes place more effectively with increase in the H_2O concentration from 70% to 90%. At the same time, the exchange current increases from 1×10^{-4} A cm^{-2} to 5×10^{-4} A cm^{-2}. In the opinion of the authors cited[52], the anode reaction being considered takes place more intensively only through the formation and subsequent decomposition of a chemosorbed hydrate complex, which functions as an intermediate compound. According to their data[52], the anode current for the oxidation of hydrogen is controlled by its diffusion in metallic palladium. The activation energy of the last process is 3.5 kcal $mole^{-1}$.

According to Goret's results[5], reaction (18) is fast and reversible. The wave for the reduction of hydrogen is described by the equation

$$E = \text{const} + 0.050 \lg[(i - i_d)^2/i],$$

where i_d is the limiting current for the reduction of H_2O. The prelogarithmic coefficient calculated from the experimental data is close to 0.047.

It has also been shown[53,54] that reaction (18) at Pd [53] and Au [54] cathodes in an NaOH–KOH melt is a fast electrode reaction at 200–400 °C, and is described by the equation for diffusion kinetics. The height of the limiting current of the wave is proportional to the H_2O concentration, which decreases with time.

Since the concentration of water in the melt is proportional to the partial pressure of its vapour in the atmosphere, it is to be expected that increase in p_{H_2O} will lead to an increase in i_{d,H_2O}. This has been confirmed experimentally[6] by a potentiokinetic method at a platinum cathode at 500 °C using NaOH as background. The maxima formed, or more accurately the decrease in the current after the maxima, are attributed[6] to a decrease in the concentration of water in the catholyte. The current begins to increase at a potential of 1.3 ± 0.1 V, and, in the opinion of the authors cited, is due to reaction (18). The latter has been studied[55] by a chronopotentiometric method in an equimolar KOH–NaOH mixture at 460–530 K. An interesting feature is that the concentration of H_2O in the melt[55] was varied by adding SiO_2 to the cell. The silicon dioxide reacted quantitatively according to the scheme[56,57]:

$$SiO_2 + 4OH^- \rightarrow SiO_4^{4-} + 2H_2O \cdot$$

The chronopotentiometric curves for the reduction of hydrogen ions are described by the equation

$$E = E^0 + \frac{RT}{2F} \ln [H_2O] \left(\frac{D_{H_2}}{D_{H_2O}}\right)^{1/6} + \frac{RT}{2F} \ln \left\{2\left[1 - \left(\frac{t}{\tau}\right)^{1/2}\right]^2 / \left(\frac{t}{\tau}\right)^{1/2}\right\}.$$

Here, D_{H_2} and D_{H_2O} are the diffusion coefficients of hydrogen and water, t the time at a given point, and τ the transition time; the other symbols are generally adopted in electrochemistry.

According to the experimental data[55], the temperature dependence of the diffusion coefficient of water in the hydroxide melt is approximated by the relationship:

$$\lg D_{H_2O} = (1.143 \pm 0.18) - (2717 \pm 8.8)/T.$$

The activation energy of this process is 12.4 ± 0.4 kcal $mole^{-1}$. As noted above, polarography (volt–amperometry) can be used to determine the concentration of water in a hydroxide melt. It has been pointed out[55] that chronopotentiometry can also be used successfully for this purpose, although in the electrolyte the concentration of H_2O changes from 1 mmole kg^{-1} to 30 mmole kg^{-1}.

Most authors[3,45,58–60] consider that the subsequent increase in the cathodic current after the attainment of i_{d,H_2O} is due to the liberation of the alkali metal. This process, and also the reverse reaction, that is the ionisation of Na, have been studied[5,6]. At 220 °C in an NaOH–KOH melt, the Na^+ ion is reduced at a potential which is 0.65 V more negative than in the case of H_2O. [5] By dissolving metallic sodium in the anydrous NaOH–KOH eutectic, it was possible[5] to carry out the reaction

$$Na - e \rightarrow Na^+ .$$

The polarisation curve *5* (Fig.6) was obtained, and it was shown that this reaction, like the reverse reaction, is rapid. The result obtained makes it possible to recomment the Na/Na^+ electrode as a reference electrode in hydroxide melts. In this connection, somewhat unexpected results were obtained in a potentiokinetic study (rate of scanning 10 mV min^{-1}) [61] of the ionisation of sodium in an NaOH–KOH melt in the range 215–315 °C, where it was shown that the transfer coefficient $\beta = 0.35 \pm 0.05$, and the activation energy of this process is 6.8 ± 0.4 kcal $mole^{-1}$; the overvoltage reaches 300 mV at a current density of ~1 A cm^{-2}.

If H_2O is added to a solution of sodium in the anhydrous eutectic NaOH–KOH, the height of the wave for the oxidation of the alkali metal decreases (curve *6* in Fig.6). At the same time, a second oxidation wave is observed, the position of which is 0.5 V more electropositive than the sodium oxidation wave. Since this wave was also observed when sodium was added to the anhydrous melt in an atmosphere of hydrogen, Goret[5] tentatively attributed it to an electrode reaction involving the oxidation of the hydride:

$$2NaH - 2e \rightarrow 2Na^+ + H_2 .$$

This reaction should be slow, since the corresponding waves for the reduction of H_2O and H_2 to H^- are not observed.

Finally, published data on the characteristics of an anode reaction of the type

$$4OH^- - 4e \rightarrow 2H_2O + O_2 \qquad (19)$$

can be considered. As early as the start of the present century, LeBlanc[62], Sacher[63], and other workers, studying this reaction from the $I-V$ polarisation curves, reported that the liberation of oxygen is irreversible. Quantitative information on the discharge of OH^- ions was first obtained in a study[64] of the anodic polarisation of platinum and nickel electrodes in NaOH at 318–340 °C by automatic recording of the polarisation curves from very low current densities to 1 A cm^{-2}. It was established that reaction (19) takes place with overvoltage, which reached 0.2 V at the maximum current density used. Except for the data obtained at low current densities, the experimental results are described by the equation

$$\eta = b \lg(I/A),$$

where $A = 4–9$ mA cm^{-2}, $b = 0.121$ V.

In the liberation of oxygen into the atmosphere from alkali metal chloride melts at a zirconium anode[65] at 850–900 °C the data correspond to the semilogarithmic relationship

$$\Delta E = a + b \lg i, \qquad (20)$$

the coefficients of which are given below:

Melt		t, °C	a	b
NaCl — LiOH	(10 mole %)	850	1.348	0.785
NaCl — NaOH	(10 mole %)	850	1.117	0.655
NaCl — NaOH	(10 mole %)	900	0.925	0.310
KCl — KOH	(10 mole %)	850	1.456	0.560

Eqn.(20) indicates that the electrochemical process is irreversible. The data given were obtained on a "conditioned" (oxidised and passivated) anode. The $I-V$ curve was unstable at the start of the experiment, and became stable after several hours[65]. When "fresh" electrodes were used, the anodic polarisation curve[5,6,50,66] showed limiting currents due to the oxidation of the metals (Ni, Pt, Au) and the formation of sparingly soluble oxides on their surface. Lower oxides are formed first, followed by higher oxides. The oxides conduct electricity, and this is responsible for the subsequent increase in the current with increase in the potential. In this case, free oxygen is liberated. According to the results[5], the ability to undergo anodic oxidation, accompanied by solution of the metal in the electrolyte, decreases in the order Ag > Ni > Pt > Au.

The reaction of interest include not only the oxidation of the oxygen ions but also the reverse process, that is the electrolytic recduction of O_2 in alkali melts. The densities of the limiting current for the reduction of oxygen (mA cm^{-2}) at a smooth nickel electrode in alkali melts at 427 °C[67] are given below:

Melt	NaOH	KOH — NaOH (eutectic)	KOH	5 N KOH solution (25 °C)
$p_{O_2} = 0.2$ atm	0.66	13.3	69	—
$p_{O_2} = 1$ atm	1.08	18.6	110	0.02

These results show that the limiting currents for the reduction of oxygen in alkali melts[67] are appreciably greater than those in aqueous solutions. At the same time, i_d in KOH is two orders of magnitude greater than in NaOH, and in molten KOH–NaOH mixtures the limiting current increases with increase in the concentration of KOH in the electrolyte[22]. The value of i_d increases with increase in the concentration of water and in the temperature, and for a melt containing 78.6 mole % of KOH and 21.5 mole % NaOH the experimental data are described by the relationship

$$i_d = A \exp(-U/RT),$$

where U is the activation energy of the reduction, equal to 4.8 kcal mole^{-1}. This value is close to the activation energy for viscous flow of the melt.

From these data, it was concluded[68] that the rate of the reduction of oxygen in hydroxide melts is determined chiefly by the rate of diffusion of the reagents, and the measured limiting current is a diffusion current.

These regular features were attributed[67,69] to the formation in the electrolyte of higher oxygen compounds (Na_2O_2, KO_2), which act as carriers of oxygen from the oxygen–melt interface to the electrode surface. The general equations for the cathode processes associated with the electrolytic reduction of oxygen can be written[67,70] as follows:

$$O_2^{2-} + 2H_2O + 2e \rightarrow 4OH^-, \; E(\text{KOH}, 200\,^\circ\text{C}) = 1.45B, \qquad (21)$$

$$O_2^- + 2H_2O + 3e \rightarrow 4OH^-, \; E(\text{KOH}, 200\,^\circ\text{C}) = 1.27B. \qquad (22)$$

The limiting current for the cathodic reduction is determined chiefly by the rate of diffusion of the ions O_2^{2-} and O_2^-. Additional proof of this is provided by the observed[27,67] linear relationship between the density of the limiting current for the reduction of oxygen and the concentration of higher oxygen compounds in the hydroxide melt. The polarisation curves recorded at 200 °C at a platinum disc electrode in a KOH–H_2O (10%) melt containing KO_2 depolariser were used to calculate the valency of reaction (22), which was found to be equal to 3, and $D_{KO_2} = 8.25 \times 10^{-6}$ cm^2 s^{-1}.[24]

It follows from Eqns.(21) and (22) that for the reduction of oxygen to take place intensively, it is necessary to ensure a high rate of supply of H_2O to the electrode surface. It was established experimentally that for each specific set of conditions there is a minimum concentration of water below which the rate of the overall process is limited by its diffusion. The corresponding concentrations are marked by maxima on the $i_d = f(c_{H_2O})$ curves. The maxima divide the range of values into two sections; in one, the rate of reduction of oxygen is limited by the diffusion of peroxides and superoxides, and in the other by the diffusion of water.

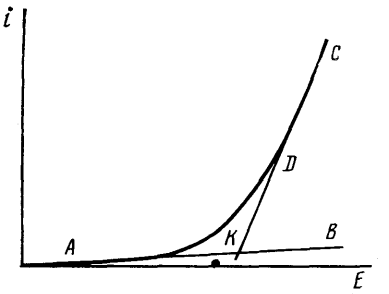

Figure 7. Determination of the decomposition voltage of an electrolyte.

In conclusion, the results of the measurement of the decomposition voltage of molten alkalis will be considered. It should first of all be noted that the concept of "decomposition voltage" has no strict scientific definition; for this reason, evidently, it is not encountered in handbooks and monographs of theoretical electrochemistry[71–73]. In textbooks on the electrochemistry of molten salts[2,3,74], the decomposition voltage is identified directly or indirectly with the e.m.f. of a reversible chemical cell, the magnitude of which can be calculated from thermodynamic data (this last assumption is rejected by Levin[75]), The concept of "decomposition voltage" has also been defined using such indefinite expressions as "visible products appear", "the e.m.f. reaches a certain definite value"[76], "minimum voltage", "for prolonged electrolysis to take place"[3].

The decomposition voltage E_d is usually determined from a graph (Fig.7) obtained by plotting current against voltage, at the point of intersection of the straight line CD with the abscissa. It should be noted that the concept of anodic decomposition voltage is encountered[77], but LeBlanc[62] does not consider it possible to record the residual current on the polarisation curve. In addition, completely different values of E_d for NaOH are obtained[62,78], depending on whether a micro-cathode or a micro-anode is used. Without going into a detailed analysis of this complex question here, it will probably be most correct to return to the source, that

is to the definition of decomposition voltage given by LeBlanc, who introduced this concept.

It is first of all necessary to take account of the fact that, in accordance with LeBlanc's theory, until the applied voltage becomes equal to or greater than the value E_d, no electrode processes are possible, and no current should pass through the cell[2]. It is obvious that this quantity E_d as a rule cannot be calculated from thermodynamic data; it depends on the nature and concentration of the electrolyte, the electrode materials, depolarisation and polarisation effects, and temperature. The experimentally determined value of E_d characterises a given specific electrolyte under fixed electrolysis conditions. In this connection, the section of the residual current A (Fig.7) distorts the determination of the decomposition voltage, which is apparently best obtained at the point K of intersection of the tangents AB and CD to the sections of the curves for the residual current and the electrolyte decomposition current.

It is generally accepted[3,45,78,85] that on the application of a direct current voltage (2.1–2.3 V) to indifferent electrodes immersed in a hydroxide melt, alkali metal is liberated at the cathode ($M^+ + e \rightarrow M$), and oxygen and water are liberated at the anode. In the case of a hydrated electrolyte, hydrogen is liberated at the cathode at a voltage of 1.1–1.3 V. The experimentally measured decomposition voltages of NaOH are given in Table 4. The decomposition voltage of molten potassium hydroxide at 390 °C is 2.1 V according to Ref.69, and 2.15 V according to Ref.79. In the latter case[79], an attempt was made to determine the decomposition voltage of molten LiOH. The value obtained at 460 °C was 1.3 V, which is clearly too low. Liberation of metal at the cathode was not observed.

Table 4. Measured values of the decomposition voltage of sodium hydroxide.

Method	Cathode	Anode	t, °C	E_d, V		Refs.
				I	II	
According to LeBlanc	Ni	Ni	350	1.3	2.2	62

Potentiodynamic (KOH - NaOH melt)	Pt	Pt	200	1.45	2.10	5
Back e.m.f. in the electrolysis vessel	Cu	Ni	325	1.35	2.25	45
Back e.m.f. in the electrolysis vessel	Cu	Ni	300	—	2.3	45
According to LeBlanc	Ni	Ni	340	—	2.2	79
Polarisation curves	—	—	450	—	2.1	85

The temperature coefficient of the decomposition voltage of NaOH is 2.95×10^{-3} V K^{-1} according to Ref.79, and 1.3×10^{-3} V K^{-1} according to Ref.31. The temperature coefficient of the decomposition voltage of KOH is 2.15×10^{-3} V K^{-1}.[79]

A number of authors report that other electrode processes take place at the cathode and the anode. Thus an inflection was recorded on the $I-V$ curve at 1.87–2.00 V,[80] and its appearance was attributed to the reduction of the oxides Na_2O and Na_2O_2. In the opinion of the authors cited[80], these oxides are formed in well dried NaOH. As early as 1902, LeBlanc[62] noted the presence of an additional inflection on the polarisation curve for dried sodium hydroxide. Two inflections were also observed[81] on the $I-V$ for NaOH, at 1.73–2.04 V and 2.12–2.2 V, in the range 460–338 °C, but the first inflection was attributed[81] to the formation of sodium hydride at the cathode:

$$NaOH + e \rightarrow NaH + O^{2-} \qquad (23)$$

and to the following reaction at the anode:

$$O^{2-} - 2e \rightarrow 1/2O_2.$$

The second inflection was attributed to the overall reaction:

$$2NaOH + 2e \rightarrow 2Na + H_2O + 1/2O_2 . \qquad (24)$$

It was shown experimentally[81] that at current densities which are lower than those at which the liberation of sodium takes place but which ensure that the first reaction takes place, NaH is obtained with a current efficiency of up to 91%. This viewpoint[81] may be confirmed by the experimental fact that the first inflection on the $I-V$ disappears at 515 °C, since NaH does not exist under these conditions. Other workers[80] also did not observe the first inflection on the polarisation curve at 543 °C, and this was attributed[81] to the same factors.

Table 5. Comparison of the experimental values of the decomposition voltage and the values calculated for reactions (23) and (24) at different temperatures and the current density (i_c) at which liberation of sodium begins at these temperatures.

t, °C	E_1, V (first inflection)		E_2, V (second inflection)		i_c, A cm^{-2}
	experiment	calculation	experiment	calculation	
338	2.04	1.68	2.28	2.34	0.11
368	1.93	1.66	2.35	2.28	0.40
401	1.86	1.64	2.21	2.24	0.51
440	1.78	1.62	2.15	2.18	0.60
460	1.73	1.61	2.12	2.14	0.65
515	—	—	2.04	2.06	0.04

The experimental values of E for the formation of NaH (Table 5) are slightly higher than the values calculated by the same authors[81] from thermochemical data; this is due to the low activity of NaH in the melt in the experiment. The low values of E_d for NaOH are due to depolarisation phenomena resulting from the absence of separation between the electrode compartments and the fact that two parallel cathode processes are taking place at similar potentials.

An even more unusual conclusion was reached by Krueger[6], from whose results it would be expected that in pure NaOH at 500 °C the reaction taking place at the cathode would be

$$2OH^- + 2e \rightarrow 2O^{2-} + H_2,$$

and not the process

$$Na^+ + e \rightarrow Na;$$

that is sodium oxide and hydrogen, and not sodium, would be obtained as cathode products. According to Krueger's calculations[6], the decomposition voltage of NaOH in this case at 500 °C by the reaction

$$2NaOH = {}^1/_2O_2 + {}^1/_2H_2O + {}^1/_2H_2 + Na_2O$$

would be 2.1 V, which is close to that observed experimentally. No proof of the anodic formation of peroxide was obtained by Krueger[6].

At the same time, as early as 1895, Janeczek[82] suggested that the discharge of OH^- anions takes place with the formation of peroxide, and that the liberation of oxygen is brought about by a secondary reaction involving the decomposition of H_2O_2. This opinion was also held by Carrier[83]. Much later, Tremillon and coworkers[7,10] concluded that the OH^- ion is oxidised to superoxide O_2^-. When appreciable concentrations of this anion are reached (this is facilitated by high current densities), the dismutation process (3) takes place, accompanied by the liberation of oxygen into the atmosphere (as is usually the case in the electrolysis).

Thus in spite of the relatively large number of studies of the decomposition voltage of molten alkalis, this question requires further detailed study. It is necessary to obtain reliable experimental proof that the liberation of oxygen is a secondary reaction which is preceded by the electrochemical production of peroxide or superoxide. It is necessary to obtain unambiguous indications of additional inflections on the cathodic polarisation curves, and reliable experimental data on the decomposition voltage of pure molten potassium and lithium hydroxides.

Nucleophilic Substitution Reactions of Cyclopropane Derivatives

V.S.Aksenov, G.A.Terent'eva, and Yu.V.Savinykh

The review is devoted to the solvolysis of cyclopropane compounds. The influence of structural and external factors on the rate and direction of the reaction are considered.
The bibliography includes 63 references.

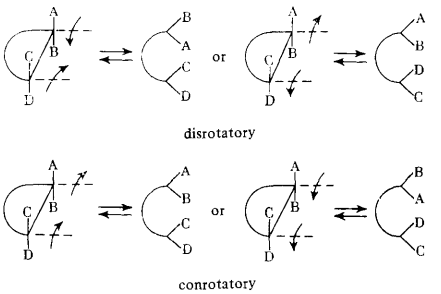
I. INTRODUCTION

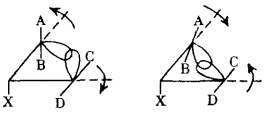
Owing to advances in the chemistry of carbenes, particularly the development of new methods for the generation of carbenes, many cyclopropane derivatives have become available, which stimulated the study of their further reactions. The increased interest in these compounds is due to the fact that, by virtue of the unusual nature of the bonds in the strained three-membered ring, they possess a whole series of properties which distinguish them sharply from other carbocylic compounds. The solvolysis of cyclopropane derivatives is particularly characteristic in this respect—in this reaction treatment with a nucleophile as a rule entails the cyclopropyl–allyl rearrangement and not substitution.



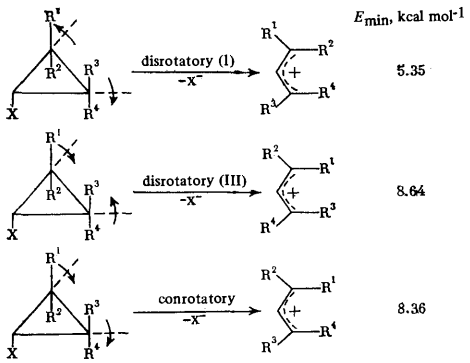
The aim of the present review is to specify the general and specific features of the solvolysis of cyclopropane derivatives.

II. THE MECHANISM OF THE SOLVOLYSIS OF CYCLOPROPANE DERIVATIVES

The specific feature of the behaviour of cyclopropane compounds in nucleophilic substitution consists in the fact that the reaction results in the formation of allyl derivatives and not substitution products. At the early stages in the relevant investigations a two-stage mechanism of the nucleophilic substitution reaction involving cyclopropane derivatives was proposed[1]: slow ionisation with formation of the cyclopropyl cation and subsequent rapid opening of the ring of the latter to give the allyl cation:

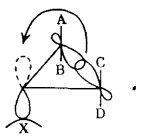


The error of this approach was demonstrated in numerous later studies. Kinetic[2,3] and quantum-chemical[4] investigations showed that the solvolysis of cyclopropane derivatives is a synchronous process involving the abstraction of an anion and the opening of the cyclopropane ring. According to the classification of Woodward and Hoffmann[5], the cyclopropyl–allyl rearrangement (opening of the three-membered ring to give the allyl cation) is an electrocyclic reaction. The authors define electrocyclic reactions as processes involving the formation of a single bond between the ends of the linear system containing k π-electrons (or the reverse process). The conversion of the cyclic form into an acyclic form and conversely can be disrotatory or conrotatory:



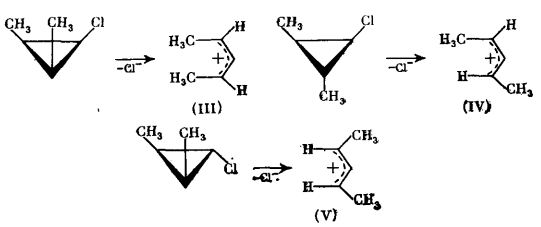
According to orbital symmetry conservation rules[5,6], thermal electrocyclic reactions are disrotatory for $k = 4n + 2$ and conrotatory for $k = 4n$. The cyclopropyl-allyl rearrangement constitutes a 2π-electrocyclic ring opening ($n = 0$). The disrotatory opening of the three-membered ring has been confirmed by quantum-chemical calculations using the MO-LCAO SCF method[7]. It has been shown[8] that the ring opening and the rotation of the methylene groups take place simultaneously; the central angle in the ring then increases from 60° to 120° and the σ-orbitals of the terminal groups are gradually converted into p-orbitals. Among all the possible structures of the $C_3H_5^+$ cation, the planar allyl cation is the most stable[4]. The energy of the cyclopropyl cation is greater by 39 kcal mol^{-1} than the energy of the allyl cation, so that there is no energy barrier to the isomerisation of the former to the latter.

In the disrotatory opening of the three-membered ring, there is a possibility of two stereochemically non-equivalent pathways—external (I) and internal (II):



Calculations based on the principle of minimum movement[9-11] for the synchronous process involving the removal of the anion and the opening of the three-membered ring show that the two disrotatory ring opening pathways [(I) and (II)] are energetically non-equivalent: in pathway (I) there is virtually no energy barrier, while in pathway (II) there is a

considerable barrier.



Here E_{min} is the minimum energy required for the rearrangement of the atoms in the molecular skeleton.

Calculation of the energies of the two pathways in the cyclopropyl–allyl isomerisation by the extended Hückel method[12,13] showed that substituents in the *cis*-position in the leading group rotate towards one another, while trans-substituents rotate away from one another, i.e. the disrotatory pathway (I) is followed regardless of the configuration. This result is a consequence of a secondary orbital effect in the transition state, which is due to the additional interaction of the molecular orbitals. This interaction does not lead to the formation of new bonds but lowers the activation energy for the reaction[14]:

Woodward and Hoffmann[5] note that in practice pathway (I) entails the S_N2 substitution of the leaving group X^- by the electrons of the ruptured C–C bond on the side opposite to that of the direction in which the X^- ion is eliminated.

A direct experimental confirmation of the validity of the disrotatory pathway (I) has been provided by the study of the allyl cations formed from isomeric 2,3-dimethylcyclopropyl chlorides by ^{1}H NMR.[15] The stereochemistry of the allyl cations confirms the stereospecificity of the opening of the three-membered ring. The formation of three individual 1,3-dimethylallyl cations (III), (IV), and (V) from the isomeric 2,3-dimethylcyclopropyl chlorides rules out the existence of the cyclopropyl cation as an intermediate. The disrotatory pathway (I) and the synchronous nature of the ionisation with ring opening have also been confirmed by the kinetics of the acetolysis of the isomeric 2,3-dimethylcyclopropyl chlorides [$k_{trans,trans}(17800) > k_{cis,trans}(210) > k_{cis,cis}$ (1)] [15] and 2,3-dimethylcyclopropyl toluene-*p*-sulphonates [$k_{trans,trans}$ (38000) > $k_{cis,trans}$ (460) > $k_{cis,cis}$ (2.2)].[16]

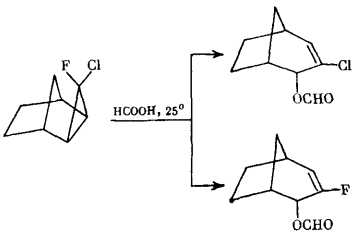
III. THE ROLE OF STRUCTURAL FACTORS IN THE SOLVOLYSIS OF CYCLOPROPYL HALIDES AND CYCLOPROPYL TOSYLATES (TOLUENE-*p*-SULPHONATES)

1. The Relative Positions of the Leaving Group and the Substituent in the Cyclopropane Ring

The fact that one of the two possible pathways in the disrotatory opening of the three-membered ring is preferred leads to different reactivities of the *cis*- and *trans*-substituted cyclopropyl halides and tosylates. According to the data in Table 1, the reactivity of cyclopropane derivatives containing substituents and the leaving group on one side of the ring is appreciably lower than the reactivity of the corresponding compounds in which the substituents and the leaving group are located on opposite sides of the ring. In the case of the *cis*-isomers ring opening is hindered by the steric interactions between the substituents in the cyclopropane ring, while in the opening of the *trans*-isomers weaker steric interactions are observed between two hydrogen atoms.

Table 1. The rates of solvolysis of isomeric 1-chloro-2,3-dipropylcyclopropanes[17] and 1-chloro-2,3-diphenylcyclopropanes[18].

2,3-Disubstituted cyclopropyl halide	Reaction conditions	k, s^{-1}
cis, cis-1-Chloro-2,3-dipropylcyclopropane	C_2H_5OH; 80°	$2.17\cdot10^{-8}$
trans, trans-1-Chloro-2,3-dipropylcyclopropane	ditto	$8.2\cdot10^{-5}$
cis, trans-1-Chloro-2,3-dipropylcyclopropane	»	$1.26\cdot10^{-6}$
cis, cis-1-Chloro-2,3-diphenylcyclopropane	CH_3COONa/CH_3COOH; 95.2°	$3.59\cdot10^{-6}$
trans, trans-1-Chloro-2,3-diphenylcyclopropane	ditto	$1.15\cdot10^{-3}$
cis, trans-1-Chloro-2,3-diphenylcyclopropane	»	$2.46\cdot10^{-4}$



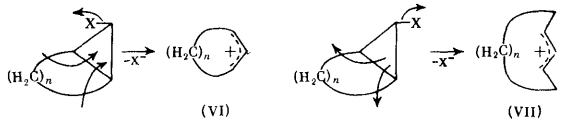
The steric repulsions of substituents in the cyclopropyl–allyl rearrangement can be so significant that *cis*-cyclopropyl halides sometimes virtually do not undergo this reaction. Thus, when a mixture of isomers of 1-chloro-2,3-dimethyl-1-phenylcyclopropane[19] or 2-aryl-1-bromo-1-fluorocyclopropanes[20] is treated with a methanol solution of silver nitrate at moderate temperatures, the *cis*-isomers remain unaltered. Under the same conditions, the *trans*-isomers undergo the cyclopropyl–allyl rearrangement. The study of the behaviour of the isomeric 2-phenylcyclopropyl halides[18,21] and cyclopropyl tosylates[12] in solvolysis showed that the *trans*-isomers react faster than the *cis*-isomers. A similar ratio of the rates has been observed also for trisubstituted cyclopropane derivatives[22,23].

Thus, in solvolysis the disrotatory ring opening of monocyclic cyclopropane systems leads to a greater ease of the elimination of the halogen in the *trans*-position with respect to the substituents in the ring.

The operation of the disrotatory pathway (I) as the only possible process involving the opening of the ring in cyclopropane derivatives has also been confirmed by the study of the solvolysis of bicyclic cyclopropane systems. The opening of a three-membered ring incorporated in a bicyclic system takes place smoothly when the leaving group is in the *endo*-position. Thus the solvolysis of *endo*-bicyclo[4,1,0]-heptyl chloride is 180 times faster than the solvolysis of the

exo-isomer[24]; *exo*-7-tosylbicyclo[4,1,0]heptane is inert under acetolysis conditions at 100 °C.[12]

The solvolysis of polycyclic asymmetric dihalogenocyclopropanes involves the hydrolytic dissociation of the *endo*-bond also in those cases where the latter is stronger than the *exo*-bond[25]:



However, the elimination of the *endo*-halogen (or tosylate) is difficult in bicyclic systems with large rings. Thus in the series of bicyclo[5,1,0]octane and bicyclo[6,1,0]nonane derivatives the *exo*-isomers are found to be more reactive[26–28].

Table 2. Relative rate constants (k_{rel}) for the acetolysis of *endo*- and *exo*-bicyclo[*n*,1,0]alkyl tosylates[27].

n	0	3	4	5	6
endo	1	2500	62	3.1	3.5
exo	1	0.01	1.7	2500	10 000

Table 2 shows that the ease of the opening of the three-membered ring at the $C_{(1)}$–$C_{(n+2)}$ bond in derivatives of bicyclo[*n*,1,0]alkanes depends on the length of the bridge. The cause of this behaviour has been formulated as follows[27]: for low values of *n*, there is a possibility only of disrotatory movement in which the *cis*-allyl cation (VI) is formed, which favours the abstraction of the *endo*-halogen. With increase of *n* from 3 to 5, the stability of the cyclic *cis*-allyl cation (VI) is reduced and the reactivity of the *endo*-isomers diminishes.

The ionisation of the *exo*-isomers is sterically hindered owing to the considerable strain in the allyl cation (VII) having two *trans*-bonds. This strain is particularly large for low values of *n*; it diminishes with increase of *n*, which leads to an increase of the reactivity of the *exo*-isomers;

Thus the disrotatory opening of the cyclopropane ring incorporated in a bicyclic system takes place with elimination of the *endo*-halogen atom for small values of *n*, in contrast to the solvolysis of monocyclic cyclopropane systems. With increase of *n*, this specific feature disappears.

2. The Influence of the Nature of the Leaving Group

The ease of elimination of halogens in nycleophilic substitution at a saturated carbon atom increases from fluorine to iodine: F < Cl < Br < I.[29] The reactivity of cyclopropyl halides varies in the same series[30]. If the leaving group is a sulphonate anion (for example the tosylate anion), then cyclopropyl derivatives exhibit certain characteristic features. Acyclic alkyl tosylates are solvolysed appreciably faster than the corresponding alkyl bromides[31]. Table 3 shows that the higher reactivity of cyclopropyl tosylates compared with the corresponding halides is manifested clearly only for the *trans*-isomers. In the case of the *cis*-isomers the bromide becomes more reactive in the presence of certain β-substituents.

The greater reactivity of β-phenyl-substituted *cis*-cyclopropyl bromides has been explained[18] by the greater energy of the ground state of the bromides compared with that of the tosylates. Sliwinski et al.[3] share this view in relation to norcarane and 2,3-dimethylcyclopropane derivatives: in these compounds the steric repulsions between the *cis*-β-substituents are the leaving group are much more pronounced in the presence of the bulky bromine atom compared with the oxygen of the tosylate group, since the sulphonate residue is oriented in such a way that it is not involved in steric interaction with the β-substituent.

Table 3. The rate constants for the acetolysis (at 100 °C) of β-substituted cyclopropyl halides[3,21,32] and cyclopropyl tosylates[3,16].

*The values of k_1 at 200 °C are quoted.

Hausser's model[18] suffers from a number of disadvantages. Firstly, despite the high energy of the ground state of the *cis*-β-t-butyl-substituted bromide compared with the corresponding tosylate[3], the latter is more reactive (Table 3). Secondly, according to Sliwinski et al.[3], the steric strain in the ground state varies in parallel with the van der Waals radii of the leaving groups: Br (1.95 Å) >Cl (1.8 Å) >O (1.4 Å); on this basis, it was to be expected that the *cis*-chlorides would be more reactive than the *cis*-tosylates. However, kinetic results (Table 3) indicate a lower reactivity of the chlorides.

The energy of the ground state of *cis*-β-substituted derivatives of cyclopropane is probably not the only factor which determines the relative reactivities in the solvolysis of the halides and tosylates.

The next distinctive feature of β-substituted cyclopropyl halides and tosylates relative to the acyclic derivatives and unsubstituted cyclopropane derivatives is the lower sensitivity of the rate of their solvolysis to the nature of the leaving group (Table 4). In the cyclopropane series the

rates of solvolysis of the halides and tosylates differ comparatively little. One of the attempts to explain this finding was undertaken by Hausser and Uchic[18], who postulated a relation between the capacity of the leaving group for elimination and the degree of opening of the three-membered ring in the transition state. This idea was rejected by Schleyer and coworkers[3], who postulated that the degree of opening of the cyclopropane ring is independent of the nature of the leaving group. The latter workers assume[3] that the weak sensitivity to the nature of the leaving group can be explained by the fact that the same β-substituent accelerates solvolysis in different ways depending on the reactivity of the leaving group (Table 5). Comparison of the relative rate constants for the solvolysis of β-substituted cyclopropane derivatives shows that β-substituents have the greatest accelerating effect on cyclopropyl chlorides and smaller on the tosylates, which abolishes the difference between the rates of reaction of the halides and tosylates.

Table 4. Influence of the leaving group on the rate of solvolysis of acyclic aliphatic derivatives[29,31] and unsubstituted and β-substituted derivatives of cyclopropane[3,18,32,33].

3. The Influence of the Nature of the β-Substituent on the Rate of Solvolysis of Cyclopropane Derivatives

As in reactions involving nucleophilic substitution at a saturated carbon atom, alkyl substituents in the β-position accelerate the solvolysis of cyclopropane derivatives. When alkyl groups are introduced in the *trans*-β-position in the cyclopropane ring, the rate of solvolysis of the halides and tosylates increases (Table 6), the acceleration becoming more pronounced with increase in the length and degree of branching of the alkyl substituent[3,30], which is consistent with the inductive effects of the alkyl groups.

trans-2-Phenyl-1-tosylcyclopropane	108	$3.2 \cdot 10^{-5}$

The accelerating effect of a *trans*-β-substituent is appreciably greater than that of a *cis*-β-substituent, which confirms the synchronous nature and the disrotatory pathway leading to the opening of the cyclopropane ring with rotation of the substituents on the outside in the case of the *trans*-isomers and on the inside for the *cis*-isomers. The steric repulsions arising in the opening of *cis*-β-substituted cyclopropyl halides and tosylates weakens the accelerating effect of the alkyl groups. The introduction of the second and subsequent *trans*-alkyl substituents is accompanied by a weaker acceleration[16].

The reactivity of cyclopropane derivatives increases also after the introduction of a phenyl substituent in the β-position (Table 7).

Under the influence of the inductive effect of the phenyl group, the rate of solvolysis of β-phenylcyclopropane derivatives should fall. The reaction is then accelerated by the +*M* effect of the phenyl group, which results in the stabilisation of the partial positive charge on the β-carbon atom in the transition state.

The change in the rate of solvolysis of cyclopropane derivatives induced by the phenyl group is greater than in the analogous substitution by the methyl group (Table 8), which can be explained by the fact that the phenyl group ensures a more effective delocalisation of the partial positive charge in the transition state. Recent studies have shown[36] that the ability of substituents to stabilise the aryl cation decreases in the sequence phenyl > cyclopropyl ≫ methyl.

The degree of acceleration of the solvolysis of cyclopropane derivatives by β-phenyl and β-methyl groups approaches that for the α- and γ-substituted allyl halides[37], which supports the existence of a proto-allyl transition state in the solvolysis of cyclopropane systems.

The study of the solvolysis of β-arylcyclopropyl derivatives showed that electron-donating substituents in the aromatic ring accelerate and the electron-accepting substituents retard the reaction (Table 9).

The correlation between the reactivity of *trans*-2-arylcyclopropyl tosylates ($\rho = -1.75$) [34] and *trans*-2-aryl-1-bromo-1-fluorocyclopropanes ($\rho = -2.0$),[20] on the one hand, and the σ^+ constants of the substituents, on the other, permitted the conclusion that the opening of the three-membered ring and ionisation take place synchronously and that the partial positive charge in the transition state is localised at the benzyl carbon atom. The value of ρ indicates an electrophilic mechanism of the rate-limiting stage and a nearly ionic transition state:

An appreciable acceleration of solvolysis is attained when an alkoxy-substituent is introduced in the β-position in cyclopropane derivatives[17,38,39] (Table 10) by virtue of the effective stabilisation of the carbonium ion by the electrons of the oxygen in the alkoxy-group.

Table 10. The relative rates of solvolysis of β-substituted dichlorocyclopropanes  (n-C_4H_9OH; Ag^+; 80 °C) [39].

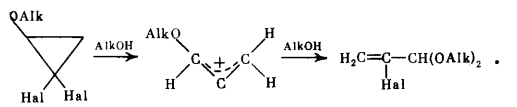
R	C_6H_5	OC_6H_5	C_6H_9	OC_6H_9
k_{rel}	0.2	0.8	1.0	20.0

4. The Influence of the Nature of the α-Substituent on the Rate of Solvolysis of Cyclopropyl Derivatives

The solvolysis of α-substituted cyclopropanes has been studied to a much lesser extent. The available literature data show that the reactivity of α-substituted cyclopropyl bromides[16,34] and cyclopropyl tosylates[32] is appreciably higher than that of the unsubstituted derivatives. Table 11 shows that the α-phenyl group stabilises more effectively the developing positive charge than the α-methyl group. The constant ρ for the series of α-arylcyclopropanes exceeds the reaction constant for the β-derivatives. According to Schleyer and coworkers[3], the high sensitivity of α-arylcyclopropyl tosylates in the solvolysis reaction to the introduction of the substituents into the aromatic ring is due to the fact that the transition state has a structure close to that of the cyclopropyl cation stabilised by the aryl group, although the solvolysis product is 2-arylallyl acetate.

The idea that the α-phenyl substituent can stabilise the cyclopropyl cation has been recently confirmed[40]: the 1-phenylcyclopropyl cation has been "captured" with the aid of the hydroborate anion before it could isomerise to the allyl cation.

Yet another argument has been adduced[34] against the existence of a transition state of the allyl type in the solvolysis reactions of α-arylcyclopropyl tosylates, namely the weak sensitivity of the solvolysis of 2-arylallyl tosylates to the introduction of substituents into the aromatic ring ($\rho = -0.4$).



IV. THE INFLUENCE OF EXTERNAL FACTORS ON THE RATE AND DIRECTION OF SOLVOLYSIS OF CYCLOPROPANE DERIVATIVES

As shown in Section II, the solvolysis of cyclopropyl halides and tosylates leads to the formation of allyl derivatives. The charge distribution in the substituted allyl cation must be regarded as one of the factors which determine the site of addition of the anion to the allyl cation.

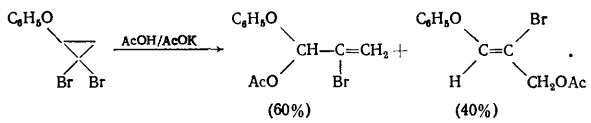


Table 11. The effect of α-methyl-[16,32] and α-phenyl-substitution[34] in the solvolysis of cyclopropane derivatives.

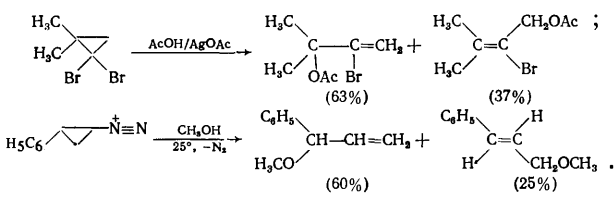
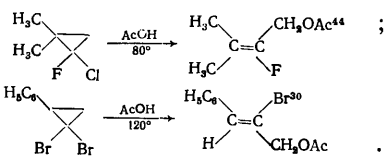
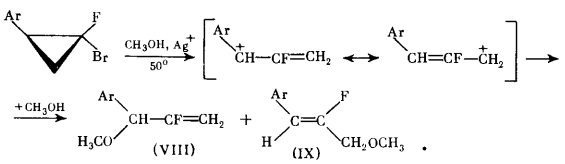
Compound	k_{CH_3}/H	$k_{C_6H_5}/H$	ρ (R=Ar)	Reaction conditions
	1100	390 000	—4.31(σ⁺),(108°)	CH_3COOH; 25°
	40	—	—	50% C_2H_5OH; 130°



The localisation of the positive charge in the α-position relative to the substituent results in the formation of the acetals of α-halogenoacroleins in the solvolysis of alkoxydihalogenocyclopropanes[38,40,41]:

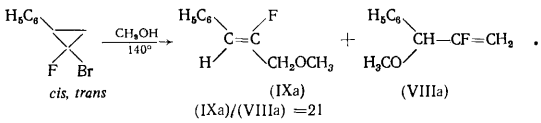


The stabilisation of the charge by the phenoxy-group is less effective owing to the conjugation of the lone electron pair of oxygen with the aromatic ring[42]:



Charge control obtains also in the solvolysis reactions of derivatives of alkylcyclopropanes[30] and phenylcyclopropanes[43]:

However, in many cases the structure of the products of the solvolysis of alkyl- and phenyl-substituted dihalogenocyclopropanes is inconsistent with the charge distribution in the intermediate allyl cation:

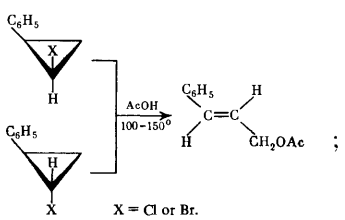


Evidently the second factor which determines the structure of the products of the solvolysis of cyclopropane derivatives is the stability of the olefins formed. It has been shown recently[20] that, under kinetically controlled reaction conditions, an allyl product with a terminal methylene group is formed preferentially:

Ar:	C_6H_5	*p*-$CH_3C_6H_4$	*m*-$CH_3C_6H_4$	*p*-BrC_6H_4	*m*-BrC_6H_4
(VIII)/(IX):	2.5	4.0	3.5	2.0	1.5

The arylallyl cation, formed as a result of the opening of the three-membered ring, reacts with methanol via both the α- and γ-carbon atoms with formation of products (VIII) and (IX) respectively. The degree of localisation of the charge on the α- and γ-carbon atoms of the allyl system, which depends on the nature of the substituent, determines the composition of the solvolysis products. The experimentally observed predominance of the yield of compound (VIII) over that of compound (IX) suggests that the charge is concentrated at the benzyl carbon atom of the arylallyl cation. The disproportion in the charge distribution increases following the introduction of electron-donating substituents into the aromatic ring and diminishes when electron acceptors are introduced.

On the other hand, under thermodynamically controlled conditions, the most stable olefins, in which the double bond is conjugated with the phenyl group (or olefins having the maximum number of substituents at the double bond), predominate:

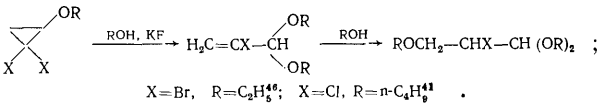


cis, trans (IXa) (VIIIa)

(IXa)/(VIIIa) =21

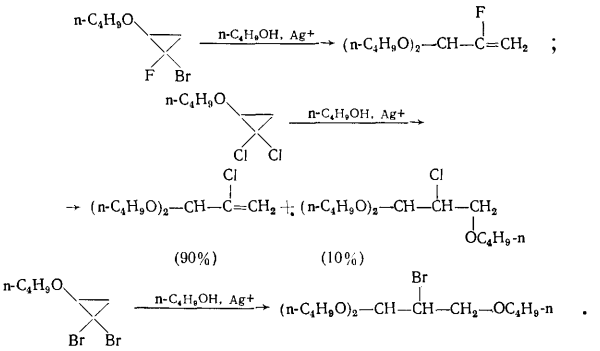
In the majority of studies on the solvolysis of arylcyclopropane derivatives[12,18,29,30,34] the formation of allyl products of the styrene type only has been observed, which must be attributed to the fairly severe reaction conditions (≥100–120 °C, 20–40 h).

It is remarkable that the acetolysis of *cis*- and *trans*-isomeric phenylhalogenocyclopropanes results in the formation of the *trans*-olefin only[21,22]:



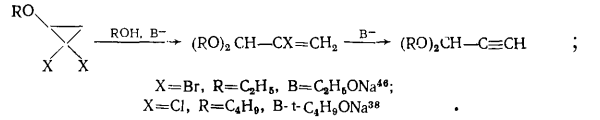
Some investigators[21] believe that the opening of the ring in *cis*-substituted halogenocyclopropanes is not subject to secondary orbital control. In other studies[45] the idea of *cis–trans* isomerisation in the allyl cation stage or of the reaction products is invoked. Bearing in mind the experimentally observed isomerisation of the *cis*-allyl cation to the *trans*-isomer[15,36], one must recognise that this view is more valid.

1. The Role of Accelerating Agents in Nucleophilic Substitution Reactions of Cyclopropane Derivatives



Electrophilic and nucleophilic accelerating additives are widely used in reactions involving nucleophilic substitution at a saturated carbon atom. The role of accelerating agents becomes still more marked in the solvolysis of cyclopropane derivatives, which are much less reactive than acyclic alkyl halides. Apart from the acceleration, electrophilic and nucleophilic additives can promote a further transformation of the allyl products formed.

Thus alcoholysis of alkoxy-*gem*-dihalogenocyclopropanes, accelerated by additives which generate an acid medium during the reaction (silver or alkali metal salts), is accompanied by secondary processes involving the addition of solvent molecules to the double bonds of the aryl derivatives:



X=Br, R=C_2H_5[46]; X=Cl, R=n-C_4H_9[41].

The ability of the dialkyl acetal of α-halogenoacrolein to combine with the alcohol is determined by the nature of the α-halogeno-group[39]:

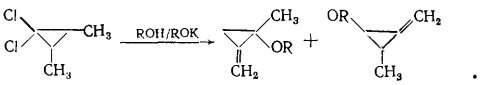
Thus the stability of the primary products of the solvolysis of alkoxy-*gem*-dihalogenocyclopropanes in an acid medium is consistent with the +*M* effect of the halogen in the molecule of the dialkyl acetal of α-halogenoacrolein.

When an organic or inorganic base is used as the reactive nucleophile, dehydrohalogenation of the primary solvolysis product is observed:

X=Br, R=C_2H_5, B=C_2H_5ONa[46];
X=Cl, R=C_4H_9, B-t-C_4H_9ONa[38].

The yield of the dialkoxypropyne increases both with increase of the basicity of the reactive agent (NaOH < KOH < n-C_4H_9.ONa < n-C_4H_9OK) and with increase of its concentration[39].

The stability of the dialkyl acetal of α-halogenoacrolein in an alkaline medium varies in the same sequence as in an acid medium: the fluoro-compounds are more stable than the chloro- and bromo-derivatives (F > Cl > Br).[39]

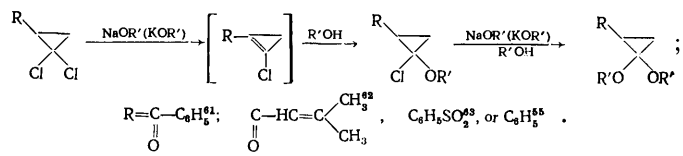


One must note that the solvolysis in the presence of strong bases proceeds with higher degrees of conversion of the primary products than in the presence of electrophilic additives. The formation of unsaturated aldehydes, enynes, and other unidentified products in solvolysis under the influence of t-C_4H_9OK has been described[47].

The cyclopropyl–allyl rearrangement, accompanied by secondary process, does not constitute the only pathway in the reactions of cyclopropane derivatives under solvolysis conditions subject to the influence of nucleophilic additives. If a strong base is used as the nucleophile then, as in the series of acyclic halogeno-derivatives, the elimination reaction competes with the substitution process.

The formation of cyclopropene from cyclopropane derivatives via β-elimination was observed for the first time by Kohler and Darling[48]. However, the isolation of the cyclopropene derivatives was not achieved for a long time owing to the instability of the three-membered ring with an *endo*-double bond. The low stability of cyclopropene and its derivatives is caused by the high strain energy of the ring[49,50]. The stability of cyclopropene compounds increases with increase of the degree of substitution, electron-donating substituents stabilising the molecule less effectively than electron-accepting substituents[51]. The high stability of polyhalogenocyclopropenes made it possible to obtain these compounds in a pure state[52].

The cyclopropenes formed under the conditions of the nucleophilic substitution reaction using highly basic additives can undergo further transformations: (a) isomerisation accompanied by the migration of the double bond outside the limits of the three-membered ring[53–55]; (b) the addition of a molecule of the nucleophile (solvent)[55] to the double bond of cyclopropene; (c) the opening of the three-membered ring with rupture of a C–C single bond in cyclopropene[39,41]. The operation of one of the above reaction pathways is determined by the structure of the initial cyclopropane or, more precisely, by the nature of its substituents.



According to the data of Ampilogova et al.[56], compounds with a double bond in the three-membered ring are thermodynamically less stable than the isomeric methylenecyclopropanes. This has been confirmed experimentally by the irreversible isomerisation of alkylcyclopropenes to methylenecyclopropanes[54]. In the solvolysis of alkylhalogenocyclopropanes in the presence of strong bases the migration of the double bond outside the limits of the ring and the addition of a solvent molecule occur simultaneously in some cases[55]:

The ability of cyclopropene derivatives to undergo nucleophilic addition reactions indicates an unusual nature of the double bond in cyclopropenes, because such reactions are not characteristic of ethylenic double bonds. According to Kosai and Meyer[57], the C–H bonds in cyclopropene have an increased amount of *S*-character, while the C–C bonds have an increased amount of *p*-character. The study of the ^{13}C NMR spectra of cyclopropene derivatives led to the conclusion that the carbon–carbon double bonds in cyclopropene resemble acetylenic bonds[58]. Data for the geometry of cyclopropene (the C=C bond length is 1.3 Å [57] or 1.28 ± 0.04 Å [59]) and spectroscopic studies on substituted cyclopropenes (stretching vibrations of the C=C bond in the range 1800–1900 cm^{-1})[60] confirm the "acetylenic" properties of the cyclopropene double bond.

The elimination of the hydrogen halide with subsequent nucleophilic addition to the cyclopropene double bond under the conditions of the solvolysis of β-substituted halogenocyclopropanes under the influence of nucleophilic additives is determined by the basicity of the latter and the mobility of the hydrogen atom in the α-position relative to the substituent. Such reactions occur when strong bases (metal alkoxides) are used as nucleophiles and the cyclopropane ring has a substituent which increases the proton mobility

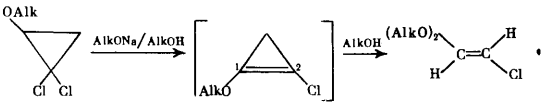
at the α-atom:

The dialkyl ketals of cyclopropanone formed are either stable under the reaction conditions or undergo further transformations.

In a study of the solvolysis of 2-aryl-1-bromo-1-fluorocyclopropane in deuterated methanol (CD_3OD) under the influence of potassium t-butoxide it was established[20] that the formal substitution products are not formed as a result of direct substitution of the halogen by the alcoholic residue but arise in the subsequent elimination–addition reaction.

Table 12. Degrees of conversion of 2-aryl-1-bromo-1-fluorocyclopropanes in methanolysis under the influence of t-C_4H_9OK (at 50 °C).

Reaction time, min	Conversion, %					
						
	cis	*trans*	*cis*	*trans*	*cis*	*trans*
10	35	17	—	—	100	100
20	60	28	—	—	—	—
30	—	—	7	4	—	—
60	80	40	17	8	—	—
90	—	—	21	12	—	—
120	92	56	29	15	—	—



The solvolysis of aryl-*gem*-dihalogenocyclopropanes[20] in the presence of a strong base is accelerated by electron-accepting substituents and retarded by electron-donating substituents in the aromatic ring, as a result of the activation or deactivation of the benzyl proton (Table 12).

The higher reactivity of the *cis*-isomers is probably associated with the preferential *trans*-dehydrohalogenation. Similar relations between the rates of reaction of the *cis*- and *trans*-isomers have been observed in the solvolysis of 2-benzoyl-1-chlorocyclopropanes[61].

Consequently, the type of accelerating additive plays a decisive role in determining the direction of the process as a whole, the relative reactivities of the *cis*- and *trans*-isomers, and also the type of influence of the substituents in the aromatic ring on the rate of solvolysis of arylhalogenocyclopropanes. As shown above, in the presence of an electrophile (Ag^+) only the opening of the three-membered ring, accelerated by electron-donating substituents in the aromatic ring, takes place, the *trans*-isomers being more reactive than the *cis*-isomers. A strong base induces preferential reactions involving the retention of the cyclopropane ring, which are accelerated by electron-donating groups in the aromatic ring; under these conditions, the *cis*-isomer is more reactive. The cause of this sharp difference consists in the reaction mechanism; the electrophile attacks the halogen atom with formation of a carbonium ion, while the strong base attacks the mobile benzyl proton.

As already mentioned, the possibility of the solvolysis of halogenocyclopropanes with retention of the three-membered ring depends on the presence of a β-substituent activating the geminal proton. If the β-substituents are groups such as C_6H_5S [47] and OAlk,[39,41] then, under solvolysis conditions in the presence of both an electrophile and a strong base, the cyclopropyl–allyl rearrangement takes place. In the solvolysis of asymmetric alkoxy-*gem*-dihalogenocyclopropanes[39] the *trans*-isomer is more reactive in both cases.

Together with the products of the cyclopropyl–allyl rearrangement, the dialkyl acetals of *trans*-β-chloroacrolein are formed in the solvolysis of 2-alkoxy-1,1-dichlorocyclopropanes[39,41]:

The first stage probably involves the formation of 1-alkoxy-2-chlorocyclopropene, in which the $C_{(1)}$–$C_{(2)}$ bond is ruptured under the reaction conditions with addition of an alcohol molecule.

---o0o---

The above analysis of the influence of various factors on nucleophilic substitution reactions in the series of cyclopropanes showed that, in contrast to the usual S_N processes, the opening of the three-membered ring, controlled by orbital symmetry, takes place, while the elimination reaction under the influence of strong bases is undergone by both the initial compounds and the primary reaction products.

Aromatic Monocarbonylpolyfluoro-compounds

T.N.Gerasimova and E.P.Fokin

The literature data on the methods of synthesis and chemical and photochemical reactions of aromatic polyfluoro-substituted aldehydes and ketones are surveyed and arranged systematically. Attention is concentrated on the most characteristic reactions of these compounds with nucleophiles. The characteristics of the structure and reactivity of monocarbonylpolyfluoro-compounds due to the presence of electron-accepting fluorine atoms in their molecules are considered. Methods are described for the preparation of aromatic *o*-hydroxy- and *o*-amino-substituted polyfluoroketones and certain aspects of their employment in the synthesis of polyfluoro-substituted benzoheterocycles are examined.
The bibliography includes 148 references.

I. INTRODUCTION

During the last two decades, there has been an intense development of the chemistry of aromatic polyfluoro-compounds. In recent years a number of reviews devoted to the methods of synthesis[1,2] and individual types of their reactions[3-6] as well as problems of the influence of polyfluorobenzene ring and the reactivity of the functional groups linked to it[7,8] have been published. However, the volume of experimental data has increased so much that its detailed consideration and survey in terms of individual classes of compounds has become necessary. In the present review an attempt is made to do this in relation to aromatic carbonyl polyfluoro-compounds. The review includes data on the methods of synthesis and chemical properties of aromatic polyfluoro-substituted aldehydes and ketones of the type Ar_FCHO and Ar_FCOR containing the C=O group linked directly to the aromatic polyfluoro-ring. Polyfluorobenzoic acids and their derivatives are not considered in this review.

II. METHODS OF SYNTHESIS OF AROMATIC POLYFLUORO-SUBSTITUTED ALDEHYDES AND KETONES

The classical method of synthesis of aromatic ketones—the Friedel–Crafts acylation[9]—has not been used widely in the chemistry of aromatic polyfluoro-compounds. Only isolated instances of the application of this reaction in the preparation of aromatic polyfluoroketones are known. Thus the possibility of synthesising pentafluorobenzophenones by the reaction of pentafluorobenzoyl chloride with benzene and alkylbenzenes has been demonstrated[10-12]:

$$C_6H_6 + C_6F_5COCl \xrightarrow[90-100^\circ]{AlCl_3} \underset{(55\%)}{C_6H_5COC_6F_5} \ ;$$

$$C_6Alk_6 + C_6F_5COCl \xrightarrow[20^\circ]{AlCl_3} \underset{(26-50\%)}{C_6Alk_5COC_6F_5} \ ;$$

Alk=Me, or Et .

The acylation reactions of pentafluorobenzene in the presence of aluminiumchloride take place under severe conditions and are complicated by side processes[10], but the synthesis of decafluorobenzophenone and a number of aliphatic aromatic polyfluoroketones by the reaction of pentafluorobenzene with carboxylic acid anhydrides and halides in antimony pentafluoride has been described[13]:

$$C_6F_5H \xrightarrow[SbF_5]{R_FCOX \text{ или } (R_FCO)_2O} \underset{(20-80\%)}{C_6F_5COR_F} \qquad R_F=Alk_F, \text{ or } C_6F_5 \ .$$

Polyfluorobenzophenones have also been obtained by the hydrolysis of the salts of α-fluorodiarylmethyl cations synthesis from partly fluorinated aromatic hydrocarbons and trifluoromethylbenzenes in antimony pentafluoride[14,15]:

$$R^1C_6F_4CF_3 + R^2C_6F_4H \xrightarrow{SbF_5} R^1C_6F_4\overset{+}{C}FC_6F_4R^2 \xrightarrow{H_2O} \underset{(75-93\%)}{R^1C_6F_4COC_6F_4R^2} \ ;$$

R^1=H, or F; R^2=H, F, or Me .

The most widely used method of synthesis of aromatic polyfluoro-substituted aldehydes and ketones is based on organoelemental compounds. Penta- and tetra-fluorobenzaldehydes have been obtained from the corresponding polyfluorophenylmagnesium halides and *N*-methylformanilide in 50–80% yield[16-19]. The attempts to carry out the reaction with ethyl formate or orthoformate resulted in appreciable reduction of the yield of products[16,20]. Pentafluorophenyl-lithium has been used successfully instead of a Grignard reagent[21-23].

Aromatic and aliphatic-aromatic polyfluoroketones are usually obtained by the interaction of polyfluorophenyl derivatives of metal—magnesium, copper, cadmium, and aluminium—with carboxylic acid derivatives[16,17,24-33]. There are extremely few examples of the use of aromatic polyfluoro-substituted carbonyl compounds or their analogues in such reactions[34-36]:

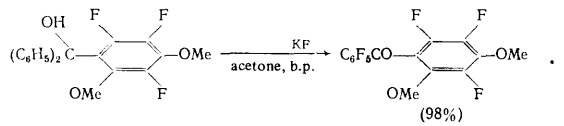
$$C_6F_5MgX \xrightarrow{(MeCO)_2O} C_6F_5COMe \quad (48\%)$$

$$C_6F_5MgX \xrightarrow{CF_3CO_2Li} C_6F_5COCF_3 \quad (71\%)$$

$$C_6F_5MgX \xrightarrow{PhCOCl} C_6F_5COPh \quad (62\%)$$

$$C_6F_5MgX \xrightarrow{ClCO_2Me} C_6F_5COC_6F_5 \quad [(33\%) \ ;$$

$$C_6F_5CN \xrightarrow{RMgX} \underset{(40-60\%)}{C_6F_5COR}; \quad R=Me, \text{ or } Ph \ ;$$



$$C_6F_5COCl \xrightarrow{Me_2Cd} \underset{(56\%)}{C_6F_5COMe} \ .$$

A preparatively important version of this method is based on the interaction of benzaldehyde or its substituted derivatives with Grignard reagents in combination with the classical reaction involving the oxidation of the secondary alcohols thus produced. The oxidant is usually chromium trioxide in glacial acetic acid[16,37–43]. Polyfluoro-substituted benzo- and aceto-phenones containing various functional groups have been prepared by this method[43–45].

Aliphatic-aromatic polyfluoroketones with ester and other functional groups have been synthesised successfully with the aid of the disodium salt of iron hydrocarbonyl[46]:

$$Na_2Fe(CO)_4 + n\text{-}C_5H_{11}OCO(CH_2)_4CH_2Br + C_6F_5COCl \rightarrow C_6F_5CO(CH_2)_5CO_2C_5H_{11}\text{-}n \ .$$

A specific reaction for the synthesis of aromatic polyfluoroketones involves the cleavage of polyarylfluorocarbinols in an alkaline medium[47–49]. The use of anhydrous potassium fluoride as the base ensures that the process proceeds unambiguously and is preparatively valuable[36,50]:

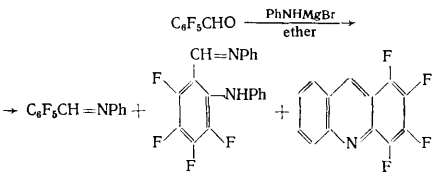
(98%)

A number of other methods normally employed in the chemistry of non-fluorinated analogues have also been applied successfully in the synthesis of aromatic polyfluoro-substituted carbonyl compounds. Pentafluorobenzaldehyde has been obtained from pentafluorobenzonitrile by reduction with stannous chloride[34] or Raney nickel[35]. The formation of polyfluorobenzophenones by the oxidation of olefins[51] and by the thermolysis of salts of polyfluorobenzoic acids[52–55] or pentafluorobenzoyl chloride in the presence of alkali metal salts[56] has been described.

III. CHEMICAL PROPERTIES

The substitution of hydrogen atoms in the aromatic ring of the carbonyl compound by fluorine atoms, which are highly electronegative, alters the electronic character of the aromatic ring and the properties of the carbonyl group linked to it. In aromatic polyfluoro-substituted carbonyl compounds the $-I$ effect of the pentafluorophenyl group[57,58] is enhanced by the breakdown of the coplanarity of the molecules, which hinders the conjugation of the carbonyl group with the aromatic ring. The difficulty of the rotation of the C_6F_5 groups about the $C_{arom}-C_{C=O}$ bond has been noted for decafluorobenzophenone[59]. The determination of the dipole moments of pentafluorobenzaldehyde and pentafluoroacetophenones in solution and their comparison with the calculated values showed that the formyl and acetyl groups deviate from the plane of the ring (the dihedral angles are 28° and 58° respectively) largly due to the Coulombic repulsion between the oxygen atoms or between the methyl group and fluorine atoms[60]. It is noteworthy that the molecules of the non-fluorinated analogues of these compounds are planar. Direct evidence for the greater electron-accepting influence of the pentafluorophenyl group compared with the phenyl group is provided by the hypsochromic shift (by 20–30 cm^{-1}) of the stretching vibration band of the carbonyl group in the infrared spectra of aromatic polyfluoro-substituted aldehydes and ketones[61].

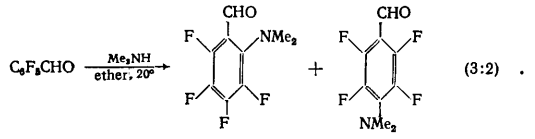
The $-I$ effect of the pentafluorophenyl residue should lead, on the one hand, to an enhancement of the electrophilic properties of the carbon atom of the carbonyl group linked to it and to a facilitation of nucleophilic attack via this carbon atom and, on the other hand, to a decrease of the basicity of the C=O group and a greater difficulty of acid catalysts, which plays an important role in many reactions of carbonyl compounds. Unfortunately there are no quantitative literature data for the relative basicities of aromatic polyfluoro-substituted aldehydes and ketones. It has only been shown that perfluorobenzophenone is appreciably protonated on dissolution in sulphuric or fluorosulphonic acids[62] and forms the corresponding oxycarbonium in in the SbF_5–HF–SO_2ClF system[63].



The presence of the polyfluoroaryl residue in the molecule of the aromatic polyfluoro-substituted carbonyl compound not only transforms the properties of the carbonyl group but is also responsible for the possibility of nucleophilic substitution in the fluorine atoms. The carbonyl group has an activating influence on this process. Overall, aromatic polyfluoro-substituted aldehydes and ketones are polyfunctional compounds, the characteristics and chemical properties of which are determined by the mutual influence of the carbonyl and polyfluorophenyl groups linked directly.

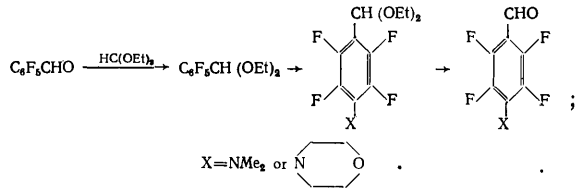
1. Reactions with *N*-Nucleophiles

The interaction of aromatic aldehydes and ketones with nitrogen bases, which is the most important and most thoroughly investigated type of their reactions, usually leads to the formation of derivatives of the carbonyl group. The reactions of aromatic polyfluoro-substituted carbonyl compounds with *N*-nucleophiles are less unambiguous. Depending on the structure of the reactants under the reaction conditions, they can involve both the carbonyl group, with formation of the corresponding nitrogen-derivatives, or the haloform decomposition of the initial compound, or the substitution of fluorine atoms.



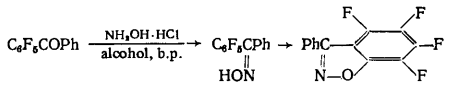
Aromatic polyfluoroaldehydes react with hydrazine, semicarbazide, thiosemicarbazide, and 2,4-dinitrophenylhydrazine, forming the corresponding derivatives of the carbonyl group under the usual conditions[18–20,34,64,65]. When pentafluorobenzaldehyde was allowed to react with *O*,*N*-bis(trifluoroacetyl)-hydroxylamine—a new reagent for the carbonyl group—pentafluorobenzonitrile was obtained in 76% yield[66].

Pentafluorobenzaldehyde exhibits a high reactivity in relation to primary aliphatic and aromatic amines via its carbonyl group. It reacts with ethylamine in water without the elimination of fluoride ions, forming *N*-(pentafluorobenzylidene)-ethylamine[64]. Its react with aniline and the very weakly basic pentafluoroaniline ($pK_a = -0.28$) [67] leads to the formation of the corresponding Schiff bases[16,17,68]. The interaction with the more nucleophilic bromomagnesylaniline results in the formation not only of the anil of pentafluorobenzaldehyde but also of products of its further reactions[68]:

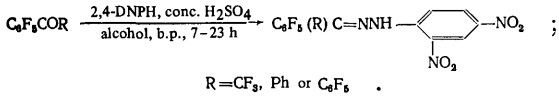


Pentafluorobenzaldehyde reacts with dimethylamine in ethereal solution at room temperature, the process involving the substitution of a fluorine atom by the dimethylamino-group[64]. The preferential *ortho*-directing effect observed in

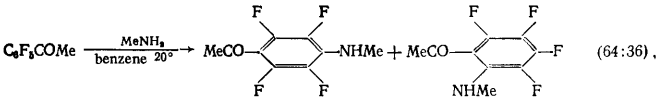
this reaction is in all probability caused by the specific interaction of the reagent with the formyl group:



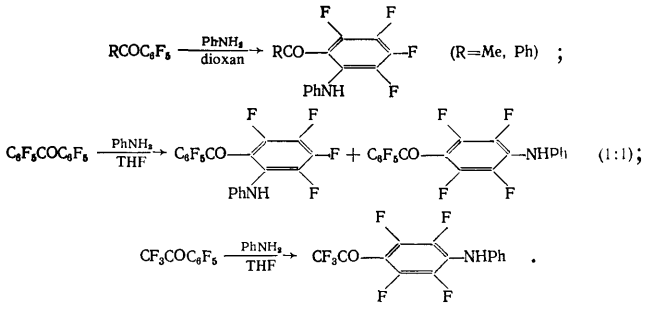
p-Aminotetrafluorobenzaldehydes can be obtained by an indirect method via the diethyl acetal of pentafluorobenzaldehyde[69]:



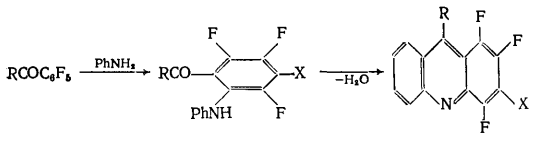
2,3,4,5,6-Pentafluoroacetophenone† exhibits a reactivity towards substituted hydrazines which resemble that of the non-fluorinated analogue[34,70]. Octafluoroacetophenone, containing the highly electronegative trifluoromethyl group, reacts vigorously with free hydrazine[71]. However, in contrast to aliphatic polyfluoroketones[72,73], it does not then form a stable geminal addition product, but undergoes the haloform decomposition with elimination of the relatively stable pentafluorophenyl anion[8]. Reactions with the less nucleophilic phenylhydrazine and hydroxylamine take place on heating and lead to appreciable elimination of fluoride ions and formation of complex mixtures. Derivatives of the carbonyl group have been obtained on refluxing octafluoroacetophenone with the hydrochlorides of the corresponding bases in an aqueous alcoholic medium[71,74]:



The oximes of 2,3,4,5,6-pentafluoro- and decafluoro-deoxybenzoins[75] as well as the oxime of pentafluorobenzophenone have been obtained similarly. The latter is unstable and undergoes spontaneous cyclisation to an oxazole derivative[16,74]:



Polyfluorobenzophenones react with hydrazine and phenylhydrazine with substitution of a fluorine atom by the RNHNH group and do not change on prolonged refluxing with their hydrochlorides in an aqueous alcoholic solution[39,71]. The lack of interaction with free bases via the carbonyl group can be accounted for by the influence of a number of factors, the most important of which is apparently the steric effect of the *ortho*-fluorine atoms, which hinder the approach of the nucleophile to the central carbon atom[16,71,76]. The reduced reactivity of aromatic polyfluoroketones under the conditions of acid catalysis, caused by their low basicity, is also manifested under very severe conditions, compared with the non-fluorinated analogues, in the synthesis of 2,4-dinitrophenylhydrazones[39,71]:



Aromatic polyfluoroketones react with ammonia and aliphatic amines with substitution of one or several fluorine atoms by the corresponding amino-groups, exhibiting at the same time a higher reactivity than hexafluorobenzene[48,77-79]. A preferential *para*-directing effect is shown in a polar medium, while the reaction is a non-polar solvent can lead to an increased content of the *ortho*-isomer in the product[77]:

The interaction of polyfluoro-substituted aceto- and benzophenones with aromatic amines in aromatic solvents proceeds only via the substitution of fluorine by the arylamino-group. The isomeric composition of the reaction product depends on the structure of the initial ketones and on the polarity of the medium[80-82]:

When the reaction of aromatic polyfluoroketones with aniline is carried out without a solvent in the presence of an excess of aniline, somewhat different results are obtained. The main reaction products are in this case polyfluoroacridines, the formation of which can be represented schematically in the following manner[80]:

The unusual conditions of the intramolecular cyclisation of *o*-anilinoketones, which usually occurs in acid media, are striking[83]. Presumably in this instance the $PhNH_3^+$ ions, formed as a result of the nucleophilic substitution of fluorine, play the role of the acid catalyst. Accordingly, the addition of potassium carbonate to the reaction mixture prevents the formation of acridines[80,81].

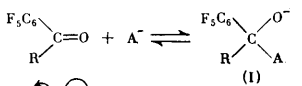
† Henceforth the positions of the fluorine atoms in 2,3,4,5,6-pentafluoroacetophenone and 2,3,4,5,6-pentafluorobenzophenone will not be indicated in this review.

2,4-DNPH = 2,4-dinitrophenylhydrazine [2,4-$(NO_2)_2C_6H_3$.$NHNH_2$].

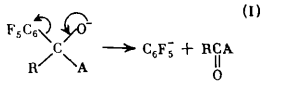
The study of the interaction of aromatic polyfluoroketones with aniline showed that nucleophilic addition to the carbonyl group, leading to the formation of anils, takes place to an appreciable extent only for octafluoroacetophenone[80]. A method of synthesising anils from other ketones of this series has been recently discovered[84]. It consists in the interaction of the ketone with aniline in benzene or chlorobenzene in the presence of anhydrous aluminium chloride. The role of the latter evidently reduces to the activation of the carbonyl group with respect to nucleophilic attack as a result of complex formation via the oxygen atom:

$$C_6F_5COR \xrightarrow[C_6H_6 \text{ or } C_6H_5Cl]{PhNH_2,\ AlCl_3} C_6F_5C(R)=NPh\ ;$$
$$R=Me,\ Ph,\ \text{or}\ C_6F_5\ .$$

2. Reactions with *O*-Nucleophiles



Aliphatic perfluoro-substituted aldehydes and ketones, in which the electrophilic properties of the carbonyl group are greatly enhanced as a result of the strong electron-accepting influence of the perfluoroalkyl groups, react extremely readily with compounds of the type ROH (R = H or alkyl), forming geminal addition products[72,73,85].



Decafluorobenzophenone, which is an aromatic perfluoroketone, does not form a hydrate[16]. In contrast to its non-fluorinated analogue, pentafluorobenzaldehyde reacts with methanol in the absence of acid to form a hemiacetal. Its acetals have been obtained only after prolonged refluxing with alcohols in the presence of concentrated hydrochloric acids[64]. The use of orthoformic ester instead of alcohol made it possible to obtain a high yield of the diethyl acetal of pentafluorobenzaldehyde[69].

In contrast to its non-fluorinated analogue, pentafluorobenzaldehyde exhibits a very high tendency towards the haloform decomposition; under the conditions of the Cannizzaro reaction, it is cleaved with formation of pentafluorobenzene and formic acid[16,86]. 4-X-tetrafluorobenzaldehydes[64] as well as aromatic polyfluoroketones[16,38,45,71] undergo a similar reaction in an alkaline medium. Among the latter, the highest reactivity is shown by decafluorobenzophenone, which decomposes at room temperature under the influence of 10% KOH:[71]

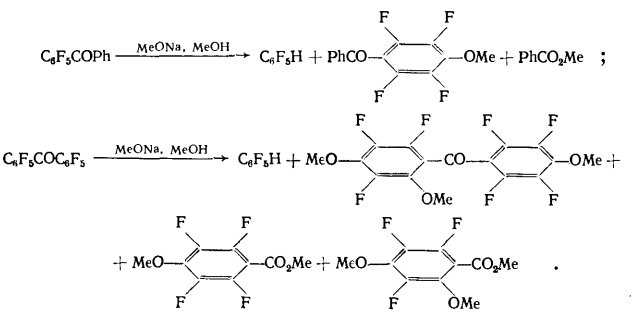
$$C_6F_5COC_6F_5 \xrightarrow[H_2O,\ 20^\circ]{KOH} C_6F_5H + C_6F_5CO_2H\ .$$

The mechanism of the cleavage of aromatic polyfluoro-substituted carbonyl compounds is in all probability analogous to that proposed earlier for the decomposition of non-enolising ketones in an alkaline medium[87]:

(1)

(2)

(3)



The increased tendency of aromatic polyfluoroketones to undergo cleavage compared with their non-fluorinated analogues can be explained by the more marked electrophilic properties of the carbon atom of the carbonyl group and also by the possibility of the elimination of the stable pentafluorophenyl anion. The relative ease of decomposition of decafluorobenzophenone is evidently caused by the favourable energy change in stage (2) in consequence of the steric strain in the intermediate anion (I) and also the electron shift, indicated in the above scheme by arrows, under the influence of the two electron-accepting pentafluorophenyl groups.

The mode of the cleavage reaction is determined by the relative stability of the carbanions, which are potential leaving groups. A detailed analysis of the products of the cleavage of aliphatic-aromatic polyfluoroketones, carried out by Coe et al.[38] (see Table), confirmed this view. The relative stability of the anions corresponding to the hydrocarbons formed decreases in the sequence [8,88] $CCl_3^- > C_6F_5^- > CF_3^- > C_6H_5^-$.

The haloform decomposition of aliphatic-aromatic fluoroketones (4 *N* KOH, refluxing for 4 h).[38]

Initial ketone	Reaction product	
	hydrocarbon	acid
C_6F_5COMe	C_6F_5H	$MeCO_2H$
$C_6F_5COCH_2Br$	C_6F_5H	$BrCH_2CO_2H$
$C_6F_5COCHCl_2$	C_6F_5H	Cl_2CHCO_2H
$C_6F_5COCF_3$	C_6F_5H	CF_3CO_2H
$C_6F_5COCCl_3$	$CHCl_3$	$C_6F_5CO_2H$
$C_6H_5COCF_3$	CHF_3	$C_6H_5CO_2H$

The haloform decomposition reaction is extremely characteristic of aromatic polyfluoro-substituted carbonyl compounds and proceeds in the presence of not only aqueous alkali but also of other charged nucleophiles. It is possible that this process is in fact the cause of the low yield of 4-methoxytetrafluorobenzaldehyde, obtained by the reaction of pentafluorobenzaldehyde with sodium methoxide in methanol[64]. In contrast to their non-fluorinated analogue, which is stable under the conditions of prolonged refluxing with sodium methoxide in methanol, penta- and deca-fluorobenzophenones undergoe reactions of two kinds in this medium at room temperature; nucleophilic substitution of fluorine atoms by methoxy-groups and cleavage with elimination of the pentafluorophenyl residue and the formation of methyl esters of benzoic and pentafluorobenzoic acids[38,89]:

In order to reduce the extent of the second process and to increase the yield of methoxy-ketones, one must prevent the presence of an excess of sodium methoxide in the reaction mixture[62].

3. Reactions with Sulphur Compounds

Pentafluorobenzaldehyde forms a bisulphite compound on being shaken with a saturated solution of sodium bisulphite[16]. Its equimolar mixture with thiophenol in acetone gives rise to a crystalline hemithioacetal partly dissociated into the initial components on dissolution in carbon tetrachloride or acetone[64].

On the other hand, according to other data[90], pentafluorobenzaldehyde does not react appreciably, like its non-fluorinated analogue, with propane-1-thiol in methylene chloride solution in the absence of acid; the addition of the latter leads to the formation of the thioacetal. The diethyl thioacetal has been obtained from pentafluorobenzaldehyde by reaction with ethanethiol in the presence of concentrated hydrochloric acid[64] or with phenyldi(ethylthio)borane[91].

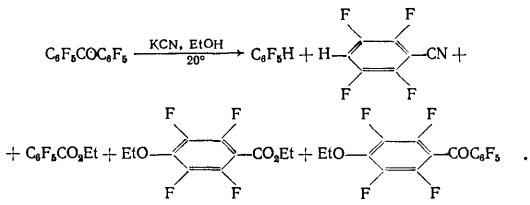
$$C_6F_5CHO + PhB(SEt)_2 \rightarrow 1/3\,(PhBO)_3 + \underset{(45\%)}{C_6F_5CH(SEt)_2}\quad .$$

Several examples of the nucleophilic substitution of fluorine in pentafluorobenzaldehyde by sulphur-containing residues are known[64]. 4-Mercaptotetrafluorobenzaldehyde has been obtained in 61% yield by the reaction of pentafluorobenzaldehyde with sodium hydrogen sulphide in dimethylformamide (DMF) at 0 °C. The reaction with sodium thiophenoxide in DMF proceeds with evolution of heat and the substitution of all five fluorine atoms by PhS groups; in methanol the main reaction product is 4-phenylthiotetrafluorobenzaldehyde (yield 68%).[64]

The interaction of aromatic polyfluoro-sbustituted aldehydes and ketones with sulphur tetrafluoride leads to the substitution of the carbonyl oxygen atom by two fluorine atoms. The reaction conditions depend on the structure of the initial carbonyl compound and the introduction into its molecule of electron-accepting groups leads to a decrease of reactivity. The reaction with perfluoroketones requires either a high temperature or the presence of acid catalysts. This reaction can serve as a method for the preparation of polyfluorinated hydrocarbons containing fluorine atoms in both the aromatic ring and in the side chain, which are otherwise difficult to obtained:

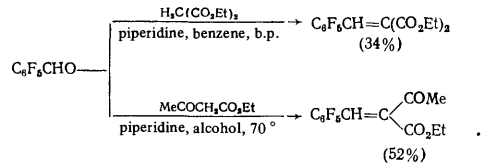
$$C_6F_5COR \xrightarrow{SF_4} C_6F_5CF_2R\quad ;$$

R=H, 140—170°, yield 51%[92] or 100°, HF, 80%[93]; R=Me, 115°, 79%[93];



R=CF_3, 170°, HF, 85%[93]; R=Alk_F, 180°, AlF_3, 90%[91,94];

R=Ph, 180°, 40%[95]; R=C_6F_5, 235°, 88%[95].



4. Reactions with *C*-Nucleophiles

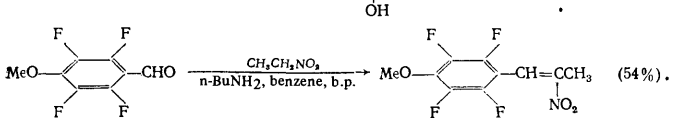
(a) *Reactions with pseudoacids.* In contrast to its non-fluorinated analogue, pentafluorobenzaldehyde does not undergo the benzoin condensation with potassium cyanide in aqueous alcoholic solution[86]. Its cyanohydrin has been obtained in a low yield by the reaction of the bisulphite derivative with NaCN in aqueous solution[20].

In contrast to hexafluoroacetone, which forms stable cyanohydrin salts on interaction with sodium or potassium cyanides in tetrahydrofuran[96], aromatic polyfluoroketones remain unchanged on being refluxed with KCN in this solvent. In alcohol the reaction proceeds in several ways, the main one involving the haloform decomposition of the initial ketone and also of the product of the substitution of the *p*-fluorine atom of the carbonyl group can be in this instance either the cyanide ion or the EtO^- ion. The presence of the latter in the reaction mixture is indicated by the formation of the corresponding nucleophilic substitution products. Among aromatic polyfluoroketones, the most reactive is decafluorobenzophenone, which forms a complex mixture of products on reaction with KCN in alcohol at room temperature[44]:

Polyfluorobenzaldehydes undergo aldol condensation with compounds containing active methyl or ethylene groups, exhibiting the usual reactivity or a reactivity which is somewhat reduced compared with its non-fluorinated analogues. Pentafluorobenzaldehyde reacts with malonic and acetoacetic esters in the pesence of piperidine under more severe conditions than does benzaldehyde, forming the corresponding α,β-unsaturated carbonyl compounds[97]:

2,3,4,5-Tetrafluorocinnamic acid has been obtained by the reaction of 2,3,4,5-tetrafluorobenzaldehyde with malonic acid (in pyridine, in the presence of piperidine)[19]. On the other hand, the initial condensation product (the hydroxy-acid) was obtained under similar conditions from pentafluorobenzaldehyde and then converted into 2,3,4,5,6-pentafluorocinnamic acid by heating with concentrated H_2SO_4.[16]

Pentafluorobenzaldehyde could not be made to undergo the Claisen–Schmidt reaction with acetone and acetaldehyde in the presence of aqueous alkali[97]. In alcoholic solutions of alkalis the reaction with acetone leads to a low yield of 2,3,4,5,6-pentafluorobenzylideneacetone and its *p*-alkoxy-derivative[98]:



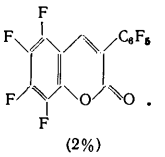
$$C_6F_5CHO \xrightarrow[HO^-,\,ROH]{(CH_3)_2CO} \underset{(6—13\%)}{C_6F_5CH{=}CHCOCH_3} + \underset{(26\%)}{n\text{-}ROC_6F_4CH{=}CHCOCH_3}\quad .$$

The condensation of pentafluorobenzaldehyde with acetaldehyde was achieved only in an anhydrous medium in the presence of piperidine and the formation of the aldol (II) was detected[97]:

$$C_6F_5CHO \xrightarrow[\text{piperidine, }35°]{CH_3CHO} \underset{OH\ (II)}{C_6F_5CHCH_2CHO} \xrightarrow{I_2} C_6F_5CH{=}CHCHO\quad (47\%).$$

The increased stability of the aldol addition products, obtained from pentafluorobenzaldehyde, is in all probability due to the electron-accepting influence of the pentafluorophenyl group, which hinders dehydration by increasing the amount of double bond character of the C=O linkage and strengthening it[16,97]. The formation of nitroalcohols instead of nitro-olefins from pentafluorobenzaldehyde and nitroalkanes when the reaction is carried out in aqueous alcoholic alkali at 0 °C can be explained similarly[34,99,100]. More severe reaction conditions are essential for the synthesis of nitro-olefins[23]:

$$C_6F_5CHO \xrightarrow[MeOH—H_2O,\ 0°]{CH_3NO_2,\ NaOH} \underset{OH}{C_6F_5CHCH_2NO_2}\quad (78\%)\quad ;$$



Pentafluorobenzaldehyde has been successfully made to undergo the Perkin reaction[16]:

$$C_6F_5CHO \xrightarrow[130^\circ]{(CH_3CO)_2O,\ CH_3CO_2K} C_6F_5CH{=}CHCO_2H \quad (36\%) \ .$$

The interaction with 2,3,4,5,6-pentafluorophenylacetic acid gives rise to decafluoro-α-phenylcinnamic acid with an admixture of 3-pentafluorophenyl-5,6,7,8-tetrafluorocoumarin, which is apparently a product of the subsequent reaction of the latter[101]:

$$C_6F_5CHO + C_6F_5CH_2CO_2H \xrightarrow[Et_3N,\ b.p.]{(CH_3CO)_2O} C_6F_5CH{=}C(C_6F_5)CO_2H + \underset{(64\%)}{}$$

(2%)

The condensation of polyfluorobenzaldehydes with thiocyanogen[18] and hippuric acid[102–104] has been described. A complex mixture of products has been obtained from pentafluorobenzaldehyde and 2,3,4,5,6-pentafluorophenylacetonitrile in dimethoxyethane in the presence of KF.[105]

The reaction of pentafluorobenzaldehyde with acetophenone in aqueous alcoholic alkali leads to the formation of 2,3,4,5,6-pentafluorobenzylideneacetophenone[27,97]. Pentafluoroacetophenone can serve as the methylene component; the concentration of alkali should not exceed 1.5% to avoid the subsequent haloform decomposition of decafluorobenzylideneacetophenone into pentafluorobenzene and pentafluorocinnamic acid:

$$C_6F_5CHO + CH_3COAr \xrightarrow[\text{aq. alcohol}]{NaOH} C_6F_5CH{=}CHCOAr \ ;$$
$$Ar = Ph \text{ or } C_6F_5 \ .$$

The condensation of pentafluoroacetophenone with aromatic aldehydes can proceed in the presence of a strong protic acid, but in this case it is accompanied by the interaction of the resulting benzylideneacetophenones with the initial ketone, which leads to the formation of pentafluorophenylpyrylium salts[106].

The use of pentafluoroacetophenone as the methylene component in condensation reactions with aromatic and aliphatic acid esters has been described[28,107,108].

On the basis of general ideas concerning the mechanisms of the reactions of carbonyl compounds with C–H acids[109], presumably the enolic form of pentafluoroacetophenone, which can be formed under the influence of both a base and an acid§, can serve as an intermediate in the reactions of this compound described above regardless of the medium. The ambident behaviour of the aromatic fluorine atom of the enolate pentafluoroacetophenone anion, obtained by the reaction of sodium hydride in polar aprotic solvents, has been demonstrated[111] in a nucleophilic substitution reaction:

$$C_6F_5COCH_3 + C_6F_5CF_3 \xrightarrow[\text{diglyme}]{NaH} \underset{(26\%)}{p\text{-}CF_3C_6F_4CH_2COC_6F_5} + \underset{(25\%)}{p\text{-}CF_3C_6F_4OC(C_6F_5){=}CH_2} \ .$$

The enol of pentafluoroacetophenone is evidently an intermediate in its bromination to α-bromopentafluoroacetophenone[34,38,112]. By virtue of the strong electron-accepting influence of the pentafluorobenzoyl group, the bromine atom in the latter assumes to a large extent the character of a positively charged halogen atom and is readily substituted by hydrogen on treatment with dilute aqueous alkali or sodium iodide in alcohol[112]. This is also the cause of the different behaviour, compared with its non-fluorinated analogue, of α-bromopentafluoroacetophenone in reactions with sodioacetoacetic ester in an ethereal medium[112] and also with solutions of sodium methoxide or potassium fluoride in methanol[113].

(b) *Reactions with organometallic compounds.* Organomagnesium synthesis using carbonyl compounds plays an extremely important role in the chemistry of aromatic polyfluoro-compounds. The reactions of polyfluorophenylmagnesium halides with non-fluorinated carbonyl compounds are very widely used[1,114]. On the other hand, very little is known about the interaction of aromatic polyfluoro-substituted carbonyl compounds with Grignard reagents.

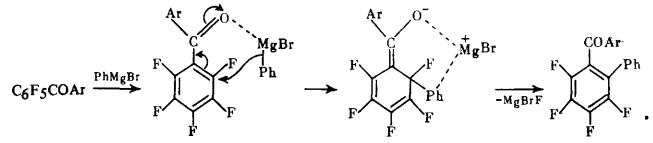
Pentafluorobenzaldehyde reacts with organomagnesium compounds in the usual way with formation of secondary alcohols. Both alkyl- and arylmagnesium halides, including derivatives of halogenopolyfluorobenzenes, can be introduced into the reaction. The reaction of 4-methoxytetrafluorobenzaldehyde with 2,3,4,5-tetrafluorophenylmagnesium bromide has also been described[45]:

$$C_6F_5CHO \xrightarrow[\text{ether}]{RMgHal} C_6F_5CH(OH)R \qquad R{=}CH_2Ph^{64},\ Ph^{68},\ C_6F_5^{16},$$
$$p\text{-}XC_6F_4^{39,44},\ \text{or } 2,3,4,5\text{-}F_4C_6H^{41} \ .$$

The interaction of aromatic polyfluoroketones with organomagnesium compounds is more complex and more ambiguous. The type of reaction depends on the structure of the ketone and the Grignard reagent. Thus tris(pentafluorophenyl)-methanol has been obtained from decafluorobenzophenone and pentafluorophenylmagnesium bromide in tetrahydrofuran (THF).[115] On the other hand, phenylmagnesium bromide reacts with polyfluorobenzophenone in two ways: via the carbonyl group with formation of a tertiary alcohol (and predominantly), via substitution of the *o*-fluorine atom by the phenyl group[116,117]. Pentafluorophenyl(diphenyl)methanol and 3,4,5,6-tetrafluoro-2-phenylbenzophenone have been obtained from pentafluorobenzophenone under these conditions. In the case of decafluorobenzophenone more than 70% of F^- is split off and a complex mixture of products is formed whose infrared spectrum contains C=O and OH absorption bands and from which 2,2-diphenyloctafluorobenzophenones was isolated[117]:

$$C_6F_5COPh \xrightarrow[\text{ether, } 20^\circ]{PhMgBr} \underset{(27\%)}{Ph_2(C_6F_5)COH} + PhCO\text{–}C_6F_3Ph\text{–}F \ ;$$

(52%)



$$C_6F_5COC_6F_5 \xrightarrow[\text{ether, } 20^\circ]{PhMgBr} F\text{–}C_6F_2Ph\text{–}CO\text{–}C_6F_2Ph\text{–}F \quad (25\%) \ .$$

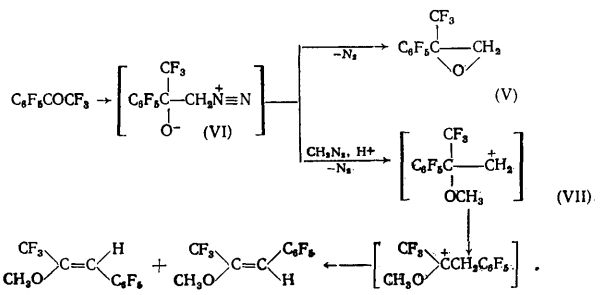
Pentafluoroacetophenone reacts with phenylmagnesium bromide without elimination of F^- and with formation of 1-pentafluorophenyl-1-phenylethanol, while octafluoroacetophenone gives rise to a complex mixture of products[117].

The reaction involving the substitution of a *o*-fluorine atom in polyfluorobenzophenones by the phenyl residue is caused, in all probability, by two factors: the reduced reactivity of their carbonyl group with respect to phenylmagnesium bromide owing to the presence of two (or four) o-fluorine atoms and also by the extremely high nucleophilic mobility of the latter. The specific *o*-directing effect in the process indicates the formation in the transition state of a type (III) cyclic complex with participation of the C=O group of the

§ The anomalous course of the reaction of pentafluoroacetophenone with the Vilsmeier reagent is apparently due to the influence of the *o*-fluorine atoms[110].

ketone and a PhMgBr molecule[116], which is promoted when weakly polar ethyl ether is used as the solvent:

(III)



Methylmagnesium iodide, whose reactions via the carbonyl group are less sensitive to steric hindrance[118], reacts with polyfluorobenzophenones and also with octafluoroacetophenone mainly via the carbonyl group with formation of tertiary alcohols[117,119]. On the other hand, the reaction of pentafluoroacetophenone with methylmagnesium iodide is complicated by the aldol condensation. The diol (IV) isolated is a product of the interaction of the intermediate aldol with the reagent:

$$C_6F_5COMe \xrightarrow[\text{ether, } 20^\circ]{MeMgI} \underset{\substack{|\\OH}}{C_6F_5CMe_2} + \underset{\substack{|\\OH}}{C_6F_5(Me)CCH_2}\underset{\substack{|\\OH}}{C}(Me)C_6F_5$$

(32%) (IV)

The interaction of aromatic polyfluoro-substituted carbonyl compounds with organolithium compounds has been little investigated. It has only been shown that aromatic polyfluoroketones react with pentafluorophenyl-lithium via the carbonyl group with formation of tertiary alcohols[120,122]. Presumably their interaction with other organolithium compounds is complicated by the reaction involving the substitution of fluorine atoms.

(c) *Reactions with diazomethane.* Acetophenone reacts with diazomethane at an appreciable rate only in the presence of an acid catalyst[123]. Pentafluoroacetophenone also remains unchanged when the reaction is carried out in ether at room temperature without added catalyst[124]. Like aliphatic polyfluoroketones[125], octafluoroacetophenone reacts readily with diazomethane in an ethereal solution at 0 °C, being wholly converted into a mixture of substances whose main component is 1-pentafluorophenyl-1-trifluoromethylepoxyethane (V).[124] Furthermore, the geometrical isomers of 1-methoxy-2-pentafluorophenyl-1-trifluoromethylethylene have been isolated from the mixture. They are not products of the conversion of the epoxide (V), since it has been established that the latter is resistant to the action of diazomethane at room temperature. Their formation can be represented by the following scheme, which includes stages where the intermediate species (VI) is methylated with subsequent rearrangement of the carbonium ion (VII) via the migration of the C_6F_5 group to a neighbouring electron-unsaturated carbon atom:

(V) (VI) (VII)

The possibility of such migration has been confirmed in relation to the acid-catalysed conversion of decafluorodiphenylacetaldehyde into decafluorodeoxybenzoin[33].

5. Reactions with Phosphorus Compounds

Like other aromatic aldehydes containing electron-accepting substituents[126], pentafluorobenzaldehyde readily reacts with tris(dimethylamino)phosphine to give a mixture of diastereoisomeric oxides of decafluorostilbene[33]:

$$2C_6F_5CHO + (Me_2N)_3P \rightarrow C_6F_5CH{-}CHC_6F_5 + (Me_2N)_3P{=}O$$

Triphenylphosphine imine causes the haloform decomposition of octafluoroacetophenone in ether at room temperature[71]:

$$C_6F_5(CF_3)C{=}O \xrightarrow[\text{ether, } 20^\circ]{Ph_3P{=}NH} C_6F_5H + CF_3CON{=}PPh_3$$

A similar reaction has been observed[127] in an attempt to explain the imine of nitroperfluoroacetone. The interaction of octafluoroacetophenone and also 4-anilineheptafluoroacetophenone with triphenylphosphine *N*-phenylimine, which is less nucleophilic than $Ph_3{=}NH$, led to the formation of their anils[71]:

$$Ar_F(CF_3)C{=}O \xrightarrow[\text{ether}]{Ph_3P{=}NPh} Ar_F(CF_3)C{=}NPh \quad (58\text{—}83\%)$$

$Ar_F = C_6F_5$ or *p*-$PhNHC_6F_4$.

Pentafluoroacetophenone and pentafluorobenzophenone do not react with triphenylphosphine *N*-phenylimine on refluxing in ether. Decafluorobenzophenone reacts with the latter compound to form a very complex mixture of products from which *p*-anilinononafluorobenzophenone was isolated[71] in a low yield. The ability of triphenylphosphine *N*-phenylimine to substitute fluorine via a nucleophilic mechanism had been pointed out earlier[128].

Pentafluorobenzaldehyde reacts with pentafluorophenyl- and pentafluorobenzoylmethylenetriphenylphosphoranes, the corresponding products of the reaction via the carbonyl group being formed[129,130]:

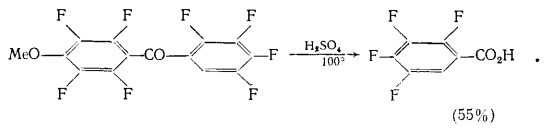
$$C_6F_5CHO \xrightarrow{RCH{=}PPh_3} C_6F_5CH{=}CHR \quad (32\text{—}50\%)$$

$R = C_6F_5$ or C_6F_5CO.

The attempt to carry out the Wittig reaction between aromatic polyfluoroketones and methylenetriphenylphosphorane led to their haloform decomposition[71]. Phosphorus pentachloride reacts with pentafluorobenzaldehyde and octafluoroacetophenone to form the corresponding dichloro-derivatives:

$$C_6F_5(R)C{=}O \xrightarrow[100^\circ]{PCl_5} C_6F_5(R)CCl_2$$

R=H, yield 100%[16];



$R = CF_3$, yield 87%[38].

The resistance of decafluorobenzophenone to the action of PCl_5 under severe conditions has been noted[131].

6. Oxidation Reactions

Only a few examples of the oxidation of polyfluorobenzaldehydes to the corresponding acids are known. Pentafluorobenzaldehyde is oxidised smoothly to pentafluorobenzoic acid in oxygen at 110 °C.[16] The oxidation can be carried out under the influence of potassium or sodium dichromate in sulphuric acid at 100 °C. This method is convenient and can be used in the preparative synthesis of polyfluorobenzoic acid[132] and also for the oxidation of other polyfluorobenzaldehydes[19,69] or their diacetals[69]. It has been shown[45] that *p*-methoxy-2,2',3,3',4,5,5',6-octafluorobenzophenone undergoes oxidative cleavage with formation of 2,3,4,5-tetrafluorobenzoic

acid on heating with concentrated sulphuric acid at 100 °C:

(55%)

7. Reduction Reactions

The reduction reactions of aromatic polyfluoro-substituted carbonyl compounds take place under the usual conditions, but are in many instances complicated by the side processes.

Polyfluorobenzaldehydes are reduced to the corresponding alcohols by refluxing with Raney nickel in alcohol[64] and with lithium tetrahydroaluminate in ether at 20 °C.[16,22] Decafluorodiphenylmethanol has been obtained in a low yield by the reaction of decafluorobenzophenone with $LiAlH_4$.[131] When this method of reduction is used for aromatic polyfluoro-substituted carbonyl compounds, one should bear in mind that the reaction may be accompanied by the substitution of the *o*-fluorine atom by hydrogen[42].

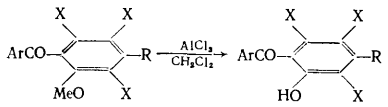
The reduction of decafluorobenzophenone with hydriodic acid in the presence of red phosphorus at 170–200 °C yielded bis(pentafluorophenyl)methane[131]. At the instant of evolution (Zn + acetic acid) hydrogen reduces this ketone to decafluorodiphenylmethanol, while pentafluorobenzophenone is reduced to the corresponding pinacol[40]. The reduction of pentafluorobenzaldehyde by metallic zinc in the presence of hydrochloric acid in alcohol did not lead to the formation of the expected decafluorohydrobenzoin, the corresponding acetal of the initial aldehyde being produced instead[86]:

$$3C_6F_5CHO \xrightarrow[\text{alcohol}]{Zn+HCl} C_6F_5CH\begin{matrix}OCHC_6H_5\\ |\\ OCHC_6F_5\end{matrix} \quad (78\%)$$

The photochemical reduction of aromatic ketones is a convenient preparative method for the synthesis of pinacols. The ability of carbonyl compounds to undergo photochemical reduction depends mainly on the nature of the lowest triplet state and its energy. A high efficiency of the intercombination transition is characteristic of decafluorobenzophenone as well as its non-fluorinated analogue and the n,π^*-triplet state has the lowest energy[133]. Its energy in polar and non-polar media is close to that of the corresponding excited state of benzophenone.

The initial stages of the photochemical reduction of decafluorobenzophenone, involving the abstraction of a hydrogen atom from the medium and the formation of a ketyl radical, are analogous to the reactions of benzophenone, but they are much faster owing to the higher polarisation of the charge in the triplet state caused by the inductive effect of the fluorine atoms. The EPR spectrum of the radical obtained by the ultraviolet irradiation of decafluorobenzophenone in alcohol at 80 °C in the cuvette of the EPR spectrometer has been described[134] and agrees fully with the calculated spectrum. The addition of sodium methoxide to the irradiated solution enabled the authors[135] to observe the EPR spectrum of the corresponding radical-anion. Unsuccessful attempts to obtain the latter had been reported earlier[136,137].

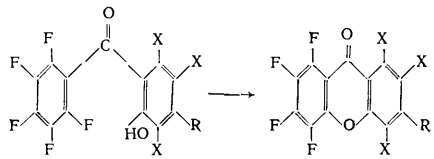
The ketyl radicals generated by irradiating decafluorobenzophenone in cyclohexane undergo recombination and radical–radical aromatic substitution reactions to give a tertiary alcohol and cyclohexylnonafluorobenzophenones[133]:



$$(C_6F_5)_2C{=}O \xrightarrow{h\nu} (C_6F_5)_2\dot{C}{-}\dot{O} \xrightarrow{RH} (C_6F_5)_2\dot{C}{-}OH \rightarrow C_6H_{11}\overset{OH}{\overset{|}{C}}(C_6H_5)_2 +$$
$$+ C_6F_5COC_6F_4C_6H_{11}\text{-}n + C_6F_5COC_6F_4C_6H_{11}\text{-}o \quad .$$

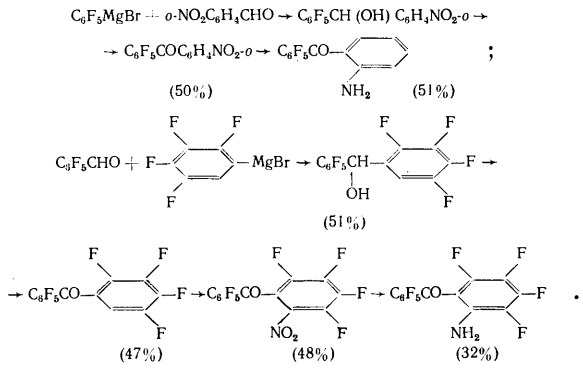
In contrast to its non-fluorinated analogue, decafluorobenzophenone does not give rise to perfluoropinacol (VIII) on irradiation in a hydrocarbon medium or in isopropyl alcohol even in the presence of reducing agents[40,133,138–140]. Evidently the dimerisation of ketyl radicals is difficult owing to the repulsion of the C_{ortho}–F bond dipoles and also owing to the shift of the unpaired electron density to the ring as a result of the electron-accepting influence of the fluorine atoms.

The pinacol (VIII) has been obtained by the photolysis of a solution of decafluorobenzophenone in perfluoromethylcyclohexane containing isopropyl alcohol[141]. It is unstable and decomposes in alcohols with formation of decafluorobenzophenone and decafluorodiphenylmethanol; in ether and hydrocarbons this process is much slower. The pinacols (IX) and (X), obtained by the photochemical reduction of octafluoroacetophenone[142] and pentafluorobenzophenone[40], are stable compounds:



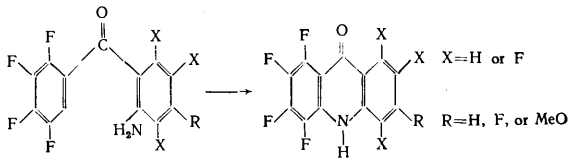
$$C_6F_5COR \xrightarrow{h\nu} C_6H_5(R)\,C\text{—}C(R)\,C_6F_5 \quad ;$$
$$\quad\quad\quad

chloride[36]:

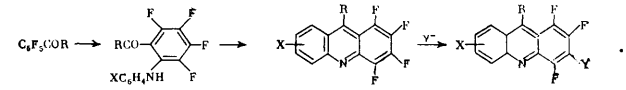


Ar=Ph or C_6F_5, X=H or F; R=H, MeO, or OH.

The presence of an intramolecular hydrogen bond, whose strength is comparable to that in non-fluorinated analogues, has been established in 2-hydroxypolyfluorobenzophenones by infrared and ultraviolet spectroscopy and ^1H NMR.[49] They readily undergo the intramolecular nucleophilic substitution of fluorine, giving rise to polyfluoroxanthones. The much milder, compared with 2-halogeno-2-hydroxybenzophenones[146], conditions in the cyclisation reaction, which partly occurs on simple dissolution in aqueous alkali or in polar solvents such as DMF, are due to the high nucleophilic mobility of the fluorine atoms in aromatic polyfluoroketones. Polyfluoroxanthones have been obtained in high yields on refluxing 2-hydroxypolyfluorobenzophenones with anhydrous KF in acetone or under the influence of ignited potassium carbonate in DMF at room temperature[36]:



X=H or F; R=H, OH, or MeO.



The reactions of aromatic polyfluoroketones with aqueous ammonia and aliphatic amines in organic solvents leads to the preferential substitution of the *p*-fluorine atom[48,77] and cannot therefore be used as a method for the synthesis of *o*-aminoketones. They were synthesised by the reduction of the corresponding nitro-compounds, which were obtained in their turn from aromatic carbonyl compounds and polyfluorophenylmagnesium bromides in accordance with the schemes presented below[41,43,45]:

2-Aminopolyfluorobenzophenones have been converted into polyfluoroacridones by electrolytic oxidation or by heating with KF in anhydrous DMF:[41,45]:

The above methods for the synthesis of polyfluoroacridine derivatives can be of no preparative value in view of the large number of their stages and their limited applicability. A more promising approach has been demonstrated in other studies[80,81,147,148]. It includes as the first stage the nucleophilic substitution of the *o*-fluorine atom in aromatic polyfluoro-substituted carbonyl compounds by an arylamino-group and makes it possible to obtain a large set of polyfluoroacridines from readily available aromatic polyfluoro-compounds:

Thus the chemical properties of aromatic polyfluoro-substituted aldehydes and ketones are to a large extent different from those of their non-fluorinated analogues. The presence in their molecules of several electron-accepting fluorine atoms not only alters their reactivity in relation to nucleophiles but also greatly complicates the reactions owing to the ease of the haloform decomposition with ejection of the relatively stable polyfluorophenyl anion, and also because of the possibility of the nucleophilic substitution of one or several fluorine atoms. This wide variety of chemical reactions of aromatic polyfluoro-substituted carbonyl compounds and their relative availability are responsible for the continued interest in these compounds by investigators and lead to wide possibilities for synthesis.

The Synthesis of Carbohydrates from Formaldehyde

T.I.Khomenko, M.M.Sakharov, and O.A.Golovina

The problems of the synthesis of carbohydrates from formaldehyde are examined and the catalysts and conditions of the synthesis are described. The kinetics and current ideas concerning the mechanism of this process as well as different versions of its application in the regeneration of food products in manned spacevessels are discussed. The bibliography includes 141 references.

I. INTRODUCTION

The rapid growth of the duration of space flights has given rise to new problems in the field of the construction of life support systems for the crews of space vessels. It is already insufficient merely to eliminate harmful substances from the atmosphere of the cabin in the space vessels and to provide stores of substances ready for consumption—water, oxygen and food. In the flights of manned spaceships and stations not less than 4–5 litres of water[1], approximately 1 kg of oxygen[2], and 1–1.3 kg of food[3] is the daily requirement per member of the crew. These figures show that space flights lasting several months require at least partial regeneration of water and oxygen, so that the starting weight of manned space vessels is not unduly large; for flights lasting more than a year the problem of the regeneration of food products becomes of urgent importance.

There is a possibility of two fundamentally different ways of constructing a life support system in space vessels: on physicochemical and biotechnical bases. Studies in both fields are in the initial stage.

Table 1. The compositions and caloric values of the diet of cosmonauts.

Spacevessel	Content of food products			Moisture, ml	Caloric value, kcal
	proteins, g	fats, g	carbohydrates, g		
Soyuz-3	120.9	118.5	267.1	521.5	2755.0
Soyuz-4, Soyuz-8	110.7	98.2	297.0	672.0	2586.0
Soyuz-9	109.7	100.3	339.2	756.3	2852.0
Soyuz-10, Soyuz-23	126.5	116.7	338.3	697.8	2992.3
Soyuz-19	129.2	135.1	289.5	747.6	2975.7
Salyut-3, Salyut-5	129.2	135.1	289.5	747.6	2975.7

Table 1 presents data[3] concerning the composition and caloric value of the food consumed by cosmonauts in Soviet spaceships and stations. Evidently the fraction of carbohydrates in the cosmonauts' food ration is more than 60% of the entire dry weight of the food, reaching in terms of weight 270–350 g per day. In view of the dominant carbohydrate content in the food, the attention of investigators should be devoted to the search for physicochemical or biotechnical methods of synthesis of carbohydrates from the main final products of the vital activity of the human organism—carbon dioxide and water.

At the present time only one suitable chemical synthesis of carbohydrates from simple molecules is know—the condensation of formaldehyde in aqueous solutions in the presence of a number of organic bases as process catalysts. This procedure was discovered by Butlerov as early as 1861.[4,5]

The synthesis of formaldehyde from CO_2 and H_2O under the conditions of the spaceship could be achieved in the following two ways[2]: by hydrogenating carbon dioxide to methane and by oxidising the latter to formaldehyde:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad ,$$
$$CH_4 + O_2 \rightarrow HCHO + H_2O \quad ,$$

or by hydrogenating carbon dioxide to methanol, the oxidation of which can also yield formaldehyde:

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O \quad ,$$
$$CH_3OH + {}^1/_2O_2 \rightarrow HCHO + H_2O \quad .$$

The first procedure can be achieved under atmospheric pressure, which is extremely important in relation to the conditions in space vessels. However, it is not so far been possible to overcome a number of significant disadvantages of this method of synthesis of formaldehyde—low selectivity in the oxidation of methane to formaldehyde and low yields of the latter under optimum process conditions. The second method is free from these disadvantages, but the need to use high pressures in order to obtain methanol at the present level of technology precludes its employment in space vessels.

Since the synthesis of formaldehyde by the above methods in space vessels is in principle feasible, the interest in the synthesis of carbohydrates from formaldehyde as an acceptable concluding stage in the conversion of the final products of the vital activity in a manned spaceship to food products is understandable. Hexoses, which are the most valuable carbohydrates as regards food, can be obtained by the condensation of six formaldehyde molecules:

$$6HCHO \rightarrow C_6H_{12}O_6 \quad .$$

However, a significant disadvantage of the synthesis of carbohydrates from formaldehyde, which has still not been overcome, is the low selectivity of this process. Apart from the small fraction of hexoses which can be assimilated by the human organism (D-modifications of glucose, fructose,

galactose, and mannose), the main bulk of the products of the synthesis consists of non-assimilable carbohydrates. This disadvantage of the method is aggravated by the formation of appreciable amounts of branched carbohydrates[6], which, according to some hypotheses, may exhibit a toxic activity when taken with food. Therefore, despite the fact that the synthesis of carbohydrates from formaldehyde takes place under readily realisable conditions—in aqueous solutions at atmospheric pressure and temperatures only a little above room temperature—it is not so far used in practice.

For the synthesis to be carried out in practice, it is necessary to increase greatly its selectivity, which requires detailed information about the kinetics and mechanism of the process. Particular attention has been devoted to these problems in studies during the last decade, in which the classical kinetic methods have been supplemented by an improved chromatographic technique for the analysis of products and by isotopic and spectroscopic methods. The use of a gradient-free reactor made it possible to obtain particularly valuable information about the kinetics of the synthesis. The search for optimum catalysts and conditions for the synthesis of carbohydrates is being vigorously prosecuted.

This review deals with the following problems: catalysts and conditions of the synthesis of carbohydrates from formaldehyde and the kinetics and mechanism of the process. In the concluding section of the review different versions of the application of this process in the regeneration of food products in manned space vessels are discussed.

II. CATALYSTS AND CONDITIONS FOR THE CONDENSATION OF FORMALDEHYDE TO CARBOHYDRATES

As already mentioned, sugars were obtained from formaldehyde for the first time by Butlerov[4,5]. The reaction took place in an aqueous solution at 100 °C using $Ca(OH)_2$, $Ba(OH)_2$, Na_2CO_3, and K_2CO_3 as catalysts. Subsequently a wide range of inorganic compounds were tested for catalytic activity in this process. Thus Loew[7-12] used in 1886 calcium hydroxide with added NaCl, KNO_3, and CH_3COONa as catalyst and observed that among these salts only NaCl has no inhibiting effect. According to Loew's data, sugars are formed when formaldehyde is acted upon by alkaline earth metal carbonates and lead oxide. In subsequent studies DL-fructose, DL-glucose, DL-sorbose, and DL-arabinose were isolated from syrups obtained by Loew's method[13-15].

The influence of calcium, barium, sodium, and iron hydroxides as well as $CaCO_3$ on the condensation of formaldehyde was investigated[16-18] and it was established that calcium hydroxide is the best catalyst. The use of potassium, sodium, and calcium phosphates[19] did not yield a positive result; when $MgSO_4$ was employed, it was possible to obtain a syrup in which fructose, sorbose, and arabinose were identified.

Schmalfuss[20-22] achieved for the first time the condensation of formaldehyde to carbohydrates at a high pressure and temperature (2 atm, 120 °C). MgO, Al_2O_3, CaO, $Ca(OH)_2$, NaOH, and $Al(OH)_3$ were used as catalysts. The carbohydrates were formed in all cases except when Al_2O_3 and $Al(OH)_3$ were used. In the presence of NaOH carbohydrates were formed 2 min after the start of the experiment but then began to decompose very rapidly. In the 1950's[23] a new highly active catalyst (TlOH) was introduced, the synthesis of carbohydrates in its presence being completed after 20 min at 60 °C. The activity of magnesium, calcium, zinc, cadmium, mercury, aluminium, lead, tin, antimony, bismuth, and manganese oxides has been investigated[24,25] in the condensation reaction. It was noted that only magnesium, calcium, and lead oxides exhibit a catalytic activity in the temperature range 75–100 °C.

Thus by the end of the 1960's it was established that the most active catalysts in the condensation of formaldehyde to carbohydrates are fairly strong bases—alkaline earth metal hydroxides and oxides, thallium hydroxide, and lead oxide. In subsequent years it was observed that certain tertiary amines[26], lanthanice hydroxides[27,28] and aluminosilicates[29,30] can function as condensation catalysts.

The catalytic activities of the following tertiary amines have been demonstrated[26]: triethanolamine, dimethylaminoethanol, pyridine, *N*-methylpiperidine, α-picoline, collidine, *N*-methylmorpholine, tetraethylammonium hydroxide, and a mixture consisting of β and γ-picolines. Their activities are appreciably lower than those of alkaline earth metal hydroxides. When the above organic bases are used as catalysts, the synthesis must be carried out at high temperatures (100 °C) and as a rule in the presence of a large excess of the base relative to formaldehyde. The catalytic activities of the organic bases have been confirmed[31]. Berlin and coworkers[27,28] observed a catalytic activity of lanthanide (La, Tb, Ho, Tm, Gd, Dy, Er, Sm, and Yb) hydroxides in the synthesis of carbohydrates at high temperatures (optimum process conditions 110 °C and 1.8 atm).

In contrast to early studies, Gable and Ponnamperuma[29] found that appreciable amounts of carbohydrates are obtained after a boiling solution of formaldehyde has been in contact with Al_2O_3 for 5 h. According to their data, the formation of hexoses in the presence of Al_2O_3 is favoured by the use of low formaldehyde concentrations (10^{-2} M). They also showed[29] that aluminosilicates such as kaolinite and illite are catalytically active in the synthesis of carbohydrates. Appreciable amounts of carbohydrates are formed in their presence after many hours of contact with a boiling solution of formaldehyde. It has been shown[30] that the NaX zeolite exhibits an appreciable catalytic activity in the synthesis of carbohydrates at 95 °C when the pH of the solution is sufficiently high (>10 at the outlet from the flow reactor).

Appreciable formation of carbohydrates has been observed[32] on prolonged refluxing of formaldehyde with a suspension of a carbonate-containing apatite.

III. GENERAL CHARACTERISTICS OF THE CONDENSATION REACTION

In the very earliest studies[8-12] it was already observed that the condensation of formaldehyde to carbohydrates is accompanied by the dismutation reaction

$$2CH_2O + H_2O \rightleftarrows CH_3OH + HCOOH$$

which leads to the formation of formic acid and methanol (the Cannizzaro reaction).

In 1895 Henry[33] identified glyceraldehyde and dihydroxyacetone in the formaldehyde condensation products and suggested that they are intermediates in the formation of hexoses. Neuberg[34] suggested in 1902 that glycolaldehyde is the first condensation product and is formed from formaldehyde at a low rate. According to Neuberg, the reaction is autocatalytic and heavier carbohydrates (starting from C_3) are formed at high rates.

In 1915 Franzen and Hauck[35] isolated salt-like compounds resulting from the combination of formaldehyde and calcium hydroxide and investigated the possibility of their presence as intermediates in the condensation reaction. They suggested

that in dilute solutions the first stage involves the interaction of methylene glycol (the main form of monomeric formaldehyde in aqueous solutions) with calcium hydroxide:

$$CH_2(OH)_2 + Ca(OH)_2 \rightarrow HOCH_2OCaOH + H_2O \quad .$$

In the next stage the interaction of two such molecules leads, in their view, to the formation of glycolaldehyde:

$$2HOCH_2OCaOH \rightarrow HOCH_2CHOHOCaOH + Ca(OH)_2.$$

However, Franzen and Hauck do not present any data in support of their ideas concerning the process mechanism apart from the possible composition of the salt-like products.

Schmalfuss[20-22] used for the first time as the catalyst the product of the condensation of formaldehyde carried out in the presence of MgO and observed its high catalytic activity. He also noted that the rate of condensation increases greatly following the addition of glucose to the reaction mixture. On the basis of these experiments, Schmalfuss arrived at the conclusion, reached previously by Neuberg, that the condensation is autocatalytic. This view was subsequently expressed by Trigerman et al. [36] Orther and Gerisch[37] analysed the composition of the products in the reaction carried out in the presence of lead hydroxide: after hydrogenation and subsequent fractionation of the condensate, it was possible to isolate glycerol, tetritols, pentitols, and hexitols. According to their reaction mechanism, carbohydrates ranging from C_3 to C_6 are formed via the self-condensation of formaldehyde, for example:

$$3CH_2O \rightarrow \text{trioses},$$

$$4CH_2O \rightarrow \text{tetroses, etc.}$$

Kuzin[38-44] continued Schmalfuss's experiments to elucidate the role of organic compounds added to the reaction mixture. He established that the addition of compounds such as polyhydric alcohols, acetone, penta-acetylfructose, and polysaccharides does not affect the rate of condensation when $Ca(OH)_2$ is used as for the catalyst. On the other hand, compounds such as hydroxyoxosuccinic acid, ethoxyacetaldehyde, benzoin, and acetoin eliminated or at least shortened the induction period on being added together with the hydroxide. Nowadays such compounds are regarded as cocatalysts. Kuzin attributed their catalytic activity to their ability to form enediols:

$$-\underset{\underset{OH}{|}}{CH}-\underset{\underset{O}{\|}}{C}- \rightleftarrows -\underset{\underset{OH}{|}}{C}=\underset{\underset{OH}{|}}{C}- \quad .$$

He regarded enolisation as a preliminary condition for the appearance of the activity of the cocatalyst.

Langenbeck[45-51] used as cocatalysts higher and lower monosaccharides, benzoylcarbinol, and a number of its derivatives. The kinetic measurements quoted by the authors show that the individual cocatalysts differ only by the induction period, and the corresponding kinetic curves are almost parallel. It was shown that glycolaldehyde and dihydroxyacetone are the most active cocatalysts. According to Langenbeck[47], the role of other cocatalysts, with a long induction period, reduces to the formation of glycolaldehyde or dihydroxyacetone with their participation. Langenbeck[51] suggested that the organic cocatalyst behaves as an activator of formaldehyde, which gives rise to glycolaldehyde on combining with a non-activated formaldehyde molecule:

$$R-CHOH-CO-R + CH_2O \rightarrow R-\underset{\underset{OH}{|}}{\overset{\overset{CH_2OH}{|}}{C}}-CO-R \rightarrow R-CHOH-CO-R + CH_2O^* \quad ;$$

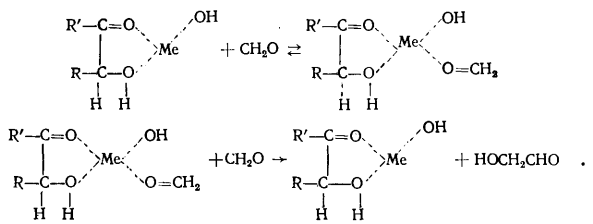
$$CH_2O^* + CH_2O \rightarrow CH_2OHCHO \quad .$$

Here CH_2O^* is an activated formaldehyde molecule. Like, incidentally, Kuzin, Langenbeck assumed that the hydroxide plays only a secondary role. According to Kuzin's views, the hydroxide promotes the formation of enediol groups, ensuring the required pH and interacting with the hydrated forms of the carbohydrates and formaldehyde. However, this treatment conflicts with the specific catalytic action of a number of cations, which has now been demonstrated.

The formaldehyde condensation reaction has been thoroughly investigated in a series of studies[23,52-52] using alkali and alkaline earth metal hydroxides as catalysts. The kinetics and mechanisms of the Cannizzaro reaction were especially considered. The experimental results showed that the weaker the base the more effectively does it catalyse the Cannizzaro reaction:

$$Ca(OH)_2 \gg Tl(OH)_3 > Ba(OH)_2 > LiOH > NaOH,\ KOH.$$

It was also shown that low-molecular-weight alcohols, ethylene glycol, glycerol, dioxan, and tetrahydrofuran, added to the reaction mixtures, suppress the Cannizzaro reaction and increase thereby the yield of sugars. On the basis of paper chromatographic analyses of the products, the authors concluded that the primary reaction products is glycolaldehyde, which then condenses either with itself or with formaldehyde to give a wide range of reaction products—from trioses to hexoses. A stepwise mechanism of the formation of higher carbohydrates by the successive addition of a formaldehyde molecule to molecules of lower carbohydrates was put forward for the first time taking into account the keto–enol tautomerism and epimerisation[55]. Furthermore, the authors took into account in their scheme the fact that higher carbohydrates can be formed from lower carbohydrates as a result of the self-condensation of the latter:

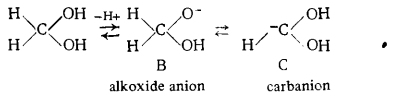


$$2CH_2OHCHO \rightarrow \text{tetroses},$$

$$2CH_2OHCHOHCHO \rightarrow \text{hexoses},$$

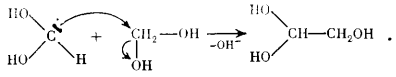
$$CH_2OHCHO + CH_2OHCHOHCHO \rightarrow \text{pentoses}.$$

It has been shown by a number of workers[56-62] that the carbohydrate self-condensation reactions proceed at a fairly high rate in alkaline solutions and should therefore play an important role in the mechanism of the formation of higher carbohydrates.



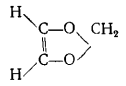
Pfeil and coworkers[56] suggested that the condensation proceeds at a complex of the undissociated metal hydroxide, the hydroxyoxo-compound, and formaldehyde:

Despite the fact that the existence of the complex of the hydroxyoxo-compound has not been demonstrated by any direct methods, one should note that Pfeil and coworkers were the first to draw attention to the possible decisive role of complexes of this kind in the synthesis of carbohydrates.



Other ideas about the mechanism of the action of bases on the condensation reaction were put forward by Runge and Mayer[26]. They established that in the presence of organic bases the Cannizzaro reaction does not take place. At the same time, under the influence of both inorganic and organic

bases (pyridine, dimethyl-aminoethanol, etc), the condensation reaction is characterised by an induction period and an autocatalytic period. The reaction time falls appreciably also after the addition of substances capable of forming enediol groups. The reaction mass, analysed by paper chromatography, does not differ in composition from the condensate obtained under the influence of an inorganic catalyst. On the basis of these extremely qualitative data, it was concluded that the mechanisms of the condensation reaction catalysed by organic and inorganic bases should be similar. Bearing in mind that organic catalysts such as tertiary amines cannot form complexes, Krylov et al.[27] proposed a mechanism in which a secondary role is assigned to the base. In the first stage a proton is abstracted in the presence of the base from the hydrated formaldehyde molecule with formation of structures corresponding to alkoxide and carbanionic forms:



B alkoxide anion C carbanion

In such a system there is a possibility, albeit with a low probability, of the interaction of the carbanions of formaldehyde and its hydrated molecules to form a glycolaldehyde molecule:

The autocatalytic nature of the process is caused, according to the authors[27], by the intermediate formation of the five-membered ring

from the enediol form of glycolaldehyde and formaldehyde and by the ease of the successive interaction of this ring with two other formaldehyde molecules to form a new glycolaldehyde molecule with regeneration of the ring.

This mechanism suffers from the same significant disadvantage as those of Kuzin and Langenbeck. It cannot explain the dependence, observed by Pfeil as early as 1952, of the rate of reaction on the nature of the cation. The possibility of the formation of a ring of the above type is also doubtful.

IV. CURRENT STUDIES ON THE KINETICS AND MECHANISM OF THE SYNTHESIS OF CARBOHYDRATES

The kinetics of the synthesis of carbohydrates have been investigated by Krylov, Sinyak, and others[63–67] using alkaline earth metal hydroxides as catalysts. According to these workers, calcium and strontium hydroxides are much more active than $Ba(OH)_2$ and $Mg(OH)_2$; no catalytic activity has been found in $Be(OH)_2$. It has been discovered that only at a CH_2O concentration below 0.5% is there a linear relation between the rate of reaction and the CH_2O concentration; on the other hand, in the range 2.5–10% the rate is independent of the CH_2O concentration. Experiments carried out in the presence of various monosaccharides (C_3–C_6) showed that the variation of the rate of reaction with the cocatalyst concentration is also non-linear. At a monosaccharide concentration below $(3–4) \times 10^{-2}$ M and for degrees of conversion of formaldehyde up to 50%, the reaction kinetics in the presence of $Ca(OH)_2$ and $Sr(OH)_2$ can be described satisfactorily by the autocatalytic equation[64,65]

$$\frac{dx}{dt} = K(c_0 - x)(x_0 + x),$$

where c_0 and x_0 are the initial concentrations of formaldehyde and the monosaccharide and x is the current concentration of the reaction products. It was found[65] that the autocatalytic effect diminishes with increase of the number of carbon atoms in the monosaccharide and also that ketoses are more active than aldoses.

On the other hand, comparative experiments on the kinetics of the condensation of formaldehyde in the presence of a specific amount of $Ca(OH)_2$ in the form of a suspension and after filtering off the insoluble calcium hydroxide, carried out by the same workers[68], showed that the kinetic curves for the consumption of formaldehyde coincide. These experiments demonstrated the homogeneity of the reaction involving the condensation of formaldehyde to a sugar in the presence of $Ca(OH)_2$. Evidence for the homogeneous-catalytic nature of the process in the presence of $Ca(OH)_2$ was also obtained in other investigations[69–72].

The observed appreciable increase of the solubility of $Ca(OH)_2$ under the conditions of the synthesis has been explained[68] by the formation of a complex of the Ca^{2+} ion with formaldehyde and the reaction product—monosaccharides. The authors concluded that the elementary stages of the reaction take place in the coordination sphere of the catalytically active cation and put forward the following general kinetic equation for the reaction:

$$-\frac{d[CH_2O]}{dt} = k[Ca(OH)_2] \cdot \frac{b[CH_2O]}{1 + b[CH_2O]} \cdot \frac{b'[Pr]}{1 + b'[Pr]},$$

where b and b' are the complex formation equilibrium constants analogous to adsorption coefficients and Pr are reaction products. Different stages of the reaction are characterised by different reaction orders:

(1) For low conversions, when the concentration of CH_2O is low $\{b[CH_2O] \gg 1\}$ and

$$-\frac{d[CH_2O]}{dt} = k[Ca(OH)_2]\, b'[Pr]$$

the kinetics are described by the autocatalytic equation;

(2) For high conversions $\{b'[Pr] \gg 1\}$ and

$$-\frac{d[CH_2O]}{dt} = k[Ca(OH)_2]\, b[CH_2O]$$

the reaction is of first order with respect to formaldehyde:

(3) For moderate conversions $\{b[CH_2O] > 1;\ b'[Pr] > 1\}$, we have

$$-\frac{d[CH_2O]}{dt} \simeq k[Ca(OH)_2],$$

i.e. the reaction is of zero order with respect to formaldehyde.

Another important result of the investigations by the same workers was the discovery of a new class of catalysts—lanthanide hydroxides[27,28,73,74]. The authors suggested that new catalysts should be sought among the hydroxides of metals whose ionic radius is close to that of the metals in the catalysts already known. According to this hypothesis, the hydroxides of elements whose ionic radii is between 0.98 and 1.15 Å (Ca^{2+}–1.06 Å, Tl^{3+}–1.05 Å) should catalyse the condensation of formaldehyde to sugars. In this instance the groups of catalytically active cations includes those of lanthanide metals. Indeed, in the presence of La, Tb, Ho, Tm, Gd, Dy, Er, Sm, and Yb hydroxides, 100% conversion of formaldehyde was reached in the process after 5–6 h in an autoclave at 110 °C and a pressure of 1.8 atm. As for other catalytically active bases, the kinetics of the decrease

of the amount of formaldehyde were characterised by an induction period and auto-catalytic acceleration. The fact that the reaction proceeds wholly in an acid medium (the pH of the initial solutions at 110 °C in the presence of various catalysts varied in the range from 7 to 4) is of great interest. The conversion of formaldehyde via the Cannizzaro reaction takes place to an insignificant degree and the selectivity of the synthesis of carbohydrates in the presence of these catalysts is therefore greater than in the presence of $Ca(OH)_2$. These studies showed that the region where the condensation reaction can occur is not limited to an alkaline medium.

A kinetic equation analogous to that quoted by Krylov et al.[27] was obtained simultaneously and independently by Weiss et al.[75]. In a series of studies, carried out under Weiss's supervision, a detailed investigation was made of the kinetics of the condensation of formaldehyde in the presence of $Ca(OH)_2$ in a gradient-free reactor. At the same time a study was made of the Cannizzaro reaction[76]. The authors[75] began with the hypothesis that the following reactions take place in the formation of carbohydrates:

$$A_1 + Ca(OH)_2 \rightleftarrows A_1^* \quad , \qquad (1)$$

$$A_n + Ca(OH)_2 \rightleftarrows A_n^* \quad , \qquad (2)$$

$$A_n^* + A_1^* \rightleftarrows A_{n+1}^* + Ca(OH)_2 \quad , \qquad (3)$$

$$A_{n+1}^* \rightarrow A_{n+1} + Ca(OH)_2, \qquad (4)$$

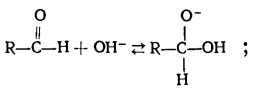
where A_1 is formaldehyde, A_n a carbohydrate with n carbon atoms in the chain, and A_1^* and A_n^* are complexes of $Ca(OH)_2$ with formaldehyde and the carbohydrate respectively. In conformity with literature data[35,77], according to which formaldehyde and low-molecular-weight carbohydrates form complexes relatively readily, the authors[75] believe that stages (1) and (2) cannot be rate-limiting. The relatively low activation energy (16 kcal mol^{-1}) found by the authors made it possible to assume that stage (3) is likewise not rate-limiting. Assuming that stage (4) is rate-limiting, the authors derived the following equation:

$$r_F = k_4 K_1 K_2 K_3 S A_1 A_n / (1 + K_1 A_1 + K_2 A_n + K_1 K_2 K_3 A_1 A_n),$$

where r_F is the rate of reaction, K_1, K_2, and K_3 are the equilibrium constants of stages (1), (2), (3), k_4 is the rate constant for stage (4) in the forward direction, A_1 and A_n are the concentrations of formaldehyde and the carbohydrate respectively, and S is the concentration of $Ca(OH)_2$ equal to the sum of the concentrations of the hydroxide in a free state and in the form of a complex.

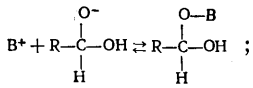
The equation obtained gives a formally satisfactory description of the observed kinetic relations for the reaction: autocatalysis for low conversions, zero order for intermediate conversions, and first order with respect to formaldehyde for high conversions. However, the above mechanism does not include the slowest stage, involving the dimerisation of formaldehyde, and cannot therefore explain the nature of the autocatalysis. In their purely kinetic study, Weiss and coworkers did not have as their aim a special investigation of the nature of the intermediate complexes. At the same time, the authors first complete analysis of the reaction products by a combination of gas chromatography and mass spectrometry[6,78,79] was a major step forward in this field. An important result of their investigation was the detection of a considerable content of branched carbohydrates in the reaction product.

Following Breslow[80,81], Weiss et al.[75] attribute an important role in the process to the Lobry de Bruyn–van Ekenstein rearrangement, the occurrence of which determined the ratio of the aldoses and ketoses in the reaction products. The rearrangement is based on the formation of the enediol form from the carbonyl form. As a result of the reversibility of this process, there is a possibility of the reformation of the carbonyl form together with its epimer and the ketose. The reaction is catalysed by both acids and bases. This rearrangement therefore always accompanies the condensation reaction, complicating the composition of the final products.



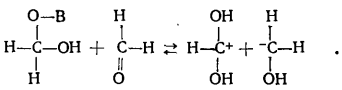
Weiss and coworkers[75,76] also investigated the ratio of the rates of the condensation and Cannizzaro reactions. The rate of the latter passes through a maximum near 50% conversion.

A single mechanism has been proposed for the Cannizzaro reaction and the reaction involving condensation to sugars[82]. On the grounds that the reaction does not require high concentrations of calcium cations, the authors conclude that the entire process is catalysed by the singly dissociated form of the calcium hydroxide formed on dissolution of $Ca(OH)_2$:



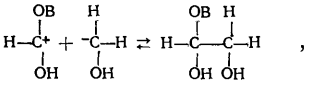
$$Ca(OH)_2 \rightleftarrows CaOH^+ + OH^- \quad ,$$
$$CaOH^+ \rightleftarrows Ca^{2+} + OH^- \quad .$$

The overall mechanism is based on the hypothesis of the decisive role of the interaction of the carbonion and the carbonium ion formed from formaldehyde molecules via the following mechanism:

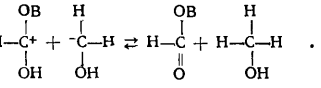


(a) the aldose or formaldehyde interacts with a hydroxide ion to form the anionic form:

(b) the anionic form interaction with the hydroxide cation (in the present instance, with $CaOH^+$), giving rise to a salt-like complex:



(c) the initiation of the condensation begins with the transfer of a hydride ion from the salt-like formaldehyde complex to a free formaldehyde molecule:



After this, two reactions pathways are possible:

(d) either recombination of the ions with formation of carbohydrate molecules—condensation (in the simplest case a salt-like complex of glycolaldehyde is produced):

(e) or proton transfer from the carbonium ion with formation of methanol (or a polyol) and a formate (the Cannizzaro or cross-Cannizzaro reactions):

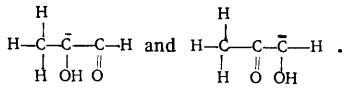
It is believed[82] that the nature of the base affects the ratio of the rates of the last two stages and is therefore responsible for the process selectivity. The authors think that stage (d) is highly reversible on the grounds that, for low conversions, small amounts of glycolaldehyde are formed, while stage (e) is almost irreversible. Stage (d) explains the formation of the first condensation products. Further formation of carbohydrates proceeds mainly as a result of the aldol condensation, which the authors believe is also based on stage (d). However, the transfer of a hydride ion is inconsistent with modern ideas concerning the mechanism of the aldol condensation and requires at least special demonstration.

In the same study[82] the authors observed instances of instability of the rate of reaction for slight changes in the concentrations of the hydroxide and the components of the reaction, the pH, or temperature. The authors attribute this instability to the specific features of the autocatalytic reaction in a gradient-free reactor. The possibility of concentration instabilities in autocatalytic processes has been accounted for theoretically[83].

An interesting phenomenon—the inhibiting effect of transition metal hydroxides on the condensation of formaldehyde in the presence of calcium hydroxide—has been observed by Morozov and Levanevskii[84]. In their experiments $\sim 10^{-4}$ M transition metal hydroxide was introduced into the reaction mixture in the presence of a $Ca(OH)_2$ concentration of $\sim 10^{-2}$ M. As a rule, an appreciable increase of the induction period was observed. The induction period was longest in the presence of Fe^{2+} and Mn^{2+}. Under these conditions, the Cannizzaro reaction was not inhibited. It was established that the nature of the kinetic curves depends on the instant when the inhibitor is introduced and on the nature of the cocatalyst. The introduction of monosaccharides, such as C_2 and C_3, into the reaction mixture reduces the inhibition.

It was later established[85] that the inhibiting effect on the synthesis in the presence of $Ca(OH)_2$ can also be shown by lanthanide hydroxide. The experiments were performed at 60 °C and a concentration of hydroxides of $\sim 10^{-4}$ M. Praseodymium(III), gadolinium(III), terbium(III), and ytterbium(III) hydroxides have the strongest inhibiting effect. Lanthanum(III), europium(III), dysprosium(III), and erbium(III) hydroxides are weak inhibitors. Cerium(III), neodymium(III), samarium(III), holmium(III), and thulium(III) hydroxides exhibit an intermediate inhibiting activity. The composition of the condensation products is in all cases almost the same as in the presence of pure calcium hydroxide. The main reaction products are pentoses and hexoses. The addition of glyceraldehyde to the initial mixture reduced the inhibiting effect of lanthanide hydroxides. On the basis of these results, the authors conclude that the inhibiting effect of transition metal and lanthanide hydroxides is associated with the inhibition of the slowest stage—involving the formation of a molecule of glycolaldehyde from two formaldehyde molecules. The authors do not discuss the reasons why lanthanide cations, which are catalytically active in the synthesis of carbohydrates in the absence of calcium hydroxide, exhibit an inhibiting effect when the latter is introduced. In the same study[85] inhibitors of another type, inhibiting the condensation proper, were investigated. They include nitrobenzene and copper hydroxide. The inhibition at this stage is associated with the oxidative breakdown of the organic cocatalyst—the carbohydrate formed during the induction period. Such inhibition was first discovered by Langenbeck[47].

The condensation of formaldehyde to carbohydrates has been investigated in the presence of lead oxide[72,86-90]. The authors found that, in the presence of PbO, the rate of conversion of CH_2O into carbohydrates is independent of the surface area of the catalyst. As in the experiments with alkaline earth metal hydroxides, sugars greatly accelerate the reaction. The authors believe that these findings indicate a homogeneous autocatalytic mechanism of the condensation of CH_2O in the presence of PbO, which forms a soluble catalytically active complex with carbohydrates.

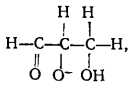


The influence of added alkaline earth and lanthanide oxides [MgO, CaO, BaO, Dy_2O_3, Sm_2O_3, and $Eu(OH)_3$] as well as the oxides of variable-valence metals tending to form complexes (Fe_2O_3, Co_2O_3, ZnO, and CuO) on the rate of condensation under the influence of the lead catalyst has been investigated[87]. The oxides were introduced at concentrations of 10 wt.% relative to the weight of PbO and 1 wt.% relative to the weight of CH_2O. It was found that BaO, CaO, and MgO intensify the effect of lead oxide, a synergistic and not an additive effect being produced. Lanthanide oxides have an inhibiting effect, while the oxides of effective complex-forming metals, cobalt(III) and copper(II), are still more powerful inhibitors. The addition of Fe_2O_3, and NiO, and ZnO has almost no influence on the condensation reaction.

One should also note that the condensation in the presence of both pure PbO and a mixture of oxides proceeds at comparatively low pH values. Thus, for conversions α not exceeding 25% in an experiment with pure PbO, the pH is 6.8 ($\alpha = 16\%$), while in the presence of added MgO ($\alpha = 7\%$), CaO ($\alpha = 25\%$) and BaO ($\alpha = 20\%$) the pH values are 8.9, 7.5, and 6.7 respectively. The condensation does not begin at pH values below 5 and is appreciably accelerated when the initial pH is raised to 8.0, while in the presence of $Ca(OH)_2$[71,72] at 50 °C the synthesis no longer occurs even at pH less than 9.5. According to the authors[87], the action of metal oxide added to PbO consists both in altering the pH and in the involvement of the dissolving metal ions in complex formation, which promotes or hinders the formation and subsequent reactions of complexes capable of propagating the condensation process. It has been suggested that the synergism may be associated with the formation of polynuclear complexes with a higher catalytic activity than the complexes of lead alone. The inhibiting effect of a number of oxides is attributed to the possibility of the decomposition of catalytically active complexes on the surface of these oxides.

The attempt to demonstrate with the aid of ultraviolet spectroscopy the formation of complexes of glucose and the products of condensation with PbO did not yield clearcut results[88,89]. In a study over a comparatively narrow spectral range (40000–54000 cm^{-1}), adjoining the far ultraviolet, the authors observed in the spectra of solutions of PbO containing glucose and the condensate an intense band having a maximum at ~ 48000 cm^{-1}, corresponding to the Pb^{2+} ion. The appearance of this band, which is absent from the spectra of aqueous solutions of PbO owing to the low solubility of the latter, was attributed to the formation of lead complexes with glucose and other carbohydrates. The absence of other specific bands in this part of the spectrum did not allow the authors to put forward a hypothesis concerning the possible structure of the complexes.

Other ideas about the mechanism of the condensation of formaldehyde have been put forward[91-97]. The mechanism proposed by the above workers is based on the hypothesis that the active intermediate compounds are the carbanionic forms of formaldehyde and the carbohydrates. For glyceraldehyde and dihydroxyacetone, this form is, according to the authors, the carbanion R^-, having the following limiting



structural formalae:

The mechanism of the condensation of formaldehyde in the absence of an organic cocatalyst is not considered by the investigators. The following pathways leading to the formation of carbanions R^- are postulated: (a) via the interaction with hydroxide ions ($C_{3A} + OH^- \rightarrow R^- + H_2O$) and (b) as a result of the interaction with formaldehyde or glyceraldehyde alkoxide anions:

$$C_{3A} + C_{3A}^- \rightarrow R^- + C_{3A}\ , \quad C_{3A} + F^- \rightarrow R^- + F\ ,$$

where C_3A is a molecule of glyceraldehyde and C_{3A}^- is its alkoxide anion having the structure

F^- is the alkoxide anion derived from formaldehyde, and R' is the glyceraldehyde carbanion.

The carbanion is consumed in the condensation reaction, in isomerisation to a dihydroxyacetone molecule, and in the formation of alkoxide anions derived from formaldehyde and trioses. The proposed overall mechanism consists of eleven stages, taking into account the processes enumerated above, and of four possible processes involving the formation of alkoxide anions:

$$OH^- + F \rightleftarrows F^- + H_2O,\ OH^- + C_{3A} \rightleftarrows C_{3A}^- + H_2O\ ,$$
$$OH^- + C_6 \rightleftarrows C_6^- + H_2O\ ,\quad OH^- + C_4 \rightleftarrows C_4^- + H_2O\ .$$

The authors were the first to take into account the equilibrium between the monomeric formaldehyde and its polymeric forms[94]. Applying the principle of steadystate values in relation to R^-, the authors determined the ratio of the rate constants for the following stages:

$$R^- + C_{3A} \xrightarrow{k_1} C_{3K} + C_{3A}^-\ ,\quad R^- + H_2O \xrightarrow{k_2} C_{3K} + OH^-\ ,$$
$$R^- + F \xrightarrow{k_3} C_4^-\ ,\quad R^- + C_{3A} \xrightarrow{k_4} C_6^-\ .$$

where C_3K is a dihydroxyacetone molecule. The following values were obtained: $k_3/k_4 = 0.6$, $k_2/k_4 = 0.15$ mol litre^{-1}, and $k_1/k_4 = 0.03$.

Salt-like compounds of formaldehyde and hydrocarbons with calcium hydroxide, analogous to the compounds isolated by Franzen and Hauck[35], were isolated in two investigations[95,96]. However, the authors[95,96] believe that these compounds do not play a significant role in the condensation mechanism. The possible causes of the specific action of the cations derived from the hydroxides on the rate and selectivity of the synthesis have not been considered[91-97].

Towards the end of the 1960's and the beginning of the 1970's, studies on the reaction mechanism as well as those designed to elucidate the possible practical applications of the carbohydrates obtained were initiated by Japanese investigators. Nakai et al.[98] investigated the condensation in the presence of $Ca(OH)_2$ at 50 °C and found that the yield of sugars per gram of formaldehyde is a maximum when solutions with formaldehyde concentrations in the range of 0.81–4.05% are used. The employment of small amounts of monosaccharides as cocatalysts tends to increase the yield of sugars and decrease the reaction time. As in an earlier study[65], it was found that ketoses are more effective as cocatalysts than aldoses.

Mizuno et al.[31] investigated the catalytic activity of a number of inorganic and organic bases in the condensation reaction: $Ca(OH)_2$, $Ba(OH)_2$, $Sr(OH)_2$, $Mg(OH)_2$, $Pb(OH)_2$, KOH, TlOH, pyridine, picoline, collidine, *N*-methylpiperidine, *N*-methyl-morpholine, 2-(dimethylamino)ethanol, triethanolamine, and tetraethylammonium hydroxide. According to their data[31], the best catalyst at 50 °C is $Ca(OH)_2$ (the yield of carbohydrates is 55%). The sugars were analysed by all possible chromatographic methods: paper, thin-layer, gas–liquid, and liquid adsorption chromatography[99,100]. The authors were able to identify 33 carbohydrates ranging from C_2 to C_7, the main components being hexoses and pentoses. Methods for the isolation of various carbohydrates for subsequent toxicological tests have been developed[101,102].

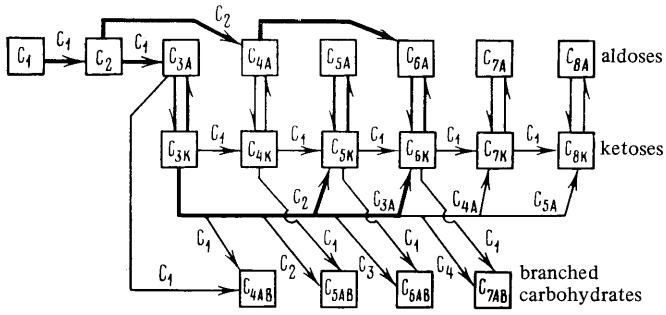


Figure 1. Schematic illustration of the formation of carbohydrate products in the formaldehye condensation reaction (according to Mizuno[103]); C_iA = aldoses with i carbon atoms; C_iK = ketoses with i carbon atoms; C_iAB = branched carbohydrates with i carbon atoms.

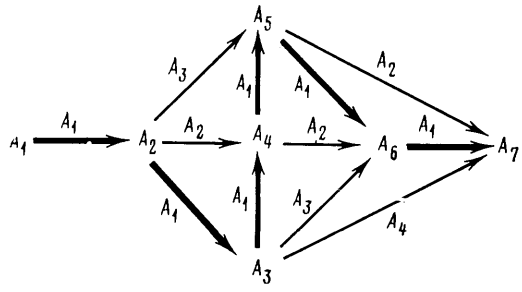

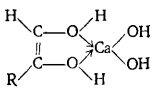

Figure 2. Schematic illustration of the formation of carbohydrate products in the formaldehyde condensation reaction (according to Weiss et al.[75]); A_i = carbohydrate with i carbon atoms. Thick arrows—tentative pathway leading to the formation of carbohydrates.

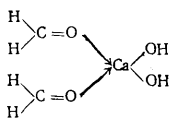
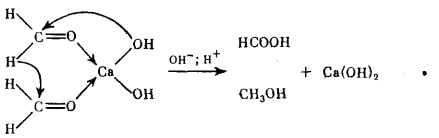
On the basis of gas-chromatographic and mass-spectrometric analyses of the reaction products, a new condensation mechanism (Fig.1), differing appreciably from Weiss's scheme[75] (Fig.2), has been proposed[103]. The controversial hypothesis has been put forward that, among all the carbohydrates, starting from C_3, only ketoses undergo cocondensation with formaldehyde. However, according to Mizuno, this is not

the main reaction pathway. According to the scheme in Fig.1, C_4 aldoses are formed mainly as a result of the self-condensation of glycolaldehyde, while C_6 aldoses are produced by its cocondensation with tetroses. Among ketoses, the highest reactivity is attributed to dihydroxyacetone. Its cocondensation with glycolaldehyde is regarded as the main pathway leading to the formation of pentoses and its cocondensation with glyceraldehyde is believed to be the main pathway to the ketohexoses. In the transformations of tetroses the Lobry de Bruyn–van Ekenstein equilibrium is not considered (without adequate justification). The controversial nature of a number of postulates of the above mechanism is evidently due to the limited amount of experimental data on which it is based.

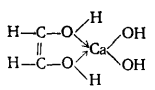


Fujino and Kobayashi[69,70] were the first to draw attention to the structure of the intermediate compounds of carbohydrates with hydroxides, which apparently play the role of condensation catalysts. The existence of these compounds has been postulated but has been in no way demonstrated in the series of the above studies. Fujino and Kobayashi[69,70] investigated the physicochemical properties of homogeneous systems such as CaO–glucose and CaO–xylose obtained after prolonged mixing of CaO with the carbohydrates at 10 °C and after filtering off the undissolved CaO. The study was carried out by NMR and infrared spectroscopy. On the basis of the results, the authors concluded that complexes of the calcium hydroxide with carbohydrates, having the structure



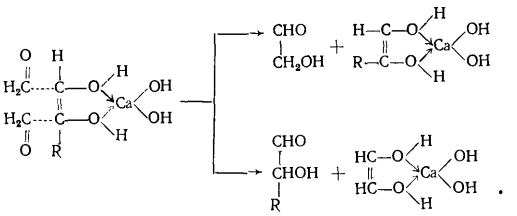
(I)

are formed.



Fujino and Kobayashi[69,70] performed experiments on the condensation of formaldehyde at 50 °C in the presence of complexes of calcium hydroxide with glucose and xyloses and also with formaldehyde, prepared beforehand by the method indicated above. The results of these experiments led to the conclusion that, under the formaldehyde condensation conditions, two types of calcium hydroxide complexes are formed: (1) with the carbohydrate in the enediol form, having the structure given above and (2) with formaldehyde. having the structure

The complexes of the first type catalyse the condensation to carbohydrates and those of the second type catalyse the Cannizzaro reaction via the mechanism



In the absence of an organic cocatalyst, there is, however, a possibility of the formation of the complex

(II)

This complex of glycolaldehyde and the hydroxide has an enediol group and, like complex (I), is the catalyst of subsequent condensation, which proceeds via the following mechanism according to the authors:

The rate constants for the synthesis of carbohydrates and the Cannizzaro reaction in the presence of alkaline earth metal hydroxides have also been determined[70]. When glucose was used as the cocatalyst, their activity in the synthesis of carbohydrates fell in the sequence

$$Ca(OH)_2 > Sr(OH)_2 > Ba(OH)_2.$$

An analogous activity series had been established earlier[64]. The activity series of the above hydroxides for the Cannizzaro reaction in the presence of glucose is the opposite to that found for the synthesis of carbohydrates, while in the absence of glucose it is identical. The authors[70] also found the ratios of the zero-order rate constants for the synthesis of carbohydrates and the Cannizzaro reaction at 50 °C:

$Ca(OH)_2$	$Sr(OH)_2$	$Ba(OH)_2$
4.1	2.1	0.73

These ratios virtually agreed with the ratios of the degrees of involvement, determined previously[26], of CH_2O in the synthesis of carbohydrates and in the Cannizzaro reaction (4.0 : 2.3 : 0.8).

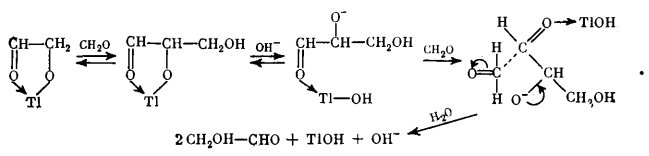
In recently published studies[104–106] an attempt was made to use the potentiometric method for the investigation of the kinetics of the synthesis of carbohydrates in the presence of $Ca(OH)_2$. The authors determined the end of the induction period from the time required for the attainment of a minimum in the oxidation-reduction potential of the reaction system, while the time required to reach its maximum corresponded, according to their data, to the complete conversion of formaldehyde. Using this relatively insensitive method, the authors found that, after the end of the induction period, the kinetics of the syntheses correspond to first order with respect to CH_2O and zero order with respect to $Ca(OH)_2$. Like Weiss and coworkers[82], they concluded that the true process catalyst is $CaOH^+$. Despite the contradictory nature of the kinetic relations found by these workers and by Weiss et al.[75], the former[104–106] believe that their investigation confirmed the mechanism of the synthesis of carbohydrates proposed by Weiss[82].

The result obtained[107] on precipitation of Ca^{2+} ions by oxalic acid at the end of the induction period is of interest. It was observed that, following the subsequent addition of KOH and the adjustment of pH to 12, the synthesis at 60 °C can be carried out selectively in the direction of the formation of a few branched carbohydrates and the corresponding alcohols (the alcohols 2-hydroxymethylglycerol, 2,4-hydroxymethylpentitol, and 3-hydroxymethylpentitol are formed preferentially).

Harsch et al.[108] used for the first time high-pressure liquid chromatography to obtain kinetic data for the change in the content of products during the synthesis of carbohydrates from formaldehyde. They studied model reactions

involving the cocondensation of formaldehyde with glycolaldehyde, glyceraldehyde, and dihydroxyacetone in the presence of $Ca(OH)_2$. The results confirmed the stepwise mechanism of this synthesis of carbohydrates[55]. In view of the absence of even traces of octoses in experiments with glyceraldehyde, the authors[108] regard as unlikely the mechanism proposed by Mayer and Jaschke[59], according to which the reactions involving the dimerisation of tetroses to octoses and their subsequent cleavage to dihydroxyacetone and aldopentose play and important role in the formation of the final products. They also criticise Breslow's mechanism of autocatalysis[81] which is based on the hypothesis of the ready cleavage of tetroses under the conditions of the synthesis. Such cleavage leads to a rapid increase of the content of glycolaldehyde in the reaction system. The secondary role of this mechanism follows from the evidence obtained by the authors[108] for the high rates of cocondensation of tetroses with formaldehyde and the extremely low rates of cleavage of tetroses.

Guillot et al.[109] investigated the kinetics of the synthesis of carbohydrates in the presence of TlOH using a number of aromatic α-ketols (benzoyl-carbinol, 1-phenyl-2-hydroxy-1-butanone, and 1-phenyl-1-hydroxy-2-butanone) as cocatalysts. It was found that, for degrees of conversion of formaldehyde of 5–95%, the kinetics are described satisfactorily by the autocatalytic equation



$$\lg\left[\frac{x}{a-x}\right]_{x_1}^{x_2} = k(t_2 - t_1),$$

where a is the initial concentration of formaldehyde, x_1 and x_2 are the amounts of formaldehyde in mol litre^{-1} which have reacted at times t_1 and t_2, and $k = k_0\,[Tl^+][OH^-]$. Benzoylcarbinol proved to be the most active cocatalyst (more active than glycolaldehyde) and phenylhydroxybutanones proved to be the least active. The induction period increased with increasing formaldehyde concentration.

In their explanation of the experimental results the authors[109] began with the hypothesis that a complex of formaldehyde with Tl^+ having the following structure can be formed in an alkaline medium:

The interaction of this complex with a second formaldehyde molecule leads in their view to the slow formation glycolaldehyde. They explain the autocatalysis by the much faster formation of glycolaldehyde on interaction of two formaldehyde molecules with the alkoxide anion derived from glycolaldehyde (or α-ketol) and coordinated to Tl^+, via the following mechanism:

The literature data considered above show that, despite much attention devoted to the study of the kinetics of the synthesis of carbohydrates and the considerable progress achieved in the analysis of the composition of the products of the synthesis during the last decade, many aspects of the mechanisms of this process remain obscure. There has been no lack of attempts to put forward new mechanisms. Such mechanisms, developed on the basis of only kinetic data and the results of the analysis of the composition, cannot be regarded as sufficiently well founded and it is not surprising that several mutually exclusive mechanisms have been proposed recently. The mechanism of the first stage of the synthesis—the dimerisation of formaldehyde to glycolaldehyde—remains completely obscure. There is no satisfactory explanation of the autocatalytic nature of the process. An important theoretical and practical task is the elucidation of the conditions for the complete suppression of the formation of branched carbohydrates. Weiss's studies in this field constitute only the first steps. Evidently success in the solution of the above problems in the synthesis of carbohydrates will be possible only by combining kinetic research techniques with modern physicochemical and physical methods.

A combined study of the mechanism of the synthesis was therefore undertaken at the Institute of Chemical Physics of the USSR Academy of Sciences in 1969[111–116] in which ultraviolet and NMR spectroscopy as well as radioactive tracers were used in addition to kinetic methods. The kinetics were studied in a static reactor in the presence of alkaline earth metal hydroxides (calcium, strontium, and barium). Gas-chromatography[6] made it possible to carry out a complete group analysis of the carbohydrates with separate determination of the linear and branched components in each carbohydrate fraction with the given number of carbon atoms in their molecules.

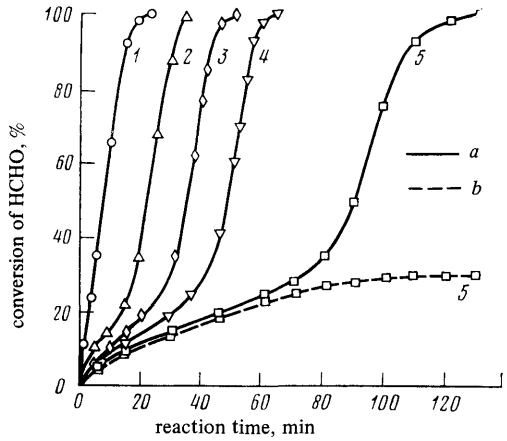


Figure 3. Kinetic curves for the overall conversion of formaldehyde (*a*) and the conversion via the Cannizzaro reaction[12] (*b*) for different molar concentrations of glycolaldehyde: 1) 0.042; 2) 0.008; 3) 0.0017; 4) 0.0008; 5) 0.0; $c_{H_2CO} = 1.53$ M; $c_{Ca(OH)_2} = 0.19$ M; $t = 40$ °C.

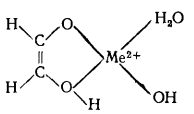
Fig. 3 presents the kientic curves obtained[112] for the condensation of formaldehyde (1.53 M) at 40 °C in the presence of $Ca(OH)_2$ (0.18 M) and variable amounts of glycolaldehyde used as the cocatalyst. Evidently a decrease of the induction period corresponds to an increase of the concentration of glycolaldehyde. At a concentration of this cocatalyst of 4.2×10^{-2} M the induction period disappeared altogether and, up to almost complete conversion of formaldehyde (~90%), the condensation proceeded as a zero-order reaction with respect to formaldehyde. Analogous kinetics were observed when glucose was used as the catalyst, but the induction period did not disappear completely even at a glucose concentration of 1×10^{-1} M. When $Ca(OH)_2$ was used as the catalyst

and glucose as a cocatalyst, it was established[113,115] that the induction period passes through a minimum with increasing NaOH content (from 0.1 to 1.0 M). In the range of conversions α from 20–30 to 80–90% the rate of condensation of formaldehyde was found to be constant but increases linearly with increasing concentration of OH^- ions. This is consistent with the zero order with respect to formaldehyde and the first order with respect to $Ca(OH)_2$ found in earlier studies[27,75] for moderate conversions.



The observed minimum in the induction period with increasing NaOH concentration in solution must be regarded as confirmation of the earlier conclusion[82] that the catalytically active form of $Ca(OH)_2$ is the cation $CaOH^+$.

It has been observed[116] by means of the radioactive tracer method, using glucose labelled with ^{14}C, that, under the conditions of the synthesis, the carbohydrates undergo the disproportionation reactions

$$C_mH_{2m}O_m + C_nH_{2n}O_n \rightarrow C_{m-k}H_{2(m-k)}O_{m-k} + C_{n+k}H_{2(n+k)}O_{n+k},$$

known previously solely as biocatalytic reactions[117]. At the same time radioisotope data show that the rates of these reactions, as well as secondary reactions in the synthesis of carbohydrates such as retroaldol cleavage, are much lower than the rate of growth of carbohydrate molecules.

Analysis of the ultraviolet spectra of alkaline solutions of carbohydrates in the presence and absence of alkaline earth metal ions[111] as well as ultraviolet spectra of samples of the solution removed from the reactor during the synthesis of carbohydrates[113–118] made it possible to attribute the appearance of the band in the range 300–340 nm in these spectra to the formation of complexes of the enediol forms of carbohydrates and hydroxides of the type

.

It was found that the position of the absorption maximum depends on the nature of the cation forming the complex. When glucose was used as the ligand, the absorption maximum was found at 342 nm for $Ca(OH)_2$, 332 nm for $Sr(OH)_2$, and 322 nm for $Ba(OH)_2$.

An important result of the ultraviolet spectroscopic study was the observation that the kinetics of the increase of the optical density of this band for different carbohydrates (glycolaldehyde, dihydroxyacetone, glyceraldehyde, arabinose, glucose, and fructorse) are similar to the initial kinetics of the synthesis using the same carbohydrates as cocatalysts. This suggested that the complexes of the above type are capable of manifesting autocatalytic activity.

In view of this conclusion, the results of the chromatographic analysis (carried out immediately after preparing the solution) of the complex of α-D-glucose and $Ca(OH)_2$ are of interest[71,72,119]. Analysis demonstrated the presence in solution of a number of other hexoses (fructose, mannose, etc.) together with glucose. This enabled Weiss[119] to conclude that the catalytically active complex is a dynamic mixture of carbohydrate complexes of different structures and not the complex of an individual carbohydrate. The application of photoelectron X-ray spectroscopy to obtain information about the structure of the catalytically active complexes of calcium hydroxide with glucose and dihydroxyacetone, isolated from solution by the method of Roy and Mitra[121], showed[120] that the corresponding complexes consist of adducts with weakly polarised bonds between Ca^{2+} and the carbohydrate molecule.

The results of this study justified the conclusion that the autocatalytic nature of the synthesis of carbohydrates is due to the possibility of the formation of glycolaldehyde via two pathways having sharply different rates: (a) via the slow dimerisation of the formaldehyde in the coordination sphere of the calcium cation and (b) via the much faster dimerisation in the coordination sphere of the calcium cation where two coordination sites are occupied by the enediol form of glycolaldehyde formed previously.

The multistage mechanism of the synthesis of glycolaldehyde from formaldehyde, which accounts for the autocatalytic nature of its formation, can be formulated as follows in accordance with the evidence presented above:

$$A + K \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} AK \quad , \tag{1}$$

$$AK + A \xrightarrow{k_2} EK \quad , \tag{2}$$

$$EK \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} K + C_2 \quad , \tag{3}$$

$$EK + A \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} EKA \quad , \tag{4}$$

$$EKA + A \xrightarrow{k_5} EK + C_2 \quad , \tag{5}$$

where A is formaldehyde, K the catalyst [the $CaOH^+$ cation for $Ca(OH)_2$], C_2 glycolaldehyde (in the non-hydrated form), EK the complex of the catalyst with the enediol form of glycolaldehyde, and EKA the complex EK whose coordination sphere contains formaldehyde A.

^1H and ^{13}C NMR showed[113,122] that, under the conditions of the synthesis, formaldehyde exists mainly in the form of unionised and singly ionised methyleneglycol. However, these data do not rule out the possibility of the involvement of formaldehyde in the proposed stages in the non-hydrated form. One should bear in mind that the concentration of this form under the conditions of the synthesis cannot exceed several hundredth per cent of the overall formaldehyde concentration[123].

The elucidation of the problem of the form in which formaldehyde participates in the proposed stages is difficult and requires additional studies.

The equation derived on the basis of the above mechanism for the rate of the initial stage of the reaction [until the attainment of a degree of conversion of formaldehyde of ~20% when part of $Ca(OH)_2$ still remains in the precipitate] has the following form[113,118]:

$$w = (k_2K_I[A]^2 + k_5K_{III}K_{IV}[A]^2[C_2])[Ca(OH)_2]_0 \times \\ \times (1 + K_w/K_I'[H^+] + K_{II}'[H^+]/K_w)^{-1} \quad ,$$

where k_2 and k_5 are the rate constants for stages (2) and (5), K_I, K_{III}, and K_{IV} are the rate constants for the formation of complexes in stages (1), (3), and (4), K_W is the ionic product of water, and K_I' and K_{II} are the first and second dissociation constants of $Ca(OH)_2$. Since $k_5 \gg k_2$, the term $k_2K_I[A]^2$ in the expression for the rate of reaction can be neglected, whereupon the above expression reduces to the form typical for autocatalytic reactions:

$$w = k_5K_{III}K_{IV}[A]^2[C_2][Ca(OH)_2]_0(1 + K_w/K_I'[H^+] + K_{II}'[H^+]/K_w)^{-1} \quad .$$

At a constant pH and in the presence of $Ca(OH)_2$ in the precipitant, we obtain

$$w = k[A]^2[C_2] \quad .$$

The constancy of the rate of reaction in the range of values of α from 20–30% to 80–90% has been attributed[113] to the fact that, starting from $\alpha = 20$–30%, the main pathway followed in the consumption of formaldehyde is its aldol condensation with C_2–C_4 carbohydrates. According to Ingold[124], the rate-limiting stage in this process is the formation of carbanions from C_2–C_4 carbohydrates, which sould lead to the first reaction order with respect to OH^-. The rate of formation of carbanions from glycolaldehyde has been estimated by NMR[125]. The observed overall zero order of the synthetic reaction for a slight change in pH in the range of values of α from 20–30% to 80–90% shows that the rate constants for the formation of carbanions from the C_2–C_4 carbohydrates differ little and that the overall C_2–C_4 concentration hardly changes in the above range of values of α.

The first information about the significant influence of the nature of the catalyst cation on the ratio of the linear and branched carbohydrates formed has been obtained in a number of studies[112–115]. Table 2 presents the corresponding data for 100% conversion of formaldehyde using glycolaldehyde (4.2×10^{-2} M) as the cocatalyst. The data for the C_4 fraction, whose composition should be closer to that for the primary products than the composition of the C_5 and C_6 fractions, are particularly instructive. The proportion of linear carbohydrates in this fraction is 81% for $Ca(OH)_2$, 37% for $Sr(OH)_2$, and 21% for $Ba(OH)_2$. It follows from the data in Table 2 that $Ca(OH)_2$ is most selective in relation to the synthesis of linear carbohydrates but even for this hydroxide the proportion of branched carbohydrate is high.

Table 2. Fractional composition (%) of the carbohydrates[112] formed in the condensation of formaldehyde (1.53 M) in the presence of calcium, strontium, and barium hydroxides (0.19 M); cocatalyst—glycolaldehyde (4.2×10^{-2} M).

Carbohydrates	Condensation conditions*			
	$Ca(OH)_2$; 40°; 20 min; 7.2%	$Ca(OH)_2$; without cocat., 40°; 135 min; 35.5%	$Sr(OH)_2$; 40° 23 min; 6.0%	$Ba(OH)_2$; 50°; 50 min; 18%

* The catalyst, temperature, reaction time, and the degree of conversion via the Cannizzaro reaction are quoted.

The results obtained can be regarded as promising in the sense that they indicate the possibility of a considerable alteration of the proportion of linear carbohydrates when one catalyst is replaced by another or when the temperature is altered, i.e. they give rise to the hope that it may be possible to select optimum catalysts and conditions whereby the content of branched carbohydrates in the products of synthesis can be reduced to an acceptable minimum or fully eliminated. The latest results[126] show that, in principle, one can achieve a very high selectivity of the synthesis in favour of linear hexoses, provided that the synthesis is carried out at sufficiently high temperatures. Thus, at 98 °C and using $Ca(OH)_2$ as the catalyst, the proportion of hexoses reaches 84% of all the products (by weight) for a degree of conversion of 18%; 90% of the hexoses then consist of a mixture of approximately equal amounts of glucose and idose.

The data discussed above show that, despite certain advances in the elucidation of the mechanism of the synthesis of carbohydrates from formaldehyde and promising indications of a possibility of achieving a highly selective process, it is necessary to continue research into the mechanism and to develop ways of increasing the process selectivity. In particular, it is necessary to refine the structure of catalytically active complexes of carbohydrates and formaldehyde with hydroxides. As already mentioned, the problem of the form (hydrated or non-hydrated, ionised or unionised) in which formaldehyde is involved in the formation of glycolaldehyde remains unelucidated. Exhaustive kinetic information (the reaction order with respect to formaldehyde, the concentration of calcium hydroxide ions and OH^- ions, and the activation energy) for the induction period is so far lacking. The problem of the extent to which branched carbohydrates can be involved in secondary disproportionation and retroaldol cleavage reactions remains completely obscure. This evidently does not complete the list of the obscure problems of the mechanism. It is no less important to continue the search for optimum catalysts and conditions for a highly selective synthesis of assimilable carbohydrates. The results obtained hitherto in attempts to increase the process selectivity constitute only the first steps in this practically important field of study.

V. THE POSSIBLE VERSIONS OF THE CONDENSATION OF FORMALDEHYDE OF CARBOHYDRATES IN LIFE SUPPORT SYSTEMS IN SPACE VESSELS

It follows from the foregoing that the selectivity of the synthesis of carbohydrates from formaldehyde is as yet insufficient for this process to be used without significant improvement in life support systems at the concluding stage of the conversion of the final products of the vital activity of the human organism into food products. When formaldehyde is fully converted into carbohydrates in the presence of $Ca(OH)_2$, one of the most effective catalysts of this process, the proportion of hexoses in the carbohydrate products is only ~50%.[76] On the other hand, the proportion of assimilable hexoses must be less than 25% since, in view of the characteristics of the process examined above, half of all the carbohydrates should apparently be formed in the non-assimilable L-form. Furthermore, the non-assimilable carbohydrates include also all the branched and certain linear D-hexoses produced.

The low process selectivity is apparently the main cause of the negative results of toxicological assessments of the carbohydrates synthesised. After a most careful purification of the carbohydrates [precipitation of $Ca(OH)_2$, treatment of the filtered solution with a cation exchanger, an anion exchanger, and activated charcoal], prolonged feeding of rats with the product led to weight loss by the animals accompanied by a number of pathological phenomena and terminating in their death[127]. Therefore, together with the search for ways of improving significantly the selectivity of the synthesis of assimilable hexoses from formaldehyde,

it is desirable to carry out also studies designed to elucidate the possibility of employing this process in other more promising versions.

A 50 day experiment[128], showing that human diet can contain considerable amounts of glycerol (110 g per day) without any harmful consequences of health, was carried out recently. Later studies[129] showed that glycerol in the diet can constitute more than half, by weight, of the entire daily ration for man (up to 300 g per day).

On the other hand, it is known[130] that hydrogenolysis can yield glycerol as the main reaction product. At the beginning of the 1940's the first patents were taken out[131–133] for the synthesis of glycerol by the hydrogenolysis of a mixture of carbohydrates synthesised from formaldehyde.

Bearing in mind these data, Weiss et al.[134] suggested that at the end of the synthesis of carbohydrates the reaction mixture be hydrogenated and hydrogenolysed under conditions ensuring the preferential formation of glycerol. This application of the formaldehyde condensation process can ensure the recycling under the conditions of the space vessel of at most between 20 and 50% of carbon dioxide in the form of glycerol which is assimilable by the human organism.

In view of the low selectivity of the condensation of formaldehyde to assimilable carbohydrates, this verion of the process makes it possible to obviate difficulties associated with the toxic effect of complex mixtures of the carbohydrates synthesised. However, at present one can only speak of the possibility, in principle, of using this version of the formaldehyde condensation process. Comparatively few studies have been made on these lines and the selectivity achieved in the synthesis of glycerol is insufficient. Thus it can be shown[135,136] that the selectivity of the hydrogenolysis of sucrose (200–225 °C, 200 atm) in relation to the formation of glycerol is only 31%. A disadvantage of this version of the process is also the necessity to employ severe conditions—high temperatures and pressures.

Another way of obtaining glycerol from formaldehyde may therefore be more promising for the conditions in space vessels: preliminary synthesis of carbohydrates from formaldehyde under conditions ensuring the preferential formation of trioses and subsequent hydrogenation of the latter to glycerol. Studies by Weiss and coworkers[137] showed that the selective synthesis of trioses is in principle possible if the process is terminated at low degrees of conversion of formaldehyde. Thus, at 40 °C in the presence of $Ca(OH)_2$ for degrees of conversion of ~10%, the content of trioses in the carbohydrate products can be close to 80% according to the above authors' data. We obtained similar results[112]. Direct data indicating the possibility of the selective synthesis of trioses from formaldehyde have also been obtained. According to Shapira[138], in the presence of the $CaO-Al_2O_3$ catalyst and after the addition of 5% of glyceraldehyde as the cocatalyst, it is possible to obtain trioses with a selectivity of 73% for an overall conversion of formaldehyde of 71%.

The hydrogenation of trioses in the presence of fairly active catalysts (for example, ruthenium catalysts) could be carried out at a much lower temperature and pressure compared with those indicated above for hydrogenolysis; a very high hydrogenation selectivity is then achieved[138].

The above advantages of this version of the synthesis of glycerol evidently make it desirable to carry out special studies in order to elucidate the possibility of its practical application.

The selective synthesis of trioses from formaldehyde may be of particularly great interest in view of the fact that trioses can be converted with the aid of an immobilised enzyme (aldolase) into D-glucose, nutritionally the most valuable carbohydrate, with a selectivity close to 100%.[117] However, despite the known advantages of this version of the synthesis of D-glucose (not only under conditions of space vessels but also for terrestrial purposes), there have been almost no studies designed to elucidate the possibility of the practical realisation of this synthesis.

The difficulties associated with the low selectivity of the synthesis of carbohydrates and the possible toxicity of individual products can also be avoided by employing solutions of synthetic carbohydrates as the nutrient medium for the growing of yeast. This method of using synthetic carbohydrates has been proposed by Soviet and American investigators[68,139]. The yeast grown in this way can evidently serve under the conditions of prolonged space flights as a valuable additional source of food protein and vitamins. The protein content in yeast is 45% and yeast is capable of synthesising also other valuable food components: lipids, glycolipids, and sugars[140].

Yeast (or at any rate some of their species) have less stringent requirements as regards the composition of carbohydrates than the human and animal organism and the extent to which they can utilise synthetic carbohydrates can be fairly high. Thus the degree of utilisation of carbohydrates reached 30–40% in a study[68] where yeast was cultured on synthetic carbohydrates. Table 3 presents qualitative data from the study of Chermside et al.[139] for the utilisation of various sources of carbon by certain yeast species. They show that certain yeast species are capable of effectively assimilating synthetic carbohydrates.

Table 3. The utilisation of various sources of carbon by certain yeast species*.

Yeast species	Glucose	Mannitol	Glycerol	Dihydroxyacetone	Synthetic carbohydrates		
					1%	3%	5%
Candida krusoides	++	++	++	++	+	—	—
Lipolytica	++	++	++	++	+	—	—
Atilis	++	++	++	++	+	+**	—
Rhodotorula pilimanae	++	++	++	++	++	+**	—
Saccharomyces carlsbergensis	++	—	—	++	+	+**	+**
Cerevisiae	++	—	—	++	—	—	—

* Notation: ++ effective utilisation; + utilisation; — no utilisation.

** The utilisation was greater in a 14 day experiment than in a 7 day experiment.

Data obtained in a study[141] where it was shown that good results can be secured in the growing of yeast (*Candida tropicalis* CK-4) using as a source of carbon complex mixtures of organic acids obtained by oxidising synthetic carbohydrates are of interest in connection with the problem under discussion.

The literature data considered in this Section show that there are a number of promising versions of the formaldehyde condensation process for the recycling of food under the conditions of prolonged space flights. At the same time it is evident that only preliminary studies have so far been

carried out in each of the relevant fields and that extensive and thorough research is necessary before the practical application of these procedures will become possible.

Photoageing of Aliphatic Polyamides

A.L.Margolin and L.M.Postnikov

The primary photophysical and photochemical processes in the amide group of polyamides and certain individual amides are examined. The mechanisms of the photolysis and photochemical oxidation of polyamides are analysed as a function of irradiation conditions. The problems of predicting the light stability of polyamides as well as the mechanisms of the stabilisation of polyamides with respect to the action of light and the sensitisation of their photochemical ageing are discussed. The bibliography includes 224 references.

I. INTRODUCTION

When used under natural conditions, polyamides (PA) decompose under the influence of sunlight over periods ranging from half a year to one year[1]. Since the annual manufacture of polyamides runs into millions of tons, the problem of their photochemical ageing is of practical importance. It includes a wide range of questions concerning the nature of the primary and secondary photochemical process responsible for the photochemical ageing, the mechanisms of chemical and structural changes in polyamides, their relation with the changes in the characteristics of their mechanical strength, and the mechanisms of the stabilisation of polyamides with respect to the action of light and the sensitisation of their photochemical ageing.

In the present review an attempt is made at a systematic account of the experimental data on the above questions. Reviews already exist on individual aspects of the problem of the ageing of polyamides[2-7].

II. PRIMARY PHOTOPROCESSES IN ALIPHATIC POLYAMIDES AND MODEL COMPOUNDS

1. Primary Photophysical Processes

In contrast to polymers (for example, polyolefins), in which photoageing can be induced solely by the absorption of light by the chromophoric groups of impurities or oxidation products[8] and in contrast to aromatic polyamides which exhibit an intense intrinsic ultraviolet absorption[9], aliphatic polyamides absorb extremely weakly[10-13] in the region where the absorption spectrum of the chromophoric amide group of the polyamide overlaps the spectrum of sunlight at the Earth's surface (Fig.1). In the study of light-induced transformations of polyamides, one must therefore take into account both the absorption of light by impurities and the intrinsic absorption of amides.

The amide group $-CO-N\langle$ in different compounds in liquid and solid solutions has two absorption bands corresponding to the $^1\Gamma_{\pi\pi^*} \leftarrow {}^1\Gamma_1$ and $^1\Gamma_{n\pi} \leftarrow {}^1\Gamma_1$ transitions[14-17]. The short-wavelength absorption band associated with the $^1\Gamma_{\pi\pi^*} \leftarrow {}^1\Gamma_1$ transition can be assigned to charge transfer from the nitrogen atom to the carbonyl group[18-20]. The introduction of electron-donating substituents at the nitrogen atom shifts the $\pi\pi^*$-absorption maximum towards longer wavelengths, while the introduction of electron-donating substituents at the carbon atom of the carbonyl group causes a hypsochromic shift. Thus, the energies of the $^1\Gamma_{\pi\pi^*}$ state for *N*-dimethylformamide $HCON(CH_3)_2$, formamide $HCONH_2$, and acetamide CH_3CONH_2 are 6.22, 7.16, and 7.48 eV respectively[20]. With increase of solvent polarity, the $\pi\pi^*$ absorption shifts towards longer wavelengths[21]. The polyamides PA-3, PA-4, PA-6, PA-6,6, PA-6,10† and polyglycine have a $\pi\pi^*$ absorption maximum at a wavelength $\lambda_{max} = 190$ nm in the solid state[22,23], while a solution of the copolymer PA-548 in methanol has an absorption maximum at 205 nm.

The long-wavelength absorption of the amide group ($^1L_{n\pi^*} \rightarrow {}^1\Gamma_1$ transition) has small extinction coefficients $\varepsilon < 100$ litre mol^{-1} cm^{-1}.[17] According to some estimates[24], $\varepsilon \cong 0.02$ litre mol^{-1} cm^{-1} at ~300 nm for specially pure amides. The $n\pi^*$ absorption maximum is in the range 210–240 nm; thus $\lambda_{max} =$ 208 nm for the $^1\Gamma_{n\pi^*} \leftarrow {}^1\Gamma_1$ transition of acetamide in water. A decrease of solvent polarity increases λ_{max} (Fig.1). The $n\pi^*$ absorption of the amide group in solid polyamides which are characterised by a low dielectric constant, should be similar to the absorption of solutions of *N*-alkylamides in hydrocarbons. Polyamides usually exhibit a more intense absorption in the long-wavelength region than in model compounds, which is evidently due to the absorption by impurities.

It has been shown that the isolated amide group does not fluoresce on excitation with light at wavelengths in the range $250 \leq \lambda \leq 300$ nm [24-26] in contrast to the amide group conjugated with an aromatic ring[27].

---

† The numerals indicate the numbers of carbon atoms between the NH groups in the repeating elements of the chain in the case of the homopolymer. For example, PA-6,6 and PA-6 are polyhexamethyleneadipamide $-(CH_2)_6NHCO(CH_2)_4.CONH-$~ and polycaproamide ~$-(CH_2)_5CONH-$~. The first of the two numerals separated by a comma characterises the amine component of the repeating unit, while the second numeral characterises the acid component. In naming mixed polyamides the numerals separated by an oblique stroke characterise components comprising the polymer. For example, PA-6,6/6,10/6 is the copolymer of ε-caprolactam ($\overline{(CH_2)_5CONH}$, the adipate of hexamethylenediamine $HOOC(CH_2)_4CONH(CH_2)_6.NH_2$, and the sebacate of hexamethylenediamine $HOOC(CH_2)_8.CONH(CH_2)_6NH_2$, known as PA-548.

The possibility of the phosphorescence of compounds with amide groups is controversial[24-26]. Larson et al.[25] investigated a large series of aliphatic amides and showed that the phosphorescence of these compounds (if it is observed after careful purification of the compounds) is very weak and is characterised by low quantum yields ($\Phi_p < 10^{-4}$–10^{-3}) and long lifetimes ($\tau_p > 0.1$ s); the phosphorescence spectrum depends on the excitation wavelength, which indicates the possibility of the phosphorescence of single crystals or of defects in vitrified solutions (the authors[25] used mainly EPA—mixtures of ether, pentane, and alcohol—as solvents). In another study[28] the phosphorescence of amides was not observed.

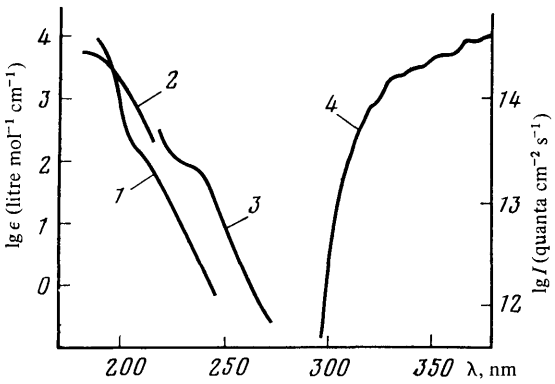

Figure 1. Ultraviolet absorption spectra[10-13] of acetamide solutions in water (curve *1*), of *N*-methylacetamide in cyclohexane (curve *2*), and of ε-caprolactam in n-heptane (curve *3*); curve *4* represents the spectrum of sunlight at the Earth's surface measured at 3 nm wavelength intervals (*I* represents the light intensity and ε is the extinction coefficient).

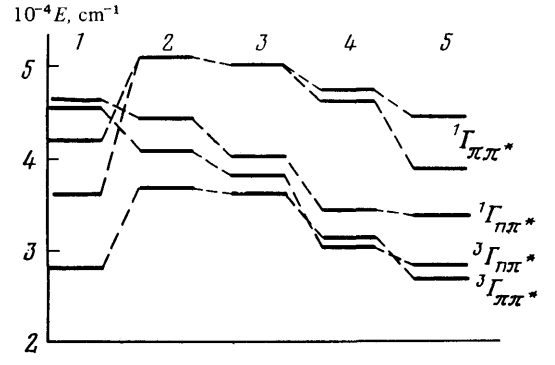

Figure 2. The energy levels (*E*) of the first electronically excited states of amides: 1) acetanilide ($\tau_p \approx 3$ s); 2) acetamide ($\tau_p > 0.1$ s, $\Phi_p < 10^{-4}$); 3) tetramethyloxamide ($\tau_p > 0.1$ s, $\Phi_p < 10^{-4}$); 4) dimethyloxamide ($\tau_p = 0.1$ s, $10^{-4} \leq \Phi_p < 10^{-3}$); 5) 1-isopropyl-5,5-dimethyl 2,3-dioxopiperazine ($\tau_p = 0.1$ s, $10^{-4} \leq \Phi_p < 10^{-3}$).

It has been concluded[24] that the amide group is responsible for the observed weak phosphorescence of vitrified alcoholic solutions of α,ω-polymethylenebishexaneamides having the general formula $C_5H_{11}CONH(CH_2)_nNHCOC_5H_{11}$, where $n = 3$, 4, 5, 6, 7, 8, or 12. The amides have been synthesised under special conditions in order to avoid contamination; subsequent purification of the substance did not affect the phosphorescence and the phosphorescence spectrum was independent of the excitation wavelength. Depending on the value of *n*, the maximum in the excitation spectra has been observed in the range from 280 to 294 nm, i.e. in the region where the amides hardly absorb. By analogy with the phosphorescence of an isolated –CO–O– group (in carboxylic acids and their salts, for example, in HCOONa), which also has no singlet–singlet absorption in the region corresponding to excitation[29], it has been suggested[24] that there is direct excitation of the amide group to the triplet as a result of the $^3\Gamma_{\pi\pi^*} \leftarrow {}^1\Gamma_1$ transition. Bellinger and Roberts[24] determined from the excitation and phosphorescence spectra the energy of the lowest triplet state of the amide group: $3.35 \leq E_{T_1} \leq 3.44$ eV.

Table 1. Characteristics of the phosphorescence observed in polyamides and model compounds (77 K).

Compound	Excitation λ, nm	Emission, λ_{max}, nm	$\lambda_{0,0}$, nm	τ_p, s	Refs.
N-Hexylhexanamide	300*	440	360	0.6	26

PA-12	270	450	—	1.0	37

*The value of λ at the maximum in the excitation spectrum.

The changes in the ultraviolet absorption spectra and luminescence properties of molecules containing amide groups have been investigated[25,30,31] as a function of the nature of the conjugation of the amide group with another chromophore, particularly with one or two amide groups. As a result, it was possible to estimate approximately the sequence of the energy levels for an isolated amide group (in relation to acetamide) (Fig.2). It was found that the lowest excited state is the triplet $^3\Gamma_{\pi\pi^*}$. The $^3\Gamma_{\pi\pi^*}$ state is characterised by long lifetimes ($\tau_p > 0.01$ s) in relation to emission[32], which makes it possible to explain the low values of Φ_p. The phosphorescence of simple molecules can be observed if the vibrational levels of the $^3\Gamma_{\pi\pi^*}$ and $^3\Gamma_{n\pi^*}$ states are mixed, which leads to a decrease of τ_p (for example, in oxamides—Fig.2).

It has been concluded[22] that the luminescence of aromatic amides is caused by the influence of the aromatic ring, which reduces the probability of radiation-less transitions; the lowest triplet level of acetamide has been estimated[31] as $E_{T_1} = 4.6$ eV. As mentioned above[20], electron-donating substituents lower the energy of the $^1\Gamma_{\pi\pi^*}$ level by ~1 eV. Under conditions where the ST-splitting is retained, one may expect that the $^3\Gamma_{\pi\pi^*}$ level of N-alkylamides (modelling the PA chain) has an energy $E_{T_1} \cong 3.6$ eV, which agrees best with the estimate $E_{T_1} \cong 3.4$ eV.[24,30,33]. It is interesting to note that similar values $E_{T_1} = 3.2$–4.0 eV have been found for the lowest $^3\Gamma_{\pi\pi^*}$ level of the –CO–O– group, which has the same number of electrons as in the –CO–NH– group[30].

Table 1 presents for comparison the parameters of the phosphorescence spectra of polyamides[28,34–44] and model compounds[24,26]. The authors of all the investigations noted that the phosphorescence observed in polyamides can be induced by impurities. It has been suggested[41] that the phosphorescence in PA-6,6 is caused by the polymer oxidation products formed under the polymerisation conditions, because, with increase of the degree of polymerisation, the intensity of the phosphorescence rises and its maximum shifts towards shorter wavelengths with a simultaneous increase of the phosphorescence lifetime. However, on thermal oxidation of PA-6 at 180 °C, a bathochromic shift of the phosphorescence λ_{max} is observed with a simultaneous decrease of the phosphorescence intensity[43].

The change in the characteristics of the phosphorescence on passing from amides to polyamides can be accounted for by the intrinsic phosphorescence of polyamides. It is known[21] that the state of aggregation of a substance has almost no influence on the energy of the triplet level. Similar values of $\lambda_{0,0}$ for amides and polyamides therefore show that the energy of the luminescent state in PA is equal to the energy of the $^3\Gamma_{\pi\pi^*}$ level of the amide group. Polar solvents increase the phosphorescence intensity, because they decrease the degree of association of the aromatic amide molecules[27] or molecules containing the –CO–O– group[29], which reduces the probability of radiationless processes. With decreased probability of radiation less deactivation, the lifetime of the excited state τ_p approaches the limiting lifetime τ_p^0 corresponding to emission in the absence of radiation less deactivation. In the amorphous regions of the polyamide specimen the association of the amide groups in the macromolecular chain is less effective than in solutions of model amides. This is the reason for the appearance of non-associated amide groups, for which the lifetime of the excited state τ_p is close to τ_p^0. Indeed, in model compounds $\tau_p = 0.2$–0.6 s whereas in polyamides $\tau_p \cong 2$ s; the increase of phosphorescence intensity on passing from amides to polyamides is associated with this factor. Thus the available experimental data do not rule out the possibility of both an intrinsic phosphorescence of polyamides and the possibility of the "superposition" on the latter of the phosphorescence due to impurities and oxidation products.

Polyamides frequently exhibit a fluorescence[37,39,41,45], which is characterised by values of λ_{max} of 365 and 445 nm in excitation and fluorescence spectra respectively. Evidently, the fluorescence of polyamides is due to impurities. The most probable impurities can be the products of the oxidation of polyamides and the initial monomers[39].

2. Primary Photochemical Processes

In the early studies on the photochemistry of polyamides and model compounds a wide variety of reactions was proposed as the possible primary photochemical processes in amides:

$$\mathrm{R(CH_2)_3CONHCH_2CH_2R'} \xrightarrow{h\nu} \begin{cases} \rightarrow \mathrm{R(CH_2)_3\dot{C}O + \dot{N}HCH_2CH_2R'}, & (1) \\ \rightarrow \mathrm{R(CH_2)_3CONH\dot{C}HCH_2R' + \dot{H}}, & (2) \\ \rightarrow \mathrm{R(CH_2)_3C\dot{O}NH + \dot{C}H_2CH_2R'}, & (3) \\ \rightarrow \mathrm{R(CH_2)_3NHCH_2CH_2R' + CO}, & (4) \\ \rightarrow \mathrm{RCH{=}CH_2 + CH_2CONHCH_2CH_2R'}, & (5) \\ \rightarrow \mathrm{RCH_2CH{=}CH_2 + HCONHCH_2CH_2R'}, & (6) \\ \rightarrow \mathrm{R(CH_2)_3CONH_2 + CH_2{=}CHR'}, & (7) \\ \xrightarrow{\text{amide}} \mathrm{R(CH_2)_3\dot{C}(OH)NH(CH_2)_2R' + R(CH_2)_3CONH\dot{C}HCH_2R'} & (8) \end{cases}$$

($\dot{R}$ and $\dot{R}'$ are alkyl radicals or terminal alkyl macroradicals).

Reactions (5)–(8) have been suggested[46,47] by analogy with the Norrish type II and III reactions, i.e. reactions involving intramolecular and intermolecular abstraction of a hydrogen atom by the oxygen atom of the carbonyl group in ketones in an electronically excited state[10]. The data concerning the nature of the excited state of the amide group suggest that reactions (5)–(8) are unlikely owing to the differences in the nature of the excitation of the carbonyl and amide groups. Thus in formaldehyde the $n\pi^*$ excitation is accompanied by the transfer of a charge of 0.64e from the oxygen atom to the carbon atom[32]. The decrease of electron density at the oxygen atom promotes the abstraction of a hydrogen atom. The $\pi\pi^*$ excitation in formamide is accompanied by the transfer of a charge of 0.7e from the nitrogen atom to the carbon atom, while the electron density at the oxygen atom remains almost unchanged[17]. The oxygen atom of the amide group in the $^3\Gamma_{\pi\pi^*}$ state does not therefore exhibit an enhanced reactivity in respect of abstraction reactions. (There is evidence[48] that on $n\pi^*$ excitation, the main contribution to absorption comes from the transfer of a non-bonding electron from an atomic orbital of nitrogen to the π orbital of the amide.)

It has been shown experimentally[49] that Norrish type II and III processes do not occur in the photolysis of N-alkylpyrrolidinones and N-alkylamides[50]. The products of reactions (5)–(7) have been detected in extremely small amounts on irradiation of N-alkylamides[46], PA-6,6, and PA-6.[51]

Investigators of the photochemical oxidation of amides[11] and polyamides[3,51] put forward reactions (2) and (3) to account for the formation of products with terminal amide groups and hydrogen. Estimates have shown[52] that the quantum yield of hydrogen formed via reaction (2) is extremely low ($\Phi_2 < 7 \times 10^{-5}$). The large yields of hydrogen, usually observed in the photolysis of amides and polyamides, have been explained by the photolysis of the products, since, with increase of the degree of photochemical reaction, the rate of accumulation of H_2 also increases significantly[52,53]. It is difficult to determine the probability of reaction (3), since unsubstituted amides have not been detected in the photolysis of N-alkylamides[53] and, as will be shown below, the main pathway leading to the formation of unsubstituted amides in photochemical oxidation involves oxidation processes.

Since the excitation of the amide group entails a partial separation of electrons forming the amide bond, presumably the most probable reaction of the amide group in an electronically excited state is dissociation of the amide linkage [reaction (1)]. Reaction (4) can be regarded as a result of reaction (1), which is followed by the elimination of CO from the acyl group and recombination of the amino and alkyl radicals in the cage.

In aromatic amides the photodissociation of the amide bond is the main primary process, which proceeds with a high quantum yield ($\Phi_1 = 0.25$).[54,55] The reverse reactions of the

acyl and amine radicals reduce the quantum yield of the photochemical reaction to 0.13 when acetanilide is irradiated in cyclohexane. High values of Φ_1 have also been observed for aliphatic amides: when *N*-alkylpyrrolidinones are irradiated in alcoholic solutions, $\Phi_1 = 0.02-0.1$ depending on the substituent[49,50], while on photolysis of *N*,*N*-dialkylamides in cyclohexane and dioxan, $\Phi_1 = 0.1-0.15$.[56] In the photolysis of solid PA-6 [7] the quantum yield of the radicals which have emerged from the cage as a result of reaction (1) is 0.01.

The primary photochemical process in both aromatic and aliphatic amides is apparently the photodissociation of the peptide bond. This conclusion does not rule out the occurrence of a multiplicity of other reactions which proceed at a significantly lower rate and give rise to a set of a wide variety of secondary products. Thus analysis of the products of the photolysis of polyamides[46,51,57-61] indicates approximately identical probabilities for the dissociation of all the C–C bonds of the polyamide and the possibility of a non-radical decomposition via reaction (5). The evolution of small amounts (less than 1% of the main volatile products—H_2 and CO) of hydrocarbons (ethane, ehtylene, propane, and propene) has also been observed in the photolysis.

The formation of the photochemical oxidation products from polyamides[2,7,62-66] has been explained by the dark reactions of radicals and by secondary photochemical processes.

III. THE FORMATION OF RADICALS IN POLYAMIDES AND IN MODEL COMPOUNDS

The results of studies by Refikov and coworkers[58], who first observed the EPR spectrum of PA-6 irradiated by ultraviolet light, indicate a radical mechanism of the photoageing of polyamides. The EPR spectrum of a single radical $RCONH\dot{C}HR'$, which we shall designate by $\dot{P}_1$, has been observed for γ-irradiated PA-6.[67] However, the EPR spectra observed on ultraviolet irradiation of polyamides are very complex and are poorly resolved, which hinders their interpretation. The situation is complicated by possible photochemical reactions of free radicals[68], which absorb light very strongly. Thus the ultraviolet spectrum of the radical P_1 has two absorption maxima[69,70]—in the regions 245–248 and 350 to 380 nm with extinction coefficients of 7000 and 2000 litre mol^{-1} cm^{-1} respectively[71]. Under the influence of light at the above wavelengths, the radicals $\dot{P}_1$ readily undergo secondary photochemical reactions[72]. The radicals $\dot{P}_1$ are therefore most conveniently observed either in the presence of photoinitiating additives[73-76], which react under the influence of light with $\lambda > 380-400$ nm, or in the absence of light, when polyamides are acted upon by high-energy radiations[72,77-79], or under mechanical degradation[80,81]. Thus the concentration of $\dot{P}_1$ can reach 0.04 mol kg^{-1} on γ-irradiation of PA-6 at 30 °C.[82]

The photochemical reactions of the radicals in PA-6 films with added iron(III) chloride have been investigated[73-76]. The radicals were initiated by reactions (9) and (10) involving the abstraction of a hydrogen atom from the PA-6 molecule (P_1H) by a chlorine atom with formation of either the radical $\dot{P}_1$ or the radical $RCONHCH_2\dot{C}HR'$ ($\dot{P}_2$). Almost all the radicals detected were identified and the sequence of their formation was found:

$$Cl + P_1H \longrightarrow \dot{P}_1 + HCl \quad , \tag{9}$$

$$Cl + P_1H \longrightarrow \dot{P}_2 + HCl \quad , \tag{10}$$

$$\dot{P}_1 + h\nu \xrightarrow{\lambda \approx 365\ nm} R\dot{C}O + NH{=}CHCH_2R' \quad , \tag{11}$$

$$\dot{P}_1 + h\nu \xrightarrow{\lambda \approx 365\ nm} \dot{P}_2 + P_1H \quad , \tag{12}$$

$$R\dot{C}O + h\nu \xrightarrow{\lambda > 365\ nm} \dot{R} + CO \quad , \tag{13}$$

$$\dot{R} + P_1H \xrightarrow{T \approx 77K} RH + \dot{P}_1 \quad , \tag{14}$$

$$\dot{R} + P_1H \xrightarrow{T \approx 77K} RH + \dot{P}_2 \quad , \tag{15}$$

$$\dot{P}_2 + P_1H \xrightarrow{T > 150K} P_1H + \dot{P}_2 \quad , \tag{16}$$

$$R\dot{C}O + P_1H \xrightarrow{T \approx 273K} RCHO + \dot{P}_1 \quad . \tag{17}$$

The concentration of $\dot{P}_1$ is extremely low even under the conditions of sensitised photolysis owing to the important reactions (11) and (12); the accumulation of $\dot{P}_1$ becomes appreciable only on irradiation with light in the region of 313 nm, to which corresponds the minimum absorption. Measurements of the stabilities of the radicals $\dot{R}$, $\dot{P}_2$, $R\dot{C}O$, and $\dot{P}_1$ showed that they begin to disappear at appreciable rates at 117, 150, 273, and 300 K respectively. Thus the radical $\dot{P}_1$ shows the greatest thermal stability among the PA radicals identified; with increase of temperature, a quantitative conversion of various radicals into $\dot{P}_1$ via reactions (14)–(17) has been observed[73-76].

The EPR spectra of the radicals $R\dot{C}O$ or $\dot{R}$ have been observed in the non-sensitised photolysis of polyamides, which indicates the occurrence of reaction (1), involving the photolysis of the amide linkage, but the possibility of secondary photolysis hinders the interpretation of the EPR spectra[58,77,78,83-85].

In the presence of oxygen, the radicals $\dot{P}_1$, which accumulated during the mechanical degradation of polyamides are converted into the corresponding peroxy-radicals $P_1\dot{O}_2$.[80] An analogous reaction has not been observed in γ-irradiated PA-6 fibres following exposure to air[78]. The exposure of γ-irradiated thin (2–5 μm) PA-6 films to a O_2 atmosphere at room temperature leads to the rapid disappearance of $\dot{P}_1$, although peroxy-radicals are not then detected[86]. It has been suggested that the diffusion time of O_2 in the polyamide specimen is longer than the lifetime of the peroxy-radicals, so that the $P_1\dot{O}_2$ species are not formed in appreciable concentrations. On mechanical degradation, the radicals are formed on the surface of the specimen where diffusion-dependent limitations are insignificant.

Ultaviolet irradiation of PA-6 in air at room temperature led to the detection[87] of radicals of two types: $\dot{P}_1$ and the radical responsible for an unidentified singlet. Since films 80 μm were used for irradiation, one cannot rule out the possibility of the presence of $\dot{P}_1$ owing to the diffusion-dependent limitations to the photochemical oxidation.

The EPR spectra of the radicals in polyamides have also been discussed in other studies[88-90].

IV. THE MECHANISM OF THE PHOTOAGEING OF POLYAMIDES

1. The Mechanism of the Photolysis of Polyamides

When polyamides are irradiated with ultraviolet light at room temperature in the absence of O_2, the following reactions can take place[7]:

$$RCONHCH_2R' \xrightarrow{h\nu} \dot{R} + CO \quad (\Phi_{18} = 5 \cdot 10^{-4}) \quad , \tag{18}$$

$$RCONHCH_2R' \xrightarrow{h\nu} R\dot{C}O + \dot{N}HCH_2R' \quad (\Phi_1 = 5 \cdot 10^{-3}) \quad , \tag{1}$$

$$RCONHCH_2R' \xrightarrow{h\nu} \dot{P}_1 + \dot{H} \quad (\Phi_2 \leqslant 7 \cdot 10^{-6}) \quad , \tag{2}$$

$$\dot{R} + P_1H \rightarrow \dot{P}_1 + RH \quad , \tag{14}$$

$$R\dot{C}O + P_1H \rightarrow \dot{P}_1 + RCHO \quad , \tag{17}$$

$$R'CH_2\dot{N}H + P_1H \rightarrow \dot{P}_1 + R'CH_2NH_2 \quad , \tag{19}$$

$$\dot{H} + P_1H \rightarrow \dot{P}_1 + H_2 \quad , \tag{20}$$

$$\dot{P}_1 \xrightarrow{h\nu} \left\{ \begin{array}{l} \longrightarrow R\dot{C}O + NH{=}CHR' \\ \longrightarrow \dot{H} + RCON{=}CHR' \end{array} \right\} (\Phi_{11,21} \simeq 1) \quad , \qquad (11)$$

$$(21)$$

$$\dot{P}_1 + \dot{P}_1 \rightarrow P_1{-}P_1 \quad . \qquad (22)$$

Here $\dot{P}_1$ denotes the central macroradical RCONHĊHR′ and $\dot{R}$ and $\dot{R}'$ are the terminal alkyl macroradicals.

Reactions (1), (2), and (18) have already been discussed. Reactions (14), (17), (19), and (20) reflect the fact that different radicals are readily converted in polyamides into the more stable radical $\dot{P}_1$. Reaction (20) proceeds very efficiently (the minimum value of the rate constant is $k_{20} = 2 \times 10^{-3}$ litre mol^{-1} s^{-1}),[91] so that no other reactions of atomic hydrogen, for example, the recombination of H atoms, compete with it. Reaction (11) has been detected[76] by EPR. Reaction (21) cannot be detected by EPR, since the disappearance of the radicals $\dot{P}_1$ via reaction (21) leads to their regeneration via reaction (20). Nevertheless, evidence for the occurrence of reaction (21) has been obtained by comparing the photolysis products of deuterated and non-deuterated alanine peptides[92]. The rate of formation of H_2 in the photolysis of polyamides corresponds to a reaction order with respect to light intensity which is intermediate between the first and the second, which also indicates the formation of hydrogen in the photolysis of the radicals[52]. As a rule, the photolysis of the radicals proceeds with high quantum yields ($\Phi \simeq 1$).[68]

The cross-linking of polyamides on photolysis is explained by reaction (22), whose occurrence has been proposed by Zimmerman[70] on the grounds that the radical $\dot{P}_1$ is the most stable among all those present. The recombination of $\dot{P}_1$ with formation of a C–C bond is sterically impossible when there are free valences at the atoms of adjacent chains when the neighbouring amide groups are hydrogen-bonded[93]. The probability of cross-linking should therefore be greater in the amorphous regions of the polymer, where the hydrogen bonds are partly disrupted and where the radicals can migrate as a result of segmental diffusion or successive hydrogen atom abstraction reactions. Indeed polyamide copolymers with a degree of crystallinity lower than in PA-6,6 are cross-linked much more readily than the latter[93]. It has been noted that polyamides are cross-linked to a lesser extent than other polymers, for example, polyethylene[94–96]. Direct evidence for the occurrence of reaction (22) has been obtained in a study[97] where the formation of a C–C bond between the α-methylene groups adjoining the nitrogen atom was observed. We may note that cross-linking via the formation of C–N bonds has been observed by NMR in the thermal degradation of polyamides[98].

2. Model Polyamide Photochemical Oxidation Reactions

In the presence of oxygen, the composition of the products of the photochemical reactions of polyamides and low-molecular-weight *N*-alkylamides, which provide the most effective models of the polyamide chain, differ from the products characteristic of photolysis. Analysis of the composition of the photochemical oxidation products (as well as thermal oxidation products[99]) indicates the important role of the oxidative reactions of a single free radical, namely $\dot{P}_1$.

In the first study on the photochemical oxidation of model compounds[47] the products of prolonged (285 h) non-sensitised photochemical oxidation of *N*-pentylcaproamide at 38 °C were investigated and measurements were made of the absorption of oxygen; the different positions in the amide $C_4H_9{-}\overset{a}{C}H_2{-}\overset{b}{C}O{-}\underset{c}{N}H{-}CH_2{-}C_4H_9$ were labelled with ^{14}C. It was noted that CO is evolved from the α-methylene group adjoining the nitrogen atom (position *c*). When position *a* was labelled with ^{14}C, the only radioactive product was caproic acid, labelling of position *b* gave caproic acid and CO_2, while labelling of positions *c* gave valeraldehyde, valeric acid, CO, and CO_2. Substitution of the hydrogen atoms of the α-methylene group adjoining the nitrogen atom by methyl groups suppressed the photochemical oxidation. These findings led to the conclusion that amides are oxidised via a stage in which a hydrogen atom is abstracted from the α-methylene group with formation of the radical $\dot{P}_1$. In order to account for the composition of the final products, Sharkey and Mochel[47] postulated (by analogy with the oxidation of hydrocarbons) a mechanism in which the following reactions involving the radical $\dot{P}_1$ take place after reaction (1) and the exchange of primary radicals in dark processes:

$$\dot{P}_1 + O_2 \rightarrow P_1\dot{O}_2 \quad , \qquad (23)$$

$$P_1\dot{O}_2 + P_1H \rightarrow P_1OOH + \dot{P}_1 \quad , \qquad (24)$$

$$P_1OOH \rightarrow P_1\dot{O} + \dot{O}H \quad . \qquad (25)$$

The radicals $P_1\dot{O}$ and ȮH formed in the radical decomposition of the hydroperoxide [reaction (25)] lead to the reformation of the radical $\dot{P}_1$, giving rise at the same time to N_1-(1-hydroxyalkyl)amide (P_1OH), which is a precursor of the products detected—the unsubstituted amide, aldehydes, and acids.

It was found subsequently that the probability of the radical decomposition of P_1OOH is low. The amide hydroperoxide was isolated for the first time[100] in the oxidation of fused ε-caprolactam. The formation of the products of the decomposition of ε-hydroperoxycaprolactam, adipimide, and water indicated the occurrence of the non-radical decomposition $\overbrace{(CH_2)_4CONHC}(OOH)H \rightarrow \overbrace{(CH_2)_4CONHCO} + H_2O$. The addition of ε-hydroperoxycaprolactam did not accelerate the oxidation of caprolactam[101,102]. The polymerisation of diallyl phthalate cannot be initiated by the hydroperoxides of *N*-alkylamides at 131 °C over a period of 6 h, while the addition of di-t-butyl peroxide or dibenzoyl peroxide under the same conditions causes the formation of a polymer after 40 and 5 min respectively[103]. It has been shown by the inhibitor method that more than 97% of P_1OOH decomposes via a non-radical mechanism at 131 °C.[104]

Analysis of the products of the thermo- and photo-sensitised oxidation of 89 different *N*-alkylamides led to a mechanism[103–106] of the model oxidation of polyamides in which the $\dot{P}_1$ initiation stage and reactions (23) and (24) are followed by the processes

$$P_1OOH \rightarrow \delta\,(P_1\dot{O} + \dot{O}H) \xrightarrow{2P_1H} \delta\,(P_1OH + H_2O + 2\dot{P}_1) \quad , \qquad (25')$$

$$P_1\dot{O}_2 + P_1\dot{O}_2 \left\{ \begin{array}{l} \longrightarrow 2RCONHCOR' + H_2O_2 \quad , \\ \longrightarrow P_1OOP_1 + O_2 \quad , \\ \longrightarrow P_1OH + RCONHCOR' + O_2 \quad , \end{array} \right. \qquad (26)\ (27)\ (28)$$

$$P_1OH \rightarrow RCONH_2 + R'CHO \quad , \qquad (29)$$

$$P_1OOH \left\{ \begin{array}{l} \longrightarrow RCONHCOR' + H_2O \quad , \\ \longrightarrow RCONHCHO + R'OH \quad , \\ \longrightarrow RCONHCH{=}CHR' + H_2O_2 \quad , \\ \longrightarrow RCONH_2 + R'CHO \quad . \end{array} \right. \qquad (30)\ (31)\ (32)\ (33)$$

At low temperatures (below 100 °C) the chain propagation reaction (24) is insignificant: the main products are formed in reactions (26)–(28) involving the destruction of peroxy-radicals. In photochemical oxidation at 0 °C the hydroperoxide P_1OOH was not detected. The high activation energies for reaction (24) $E_D > 13$ kcal mol^{-1} also shows that the chain

propagation reaction is difficult at low temperatures. In thermal oxidation the chain length increases under the experimental conditions from three units at 70 °C to 20–30 at 130 °C, where the main product becomes the hydroperoxide; its decomposition via reactions (30)–(33) gives rise to the final set of stable products. The probability δ of the liberation of radicals from the cage in the decomposition of P_1OOH is extremely low ($\delta < 0.015$ at 130 °C). When the temperature is reduced and after passing from solutions to a solid polymer, a considerable decrease of δ is to be expected as a result of the decrease of the mobility of molecules.

A similar mechanism of the photosensitised non-chain oxidation of *N*-alkylamides at 30 °C has been proposed by other workers[107], who wanted to explain the formation of the main products by the recombination reactions of the peroxy-radicals $P_1\dot{O}_2$.

Having determined all the products of prolonged (685 h) non-sensitised photochemical oxidation of *N*-butylcaproamide and their proportion relative to the amount of oxygen absorbed, Lánska and Šebenda[11] showed that the principal products are the imide, unsubstituted amides, water, CO, CO_2, hydrocarbons, and carboxylic acids. Peroxides, aldehydes, butylamine, and H_2 are formed in significantly smaller amounts. Pyrrole derivatives were present in trace amounts; other products were not detected.

3. The Influence of Experimental Conditions on the Photochemical Oxidation

The differences in the conditions of the photochemical experiments lead to differences in the composition of the products of the photochemical oxidation of *N*-alkylamides and polyamides. Thus, the main products in the non-sensitised photochemical oxidation are acids, the unsubstituted amides $RCONH_2$ and $R'CONH_2$, and the volatile products CO, CO_2, etc., but *N*-formylamide RCONHCHO was not detected. In the sensitised photochemical oxidation *N*-formylamide was detected together with the main products—imides and unsubstituted amides, but acids and volatile products were not found. It is not possible to account for the above differences by the inadequacy of the analytical methods[11].

We believe that the dependence of the composition of the products on the method of photoinitiation can be explained by differences between the primary photochemical reactions, by the competition between photochemical and dark processes, and also by the competition between primary and secondary photochemical reactions. Whereas photoinitiation as a result of the rupture of the amide bond, leading to the formation of an acyl radical whose oxidation gives rise to acids, is more probable in the non-sensitised process, in the sensitised photochemical oxidation reactions involving the abstraction of a hydrogen atom from the α-methylene group adjoining the nitrogen atom and leading to the formation of $\dot{P}_1$ are more likely. In the absence of oxidation chains, the composition of the products is determined by the photoinitiation mechanism.

The oxidation products formed can be extremely unstable. Thus the slow formation of acetone has been observed[105] on storage in the dark of preirradiated *N*-isopropylamides even at 0 °C; the liberation of acetone ceased only after 26 h. One can therefore postulate that, after very prolonged irradiation (in non-sensitised photochemical oxidation the duration of irradiation amounts to hundred of hours, while in sensitised photochemical oxidation its duration is only 1–3 h), the dark processes in certain cases compete with the photochemical processes, which alters the proportions of the products.

Finally, competition between the absorption of light by the initiating chromophoric group and the oxidation products can play an extremely important role, because in the wavelength range of the light incident on the amide usually employed ($\lambda > 250$–260 nm) amides absorb extremely weakly ($\varepsilon_{PA} < 1$–3 litre mol^{-1} cm^{-1}), while the products have extinction coefficients ε_P greater by three–four orders of magnitude than the amides. By irradiating thick layers of the amide (as a rule >1 cm), it is possible to increase the role of the secondary photolysis, since by shielding the amide from light, the products formed decrease the amount of light which it absorbs. The use of photoinitiating additives makes it possible to reduce the role of secondary photolytic reactions.

In order to assess the role of secondary photolytic reactions in the nonsensitised photochemical oxidation of polyamides, one can use[7] the equation

$$[P]_{min} = \Phi_{form} K_{PA}/\varepsilon_P, \qquad (34)$$

where $[P]_{min}$ is the minimum concentration of the product for which the rates of its formation and consumption via secondary photolysis are equal, Φ_{form} is the quantum yield in the formation of the product, ε_P the extinction coefficient of the product, and $K_{PA} = \varepsilon_{PA}[PA]$ is the absorption coefficient of PA. At 254 nm we have $K_{PA} = 32$ cm^{-1} [108] and the quantum yield in the formation of radicals is $\Phi_{form} = 0.01$. Assuming that the extinction coefficient of the radicals $\dot{P}_1$ and $P_1\dot{O}_2$ is $\varepsilon_P \cong 7 \times 10^3$ litre mol^{-1} cm^{-1},[68,71] we find from Eqn.(34) that the photolysis of radicals under the influence of light at $\lambda = 254$ nm can be come appreciable at radical concentrations of $\sim 4 \times 10^{-5}$ mol kg^{-1}. Such radical concentrations are indeed observed, for example, in the irradiation of PA-6.[109] It is possible to determine similarly the concentrations at which the photolysis of peroxides, aldehydes, etc. becomes significant.

For the photoageing of polyamides sensitised by an additive D, Eqn.(34) can be written in the form

$$[P(sens)]_{min} = \Phi_{form}\varepsilon_D [D]/\varepsilon_P. \qquad (35)$$

Compounds whose extinction coefficients $\varepsilon_D \cong 10^4$ litre mol^{-1} cm^{-1}, and whose quantum yields for the formation of radicals are extremely high ($\Phi_{form} \cong 0.1$–1), are usually employed as the initiating additives. Evidently, by selecting a suitable sensitiser and its concentration, it is possible to reduce to zero the role of secondary photolytic reactions. In this case photoageing is determined solely by initiation and dark reactions.

An additional factor influencing the photochemical oxidation—diffusion-dependent limitations—appears in the photochemical oxidation of polyamides. Even in the liquid-phase oxidation diffusion-dependent limitations can play a significant role[110]. In solid polymers the diffusion coefficients of O_2 are several orders of magnitude smaller than in the liquid phase. The range of the permissible rates of oxidation of the polymer, where the diffusion of O_2 does not limit the reaction, is therefore restricted to more severe conditions. It has been found[7] that the oxidation must proceed in the kinetic region when

$$w < 10^{11}(P/L^2)p_{O_2}, \qquad (36)$$

where w is the rate of absorption of oxygen (mol litre^{-1} h^{-1}), P the constant of the permeability of the polymer to O_2#, L

The permeability constant P is expressed[111] in cubic centimetres, adjusted to the standard temperature and pressure, of the gas which has passed in 1 s through 1 cm^2 of the area of a membrane 1 mm thick when the pressure drop is 1 cmHg.

the thickness of the film or the diameter of the fibre (μm), and p_{O_2} is the partial pressure of oxygen (atm). The values of P for different polymers have been published[111]; $P = 3.8 \times 10^{-11}$ for PA-6 at 30 °C.

Examples of the influence of diffusion-dependent limitations on the photochemical oxidation of polyamides have been published in a number of communications[112-114] and discussed by Margolin et al.[7]

4. The Sequence of the Formation of Photochemical Oxidation Products

In the liquid-phase oxidation of hydrocarbons, the primary product is as a rule the hydroperoxide whose reactions determine both the initiation and the composition of the main products[110]. As shown above, the same situation obtains also in the oxidation of *N*-alkylamides at temperatures above 100 °C, but, when the temperature is reduced, the oxidation of *N*-alkylamides proceeds via a non-chain mechanism and the primary products arise from the recombination of peroxy-radicals. In polymers, the peroxy-radical recombination reaction is difficult owing to the restricted molecular ability; the radicals can therefore participate in other reactions leading to an increased chain length for oxidation[115]. The problem of the sequence of the polyamide photochemical oxidation products therefore requires special consideration.

The first study on the accumulation of peroxides in the photochemical oxidation of polyamides was carried out by Anton[64]. When PA-6,6 fibres are irradiated in air by light at $\lambda > 270$ nm, the concentration of peroxides increases from 1.7×10^{-3} to 4.2×10^{-3} mol kg^{-1} over a period of 60 h; the polymer is then almost completely decomposed long before the attainment of a steady-state concentration of peroxides. Under the influence of light at $\lambda > 300$ nm and also $\lambda > 340$ nm, the decrease in stability takes place at lower rates but peroxides accumulate almost as much as under the influence of light at $\lambda > 270$ nm. On illumination with light at $\lambda > 415$ nm, the decrease in the stability of the polyamide is not accompanied by an appreciable change in the concentration of peroxides. We believe that the results obtained show that the main pathway in the photochemical decomposition of polyamides is unrelated to the peroxide formation reaction under the given experimental conditions.

It is of interest to note that, in the radiation-induced oxidation of PA-6 [65,116] and model *N*-alkylamides[82], peroxy-radicals are converted via parallel pathways into peroxide, carbonyl, and carboxy-compounds, which has been explained by the non-chain oxidation of PA-6 at temperatures below 100 °C.

The results of studies[108,112-114,117-120] on the kinetics of the accumulation of the non-sensitised photoageing of polyamides under the influence of light at $\lambda = 254$ nm are presented in Fig. 3 and in Table 2. Table 2 shows that the main contribution to the photodecomposition of polyamides comes from oxidation processes. Thus the increase in the quantum yield for the chain dissociation process following an increase of the O_2 partial pressure indicates that, apart from the primary ruptures S_{prim} caused by the photolysis of the amide linkage [reaction (1)], secondary ruptures S_{sec}, due to oxidative processes, also arise. The formation of peroxides does not then constitute the only pathway in the photochemical oxidation. Separate experiments have shown[121] that, for concentrations in the range 0–0.02 mol kg^{-1}, peroxides do not initiate the photochemical oxidation of polyamides. The quantum

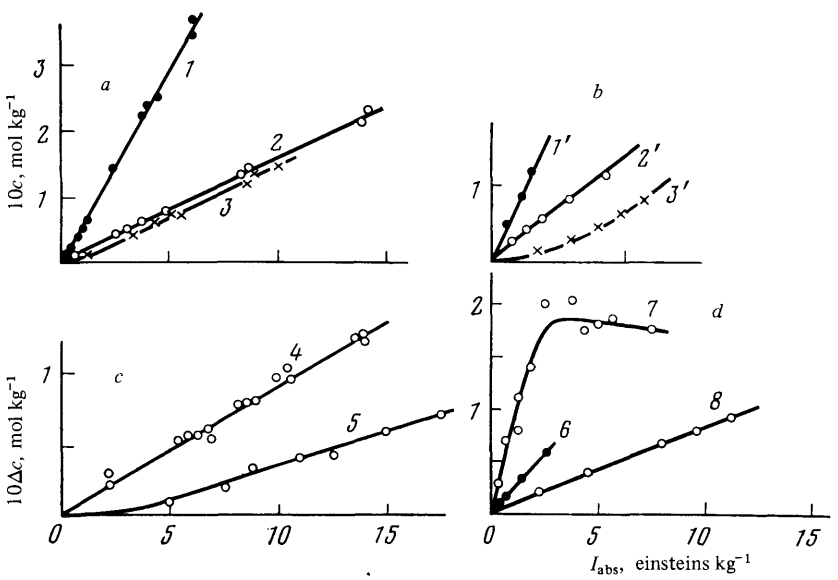

Figure 3. Photochemical oxidation of PA-6 and PA-548 films 3–6 μm thick under the influence of light at $\lambda = 254$ nm as a function of the irradiation dose I_{abs} at 25–30 °C: *a*) kinetic curves for the absorption of oxygen (curve *1*), the accumulation of breaks (curve *2*), and the evolution of CO (curve *3*) on irradiation of PA-6 (curves *1*–*3*) and PA-548 (curve *1*) in air; *b*) kinetic curves for the absorption of oxygen (curve *1'*), the accumulation of breaks (curve *2'*), and the evolution of CO (curve *3'*) on irradiation of PA-6 (curve *1'*) and PA-548 (curves *1'*–*3'*) in an O_2 atmosphere; *c*) kinetic curves for the accumulation of aldehydes (curves *4*) and carboxylic acids (curve *5*) on irradiation of PA-6 and PA-548 in air; *d*) kinetic curves for the accumulation of peroxy-compounds in air (curve *6*) and in an oxygen atmosphere (curve *7*) on irradiation of PA-548 and for the accumulation of pyrrole derivatives (curve *8*) on irradiation of PA-6 in air.

yields of a number of processes in PA-6 are identical with the yields of the corresponding processes in PA-548, which is explained by the fact that in both PA-6 and PA-548 the photoageing is caused by the absorption of light by the amide group.

A schematic sequence of the formation of products (the numbers over the arrows indicate the quantum yields of the corresponding processes in the photochemical oxidation of polyamides in air) has been proposed[7] on the basis of a comparison of the kinetic curves in Fig. 3:

Scheme I

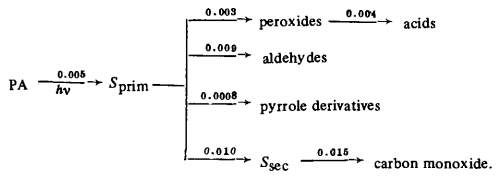

Table 2. The quantum yields of the photolysis and photochemical oxidation processes in the kinetic region on irradiation of PA-6 ($\lambda = 254$ nm; 25–30 °C).

Chemical process	Quantum yield of process (Ref.7)		
	photolysis	photochemical oxidation	
		air	oxygen
Formation of radicals	0,01[a]	—	—
Formation of carbon monoxide	$5\cdot10^{-4}$	0.015	0.030[c]
Formation of hydrogen	$7\cdot10^{-5}$	0.000[c]	0.000[c]
Ruptures in main PA chain	$5\cdot10^{-3}$[b]	0.015[c]	0.030[c]
Absorption of oxygen	—	0.060[c]	0.090[c]
Formation of carboxylic acids	$1.5\cdot10^{-4}$	0.004[c]	—
Formation of aldehydes	—	0.009[c]	—
Consumption of amino-groups	$1.5\cdot10^{-4}$	0.001[d]	—
Accumulation of peroxides	—	0.003[e]	0,007[e]
Accumulation of pyrrole derivatives	$2\cdot10^{-4}$[a]	0.0008	—

Note. [a]Estimate. [b]Estimated on the assumption that the primary process involves the dissociation of the amide bond. [c]The same value, within the limits of experimental error (10%), was obtained on irradiation of PA-548. [d]Determined from the initial rate of consumption of amino-groups. [e]Determined on irradiation of PA-548.

5. The Mechanisms of the Formation of the Products of the Photochemical Oxidation of Polyamides

The photoageing of polyamides is characterised by a large number of reactions, the relative rates of which depend on the experimental conditions. Since the same product can be formed in different reactions in the photoageing of polyamides, it is necessary to examine the possible mechanisms of the formation of the most important products: carboxylic acids, aldehydes, pyrrole and pyridine derivatives, peroxides, and carbon monoxide. Aparte from the composition of the products, in the study of the photoageing of polyamides one determines the number of breaks in the macromolecules and the decrease of stability, which, like the chemical products, characterise the process. Such processes, leading to the rupture of polyamide macromolecules and a decrease of the stability of polyamides, are examined below.

The formation of carboxylic acids. The formation of acids is attributed either to the oxidation of the acyl radical $R\dot{C}O$, which arises when the amide bond is ruptured[62], or to the oxidation (at advanced stages of the process) of aldehydes (Scheme II):[47]

Scheme II

$$R\dot{C}O + O_2 \rightarrow RC(O)O\dot{O} \quad , \tag{37}$$

$$RC(O)O\dot{O} + P_1H \rightarrow RC(O)OOH + \dot{P}_1 \quad , \tag{38}$$

$$RC(O)OOH \rightarrow RC(O)\dot{O} + \dot{O}H \quad , \tag{39}$$

$$RC(O)\dot{O} + P_1H \rightarrow RCOOH + \dot{P}_1 \quad , \tag{40}$$

$$RC(O)\dot{O} \rightarrow \dot{R} + CO_2 \quad , \tag{41}$$

$$2RC(O)OOH \rightarrow 2RCOOH + O_2 \quad , \tag{42}$$

$$R'CHO + RC(O)OOH \rightarrow R'COOH + RCOOH \quad , \tag{43}$$

$$RCHO + O_2 \rightarrow RCOOH \quad . \tag{44}$$

As in the oxidation of hydrocarbons[122], the radical decomposition of the peracid via reaction (39) hardly leads to the formation of acids owing to the rapid decomposition of the radical $RC(O)\dot{O}$ [reaction (41)], with which reaction (40) cannot compete ($k_{41}/k_{40} \cong 100$ at 85 °C). Therefore reactions (42) and (43), involving a non-radical transformation of the peracid, make the main contribution to the formation of acids and explain the low quantum yields in the formation of peroxides and acids in Scheme I. Reaction (39) should occur particularly effectively under the influence of light, resulting in the evolution of CO_2, as has been observed, for example, on irradiation of *N*-alkylamides by light at $\lambda > 300$ nm. However, in conformity with Eqn. (34) and the data in Fig. 3, the photolysis of the peracid at $\lambda = 254$ nm cannot compete with the dark reactions of the peracid, which agrees with the absence of CO_2 from the products and with the induction period with respect to the absorption of oxygen (Fig. 3, line *1*). At advanced stages of the photochemical oxidation the additional pathways leading to the formation of acids consist of photochemical and dark reactions of aldehydes and other oxidation products[11].

The formation of aldehydes. It has been suggested[7,11,123,124] that there is a possibility of the formation of aldehydes in parallel processes, which include the dark reactions of the radicals $R\dot{C}O$, $P_1\dot{O}_2$, and $P_1\dot{O}$ as well as the photochemical reaction of $P_1\dot{O}_2$ (Scheme III)

Scheme III

$$R\dot{C}O + P_1H \rightarrow RCHO + \dot{P}_1 \quad , \tag{17}$$

$$P_1\dot{O}_2 + P_1\dot{O}_2 \rightarrow P_1OH + RCONHCOR' + O_2 \tag{28}$$

$$\rightarrow RCONH_2 + R'CHO \quad , \tag{29}$$

$$P_1OOH \rightarrow P_1\dot{O} + \dot{O}H \quad , \tag{25}$$

$$P_1OOP_1 \rightarrow P_1\dot{O} + P_1\dot{O} \quad , \tag{45}$$

$$P_1\dot{O} + P_1H \rightarrow P_1OH + \dot{P}_1 \quad , \tag{46}$$

$$P_1\dot{O}_2 \rightarrow RCONHCHO + CH_2O + \dot{R}' \quad , \tag{47}$$

$$P_1\dot{O}_2 \xrightarrow{h\nu} RCONHCHO + R'\dot{C}HOH \quad , \tag{48}$$

$$P_1\dot{O}_2 + R'\dot{C}HOH \rightarrow RCONHCOR' + R'CHO + H_2O \quad . \tag{49}$$

The $P_1\dot{O}_2$ isomerisation reaction [reaction (47)] is significant only at high temperatures[123]. It has been suggested[7] that the photolysis of radicals via reaction (48) can lead to the formation of aldehydes in reaction (49).[124] The fact that, under the influence of light at $\lambda = 254$ nm, aldehydes are formed independently of peroxy-compounds makes it possible to rule out a significant contribution of reactions (25), (45), and (46) to the formation of aldehydes under the experimental conditions of Margolin et al.[7] However, under other irradiation conditions, these reactions may prove to be highly important.

The formation of pyrrole and pyridine derivatives. It has been suggested[65] that pyrroles are formed in the photochemical oxidation of PA-6,6 as a result of the condensation of dicarbonyl compounds with primary amines. Peebles and Hoffman[66] explained the formation of pyridine derivatives in the ageing of PA-6,6 and PA-10.6 by the condensation reactions of carbonyl compounds with the terminal amide groups and subsequent cyclisation. Owing to the structural characteristics of the molecule, in PA-6 the analogous reactions lead to pyrrole derivatives. The suggested derivatives explained to some extent the extremely low quantum yields in their formation (Scheme I).

The formation of peroxy-compounds. It is believed[2,7,11,47,100,101,103-107] that there is a possibility of the formation of five peroxy-compounds. There are peracids [reaction (38)], the hydroperoxide P_1OOH [reaction (24)], hydrogen peroxide [reactions (26) and (32)], the peroxide P_1OOP_1 [reaction (27)], and the terminal alkyl hydroperoxide of the type RCH_2OOH, which is formed on oxidation of the terminal alkyl radical. The above reactions result from processes involving different radicals and functional groups, which explains the dependence of the composition of the peroxy-products on the method of photoinitiation and temperature.

Breaks in the main polyamide chain and the formation of carbon monoxide. These can occur in the following reactions (Scheme IV):[7,11]

Scheme IV

$$P_1H \xrightarrow{h\nu} R'CH_2\dot{N}H + R\dot{C}O \quad , \qquad (1)$$

$$RCONHCOR' \xrightarrow{h\nu} \begin{cases} \longrightarrow RCO\dot{N}H + R'\dot{C}O \quad , & (50) \\ \longrightarrow R'CO\dot{N}H + R\dot{C}O \quad , & (51) \end{cases}$$

$$\dot{P}_1 \xrightarrow{h\nu} \begin{cases} \longrightarrow R'CH{=}NH + R\dot{C}O \quad , & (11) \\ \longrightarrow RCON{=}CHCH_2R'' + \dot{H} \quad , & (21) \end{cases}$$

$$P_1OOH \rightarrow RCONHCH{=}CHR'' + H_2O_2 \quad , \qquad (32)$$

$$RCON{=}\overset{\uparrow}{C}HCH_2R'' \xrightarrow{H_2O} \underset{RCONHCH=CHR''}{RCONH_2} + R'CHO \quad , \qquad (52)$$

$$P_1OOH \rightarrow RCONH_2 + R'CHO \quad , \qquad (33)$$

$$P_1\dot{O}_2 \rightarrow RCONHCHO + R''\dot{C}HOH \quad , \qquad (48)$$

$$P_1\dot{O}_2 + P_1\dot{O}_2 \rightarrow RCONH_2 + R'CHO + RCONHCOR' + O_2 \quad , \qquad (28)$$

$$P_1\dot{O} \rightarrow RCONHCHO + \dot{R}' \quad , \qquad (53)$$

$$P_1OOH \rightarrow RCONHCHO + R'OH \quad , \qquad (31)$$

$$P_1OOP_1 \rightarrow RCONHCHO + RCONHCOR' + R''CH_3 \quad , \qquad (54)$$

$$RCONHCHO \rightarrow RCONH_2 + CO \quad , \qquad (55)$$

$$RCHO \xrightarrow{h\nu} RH + CO \quad , \qquad (56)$$

$$R\dot{C}O \rightarrow \dot{R} + CO \quad . \qquad (18)$$

The secondary breaks can occur in the photolysis of imides [reactions (50) and (51)], alkyl radicals [reactions (11) and (21)], and peroxy-radicals [reaction (48)], as a result of the decomposition of peroxy-compounds [reactions (31)–(33) and (54)] and the radicals $P_1\dot{O}$ [reaction (53)], and the recombination of peroxy-radicals [reaction (28)]. The breaks in the polyamide macromolecules are accompanied by the evolution of CO either in the decomposition of acyl radicals [reaction (18)], or in the photolysis of aldehydes [reaction (56)], or in the decomposition of the unstable *N*-formylamide [reaction (55)][107,123]. At reduced temperatures the occurrence of reaction (55) under the influence of light is more likely. In this case it is analogous to the photolysis of aldehydes[10].

Scheme IV shows clearly that in the oxidation process all the reactions involving the rupture of the main polyamide chain lead ultimately to the formation of unsubstituted amides; the latter are obtained either directly in the dissociation reaction or on further reactions of the radicals and the unstable products formed when the chain is broken. In the oxidation process the number of breaks in the polyamide should therefore be close to the number of terminal amide groups obtained. The second product of the majority of dissociation reactions is an aldehyde or the oxidation product of the acyl radical—a peracid and an acid.

The photolysis of imides, which is significant at advanced stages of the oxidation process, leads to the rupture of the polyamide chain with formation of an unsubstituted amide and an aldehyde or acid in subsequent reactions. The unstable products of reactions (21) and (32) (enamides or their tautomers) lead to breaks via the formation of the intermediate P_1OH, the decomposition of which also gives rise to an unsubstituted amide and an aldehyde [reaction (52)]. The most probable product of the oxidation of the amino-radical, formed in reaction (1), is a primary amide.

The mechanism of reaction (53), involving the decomposition of the radical $P_1\dot{O}$, has been formulated by analogy with the decomposition reaction of secondary alkoxy-radicals, which usually constitutes the main pathway in their transformation on oxidation of hydrocarbons[110]. There is no reason to believe that the radicals $P_1\dot{O}$ are less reactive in the decomposition reactions. On the other hand, the reactivity of the radicals $P_1\dot{O}$ in the reactions involving the abstraction of a hydrogen atom should be lower than for alkoxy-radicals owing to the influence of the nitrogen atom, which increases the electron density around the oxygen atom. The analogous influence of the nitrogen atom leads to an appreciable diminution of the reactivity of the radical $\dot{P}_1$ compared with alkyl radicals. The formation of $P_1\dot{O}$ is most probable in the photolysis of peroxides.

The wide variety of alternative reactions leading to the formation of the same products via different pathways provides an idea of the complexity of the mechanism of the photochemical oxidation of polyamides in which particular reactions occur depending on the experimental conditions and the ratios of the final products differ very widely. In photochemical oxidation, where virtually all the alkyl radicals are converted into peroxy-radicals, reactions (11) and (21) are insignificant. At reduced temperatures, where the photochemical oxidation of polyamides is a non-chain process, one can neglect the contribution of the hydroperoxide decomposition reactions (31)–(33) to the chain dissociation processes. However, there remains the possibility of the formation of the peroxides P_1OOP_1, whose pohotolysis can lead to chain breaks either via the formation of the radicals $P_1\dot{O}$ or via reaction (54).

In the sensitised photochemical oxidation it is possible to neglect the photolysis of the peroxy-radicals $P_1\dot{O}_2$ via reaction (48), since the principal breaks at reduced temperatures occur on recombination of $P_1\dot{O}_2$, according to the observations of Lock and Sagar[105]. In the non-sensitised photochemical oxidation of PA-6 under the influence of light at $\lambda = 254$ nm, for small extents of oxidation (Fig.3 and Table 2) when it is possible to neglect the photolysis of aldehydes but not the photolysis of peroxy-radicals, the quantum yields of the secondary dissociation processes and the formation of aldehydes and CO have similar values. Considering the possible dissociation reactions, these relative amounts of the products can be accounted for by the photolysis of the peroxy-radicals [reaction (18)], this being followed by the evolution of CO in the decomposition of *N*-formylamide via reaction (55) and the formation of an aldehyde on recombination of the radicals [reaction (49)].

In the non-sensitised photochemical oxidation under the influence of the total light of the PRK-2 lamp aldehydes undergo vigorous photolysis at advanced stages of the oxidation process, so that their yield is extremely low and that of CO is somewhat lower than the yield of unsubstituted amides[11]. Under these conditions, the imides are photolysed via reactions (50) and (51), which makes an additional contribution to the number of breaks, and the oxidation of acyl radicals to peracids and the subsequent photolysis of the latter lead to the evolution of CO_2. In the sensitised photochemical oxidation at reduced temperatures there is no evolution of CO, despite the formation of breaks, *N*-formylamide, and aldehydes, owing to the shielding effect of the sensitiser on the photolytic reactions of *N*-formylamide and the aldehyde [reactions (55) and (56)].

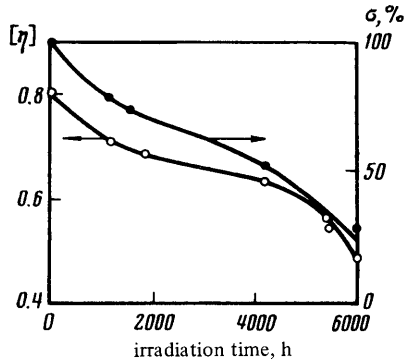

Figure 4. Photochemical ageing of PA-6.6 fibres under natural conditions {variation of the intrinsic viscosity (η) and of the loss of strength σ as a function of the duration of irradiation by sunlight with $\lambda > 300$ nm}.

6. The Decrease of the Strength of Polyamides

The impairment of the mechanical strength characteristics of polyamides on photoageing is associated with chemical processes[46]. For example, the simultaneous decrease of the tensile strength of the polymer and of its molecular weight are observed in the photoageing of PA-6,6 [46] (Fig.4).

In order to elucidate the nature of the strength of polyamides, the dependence of their lifetime τ on the applied load σ, described by Zhurkov's equation[126]

$$\tau=\tau_0 \exp[(U_0-\gamma\sigma)/kT], \qquad (57)$$

was investigated. For polyamides, the empirical parameters are $\tau_0 = 10^{-12}$ s and $U_0 = 45$ kcal mol^{-1}. The influence of the change of the molecular weight of the polyamide on the parameters τ_0, U_0, and γ has been investigated[127]. By irradiating PA-6 with different doses of ultraviolet light, the authors obtained specimens with different molecular weights; subsequently, the lifetimes of the specimens were measured in the dark. Preliminary irradiation affected only the parameter γ. A linear relation was observed[127] between $1/\gamma$ and the molecular weight and its theoretical validity was demonstrated[128]. Thus one may conclude that the breaks in the main polyamide chain lead to an increase of γ and hence to a decrease in the strength of the polymer.

The strength of the polyamide is influenced not only by the molecular weight of the polymer but also by the nature of the supermolecular structure. For example, the tensile strength of the highly oriented PA-6 is twelve times greater than that of the non-oriented material[129]. It follows from the theory[130–133] and has been confirmed by experiment[134], that $1/\gamma$ is directly proportional to the degree of extrusion. The structural changes in the photoageing of polyamides are observed as an increase in the density, the degree of crystallinity, and the surface microrelief; they are explained by the fact that the breaks in the main polyamide chain facilitate the movement of the macromolecules, which leads to more ordered structures[135–139]. Thus in this case too the breaks in the main polyamide chain lead ultimately to an alteration of the mechanical and stength characteristics of the polymer.

During use, polyamide articles can be subjected to different loads. The joint influence of the light intensity I and of the load σ, resulting in a decrease of the lifetime τ_I of the polyamide, has been investigated[140–143]. It has been shown that, for a certain load σ_{lim}, a characteristic break is observed in the experimental lg τ–σ linear plots:

$$\tau_I=\tau_0 \exp[(U_0-\gamma\sigma)/kT] \text{ for } \sigma>\sigma_{lim}; \qquad (58)$$

$$\tau_I=B(T)/IK\Phi_{0,s} \exp(m\gamma\sigma) \text{ for } \sigma<\sigma_{lim}, \qquad (59)$$

where K is the light absorption coefficient of the polyamide, m a constant coefficient, $\Phi_{0,S}$ the quantum yield of the dissociations in the main polyamide chain in the specimen not subjected to a load, and $B(T)$ a function which only slightly depends on temperature.

For $\sigma > \sigma_{lim}$, the action of light is weak compared with that of the load and can be neglected, so that the lifetime of the specimen is described by Zhurkov's equation (57). The quantity $\Phi_{0,S} \exp(m\gamma\sigma)$ is regarded as the quantum yield for dissociation in the molecules subjected to a load. It is believed that the increase of the quantum yield of the dissociation under the influence of the load occurs mainly as a result of the suppression of the cage recombination of the radicals formed on rupture of the macromolecule subjected to extending forces[144–150]. It is readily seen that the expression $IK\Phi_{0,S} \exp(m\gamma\sigma)$ in Eqn.(59) represents the number of breaks in the main polyamide chain. Thus for $\sigma < \sigma_{lim}$, the lifetime of the polyamide on irradiation in the loaded state is inversely proportional to the number of breaks.

The influence of ultraviolet irradiation and oxygen[142,143] and of nitrogen dioxide[151] on the lifetime of polyamide specimens subjected to a load has been investigated. In all the investigations a relation has been observed between the number of breaks in the main polyamide chain and the decrease of their strength. This relation makes it possible to regard the changes in the mechanical and strength characteristics as a result of chemical changes determined by the mechanism of the photoageing of the polyamide.

7. Kinetics of the Photochemical Oxidation of Polyamides

The kinetics of the destruction of macroradicals in polyamides of different structure have been studied[70,77,152,153]. It has been established that the destruction of macroradicals $\dot{P}_1$ is of second order with respect to concentration. The quadratic termination of macroradicals, including peroxy-radicals, has been observed in various polymers[154]. Presumably, peroxy-radicals $P_1\dot{O}_2$ in polyamides are also destroyed via a second-order reaction, as happens in the oxidation of model *N*-alkylamides[155,159].

The rate of photochemical oxidation of polyamides with quadratic termination can be represented by the expression

$$w = \frac{1}{2} w_{in} + (k_p/\sqrt{k_t})[P_1H]\sqrt{w_{in}}, \quad (60)$$

where $w_{in} \cong I$ is the rate of photoinitiation and k_p and k_t are the chain propagation and termination rate constants respectively.

Experiment shows[7] that the rates of absorption of O_2 and of accumulation of polyamide photochemical oxidation products under the influence of light at $\lambda = 254$ nm are proportional to the light intensity I at 20–30 °C and that with increase of temperature the order of the reaction based on the rate of initiation diminishes. Thus at 100 °C the rate of photochemical oxidation of PA-6 is proportional to $I^{1/2}$. These results can be accounted for by the absence of oxidation chains in the low-temperature oxidation owing to the unduly high rates of photoinitiation under the experimental conditions where it is possible to neglect the second term of the sum on the right-hand side of Eqn.(60). With increase of temperature, the photochemical oxidation at the same rates of photoinitiation acquires a chain mechanism as a result of the increase of $k_p/\sqrt{k_t}$.

It might have been supposed that the reaction is first order with respect to light intensity because it is a chain oxidation process with linear termination and that the decrease of the reaction order with increase of temperature is caused by a change in the termination mechanism. For long oxidation chains, the rate of absorption of O_2 determines the concentration of the radicals. It is known[70] that the efficiency of the destruction of macroradicals in polyamides depends very markedly on the supermolecular structure of the polymer. The dependence of the destruction of radicals on the supermolecular structure should influence also the rate of oxidation, as has been observed, for example, in the thermal oxidation of different polyamides[160] and other polymers[161]. However, it has been found that the rate of photochemical oxidation of PA-6 is independent of the degree of orientation and the degree of crystallinity of the specimen[162,163], which conflicts with the hypothesis of chain oxidation with linear termination.

At the same time, in the low-temperature non-sensitised photochemical oxidation of polyamides the rate of photochemical oxidation exceeds by a factor of nine the rate of the primary photoinitiation (Table 2). Under the experimental conditions, there is apparently additional initiation as a result of secondary photolysis. Indeed, a different relation between the rates of photochemical oxidation and photoinitiation is observed in the photochemical oxidation of polyamides sensitised by benzophenone under conditions where, according to Eqn.(35), secondary photolysis can be neglected[7]:

$$w \simeq w_{in} \simeq 0.11 \text{ mol kg}^{-1} \text{ h}^{-1}. \quad (61)$$

The parameter $k_p/\sqrt{k_t} = 2.7 \times 10^{-4}$ litre mol^{-1} s$^{-1/2}$ at 30 °C can be estimated from Eqns.(60) and (61); it is of interest to compare it with the kinetic parameters of the oxidation of model N-alkylamides and other compounds (Table 3).

The values of $k_n\sqrt{k_t}$ for different amides recalculated per reactive α-C–H, bond are similar and equal to $(0.2–0.3)\times10^{-4}$. On passing from low-molecular-weight amides to solid polyamides, the parameter $k_n\sqrt{k_t}$ increases by a factor of approximately 6. An analogous situation has been observed also for polypropylene and its low-molecular-weight analogue 2,4-dimethylpentane, mainly owing to the appreciable decrease of the termination rate constants k_t as a result of the limitation of molecular mobility on passing from the liquid phase to the solid polymer.

V. PROBLEMS OF CONTROLLED PHOTOAGEING

1. Prediction of the Resistance to the Action of Light

Prediction of the resistance to the action of light makes possible a fairly well-founded approach to the selection of the material for use under specific conditions. A direct prediction procedure is based on natural tests, which make it possible to estimate the time during which the useful properties of the polymer are retained when it is employed under natural conditions. The main operational property of polyamides is their strength. Therefore in tests of the resistance of polyamides to the action of light under natural conditions one investigates the changes in the mechanical strength characteristics. Fig.5 presents data[1] concerning the changes in relative elongation on rupture and of the ultimate tensile strength under conditions of natural photoageing of specimens of different polymers. Fig.5 shows that polyamides exhibit a low resistance to the action of light: all aliphatic polyamides lose their useful operational properties in all climatic zones during less than one year. A significant impairment of properties occurs after only one–two months[4,164–166].

*Determined by extrapolation of the temperature variations of k_p and k_t to 30 °C.
**Estimated from Eqns.(60) and (61).

The photoageing of polymers during their use (and in tests under natural conditions) takes place under conditions characterised by significant changes in operating factors: the intensity and spectral composition of light, temperature, humidity, and level of corrosive impurities in the atmosphere, etc. Fig.5 shows that humidity has a significant influence on certain polymers. It has been found that humidity retards somewhat the evolution of CO in the photolysis of PA-669 [167] but has almost no influence on strength when polyamide fibres are irradiated by light at $\lambda > 340$ nm and retards slightly the loss of strength by polyamides after irradiation by light at shorter wavelengths at room temperature; however, one should note that at higher temperatures (100 °C) and in the presence of titanium dioxide humidity accelerates appreciably the photoageing processes of polyamides[4,46,168,169]. The decrease of the strength of polyamides on photoageing in the vicinity of cities proceeds at higher rates than in the country[4], which indicates the possible influence of corrosive impurities in the atmosphere. Nitrogen dioxide and ozone also accelerate the photoageing of PA-6,6.[170] However, the most significant factor influencing the photoageing of polyamides is evidently the intensity and spectra composition of sunlight.

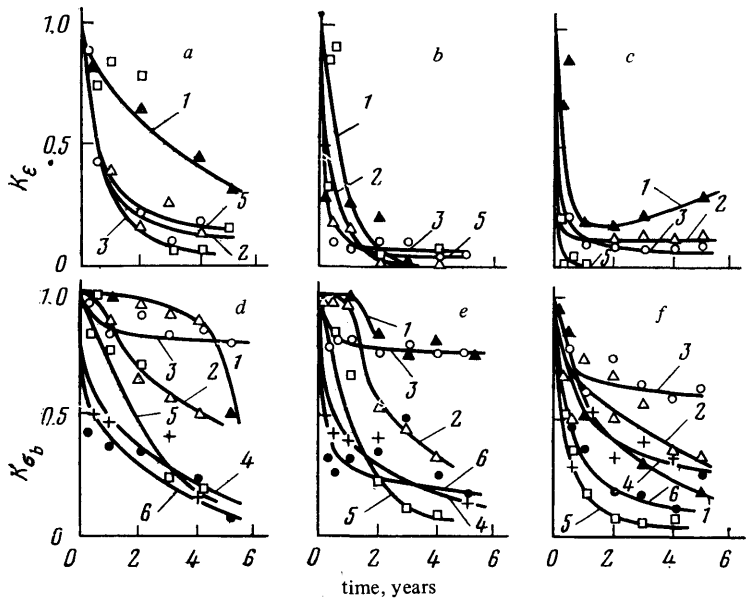

Figure 5. Dependence of the relative elongation (K_ε) on rupture (*a*, *b*, and *c*) and of the ultimate tensile strength (K_{σ_b}) (*d*, *e*, and *f*) as a function of the ageing time in moderately cold (*a* and *d*), warm and humid (*b* and *e*), and hot and dry (*c* and *f*) climatic zones for specimens of the trioxan-dioxolan copolymer (curves *1*), the formaldehyde–dioxolan copolymer (curves *2*), polycarbonate (curves *3*), PA-6 (curves *4*), PA-12 (curves *5*), and PA-6,10 (curves *6*).

A second way of predicting photoageing involves prediction based on the rsults of accelerated tests. Empirical relations, which describe with a greater or lesser degree of approximation the result of both natural and accelerated tests, are of great assistance in such tests[1,171]. In order to be able to extrapolate the results of accelerated tests to conditions corresponding to the photoageing of polyamides under natural conditions, one takes into account during the accelerated tests the factors which are significant in natural tests. Allowance for the influence of temperature, atmospheric humidity, and the content of ozone in air is achieved by a modelling procedure. An essential condition for a correlation between the results of natural and accelerated tests is also believed to be complete identity of the spectral composition of sunlight and artificial light[139,172–176]. It has been found[176] that photochemical activity is not shown by light over the entire spectral range but only by the short-wavelength part of the spectrum with $\lambda < 315$ nm; the nature of the spectra composition of light at $\lambda < 315$ nm is therefore most significant.

The intensity of sunlight in the region corresponding to absorption by polyamides, i.e. at $\lambda < 290$–300 nm, is extremely low ($I < 3.6 \times 10^{12}$ quanta cm^{-2} s^{-1}).[12] This suggests that secondary photolysis makes a major contribution to the initiated photoageing of polyamides under natural conditions. A wide variety of photochemical oxidation products—aldehydes, peroxy-compounds, and nitrogen-containing compounds (for example, imides or pyrrole derivatives, the absorption spectra of which differ)—can be involved in secondary photolytic reactions. This explains in its turn the necessity for maintaining the identity of the spectral composition of light as a condition for a correlation between the results of natural and accelerated tests.

At the same time one should note that the use of a high light intensity in accelerated tests with the remaining operating factors unchanged affects the form of chemical process occurring and alters the relative roles of different reactions. Thus, for fairly high light intensities I, the polyamide oxidation reaction has a non-chain mechanism and is determined solely by the initiation and radical destruction reactions. For very low values of I, the chain propagation stage may prove to be significant. The study of the influence of light intensity on the photoageing of polyamides therefore constitutes a more valid approach to the solution of the problem of a correlation between accelerated and natural tests.

Quantitative allowance of the factors already examined makes it possible to approach on a sounder basis the search for a correlation between the reults of natural and accelerated tests. The accuracy of such correlation is however inevitably limited by the uncertainty in the weather conditions (cloud cover, humidity, etc.). The study of the resistance of polyamides to the action of light in the presence of a wide variety of additives is of greatest interest. However, additives can influence the mechanism of the photoageing of polyamides, which also limits the scope of the correlation and of the theoretical predictions.

2. The Influence of Additives on the Photoageing of Polyamides

Titanium dioxide[46,51,62,65,177,178], which is used to etch fibres, is an active photosensitiser of the oxidation of polyamides. It has been shown[42] that the action spectrum of light on PA-6,6 in the presence of titanium dioxide is identical with the absorption spectrum of the latter and a number of possible mechanisms for the photosensitised oxidation of polyamides by titanium dioxide have been discussed.

Anthraquinone derivatives are believed to be the most powerful photosensitisers of the oxidation of polyamides[179]. Sodium anthraquinone-2-sulphonate at concentrations of 0.02 to 0.04 mol kg^{-1} increases the rate of photochemical oxidation of *N*-alkylamides by three orders of magnitude[107]. Initiation

in *N*-alkylamides takes place as a result of the abstraction of a hydrogen atom from the amide molecule by the excited sensitiser molecule and subsequent oxidation of the semiquinone radical by molecular oxygen.

Dyes such as β-Hydroxyethylsulphonium Red and Yellow and Monochlorotriazine Red and Yellow increase the rate of formation of radicals when PA-6 is irradiated by light at $\lambda = 254$ nm in air[87], the increase in the yield of radicals being directly proportional to the increase in the yield of carboxy-groups[109,180,181]. The impurities present in the initial monomers and formed in the synthesis of polyamides can also accelerate photoageing[182]. For a controlled acceleration of photoageing of polyamides, one can employ a wide variety of radical initiators, for example, iron(III) chloride, peroxides, etc.

The extensive experimental data accumulated hitherto on the stabilisation of PA with respect to the action of light have been published in reviews[3,4,6,183]. There exist literally thousands of substances and compositions which retard by factors of 2–5 the photoageing of polyamides. Apart from the large class of u.v. shields and u.v. absorbers, the action of which consists in the simple shielding of the polymer from light, among the most widely used light-stabilisers of polyamide mention may be made of copper and manganese compounds[3]. There is evidence for the efficiency of the protective action of chromium[2,6], nickel, and cobalt[184] salts, sodium and potassium halides[185], and phosphorus-containing compounds[3]. In recent years much attention has been devoted to manganese and phosphorus compounds[186–190], which prevent the photosensitising action of titanium dioxide, as well as copper and iodine compounds[191–195].

One should note that many of the compounds indicated also function as thermostabilisers of polyamides. For example, sodium bromide is effective both in thermal oxidation and in the photochemical oxidation of polyamides[196]. A qualitative correlation has been observed between the thermal and photochemical efficiencies of a number of copper-containing complexes of cyclo-1,3-phenylenethioisoindolenines used as stabilisers of PA-6.[197,198] There is also the opposite evidence: copper naphthenate, which is a powerful inhibitor of thermal oxidation of polyamides[199], does not influence the photochemical oxidation of *N*-alkylamides in an oxygen atmosphere[107], which is probably associated with the absence of oxidation chains in this instance.

Attempts have been made in a number of studies to elucidate the mechanism of the reaction of the most effective light stabilisers for polyamides—copper compounds. The changes in the supermolecular structure of PA-6 as a function of the introduction of copper-containing stabilisers (stabilines) have been studied[200]. It has been found that the introduction of stabilines tends to strengthen cord fibres, which can reduce the diffusion of oxygen into polyamides. This effect in the diffusion region of the photochemical oxidation leads to retardation of the oxidation process. However, in natural photoageing of polyamides, which lasts for months, one can hardly expect limiting by diffusion-dependent processes. Furthermore, the stabilising action of copper salts with respect to light has been observed also in the photochemical oxidation of PA-6 in the kinetic region[112].

The study of the gas evolution on irradiation of PA-6 by the total light of a moderate-pressure mercury lamp *in vacuo* has shown[201] that copper, chromium, zinc, and cadmium chlorides do not affect the gas evolution and that, on irradiation by light at $\lambda > 300$ nm, copper chloride accelerates the evolution of H_2. Under these conditions, the above stabilisers retard the decrease of the mechanical strength characteristics of PA-6. It has been suggested[201] that the action of the test compounds is due to their shielding properties. This explanation is apparently inadequate, because the shielding effect should lead solely to a decrease of the rate of gas evolution. It was shown subsequently, taking into account the shielding effects, that the protective action of copper and certain other metal salts cannot be reduced wholly to the shielding effect[112].

When PA-6 films are irradiated *in vacuo*, the addition of copper acetylacetonate (0.001–0.01 mol kg^{-1}) does not affect the evolution of CO and increase slightly the rate of evolution of H_2, which has been explained by the absence of an effect by copper acetylacetonate and the primary photochemical processes in polyamides[202]. However, at the same concentrations copper acetylacetonate reduces severalfold the quantum yields of the degradation processes, of the absorption of oxygen, and other PA-6 photochemical oxidation processes. Copper acetylacetonate retarded the benzophenone-sensitised photochemical oxidation of polyamides but did not influence the luminescence and kinetics of the consumption of benzophenone. This permits the conclusion that copper compounds are capable of inhibiting dark polyamide photoageing processes.

Since hydroperoxides were not detected in PA-6 fibres stabilised by copper salts, it was suggested that the additives suppress oxidation as a result of the formation of an inactive complex with the peroxy-radicals or as a result of the decomposition or binding of hydroperoxides with formation of inactive compounds[197,200]. An analogous effect—the absence of hydroperoxides—had been observed earlier in a study[65] of the photochemical oxidation of model amides with the addition of manganese salts, which enabled the authors to reach the same conclusion concerning manganese salts. Strictly speaking, the decreased content of peroxy-compounds may be a consequence also of other processes preventing the formation of peroxides.

A qualitative analogy between the action of copper salts and an acceptor of alkyl radicals (the 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical) has been observed[120,202]; the efficiency of the alkyl radical acceptor increases, like that of copper acetylacetonate, with decrease of the partial pressure of oxygen in accordance with the increase of the relative role of the alkyl radical participating in the photochemical oxidation of polyamides. Thus copper compounds can compete with oxygen in the alkyl radical oxidation reaction. The ability of copper(II) compounds to oxidise alkyl radicals has been demonstrated[203,204]. We believe that the protective action of copper(II) salts as a result of their interaction with alkyl radicals is most likely, although other protective mechanisms cannot be ruled out.

---o0o---

In conclusion we may note that the mechanism of the photoageing of polyamides continues to be the subject of numerous investigations.

A number of recent studies[205–214] are of interest for the elucidation of the mechanisms of the primary photochemical processes responsible for the initiation of the photoageing of polyamides. The nature of the luminescence in polyamides continues to be controversial[205,213]. Additional data[216], showing that the main primary reaction in the direct photolysis of amides is the breakdown of the amide linkage, have been obtained. It has been shown[214,215] that, in the sensitisation of the photoageing of polyamides by compounds of different classes, the principal primary initiation reaction involves the abstraction of a hydrogen atom with formation of the macroradical $RCONH\dot{C}HCH_2R'$ (P_1). Therefore the possibility of the involvement of singlet oxygen $^1O_2$ in initiation steps appear unlikely. An analogous conclusion was reached in other investigations[209,210] of the photochemical oxidation of

PA-6,6 and in a study[217] of the photochemical oxidation of low-molecular-weight amides.

A number of studies have been made on the mechanism of the photochemical oxidation of polyamides[218,219]. It has been shown experimentally for the first time[218] that the photochemical oxidation of PA-6 and PA-548 proceeds with participation of peroxy-radicals P_1O_2; measurements have been made of the rate of destruction of peroxy-macroradicals and of the corresponding rate constants [$k_d = 2.4\times10^{15}\exp(-16000/RT)$] kg mol^{-1} s^{-1} in both PA-6 and PA-548. $k_p/k_d^{1/2} = 1.4\times10^{-4}$ kg$^{1/2}$ (mol s)$^{-1/2}$ for the photochemical oxidation of PA-548 at 25 °C has been measured[219]. It was shown in the same study[219] that the chain oxidation becomes significant at extremely low rates of oxidation, comparable to the rates of photochemical oxidation of PA-6 under natural conditions.

The ideas concerning the role of secondary photolytic reactions in polyamides, discussed above, have found further confirmation in a number of investigations[212,218,220]. The possibility of the photochemical reaction of the amino-radicals has been demonstrated[212] and the photorecombination of PA peroxy-radicals, which proceeds at extremely high rates, has been observed[218].

New studies have been made on the mechanism of the stabilisation of polyamides with respect to the action of light[207, 221,222]. It has been shown[221] that the grafting of an inhibitor of radical processes (vinylhydroquinone) to PA-6 protects the polyamide against the action of light. It has been shown by EPR [222] that copper salts react with the macroradicals $\dot{P}_1$ and the rate constant for this reaction has been measured.

It can be regarded as established that the photoageing of polyamides is a radical-chain process with quadratic oxidation chain termination and that the oxidative degradation processes make the main contribution to the photochemical decomposition. Thus the photoageing of polyamides resembles the photoageing of certain carbochain polymers (for example, polyolefins, in relation to which an analogous conclusion has been reached[8]).

Whereas the photochemical oxidation of carbochain polymers is known to be initiated by hydroperoxy- and carbonyl groups, the nature of the photoinitiating groups in polyamides on irradiation by long-wavelength light continues to be controversial. The mechanism of the photoinitiated oxidation of polyamides can differ from the mechanism of the photoinitiated oxidation of other polymers. The cause of this difference may be related to the greater number of nitrogen-containing products (pyrroles, imides, and imines) which exhibit an intense ultraviolet absorption.

Although the nature of the chromophoric group responsible for the initiation of the photoageing of polyamides remains controversial, studies have shown that effective stabilisation of polyamides (as well as other polymers) with respect to the action of light can be achieved by introducing radical process inhibitors into the polyamide.

The photoageing of polyamides is characterised by a complex composition of products and a large number of reactions, the relative rates of which depend on experimental conditions. Secondary photolytic processes make a significant contribution to the photoageing process and studies of the photochemical reactions of polyamide macroradicals merit particular attention.

Thermochemistry of Organic Derivatives of Non-transition Elements

V.I.Tel'noi and I.B.Rabinovich

Studies of the enthalpies of formation (ΔH_f°) of a wide variety of organic derivatives of non-transition Group I-VI elements (450 substances), described in the literature, are discussed. The recommended values of ΔH_f° are tabulated and different versions of the enthalpy of combustion method and reaction calorimetry, used to determine the enthalpies of formation, are examined; the characteristic features, advantages, and disadvantages of specific experimental techniques are noted. All the thermochemical quantities quoted have been recalculated taking into account up to date initial data. The average dissociation energies ($\bar{D}$) of 115 chemical bonds, formed by non-transition elements (E^{nt}) in their organic compounds, have been calculated from the enthalpies of formation. The regular variation of the quantity $\bar{D}(E^{ent}-R)$, where R is an organic group, with the atomic number of the element E^{nt} down the corresponding Group in the Periodic System is demonstrated. The influence of the nature of the organic group on $\bar{D}(E^{nt}-R)$ is described.

The bibliography includes 260 references.

I. INTRODUCTION

In the last 20 years many organic derivatives of non-transition elements have found extensive applications in the national economy. For example, the use of organomagnesium halides (Grignard reagents) as intermediates in the industrial synthesis of a large number of organic substances and the use of alkyl and alkyl halide compounds of aluminium as well as lithium alkyls as components of catalytic mixtures for polymerisation processes are well known. Organosilicon compounds are used to prepare lubricating agents, rubber-like polymers with a wide temperature range of high elasticity, and polymeric films with selective gas permeability, and for other purposes. In recent years methods have been developed for the use of alkyl derivatives of a number of Group II–VI non-transition elements in the industrial synthesis of semiconductor compounds of the type $A^{III}-B^{V}$,

$A^{II}-B^{VI}$, and $A^{II}-B^{IV}$. There are also other important possibilities for the applications of the compounds under consideration.

On the other hand the thermodynamic parameters of the syntheses and reactions of many industrially important organic derivatives of non-transition elements have still not been determined or have been merely estimated. This hinders the development and improvement of the technology of the processes involved in their manufacture and their applications. Calculations of the thermodynamic parameters of the above reactions are in many instances impossible owing to the lack of literature data on the thermodynamic properties of the initial compounds. On the other hand, in other cases such data are available, but they are scattered among different literature sources and the most reliable results have not been selected. This applies in the first place to the enthalpies of formation.

The present review considers critically the enthalpies of formation of all 450 organic derivatives of non-transition elements, relevant information about which has been published in 250 papers in scientific journals of different countries up to 1977† and reliable standard enthalpies of formation of the substances indicated are recommended.

The standard enthalpy of formation of a compound $\Delta H^{\circ}_{f,298}$ is the term given to the enthalpy of its synthesis under standard conditions (298 K; 101325 Pa), in the stable physical state under the given conditions, from the elements in their stable state under standard conditions. In many instances such reactions do not really occur, since their enthalpies cannot be measured, but the above quantities can be calculated on the basis of Hess's law from the enthalpies of other (real) reactions involving the relevant compounds.

The standard enthalpies of formation of the compounds have in fact been selected as the fundamental thermochemical quantities for the calculation of the enthalpies of a wide variety of other reactions under standard conditions on the basis of Hess's law by means of the equation

$$\Delta H^{0}_{r,298} = \sum_{i} \nu_i \Delta H^{0}_{f,298}(i) - \sum_{j} \nu_j \Delta H^{0}_{f,298}(j), \qquad (1)$$

where ν is the stoichiometric coefficient of the reactant in the reaction equation and the indices i and j denote the reaction products and the starting materials respectively#. The enthalpies of reaction at 298 K can be adjusted to any temperature T by means of the Kirchhoff formula:

$$\Delta H^{0}_{r,T} = \Delta H^{0}_{r,298} + \int_{298}^{T} \Delta(\nu C_p)\,dT, \qquad (2)$$

where $\Delta(\nu C_p) = \sum_i \nu_i C_p(i) - \sum_j \nu_j C_p(j)$ and $C_p = f(T)$ is the heat capacity of the reactant at constant pressure. Here one usually employs polynomials of the type $C_p = a + bT + cT^2$, which are fitted to the experimental data. In Eqn.(2) it is assumed that in the range 298–T (K) the reactants do not undergo phase transformations. Otherwise it would be necessary to take into account also the enthalpies of these transitions.

The enthalpies of formation of organic compounds (OC) are as a rule calculated from their experimental enthalpies of combustion (ΔH°_{c}) in oxygen§ (the enthalpy of combustion method) by means of Eqn.(3) which follows from Eqn.(1):

$$\Delta H^{0}_{f,298}(\mathrm{OC}) = \sum_{i} \nu_i \Delta H^{0}_{f,298}(i) - \Delta H^{0}_{c,298}(\mathrm{OC}), \qquad (3)$$

where the index i denotes the combustion product (CO_2, H_2O, and other oxides). In many instances the quantities ΔH°_{f}(OC) are calculated from the enthalpies of other reactions involving the given organic compound (reaction calorimetry). In calculations by Eqn.(1) and (3) the values of $\Delta H^{\circ}_{f,298}$ for all the reactants except for the test substance are tabulated quantities[1,2].

The combustion of organoelemental compounds in order to determine their enthalpies of combustion is carried out in stationary or rotating bomb calorimeters. Combustion of such substances in a stationary bomb was carried out in early investigation by Berthelot[3] (1899) in a study of the thermochemistry of dimethyl- and diethyl-mercury. The specific difficulties arising in the study of organoelemental compounds in a stationary bomb calorimeter were first discovered much later when Long and Norrish[4] (1949) made a detailed study of the combustion products of a number of alkyl derivatives of zinc, cadmium, boron, and aluminium formed in the bomb. These investigators established two factors which reduce the accuracy of the measurement of enthalpies of combustion: incomplete oxidation of the initial substances and the possibility of additional reactions between the combustion products.

However, despite the experimental complications which are frequently encountered, the method of combustion in a stationary bomb calorimeter has been widely used and is at present the principal procedure for the study of the thermochemistry of organoelemental compounds. In particular it is used successfully in the investigation of organic derivatives of mercury, tin, germanium, and certain other metals, whose oxidation products in the bomb calorimeter are not difficult to identify.

In order to overcome difficulties characteristic of the combustion of substances in a stationary bomb calorimeter, Good and coworkers[5-9] developed a method for the determination of the enthalpies of combustion of organoelemental compounds of certain classes by combusting them in a rotating bomb calorimeter. This method provides for the dissolution of the combustion products in a specially selected solvent in order to obtain a thermodynamically unambiguous final state of the reaction system. This combustion method has been applied successfully to organic derivatives of boron, silicon, germanium, lead, phosphorus, arsenic, bismuth, and selenium. Nevertheless, the need to choose an appropriate solvent in each specific instance, the appearance of new sources of error, and the difficulty of many operations prevent the wide-scale employment of the rotating bomb calorimeter method.

Among the different versions of reaction calorimetry, the determinations of the enthalpies of hydrolytic and halogenation reactions have been most widely used. During the fairly rapid course of the selected reactions close to room temperature and in the absence of side reactions, these methods lead to more accurate results than the combustion of a test compound in a bomb calorimeter. However, they are difficult to apply to new relatively little investigated classes of compounds, for which it is difficult to select reactions suitable for calorimetric measurements.

†The properties of ~200 such compounds are quoted in a monograph[1] published in England in 1970 (there is no Russian translation).

#If useful work is not performed in the given process (for example, electrical work) and the process takes place at constant pressure, then its enthalpy is equal to the evolved heat or the heat absorbed from outside, corresponding to a specific mass of the substances which have reacted.

§The enthalpy of formation of molecular oxygen is zero at any temperature, like that of any other elements.

Tables 1–5 present the enthalpies of formation of organic derivatives of non-transition elements, which we selected as the most reliable as a result of the analysis of the corresponding literature sources. In choosing these quantities, we turned attention to the method of their determination, the purities of the initial preparations, the unambiguity of the analytical results for the reaction products, and the precision of the calorimetric experiment (allowance for the necessary corrections and errors of the measurements and calculations). In cases where the given substance has been investigated more than once Tables 1–5 present all the references (in chronological order) and those from which the most reliable value of ΔH_f° has been selected are printed bold. After the references to the original literature, the method of determination of the given quantity is indicated in brackets and the following notation is used: SB—combustion in a stationary bomb; RB—combustion in a rotating bomb; R—reaction calorimetry. The enthalpies of vaporisation or sublimation, required for the calculation of ΔH_f° in the gaseous monomeric state, are in most cases quoted in the reports in which the experimental enthalpies of formation in the condensed state are given. In the remaining cases they were taken from other literature sources[1,10,11].

Analysis of the literature data showed that the real accuracy of the determination of the ΔH_f° for the compounds under consideration is usually not better than to within 1 kcal mol^{-1} and only in the most favourable conditions (mainly when reaction calorimetry is used) is it approximately to within 0.5 kcal mol^{-1}. The attainment of a higher accuracy is restricted, on the one hand, by the specific features of the given calorimetric experiment, and, on the other hand, by the need to use in the calculations a number of auxiliary thermochemical quantities. The values of the latter, quoted in modern handbooks[10,11], are frequently insufficiently accurate and their agreement with one another is inadequate. The authors of the present review therefore thought it desirable to round off appropriately the selected experimental values of ΔH_f°.

All the enthalpies of formation and the average bond dissociation energies taken from the original reports were recalculated taking into account the new enthalpies of formation of the compounds and atoms quoted in Ref. 11. In the absence of the necessary information in the given handbook[11], the latter was taken from other publications[2,10,12–14].

Together with compounds containing element–carbon bonds, we examined also certain compounds without such bonds but with compositions and physicochemical properties close to those of organoelemental compounds. The review does not include organic derivatives containing, apart from C–H and C–C bonds, only bonds formed by carbon with oxygen, the halogens, nitrogen, or sulphur. For these substances, there are very many thermochemical data[1,2] and it is desirable to consider them separately.

In each of Tables 1–5 the substances are arranged in order of increasing atomic number of their non-transition elements in the given Group of the Periodic System. For the same element, related compounds are grouped together. Compounds containing, apart from the given element, only carbon and hydrogen are indicated first; next follow compounds containing also oxygen, the halogens, nitrogen, or sulphur. Heterocyclic compounds have been isolated in individual groups and have been arranged in an analogous sequence. The physical states of the substances, to which the values of ΔH_f° refer, are denoted by the following symbols: (c) = crystal; (l) = liquid (appended to the formulae of the compounds), and (g) = gas [appended in brackets to the symbol of the enthalpy of formation: $\Delta H_{f\,(g)}$].

The enthalpies of formation (ΔH_f°) examined in this review are expressed in thermochemical kilocalories (1 kcal = 4.1840 kJ) and are referred to the standard pressure of 101325 Pa (this is indicated by superscript 0) and the standard temperature of 298.15 K.

II. COMPOUNDS OF GROUP I NON-TRANSITION ELEMENTS

The recommended enthalpies of formation of these substances are listed in Table 1.

Table 1. Standard enthalpies of formation of organic derivatives of Group I non-transition elements (kcal mol^{-1}).*

Lebedev et al.[16] determined the enthalpies of formation of ethyl-lithium and n-butyl-lithium by the enthalpy of combustion method. The above compounds were oxidised under the conditions of a stationary bomb calorimeter to LiO_2(c), CO_2(g), and H_2O(l). Chemical analysis of the solid combustion products showed that significant amounts of Li_2O_2 and Li_2CO_3 were absent.

A number of workers[15,17–20] believe that different versions of reaction calorimetry constitute a more reliable method for the determination of the enthalpies of formation of organolithium compounds. Thus the enthalpy of formation of n-butyl-lithium has been calculated[17] from the enthalpy of its hydrolysis measured calorimetrically: ΔH_f°[n-C_4H_9Li(l)] = −31.4 ± 0.7 kcal mol^{-1}. However, this value is close to that found by the enthalpy of combustion method[16] (−31.8 ± 1.7 kcal mol^{-1}). Table 1 lists the average of the above values[16,17] as the enthalpy of formation of n-butyl-lithium. The interactions of organolithium compounds with gaseous HBr are also suitable for calorimetric measurements. The study of the thermochemistry of these processes, occurring in petroleum ether at room temperature, made it possible[15] to calculate the enthalpies of formation of 11 organic derivatives of lithium.

The enthalpies of formation of alkali metal ethoxides have been found[19,20] from the enthalpies of their reactions with aqueous sulphuric acid solution determined calorimetrically. The calculation of the ΔH_f° for the compounds under consideration in the gaseous state requires, apart from the data in Table 1, the corresponding enthalpies of sublimation (vaporisation), which are not available in the literature. The temperature variation of the vapour pressures of ethyl-lithium and n-butyl-lithium has been studied[16,21]. However, the calculation of the enthalpies of sublimation (vaporisation) from these data is complicated by the fact that the above

compounds vaporise in the form of associated species. Thus ethyl-lithium sublimes in the form of tetrameric and hexameric molecules[22,23]. The association of gaseous n-C_4H_9Li has not been studied, but it is known[24] that gaseous t-butyllithium is tetrameric.

III. COMPOUNDS OF GROUP II NON-TRANSITION ELEMENTS

The recommended enthalpies of formation of the above substances are listed in Table 2.

The application of the enthalpy of combustion methods to organozinc compounds involves serious experimental difficulties. Firstly, the degree of oxidation of these compounds in the bomb calorimeter never reaches 100%. Thus, in a study of diethylzinc, Long and Norrish carried out 50 combustions of this substance, but complete combustion was never achieved, as shown both by visual inspection of the contents of the bomb calorimeter after the experiments and by chemical analysis of the combustion products. Secondly, there is a possibility of reactions between the combustion products which are difficult to take into account. For example, in the combustion of dimethylzinc the zinc oxide formed was partly hydrated and partly (to the extent of ~8%) reacted with carbon dioxide to form zinc carbonate. The interpretation of the experimental results[4] therefore involved the calculation of corrections due to both the incomplete combustion of the zinc compounds investigated and to the occurrence of side reactions between their combustion products.

In order to find the ΔH_f° for the methyl and ethyl compounds of zinc and cadmium, Skinner and coworkers[30,34] measured the enthalpies of their hydrolysis, iodination, and reaction with aqueous sulphuric acid solution. The hydrolytic reactions led to the formation of the metal hydroxides and the modifications of the $Zn(OH)_2$ and $Cd(OH)_2$ formed were not established, which introduced an error into the calculation of the ΔH_f° for the test compounds.

The study of iodination processes[30,34] was complicated by side reactions. For example, in the case of ethyl compounds the main process

$$(C_2H_5)_2M + 2I_2 \rightarrow MI_2 + 2C_2H_5I,$$

where M = Zn or Cd, was accompanied by the reactions

$$(C_2H_5)_2M + I_2 \rightarrow MI_2 + C_4H_{10},$$

$$(C_2H_5)_2M + 2I_2 \rightarrow MI_2 + C_2H_4I_2 + C_2H_6.$$

The thermal corrections caused by the above side reactions were taken into account by the authors[30,34] in their calculations of the enthalpies of formation of the test substances. The interaction of zinc and cadmium alkyls with aqueous sulphuric acid proved to be more convenient for the calorimetric study than hydrolysis and iodination of the same compounds in view of its high rate and the lack of uncertainty as to the products.

The application of these versions of reaction calorimetry to each of the above compounds yielded satisfactorily concordant results. Thus the authors[30] obtained +4.7 ± 0.3 kcal mol^{-1} (by the hydrolytic reaction), +4.0 ± 1.0 kcal mol^{-1} (by the iodination reaction), and + 2.8 ± 0.5 kcal mol^{-1} (by the reaction with sulphuric acid) for $\Delta H_f^\circ[(C_2H_5)_2Zn(l)]$, while the corresponding values found in the same way[30,34] for $\Delta H_f^\circ[(CH_3)_2Cd(l)]$ were respectively +15.2 ± 0.2, +17.0 ± 0.1, and +15.7 ± 0.3 kcal mol^{-1}.

For organozinc compounds, a satisfactory agreement has been observed in addition between the values of ΔH_f° found by reaction calorimetry[30] and by the enthalpy of combustion method[4]. We therefore based the choice of the ΔH_f° for the above compounds on the results obtained by both methods.

In the case of organocadmium compounds there are significant differences between the values of ΔH_f° obtained by different calorimetric methods. Thus the enthalpies of formation of liquid $(CH_3)_2Cd$ and $(C_2H_5)_2Cd$ by the combustion method were found to be[4,31–33] +20.5 ± 2.8 and +20.9 ± 0.8 kcal mol^{-1}, while the values obtained by reaction

Table 2. Standard enthalpies of formation of organic derivatives of Group II non-transition elements (kcal mol^{-1}).*

*For the explanation of the Table, see the introduction.

**The enthalpies of formation of etheral solutions of a series of halogen-containing organomagnesium compounds are quoted by Carson and Skinner[55] and Holm[46].

calorimetry[30,32] were +16 ± 1 and +13 ± 1 kcal mol^{-1} respectively. The authors[4] note that, when organocadmium compounds are combusted in a bomb calorimeter, the solid combustion products always contain appreciable amounts of metallic cadmium and unoxidised carbon in addition to the oxide CdO. The exact calculation of the relevant corrections is difficult, which might have been the reason for the erroneous results in a number of studies[4,31–33]. Therefore, in choosing the values of ΔH_f° for cadmium compounds, we took into account only the results[30,34] obtained by reaction calorimetry.

The study of organomercury compounds has attracted much attention by thermochemists. When these substances are combusted in a bomb calorimeter, they are converted into carbon dioxide, water, and liquid mercury. A small amount of mercury (up to 10%) is then oxidised to HgO and $HgNO_3$, which requires allowance for the corresponding heat corrections. When the latter are applied correctly, it is possible to obtain fairly reliable results, as shown by the agreement, to within 1 kcal mol^{-1}, between the values of ΔH_f° for dimethyl-, diethyl-, and diphenyl-mercury found, on the one hand, by the combustion method[36,41,42], and, on the other hand, by reaction calorimetry[35,37,40].

The enthalpies of formation of the compounds R_2Hg, where $R = CH_3$, C_2H_5, C_3H_7, or C_6H_5, were obtained by Skinner and coworkers[35,37,39,40] by studying the enthalpies of bromination and iodination of the above substances.

The same workers investigated the thermochemistry of processes

$$R_2Hg + HgX_2 \rightarrow 2RHgX,$$

where X = Cl, Br or I, which made it possible to calculate the ΔH_f° for the products RHgX from the enthalpies of formation of the compounds R_2Hg found beforehand (Table 2).

IV. COMPOUNDS OF GROUP III NON-TRANSITION ELEMENTS

The recommended enthalpies of formation of the above substances are listed in Table 3.

The thermochemistry of organoboron compounds has been studied comparatively thoroughly. In the first studies in this field[4,47,48,54] the enthalpies of combustion of a number of alkylboron compounds were measured using a stationary bomb calorimeter. A number of methodological difficulties, characteristic of these substances were discovered. However, the above studies did not lead to the creation of a thoroughly developed method for the determination of the enthalpies of combustion of these compounds. Furthermore, some of the above workers expressed doubts concerning the possibility of the successful combustion of such substances in a stationary bomb calorimeter.

Gal'chenko[128], who developed a reliable method for the combustion of organoboron compounds in a stationary bomb calorimeter and applied it to a large number of organic substances containing 5–75 wt.% of boron (Table 3), made a major contribution to the development of the thermochemistry of such compounds. He established[128] that the products of their incomplete combustion include boron carbide, free carbon, and boron, and, in the case of nitrogen-containing compounds, also boron nitride. Furthermore, the combustion of the initial substance is accompanied by secondary reactions between the combustion products: the hydration of the boron oxide formed and the dissolution of part of boric acid in the water present in the bomb. However, for a high degree of combustion of the test compounds, which constitutes a necessary condition for the application of this method and is readily achieved by varying the oxygen pressure in the bomb, the mass of the specimen, the size of the crucible, and other conditions, the calculation of corrections for the incomplete combustion and secondary processes does not present special difficulty.

The correction for incomplete combustion, calculated from the determinations of carbon dioxide and boric acid in the combustion products, did not exceed 1% of the total amount of energy evolved during the experiment in most instances. It was also shown that the hydration of boron oxide and dissolution of the boric acid thus formed proceed comparatively rapidly and do not distort the variation of the temperature in the final period of the experiment. This method was used by Gal'chenko and coworkers for both liquid[50,52,53,56,60,61,63–65,74–80,85,90,103] and solid[91–102] boron compounds, the accuracy of the determination of their enthalpies of combustion being to within 0.05–0.10%.

The difficulties in the combustion of boron-containing compounds in a stationary bomb calorimeter led Good and coworkers[8,9] to develop a method involving their combustion in a rotating bomb calorimeter. By this procedure, the authors[8,9] measured the enthalpies of combustion of trimethyl- and tirethyl-amineborane. Specimens of the test substances mixed with vinylidine fluoride $(CH_2CF_2)_n$ were placed in polyester tubes. The combustion was carried out in a platinised bomb calorimeter containing an excess of aqueous HF solution. On rotation of the bomb, the combustion products interacted with the hydrogen fluoride solution and a solution of $HBF_4.14.67HF.58.72H_2O$, preliminary values of the enthalpy of which had been found in other experiments, was obtained. No solid combustion products were detected after the experiments.

The use of this combustion method involves certain difficulties as regards the assignment of the experimental results to a standard state. For example, there are not data for the solubility and enthalpy of solution of the resulting carbon dioxide in aqueous HBF_4 and HF solutions. In order to take into account the corresponding corrections, the authors[8,9] performed the so called "comparison experiments" in addition to the main experiments. In the "comparison experiment" a substance (benzoic acid or paraffin) with an accurately established enthalpy of combustion was used instead of the test compound. The amount of this substance as well as the concentration and volume of the aqueous HBF_4 and HF solution introduced into the bomb calorimeter were selected so that the final states of the reaction systems in both the comparison experiments and in the experiments designed to combust the boron compound were as far as possible similar.

The methods of reaction calorimetry have come to be widely used in the thermochemical studies of organoboron compounds. This is due to the high reactivity of the above compounds and the availability for many of them of reactions suitable for thermochemical measurements. The enthalpies of hydrolysis of the compounds have been measured most frequently. In many cases such reactions rapidly reach completion at room temperature and give rise to products whose properties have been studied in detail and which can be easily identified. Thus, in order to find the enthalpies of formation of alkoxyboron compounds, Skinner and coworkers[59] measured the enthalpies of the reactions

$$(C_nH_{2n+1}O)_3B\ (l) + 3H_2O\ (l) \rightarrow H_3BO_3\ (c) + 3C_nH_{2n+1}OH\ (l).$$

*For the explanation of the Table, see the introduction.

The reactions were carried out by breaking under water a glass bulb containing a specific amount of the test compound. The water also served as the calorimetric liquid. The process reaches completion rapidly and unambiguously at room temperature. From the results of the measured enthalpies of hydrolysis, Skinner and coworkers[59,68,72,73,86] as well as

Finch, Gardner, and coworkers[57,70,87-89], calculated the enthalpies of formation of a large number of organoboron compounds of different classes: alkoxy- and alkylthio-compounds, substances containing halogens, etc.

The enthalpies of formation of a series of trialkylboron compounds were calculated by Skinner and coworkers[49,55] from the enthalpies of hydroboration of olefins measured by a calorimetric method[49,55]:

$$B_2H_6\,(g) + 6C_nH_{2n}\,(g) \rightarrow 2\,(C_nH_{2n+1})_3B\,(l)$$

This process was carried out by passing diborane through a saturated solution of the olefin in diglyme. Owing to the possible occurrence of side reactions, the hydroboration reactions are less convenient for the determination of the enthalpies of formation of boron compounds than the hydrolytic reactions. For example, when $n = 6$, 7, 8, the main olefin hydroboration product is accompanied by the formation of ~6% of its isomers in which the boron atom is attached to the second and not the first carbon atom, which requires the calculation of the appropriate corrections in the interpretation of the experimental results.

The thermochemistry of organoaluminium compounds has been less thoroughly investigated than that of boron-containing substances. Furthermore, the results obtained by different workers for the same compound differ markedly. Thus the literature values of the enthalpy of formation of liquid $(CH_3)_3Al$ include -28.7 ± 2.3 and -21.4 ± 3 kcal mol^{-1} found by the method of combustion in a stationary bomb calorimeter[4,107] and -36.1 ± 1.3 kcal mol^{-1} obtained[106] by reaction calorimetry. Bearing in mind the difficulty of attaining the complete combustion of organoaluminium compounds, we gave preference to the value[106] calculated from the measurements of the enthalpy of reaction of trimethylaluminium with acetic acid.

Even more contradictory data are available for triethylaluminium, the enthalpy of formation of which has been found to be -32.4 ± 3, -51.9 ± 2.2, -41.4 ± 1.1, and -56.6 ± 0.8 kcal mol^{-1} by the combustion method in Refs. 107–109 and 129 respectively and -36.5 ± 5 kcal mol^{-1} by reaction calorimetry[44]. The last value, calculated from the experimental enthalpy of hydrolysis of $(C_2H_5)_3Al$, cannot be regarded as reliable owing to the lack in the relevant report[44] of a detailed analysis of the gaseous products of the above reactions and the inaccuracy of the value of ΔH_f° of the amorphous product $Al(OH)_3$ formed in the hydrolysis.

The most accurate value $\Delta H_f^\circ[(C_2H_5)_3Al(l)] = -52 \pm 2$ kcal mol^{-1} has been obtained by the combustion method in a study[108] where the combustion products were analysed quantitatively and in the interpretation of the experimental results account was taken of the corresponding corrections for the incomplete combustion of the initial compound.

Measurements of the enthalpies of combustion of 30 aluminium-containing substances, including alkylaluminium hydrides and alkylaluminium chloride have been reported[129,130]. However, the above studies were carried out using insufficiently accurate calorimetric measurements. For example, the chlorine-containing substances were combusted without the use of reducing agents (hydrazine or arsenic oxide), which ensure unambiguously the state of chlorine in the combustion products; the internal surface of the bomb was not protected from the action of chlorine-containing products formed in the oxidation of the initial compound, etc. Furthermore, insufficiently purified specimens of the test compounds were used in the combustion experiments. Thus the purity of aluminium trialkyl and dialkylaluminium hydrides studied by Pawlenko[129] was between 94 and 99.5%, while that of alkylaluminium chlorides investigated in another study by Pawlenko[130] ranged from 93 to 97%.

Owing to the above deficiencies, Pawlenko[129] obtained $\Delta H_f^\circ[(\text{iso-}C_4H_9)_3Al(l)] = -92.8 \pm 2$ kcal mol^{-1}, while more careful measurements[111] lead to -69.9 ± 7.2 kcal mole^{-1}; he obtained[129] $\Delta H_f^\circ[(C_2H_5)_2AlH(l)] = -48.7 \pm 1$ kcal mol^{-1}, which does not agree with the more reliable value -73.5 ± 4.5 kcal mol^{-1} found by Shaulov et al.[108]; he quotes[130] $\Delta H_f^\circ[(C_2H_5)_2.AlCl(l)] = -56.9 \pm 1.0$ kcal mol^{-1}, while the values found in other investigations[119,120] are respectively -99.2 ± 1.3 and -96.0 ± 1.5 kcal mol^{-1}, etc. For these reasons, Pawlenko's results[129,130] have not been included in Table 3.

Smith[120] believes that calorimetric study of reactions of the type

$$^2/_3R_3Al + {}^1/_3AlX_3 \rightarrow R_2AlX,$$

where R = alkyl group and X = Cl, Br, or I, constitutes a convenient method for the determination of the enthalpies of formation of alkylaluminium halides. To reduce the rate, these processes were carried out[120] in hexadecane, where they reached completion in the course of several minutes at room temperature. The ΔH_f° for halogen-containing aluminium compounds, calculated from the experimental enthalpies of the above reactions, are listed in Table 3.

Smith[120] also discusses the agreement between the literature values of ΔH_f° for different classes of organoaluminium compounds and his own results. He examined (1) the variation of ΔH_f° within each class of organoaluminium compounds as a function of their alkyl group, (2) the difference between the enthalpies of formation of aluminium compounds of different classes, and (3) the agreement between the enthalpies of reaction found experimentally (directly) and calculated from the enthalpies of formation of the reactants. This analysis showed, in particular, that Pawlenko's results discussed above[129,130] are incorrect. Thus, direct measurements[120] of the enthalpies of the reactions

$$^2/_3(C_2H_5)_3Al\,(l) + {}^1/_3AlCl_3\,(c) \rightarrow (C_2H_5)_2AlCl\,(l),$$

$$^1/_3(C_2H_5)_3Al\,(l) + {}^2/_3AlCl_3\,(c) \rightarrow C_2H_5AlCl_2\,(l)$$

yielded -5.3 ± 0.1 and -1.2 ± 0.3 kcal mol^{-1} respectively, while calculations of the corresponding enthalpies from the ΔH_f° for the reactants, obtained by Pawlenko[129,130], lead to unrealistic values for the above reactions of $+37 \pm 1$ and $+56 \pm 1$ kcal mol^{-1}.

There have been several studies[117,121-127] devoted to the investigation of the thermochemical properties of organic derivatives of gallium, indium, and thallium (Table 3). The satisfactory agreement between the values of ΔH_f° for liquid trimethylgallium calculated from its enthalpy of combustion[121] ($\Delta H_f^\circ = -19.1 \pm 1.7$ kcal mol^{-1}) and enthalpy of iodination[122] ($\Delta H_f^\circ = -18.6 \pm 2.2$ kcal mol^{-1}) suggests that the combustion method can be used successfully also for other gallium compounds.

V. COMPOUNDS OF GROUP IV NON-TRANSITION ELEMENTS

The recommended enthalpies of formation of the above substances are listed in Table 4.

In connection with the applications of organosilicon compounds in technology, numerous studies have been made on their thermochemistry. In most instances the enthalpies of formation of the compounds were calculated from their enthalpies of combustion measured in a stationary bomb calorimeter. The use of this method in such cases is extremely difficult owing to the formation of a film of silicon dioxide on combustion of the test compounds. The film

covers the test substance and hence hinders contact between it and oxygen, which precludes the attainment of complete combustion. In the present instance the combustion products can contain, together with CO_2, H_2O and SiO_2, elemental carbon and silicon, carborundum, carbon monoxide, and a wide variety of pyrolysis products of the initial compound. The exact analysis of the combustion product formed is frequently impossible, so that reliable heat corrections, associated with the incomplete oxidation of the initial compounds, could not be found.

Table 4. Standard enthalpies of formation of organic derivatives of Group IV non-transition elements (kcal mol^{-1}).*

*For the explanation of the Table, see the introduction.

The above factors led a number of workers to the assumption that all the values of ΔH_f° for silicon-containing substances obtained by the combustion method in a stationary bomb calorimeter are certain to be erroneous and do not merit any consideration. In particular, the values of ΔH_f° for silicon compounds found by the above method have been fully excluded from the monograph of Cox and Pilcher[1], the handbook of Wagman et al[10], Skinner's review[44], etc. However, in the majority of studies carried out using a stationary bomb calorimeter the investigators concerned made a detailed study of the products of incomplete combustion apart from creating the best possible conditions for the complete combustion of the starting material. This made it possible to apply the corresponding thermal corrections. The results of the above investigations may be suitable for various approximate calculations in cases where more accurate data are not available. For this reason, we have omitted from the present review only clearly erroneous results. Other values of ΔH_f° for silicon-containing compounds are included in Table 4 and are discussed regardless of the method used to determine them.

The enthalpies of combustion of a series of organosilicon compounds were first determined in a stationary bomb calorimeter by Reuther[152]. The lack of a detailed description of the method used precludes an assessment of the reliability of the results.

Tannenbaum et al.[131] measured the enthalpies of combustion of eleven organosilicon compounds. The substances, contained in glass or gelatine bulbs, were ignited in a nickel crucible having a number of apertures. The degree of combustion was checked by the visual inspection of the contents of the bomb after the experiments. The incomplete combustion products, in the form of dark spots on the inner surface of the bomb were observed even in the best experiments. Tannenbaum et al.[131] noted difficulties in creating conditions in the bomb which would ensure the complete combustion of the test compounds. For example, 25 combustions were carried out for vinylsilane and the necessary degree of combustion was achieved in only two experiments. For the remaining substances, only the results of the three best experiments were taken into account in calculating ΔH_f°. The authors believe[131] that the error of the ΔH_f° obtained ranges from −1.3 to +0.5%.

In his measurements of the enthalpies of combustion of polymethylsiloxanes, Thompson[161] used a novel method to ensure their complete combustion. The substance, enclosed in two bulbs of different strength, was placed in a glass crucible in the bomb. One of the bulbs was ruptured during the filling of the bomb with oxygen as a result of which the second stronger bulb was immersed in the liquid spilled out of the first bulb. At the required instant this liquid was ignited and, as a result of the evolution of heat, the second bulb exploded and, according to the author[161], the entire mass of the substance taken for the experiment was combusted, which he inferred from a visual inspection of the contents of the bomb after the experiment. The use of this combustion procedure involves difficulties associated with the preparation of bulbs capable of withstanding the oxygen pressure in the bomb and yet exploding on heating.

A series of studies on the measurements in a stationary bomb calorimeter of the enthalpies of combustion of organosilicon compounds of different structure were published by Tanaka and coworkers[147–149,153,154,178,179]. The liquid substances were ignited in glass or gelatine bulbs and solid substances were ignited in paper bags. The degree of combustion was inferred from the visual inspection of the solid combustion products formed. In his first studies Tanaka[147–149] did not report the difficulties encountered in attaining the complete combustion of the test compound. However, in later investigations[178,179] he noted the presence in the solid combustion products of, apart from amorphous SiO_2, amorphous carbon, silicon carbide, and a polymeric silicon-containing substance. The appropriate corrections were calculated in the interpretation of the experimental results.

Lautsch et al.[33] measured the enthalpies of combustion of tetramethyl- and tetraethyl-silanes. The substances were ignited in glass bulbs rolled up in a polyethylene film. However, complete combustion could not be achieved.

Several organosilicon compounds were investigated by Shaulov and coworkers[157,160,172,173,176]. The substances were placed in a bomb in polyethylene bulbs. The combustion products were analysed for carbon dioxide, unoxidised carbon, and silicon, and in the case of nitrogen-containing compounds, silicon nitride. It was established that the corrections for the presence of silicon and silicon nitride are insignificant and can be neglected.

A series of organosilicon compounds have also been combusted in a stationary bomb calorimeter in studies by the authors of the present review[134–136,150,171,174]. The liquid substances were ignited in polyethylene bulbs and the solid substances, in the form of several 0.1 g discs, were ignited in a thin platinum crucible. The analytical results for the solid combustion products showed that they contained as impurities unoxidised carbon and traces of unoxidised silicon and silicon carbide. For each substance, the experimental amount of CO_2 in the gaseous combustion products agreed, when account was taken of the incomplete combustion, to within 0.1% with the amount calculated from the chemical formula.

The use of the rotating bomb calorimeter method for organosilicon compounds is associated with two important conditions: the choice of the auxiliary substance ensuring a high degree of oxidation of the test compound and the choice of a solvent capable of rapidly dissolving the combustion

products formed. This method was first used by Good et al.[7] in a study of hexamethyldisiloxane. The substance was ignited in a mixture with trifluoromethylbenzene ($C_6H_5CF_3$). Trifluoromethylbenzene was chosen as the auxiliary substance because of the ease with which it can be purified and because of its ability to burn in the bomb calorimeter without the formation of carbon tetrafluoride. The mixture prepared in this way was ignited in a container of polyester film and the amount of energy consumed was ~69% in the combustion of trifluoromethylbenzene, ~25% in the combustion of hexamethyldisiloxane, and ~6% in the combustion of the film relative to the total amount of energy evolved during the experiment. The bomb was first charged with a specific amount of water or an aqueous HF solution, which came into contact with the combustion products on rotation of the bomb and reacted with the latter to form a solution of H_2SiF_6.HF. .H_2O. The enthalpy of formation of the resulting solution had been determined in preliminary experiments. In order to take into account a series of side effects, for example, the dissolution of carbon dioxide in aqueous solutions of H_2SiF_6 and HF, Good et al.[7] carried out the so called comparison experiments. In these experiments they combusted benzoic acid or liquid hydrocarbons; the amounts of the latter as well as the concentration of the aqueous solution of H_2SiF_2 and HF introduced into the bomb was selected in such a way that the final states of the reacting systems in the comparison experiments and the experiments involving the combustion of siloxane were as far as possible similar.

The enthalpy of formation of hexamethyldisiloxane obtained by Good et al.[7] was subsequently confirmed by Iseard et al.[137], who used a similar combustion method. However, they employed another auxiliary compound, namely *m*-trifluoromethylbenzoic acid ($C_6H_4CF_3COOH$). Iseard et al.[137] determined also the enthalpies of combustion of two other silicon compounds: tetraethylsilane and hexamethyldisilane. The combustion method proposed by Good[7] was also used by Genchel' et al.[162,177,180], who measured the enthalpies of combustion of several cyclic silicon compounds, and by Steele[132], who obtained an accurate value of ΔH_c° for tetraphenylsilane.

Another approach to the problem of the application of bomb calorimetric methods to silicon compounds was proposed by Gadzhiev[156]. He determined the enthalpies of combustion of a series of liquid chloromethylsilanes[156] by the explosive combustion method, which he developed[163–166]. This method consists in the vaporisation of part of the substance (not more than 10%) during the experiment and subsequent ignition of the mixture of its vapour with oxygen, which is stated[156,163–166] to cause the explosive combustion of both the gaseous and liquid parts of the substance with formation, apart from CO_2 and H_2O, of a stoichiometric amount of amorphous SiO_2. Gadzhiev and coworkers[133,140,141,155,156,181,182] recommend that solid organosilicon compounds be combusted in the presence of certain oxidants (potassium nitrate, potassium hypochlorite, benzoyl peroxide), which they say ensures the complete oxidation of the starting materials. However, one should point out that the value of ΔH_f° obtained in their studies[133,181,182] differ sharply from the corresponding data of other investigators[162,177,180] found using the more sophisticated combustion method developed by Good et al.[7] and used successfully in a later investigation[137]. This factor indicates the preliminary nature of both the methodological recommendations of Gadzhiev et al.[133,181,182] and of their results.

Failure to attain the complete combustion of organosilicon compounds in a stationary bomb calorimeter and the complexity of the experiments in a rotating bomb calorimeter led many investigators to resort to other methods for the thermochemical investigation of such substances. The study of their hydrolytic reactions proved to be extremely fruitful[144–146,159,167,168,170]. These reactions frequently take place at room temperature with formation of readily identifiable products. The widescale employment of the above procedure for the investigation of the methyl compounds of silicon has been favoured to a large extent by the fact that the enthalpy of formation of their main hydrolysis product (hexamethyldisiloxane) had been reliably established in the above investigations[7,137].

Despite the large number of organogermanium compounds synthesised and their practical importance, the study of their thermochemistry began comparatively recently namely in 1963, when the authors of the present review published the results of measurements of the enthalpies of combustion of tetraethylgermane and hexaethyldigermane[184]. As shown in one of the subsequent studies of the present authors[134,136,143,150,171] and also in the studies of Skinner[185] and Shaulov[183,187,189,196–198], organogermanium compounds are readily oxidised under the conditions of the stationary bomb calorimeter and the attainment of a high degree of their oxidation does not present special difficulties. All the above investigators ignited the test substances in polyethylene or polyester bulbs placed in a quartz crucible. In some cases the solid combustion products contained, together with hexagonal germanium dioxide, small amounts of unoxidised carbon and germanium, which were reliably taken into account by the appropriate corrections.

The combustion of organogermanium compounds in a rotating bomb calorimeter was first used by Bills and Cotton[186], who measured the enthalpy of combustion of liquid tetraethylgermane. The liquid in the bomb, used to dissolve the condensed combustion products, was an aqueous HF solution, which led to the formation of an aqueous solution of H_2GeF_6. This method was subsequently used in other studies[190,192] to determine the enthalpies of combustion of tetraphenylgermane, hexaphenyldigermane, and tetrabenzylgermane; however, the bomb liquid consisted of aqueous KOH. The enthalpies of solution in the above solvent of the germanium and carbon dioxides formed in the experiments were determined beforehand. The combustion products also contained a "solid residue", which did not dissolve in the bomb liquid. The authors[190,192] suggested that it consisted of a mixture of unoxidised carbon and the initial germanium compound. The correction taking into account the presence of this "solid residue" did not exceed 0.5% of the overall amount of energy evolved in the experiment.

It has been suggested[186] that the exact determination of the enthalpy of combustion of organogermanium compounds in a stationary bomb calorimeter is impossible owing to their incomplete oxidation in the corresponding experiments. However, the similarity of the values of ΔH_f° found for tetraethylgermane by the method of combustion in a stationary bomb calorimeter[183–185] (-52.2 ± 1.0, -52.6 ± 1.5, and -48.9 ± 1.0 kcal mol^{-1} respectively) and by the method of combustion in a rotating bomb calorimeter[186] (-50.4 ± 1.5 kcal mol^{-1}) suggests that reliable values of ΔH_f° can be obtained for germanium compounds also in stationary bomb calorimeters¶.

¶There is a sharp difference between the individual values of ΔH_f° for tetraphenylgermane found in a stationary bomb calorimeter[138,189] and between these and the result obtained by the rotating bomb calorimeter method[190]. However, it is apparently associated with the inadequate purity of the specimens investigated[138,189]. The error of Birr's result[138] and its possible cause were pointed out by Tel'noi and Rabinovich[139].

The only study in which reaction calorimetry was used to investigate the thermochemistry of germanium compounds is that of Baldwin et al.[145], who measured the enthalpies of hydrolysis of several trimethylgermane derivatives. The comparatively high error of the enthalpies obtained (±2 kcal mol^{-1}) is mainly due to the inaccuracy of the estimated enthalpy of formation of hexamethylgermanoxane (−136 ± 4 kcal mol^{-1}), formed in the hydrolysis of the above substances, which was used in the calculations.

The measurement of the enthalpies of combustion of organotin compounds presents no difficulties, since the latter are fully oxidised under the conditions of the stationary bomb calorimeter. This factor led to the accumulation in the literature of a large number of thermochemical data obtained by the combustion of organotin compounds in the stationary bomb calorimeter. Their combustion products contained in some cases unoxidised tin and carbon. However, in these experiments corrections for incomplete combustion could be determined exactly by heating the solid combustion product to constant weight and by the simultaneous determination of the carbon dioxide produced in this process[134,203]. In order to improve the combustion, the test substances are frequently placed in polyethylene or polyester bulbs. One should note that some of the investigations[138,200,201] in which the stationary bomb calorimeter method was applied to organotin compounds were experimentally imprecise and the difference between their results and those of the corresponding exact data[203,209,210] (Table 4) did not indicate any methodological complications arising in the study of the given substances in a stationary bomb calorimeter.

The existence of a large number of chemical reactions of organotin compounds suitable for calorimetric studies made it possible to determine the enthalpies of formation of many of these substances by reaction calorimetry. A study of the enthalpies of halogenation[204,205,208,213] and hydrolysis[145] proved to be the most fruitful. The methods of reaction calorimetry are particularly suitable for the determination of the enthalpies of formation of halogen-containing tin compounds whose combustion in a bomb calorimeter is complicated by a number of side reactions.

The combustion of organolead compounds in a stationary bomb calorimeter does not yield exact enthalpies of combustion because of the formation on combustion of a mixture of inorganic lead compounds which cannot be subjected to a reliable quantitative analysis. Good and coworkers[5,6] therefore used the method of combustion in a rotating bomb calorimeter in the study of tetramethyl- and tetraethyl-lead. A solution of nitric and arsenous acids was used as the bomb liquid, as a result of which the entire lead present in the combustion products was converted into Pb^{2+} ions. The test substances were combusted in a quartz crucible which was fairly inert in relation to the hot lead oxides formed. The use of glass bulbs and of a platinum crucible is inconvenient in this instance, since fused lead oxides or unoxidised lead react with glass and are fused together with platinum. Since explosive combustion is characteristic of tetramethyl-lead, it was diluted with a liquid-hydrocarbon before combustion and was placed in a polyester bag. The enthalpy of solution of tetramethyl-lead in the hydrocarbon as well as the enthalpy of solution of the carbon dioxide (formed in the experiments) in the final bomb solution were determined in special experiments. A combustion method analogous to that examined above was also used[215] in a study of tetraphenyl-lead.

The use of methods of reaction calorimetry for the determination of the enthalpies of formation of organolead compounds is limited to the studies of Butler et al.[217,218], who measured the enthalpies of halogenation of crystalline tetraphenyl-lead. The enthalpies of formation of certain bromo- and iodo-derivatives of the above compounds were calculated from the results (Table 4).

One must note that the literature values of the enthalpies of formation of organolead compounds, obtained by combustion in a stationary bomb calorimeter, are erroneous for the reasons examined above. For example, according to data[33] obtained in a stationary bomb calorimeter, the standard enthalpy of formation of crystalline $(C_6H_5)_4Pb$ is +221 ± 3 kcal mol^{-1}, while the use of the rotating bomb calorimeter[215] yields $\Delta H_f^\circ = +123 \pm 4$ kcal mol^{-1} for the same substance. All

*For the explanation of the Table, see the introduction.

the values of ΔH_f° calculated from the results of the combustion of organolead compounds in a stationary bomb calorimeter are therefore disregarded in this review and are not included in Table 4.

VI. COMPOUNDS OF GROUP V NON-TRANSITION ELEMENTS

The recommended enthalpies of formation of the above substances are listed in Table 5.

The determination of the enthalpies of combustion of organophosphorus compounds in a stationary bomb calorimeter has a number of characteristic features, which make it difficult to obtain sufficiently reliable results. Their combustion products contain, apart from CO_2 and H_2O, orthophosphoric acid (in aqueous solution), which, however, may be accompanied by other phosphorus-containing acids in solution: H_3PO_3, $H_4P_2O_7$, and $H_5P_3O_{10}$; the concentrations of the acids formed in different parts of the bomb differ significantly. This factor may appreciably distort the results of the calculation of the ΔH_f° of the test substance owing to the comparatively high enthalpies of solution of phosphoric acids in water. Furthermore, it is difficult to achieve the complete combustion of organophosphorus compounds—all the investigators have noted the presence of significant amounts of unoxidised carbon in their combustion products. In view of the corrosive nature of phosphoric acids in relation to the material of the crucible in which the test substance is to be combusted, the choice of the crucible is important.

The method of combustion in a stationary bomb calorimeter was used[226] in a study of two phosphoric acid dianilides. The combustion products were analysed for ortho-, pyro-, and meta-phosphoric acids. It was found that 93–96% of the phosphorus was oxidised to orthophosphoric acid. The authors[226] disregarded corrections for the formation of other acids. They also established that the concentration of the H_3PO_4 solution formed on combustion of the test substances was 0.5 M on the walls of the bomb and 2 M in the crucible and that the main bulk of the acid (~85%) was on the walls of the bomb. The difference between the concentrations of orthophosphoric acid in different parts of the bomb was taken into account in the interpretation of the experimental data. The error of the calculated ΔH_f° (Table 5) is several kcal mol^{-1}.

In the combustion of trimethylphosphine[220] magnesium ribbon was used to ignite the substance and to improve its combustion. However, its employment introduced additional difficulties owing to the formation of magnesium oxide in the combustion products, which partly dissolves in aqueous orthophosphoric acid. The trimethylphosphine combustion products were analysed to determine (a) the mass of magnesium oxide dissolved in phosphoric acid (an aqueous $MgHPO_4$ solution was formed), (b) to determine the mass of unoxidised carbon, (c) to test for the presence of lower phosphorus acids, and (d) to determine the masses of meta- and pyro-phosphoric acids. The analyses showed that orthophosphoric acid amounted to not less than 95% of the overall mass of all the phosphorus-containing acids formed. In the calculation of ΔH_c° corrections were applied for the presence of phosphorous acid, free carbon, etc. in the combustion products.

In another study[223] triphenylphosphine was combusted in polyethylene bulbs, which consumed ~60% of the energy evolved in the experiment. A mixture of H_3PO_4 and H_3PO_3 was detected in the combustion products. Corrections for the auxiliary materials and the presence of unoxidised carbon and phosphorus acid in the combustion products were applied in the calculations of ΔH_c°. The value $\Delta H_f^\circ = +52.9 \pm 3.6$ kcal mol^{-1} found by the author[223] agrees within the limits of experimental error with $+54.8 \pm 2.4$ kcal mol^{-1} obtained analogously in another investigation[224].

The enthalpies of combustion of a series of organophosphorus compounds were measured by Mortimer and coworkers[224, 238,239]. To improve the combustion, certain substances (discs) were placed in polyester bulbs. To prevent the scattering of the hot substances, the crucible was covered by a platinum gauze. The mass of the combusted compound was determined from the masses of CO_2 and free carbon found in the combustion products. It was assumed that all the auxiliary substances were completely combusted. Chemical analysis of the wash water from the bomb after the experiments demonstrated the presence of only one phosphorus-containing acid (H_3PO_4).

The method of measurement of ΔH_c° for phosphorus-containing substances was improved in a number of investigations[222,232,234]. Much attention was devoted to the selection of the material of the crucible, fairly inert with respect to the combustion products of the test compounds. Corundum crucibles, which proved in this respect to be better than stainless steel, titanium, quartz, or porcelain crucibles, were used. Together with orthophosphoric acids, a certain amount of pyrophosphoric acid was found in the combustion products, which conflicts with data obtained in investigations[224,238,239] where only orthophosphoric acids was found in the products. (Nikolaev et al.[234] explained this by the inaccuracy of the analytical methods employed in the earlier investigations[224,238,239].) In the interpretation of the experimental data account was taken of the thermal corrections for the enthalpy of solution of phosphoric acids and unoxidised carbon. The authors[222,232,234] explained the comparatively large error in the values of ΔH_c° obtained, amounting in certain cases to ~0.5%, by the impossibility of attaining the complete oxidation of phosphorus-containing substances under the conditions of the stationary bomb calorimeter.

The enthalpies of combustion of the three phosphorus-containing acids have been measured[227] in an adiabatic stationary bomb calorimeter not designed for precision measurement. Discs of the test substances were placed in a platinum crucible together with a disc of benzoic acid, which ensured a more complete combustion. Part of the water introduced into the bomb before the experiment wetted its inner walls, which tended to equalise the concentrations of the orthophosphoric acid formed in different parts of the bomb according to the authors[227]. The chemical composition of the wash water from the bomb after the experiments was determined by method proposed previously[224,238,239] and, as in those investigations, the authors[227] demonstrated the quantitative oxidation of phosphorus to orthophosphoric acid without the formation of other phosphoric acids.

The enthalpies of combustion of three cyclic phosphorus compounds containing also nitrogen and chlorine were determined by Fleig and Berke-Goehring[240] using a tantalum stationary bomb calorimeter. The substances were combusted together with paraffin. In the experiment with the chlorine-containing compound the bomb was charged with quartz wool impregnated with an aqueous solution of As_2O_3. Under these conditions, molecular chlorine, formed to some extent on combustion of the test compound, was fully reduced to HCl. Together with orthophosphoric acid, the authors detected small amounts of pyrophosphoric acid in the wash water from the bomb. However, the corrections due to the presence of the latter were insignificant and were therefore disregarded.

The possibility of the combustion of phosphorus compounds in a rotating bomb calorimeter has been examined in detail[233]. It was suggested that triphenylphosphine oxide be used as the standard substance for the thermochemical study of organophosphorus compounds[233]. A disc of the above compound was ignited in a small gold crucible by means of a polyethylene ribbon. The formation of soot in this case was insignificant. The bomb liquid consisted of an aqueous solution of perchloric acid. When the combustion product dissolved in it, only one phosphoric acid was formed, namely H_3PO_4. The amount of CO_2 found in the combustion products of triphenylphosphine oxide was 99.97 ± 0.01% of the amount calculated from its chemical formula. The enthalpy of combustion of the test compound was determined to within ±0.04% (which is significantly more accurate than the results obtained in the study of phosphorus-containing compounds in a stationary bomb calorimeter). $\Delta H_f^\circ = -26.2 \pm 1.0$ kcal mol^{-1}, calculated from the above heat of combustion, differs significantly from the value $\Delta H_f^\circ = -15.1 \pm 3.0$ kcal mol^{-1} found[224] in a stationary bomb calorimeter, which is probably due to the difficulty of the analysis of the combustion products formed when the authors' method is used[224].

The thermochemistry of a number of phosphorus-containing compounds has been studied by reaction calorimetry. In these studies the enthalpies of hydrolysis[228,230,231,241] or the enthalpies of oxidation of the test compounds by an aqueous solution of hydrogen peroxide[221,222,228,230] were frequently measured. Reliable thermochemical data have been obtained also by measuring the enthalpies of reaction of chlorine-containing phosphorus compounds with a cyclohexane solution of the corresponding alcohol and a substituted amine[225,226,235]. The role of the amines consisted in binding the hydrogen chloride formed in the processes. The experimental conditions selected ensured that the reactions took place at temperatures close to the standard temperature and the duration of the experiments in most cases did not exceed 60 min. The results of these investigations are presented in Table 5.

Mortimer and Skinner[249] were the first to investigate the thermochemistry of organoarsenic compounds. They showed that many of these compounds readily interact with iodine even at room temperature and that such reactions are extremely convenient for calorimetric study. The above workers measured[249,250] the enthalpies of the reactions

$$(CH_3)_2AsAs(CH_3)_2\ (l) + I_2\ (c) \rightarrow 2\,(CH_3)_2AsI\ (l),$$
$$C_6H_5AsH_2\ (l) + 2I_2\ (c) \rightarrow C_6H_5AsI_2\ (l) + 2HI\ (g),$$

occurring in methanol and carbon tetrachloride respectively. However, the results did not allow the calculation of ΔH_f° of any one arsenic-containing reactant. Later the enthalpies of formation of three alkoxyarsenic compounds were determined[245] from measurements of the enthalpies of their hydrolysis in the presence of an excess of NaOH. These reactions take place rapidly and quantitatively at room temperature. The presence of alkali is necessary for the rapid dissolution of the arsenic trioxide formed.

The applicability of the enthalpy of combustion method to arsenic compounds was first investigated by Long and Sackman[242], who measured ΔH_c° for trimethylarsenic in a stationary bomb calorimeter. They established that the combustion products of the above compound have a composition very difficult to analyse. Indeed, the combustion products contained unoxidised arsenic and carbon, solid As_2O_3, As_2O_4, and As_2O_5, and a solution containing arsenic(III) and arsenic(V) compounds. This made it necessary to develop a method for the exact analysis of the above mixture. The arsenic content found in the combustion product by the method developed above amounted on average to 99.8% of the expected value, which confirmed the validity of the proposed analytical procedure. The enthalpy of combustion of triethylarsenic has been measured[31-33] in a stationary bomb calorimeter and only one arsenic oxide (As_2O_3) was found in the combustion product.

The same method has been used[243] to investigate triphenylarsenic. A method proposed previously[242] was used to analyse the combustion products, among which the oxides As_2O_3, As_2O_4, and As_2O_5 were found. However, the enthalpy of formation of the above compound thus obtained (+93.6 ± 2.0 kcal mol^{-1}) differs appreciably from the reliable value of this quantity (+71.0 ± 2.0 kcal mol^{-1}) found by Mortimer and Sellers[244], who used the method of combustion in a rotating bomb calorimeter with aqueous NaOH as the bomb liquid. In this case dissolution of the combustion products in the bomb resulted in the formation of a solution of sodium arsenate, arsenite, carbonate, and hydroxide. The enthalpies of reaction of the combustion products with the bomb liquid, necessary for the calculation of ΔH_f° for the test compound, were measured[244] in a special calorimeter.

Few data are available for the thermochemical properties of organoantimony compounds. They were all obtained by the combustion of the test substances in a stationary bomb calorimeter. The enthalpy of combustion of trimethylantimony was determined by Long and Sackman[247] who inserted the test substance in thin-walled glass bulbs and then placed them in the bomb. Analysis of the solid combustion products showed that they consisted mainly of crystalline Sb_2O_4. Sb_2O_3, unoxidised antimony, and carbon were also found as impurities. The analytical method developed for this mixture made it possible to take into account accurately the products of the incomplete oxidation of the initial compound. The enthalpy of hydration of Sb_2O_3, specially measured in preliminary experiments, proved to be insignificant and was disregarded in the interpretation of the experimental data.

The enthalpy of combustion of triethylantimony has been measured[31-33]. The selected experimental conditions ensured the formation of only a single antimony oxide, namely Sb_2O_3. The enthalpy of combustion of triphenylantimony was determined by Birr[223]. To improve the combustion, the test substance was ignited in a polyethylene bag. The resulting solid combustion product consisted of a mixture of unoxidised carbon and the oxides Sb_2O_3 and Sb_2O_4. It was analysed by the method of Long and Sackman[247].

The enthalpies of combustion of trimethyl-, triethyl-, and triphenylbismuth have also been measured[31-33,243,246], by combustion in a stationary bomb calorimeter. Long and Sackman[246] placed samples of trimethylbismuth to be combusted in thin-walled glass bulbs, on which a magnesium ribbon, connected to an iron wire used for ignition, was wound. Only the bismuth oxide Bi_2O_3 was found in the solid combustion products. Small amounts of metallic bismuth and free carbon were found as impurities. Analysis for unoxidised bismuth and carbon was carried out after each experiment and the corrections due to their presence were taken into account in the calculation of ΔH_f° for the test substance.

Steele[219] determined the enthalpy of formation of triphenylbismuth by the rotating bomb calorimeter method. The bomb liquid was an aqueous HCl solution in which the bismuth-containing combustion products were converted into $BiCl_3$. The value $\Delta H_f^\circ[(C_6H_5)_3Bi(c)] = 117.0 \pm 1.2$ kcal mol^{-1} obtained in this investigation[219] is close to $\Delta H_f^\circ = 112 \pm 2$ kcal mol^{-1} found for the same compound by combustion in a stationary bomb calorimeter[243].

VII. COMPOUNDS OF GROUP VI NON-TRANSITION ELEMENTS

Among organic compounds containing Group VI non-transition elements, only sulphur-containing substances have been investigated in fair detail. The monograph of Cox and Pilcher[1] presents the enthalpies of formation (obtained as a rule by combustion in a rotating bomb calorimeter) for approximately 170 such compounds. As already mentioned in the introduction, these data are not repeated here.

As regards the thermochemistry of organic substances containing other Group VI non-transition elements, there have been only three studies in which the enthalpies of formation of organic compounds of selenium and tellurium were determined.

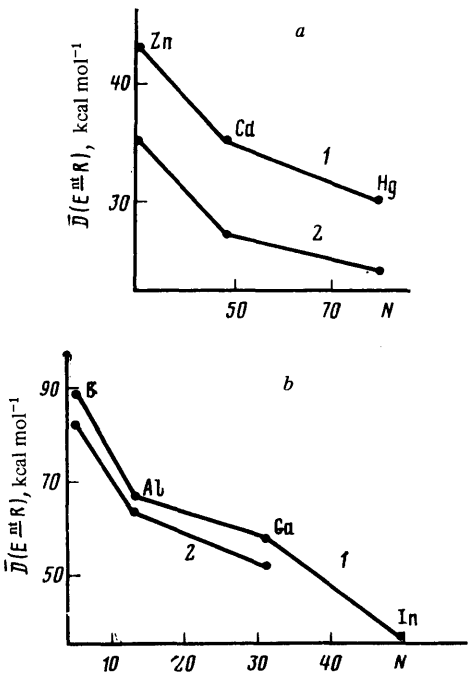

Figure 1. Variation of the average dissociation energy of the element–organic group bonds formed by Group II non-transition elements in the compounds $E^{nt}R_2$ (*a*) and Group III elements in the compounds $E^{nt}R_3$ (*b*) with increase of the atomic number of the element *N*; R: 1) CH_3; 2) C_2H_5.

The enthalpy of formation of liquid diethyl selenide, which is -23 ± 1 kcal mol^{-1}, has been calculated[251] from the results of the combustion of this substance in a stationary bomb calorimeter. It was combusted together with paraffin, which increased the degree of combustion. The same value of $\Delta H_f^\circ[(C_2H_5)_2Se(l)]$ was obtained[248] by measuring the enthalpy of reaction of diethyl selenide with an excess of bromine. After taking into account the enthalpy of vaporisation of this compound, which amounts to[248] 9.3 ± 0.4 kcal mol^{-1}, we obtain $\Delta H_f^\circ[(C_2H_5)_2Se(g)] = -14 \pm 1$ kcal mol^{-1}.

Barnes and Mortimer[252] calculated ΔH_f° for liquid diphenyl selenide from the enthalpy of combustion measured in a rotating bomb calorimeter and obtained $\Delta H_f^\circ = -54 \pm 1$ kcal mol^{-1}. The test substance was ignited in a polyester bag in a quartz crucible. Distilled water (50 cm^3), in which the combustion products obtained dissolved, was first placed in the bomb. The enthalpy of vaporisation of $(C_6H_5)_2Se$, amounting to 15.2 ± 0.6 kcal mol^{-1}, was calculated in the same study from its boiling point at different pressures. Taking into account this quantity, we have $\Delta H_f^\circ[(C_6H_5)_2Se(g)] = +69 \pm 1$ kcal mol^{-1}.

$\Delta H_f^\circ[(C_2H_5)_2Te(l)] = -3 \pm 1$ kcal mol^{-1} was calculated from measurements of the enthalpy of mixing of diethyl telluride with an excess of bromine and, after taking into account the enthalpy of vaporisation, equal to 10.0 ± 0.5 kcal mol^{-1}, the enthalpy of formation in the gaseous state was found to be $\Delta H_f^\circ[(C_2H_5)_2Te(g)] = +7 \pm 1$ kcal mole^{-1}.[248]

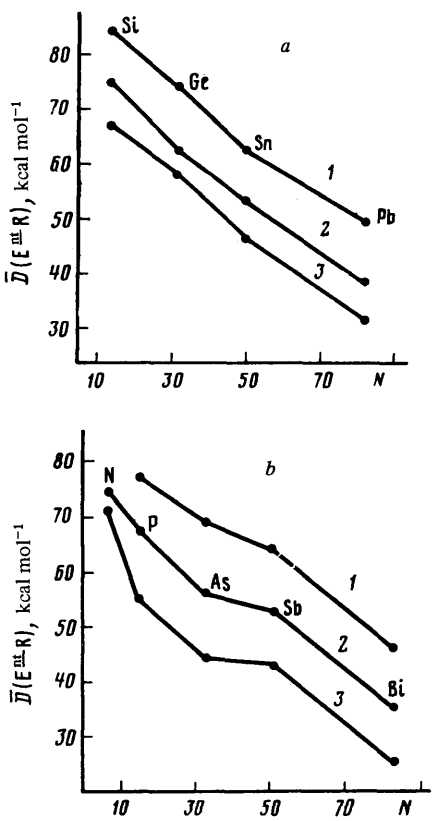

Figure 2. Variation of the average dissociation energy of the element–organic group bonds formed by Group IV non-transition elements in the compounds $E^{nt}R_4$ (*a*) and Group V elements in the compounds $E^{nt}R_3$ (*b*) with increase of the atomic number of the element; R: 1) C_6H_5; 2) CH_3; 3) C_2H_5.

VIII. THE AVERAGE DISSOCIATION ENERGIES OF THE CHEMICAL BONDS FORMED BY NON-TRANSITION ELEMENTS IN THEIR ORGANIC COMPOUNDS

The elucidation of the dependence of the strength of chemical bonds on the nature of the atoms involved in them is of considerable theoretical interest. However, determination of the dissociation energy of an individual bond in a

specified compound is usually a very difficult experimental problem. For this purpose one therefore frequently employs the average bond dissociation energies ($\bar{D}$). $\bar{D}$ is the enthalpy of the process

$$ER_n\ (g) \rightarrow E\ (g) + nR\ (g),$$

divided by the number of bonds n, where ER_n is the molecule of the given substance in the gaseous state, E the element, and R the atom, group, or ligand, also in the gaseous state. This quantity can be calculated by the formula

$$\bar{D}\ (E-R) = \frac{1}{n}\left\{\Delta H_f^0\ [E\ (g)] + n\Delta H_f^0\ [R\ (g)] - \Delta H_f^0\ [ER_n\ (g)]\right\},$$

from experimental (tabulated) enthalpies of formation of the reactants involved in the given reaction in the gaseous state.

Table 6. Average dissociation energies ($\bar{D}$) of element–organic group chemical bonds formed by Group II–VI non-transition elements (kcal mol^{-1}).

Table 6 presents the values of $\bar{D}$(E–R) for a series of compounds of Group II–VI non-transition elements calculated by the authors of the review by this method from the data in Tables 1–5 in this review and in a handbook[11]. The data in Table 6 made it possible to establish the following relations for the dissociation energies $\bar{D}$ of the bonds formed by non-transition elements in their organic compounds.

1. In compounds $E^{nt}R_n$ of non-transition elements (E^{nt}) in the same Group of the Periodic System and with the same alkyl or phenyl group (R) and the same value of n, the average dissociation energy of the E^{nt}–R bond diminishes with increasing atomic number of the element E^{nt} down the Group (Figs. 1–3)†.

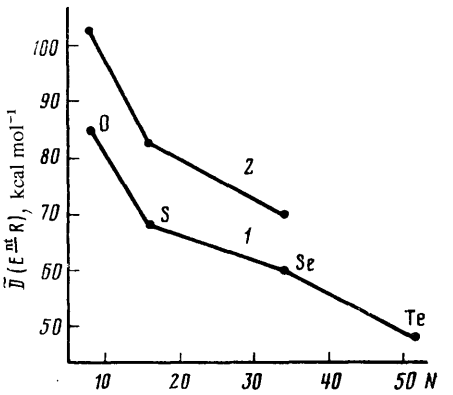

Figure 3. Variation of the average dissociation energy of the element–organic group bonds formed by Group VI non-transition elements in the compounds $E^{nt}R_2$ with increase of the atomic number of the element; R: 1) C_2H_5; 2) C_6H_5.

2. In all cases $\bar{D}(E^{nt}-C_6H_5) > \bar{D}(E^{nt}-CH_3) > \bar{D}(E^{nt}-C_2H_5) \cong \bar{D}(E^{nt}$-n-$C_3H_7) \cong \bar{D}(E^{nt}$-n-$C_4H_9)$.

3. The average dissociation energy of the E^{nt}–n-R bond exceeds by 1–4 kcal mol^{-1} $\bar{D}(E^{nt}$–iso-R). [The failure of $\bar{D}$(Ge-n-C_4H_9) and $\bar{D}$(Ge–iso-C_4H_9) to obey this rule is probably due to the inaccuracy of experimental data used to calculate these quantities.]

4. The average dissociation energies of the E^{nt}–OR bonds, where R is an alkyl group, exceed by 14±2 kcal mol^{-1} the corresponding values of $\bar{D}(E^{nt}$–$OC_6H_5)$. The high dissociation energies of the bonds formed by silicon and germanium with oxygen in the compounds $(R_3E)_2O$ compared with the corresponding values for $(RO)_4E$ are striking.

5. The average dissociation energies of the E–R bonds, where R is an alkyl or phenyl group and E = Si, Ge, or Sn, in the compounds ER_4 and $(ER_3)_2$ with the same elements and groups have similar values (Table 6). This corresponds to the equality, within the limits of the error of the determination, of the E–R bond lengths in the compounds ER_4 and $(ER_3)_2$ with identical E and R.[256–259]

†As a general relation, this was first established by the present authors[253]. In the compound E^tL_n of transition elements (E^t) belonging to the same Group and with the same ligand (L) and the same n, $\bar{D}(E^t$–L) increases with increasing atomic number of the element down the Group[254,255].

The values of $\bar{D}$(E–R) for compounds of the type $(ER_3)_2$ were calculated from the equation

$$\bar{D}(E-R) = {}^1/_6 \{6\Delta H_f^0[R(g)] + \Delta H_f^0[E_2(g)] - \Delta H_f^0[(ER_3)_2(g)]\}.$$

If, bearing in mind the observed similarity of the values of $\bar{D}$(E–R) in ER_4 and in $(ER_3)_2$, one assumes that $\bar{D}$(E–E) for the corresponding gas-phase molecules of E_2 and $(ER_3)_2$ are also similar, then we obtain the following values for the compounds $(ER_3)_2$: $\bar{D}$(Si–Si) ≅ 74 kcal mol^{-1}, $\bar{D}$(Ge–Ge) ≅ 66 kcal mol^{-1}, and $\bar{D}$(Sn–Sn) ≅ 45 kcal mol^{-1}.

Unfortunately there are no thermochemical data for the strength of the bonds between non-transition elements. a mass-spectrometric study[260] of the compounds $(C_5H_5)_3(CO)_3E^1E^2(CH_3)_3$, where E^1 = Cr, Mo, or W and E^2 = Ge or Sn, led to the following results:

Bond	Cr–Ge	Mo–Ge	W–Ge	Cr–Sn	Mo–Sn	W–Sn
D, kcal mole^{-1}	46.8	60.0	64.8	53.5	71.0	75.6

Thus $\bar{D}(E^1–E^2)$ increases with increasing atomic number of both the transition and non-transition element down the Groups of the Periodic System. In this case the behaviour characteristic of the bonds formed by transition metals, considered in detail in our previous reviews[245,255], is manifested.

Methods of Calculating pK_{BH^+} for Weak Bases

Yu.L.Khaldna

Methods of calculating pK_{BH^+} for weak bases from spectrometric data are discussed, with special emphasis on methods based on the principle of free energy linearity. It is shown that the ionisation of a weak base in a strongly acid medium is described by two quantities: pK_{BH^+} and the solvation parameter. 77 references.

I. INTRODUCTION

Over 2000 papers on the basicity of weak bases have been published in the last 20 years[1]. Various aspects of this problem are dealt with in special reviews and monographs[1-10]. The basis of any discussion of the basicity of weak bases is still the Brønsted–Lowry scheme[11,12]

$$BH^+ \rightleftharpoons B + H^+, \quad (1)$$

where B and BH^+ denote the weak base and its conjugate acid respectively. The equilibrium (1) is characterised by the basicity constant of the base[4,5]

$$K_{BH^+} = a_B a_{H^+}/a_{BH^+}. \quad (2)$$

Within the framework of this approach specific solvation phenomena involving both the B and the BH^+ form of the bases are not considered in detail. The influence of these factors on the position of the equilibrium (1) is allowed for by varying the appropriate activity coefficients (f_B and f_{BH^+}).

The basicity of weak bases is usually studied in strongly acid media, where the equilibrium (1) lies very far towards the left. The binary water–sulphuric acid and water–perchloric acid systems are most frequently used, and the indicator ratio[4,5] $I = [B]/[BH^+]$ of the base is determined as a function of the composition of the medium for different concentrations of H_2SO_4 or $HClO_4$.

Up to 1970 the I values were determined mostly by u.v. spectroscopy[4,5]:

$$I = [B]/[BH^+] = (\varepsilon - \varepsilon_{BH^+})/(\varepsilon_B - \varepsilon), \quad (3)$$

where ε_B, ε_{BH^+}, and ε are the molar absorption coefficients of the B form, the BH^+ form, and their mixture respectively. This method can be used to study the basicity of bases whose solubility is very low, because it can handle concentrations as low as 10^{-4}–10^{-5} mole litre^{-1}. However the u.v. spectra are often complicated by the so-called medium effects, resulting in lack of constancy of ε_B and ε_{BH^+} under conditions when the shift of the equilibrium (1) is extreme[13,14]. Various methods have been proposed to overcome this difficulty, but we shall not discuss them here because they are examined in detail in Bernshtein and Kaminskii's book[15].

Following recent developments and improvement in NMR spectroscopy this technique has been widely used since 1970 to determine the indicator ratio of weak bases in water–strong acid systems. Very dilute solutions of the weak bases can be used in the PMR method: in most cases the concentration of the weak base is varied between 0.005 and 0.15 mole litre^{-1}.[16-24] The main disadvantage of the PMR method is that the shift of the signal is very sensitive to specific solvation effects[23,25-28]. Therefore the ^{13}C NMR method is preferable, in principle, because its signal is generated from a nucleus close to the basicity centre[28]. However the signal from the ^{13}C nucleus is ~64 times weaker than the signal from ^1H (assuming equal numbers of carbon and hydrogen atoms in a constant magnetic field)[29], and therefore the ^{13}C NMR method requires a higher concentration of the base B in solution (usually 0.5–1.0 mole litre^{-1}).[29-31]

In both the PMR and the ^{13}C NMR method the indicator ratio is calculated by the equation[30]

$$I = [B]/[BH^+] = (\nu - \nu_{BH^+})/(\nu_B - \nu), \quad (4)$$

where ν_B, ν_{BH^+}, and ν are the characteristic frequencies for the B form, the BH^+ form, and their mixture respectively.

There is still some doubt about the degree of agreement of I values calculated by Eqn.(4) using NMR data for different nuclei (^1H, ^{13}C, and even ^{31}P). Thus some substantial discrepancies between I values obtained from NMR data for different nuclei have been pointed out[23,24].

In spite of these difficulties we shall assume throughout this review that the effect of the composition of the water–strong acid system on the indicator ratio of the weak base is known, either from u.v. spectroscopy or from NMR (^1H or ^{13}C) data.

II. PRESENT STATE OF THE ACIDITY FUNCTION METHOD

Once the I values have been determined from Eqns.(3) or (4) and from experimental data as a function of the concentration of H_2SO_4 or $HClO_4$ we have to choose a method of calculating the basicity constant of the weak base. The classical approach is to use the appropriate acidity function[4]

$$pK_{BH^+} = H_X - \lg I, \quad (5)$$

where H_X is the acidity function, which describes the extent of protonation of the base B. This method of calculating pK_{BH^+} was widely used up to the late 1960's, because it was thought that all electrically neutral bases which are protonated according to Eqn.(1) must follow the Hammett acidity function H_0.[5,32,33] However more than 10 mutually inconsistent acidity functions have now been reported[4,20,32-48]:

$$H_X = -\lg a_{H^+} - \lg \frac{f_X}{f_{XH^+}}, \quad (6)$$

where f_X and f_{XH^+} are the activity coefficients of the indicator X and of its ionised form XH^+. Since the acidity function ceased to be unique, the Hammett postulate[4,5]

$$f_X/f_{XH^+}=f_B/f_{BH^+} \quad (7)$$

became the exception rather than the rule[1,10]. If the condition (7) is not satisfied in the concentration range of the strong acid for which the I values have been calculated by Eqn.(3) it follows that the pK_{BH^+} value given by Eqn.(5) is not a thermodynamic quantity[4,18]. From the practical point of view we have to decide whether the published acidity function describes the protonation of the base under study with sufficient precision (see below)[25]. It is essential to bear in mind that pK_{BH^+} values calculated by using different acidity functions cannot be intercompared directly, in the sense that the most negative values of pK_{BH^+} will not necessarily correspond to the base which is protonated to 50% ("half-protonation") in the most concentrated acid solution.

In recent years pK_{BH^+} values have been calculated from Eqn.(5) only in some special cases, such as studies of the basicity of a series of structurally similar compounds protonated according to some acidity function H_X common to the whole series. Correct application of this method of calculating pK_{BH^+} implies a test of the precision with which the protonation of the base under study is described, in each case, by the given acidity function H_X. For this purpose, Eqn.(5) is conveniently re-written[32]

$$\lg I=aH_X-pK_{BH^+}, \quad (8)$$

where a is the slope of the plot of $\lg I$ against H_X [often referred to as $d(\lg I)/dH_X$].[4,7] Eqn.(8) is solved by least squares, minimising the deviations in $\lg I$.[49] If the protonation of the given base corresponds to the function H_X the regression coefficient of a will be close to unity (as confirmed by considering the width of the confidence interval of the a values)[49]. It is usually assumed that the base B is protonated according to H_X if $a=1\pm0.1$.[14,32]

In addition to the a coefficient, we can calculate pK_{BH^+} and its confidence interval by the least squares method. When applying Eqn.(8) we should remember that the $\lg I$ values are not uniformly precise; the most precise values are those close to zero[15,50,51]. Usually when the modulus of $\lg I$ is greater than unity the value is so inaccurate that its use in Eqn.(8) is not permissible[15]. To allow for the uneven accuracy of $\lg I$ values we can attach to them the weight $w=[s(\lg I)]^{-2}\cdot\text{const}$, where the standard deviation of the determination of $\lg I$ is calculated by the equation[15,32,50-52]

$$s(\lg I)=\pm0.434\,\frac{I+1}{I\Delta R}\sqrt{s_{BH^+}^2+(I+1)^2s^2+I^2s_B^2}, \quad (9)$$

in which $\Delta R=\varepsilon_B-\varepsilon_{BH^+}$ [or $\Delta R=\nu_B-\nu_{BH^+}$, see Eqns.(3) and (4)]; s_{BH^+}, s, and s_B are the standard deviations of the determination of ε_{BH^+} (or ν_{BH^+}), ε (or ν), and ε_B (or ν_B) respectively. If $s_{BH^+}=s=s_B$ we can write[15,32]

$$w=1200\,I^2/(1+I)^2(1+I+I^2). \quad (10)$$

The factor 1200 is introduced into Eqn.(10) in order to make $w=100$ for $I=1$.[15]

The view that each weak base is protonated according to its own acidity function is now widely held[1,7,10,30,39]. Hence the condition $d(\lg I)/dH_X=1$ will apply to a series of bases only if the individual acidity functions (H_B) vary linearly with H_X, with a unit slope. We note from Eqn.(6) that all the acidity functions contain the term $\lg a_{H^+}$, which is a parameter of the medium and is independent of the nature of the weak base X. The dependence of $\lg a_{H^+}$ on the composition of the water–sulphuric acid or water–perchloric acid system is fairly accurately known, though the results of different workers for concentrated solutions show some discrepancies (see Table 1).

Table 1. Values of $\lg a_{H^+}$ for aqueous solutions of sulphuric and perochloric acid at 25 °C.

Acid concn., wt.%	H_2SO_4 solution		$HClO_4$ solution	
	Ref.53	Ref.54	Ref.53	Ref.54
5	0.01	−0.12	−0.02	−0.04

50	6.00	5.72	7.22	7.11
60	7.97	7.44	—	9.41
70	—	9.48	—	—

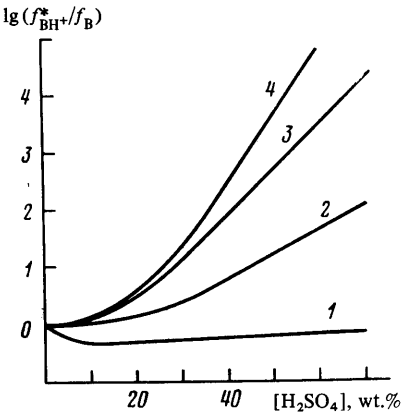

Figure 1. Plots of $\lg(f^*_{BH^+}/f_B)$ against concentration of sulphuric acid in the H_2O–H_2SO_4 system: *1*) for olefins, *2*) for *N*,*N*′-dimethyl substituted aromatic amines (H_0''' indicators[39]), *3*) for substituted aromatic amines (H_0' indicators[32]), *4*) for substituted benzamides (H_A indicators[34]).

It follows from the above that the non-coincidence of different acidity functions is probably due to differences in the dependence of $\lg f_X/f_{XH^+}=\phi$ on the acid concentration for different types of base. The activity coefficient of the non-ionised form f_X can be determined relatively easily either from solubility data or from the distribution coefficient[5,7,10]. It is found that for bases of different structure the variation of f_X with concentration of H_2SO_4 (or $HClO_4$) can be very different: this problem is considered in detail in a special review article[10]. The activity coefficient of the ionised form (f_{XH^+}) is not measurable, and therefore (as suggested by Boyd[6,55]) f_{XH^+} is replaced by the ratio

$$f^*_{XH^+}=f_{XH^+}/f_{Et_4N^+} \quad (11)$$

whose variation with the concentration of H_2SO_4 (or $HClO_4$) can be measured.

The method of determining $f^*_{XH^+}$ is discussed in Refs.6, 55, and 56. It is assumed that the screening of the positive charge on the nitrogen atom by the ethyl groups ensures that the Et_4N^+ ion cannot undergo specific solvation[6,26,57]. Since this type of solvation is the main reason for the deviation of the activity coefficients from unity we can write $f_{Et_4N^+}=1$ for all solutions (from those in pure water to those in concentrated solutions of acids)[6,26,53]. However the ratio $f_X/f^*_{XH^+}$ is found to depend both on the concentration of the strong acid and on the nature of the base X (see Fig.1). We shall not dwell on the reasons for the deviation of f_X and $f^*_{XH^+}$ from unity because they are discussed at length in review articles[1,7,10].

The difference between two arbitrarily chosen acidity functions (H_X and H_Y) at a given concentration of the strong acid is determined by the expression

$$H_X - H_Y = \lg \frac{f_Y f_{XH^+}}{f_{YH^+} f_X}, \qquad (12)$$

from which we can judge the correctness of independently obtained[7,10] values of $f_X/f^*_{XH^+}$ and $f_Y/f^*_{YH^+}$. This type of test has shown that the difference between acidity functions can be calculated from the values of $f_X/f^*_{XH^+}$ and $f_Y/f^*_{YH^+}$.[20,58] Therefore there is no longer any doubt that in general, for any acidity function H_X, the ratio $f_X/f_{XH^+} \neq 1$.[1,10] This is what makes compliance with the Hammett postulate (7) a rare event, and detracts from the value of the classical method of calculating pK_{BH^+}.[58-62]

III. THE YATES–McCLELLAND METHOD

This method was developed[63] because an acidity function H_X for which $d(\lg I)/dH_X = 1.00$ could not be found for many weak bases. According to Yates and McClelland, to a first approximation a simple proportionality always exists between the quantities H_X and H_0:[63]

$$H_X = mH_0. \qquad (13)$$

Inserting (13) into (5) we obtain the Yates equation for calculating pK_{BH^+}:[63]

$$\lg I = mH_0 - pK_{BH^+}. \qquad (14)$$

This equation can be solved by least squares with allowance for the unequal precision of the $\lg I$ values [see Eqns.(9) and (10)].

The pK_{BH^+} value calculated by Eqn.(14) expresses the basicity of the substance B in its own individual acidity scale $H_B = -\lg a_{H^+} f_B/f_{BH^+}$: in other words this value of pK_{BH^+} gives us the H_B value for a solution in which $\lg I = 0$.[14] Often instead of pK_{BH^+} one calculates the H_0 value for a solution in which $\lg I = 0$, i.e. the quantity $H_0^{(1/2)}$. Inserting $\lg I = 0$ into Eqn.(14) we obtain

$$H_0^{(1/2)} = \frac{1}{m} pK_{BH^+}. \qquad (15)$$

The H_0 value at half-protonation of the unknown base ($H_0^{1/2}$) is often identified[32,33] with the pK_{BH^+} value of the base in the H_0 acidity scale[9,17,19,64,65].

The Yates–McClelland method relies on the assumption of a direct proportionality between H_X and H_0 [Eqn.(13)]. This linear variation is obeyed only approximately in practice, with a break near $H_0 = 0$, since in this pH region $m = 1$ for all values of H_X (see Fig.2). As a result, the pK_{BH^+} values calculated by Eqn.(14) lose some of their physical significance, and they cease to be thermodynamic quantities referred to a standard state in water. In the most favourable case these pK_{BH^+} values can be treated as referred to a standard state in an acid solution for which $H_0 = 0$ (i.e. 4.8 wt.% H_2SO_4 or 4.0 wt.% $HClO_4$).

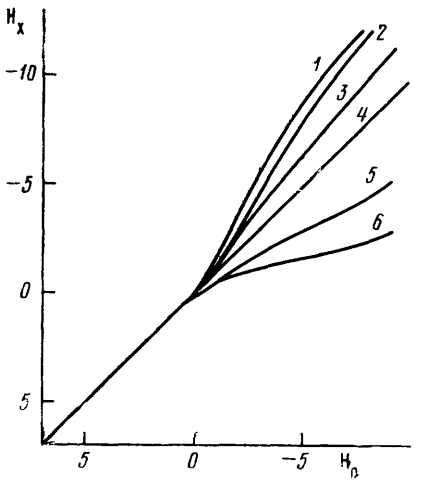

Figure 2. Plots of different acidity functions (H_X) against H_0 [32] in aqueous solutions of sulphuric acid at 25 °C: *1*) $H_{R'}$,[43] *2*) H_C,[35] *3*) H_0''',[39] *4*) H_0,[32] *5*) H_A,[34] *6*) H_{ROH}.[40]

IV. THE BUNNETT–OLSEN METHOD

The Bunnett–Olsen method[66] of calculating pK_{BH^+} is based on the linear expression

$$\lg Q_1 = a \lg Q_2 + b, \qquad (16)$$

where $Q_1 = [B_1][H^+]/[B_1H^+]$; $Q_2 = [B_2][H^+]/[B_2H^+]$; B_1 and B_2 are arbitrarily chosen weak bases; the concentration $[H^+]$ is taken to be numerically equal to the molar concentration of H_2SO_4 or $HClO_4$.[66] The validity of the linear relationship (16) has been tested[58,66,67] for several bases B_1 and B_2: the equation was found to be generally applicable, deviations from it being smaller than experimental error[67].

In order to obtain an equation for calculating pK_{BH^+}, Bunnett and Olsen[66] standardised their reference scale, i.e. the choice of the base B_2. They defined their standard base as a hypothetical primary aromatic amine with $pK_{BH^+} = 0$, for which $\lg [B_2]/[B_2H^+] = H_0$, and

$$\lg Q_2 = H_0 + \lg [H^+]. \qquad (17)$$

We should stress that the choice of the acidity function H_0 as the reference scale has no fundamental significance: in principle H_0 in Eqn.(17) can be replaced by any similar acidity function. The function H_0 is chosen simply because it has been carefully measured and is widely known.

After combining (17) and (16) and simplifying we obtain the expression

$$H_0 - \lg I_1 = \Phi(H_0 + \lg [H^+]) - b, \qquad (18)$$

where $I = [B_1]/[B_1H^+]$ and $\Phi = 1 - a$. If the condition $\Phi = \text{const}$ is obeyed at all concentrations, from the standard state in water (for which $H_0 - \lg [H^+] = 0$) to the acid solutions used for measuring I_1, we can easily see that $-b = pK_{B_1H^+}$ (since

in the standard state $H_0 - \lg I_1 = pK_{BH^+}$). Inserting $-b = pK_{B_1H^+}$ into Eqn.(18) we arrive at the Bunnett–Olsen equation for $pK_{B_1H^+}$:[66]

$$H_0 - \lg I_1 = \Phi(H_0 + \lg [H^+]) + pK_{B_1H^+} . \quad (19)$$

When applying Eqn.(19) we must make allowance for the uneven precision of the $\lg I_1$ values [see (9) and (10)], and treat the H_0 and $[H^+]$ values as exactly known.

By comparing formulae (5) and (19) we can easily show that[1,68]

$$H_X + \lg [H^+] = (1-\Phi)(H_0 + \lg [H^+]). \quad (20)$$

This relationship between the acidity functions H_X and H_0 is free from the shortcomings found in the simpler Yates–McClelland formula (13). It does not show the characteristic break near $H_0 = 0$ given by Eqn.(13) (see Figs.2 and 3), since both $H_X + \lg [H^+]$ and $H_0 + \lg [H^+]$ tend towards zero as we approach the standard state in water. According to the expression (20), plotted in Fig.3, we can judge the constancy of the parameter Φ in all cases from water to concentrated solutions of strong acids. We see from Fig.3 that Φ = const in moderately concentrated solutions of acids. At high concentrations of H_2SO_4 the quantity Φ is often not constant. This effect introduces some uncertainty into the pK_{BH^+} values obtained by Eqn.(19) through a long extrapolation (from concentrated solutions of acids).

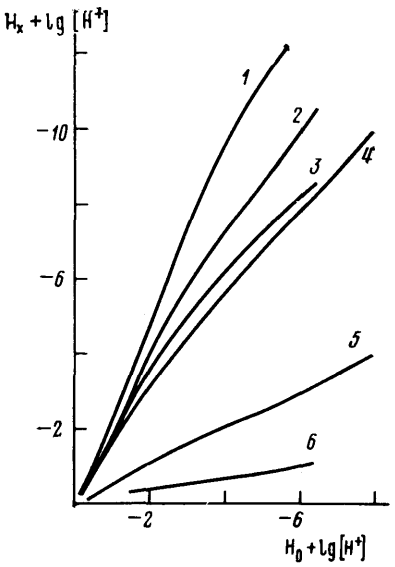

Figure 3. Relationship between the acidity functions according to Bunnett and Olsen[66,68] [see Eqn.(20), aqueous solutions of sulphuric acid at 25 °C]: *1)* $H_X = H_R$,[43] *2)* $H_X = -\lg a_{H^+}$,[54] *3)* $H_X = H_M$,[42] *4)* $H_X = H_0$,[32] *5)* $H_X = H_A$,[34] *6)* $H_X = H_{ROH}$.[40]

The possible error range of the pK_{BH^+} values obtained from Eqn.(19) was evaluated[69,70] by noting that in principle the function H_0 in that equation can be replaced by any analogous acidity scale. The criterion for the validity of such a scale is the linearity of expressions of the type of (20). If the standard base B_2 in Eqn.(16) is taken to be a hypothetical base with $pK_{BH^+} = 0$ which is protonated without specific solvation effects, i.e. according to the $\lg a_{H^+}$ acidity scale, Eqns.(19) and (20) become, respectively,

$$-\lg a_{H^+} - \lg I_1 = \Phi(-\lg a_{H^+} + \lg[H^+]) + pK_{B_1H^+}, \quad (21)$$

$$H_X + \lg[H^+] = (1-\Phi)(-\lg a_{H^+} + \lg[H^+]). \quad (22)$$

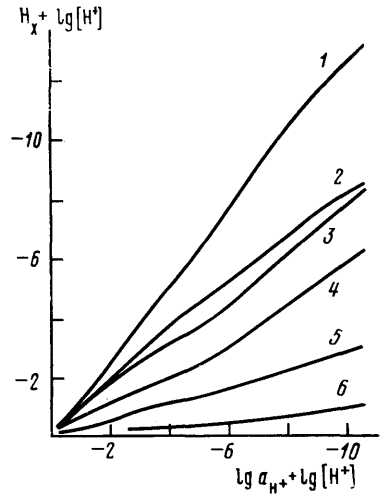

Figure 4. Variation of $H_X + \lg [H^+]$ with $(-\lg a_{H^+} + \lg M)$ for different acidity functions H_X in aqueous solutions of sulphuric acid at 25 °C: *1)* $H_X = H_R$,[43] *2)* $H_X = H_M$,[42] *3)* $H_X = H_0''$,[39] *4)* $H_X = H_0$,[32] *5)* $H_X = H_A$,[34] *6)* $H_X = H_{ROH}$.[40]

We note from Fig.4 that the proportionality (i.e. the condition Φ = const) is more accurately obeyed by Eqn.(22) than by the analogous expression in terms of H_0 [Eqn.(20), see Fig.3].[70] Therefore the $pK_{B_1H^+}$ values calculated by (21) are more nearly equal to the corresponding thermodynamic quantities than those calculated by (19). For $pK_{BH^+} > -3$ the difference between the pK_{BH^+} values given by formulae (19) and (21) is insignificant[69]. However for very weak bases with $pK_{BH^+} < -3$ the discrepancy between the pK_{BH^+} values given by (19) and (21) can be as high as three units of pK_{BH^+}.[69] These discrepancies arise primarily from the loss of linearlity of Eqn.(20) at high concentrations of the strong acid[70].

Because of the wide use made of the Bunnett–Olsen method it is becoming generally assumed that in order to characterise the basicity of a weak base quantitatively we need to know the solvation parameter Φ as well as pK_{BH^+}. This interpretation of the parameter Φ was originally proposed by Hammett[68], and further developed by Modena and Scorrano[1]. The solvation parameter Φ is independent of pK_{BH^+} for a weak base, but is determined by the nature of the base. It is normalised to give $\Phi = 1$ for water[1,20] and $\Phi = 0$ for primary amines[1,66]. Different types of weak bases are assigned the following values of Φ:[1] aryl carbinols from −1.02 to −1.59, azulenes −0.70, tertiary aromatic amines from −0.33 to −0.48, amides from +0.42 to +0.55, alcohols +0.85, etc. The relationship between the value of Φ and the solvation effects during the protonation of weak bases is discussed in Ref.1.

In order to compare Φ with m we note, from Eqn.(14), that at high acid concentrations the quantity $\lg [H^+]$ is small in comparison to the absolute value of H_0. Hence under these conditions Eqn.(19) is equivalent to Eqn.(14) with $m = 1 - \Phi$, which can be confirmed by directly comparing the values of m and $1 - \Phi$.[1]

Both the classical Bunnett–Olsen equation (20) and its modification [Eqn.(22)] are linear free energy functions. Thus from Eqns.(20) and (22) respectively we can obtain[66,69]

$$\lg \frac{f_{H^+} f_X}{f_{XH^+}} = (1 - \Phi) \lg \frac{f_{H^+} f_B}{f_{BH^+}}, \quad (23)$$

$$\lg \frac{f_{XH^+}}{f_X} = \Phi \lg f_{H^+}. \quad (24)$$

These expressions indicate linear relationships between the changes in free energy of the corresponding particles.

V. THE MCP AND COX–YATES METHODS

Bunnett and Olsen's expression (23) was critically examined by an Italian group of workers (Marziano, Cimino, and Passerini, abbreviated to MCP), who concluded[71] that the Hammett acidity function H_0 should not be used to construct a comparative scale of $\lg (f_{H^+} f_B / f_{BH^+})$ [in Eqn.(20)]. Instead, they suggested a description of weak bases involving partially overlapping ionisation regions[71]:

$$\lg \frac{[X]}{[XH^+]} + \lg [H^+] = n_X \left(\lg \frac{[B]}{[BH^+]} + \lg [H^+] + pK_{BH^+} \right) - pK_{XH^+}, \quad (25)$$

where $[H^+]$ is the molar concentration of strong acid, and X is a slightly weaker base than B. The linear relationship (25) allows us to determine pK_{XH^+} for the next indicator X of a given series, and the corresponding slope of the plot of Eqn.(25):

$$n_X = \lg \frac{f_{H^+} f_X}{f_{XH^+}} \Big/ \lg \frac{f_{H^+} f_B}{f_{BH^+}}. \quad (26)$$

Applying Eqn.(25) to the next indicator Y of the series (with $pK_{YH^+} < pK_{XH^+}$) we can evaluate n_Y:

$$n_Y = \lg \frac{f_{H^+} f_Y}{f_{YH^+}} \Big/ \lg \frac{f_{H^+} f_X}{f_{XH^+}}. \quad (27)$$

By stepwise repetition of this procedure we can determine all the slopes n_X, n_Y, ..., n_Z up to that of the weaker base Z. Assuming that n_X, n_Y, ..., n_Z are constant, i.e. that differentials of the type of $d(\lg f_{H^+} f_Y / f_{YH^+}) / d(\lg f_{H^+} f_X / f_{XH^+})$ are independent of the I value [defined by Eqn.(3)] of the base, we can easily relate the first term B of a given series to the subsequent terms X, Y, ..., Z:

$$\lg \frac{f_{H^+} f_B}{f_{BH^+}} = \frac{1}{n_X} \lg \frac{f_{H^+} f_X}{f_{XH^+}} = \frac{1}{n_X n_Y} \lg \frac{f_{H^+} f_Y}{f_{YH^+}} = \ldots = \frac{1}{n_X n_Y \ldots n_Z} \lg \frac{f_{H^+} f_Z}{f_{ZH^+}} = -M_c. \quad (28)$$

Eqn.(28) was used to calculate the "function of the activity coefficients" M_c [71] in terms of n_X, n_Y, ..., n_Z and of the quantity

$$\lg \frac{f_{H^+} f_Z}{f_{ZH^+}} = -pK_{ZH^+} - \lg \frac{[Z][H^+]}{[ZH^+]}. \quad (29)$$

If the function M_c is known the pK_{BH^+} value of an arbitrarily chosen weak base B can be obtained from the linear expression[71]

$$\lg I + \lg [H^+] = n_B M_c - pK_{BH^+} \quad (30)$$

using the method of least squares and allowing for the unequal precision of the I values given by Eqn.(3) [see Eqn.(10)].

Unfortunately the M_c scales calculated from different series of weak bases do not coincide† when the solution contains more than 40 wt.% of H_2SO_4.[71] The authors recommend the use of the M_c scale calculated from the ionisation of Hammett indicators (whose protonation proceeds in the same sense as the acidity function H_0).[71] Therefore the MCP group developed a new method of calculating the M_c scale from all possible values of I for the whole of the ionisation region (usually $0.1 \leq I \leq 1$). However their following paper[72] gives only the new M_c values for aqueous solutions of sulphuric acid (see Table 2) without describing the method of calculating M_c.

Table 2. Values of M_c, X, and $\lg c_{H^+}$ for aqueous solutions of sulphuric and perchloric acid.

Acid concn., wt.%	H_2SO_4 solution			$HClO_4$ solution	
	$-10 \cdot M_c$ (Ref.72)	X (Ref.73)	$\lg c_{H^+}$ (Ref.73)	X (Ref.73	$\lg c_{H^+}$ (Ref.69)
5	0.172	0.103	−0.205	0.091	−0.293
10	0.354	0.231	0.117	0.212	0.018

70	5.338	4.459	1.097	6.220	1.022
74	5.896	5.080	1.118	6.983	1.057
80	6.786	6.150	1.143	—	—
84	7.427	6.906	1.133	—	—
90	8.547	7.985	0.996	—	—
95	9.808	8.989	0.654	—	—
99	—	10.754	−0.153	—	—

At approximately the same time (1976–1977) and independently of the MCP group Cox and Yates[73] also worked on this problem. Accepting the universality of Eqn.(23), they wrote it in the form of

$$\lg \frac{f_{H^+} f_B}{f_{BH^+}} = m^* \lg \frac{f_{H^+} f_{B^*}}{f_{B^*H^+}} = m^* X, \quad (31)$$

where B* is a hypothetical standard base. The quantity X is identical to $-M_c$, but Cox and Yates prefer to call it the "excess acidity"[73]. They calculate the pK_{BH^+} value of the weak base B by the equation[73]

$$-\lg I - \lg c_{H^+} = m^* X + pK_{BH^+}, \quad (32)$$

where c_{H^+} is the concentration of hydrated protons in solution (see Table 2). This equation can be solved by least squares allowing for the uneven precision of the I values [see Eqn.(10)].

† The discrepancies between the M_c scales arise from the use of I values [obtained by Eqn.(3)] in the overlap regions of successive indicators where the modulus of $\lg I$ is greater than (0.7–1.1) and the uncertainty in its determination is relatively high [see Eqn.(10)].

Unlike the MCP group[72], Cox and Yates describe in great detail the mathematical procedures adopted in the calculation of X.[73] Without reproducing their algorithm, we shall only point out that the X values are obtained by an iterative method, using the equation

$$X = \frac{1}{m^*}(-\lg I - \lg c_{H^+} - pK_{BH^+}), \qquad (33)$$

in which arbitrary values of pK_{BH^+} and m^* are inserted at first. The first, approximate estimate of the scale is then used to obtain more precise values of pK_{BH^+} and m^* by Eqn. (32), and so on. The procedure is repeated until the values of X become invariant[73]. These workers used I values obtained by Eqn.(3) over the whole ionisation region for 165 bases in solutions containing 0–99.5 wt.% H_2SO_4, and for 76 bases in solutions containing 0–78 wt.% of $HClO_4$.

The X scales for aqueous solutions of sulphuric acid and perchloric acid are given in Table 2. We can see that in general the X values are close to the $-M_c$ values multiplied by 10 (the introduction of this scaling factor affects only the solvation parameter). In spite of this similarity the pK_{BH^+} values calculated by using X and M_c respectively differ by more than 0.3 units of pK_{BH^+}.[73] Of course, this conclusion applies to the pK_{BH^+} values obtained with the original M_c scale[71], to which the authors themselves no longer subscribe, but as yet no pK_{BH^+} values appear to have been obtained from the new M_c scale[72]. Its authors[72] are themselves unwilling to apply the new scale until the method of calculating pK_{BH^+} has been improved so that the quoted uncertainty limits can reflect the uncertainty limits of the M_c scale [see Eqn.(30)].

Extensive comparisons of pK_{BH^+} values obtained by using the X scale [Eqn.(32)], the Bunnett–Olsen method [Eqn.(19)], and the acidity function [Eqn.(5)] are given in the Tables of Ref.73. In most cases the pK_{BH^+} values are not very different (within ±0.2 pK_{BH^+} unit), but differences in excess of 1 pK_{BH^+} unit are occasionally found. We note that Eqns.(5) and (32) will give identical pK_{BH^+} values only if all the indicators used to construct the acidity function H_X have the same m^* value [to within ±0.1,[74] see Eqn.(32)].

VI. CALCULATION OF pK_{BH^+} WITHOUT USING THE INDICATOR RATIO

All the methods of calculating pK_{BH^+} discussed so far use the indicator ratio I, calculated by Eqn.(3) or (4). Recent developments in the application of computers make it possible to calculate pK_{BH^+} (and the solvation parameter) directly from experimental results, i.e. from the ε or ν values, without going through the stage of determining I by Eqns.(3) or (4).[20,75] This approach involves the following steps. From Eqn.(3) we readily obtain

$$\varepsilon = \frac{I\varepsilon_B + \varepsilon_{BH^+}}{1 + I} \qquad (34)$$

and a similar expression is obtained from Eqn.(4). Then, using any of the above methods of calculating pK_{BH^+} [i.e. using Eqn.(8), (14), (19), (21), (30), or (32)], we find the variation of $\lg I$ with pK_{BH^+} for the medium parameter P and the solvation parameter S (relating H_0, H_X, c_{H^+}, X, and M_c to the medium parameters P; and m, Φ, n, and m^* to the solvation parameters S):

$$\lg I = F(pK_{BH^+}, P, S),$$

whence

$$I = 10^{F(pK_{BH^+}, P, S)}. \qquad (35)$$

Inserting (35) into (34) we obtain a system of k transcendental equations ($k \geq 3$) with two unknowns (pK_{BH^+} and S). The problem now reduces to finding values of pK_{BH^+} and S which minimise a function of the difference between calculation and experiment such as

$$\Psi = \sum_{i=1}^{i=k} (\varepsilon_{i,\text{calc}} - \varepsilon_{i,\text{exper}})^2 . \qquad (36)$$

Because of the non-linearity of the system of equations the minimum of the function Ψ cannot be found by the standard methods of regression analysis. The problem must therefore be solved by one of the iteration methods commonly used[76] to solve systems of equations. These include Newton's method and its modifications[76], the method of steepest descent[76], and the coefficient variation method[77]. The best choice of method for solving the system of transcendental equations depends on the type of computer to be used and on the availability of appropriate subprograms.

We note that in principle this method of treating experimental data allows us to determine not only pK_{BH^+} and S, but also one of the parameters of the limiting forms[20] (ε_B or ε_{BH^+}) which appear in Eqn.(34). In this case we evaluate three rather than two unknowns from the system of transcendental equations ($k \geq 4$). However there is a risk of being caught up in the "numbers game": the risk is greatest when the plot of ε against composition of the medium lacks a clear plateau near the limiting form ε_B or ε_{BH^+}.

Thus in recent years the methods of calculating pK_{BH^+} for weak bases have undergone some radical changes. The acidity function method [Eqn.(5)] and the Yates–McClelland method [Eqn.(14)] are no longer at the forefront. The former was abandoned when the limitations of the Hammett postulate (7) (leading to a multiplicity of acidity functions) were realised. The Yates–McClelland method proved too empirical and approximate, as well as relying on the basic acidity function devoid of physical significance (H_0).

These older methods are now being replaced by new methods based on the principle of free energy linearity (FEL) [see Eqn.(23)]. Of these, the Bunnett–Olsen method has proved most popular so far [Eqn.(20)], but since it relies on the acidity function H_0 based on the Hammett postulate (7) its use cannot be recommended. Some of the even newer methods are free from this shortcoming: these include the essentially identical MCP method (based on the M_c function) and Cox–Yates method (based on the X function). The advantages of these methods include: firstly, that the calculation of pK_{BH^+} by using the function X (or M_c) relies on a very simple and clear theoretical foundation (the assumption that the FEL principle (23) applies), and secondly that these methods do not require the use of a multitude of acidity functions. Each strong-acid system is characterised by a single function of the X (or M_c) type, and each weak base has two parameters (pK_{BH^+} and m^*) which describe its ionisation. The parameter m^* can be treated as a measure of the solvation interactions with the medium (thus we note that $m^* \cong 1 - \Phi$ [73]).

However, while stressing these favourable aspects of the new methods, we must repeat that a discrepancy still exists between the X and M_c scales, which points to a need for greater efforts on developing and unifying scales of the type of X.

Outer-sphere Interactions in Solutions of Labile Complexes

Yu.A.Makashev and V.E.Mironov

The principal methods for the investigation of outer-sphere interactions in solutions of labile inner-sphere complexes are arranged systematically and analysed. The modern views on the thermodynamics and structure of outer-sphere complexes are discussed and the reliability of certain hypotheses and models is examined from the standpoint of the comparison of the results of different experimental methods and theoretical ideas. A number of features of the outer-sphere interaction in solutions are formulated in relation to outer-sphere associated species formed by 3*d* metals, using certain data about the associated species of *s*, *p*, and *f* metals as well as outer-sphere associated species of inert complex cations.
The bibliography includes 203 references.

I. INTRODUCTION

Outer-sphere interaction is a phenomenon as common as the formation of inner-sphere complexes[1]. Certain problems of the theory and practice of outer-sphere association in solutions have been examined in a number of reviews[2-10]. However, in these studies attention was concentrated on the outer-sphere complexes (OSC) formed by inert Werner complexes, i.e. complexes which are formed and dissociated at a low rate and which are saturated with respect to the coordination number of the central atom[1-8]. As regards labile complexes or complexes which rapidly exchange ligands, over a period shorter than 1 min for a 50% degree of reaction, outer-sphere reactions involving them have been investigated mainly in relation to complex anions[2,3] such as $[ZnBr_4]^{2-}$, $[BiCl_6]^{3-}$, $[Fe(SCN)_6]^{3-}$, and $[AgCl_2]^-$.

Complex cations, for example, $[Co(NH_3)_6]^{3+}$, $[Cr(H_2O)_6]^{3+}$, and $[Rh(NH_3)_5Cl]^{2+}$ usually function as the coordination centres of the OSC. Anions, both simple and complex, play the role of ligands in the vast majority of cases. This can be explained by the high tendency of anions to exhibit electron-donating properties. Inert complex anions are probably capable of forming an outer (second) coordination sphere of a definite configuration, which has been confirmed by numerous investigations[1-14]. The ability of labile complex cations, for example $[Ni(NH_3)_6]^{2+}$ and $[Co(H_2O)_6]^{2+}$ to undergo outer-sphere interaction and procedures for its investigation have not so far been the subject of independent reviews. At the same time the number of systems with labile inner-sphere complexes is many times greater than the number of systems with inert compounds and the interactions in such systems are much more complicated.

Together with the increased theoretical interest in labile outer-sphere complexes[1-10], the latter also attract attention from the practical point of view, particularly in the field of homogeneous catalysis[1,12,15] and in the regulation of biological molecular processes—oxygen and energy transfer in cells, ionic equilibria in the reactions of enzymes, and other most important biological phenomena[12].

The equilibria in labile systems containing outer-sphere complexes and the thermodynamic interpretation of the experimental results associated with them have been transformed into an important and serious problem[5-10], in view of the almost simultaneous occurrence of both inner-sphere and outer-sphere interactions.

The aim of the present review is to examine critically methods for the experimental investigation of the outer-sphere interaction of labile complex cations with different ligands, to survey and analyse literature data on the thermodynamics of this type of OSC, to carry out a comparison with the results of the study of the OSC of inert cations, and to outline certain ways in which this field in the chemistry of coordination compounds can be developed.

II. METHODS FOR THE INVESTIGATION OF THE OUTER-SPHERE INTERACTION OF LABILE COMPLEX CATIONS

There exist various approaches to methods for the investigation of the outer-sphere interactions of labile complex cations as a function of an inner-sphere process, which complicates the study of the OSC.

1. Outer-Sphere Interaction Uncomplicated by Inner-Sphere Complex Formation

The most convenient method for the investigation of outer-sphere interactions for labile complex cations of different composition involves carrying out experiments in solutions containing an excess of inner-sphere ligands. This excess should almost completely suppress the dissociation of the inner sphere and should not influence appreciably the formation of the OSC investigated. This situation can only be created in systems with comparatively stable inner-sphere compounds. The absence of measurable dissociation of the inner-coordination sphere makes it possible to study the formation of OSC by any methods used in the investigation of labile inner-sphere interaction.

The formation of 1 : 1 OSC can be represented in the general form as follows:

$$[ML_N] + A \rightleftarrows [ML_N] \ldots A$$

where L and A are inner- and outer-sphere ligands (the charges have been omitted) and N is the limiting coordination number of the first sphere.

Potentiometry, which is one of the most exact and widely used methods for the investigation of inner-sphere complex formation, has been employed in the study of the association of tris(ethylenediamine)cadmium with sulphate ions in 3.0 N

aqueous solutions of mixtures of sodium perchlorate and sulphate[11,13]. Measurements were made of the changes in the e.m.f.'s of cells with ion transport comprising a cadmium amalgam electrode, where diffusion potentials were determined experimentally[13]. The dissociation of tris(ethylenediamine)-cadmium(II) was suppressed by an excess of ethylenediamine. The measured changes in the e.m.f. were related to the formation of OSC of the type $[CdEn_3](SO_4)_n^{2-2n}$ only; the values of n and the stability constants were determined by Leden's method[1].

The changes in the solubilities of a number of sparingly soluble salts containing the tris(ethylenediamine)nickel(II) ion in solutions with increasing concentrations of outer-sphere ligands and in the presence of a constant excess of ethylenediamine served as a basis for the determination of the stability constants of the OSC $[NiEn_3].L_n^{z-zn}$, where z is the charge of the ligand and L are chloride, sulphate, thiosulphate, and carbonate ions. The conductimetric method has been used[15] to study the monoligand OSC of tris(ethylenediamine)- and tris(propylenediamine)-cobalt(II) in aqueous solutions at low ionic strengths. The thermochemical method[14] led to the determination of the stability constants and enthalpies and entropies of formation of a number of tris-(ethylenediamine)nickel(II) OSC.

Electronic spectroscopy using charge transfer bands in the ultraviolet has been employed in the investigation of the OSC of tris(ethylenediamine)cobalt(II)[15,16] and a number of other cations[17]. The NMR method yielded information about the thermodynamics and structure of numerous OSC of tris(pyrazolyl)borate[18–22] as well as bis(acetylacetone)dipyridinecobalt(II)[23] in several non-aqueous solvents such as cyclohexanone or chloroform. The absorption of ultrasound has been used to investigate the OSC of tris(1,10-phenanthroline)zinc(II).[24] Extraction has been used for the same complexes and mixed complexes with acetylacetone[25]. It served as a basis also for the determination of the formation constants of the OSC of tetra(γ-picoline)dicyanatocobalt(II).[26] The influence of the composition of the external medium on the width of the EPR spectral line has been demonstrated[27].

The high stability of the hydration shell of alkali and alkaline earth metal cations as well as lanthanide ions in many instances makes it possible to investigate numerous OSC of the aquo-complexes of these metals with simple and complex anions using various research techniques[28,29]. However, in such systems there is a possibility of the superposition of the inner-sphere effect on the outer-sphere association. The degree of such superposition depends greatly on the stability of the hydration shell and the nature of the outer-sphere ligands.

2. Simultaneous Formation of Inner- and Outer-Sphere Complexes

The simultaneous formation of inner-sphere complexes (ISC) and OSC is frequently encountered in systems containing aquated cations. The effect of the outer-sphere interaction is then manifested to the maximum extent before the formation of the first inner-sphere complex[1] and is sharply reduced in subsequent coordination stages.

Processes involving the joint formation of monoligand inner- and outer-sphere complexes from an aquated metal ion $M(H_2O)_N$ and the ligand (here and in the general cases discussed below the ionic charges are omitted to simplify the formulation) can be represented by the equations:

$$\begin{array}{ccc} M(H_2O)_N + L & \overset{k_{1,2};\,\omega_{01}}{\rightleftharpoons} & [M(H_2O)_N]\cdot L \\ \uparrow\downarrow & & \uparrow\downarrow \\ & \beta_{n,0} & \\ & \rightarrow & [M(H_2O)_{N-n}L] + nH_2O \end{array} \qquad (1)$$

where n is the number of binding sites in the ligand in the given process. Thus the inner-sphere complexes examined are labile and the OSC are formed at very high rates[3,4], the equilibrium constants for the formation of 1 : 1 complexes can be characterised by the following expressions:

$$\omega_{01} = \frac{\{[M(H_2O)_N]\cdot L\}}{\{[M(H_2O)_N]\}\cdot\{L\}}, \qquad (2)$$

$$\beta_{10} = \frac{\{[M(H_2O)_{N-1}\cdot L]\}\cdot\{H_2O\}}{\{[M(H_2O)_N]\}\cdot\{L\}}. \qquad (3)$$

The square brackets define the Werner coordination sphere and the braces denote activity or concentration if the activity coefficients are constant. The subscripts to the constants indicate the number of attached inner- and outer-sphere ligands.

The ratio of the constants represented by Eqns.(2) and (3) characterises the conversion of the OSC into the inner-sphere complex:

$$K_\Pi = \frac{\{[M(H_2O)_{N-1}\cdot L]\}\cdot\{H_2O\}}{\{[M(H_2O)_N]\cdot L\}} = \frac{\beta_{10}}{\omega_{01}}. \qquad (4)$$

In systems with labile complexes it is difficult to separate the effects of the formation of inner- and outer-sphere species for their quantitative assessment. The majority of physicochemical properties or quantities (electrical conductivity, electrode potential, optical density, heat of formation, and others), characteristic of OSC and ISC, are manifested as the general property of the solution. The reactions involving the formation of OSC and ISC under equilibrium conditions are virtually identical with the parallel reactions and any property of the solution is related to the amounts of complexes by the general expression

$$\bar{P} = \sum_{i=0}^{i=n} \alpha_i\, p_i, \qquad (5)$$

where α_i are the fractions of different types of complexes and p_i are the partial values of a certain physicochemical parameter $\bar{P}$ for each type of complex. Since it is impossible to obtain the exact value of p_i either experimentally or theoretically, only an approximate solution of Eqn.(5) and an approximate determination of β_{10} and ω_{01} are possible[1,37,39,40,45,46].

The majority of the formation constants of the complexes determined previously and compiled in the literature[28,29] contain information about the overall stability of two components:

$$K = \frac{\{[M(H_2O)_N]\cdot L\}\cdot(1/\{H_2O\}) + \{[M(H_2O)_{N-1}\cdot L]\}}{\{[M(H_2O)_N]\}\cdot\{L\}} = \beta_{10} + \omega_{01}. \qquad (6)$$

At the present time extensive data have accumulated, which permit a separate estimation of the β_{10} and ω_{01} with a certain degree of approximation.

The spectrophotometric method has been greatly developed for the solution of problems of outer-sphere interactions. Changes in absorption in the visible region in the electronic spectra of d and f metals have been observed in a large number of examples[37,38] for solutions containing inner-sphere forms[31–34]. We may note that the presence of OSC does not affect the intensity and positions of the absorption bands in the visible part of the spectrum, but affects the absorption in the ultraviolet, where intense charge-transfer bands are present[34,35]. In many cases[36–38] it is possible to assign the absorption bands to different types of complexes. The difficulty of the quantitative determination of β_{10} and ω_{01} is associated, as for a number of other methods, with the fact that the partial molar extinction coefficients of the OSC and ISC (ε_{01} and ε_{10}) are unknown. These quantities can be estimated approximately[39,40]. The neglect of one of the forms present in smaller amounts[41–44] yields doubtful results,

because the degree of approximation to the exact stability constants[45,46] is difficult to determine.

The most successful approach probably involves the use of the change in the activity of water in the course of the formation of the ISC [see Eqn.(1)]. Spectrophotometric measurements for aqueous organic solutions make it possible to obtain separately the values of β_{10} and ω_{01}.[45,47] A disadvantage of this method is the necessity to extrapolate the formation "constants", more precisely coefficients, characterising the equilibria in non-aqueous solutions to the conditions in an aqueous solution.

Using a familiar method[48] for the calculation of the stability constants of 1 : 1 complexes in the visible region of the spectrum, where $\varepsilon_{01} = \varepsilon_{00}$, it is possible to obtain the following relation[45]:

$$\frac{d\bar{\varepsilon}}{d[L]} = \frac{1}{\beta_{10}^{org}(\varepsilon_{10} - \varepsilon_{00})}\left(\frac{\varepsilon_{00} - \bar{\varepsilon}}{[L]}\right)^2, \qquad (7)$$

where ε_{10} and ε_{00} are the molar extinction coefficients of the ISC and the free metal respectively.

The values of $\varepsilon_{10} - \varepsilon_{00}$ and ε_{10} can be found from $\beta_{10}^{org}(\varepsilon_{10} - \varepsilon_{00})$ and β_{10}^{org} (obtained for an aqueous–non-aqueous solution) by extrapolating the experimental values to the concentration ranges where absolute non-aqueous and aqueous solutions exist. In this case the errors due to the slight changes in absorption in the region of transitions in the electronic absorption spectrum forbidden by the selection rule are usually added to the inaccuracies associated with the extrapolation.

The method of chemical relaxation developed by Eigen and his coworkers[49-51] theoretically makes it possible to find separately the formation constants of OSC and ISC, provided that there is a significant difference between the kinetics of their formation. For $k_{12} = 10^{10} - 10^{12}$ mol s^{-1} [see Eqn.(1)], the constant k_{23} is frequently in the range 10^3–10^9 s^{-1}. If it is possible to obtain separately the relaxation times corresponding to the formation of the OSC and the ISC, then the problem of the calculation of their formation constants can be solved unambiguously. In practice one usually obtains a single relaxation time corresponding to the slow state of the process, i.e. the formation of the ISC. This relaxation time (τ) depends on both the fast and slow processes:

$$\tau^{-1} = \frac{k_{12}([M] + [L])k_{23} + k_{21}k_{32}}{k_{21} + k_{23}}, \qquad (8)$$

where [M] and [L] are equilibrium concentrations.

Bearing in mind that $k_{21} \gg k_{23}$, we obtain

$$\tau^{-1} = k_{23}\omega_{01}([M] + [L]) + k_{32},$$

where $\omega_{01} = k_{12}/k_{21}$.

Thus the values of $k_{form} = k_{23}\omega_{01}$ and $k_{diss} = k_{32}$, obtained from kinetic experiments, make it possible to determine β_{10}:

$$K = k_{23}\omega_{01}/k_{32} = K_{II}\omega_{01} = (\beta_{10}/\omega_{01})\,\omega_{01} = \beta_{10}.$$

The difficulty consists in the determination of the exact relaxation data under standard conditions. Using this method, Eigen and Tamm[50] calculated the equilibrium constants K_{II} for a series of 3*d* aquo-anions in sulphate solutions.

In some kinetic studies it has been suggested that the amplitude and form of the relaxation curve be used[52,53] to calculate the parameters of the equilibria involving OSC and ISC when these are present jointly. The two methods yield a difference between the stability constants approximately by a factor of two. The experimental accuracy of the kinetic data is still unsatisfactory for the determination of reliable data for the stability of the OSC. More than others, this method can yield an unambiguous solution, provided that the experimental technique is improved and is applied more widely to problems of the OSC.

During recent years, the NMR and EPR methods have contributed greatly to the study of outer-sphere interaction[54-58]. The separation of the effects with their aid as well as other methods is difficult owing to the rapid exchange of the ligands in the inner sphere of labile complexes[59,72]. The difference between the two forms of complexes in solution is limited by the condition $1/\tau = (\sqrt{2})\pi\Delta\nu_0$, where $1/\tau$ is the rate of the exchange reaction and $\Delta\nu_0$ is the difference between the frequencies of maximum absorption for the two forms in the absence of exchange. Thus, when the lifetime of any one form is too short ($< 10^{-3}$ s), i.e. there is rapid exchange, then ν_{10} and ν_{01} cannot be determined separately. This obtains virtually for all labile complexes.

However, the NMR and EPR methods yield very valuable structural data, obtained under the conditions of a slow exchange of atoms containing resonating nuclei or electrons[55,56]. For example, the formation of ISC together with OSC in solutions of certain copper salts has been demonstrated from the change in the *g*-factor[57,58]. OSC in the presence of different anions have been found on the basis of the line width in the hyperfine structure of the EPR spectrum of manganese(II).[60-62]

Comparison of the variations of the signal intensity and the hyperfine splitting line width in the EPR spectra made it possible to find the ratio of the OSC and ISC in solutions of the dithionate[63-65] and perchlorate[66] of manganese(II).

The NMR chemical shifts[67-69], the relaxation times[70], and the paramagnetic shift[71-76] in the resonance of the ^{1}H, ^{19}F, ^{17}O, and (to a lesser extent) heavier nuclei have been used to investigate outer-sphere interactions. In most cases the formation of a mixture of ISC and OSC was noted in solutions of inorganic salts of transition metals (Cu, Mn, Co, Ni), including solutions where complex anions were present: SiF_6^{2-}, GeF_6^{2-}, SnF_6^{2-}, and BF_4^-.[71,74-76] An attempt has been made[71] to calculate β_{10} and ω_{01} for compounds of a series of metals with the above ligands from the changes in the paramagnetic shifts of the ^{19}F signal. However, the assumptions made led to extremely approximate equilibrium constants.

Relatively inert complexes, for example aluminium sulphates[77,78], give rise to resonance absorption bands of the ISC $[Al(H_2O)_5(SO_4)]^+$ and the hexa-aquo-form $[Al(H_2O)_6]^{3+}$, which can be determined separately, but no calculations have been made by the NMR method on the two forms of complexes present jointly in these systems.

The possibility of using the rate of exchange of water in the aquo-ions of metals in the presence of non-aqueous additives has been demonstrated[74-76,79]. In this case differences are observed between the chemical shifts of inner- and outer-sphere water. The development of this method apparently makes it possible to differentiate quantitatively the OSC and ISC in mixed solvents.

The "probe" method has been used[80] to investigate the outer-sphere interaction of labile aquo-ions of the elements in the first transition series. Methylene chloride and carbon tetrachloride have been used as the outer-sphere probes. On the basis of measurements of the longitudinal (T_1) and transverse (T_2) proton relaxations, the formation of a series of OSC $[H_4Mn(H_2O)_6]_nCl_m$, where $n = 2$–4 and $m = 4$–6, in manganese(II) chloride solutions has been demonstrated[81].

In certain favourable cases vibrational spectroscopy has been used successfully as a quantitative and qualitative method for the study of outer-sphere interactions. The characteristic absorption of SCN^-, CN^-, SO_4^{2-}, and PO_3^- ions serves as a source of information about the OSC and ISC in solutions of many metal salts[82-87]. For example, the absorption bands due to the stretching vibrations of the S–O bond in the sulphate ion in the range 850–1400 cm^{-1} make it possible to identify ISC and OSC. It has been possible to demonstrate approximately[82] the presence of 8, 50, and 12% of ISC in

sulphate solutions of nickel(II), indium(III), and cerium(III) salts. Analogous data have been obtained for sulphate solutions of aluminium(III)[83,84] as well as Mn^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+}, Ni^{2+}, and Cd^{2+} in the presence of SCN^-.[85-87]

The difficulties in the quantitative estimation of the ratio of the concentrations of OSC and ISC are due to the lability of the complexes and the necessity for an accurate determination of the absorption intensity in aqueous solutions. Qualitative data have been obtained for solutions of metal perchlorates, nitrates, and sulphates from Raman spectra[88-92].

The potentiometric method has been used recently[93-95] for the simultaneous detection and subsequent calculation of the formation constants of the OSC and ISC in solutions of copper(II) chloride and bromide and manganese(II), cobalt(II), and zinc(II) chlorides. These studies were performed for a variable salt composition, which entailed the variation of the activity of water. The equilibrium constants were determined by extrapolating the concentration "constants" obtained to zero and unit activities of water. The dependence of the composition of the complexes on the activity of water, discussed above [see Eqn.(1)], and not the method of measurement plays the main role in this instance. The disadvantages of the method include the necessity to measure the equilibrium constants under non-equivalent conditions in the ionic medium and inaccurate extrapolation.

The calorimetric method sometimes makes it possible to solve the problem of whether OSC or ISC predominate. Owing to the liberation of water molecules [see Eqn.(1)] from the inner sphere on formation of the OSC, the values of $\Delta H°$ and $\Delta S°$ should be more positive when the inner sphere complex does not form strong covalent bonds. On this basis, the complexes formed in solution can be assigned either to the inner-sphere type (the ΔH and ΔS for the complex formation reactions are more positive than for the reactions involving other ligands) or to the outer-sphere type. This method of identification can be referred to as the thermodynamic criterion. Hypotheses concerning the application of a thermodynamic criterion of the type of complex formation on this basis have been put forward by both Vasil'ev and Yatsimirskii[96-100] and subsequently in Ahrland's papers[9,10].

Comparison of the values of $\Delta H°$ and $\Delta S°$ for labile and inert complexes makes it possible to make a qualitative choice in a number of instances between inner- and outer-sphere compounds[9,10,101-107]. A more reliable application of this principle is hindered by the lack of thermodynamic complex formation data obtained by calorimetric measurements and referred to zero ionic strength.

The inner- and outer-sphere complexes can be identified by measuring the specific volumes or compressibilities of solutions[108]. The sensitivity of solutions to pressure should be greater when ISC predominate[108-111]. This can be explained by the theoretically greater compressibility of ISC solutions compared with OSC solutions, because the degrees of hydration and electrostriction change more on formation of ISC. For example, the changes in the partial molar volumes of solutions for manganese(II) and magnesium(II) sulphates[109] are from −7,4 to −10 ml mol^{-1} and from −9.5 to 6.9 ml mol^{-1} when the concentration is changed from 5×10^{-4} M to 2×10^{-2} M respectively. The different directions of the changes $\overline{\Delta V}$ permit a conclusion concerning the different types of complexes formed.

The proof of the influence of the outer sphere of aquocations on the structure and properties of the solutions has also been obtained from compressibility data[110,111]. On the other hand, dilatometric measurements of the compressibilities of cobalt(III) complexes[111] in solutions containing OSC and ISC do not allow the formulation of a criterion for differentiating between these two types of complexes although the changes $\overline{\Delta V}$ for complexes with similar structures were regular.

An effective although rarely used method for the investigation of OSC in solutions is X-ray diffraction. The results of the determination of the interatomic distances in the OSC $[M(H_2O)_6]^{2+}...Cl^-$, where M = Cd(II), Co(II), or Cu(II), have been published[112]. The M–Cl distance is 4.42 Å. The distances for the ISC are much smaller: 2.27–2.60 Å.[113] The existence of OSC has been established by X-ray diffraction for associated gadolinium chloride species[114] in which the Gd–Cl distances are 4.5–5.0 Å, while in the ISC the Gd–Cl bond length is 2.8 Å.

The above brief survey of experimental methods leads to the conclusion that the study of inner- and outer-sphere complex formation is on the whole developing rapidly and involves the employment of the latest methods. Important structural results have been obtained with the aid of microwave spectroscopy, chemical relaxation, and X-ray diffraction. On the other hand, the study of the equilibria and the thermodynamics of the ISC and OSC in labile systems is advancing slowly. The problem can be probably to a large extent solved by devising apparatus whereby one can measure chemical relaxation with a high accuracy and by developing experimental and computational NMR techniques in combination with the development of the theory of solutions[115-117].

III. OUTER-SPHERE COMPLEXES OF TRANSITION METALS (*d* METALS)

Unambiguous information about the thermodynamics of the structure of OSC has been obtained for systems where outer-sphere association is not complicated by the inner-sphere interaction. Unfortunately such studies have been made only for a small number of OSC and should be extended further.

Data have now been obtained[14] on the association of tris(ethylenediamine)nickel(II) in 3.0 *N* aqueous sodium perchlorate solutions containing also the sodium salt of the ligand (Table 1). It follows from these results that the stability of the OSC decreases in the following sequence of outer-sphere anions: $S_2O_3^{2-} > SO_4^{2-} > CO_3^{2-} > Cl$, which is analogous to the sequence for tris(ethylenediamine)cobalt(III) [4] and many other inert complexes[15,30]. The existence of this sequence has been explained[4] by the changes in the charges and polarisabilities of the anions.

Table 1. The overall association constants of tris(ethylenediamine)nickel(II) with certain anions in 3.0 *N* solutions of sodium perchlorate and the sodium salt of the ligand at 25.0 °C according to solubility data[14] for $[NiEn_3]SO_4$.

Ligand ion	ω_{01}	ω_{02}
Chloride	0.08	—
Sulphate	0.70 (0.66) *	0.20 (0.57) *
Carbonate	0.58	0.06
Thiosulphate	0.92 (0.83) **	0.16 (0.22) **

* The solubilities of $[NiEn_3][PtCl_6]$ are indicated in brackets.

** According to the solubility of $[NiEn_3]S_2O_3$.

The enthalpies (−1.7 kcal g-ion^{-1}) and entropies (−5.7 e.u.) of formation show[14] that the addition of a sulphate ion to tris(ethylenediamine)nickel takes place as a result of the enthalpy component of the free energy. On the other hand,

inert tris(ethylenediamine) complexes combine with sulphate ions as a result of the increase of entropy[4]. The causes of this phenomenon require explanation.

It is of interest to note that tris(ethylenediamine)cadmium(II) forms associated species with sulphate ions having the same equilibrium constant[11] as the species formed by tris(ethylenediamine)nickel(II). This demonstrates the influence of the charge of the complex cation on the association and a very small contribution of other factors. However, tris(ethylenediamine)cobalt(II)[16] has a much smaller capacity for interaction with sulphate ions, which conflicts with the conclusion that the charge exerts the dominant influence. We believe that the properties of the OSC noted here have still been very little investigated and require extensive tests in relation to other examples.

A number of studies[18-22] of the OSC of labile but extremely strong complexes of cobalt(II), the inner sphere of which is saturated by the tridentate tripyrazolylmethane ligands, have been published. The OSC were studied by NMR. Measurements were made of the chemical shifts of the proton or ^{19}F signals for the outer-sphere ligands consisting of different molecules and ions. The outer-sphere ligands were pyridine, aniline (or its substituted derivatives), methanol, acetonitrile, acetone, benzene, hexane, hexafluorophosphorus(V), etc. It was shown that neutral molecules add to the outer sphere along the z axis[18,19], while anions add along the x axis[21]. This difference was explained by the contribution of electrostatic and van der Waals forces to the formation of outer-sphere bonds. The contribution of the latter was confirmed[22] by the increase of the association constants with increase of the dipole moment of the solvent. The results of these studies demonstrated the presence in the outer-sphere of a different configuration which determines the catalytic effect[20].

An analogous study by NMR was carried out[23] for bis(acetylacetone)dipyridinecobalt(II) in cyclohexanone. The stepwise interaction with chloroform and methyl chloride was investigated and it was observed that the outer-sphere association takes place as a result of the decrease of enthalpy accompanied by a sharp diminution of entropy (−20 e.u. in each coordination stage). It was shown that the outer-sphere ligands are coordinated via hydrogen atoms directed towards the inner-sphere ligands in the equatorial plane.

Table 2. The extinction coefficients ($\bar{\varepsilon}$) of copper(II), cobalt(II), and nickel(II) ions in 1 M Li_nL solutions at an ionic strength of 3.0 ($LiClO_4$).

Ligand ion	Cu^{2+} (λ = 800 nm)	Type of complex	Co^{2+} (λ = 510 nm)	Type of complex	Ni^{2+} (λ = 720 nm)	Type of complex
Perchlorate	11.9	OSC	5.5	OSC	2.2	OSC
Sulphate	12.1	OSC	5.6	OSC	2.3	OSC
Fluoride	>12.5	OSC,ISC	5.5	OSC	2.2	OSC
Chloride	22.1	ISC	6.0	OSC	2.2	OSC
Bromide	21.8	ISC	5.9	OSC	2.2	OSC

An extraction study[26] demonstrated the occurrence of successive double addition of chloroform to the outer-sphere of dithiocyanatotetrakis(γ-picoline)cobalt(II) via hydrogen bonds formed between chloroform and the picoline π electrons.

However, in the case of labile ISC systems the greatest amount of data has been obtained for acido-OSC formed by the complexations of transition elements of the first series with F^-, Cl^-, Br^-, SO_4^{2-}, NO_3^-, etc. In these systems both types of complex formation occur simultaneously, inner- and outer-sphere associated species being produced. In such cases the absorption spectrum in the visible region, due to the breakdown of symmetry in the inner sphere, undergoes a change in intensity. Table 2 presents data concerning the variation of the absorption of certain cations under comparable conditions[39,101-103].

Table 3. Thermodynamic data for inner- and outer-sphere complex formation (at 25 °C) involving inert and labile complexes according to the equilibria:

** Determined from the temperature variation of the formation constant.

*** At 40 °C.

The results in Table 2 indicate at least the coexistence of OSC and ISC for the majority of associated copper(II) species and predominantly ISC for cobalt(II) and nickel(II).

The results of the measurements of the heats of formation of these complexes lead to the same conclusion. Table 3 presents the experimental $\Delta H°$ and $\Delta S°$ obtained by different workers together with qualitative estimates of the dominant types of complexes in the reaction mixture. The data for inert complexes, which form only OSC, are included as selection criteria.

The numerical data in Table 3 permit the utilisation of the thermodynamic criterion described above and lead to a conclusion concerning the dominant type of complex formation in systems comprising the labile compounds. The analogy with inert OSC in terms of thermodynamic properties is apparently fully justified, since kinetic properties should not influence the thermodynamics of the compounds. The OSC of inert "hydrophilic" complex cations are characterised by low values of ΔH and as a rule by positive values of ΔS, while the corresponding quantities for the ISC are more positive. Ionic strength has little influence on the ΔH for the complexes but, it apparently should have a significant influence on the entropies of formation of the OSC, since in this case the outer sphere is desolvated[105,106]. On the other hand, careful calorimetric measurements for the OSC formed by inert complexes[15,30,125,126] demonstrated that the entropy is approximately constant at $\Delta S° \cong 15$ e.u. for "hydrophilic" complex cations of any charge and doubly charged anions at zero ionic strength. By analogy, it is sometimes possible to decide which type of OSC predominates in the case of labile aquo-complexes and other "hydrophilic" complexes (Table 3).

In conformity with the thermodynamic criterion, the majority of the results obtained agree with spectroscopic measurements on solutions of salts of 3*d* metals. Unfortunately the amount of calorimetric data on complex formation at zero ionic strength is still inadequate. The development of studies on these lines is essential. On the other hand, one should point out the limitations of the thermodynamic criterion. It is inapplicable to "soft" acceptors and donors and to "hydrophobic" ions {see the OSC of $[CoDipy_3]^{3+}$ and $[CoPhen_3]^{3+}$, Table 3} whose hydration and solvation processes contribute less to the free energy[9,10,15,30].

Aruga[105,106] assigned the monoligand associated cobalt(II) and nickel(II) thiosulphate species in solutions as well as the manganese(II), cobalt(II), nickel(II), copper(II), and zinc(II) nitrate and chlorate species predominantly to the class of outer-sphere complexes in view of the negative values of ΔS at an ionic strength of 1.0. For $\Delta S = -1.2 - -6.8$ e.u., ΔH was $-0.65 - -1.55$ kcal mol^{-1}, which apparently characterises the interaction of ions of class *a*.

Larsson[107] calculated $\Delta S°$ for the dissociation of the OSC of the type MSO_4, where $M^{2+} = Mg^{2+}$, Zn^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, or Ca^{2+}. These functions were found to be in the range between -14.7 and -17.8 e.u. Theoretically the partial molar entropies $\Delta S°$ for the OSC differ from those for the ISC by the entropy of liberation of water (7.3 e.u.). Then judging from the $\Delta S°$, zinc(II) and magnesium(II) sulphates should exist in the form of the OSC, while calcium(II) and cadmium(II) should be predominantly in the form of ISC.[107]

As mentioned above, the stability constants of the ISC and OSC can be determined separately with certain approximations, but in the majority of methods no estimate of the degree of approximation is made. The most reliable results have been so far obtained by relaxation and spectrometric methods, the dependence of the equilibria on the composition of the solvent being used in the latter case. Table 4 gives a systematic list of the results of the determination of the stability constants of the OSC and ISC by different methods in systems comprising labile complexes. Table 4 also includes the results of the determinations of the overall stability constants for systems in which the appearance of both types of compounds has been demonstrated, the type of complex being determined on the basis of the experimental criteria of each method.

Many of the results in Tables 3 and 4 demonstrate unambiguously the dominance of the outer-sphere interaction in aqueous solutions of the salts of many ions of 3*d* elements. Nickel(II), cobalt(II), and copper(II) ions form mainly outer-sphere species of the type $\{[M(H_2O)_6].L\}$, while manganese(II) and iron(III) complexes have a mixed composition. The stability of purely outer-sphere species varies in the majority of systems in accordance with the following series of metals: $Cu^{2+} > Ni^{2+} \geqq Co^{2+} > Mn^{2+} \ll Fe^{3+}$, which constitutes a complete analogy with inner-sphere complex formation and corresponds to the same extent with the energy of stabilisation by the crystal field.

The size of the ligands apparently also plays a definite role in the formation of the ISC. Large polyatomic ions SO_4^{2-}, NO_3^-, ClO_3^-, and SiF_6^- form ISC more rarely than the monatomic ions F^- and Cl^-. The stability series for the OSC with different ligands is as follows:

$$F^- > SO_4^{2-} > ClO_3^- \simeq NO_3^-, \quad Cl^- > Br^-.$$

The ISC and OSC of bivalent manganese, cobalt, nickel, and copper have been studied systematically[71] by NMR on the basis of chemical, paramagnetic, and isotopic shifts, line widths, and spin–spin and hyperfine interaction constants. The ligands were the fluoride and oxide fluoride complexes of a number of metals. These large ions formed mainly OSC. If it is assumed that the assumptions made[67,71] in the calculation of the association constants do not introduce large errors, then the tendency of these ions towards the formation of both ISC and OSC diminishes in the following sequences:

$$MoO_2F_4^{2-} > WO_2F_4^{2-} > TiF_6^{2-} > SnF_6^{2-} > GeF_6^{2-} > SiF_6^{2-} > BF_4^-;$$
$$Fe^{2+} > Mn^{2+} > Co^{2+} > Ni^{2+} > Cu^{2+}.$$

These sequences are determined not only by the charges and dimensions of the ions but also by the nature of the M–F bond and the lability of the hydration shell of the cation.

However, the extremely significant difference between the data for the stabilities of the associated species under consideration is striking. The stability constants of such species are much higher, according to the results of new investigations[71] than those based on the results of earlier studies, although the methods of investigation and conditions were analogous.

It is of interest to note that molybdenyl and tungstyl tetrafluorides interact[71] via the fluoride ions in the *trans*- and *cis*-positions with respect to oxygen, forming equatorial and axial OSC with the cations, the former predominating.

The association of the cation with the perchlorate ions of the supporting salt plays a significant role in outer-sphere complex formation. The dependence of the stability constants on the ionic strength of the solution should be greater than is in reality the case. Nevertheless, despite the competition by the perchlorate ions, the ligand series quoted here confirm the occurrence of a predominantly ionic interaction, as has in fact been suggested for outer-sphere complex formation[7].

A common feature of the OSC is their low thermodynamic stability. When the overall complex formation reactions lead to stable complexes, for example, those of iron(III) with acetate or formate ions, the OSC are not manifested thermodynamically and play only a kinetic role.

Table 4. The stability constants of inner- and outer-sphere 1 : 1 complexes of the aquo-ions of *d* elements with different ligands (at 25.0°).

* Notation: SP = spectrophotometry; KIN = kinetic method; C = calorimetry; S = solubility; P = potentiometry.

It is noteworthy that the thermodynamics of the formation of OSC change fundamentally[15] on passing from "hydrophilic" to "hydrophobic" complex cations. The thermodynamic parameters examined above, which indicate the structure of the associated species, are valid only when the outer-sphere ligands interact with "hydrophilic" complex cations.

Analysis of data on the stability of the OSC of 3d metals shows that the order in which the stabilities vary for a series of metals depends little on the nature of the anion in the outer sphere. This indicates a major role of the central atom in the outer-sphere bond, the latter being subjected to its influence owing to the alteration of the properties of the coordinated inner-sphere ligand.

IV. OUTER-SPHERE COMPLEXES OF NON-TRANSITION (*s*,*p*), LANTHANIDE, AND ACTINIDE ELEMENTS (*f* METALS)

Metals whose valence is determined solely by *s* and *p* electrons exist in aqueous solution as singly- and doubly-charged ions. These are, in particular, alkali and alkaline earth metals. The stability of the hydration shells of these ions is high and increases with decrease of their atomic weight.

Aqueous solutions of the majority of salts of these metals with singly charged anions contain only outer-sphere associated species at concentrations below the total hydration limit. The stability of these species usually increases with decrease of the stability of the solvation shell from lithium to caesium and from beryllium to barium[28,29]. The tendency towards association with hydroxide, fluoride, acetate, and lactate, and similar ions varies in the opposite direction, indicating the dominant influence of the inner sphere interaction.

The 1–2- and 2–2-valent electrolytes based on these metals frequently exist in dilute aqueous solutions in the form of outer-sphere associated species. The contribution of the inner-sphere interactions in such solutions increases sharply, becoming dominant on passing from 1–2- to 2–2-valent electrolytes, on replacement of weakly polarisable anions by highly polarisable anions with a high electron-donating capacity, and with increase of the concentration of the solutions. The validity of the above postulates is confirmed by the satisfactory agreement between the results obtained using different experimental techniques[28,29].

Fairly extensive information about the thermodynamics of associated species formed by complex anions with alkali and alkaline earth metal cations has been examined by Mironov[2,3]. It shows unambiguously that complex anions are in many respects analogous to simple anions as regards their capacity for addition to the outer-spheres of alkali and alkaline earth metal aquo-cations. However, the outer-sphere association of unstable complex anions with cations usually leads to the additional incorporation of simple anionic ligands in the inner sphere of the complex anion as a result of the decrease of the negative charge of the entire associated species owing to the interaction of the complex anions with the alkali or alkaline earth metal cation[2]:

$$K^+ + [PbCl_3(H_2O)]^- \rightarrow K^+ \ldots [PbCl_3(H_2O)]^- \xrightarrow{+Cl^-} K^+ \ldots [PbCl_4]^{2-} + H_2O\,.$$

The interaction of triply and quadruply charged anions with alkali and alkaline earth metal cations is determined by the nature of the anions. In these systems the anions are usually incorporated in the inner coordination sphere, displacing water, and forming mixtures of ISC and OSC only occasionally in a small number of systems[2,3]. Judging from the infrared spectra of solutions, a good example of such OSC[86] is provided by magnesium and calcium compounds with certain doubly, triply, and quadruply charged ligands of the type of $CH_3PO_4^{2-}$, $CH_3P_2O_7^{3-}$, and $AP_3O_{10}^{4-}$, where A is adenosine. It is of interest to note that these ligands also form mainly OSC with doubly charged manganese, cobalt, and nickel ions, but are incorporated in the inner spheres of copper(II) and zinc(II).[86] In our view the validity of these postulates requires confirmation.

On the other hand, the interactions of alkali and alkaline earth cations (as well as cations of *p* and *f* metals even with singly charged anions at fairly high concentrations of aqueous solutions lower the symmetry of complex ligands. Thus Raman spectra demonstrate unambiguously[90] the decrease of the symmetry of the nitrate ion to C_{2v}. This effect weakens in the following sequence of cations:

$$Th^{4+} > In^{3+} > Cu^{2+} > Hg^{2+} > Ce^{3+} > Ca^{2+} > Zn^{2+} > Al^{3+} > Ag^+ > Na^+ \simeq K^+ \simeq NH_4^+\,.$$

It is believed[90] that the decrease of the symmetry is the result of the formation of ion pairs. Raman bands corresponding to the M–O bond have not been observed, but, bearing in mind the low sensitivity of Raman spectra, the presence of covalent bonds cannot be fully ruled out in all the systems investigated. One may assert[135] that only OSC are formed in solutions of alkali metal nitrates, but, judging from a comparison of the Raman and infrared spectra, the nitrate ion is partly incorporated in the inner spheres of zinc(II), copper(II), mercury(II), calcium, indium(III), and cerium(III) cations[136,137].

The decrease of the symmetry of the ligand cannot be always regarded as a criterion of the occurrence of the ISC or OSC interaction, since the tetrahedral structure of the sulphate and perchlorate ions is not distorted[135] by certain cations. In dilute solutions the sulphate ion, for example, does not in fact enter into the inner spheres of many cations, but, with increase of concentration, the main bulk of the OSC are converted into ISC. This has been observed[83] for the sulphate complexes of aluminium and certain other metals[138,139].

It has been shown[140,141] that *s* and *p* metals in perchlorate solutions bind and polarise outer sphere water and induce structure formation in the latter more vigorously than *d* elements, which are more likely to have a structure breaking effect on the outer-sphere water. Consequently the formation of OSC by *s* and *p* metals should be more accurately regarded as substitution or displacement of outer-sphere water molecules. Studies[53,142–144] of the association of beryllium(II) with sulphate ions, which have been discussed in detail[143], are of interest from this point of view. As an illustration, Table 5 presents the thermodynamic functions for the outer-sphere complex $[Be(H_2O)_4].SO_4$ and for its conversion into the inner-sphere complex $[Be(SO_4)(H_2O)_3]$ obtained from measurements of the relaxation time of the pressure jump[144] and by an iterative procedure[52–54,142].

Table 5. Thermodynamic constants for the formation of $[Be(H_2O)_4].SO_4$ and for its conversion into $[Be(SO_4)(H_2O)_3]$ at 25 °C and zero ionic strength of the solution[143].

Complex and equilibrium	ω_{01} ($K_П$)	ΔH°, kcal mol^{-1}	ΔS°, e.u.	ΔV°, cm^3 mol^{-1}
$[Be(H_2O)_4]\cdot SO_4 \rightleftarrows [Be(SO_4)(H_2O)_3]$	100±20 (0.65±0.1)	1.4±0.8 (0.9±0.3)	14.0±0.3(2.2±1.5)	10±3 (3±2)

The data in Table 5 show that OSC predominate in the system of beryllium sulphate complexes, being formed with increase of entropy and molar volume. These OSC consist of $Be(H_2O)_4^{2+}$ tetrahedra and sulphate ions in contact with three water molecules of tetraaquoberyllium[143]. The entropy of formation of OSC by tetrahedral aquo-complexes is the same as that of the formation of "hydrophilic" OSC having an octahedral structure[15,30].

Aluminium and gallium sulphate complexes have been investigated by the analogous method involving the measurement of the pressure jump[145]. The predominance of OSC has been observed to an even greater extent for these compounds in solutions at ionic strengths of 0.1 than for beryllium. Here the equilibrium constant for the transformation of the OSC into the ISC is in the range 10^{-2}–10^{-1}.

Comparison of aluminium(III), gallium(III), and indium(III) monosulphate complexes shows that in this series the contribution of the inner-sphere interaction to the overall complex formation increases from aluminium(III) to indium(III). The considerable contribution or complete dominance of the OSC of metals with singly charged anions in aqueous salt solutions has been pointed out in many studies[134,146–166]. An increase of the degree of formation of OSC is observed with increase of the concentration of the supporting salt. The decrease of the activity of water under these conditions, of the kind which occurs after the introduction of non-aqueous solvents, has a particularly marked influence on the nature of the complexes of the light lanthanides[162]. This is associated with the greater stability of the aquo-complexes of the yttrium group compared with the cerium group[156].

The influence of non-aqueous solvents on the formation of the OSC of the lanthanides is determined mainly by the dielectric constant of the medium, while the formation of ISC is greatly influenced by the electron-donating properties of solvent molecules[163]. However, doubtful claims have been

made[156] that erbium(III) does not form ISC in methanol; certain objections have been made to this claim[165]. There has also been disagreement in the estimates for the formation of OSC by lanthanides, for example as regards the linkage of the perchlorate ion in the inner sphere[162,165] and the purely inner-sphere nature of fluoride and iodate associated species[155]. The cause of the presence of a covalent bond between lanthanide and nitrate ions in aqueous solutions[167] and of the absence of such a bond in tributyl phosphate solutions[147] has not been elucidated.

The attempts to solve the problem concerning the inner- and outer-sphere nature of the complexes of lanthanides with singly charged anions on the basis of the enthalpies and entropies of formation yielded doubtful results. This is because the above functions are small and are usually determined from the temperature variation of the equilibrium constants[28,29]. This can be seen in relation to the complexes with SO_4^{2-} and $Fe(CN)_6^{3-}$; on passing to doubly and triply charged anions, the contribution of lanthanide ISC increases[168-172].

The OSC of the actinide ions have been investigated in less detail than those of lanthanide ions. The chloride, thiocyanate, and polyaminocarboxylate complexes of tervalent actinides have been thoroughly investigated. Inner-sphere polyaminocarboxylate complexes of the actinides are more stable than those of the lanthanides[173-176]. The stability constants of the chloride complexes in 1–4 M solutions in LiCl are almost identical for tervalent actinides and lanthanides with the same ionic radii[150,177]. Only OSC are formed under the conditions indicated[150]. In solutions 10 M in LiCl the actinides (III) form mainly ISC,[178] like the lanthanides, the actinide complexes being more stable than the lanthanide complexes. An analogous situation has been observed[151,174,179-183] also on comparing the stability constants of lanthanide and actinide nitrate and thiocyanate complexes. In view of the similarity of the stability constants, it is possible to determine the type of coordination (in the inner or outer sphere) by analysing the enthalpies and entropies of formation[151,174,180].

Appreciable differences have been observed in the behaviour of the OSC of the actinides relative to the corresponding lanthanide complexes. In aqueous solutions of lanthanide chlorides and perchlorates without added ligands only OSC are formed[184], as in dilute solutions of the nitrates. Judging from the heats of dilution of solutions of these salts, their behaviour is determined by a two-group effect[184], i.e. by the influence of the properties of the cerium and yttrium group. The apparent molal enthalpies of aqueous solutions of these salts increase with increasing radius of the cations (as is shown particularly clearly for the chlorides), which is associated with the presence of hydration shells in the cations. A similar effect has not been observed for the actinide complexes.

Actinide(III) sulphate complexes probably involve the same contribution of the outer-sphere interaction as their lanthanide analogues, i.e. approximately 10%.[169,185] The formation of OSC on interaction of thorium(IV) and neptunium(IV) with sulphate ions[10,186] does not produce a notable effect.

The principal causes responsible for the contributions of different types of forces to the formation of OSC and ISC have been discussed[187]. Analogous but more general attempts had been made also in earlier studies[1-10,188].

V. CERTAIN FEATURES OF THE OUTER-SPHERE INTERACTION OF LABILE OUTER-SPHERE COMPLEXES

The above postulates and certain literature data quoted below make it possible to formulate a number of features of the outer-sphere interaction.

In the majority of systems of labile complexes the coordination "centres" forming the outer (second) coordination sphere are, as for the inert complexes, coordination-saturated cations and to a lesser extent anions. Complex cations with a labile first coordination sphere as well as those with an inert first coordination sphere interact consecutively with the ligands in the second sphere, which are located at definite points in space determined by the inner-sphere ligands. This has been satisfactorily confirmed[18-23,189,190] by the study of inert and, especially, labile OSC in which the strength of the bonds in the second sphere is as a rule much smaller than in the first. The forces of such interaction are predominantly electrostatic: $[ML_6]^{n\pm}...A^{m\pm}$.

At the same time numerous experimental data on the equilibria involving inert and labile[3-5,14,15] compounds, particularly neutral species[16], based on structural data obtained by NMR[18-23,67-80], EPR[27,62-65], and X-ray diffraction[112] as well as the influence of non-aqueous additives[45,47,95,198,199] confirm the important role of the inner-sphere ligand[5,143,199] in outer-sphere interactions. The donor–acceptor interaction of the outer-sphere ligand with the active centres of the inner sphere is outstanding in this respect. This type of interaction includes also hydrogen bonding[138]. The interaction can be represented schematically by $[M(L_6\text{-}l)]...A$, where $(L_6\text{-}l)$ are ligands containing free electron-donating or electron-accepting atoms l.

The coordination number, structure, nature of the bond, and the influence of OSC on the inner sphere are determined by the type of the $l \leftrightharpoons A$ interaction. The concept of the outer-sphere complex becomes much broader in this approach.

The thermodynamic properties of the OSC are determined by the contributions of the electrostatic and donor–acceptor interactions. In many systems the thermodynamic strengths of the binding of the ligands in the first and second coordination spheres are comparable[2]. In such cases it is usually impossible to observe a stepwise outer-sphere interaction. The first ligand, having become attached to the outer-sphere, then passes to the inner sphere. For example, anionic ligands[43-45,127] behave in this way in relation to solvated cations. In the systems indicated the effect of the outer-sphere interaction is manifested most clearly after the addition of the first ligand and then diminishes sharply[82] when the first ligand has been incorporated in the inner sphere.

The features examined above refer to the addition of the first ligand to the outer sphere. As in the stepwise interaction in the second sphere, this ligand adds to energetically favourable positions, determined by geometrical factors, within the complex cation with a saturated inner sphere[18-23]. The systems considered can be divided into three groups: (a) systems in which the formation of OSC greatly predominates; (b) systems with comparable amounts of OSC and ISC; (c) systems in which the formation of ISC greatly predominates. Systems of the first and third types can be studied by the usual methods, neglecting the formation of ISC or OSC. The majority of systems are of this kind.

The principal complications arise in the presence of comparable amounts of OSC and ISC. The formation of OSC and ISC is greatly influenced by the ionic strength of the solution and non-aqueous additives[45,127,189,191]. An increase of ionic strength and of the fraction of the non-aqueous additive reduces the contribution of the OSC and increases that of the ISC. A fairly considerable decrease of ionic strength can lead to the formation of OSC alone, while an increase of the amount of the non-aqueous additive, which lowers the dielectric constant of the medium, can lead to the formation of ISC only. These factors can be used in estimating the contributions of the OSC and ISC in systems where their amounts are comparable.

If the complex formation proceeds via the mechanism initial ions ⇋ OSC ⇋ ISC [see equilibrium (1)], then the overall equilibrium constant K_1 can be formulated thus: $K_1 = \omega_{0,1} + \beta_{10} = \omega_{0,1}(1 + K_\Pi)$.

We shall consider the influence of certain factors on $K_1, \omega_{0,1}$, and K_Π when ionic bonds predominate. For a series of identically charged cations, a number of changes occur when their radii increase[188].

1. The M–L attraction diminishes with increase of the distance between M and L. This effect entails a decrease of $\omega_{0,1}$ and K_Π.

2. The extent of local hydrolysis diminishes owing to the depolarisation of the inner-sphere water, which leads to a decrease of $\omega_{0,1}$.

3. (a) The degree of hydration of the cation diminishes, i.e. there is a partial displacement of water, which facilitates the entry of the anion into the coordination sphere;

(b) the degree of hydration of the cation decreases without the displacement of water from its first coordination sphere, which facilitates the incorporation of L into the first coordination sphere of M. Both these effects increase K_Π.

4. The energy of the stabilisation of the aquo-cation, arising as a result of the polarity of the water in the second sphere, progressively diminishes as L approaches M, which leads to a decrease of $\omega_{0,1}$ and K_Π.

Sometimes when M and L have electrostatic properties similar to those of the dipolar water molecules, the increase of K_Π by the third and fourth factors can be selective in relation to the enhancement of the M–L interaction or the increase of the dipole moment of water.

Using the above factors, it is possible to explain the characteristic features of the changes in many formation constants of OSC and ISC.

In the vast majority of the OSC examined the bond between solvated M and L is predominantly ionic, being complicated by the operation of dispersion and van der Waals forces as well as the contributions of the hydrogen bonds and charge transfer in accordance with the scheme M ← L.[194–197] As a rule the charges (or the charge and the dipole moment of L) as well as the radii of M and L determine the stability of the OSC formed. The contribution of the energy of stabilisation by the crystal field or the covalence of the M–L bond can increase K_Π and the sum $\beta_{10} + \omega_{0,1}$. From these standpoints, it is possible to account for the increase of the stability of the OSC with increasing charges on M and L, but the fraction of the OSC relative to the sum of the complexes then diminishes.

Analysis of the thermodynamics of the formation of the ISC and OSC leads to a thermodynamic criterion, which determines the type of complex predominant in the system. New thermodynamic results require correction for the conditions under which the criterion is applied: it is applicable only to "hydrophilic" cations and partly to "soft" anions, in terms of Pearson's terminology, which form OSC with a predominantly ionic bond.

The available literature data[28,29] for the OSC in systems of labile OSC refer mainly to acceptors M of class *a*, i.e. "hard" ions. For these acceptors, the overall stability of the halide complexes diminishes in the sequence of the anions $F^- \gg Cl^- > Br^- > I^-$. The contribution of the OSC to the overall effect of the interaction usually increases in the opposite sequence (from I^- to F^-), although frequently large, for example, complex anions with identical charges, form compounds with M, in which there is an increased contribution of the OSC.[2,3]

For copper(II) complexes, an increased tendency for ligands to enter the inner sphere compared with nickel(II) and cobalt(II) has been observed[38,45,127,133]. This property can probably be accounted for by the anisotropy[197] of the copper(II) ISC formed due to the Jahn–Teller effect.

Regardless of their composition, structure, and charge, all the "hydrophilic" complex cations form monoligand OSC on interaction with doubly charged anions, for which $\Delta S^\circ \cong 15$ e.u. in solutions at zero ionic strength[15]. This constancy of ΔS°, which so far is not altogether explicable, has been observed mainly for inert complexes and, if it is confirmed for labile systems, the problem of the identification of OSC will be solved.

Data for the variation of the stability of OSC and of their contribution to the overall complex formation effect as a function of the nature of the central ion are contradictory, although a correlation with the number of *d* electrons has been sometimes noted[127,192]. However, it is clear that the series of central ions corresponding to the variation of the stability of OSC and ISC are different[127]. These differences increase with increasing degree of covalence of the M–L bond in the first coordination sphere and with increase of the complexity of the interaction of the inner- and outer-sphere ligands.

Outer-sphere coordination entails a change in the length of the inner-sphere bond[198,199] in consequence of the enhancement of the polarisation of ligands. This induces a far-reaching rearrangement of the inner sphere, which is manifested by the enhancement of the acid properties of the metal aquo-ion[199], a change of the structure of the inner-sphere complex in the melt[200] and in the crystal[201], a change in the stretching vibration frequencies of the bonds[202,203], and ultimately a change in the reactivity of the compound[203]. All these phenomena, which fit within the framework of the fundamental concept of the mutual influence of ligands, have the specific features of an individual property of outer-sphere complexes, and can be referred to as the outer-sphere effect.

However, the insufficiency of data on the thermodynamics, structure, and kinetic properties of the OSC greatly hinders the extension of the generalisations. In order to be able to reach deeper conclusions, a considerable increase of the amount of information in this field is necessary.

Diastereotopy in Transition Metal Complexes

G.B.Shul'pin

Cases of diastereotopy—the stereochemical non-equivalence of atoms or groups within a single molecule—in transition metal complexes are examined. The application of the concept of diastereotopy, introduced into stereochemistry several years ago, makes it possible to interpret correctly complex nuclear magnetic resonance spectra and to reach on their basis conclusions about the fine structure of the molecule. Instances of the diastereotopy of the atoms of coordinated ligands and other groups in π-complexes are classified.
The bibliography includes 63 references.

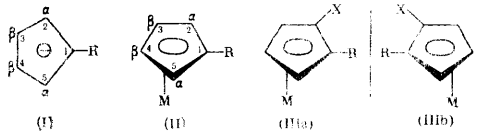
I. INTRODUCTION

In the middle of the 1960's enormous factual NMR data required a detailed analysis of the stereochemistry of molecules containing seemingly equivalent atoms or groups of atoms, which, however, are manifested in the spectra by different signals. Such generalisations were made by Mislow and Raban[1]

It was found that sometimes atoms or groups, which are at first sight identical, are in fact in different steric environments. Structurally identical atoms or groups have been divided into three categories in accordance with the stereochemical characteristics of the environment. Atoms or groups capable of being interchanged by simple rotation of the molecule about an n-fold axis are called equivalent. As an example, one may quote the hydrogen atoms in methyl chloride (rotation about the threefold axis passing through the carbon and chlorine atoms), the geminal hydrogen atoms in ethylene, the methyl groups in acetone (in both cases the atoms or groups are interchangeable on rotation about the twofold axis passing along the double bond). It the atoms or groups are not interchangeable on rotation but each occupies the site of the other on reflection in a mirror plane (in the more general case when they are linked by a rotation-reflection axis S_n), then such atoms are referred to as enantiotopic (by analogy with the relations between molecules linked by mirror symmetry, which are known as enantiomers). An example of enantiotopic atoms is provided by the two protons in bromochloromethane.

Equivalent and enantiotopic atoms and groups are subject to identical magnetic shielding and hence are manifested in NMR spectra by signals having equal, equivalent chemical shifts. One should note that in the majority of molecules two stereochemically equivalent or enantiotopic nuclei respond differently to other nuclei in the molecule as regards spin–spin interaction. Thus the equivalent hydrogen atoms in the molecule of 1,1-difluoroethylene should have spin–spin coupling constants with two fluorine atoms (for each hydrogen nucleus, one of the fluorine nuclei is in the *cis*-position and the other is in the *trans*-position). Such hydrogen nuclei are referred to as magnetically non-equivalent (as regards the spin–spin coupling). Two nuclei with identical chemical shifts are magnetically equivalent as regards spin–spin coupling only when they are disposed symmetrically relative to any "trial" nucleus within the limits of the given group of magnetically interacting nuclei. Magnetically equivalent nuclei should be interchangeable on reflection in a plane perpendicular to the line connecting these nuclei and passing through the "trial" nucleus[2]. In *p*-chloronitrobenzene the stereochemically equivalent *ortho*-protons have the same chemical shift. However, two such protons interact differently with one of the *meta*-protons and are therefore non-equivalent as regards spin–spin coupling. The four protons of *p*-chloronitrobenzene form the AA'XX' system.

Cases are possible in which structurally identical atoms or groups within the limits of a single molecule are in diastereoisomeric environments and cannot change places whatever the symmetry operation. Such atoms or groups have been called diastereotopic (by analogy with diastereoisomeric relations between molecules). The hydrogen atoms of the methylene groups of chlorocyclobutane (two pairs of diastereotopic atoms) and of bromodichloroethane $ClCH_2$–$CHClBr$ are diastereotopic; in the second molecule the methylene group is linked to an asymmetric tetrahedral carbon atom. However, it must be emphasised that the presence of a chiral centre in the molecule is not an obligatory condition for the occurrence of diastereotopy. Thus the chlorocyclobutane molecule is achiral†. Another important example is the diastereotopy of the geminal protons in achiral monosubstituted ethylene. Since the diastereotopic atoms are in somewhat different steric environments, their magnetic shielding should differ (for example, the hydrogen atoms in the chlorocyclobutane molecule in the *trans*-position with respect to chlorine are influenced by the halogen atom less than the *cis*-atoms) and in the general case diastereotopic atoms should be manifested in the NMR spectra in the form of signals with different chemical shifts (it is said that such atoms are anisochronous). Naturally the resolving power of a specific NMR apparatus can be insufficient to detect different signals for diastereotopic nuclei: diastereotopic nuclei remain isochronous.

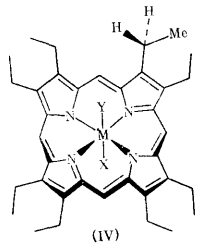


The groups $-CH_2R(R \neq H)$ and $-C(CH_3)_2R(R \neq CH_3)$ proved to be convenient and fairly sensitive indicators reflecting the stereochemistry of the molecule. In most cases these groups are enantiotopic and hence isochronous. When a

† The molecule is called chiral, if it cannot be made to coincide with its image in a planar mirror[3].

chiral centre is introduced into the molecule the H atoms or CH_3 group become diastereotopic, which is reflected in the splitting of the corresponding signals in the NMR spectra. We may note that the carbon atoms linked to H or CH_3 in these groups are prochiral centres, since the replacement of one of the hydrogen atoms or one of the methyl groups by some other atom or group makes the carbon atoms chiral.

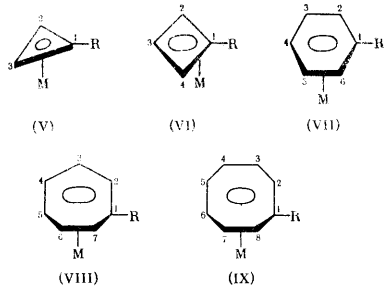
Potentially diastereotopic organometallic groups have been recently attracting increasing attention. In the monosubstituted cyclopentadienyl anion (I) the α-atoms (as well as β-atoms) of carbon and hydrogen are stereochemically equivalent, since they are linked by a twofold axis of rotation passing through the substituent and the nodal $C_{(1)}$ atom. The coordination of the cyclopentadienyl anion to a metal atom as in formula (II) makes the two sides ("above" and "below") of the plane of the cyclic ligand non-equivalent and the atoms in the α-position with respect to the substituent become enantiotopic, because they can be interchanged only on reflection in the mirror plane passing through the substituent, the $C_{(1)}$ atoms linked to it, and the metal atom; the same applies also to the β-atoms. At the same time the protons in the 2- and 5- (or 3- and 4-) positions in a monosubstituted cyclopentadienyl anion (stereochemically equivalent) and ferrocene (enantiotopic) are magnetically non-equivalent as regards spin–spin coupling. Indeed the 2- and 5-nuclei are disposed asymmetrically relative to the 3-nucleus and interact with the latter in different ways. The system of four magnetically interacting protons in a monosubstituted metallocene can be described as AA'BB'.



We may note that the replacement of one of the hydrogen atoms of the substituted cyclopentadienyl (CPD) by a group X gives rise to chirality in the molecule, the so called planar chirality. Two enantiomers (IIIa) and (IIIb) are therefore possible:

(I) (II) (IIIa) (IIIb)

Thus the monosubstituted CPD ligand coordinated to a metal atom is a group with enantiotopic carbon and hydrogen atoms within the 2/5 and 3/4 pairs; under certain conditions, these atoms can be converted into diastereotopic atoms. The present review is devoted to the discussion of various cases of the diastereotopy of atoms in this and similar indicator groups.



The study of the diastereotopy of atoms and groups is important for several reasons. Such analysis permits an exact interpretation of the NMR spectra of the compounds synthesised and is therefore essential for the determination of their structures. Enantiotopic and diastereotopic relations between atoms within a single molecule are linked directly to the stereochemical (enantiomeric and diastereoisomeric) relations between molecules. For example, the diastereotopy of indicator groups makes it possible to establish in many instances the presence of chirality in the molecule (either its appearance or disappearance). Thus the appearance of diastereotopy in the $-Sn(CH_3)_2R$ indicator group when the migration of this fragment in the cyclopentadiene ring is retarded, has been used to determine the energetics of the metallotropic process[4]. The observation of diastereotopy makes it possible to establish the fine features of the molecular structure. Thus the diastereotopy of the protons of the methylene groups in derivatives of metal octaethylporphyrinates (IV)[5] indicates either the coordination of two different ligands X and Y to the metal atom or the displacement of the metal atom from the plane of the porphyrin ring.

(IV)

In both cases the diastereotopy is due to the non-equivalence of the two sides of the porphyrin ring arising under these conditions (consequently the difference between the chemical shifts is not related to the hindered rotation of the ethyl groups). Finally, diastereotopic atoms have somewhat different reactivities, which must be taken into account, in particular, in the study of reaction mechanisms. Analysis of the stereochemical relations of the atoms and groups within the limits of a single molecule makes it possible to predict the direction of the reaction. It is not therefore surprising that such analysis is beginning to be formulated as a special branch of stereochemistry. We may note several reviews devoted to the theory of diastereotopy[1,2,8] (see also Sokolov[6] and Shul'pin[7]). The diastereotopy of the nuclei in transition metal complexes has not been considered in special reviews.

A coordinated monosubstituted CPD ligand is one of the most convenient organometallic indicator groups which have been investigated in comparative detail. However, the coordination of other cyclic ligands to transition metal atoms should also lead to the appearance of the enantiotopy of the atoms in these ligands and under certain conditions should also lead to diastereotopy. In a coordinated cyclopropenylium cation (V) this refers to the 2/3 pair of atoms. In the cyclobutadiene ligand (VI) and 2/4 nuclei are enantiotopic (and can become diastereotopic). In the coordinated substituted benzene (VII) there are two pairs of enantiotopic atoms (2/6 and 3.5), as in CPD. In the cycloheptatrienyl ligand (VIII) there are three such pairs: 2/7, 3/6, and 4.5. In the cyclooctatetraenyl groups (IX) there are also three such pairs: 2/8, 3/7, and 4/6. The observation of the diastereotopy of the nuclei in some of these systems is a task for the future.

(V) (VI) (VII)

(VIII) (IX)

As already pointed out, the diastereotopy of atoms is not always manifested in NMR spectra, i.e. such atoms are not necessarily anisochronous. Whether or not diastereotopy is detected in the spectra depends on many factors. The account below will make it clear that the diastereotopy of a coordinated substituted CPD ligand has been observed much more frequently in ^{13}C NMR spectra than in proton resonance spectra. It is therefore understandable why the phenomenon of the diastereotopy in metallocenes has attracted the attention of investigators only recently when ^{13}C NMR has begun to be used widely. The manifestation of diastereotopy in the spectra is influenced greatly by the solvent. The overall signal of the diastereotopic atoms is sometimes split on

passing to a more polar solvent. We may note that in the general case enantiotopic atoms can become anisochronous in an enantiomeric solvent[1].

Certain cases of the diastereotopy of the atoms in a substituted coordinated cyclopentadienyl group and other cyclic ligands, caused by the stereochemical features of the metallocene molecules, are examined below. The diastereotopy of other indicator groups, indiced by the chirality of the metallocenyl fragment linked to them and the chemical non-equivalence of the diastereotopic nuclei in ferrocene derivatives, are discussed in the last sections of the review.

II. DIASTEREOTOPY IN CYCLIC LIGANDS LINKED TO AN ASYMMETRIC ATOM

1. The Classical Asymmetric Carbon Atom

The ^{1}H NMR spectrum of a coordinated monosubstituted CPD ligand depends greatly on the electron-donating or electron-accepting capacity of the substituent. In the spectra of monosubstituted ferrocenes and other metallocenes with electron-accepting substituents (for example, with the acetyl group) the protons of the substituted ring are manifested by two pseudotriplets in the range $\delta = 4-5$ p.p.m. relative to tetramethylsilane (TMS). The unsubstituted ring gives rise to a singlet with a chemical shift of ~4 p.p.m. In the spectra of alkyl derivatives of metallocenes the protons of the substituted ring usually give rise to a narrow multiplet and are frequently manifested actually in the form of a singlet signal. Thus the ^{1}H NMR spectrum of 1,1'-di-(2-cyanoethyl)ferrocene has a single fairly narrow unresolved multiplet centred at 4.09 p.p.m. In the calculated spectrum the chemical shift of the α-protons is assumed equal to -1.1 Hz and that of the β-protons is assumed to be +1.1 Hz from the centre of the multiplet (in $CHCl_3$ at a frequency of 90 MHz).[9] It is not therefore surprising that for a long time it was impossible to observe the effect of the stereochemistry of the substituent in the ^{1}H NMR spectra of metallocenes.

Table 1. The chemical shifts of the protons of the substituted CPD ring in the ^{1}H NMR spectra of cymantrenes containing an asymmetric carbon atom in the substituent [in $CHCl_3$, δ(p.p.m.) relative to TMS].[11,12]

The stereochemical non-equivalence of the α-protons of the CPD ring was first observed in 1971 in the ^{1}H NMR spectra of 1,1,1-trifluoro-2-hydroxyethylcymantrene[10]. The α-protons were manifested in the spectrum in the form of two signals (Table 1). The splitting of the signals of both α- and β-protons was observed in the spectra of cymantrenes containing some cumbersome asymmetric substituents with a phosphorus atom[11]. On the other hand, the influence of the asymmetry of a substituent such as the α-hydroxyethyl group was insufficient to split the signals even in the case of α-protons.

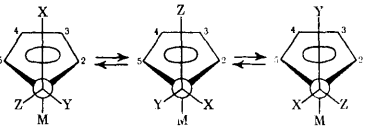

Figure 1. Certain conformations of a metallocene containing a substituent with an asymmetric carbon atom: M = $Mn(CO)_3$, FeC_5H_5, etc.

Fig.1 shows that, in the presence of the classical asymmetric carbon atom, linked directly to the CPD ligand of the metallocene, the 2- and 5-atoms (or 3- and 4-atoms) are subjected to different shielding in any possible conformation. The presence of the asymmetric centre leads to the appearance of two enantiomers. However, the spectra of the two enantiomers are identical. The 2-nucleus in the molecule of one of the enantiomers has the same shielding as the nucleus designated by the same number in the molecule in the second enantiomer (Fig.2). This also applies to the remaining nuclei in these molecules.

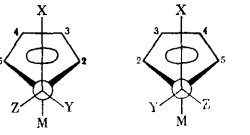

Figure 2. Enantiomers of a metallocene with an assymetric carbon atom.

Whereas the diastereotopy of the 2/5 and 3/4 nuclei of the CPD ring has been observed in the ^{1}H NMR spectra only for certain cymantrenes containing an asymmetric carbon atom in the substituent, following the introduction of ^{13}C NMR it was possible to distinguish the diastereotopic nuclei in the ferrocene analogue, ruthenocene, and other metallocene derivatives as well as derivatives of benzenechromium tricarbonyl and cyclobutadieneiron tricarbonyl. The splitting of the 2/5 and 3/4 signals was first observed in the spectra of α-hydroxyethyl- and α-hydroxybenzylferrocenes[13], although it was not explained #. Fairly numerous examples of the diastereotopy of the nuclei of a monosubstituted CPD ligand, with an asymmetric carbon, in different transition metal complexes have been found in recent years, (Table 2).

Bridged metallocenes constitute a special case[25], because the substitution of one hydrogen atom in the bridge of such compounds can lead to the appearance of an asymmetric carbon atom, which induces in its turn the diastereotopy of the

See also the study of Sokolov et al.[53], which is discussed in Section V.

nuclei of two ligands at once. It a ferrocenophane drivative[3] (X) one of the CPD rings (*A*) adjoins directly an asymmetric carbon atom, while the *B* ring is separated from it by a chain of two carbon atoms. The signals of the 2/5 and 3/4 atoms of both rings were found to be split in the ^{13}C NMR spectrum of this compound[19] (seven peaks: 67.2, 71.1, 71.8, 68.6, 69.5, 68.0, and 72.2 p.p.m.). In the molecule of the isomeric ferrocenophane (XI) the asymmetric carbon atom is separated by equal distances from the ligands. In the carbon resonance spectrum of compound (XI) the 2-, 3-, 4-, and 5-atoms of the CPD rings give rise to eight signals (*A* ring: 69.6, 70.1, 68.0, and 72.0 p.p.m.; *B* ring: 73.2, 72.0, 72.4, and 66.4 p.p.m.). It is of interest that in compounds (X) and (XI) the protons in the two rings are also spectroscopically distinguishable. In the ^{1}H NMR spectrum of compound (X) the protons of the *A* ring give signals at $\delta = 4.64$, 4.05, 3.94, 4.46 p.p.m. The *B* ring also gives rise to four signals: 4.87, 4.33, 4.29, and 4.70 p.p.m. The spectrum of compound (XI) consists of eight signals (*A* ring: 4.68, 4.07, 3.90, and 4.39 p.p. m.; *B* ring: 5.02, 4.36, 4.28, and 4.61 p.p.m.). In the ^{13}C NMR spectrum of the bridged cyclopentadienyl derivative of titanium (XII) the 2-, 3-, 4-, and 5-carbon atoms in the two rings give seven signals: 115.4, 116.8, 121.3, 121.6, 123.5, 123.7, and 123.9 p.p.m. [19]

*The $C_{(2,3,4,5)}$ signals of both CPD ligands.

The diastereotopy of the 2/6 and 3/5 nuclei was observed in the ^{13}C NMR spectra of benzenechromium tricarbonyl derivatives [VII, $M = Cr(CO)_3$] containing an asymmetric carbon atom in the substituent. Thus, for $R = CH(OH)C_6H_5$, the unsubstituted carbon atoms of the benzene ring give rise to four signals: 90.1, 91.7, 91.9, and 92.1 p.p.m. The diastereotopy of both pairs is reflected in the spectrum of the analogous derivative with $R = C(OH)(CH_3)C_6H_5$: $\delta = 90.0$, 90.6, 92.8, 93.1, and 94.1 p.p.m.[26] The splitting of the signal due to the 2/4 nuclei was also discovered in the ^{13}C NMR spectra of carbinols of the cyclobutadieneiron tricarbonyl series [VI, $M = Fe(CO)_3$]: $\delta = 62.6$ and 62.7 p.p.m. for $R = CH(OH)CH_3$ and $\delta = 63.4$ and 63.6 p.p.m. for $R = CH.(OH)C_6H_5$.[27]

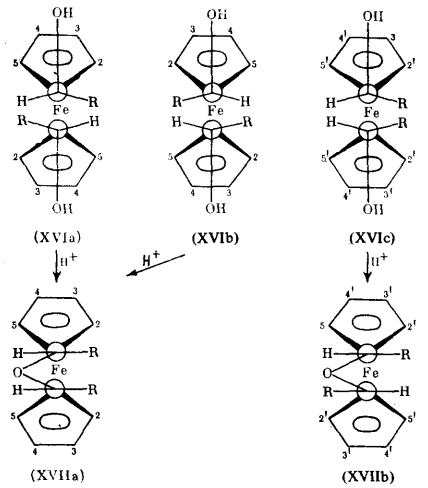
The splitting of the signal of the 2/5 and 3/4 carbon atoms in the cyclopentadienyl complexes containing a substituent with an asymmetric carbon atom in the ring was used to determine the nature of the bond in the cyclopentadienyl complexes of thallium[15].

2. The Asymmetric Transiton Metal Atom

The diastereotopy of the atoms in a substituted cyclic π-ligand arises also when the chiral centre of the molecule consists of the transition metal atom itself. In compound [XIII, M = Ti, $R = CH_3$, $X = OC_6H_3(CH_3)_2$-*o*,*o*] the titanium atom is linked to four different substituents. Four signals due to the 2-, 3-, 4-, and 5-atoms of the substituted CPD ring were found in the ^{13}C NMR spectrum of this complex with the chemical shifts $\delta = 109.6$, 115.6, 121.1, and 121.8 p.p.m.[19]

Cymantrene gives rise to extensive possibilities in this sense. The diastereotopy of the 2/5 and 3/4 nuclei was observed for two types of complexes. The first type (XIV) is formed when one of the CO ligands in the monosubstituted cymantrene is replaced by NO and the other arises when it is substituted by an *n*-donor (phosphine, arsine). In this case the complex has a positive charge. The second type of compound with a chiral manganese atom (XV) has been obtained on replacement of two carbonyl ligands by different *n*-donors (phosphine and phosphite). The NMR data for complexes of both types are listed in Table 3. It is of interest that the slight difference between triethyl phosphite and trimethyl phosphite is not reflected in the spectrum—diastereotopy is not manifested for these ligands.

3. The Asymmetric Carbon Atoms



Numerous ferrocene derivatives containing two identical asymmetric carbon atoms in two different rings are known. Such compounds are usually obtained on reduction of heteroannular diacylferrocenes. The presence of two asymmetric centres leads to the appearance of two diasteroisomers. For identical centres, these consist of a pair of enantiomers [for example, (XVI, a and b)] and the *meso*-form (XVIc). Naturally the diasteroisomers should give rise to different NMR spectra and in the spectrum of each diastereoisomer one should be able to observe the diastereotopy of the 2/5 and 3/4 nuclei of each CPD ring.

In the ^{13}C NMR spectrum of a mixture of diastereoisomers of 1,1'-di-(1-hydroxyethyl)ferrocene (XVI, *a,b*, and *c*, R = CH_3) (in CH_2Cl_2) nine signals were found in the range δ = 60–70 p.p.m.[30]: 65.2, 65.5, 65.7, 66.1, 66.3, 66.7, 67.5, and 67.7 (with a double intensity), and 68.0 p.p.m. Two of these peaks correspond to the carbon atoms linked to the hydroxy-group and the remaining seven signals indicate the non-equivalence of the 2/5, 3/4, 2'/5', and 3'/4' atoms (two signals are accidentally superimposed). The signals with δ = 25.3 and 26.0 p.p.m. correspond to the methyl groups of different diastereoisomers. In the spectrum of the mixture of the diastereoisomers of 1,1'-di-(1-hydroxybenzyl)ferrocene (XVI, a, b, and c; R = C_6H_5) (in CH_2Cl_2) ten signals were found[30] for the 2/5, 3/4, and 2'/5', 3'/4', and C–OH atoms: 66.3, 66.7, 66.9, 67.3, 68.0, 68.2, 68.4, 68.5, 71.9, and 72.8 p.p.m. The signals with δ = 94.0 and 94.5 p.p.m. refer to the 1- and 1'-atoms of the two diastereoisomers [in the spectrum of (XVI, a, b, and c; R = CH_3) the key 1- and 1'-atoms give rise to a single peak at 95.3 p.p.m.].

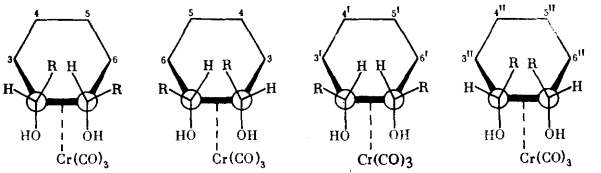
		$P(OCH_3)_3$	$P(OC_6H_5)_3$	4.93	4.41	—	—	29

On treatment with acid, the isomers are converted stereoselectively into oxygen-containing ferrocenophanes[31]: the racemate of the enantiomers (XVI, a and b) gives rise to the *cis*-isomer (XVIIa) and the *meso*-form (XVIc) is converted into the *trans*-isomer (XVIIc). Eight signals, two of which are due to the C–OH atoms and the remainder are associated with the 2-, 3-, 4-, 5-, 2'-, 3'-, 4'-, and 5'-carbon atoms in the ring, were observed in the spectrum of ferrocenophane (XVII) obtained from (XVI, R = CH): δ (in CH_2Cl_2) = 62.6, 65.3, 67.5, 68.3, 69.4, 70.2, 71.4, and 72.1 p.p.m.[30] Presumably only the signals of the 2/5 and 2'/5' pairs are split. In addition, two signals for each of the 1- and 1'-atoms (89.2 and 90.9 p.p.m.) and for the methyl groups (19.3 and 22.3 p.p.m.) were found in the spectrum.

Only two signals due to the peak $C_{(1)}$ atoms, corresponding to two different types of ferrocene fragments (mono- and di-substituted ferrocene rings), were found in the ^{13}C NMR spectrum of 1,1'-di-[2-ferrocenyl-4-methoxycarbonyl)butyl]-ferrocene containing two identical asymmetric centres §. In the region of the signals due to the 2-, 3-, 4-, and 5-nuclei six peaks were observed, which indicates the diastereotopic anisochronicity of only the 2/5 atoms in each type of ferrocene fragment[32].

Two asymmetric carbons can be linked to the same π-ligand. In this case three isomers are possible for compounds with two identical asymmetric centres: the racemate of the two enantiomers (XVIII, a and b) and the two *meso*-forms (XVIIIc) and (XVIIId).

In the benzenechromium tricarbonyl compounds (XVIIIc) and (XVIIId) there is a plane of symmetry, by virtue of which the atoms within the 3'/6' and 4'/5' pairs in the first compound and the 3''/6'' and 4''/5'' pairs in the second are enantiotopic. Indeed, two overall signals were observed in the ^{13}C NMR spectrum of each compound for these atoms: 90.2 and 93.3 p.p.m. in the spectrum of (XVIIIc) and 91.5 and 93.5 p.p.m. in the spectrum of (XVIIId). The carbon atoms linked to the substituents in the two compounds are isochronous [118.2 p.p.m. for (XVIIIc) and 114.4 p.p.m. for (XVIIId)].



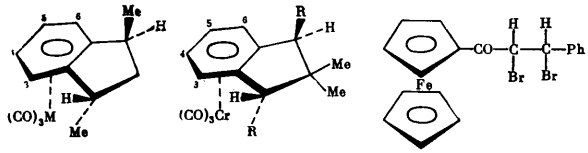


Table 4. ^1H NMR spectra of arenechromium tricarbonyl and arenemolybdenum tricarbonyl derivatives [δ (p.p.m.) relative to TMS].[33]

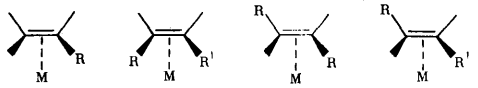
Compound	H(3)	H(4)	H(5)	H(6)
(XIX), M=Cr	5.12	5.36	5.00	5.43
(XIX), M=Mo	5.52	5.66	5.35	5.73
(XX), R=$OCOCH_3$	5.36	5.36	5.20	5.50

In either of the two enantiomers (XVIIIa) and (XVIIIb) the 3/6 and 4/5 atoms are diastereotopic, which is manifested in the carbon resonance spectra (89.7, 92.6, 92.5, and 94.5 p.p.m.) and in ^1H NMR (5.78, 5.56, 5.51, and 5.76 p.p.m.). The atoms of the benzene ring carrying substituents are also anisochronous (113.1 and 120.1 p.p.m.).[26] The non-equivalence of the 3/6 and 4/5 atoms was observed as early as 1969 in the ^1H NMR spectra of compounds (XIX) and (XX), which exist in the form of two enantiomers[33]. The chemical shifts are listed in Table 4.

§ The stereochemistry of ferrocene derivatives containing two identical or different asymmetric centres has been discussed[63].

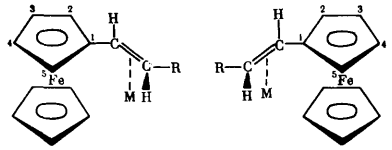
Two signals of the 2/5 protons were observed in the ^1H NMR spectrum of the substituted ferrocene (XXI) ($\delta = 4.90$ and 4.66 p.p.m.).[34] However, one should note that the splitting of the signal of the α-protons can be induced both by the diastereotopy of the 2/5 atoms and by the non-equivalence of the α-protons in the two diastereoisomers of compound (XXI) containing two asymmetric carbon atoms in the side chain.



(XIX) (XX) (XXI)

III. DIASTEREOTOPY INDUCED BY PLANAR CHIRALITY

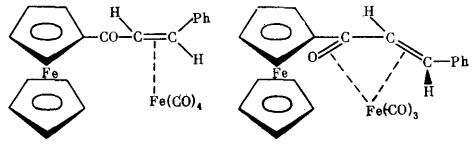
The coordination of a planar cyclic (cyclopentadienyl, benzene) or non-cyclic (monoolefin, diene) π-ligand to a transition metal atom makes the hitherto equivalent sides of the ligand non-equivalent. If two different substituents are linked to a cyclic ligand, then, after coordination, there is a possibility of two different dispositions of these substituents [see structures (IIIa) and (IIIb)] and two enantiomers appear. Such planar chirality (induced by the non-equivalence of the sides of planar ligands) is most typical for organometallic complexes of transition metals, although one can imagine cyclophane, triquinacene, and corannulene molecules containing two different substituents in the ring and exhibiting planar chirality. Chiral cyclophanes have been obtained in an optically active form.



One of the important instances of the manifestation of planar chirality is the existence of the enantiomers of mono-olefins coordinated to organometallic groups. The enantiomers can be obtained for a monosubstituted olefin (XXII), a disubstituted olefin with different substituents in the *cis*-positions (XXIII) and also with identical [compound (XXIV)] or different [compound XXV] substituents in the *trans*-positions.

(XXII) (XXIII) (XXIV) (XXV)

1. Planar Chirality of the Substituent

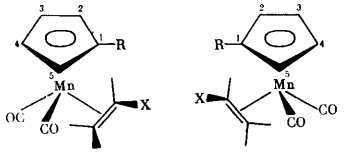


When rotation about the C^1–CH= bonds is possible in the vinylferrocene molecule, the 2/5 and 3/4 atoms of the CPD ligand are enantiotopic. The coordination of the double bond to the organometallic group leads to diastereotopy of these nuclei. In the resulting enantiomers (XXVIa) and (XXVIb) the nuclei having identical environments are designated by identical numbers ¶.

(XXVIa) (XXVIb)

¶ The molecules of the enantiomers (XXVIa) and (XXVIb) have a planar chiral fragment (a double bond coordinated to the metal atom) and a planar prochiral fragment FeC_5H_4X.

The diastereotopy of the 2/5 and 3/4 nuclei of the CPD ligand, induced by the presence of a chiral fragment in the substituent—a coordinated double bond—was observed for the complexes of certain vinylferrocenes with iron tetracarbonyl and iron tricarbonyl groups and also with the cyclopentadienylmanganese dicarbonyl group (Table 5).[35-37] Two features may be noted. Diastereotopy was not manifested in the ^{13}C NMR spectrum of the complex of cinnamoylferrocene with the iron tetracarbonyl group (XXVII) using CH_2Cl_2 as the solvent. In the more polar solvents acetone and nitromethane it was possible to observe the splitting of the signals due to the 2/5 and 3/4 nuclei. In the ^1H NMR spectra the anisochronicity of the nuclei of the CPD ring of ferrocene was not observed with the exception of the complex of cinnamoylferrocene with iron tricarbonyl (XXVIII). In this case the presence of a very cumbersome chiral group led to the splitting of the H 2/5 signal (4.64 and 4.99 p.p.m. in $CHCl_3$).



(XXVII) (XXVIII)

Table 5. Chemical shifts in the ^{13}C NMR spectra of certain derivatives of vinylferrocenes [δ(p.p.m.) relative to TMS].

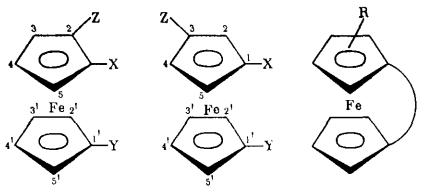
(XXVII)	$Fe(CO)_4$	—	$(CH_3)_2CO$	69.1; 71.2	72.6; 72.9	35,36
(XXVII)	$Fe(CO)_4$	—	CH_3NO_2	69.8; 71.8	73.2; 73.6	35,36
(XXVIII)	—	—	CH_2Cl_2	67.8; 71.2	71.5; 72.8	35,36
(XXVI)	$Mn(CO)_2C_5H_5$	H	CH_2Cl_2	67.4; 68.1	68.6	37
(XXVI)	$Mn(CO)_2C_5H_5$	COC_6H_5	CH_2Cl_2	62.4; 68.1	68.6	37



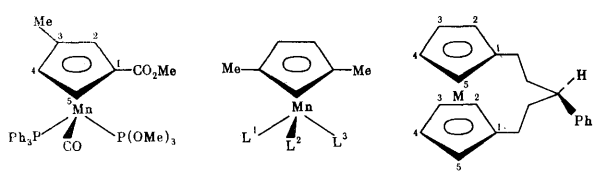
The diastereotopy of the 2/5 and 3/4 nuclei of the monosubstituted CPD ring can be expected in the NMR spectra of the complex of cyclopentadienylmanganese dicarbonyl with a monosubstituted olefin. In this case there is a possibility of two enantiomers (XXIXa) and (XXIXb).

(XXIXa) (XXIXb)

2. The Planar Chirality of the Metallocene Molecule

In chiral trisubstituted ferrocenes (XXX, a and b; $X \neq Y \neq Z \neq H$ or $X = Y \neq Z \neq H$) the 2'/5' and 3'/4' atoms of the monosubstituted ring are diastereotopic. The possibility of the anisochronicity of these nuclei is most evident in the case of monosubstituted ferrocenophanes (XXXI, R = acetyl, for example).

(XXXa) (XXXb) (XXXI)



Indeed it is seen from literature data[38-40] that the α-protons (as well as the β-protons) of the monosubstituted ring in the spectra of compounds (XXXI) in general give rise to different signals. It is more difficult to observe the anisochronicity of the protons of the monosubstituted ring in the spectra of non-bridged derivatives (XXX). However, on comparing the results of a whole series of investigations[41-45], one may conclude that the appearance of a multiplet structure in the signal of the monosubstituted ring protons (a CPD ring linked to a single alkyl substituent usually gives rise to a narrow singlet) is associated precisely with the diastereotopy of the 2′/5′ and 3′/4′ protons. It is of interest that the anisochronicity of the monosubstituted ring protons is more distinct when two different substituents in the second ring occupy the 1- and 3-positions. Thus, whereas in the spectra of compounds (XXXa, $X = Y = C_2H_5$, $Z = CH_2^+$ [43] or $X = Y = CH_2C_6H_5$, $Z = COCH_3$ or COC_6H_5) [45] the signal due to the protons in the ring with the substituent Y consists of a narrow singlet, in the spectra of the corresponding derivatives (XXXb) the monosubstituted ring is manifested by a fairly broad multiplet.

The splitting of the signal due to the 2′/5′ and 3′/4′ nuclei in the ^{13}C NMR spectra has been observed for compounds [XXXb, $X = Y = CH_3$, $Z = C(OH)(CH_3)_2$ [18] and $X = Y = CH_2C_6H_5$, $Z = COC_6H_5$ [45]]. As in the case of proton resonance, the signals of the 2′/5′ and 3′/4′ atoms in the ^{13}C NMR spectrum of the 1,2-isomer of (XXXa, $X = Y = CH_2C_6H_5$, $Z = COC_6H_5$) are not split[45].

3. Combination of an Asymmetric Atom and Planar Chirality

The presence in one ring of a metallocene molecule of two different substituents, one of which contains a chiral centre, leads to the appearance of two diastereoisomers [a more complex case, involving two chiral substituents in a single ring, was analysed above in relation to compound (XVIII)]. Such diastereoisomers of the 1,2-isomers of [XXXa, $X = Y = CH_3$, $Z = CH(OH)CH_3$ [46-48] or $X = Y = CH_2C_6H_5$, $Z = CH(OH)CH_3$ [45]] can be separated chromatographically. They give rise to readily distinguishable ^1H NMR spectra. It is of interest that in the case of compounds [XXXa, $X = Y = CH_2C_6H_5$, $Z = CH(OH)CH_3$] the diastereotopy of the protons in the methylene group is observed for only one isomer[45].

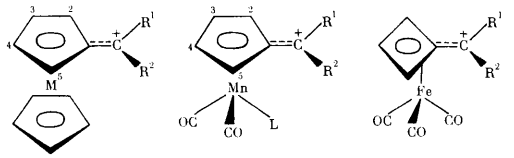
An example of the combination in one molecule of planar chirality and a chiral transition metal atom is known. Since the manganese derivative (XXXII) exists in the form of two diastereoisomers, the ^1H NMR spectrum of their mixture was found to contain four signals associated with the 2/5 atoms and two signals associated with the 4-atom[29].

(XXXII) (XXXIII) (XXXIV)

The two methyl groups in the CPD ring of the complex with a chiral manganese atom are diastereotopic. They give rise to two signals in the proton resonance spectra ($\delta = 1.86$ and 1.93 p.p.m.) for compound [XXXIII, $L^1 = P(OMe)_3$, $L^2 = PPh_3$, $L^3 = CO$]. [29] If the methyl groups are in the 1- and 3-positions, then the hydrogen and carbon atoms in the 4/5 positions are also diastereotopic. When the methyl groups are in vicinal positions, the 3/5 atoms of the CPD ring are diastereotopic.

IV. DIASTEREOTOPY IN ACHIRAL MOLECULES

An achiral molecule can also contain diastereotopic atoms and groups. In the series of metallocenes such a compound is, for example, the phenyl derivative of [5] ferrocenophane (XXXIV, M = Fe). In contrast to the unsubstituted [5] ferrocenophane, whose molecule is divided by a plane of symmetry passing through the iron atom and through all the carbon atoms of the bridge and $C_{(1)}$ and in which the 2/5 and 3/4 atoms of both rings are enantiotopic, in the phenyl derivative there is no plane of symmetry. As a result, the 2/5 and 3/4 atoms in the molecule of compound (XXXIV) become diastereotopic in each ring. It is of interest that the atoms in different rings, designated by identical numbers, form enantiotopic pairs, since they are linked by a mirror plane. In order to account for the non-equivalence of the 2/5 and 3/4 nuclei in compounds resembling (XXXIV), one can also employ a different, more traditional approach. The point is that the above nuclei are involved in *syn/anti (cis/trans)* relations with the phenyl substituent.



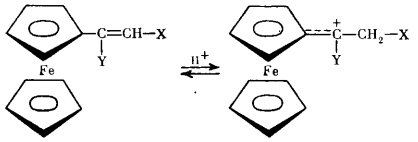
As was to be expected, two common signals for the 2/5 and 3/4 atoms of both rings are observed in the ^{13}C NMR spectrum of [5] ferrocenophane[49] ($\delta = 68.4$ and 66.9 p.p.m. in CH_2Cl_2 at 15 °C). In the spectrum of the γ-phenyl derivative of (XXXIV, M = Fe), the 2-, 3-, 4-, and 5-carbon atoms of the CPD rings give rise to four signals ($\delta = 66.0$, 66.9, 67.8, and 68.9 p.p.m. in CH_2ClCH_2Cl at 30 °C). [50] Analogous splitting has been observed in the spectrum of the γ-phenyl derivative of [5] ruthenocenophane (XXXIV, M = Ru): 68.0, 68.8, 71.1, 72.6 p.p.m. [51] We may note that in both cases the 2/5 and 3/4 carbon atoms of the CPD rings are sensitive to the introduction of a substituent in the γ-position in the bridge, separated from the ring by 2–3 atoms. For comparison, we may point out that the diastereotopy of the 2/5 and 3/4 atoms could not be observed when the asymmetric carbon atom was separated from the ring by one methylene group [the compound $C_5H_5FeC_5H_4CH_2CH(CH_3)COOH$; see Table 2]. Naturally, the fact that in the above compound the γ-methylene group with the methyl substituent is in spatial proximity to the ferrocene ring has an effect in the case of ferrocenophane.

In contrast to compounds (XXXIV), the molecules of the bridged metallocenes (X), (XI), and (XII) are no longer achiral, because the carbon atom in the bridge, linked to the substituent, is also linked to four different groups and in this case one can assume that the diastereotopy of the 2/5 and 3/4 nuclei is induced by the presence of an asymmetric carbon atom in the bridge.

V. DIASTEREOTOPY IN α-METALLOCENYL-SUBSTITUTED CARBONIUM IONS

When carbinols, containing metallocenyl (ferrocenyl, ruthenocenyl, osmocenyl, cymantrenyl, and cyclobutadiene-iron tricarbonyl) fragments in the α-position are dissolved in acids, unusually stable carbonium ions are formed[52]. The

signals of the 2/5 and 3/4 atoms of the CPD ligand are found to be split in both ^1H and ^{13}C NMR spectra of such ions containing two different substituents at the carbonium centre in addition to the metallocenyl fragment. This served as a basis for the hypothesis that the rotation about the $\overset{+}{C}-C_{(1)}$ bond is hindered, because such a bond has partial double bond character. The ^1H and ^{13}C NMR data for certain metallocenes having a single carbonium centre as a substituent are compiled in Tables 6 and 7. More complex carbonium ions, particularly those of the ferrocenophane series, have been discussed in the literature[41-44,47,48,57].



(XXXV) (XXXVI) (XXXVII)

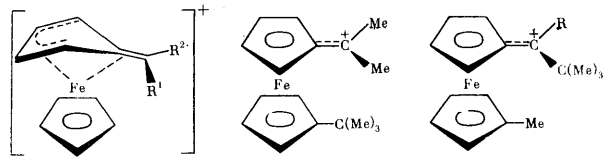
The splitting of the signals due to the 2/5 and 3/4 carbon atoms in the spectra of α-ferrocenylcarbonium ions was first noted by Sokolov et al.[53]. Subsequently the ^{13}C NMR spectra of metallocenylcarbonium ions were discussed frequently[16-18, 20,22-24,27,55,56]. The exact assignment of the signals to the 2/5 and 3/4 atoms was made by Koridze et al.[16] Nesmeyanov et al.[55] observed for the first time the splitting of the signals of the 2/5 and 3/4 carbon atoms in the spectra of the carbonium ion (XXXIX) formed on protonation of the double bond in the vinylferrocenes [XXXVIII, X = C_6H_5, Y = H(a); X = $CO_2C_2H_5$, Y = CH_3(b)]. However, it was given an incorrect explanation. The cation (XXXIXb) was investigated in greater detail in another study by Nesmeyanov et al.[56]



(XXXVIIIa and b) (XXXIXa and b)

The spectra of the derivative (XXXVII) show that the 2- and 4-carbon atoms are also anisochronous [δ(2/4) = 78.8 and 80.4 p.p.m. for R^1 = H and R^2 = CH_3], but, for R^1 = H and R^2 = C_6H_5, the chemical shifts of the 2- and 4-atoms fortuitously coincide and a common signal with δ = 80.0 p.p.m. is observed[27].

Table 7. Chemical shifts in the ^{13}C NMR spectra of certain α-metallocenylcarbonium ions [δ(p.p.m.) relative to TMS].

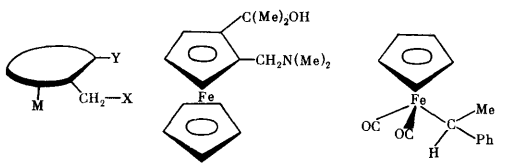
The diastereotopy of the 2/5 nuclei in metallocenylcarbonium cations shows some similarity with the diastereotopy of the geminal protons in monosubstituted olefins. Even if the carbonium ion has the non-planar structure (XL), as was assumed, the diastereotopy of the 2/5 and 3/4 nuclei should persist for $R^1 \neq R^2$.



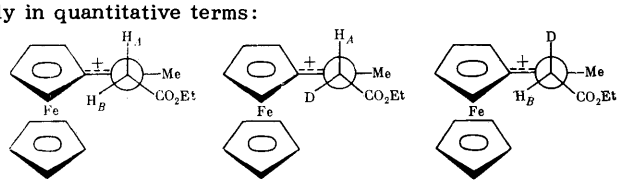
(XL) (XLI) (XLII)

An attempt has been made[44,48] to demonstrate the deviation of the carbonium fragment from the planar configuration. A comparison was made of the ^1H NMR spectra of the two isomeric carbonium ions (XLI) and (XLII, R = CH_3) or (XLIIa). The spectrum of compound (XLI), due to the protons of the ring to which the t-butyl group is attached, is manifested by a slightly broadened singlet. Hence it follows that the differences in the shielding of the 2'-, 3'-, 4'-, and 5'-protons are small. In the spectrum of the cation (XLIIa) the protons of the ring linked to the methyl group give rise to two well resolved multiplets. The authors[44,48] concluded that the mutual rotation of the rings in this compound is hindered, which leads to a time-averaged non-equivalence of the α- and β-protons of the methyl-substituted ring. Since the rotation is not hindered in the first isomer, it is concluded that in compound (XLIIa) rotation is hindered by the mutual repulsion of the $C(CH_3)_3$ and CH_3 groups, arising in connection with the deformation illustrated in structure (XL). However, an alternative explanation is also possible[45]. The hydrogen atoms in the ring without a cationic centre (2'/5' and 3'/4') are enantiotopic in compound (XLIIa), while in compound (XLIIa) they are diastereotopic (this is a special case of diastereotopy associated with the planar chirality of the molecule discussed above) and can be anisochronous. However, one cannot rule out the possibility that the anisochronicity of the diastereotopic 2'/5' and 3'/4' nuclei is manifested solely by virtue of the deformation postulated by the authors[44,48]. An unambiguous choice in favour of one of the explanations could be made by measuring the spectrum of

compound [XLII, R = $C(CH_3)_3$]. In this molecule the 2'/5' and 3'/4' atoms again become enantiotopic, but the postulated hindered rotation persists.

VI. CERTAIN OTHER CASES OF DIASTEREOTOPY

The diastereotopy of different groups in the molecules of π-complexes of transiton metals may not be associated with the specific features of the geometry of the metallocene (it can be caused, for example, by the presence of an asymmetric carbon atom in the side chain), but it is possible to quote examples where the structure of the metallocene sandwich does in fact induce diastereotopy. Thus, if one of the substituents in the homoannular disubstituted metallocene contains a methylene group, then its protons will be diastereotopic [see compound (XLIII)]. This phenomenon was observed for the first time in the spectra of the substituted ferrocene (XLIV) (the methyl groups in the neighbouring substituent are also diastereotopic).[58] Similarly the diastereotopy of the protons of the CH_2 groups was noted in a derivative of benzenechromium tricarbonyl[59]. It is of interest that in the ^1H NMR spectra of acetyl-1,1'-dibenzylferrocenes the diastereotopic anisochronicity could be observed only for the protons of the benzyl group in the disubstituted ring and only when the acetyl group was located in the α-position relative to this group[45].



(XLIII) (XLIV) (XLV)

The diastereotopic anisochronicity of the carbonyl groups (δ = 217.1 and 217.5 p.p.m.), due to the presence of the asymmetric carbon atom, has been observed in the ^{13}C NMR spectrum of compound (XLV).[60] The magnetic non-equivalence of phosphorus atoms has been noted in cationic phosphine complexes of a cymantrene derivative[61]. The non-equivalence of the methyl groups has been observed in derivatives of dicyclopentadienyl compounds of zirconium and hafnium containing asymmetric metal atoms[62].

VII. CHEMICAL NON-EQUIVALENCE OF DIASTEREOTOPIC ATOMS

The observation of the chemical non-equivalence of diastereotopic atoms is an important and interesting task. Naturally, diastereotopic atoms have different chemical properties only in quantitative terms:

(XXXIXb) (XLVIa) (XLVIb)

In the carbonium ion (XXXIXb) the hydrogen atoms of the methylene group are diastereotopic. They are manifested in the ^1H NMR spectrum by an *AB* quartet [δ = 3.53 and 3.87 p.p.m.; $J(AB)$ = 16 Hz].[56] It was found that these protons undergo deuterium exchange at different rates. The more rapid exchange was observed for the H_A proton whose signal is at a higher field. Evidently the H_A proton, sterically less shielded than the H_B proton, should in fact be more reactive. The diastereoisomer (XLVIb) is formed more rapidly as a result of the exchange[56].

Stereochemistry of Four-coordinate Chelate Compounds of Schiff Bases and Their Analogues

G.V.Panova, N.K.Vikulova, and V.M.Potapov

The problem of the configuration of the chelate group and the metal ring in chelates of transition metals with Schiff bases and their analogues is discussed, and the influence of various factors analysed, in particular the nature of the central metal atom and the steric and electronic effects of the ligands. Various types of conformational changes in conjugated metal rings in bicyclic and tricyclic chelates are surveyed, and factors influencing these changes are noted. The conformation of the non-conjugated metal rings in tricyclic chelates is discussed. A list of 188 references is included.

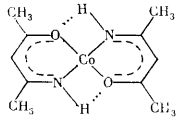
I. INTRODUCTION

A fundamental aspect of the chemistry of chelate compounds is their spatial and electronic structure, not only of theoretical interest but also very important for the practical application of chelates. The geometrical structure is related to the arrangement of energy levels in the molecule, which in turn determines the luminescent and phosphorescent properties. Stereochemical and electronic factors largely govern the reactivity and the stability of chelate compounds[1-3], as well as the possibility of using the ligands as analytical reagents[4].

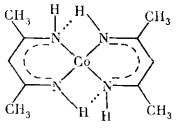
Undervaluation of the structure of reagents and chelates has been a serious defect in theoretical and practical work on the extraction of chelate compounds[5]. The sterochemistry and the electronic structure of chelates determine also their redox properties[4], reactivity[6], and ability to form adducts[7-10], which is quite important for an understanding of many catalytic processes[11] and phenomena occurring in living organisms[12].

Chelate compounds containing a bis(oxa,aza)-chelate group form one of the most common and important classes of chelates. They are model analogues of certain metal enzymes and group-B vitamins[13,14]. Furthermore, these chelates develop considerable fungicidal and antimicrobial activity[15,16]. Therefore many investigations have been published on chelates of this type.



Chelate compounds obtained from Schiff bases and enaminoketones are convenient for the study of chelate structure, since varying the substituents in the metal rings permits variation in the three-dimensional structure of the molecule within wide limits. Some of the sterochemical results for such chelates have been summarised in reviews[17-22]. In the present Review, therefore, attention is directed mainly at work done during recent years, with the chief aim not of describing sterochemical features of individual chelates[18,21] but of examining the factors influencing their spatial structure.

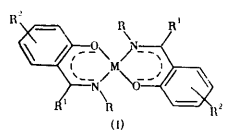
II. CONFIGURATION OF CHELATE GROUP IN FOUR-COORDINATE COMPOUNDS



1. Effect of Nature of Metal Atom on Configuration of Chelate Group

The configuration of the chelate group in four-coordinate compounds may be square planar (with *cis* or *trans* arrangement of donor atoms around the central metal atom), tetrahedral, distorted tetrahedral, or distorted pyramidal with the metal atom at the apex. The configuration depends primarily on the nature of the metal atom, but also on the magnitude and symmetry of the ligand field. It is affected significantly also by steric hindrance in the molecule resulting from the interaction of non-bonded atoms and functional groups. Crystal packing effects must also be taken into account when the stereochemistry of a chelate in the solid state is being considered.

We can usefully consider each of these factors in greater detail on the basis of published information on the configuration of the chelate group formed by Schiff bases and enaminoketones, as summarised in Tables 1–4. These show that almost all cobalt(II) chelates, independently of the structure of the ligands, contain a chelate group of tetrahedral configuration, the most advantageous for such compounds[123]. Exceptions are bicyclic chelates of acetylacetone-mono- and di-imines[124,96] and tricyclic chelates in which 1,2-diamines serve as amino-components in the ligands[14,125-127]. However, in the first case the structure of the chelate is probably stabilised by intramolecular hydrogen bonding



(V)

(VI)

and in the second case the structure is rigidly fixed by the shortness of the ethylene bridge.

** From results of X-ray structural analysis.

In almost all chelates of bivalent zinc, mercury, and beryllium, like those of cobalt, a tetrahedral structure is energetically most advantageous independently of the structure of the ligand. The energy of stabilisation of tetrahedral chelates by the crystal field is greatest in the case of beryllium. As a consequence, this metal differs from cobalt and zinc in not forming a planar tricyclic chelate with ethylenebis-*N*-salicylideneimine, but gives the tetrahedral bicyclic chelate[81]

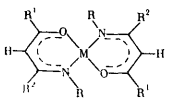
** Results of X-ray structural analysis.

Chelates of bivalent palladium and platinum are mostly characterised by a square planar configuration[123]. The tendency of these metals to form such chelates is so great that this configuration appears even under exceptionally unfavourable steric conditions. Thus the chelate of palladium(II) with *N*-t-butylsalicylideneimine retains a planar structure[88] despite strong steric interactions of the t-butyl group with the azomethine hydrogen atom and with the oxygen atom of the adjacent ligand molecule.



Besides the above extreme cases there exist many chelate compounds for which planar and tetrahedral structures differ little in energy of stabilisation by the crystal field. This applies especially to chelates of bivalent nickel and copper, whose stereochemistry is determined mainly by three-dimensional and electronic structural features of the ligands.

2. Effect of Structure of Ligands on Configuration of Chelate Group

(a) Steric effect of ligands

We must first consider briefly the structure of nickel and copper chelates. X-Ray results show (Tables 1 and 2) that in the solid state the chelate groups possess either a planar or a variously distorted tetrahedral configuration depending on the structure of the ligands. In solution the situation is more complicated: measurements of magnetic and dipole moments, proton magnetic resonance spectra, and electronic absorption spectra suggested[21] that an equilibrium is established between planar and tetrahedral forms of nickel(II) chelates of Schiff bases and enamino-ketones, whose position depends on the structure of the ligand and the temperature. However, other workers[128–130] are very doubtful about the establishment of such an equilibrium. Nevertheless, such studies are few and, in spite of some ambiguity in the treatment of several experimental facts, the hypothesis that an equilibrium is established between planar square and tetrahedron is generally accepted in discussion of the configuration of nickel(II) chelates in solution[131].

* Abbreviations as in Table 1.

There is no generally accepted view on the structure of copper(II) chelates in solution. From measurements of dipole moments Soviet workers[39,132–134] suggested that an equilibrium between planar and tetrahedral forms was established in solutions of certain such chelates. However, this hypothesis is inconsistent with the electronic absorption spectra of copper(II) chelates, which differ from those of nickel(II) chelates in being almost identical for solid specimens and for solutions[30,31,135,136] and furthermore hardly change with temperature. This indicates that only one form of the chelate is present in solution, with either a planar or a distorted tetrahedral configuration of the chelate group depending on the structure of the ligand.

* Abbrevations as in Table 1.

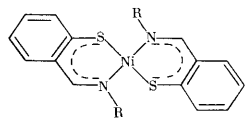
A similar conclusion has been reached[33] from a structural study by electron spin resonance of bicyclic copper(II) chelates of salicylideneimines *N*-substituted by n-butyl, isopropyl, or t-butyl. It was demonstrated unambiguously that these chelates exist in only one form either in the solid state or in solution, with the *g*-factor varying in parallel with the angle between the two metal rings. This view is probably more soundly based, and we shall adhere to it in describing the stereochemistry of copper(II) chelates in solutions.

It can be concluded from Tables 1–4 that all copper(II) chelates and most of the nickel chelates obtained from sterically inactive ligands have a planar chelate group. If to the nitrogen atom of the ligand are attached bulky radicals capable of interacting sterically with a radical on a neighbouring carbon atom and with the oxygen atom of the second ligand, the chelate group becomes tetrahedrally distorted in the case of copper(II) complexes, but either a tetrahedral form appears or its content increases siginificantly in the case of nickel(II) chelates. The degree of distortion and the percentage of the tetrahedral form increase with the volume of the radical attached to the nitrogen atom.

Steric stresses may increase not only with change in the *N*-substituent but also on the introduction of various substituents R^2 into the salicylaldehyde ring:

(VIII)

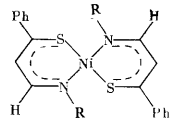
The greatest effect will obviously be exerted by radicals present at position 3 in the aromatic ring. Indeed, Japanese workers have found[138] that the chelate group in copper(II) complexes from 3-t-butyl- and 3-cyclohexylsalicylaldehydes is more distorted than in chelates of the unsubstituted aldehyde. Similarly, the content of the tetrahedral form in the nickel(II) chelate of *N*-isopropyl-3,4-benzosalicylideneimine ($R = iso\text{-}C_3H_7$, $R^2 = 3,4$-benzo) has increased to 68% from the 50% in *N*-isopropylsalicylideneimine ($R = iso\text{-}C_3H_7$, $R^2 = H$),[65] which is due to the steric effect of the bulky 3,4-benzo-group. The tetrahedral structure of the nickel chelate of 3-methoxy-*N*-*p*-methoxyphenylsalicylideneimine ($R = p\text{-}CH_3O.C_6H_4$, $R^2 = 3\text{-}CH_3O$)[66] is probably also a consequence of steric effects of the 3-methoxy-group.



(b) Electronic effect of ligands

Ring substituents in salicylaldehyde are able to exert not only a steric but also an electronic effect on the configuration of the chelate group, with the latter effect quite often opposing the former. Such an electronic influence is most clearly evident when the steric demands made by the nature of the *N*-substituent require a minimal difference in energies of stabilisation of planar and tetrahedral forms by the crystal field.

This principle is illustrated by the stereochemical investigation[30,31,61,64,65,139] of chelates (I: M = Cu, Ni; $R = n\text{-}C_3H_7$, $iso\text{-}C_3H_7$, $t\text{-}C_4H_9$; and $R^2 = 3,4$- or 5,6-benzo, 3- or 5-Cl, 3- or 5-NO_2), showing that, independently of the nature of R^2, all the chelates with $R = n\text{-}C_3H_7$ have a planar chelate group, but those with $R = t\text{-}C_4H_9$ have a tetrahedral or distorted tetrahedral structure. Yet the configuration of the chelate group when $R = iso\text{-}C_3H_7$ depends significantly on R^2. In the solid state the structure is distorted tetrahedrally when $R^2 = H$, 3,4-benzo, and planar when $R^2 = 5,6$-benzo, 3- or 5-Cl, 3- or 5-NO_2. The nickel(II) chelate containing 5,6-benzo retains a planar structure even in solution, whereas the corresponding chelate with $R^2 = H$ contains 50% of the tetrahedral form in solution. The electronic influence of chlorine atoms, which tends to flatten the chelate group as with a 5,6-benzo-substituent, can be traced in nickel(II) chelates by comparing the square–tetrahedron equilibrium free energies: for chelates with $R^2 = H$, 3-Cl, 5-Cl, ΔF has the respective values −0.52, 0.35, and 0.15 kcal $mole^{-1}$ at 120 °C.

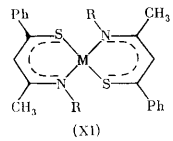


In connection with the effect of isosteric ligands on the configuration of nickel(II) chelates considerable interest attaches to a comparison[140] of chelates from amino-derivatives of 3-hydroxymethylenecamphor with analogous chelates from enamino-ketones of pentane-2,4-dione (III: M = Ni and $R^1 = R^2 = CH_3$), 1-phenylbutane-1,3-dione (III: M = Ni, $R^1 = C_6H_5$, and $R^2 = CH_3$), and Schiff bases of salicylaldehyde (I) and pyrrole-2-aldehyde(II). An attempt was made[140] to assess qualitatively the tendency of different isosteric ligands, containing the same *N*-substituents, to form tetrahedral chelate groups. The results showed this tendency to be greatest for chelates from amino-derivatives of 3-hydroxymethylenecamphor, and least for chelates of Schiff bases of pyrrole-2-aldehyde. These differences are most probably a consequence of different ligand field strengths in these chelates. Schiff bases of pyrrole-2-aldehyde are ligands having a strong field, and therefore tend to form planar chelate groups. But steric features of the five-membered camphor ring lead to a weak ligand field, so that they give chelates with a maximum content of the tetrahedral form.

The ligand field strength depends not only on the substituents in the metal ring but also on the nature of the donor atoms. Such an effect is clearly demonstrated by an investigation of the nickel(II) chelates with certain sulphur analogues of Schiff bases and enamino-ketones[98,141,142]

(IX)

R = CH_3, C_2H_5, $iso\text{-}C_3H_7$, $s\text{-}C_4H_9$, $t\text{-}C_4H_9$



(X)

R = $(C_2H_5)_2CH$, $iso\text{-}C_4H_9$, $iso\text{-}C_5H_{11}$, C_6H_5

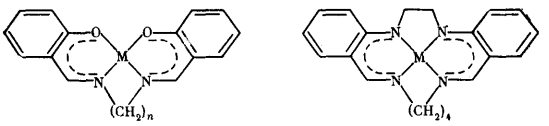
Almost all chelate groups formed by *N*-alkyl-*o*-mercaptobenzylideneimines have a square planar structure[141]. The only exception has $R = t\text{-}C_4H_9$, whose strong steric effect prevails over the electronic effect of the sulphur atom. Flattening of the chelate group on the replacement of oxygen by sulphur is indicated also by the fact that the content of the tetrahedral form in solutions of chelates of enamino-thiones is little more than half that for the corresponding enamino-ketones[98].

3. Competitive Effects of Nature of Metal and Ligand on Configuration of Chelates

When considering the effect of various factors on the configuration of a chelate group, we must bear in mind that in many cases one such factor is dominant, while the remainder operate only on the background of this main effect. For example, the electronic effect of the sulphur atom in zinc and cadmium chelates of enamino-thiones is insufficient to balance the tendency of these metals to form tetrahedral chelates, so that the compounds

(XI)

M = Zn, Cd;
R = $iso\text{-}C_3H_7$, $C_6H_5{-}CH_2$, $C_6H_5{-}CH(CH_3)$



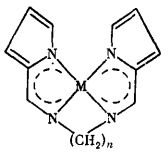
have a tetrahedral structure[143]. The absolute configuration of the chelate group in them may be either Δ or Λ: because of the absence of factors stabilising either absolute configuration, the proton magnetic resonance spectra for these chelates indicate rapid inversion $\Delta \rightleftharpoons \Lambda$, with intermediate formation of a planar chelate. This inversion occurs far more rapidly in chelates from enamino-thiones than in corresponding chelates from enamino-ketones. The difference is attributed[143] to the "flattening effect" of the sulphur atom discussed above.

Another example is provided by the stereochemistry[144] of nickel(II) and zinc(II) chelates with (−)-propylenebis-*N*-salicylideneimine. The steric demands of the ligand are

such that the chelate group in these compounds should be planar. However, this configuration is realised only in the nickel chelate, whereas the zinc chelate is non-planar owing to the tendency of this metal ion to form a tetrahedral configuration.

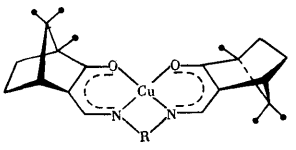
It is generally difficult to predict which of the factors will predominate, and hence the structure of the resulting chelate. The only exceptions are found when the factors act in the same direction, as e.g. in cobalt(II) and zinc(II) chelates in which bulky branched amines have been used in the ligand. The tetrahedral structure of these chelates is due both to steric features of the ligands and to the energy requirements of the metal ion. If, however, the different factors do not act in parallel, the structure of the chelate group will be determined by competition between them. Thus comparison of results for the three-dimensional structure of bivalent palladium, copper, and nickel chelates with ligands containing isopropylamine[86,35,60] shows that the tendency of the palladium ion to form planar complexes prevails over the steric requirements of the ligands, and the chelate has a square planar structure. In the nickel and copper chelates, however, the steric effect of the ligand predominates over the tendency of these metal ions to form planar chelates, so that the resulting compounds have a distorted configuration.

Another example is provided by investigations[145–153] on the tricyclic chelates



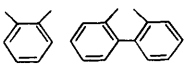
(XII)

M = Co, Ni, Cu; n = 2–4

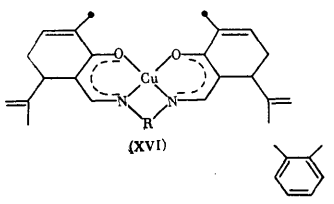


(XIII)

M = Co, Ni, Cu



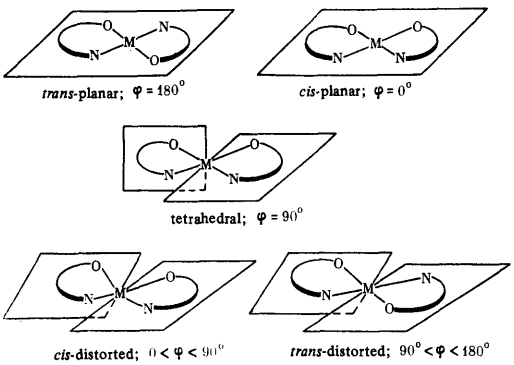
(XIV)



M = Cu, Ni; n = 2–5

(XV)

R = $(CH_2)_n$, where n = 2–6, 8;



(XVI)

$R = (CH_2)_n$, where n = 2—6,8,10;

(see also Table 4). Inspection of geometric models of these chelates shows that lengthening the polymethylene bridge should cause distortion of the planar configuraiton of the chelate group owing to diminished interaction of non-bonded atoms in the distorted structures. However, this distortion is readily and completely realised only in cobalt(II) chelates, and is completely absent from nickel(II) chelates.

The structure of tricyclic copper(II) chelates is most interesting. Various structures can be realised when the planes of the metal rings undergo mutual rotation through an angle ϕ:

trans-planar; $\varphi = 180^\circ$

cis-planar; $\varphi = 0^\circ$

tetrahedral; $\varphi = 90^\circ$

cis-distorted; $0 < \varphi < 90^\circ$

trans-distorted; $90^\circ < \varphi < 180^\circ$

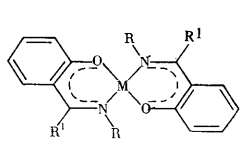
Electron spin resonance and spectropolarimetric studies[150–153] on such chelates obtained from enamino-ketones of oxymethylene-camphor and -carvone have shown that chelates containing a polymethylene bridge with $n = 2$ have a planar *cis* structure, whereas those with $n = 8$, 10 have a *trans* structure with a planar arrangement of the chelate group. The *trans*-planar configuration of the latter is probably a consequence of the considerable length of the octa- and decamethylene bridges, which enables the chelate molecule to assume the energetically most favourable *trans*-planar configuration. Owing to the greater length of the trimethylene bridge, chelates with $n = 3$ are somewhat distorted relative to a planar structure.

The e.s.r. spectra of solid chelates with $n = 4–6$ indicate that they are individual compounds existing in the same form with distortion of the chelate group to ensure denser packing. Yet the e.s.r. spectra of these chelates in low-temperature toluene glasses indicated[150–152] that solutions of each of the chelates contain three isomeric complexes, α, β, and γ with chelate groups differing in stereochemistry and distinguished by the angle of rotation ϕ of the planes of the two metal rings.

The current absence of the exact dependence of the g-factor on the angle ϕ prevented these workers from estimating the latter for each isomer. However, comparison of the e.s.r. parameters of these chelates with those of related compounds of known stereochemical structure indicated that all the γ-isomers were *trans*, with the chelate group most distorted tetrahedral in the presence of a tetramethylene bridge ($n = 4$). On the other hand, the α and β-isomers have a distorted tetrahedral configuration of the coordination sphere with a *cis* arrangement of the donor atoms; the latter isomers are considerably more distorted than the former. In the β-isomers, as in the γ-isomers, the degree of distortion of the chelate group diminishes as the polymethylene bridge becomes longer. The initial proportions of rotational isomers appearing after dissolution do not remain constant[150–152], but change with time, with a gradual increase in the concentration of the α-isomer, whose chelate group is least distorted relative to a planar *cis* structure.

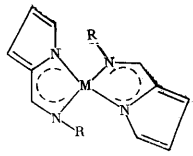
To summarise, it can be concluded that the tendency of the planar configuration of the chelate group to be distorted increases as the chelating metal changes in the sequence

$$Pd<Cr<Cu\approx Ni<Co<Fe<Zn<Cd<Be.$$



The tendency of the metal ion to form chelates having a tetrahedral configuration varies in the same sequence, provided that the ligand favours such a configuration. The chelate group in compounds of the same metal with isosteric ligands will be more "flattened" the more intense the ligand field in the chelate.

III. CONFORMATION OF CHELATES OF SCHIFF BASES AND THEIR ANALOGUES



Comparatively few papers have appeared on the conformations of chelates, although this problem is of no less interest than the configuration of the chelate group. This is probably due to the complexity involved in investigating the structure of chelate molecules, since the great majority of physicochemical methods used to study chelate compounds are incapable of registering conformational changes. X-Ray structural analysis is the most accurate method for determining the conformation of a metal ring in the solid state. Proton magnetic resonance and spectropolarimetry are used to study the conformational structure of chelates in solution.

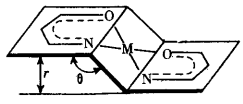
1. Conformation of Conjugated Metal Rings

X-Ray examination of four-coordinate chelates has shown that flat molecules with a completely coplanar arrangement of all the atoms are atypical. The only examples[51,89] of planar chelates are

(XVII)

(XVIII)

with M = Ni and R = R¹ = H in (XVII), and M = Cu and R = H in (XVIII), in both of which no atom departs significantly from the plane. Far more often chelates are met in which the general coplanarity of the molecule is disturbed by folding of the conjugated metal rings along the O....N line, so that the molecule as a whole has the form of a step:



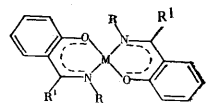


Table 5 summarises published data on the step distortion of metal rings in chelate compounds of several metals with Schiff bases.

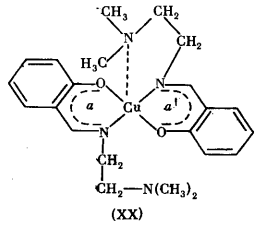
The cause of step distortion in chelates obtained from Schiff bases is steric interaction of substituents in the metal ring, the distance between which is significantly less[46] than the sum of the van der Waals radii. Such distortion disturbs the coplanarity of the system and hence diminishes the degree of delocalisation of electron density in the quasi-aromatic metal ring, which is disadvantageous energetically. However, this is balanced by the increased distance between non-bonded atoms resulting in all cases from step distortion along the O...N lines, which lessens steric stresses in the molecule and also lowers its total energy.

Table 5. Data on the conformational structure of the chelates.



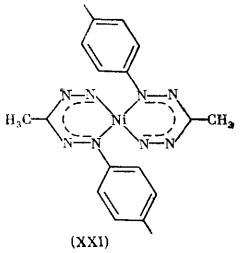
(XIX)

M	R¹	R	r, Å	Ref.
Cu	H	H	0.29	23
Cu	H	C_6H_5	0.24	27
Cu	H	n-C_3H_7	0.32	29
Cu	H	iso-C_3H_7	0.34	35
Cu	H	n-C_4H_9	0.74	32
Cu	H	t-C_4H_9	0.67	36
Cu	H	C_6H_5	0.89	38
Cu	H	p-CH_3-C_6H_4	0.90	50
Cu	H	OH	0.13	154
Cu	CH_3	H	0.48	44
Cu	CH_3	CH_3	1.91	46
Cu	CH_3	iso-C_3H_9	2.24	155
Cu	CH_3	n-C_8H_{17}	2.66	46
Cu	CH_3	n-$C_{10}H_{21}$	2.34	48
Cu	CH_3	C_6H_5—CH_2	1.68	46
Cu	CH_3	$C_6H_5CH(CH_3)$	1.22	46
Ni	H	C_6H_5	1.78	55
Ni	H	C_6H_{13}	0.65	57
Pd	H	iso-C_3H_7	0.42	86
Pd	H	t-C_4H_9	1.72	89

It must therefore be expected that the magnitude of the distortion will depend on the volumes of the substituents R and R¹ in the metal ring and on the related steric stresses within the molecule. Indeed, it is readily seen from Table 5 that r is significantly greater for chelates of Schiff bases obtained from o-hydroxyacetophenone ($R^1 = CH_3$) than for corresponding chelates based on salicylaldehyde ($R^1 = H$). In the former case attachement of methyl to the azomethine carbon atom enhances significantly the steric stresses within the molecule, with a consequent increase in step distortion of the metal rings.

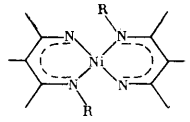
Simple relations between the volume of the radical R and the distance r have not yet been found. The probable reason is that variation in R leads to change not only in the relative arrangement of the metal rings but also in the configuration of the chelate group and the length of the carbon–nitrogen bonds.

Steric stresses in a chelate molecule and the associated step distortion of the metal rings can be caused not only by interaction of juxtaposed atoms and groups but also by certain other structural features of the ligands. An example is provided by X-ray results[156] for the chelate



(XX)

in which one molecule of the Schiff base is terdentate, whereas the other is bidentate. Coordination of the ligand through three donor atoms increases the stress in this moiety, leading to conformational non-equivalence of the metal rings *a* and *a'*, with *a* almost planar and *a'* having $r = 0.13$ Å.

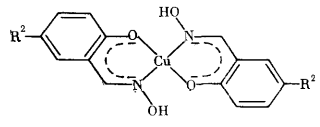


Analogous conformational non-equivalence of the two metal rings has been found in the zinc(II) chelate of *N*-*o*-methoxyphenylsalicylideneimine[157], which has a *cis*-octahedral structure owing to coordination of the zinc atom with the methoxyl-oxygen atom. One of the metal rings is planar, whereas for the other $\theta = 31.5°$. Such non-equivalence of the metal rings is attributed[157] to the difference in the angles of rotation of the anisidino-rings about the two conjugated metal rings.

Steric stresses in a molecule can be eliminated not only by a stepped conformation of the metal rings but also by distortion of the planar configuration of the chelate group to a tetrahedral or distorted tetrahedral configuration. Which path is followed depends primarily on the tendency of a given metal atom to form the energetically most stable configurations Since, as already mentioned, a tetrahedral configuration is the most stable for four-coordinate cobalt(II) chelates, steric stresses are removed from such chelates mostly by the formation of compounds having a tetrahedral chelate group and almost planar metal rings[65,71,73]. However, a stepped structure is formed with all sterically hindered chelates of metal ions that cannot give a tetrahedral configuration. Thus in the palladium(II) chelate of *N*-t-butylsalicylideneimine[88] the chelate remains planar, but the metal rings are strongly deflected from the plane at an angle $\theta = 36°$.

The situation is far more complicated with chelates of metals for whose ions planar and tetrahedral configurations do not differ greatly in energy, as with the nickel(II) chelates

(XXI)



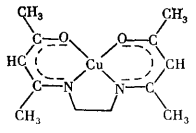
(XXII)

R = Alk, Ar

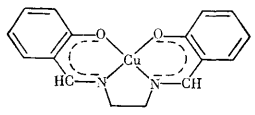
Thus the diamagnetic chelate (XXI) has a planar chelate group and a strongly step-distorted metal ring ($\theta = 37°$, $r = 1.6$ Å),[158] but in paramagnetic chelates (XXII) steric stresses are removed mainly by distortion of the planar geometry of the chelate group[159].

The magnitude of the step distortion of metal rings depends not only on steric factors but also on electronic structural features of the ligand. The ligand field intensity affects not only the conformation of the chelate group (Section II, 2*b*) but probably also the conformational structure of the metal rings. Thus comparison of X-ray structural data for copper(II) chelates of *N*-t-butylsalicylideneimine[36] (XVII: M = Cu, R = t-C_4H_9, and R^1 = H) and *N*-t-butylpyrrolideneimine[92] (XVIII) M = Cu and R = t-C_4H_9) shows that the latter chelate, in contrast to the former, has an almost planar metal ring. This is probably due to intensification of the ligand field when the donor oxygen atom in (XVII) is replaced by a donor nitrogen in (XVIII).

The effect of the ligand field intensity on the step distortion of the metal ring is confirmed also by X-ray results for the copper chelates of the oximes of salicylaldehyde and its 5-chloro-derivative[154,160]



(XXIII)

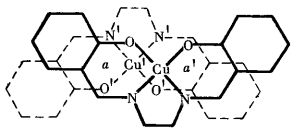


R^2 = H, Cl

Introduction of the chlorine atom weakens the ligand field, which in turn increases considerably the distortion of the metal rings: values of *r* for the chelates obtained from unsubstituted and substituted salicylaldehyde oximes are respectively 0.13 and 0.76 Å.

Interesting information on the effect of ligand field intensity on the general planarity of the molecule has resulted from a structural investigation[161–165] of outer-sphere adducts of *NN'*-ethylenebis(acetylacetoneiminato)copper(II) and *NN'*-ethylenebis(salicylideneiminato)copper(II)

(XXIV)

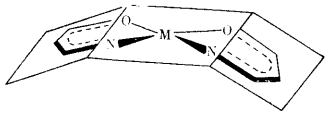


(XXV)

having the compositions (XXIV).$\frac{1}{2}H_2O$, (XXIV).$[CH_3NH_3]^+[ClO_4]^-$, (XXV).$CHCl_3$, and (XXV).*p*-HO.C_6H_4.NO_2. The water, chloroform, and *p*-nitrophenol molecules and the methylammonium ion form hydrogen bonds with the oxygen atom of the metal ring, which tend to increase the π back-bonding of the oxygen atom to the d_π orbitals of the copper atom, i.e. to strengthen the field of the ligands in the chelates. Since water is less capable than methylammonium of forming hydrogen bonds, and chloroform less than *p*-nitrophenol, the ligand field strength will gradually increase on passing from (XXIV) to the hemihydrate and then to the methylammonium adduct, and also on passing from the very weak adduct of (XXV) with chloroform to that with *p*-nitrophenol. X-Ray results for these chelates show that the degree of distortion of the metal rings decreases in the same sequence. Thus, whereas the angle of fold of the metal ring $\theta = 15.5°$ in the chelate (XXIV),[161] it is only 3.5° in the hemihydrate[162], and the metal rings are completely planar in the methylammonium adduct[163]. Similarly, the step distortion of the metal rings $r = 0.55$ and 0.2 Å in the adducts of (XXV) with chloroform and with *p*-nitrophenol respectively. It was concluded[161–165] from these results that the planarity of the molecule can even serve as a criterion for assessing the ligand field strength in a chelate: the greater the general planarity of a molecule the stronger the ligand field in it.

Furthermore, step distortion of metal rings is sometimes a consequence not of the structure of the ligand but of specific intermolecular interactions or lattice effects. Thus a stepped conformation of metal rings has been found in copper(II) chelates of acetylacetone[166], benzoylacetone[167], and salicylaldehyde[168,169], in which there are no steric interactions between the two metal rings and their substituents.

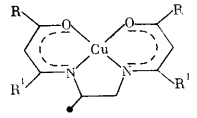
The conformational difference between the two metal rings in the chelate



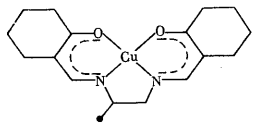
(XXVI)

has also been attributed[165] to intermolecular interactions. The angle of fold of the metal ring *a* is almost double that of *a'*. The greater "flattening" of the latter metal ring is a consequence of intermolecular interaction of the oxygen atom in ring *a* with the copper atom of a second chelate molecule.

Another example is provided by X-ray structural data[170] for the copper chelate of the Schiff base of salicylaldehyde and aminoethanol (XVII: M = Cu, R^1 = H, and R = CH_2CH_2OH). The unit cell contains two independent molecules, the angle of fold of the metal rings in one of which is almost double that in the other. The differences observed in the conformational structure of the metal rings in the two molecules are attributed[170] to effects of their crystalline packing.

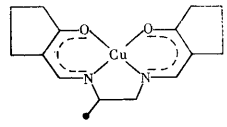


In the above systems distortion of the metal rings yields a stepped molecular structure, with the two metal rings bent in opposite directions relative to the plane of the chelate group CuO_2N_2. Recent work has shown that chelates of Schiff bases may have not only a stepped but also an "umbrella-shaped" structure

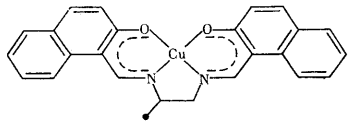


in which the two metal rings are bent in the same direction. Such an "umbrella" structure has been found in particular in the monohydrate of *NN'*-ethylenebis(acetylacetoneiminato) copper (XXIV).H_2O,[171] in which the copper atom is coordinated with the oxygen atom of the water molecule ($\theta = 11.8°$), in *NN'*-ethylenebis(salicylideneiminato)iron(III) chloride[172], in the copper(II) chelate of the Schiff base of *o*-aminobenzaldehyde and propylenediamine[173] (5°), in the dimer of *NN'*-ethylenebis(thiosalicylideneiminato)cobalt(II) (21.4°),[174] and in *NN'*-*o*-phenylenebis(salicylideneiminato)palladium(II).[122] However, the reasons for the appearance of an "umbrella" and not a stepped structure in these cases are not yet clear.

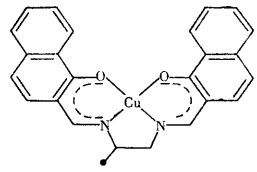
Study of the conformations of conjugated metal rings is quite complicated, since the description of the conformational structure depends on the method of choosing the median plane. Work by Porai-Koshits et al.[175] on the conformations of the metal rings in certain copper(II) and nickel(II) bis-salicylideneiminates suggests that these rings are labile, but the number of possible ways in which they can be distorted is limited. Besides a planar arrangement of all the atoms in a metal ring and folding of the ring along the O....N line, cases have also been examined[175] in which metal and nitrogen atoms are expelled from the plane of the metal ring, or metal and oxygen atoms lie on one side of the median plane, while the nitrogen and attached carbon atom lie on the opposite side.



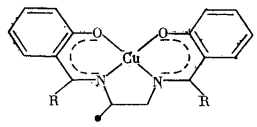
It must again be emphasised that all the structural results for conjugated metal rings considered hitherto have been obtained by X-ray structural analysis and are valid for the conformations of solid chelates. An attempt to assess the conformation of conjugated metal rings in solution involved[176,177] spectropolarimetric examination of the chelates



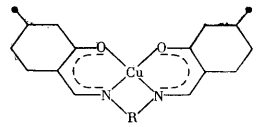
(XXVII)



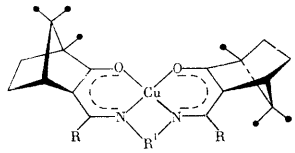
(XXVIII)



(XXIX)



(XXX)



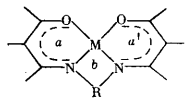
(XXXI)

(XXXII), R = H, CH_3

(XXXIII), R = $(CH_2)_2$,

(XXXIV)

R = H, R^1 = $(CH_2)_2$;



R = CH_3, R^1 = $(CH_2)_2$

The circular dichroism spectra showed a change in sign of the Cotton effect of the $d_{xy} \rightarrow d_{x^2-y^2}$ transition band and a hypsochromic shift in the intraligand $\pi-\pi^*$ transition band on replacement of the azomethine hydrogen atom by a methyl group and on passing from ethylenediamine to *o*-phenylenediamine chelates. Detailed analysis of these spectra indicated that the observed change in sign was due neither to change in conformation of the central non-conjugated metal ring nor to change in configuration of the chelate group but to change in conformation of the conjugated metal rings accompanying change in azomethine *N*- and *C*-substituents capable of steric interaction. It is emphasised[176,177] that, if the change in substituents does not affect the steric stresses in the chelate molecule (as with changes in R), the conformation of the conjugated metal rings remains unchanged.

2. Conformation of Non-conjugated Metal Rings

Besides the chelate compounds having conjugated metal rings already considered there exist a large number of chelates containing also non-conjugated metal rings. They

include primarily tricyclic chelate compounds of the type

(XXXV)

R = $(CH_2)_n$, n = 2-12

formed by quadridentate Schiff bases, in which the non-conjugated polymethylene ring *b* is fused with two conjugated rings. Chelates of this type having $n = 2$, i.e. obtained from 1,2-diamines, have been the most thoroughly studied. Thus in the work already cited[161-165,171,173] investigation of the structure of the conjugated metal rings was accompanied by detailed study of the conformation of the ethylene- and propylene-diamine rings in (XXIV), (XXV), and their adducts, and also in the copper(II) chelate of *NN'*-propylenebis-(*o*-aminobenzylideneimine). X-Ray structural data on the conformations of the non-conjugated metal rings in these chelates (Table 6) show that the most stable form of the five-membered non-conjugated metal ring is the skew conformation

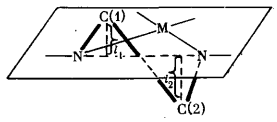


Table 6. Distances l_1 and l_2 of carbon atoms $C_{(1)}$ and $C_{(2)}$ in ethylene bridge from plane of chelate group CuO_2N_2.

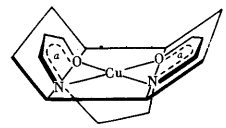

Compound	l_1, Å	l_2, Å	Ref.
(XXIV)	0.44	—0.12	161
(XXIV)·1/2H_2O	0.18	—0.11	162
(XXIV) $[CH_3NH_3]^+$ $(ClO_4)^-$	0.05	0.05	163
(XXIV)·H_2O	—0.11	—0.15	171
(XXV)	0.49	—0.24	178
(XXV)·$CHCl_3$	0.44	—0.12	164
(XXV)·p-HO—C_6H_4—NO_2	0.28	—0.20	165
(XXXVI) *	0.16	—0.14	173
(XXXVII) **	0.44	—0.22	172

* *NN'*-Propylenebis (*o*-aminobenzylideneiminato)copper(II).
** *NN'*-Ethylenebis(salicylideneiminato)iron(III) chloride.

Comparison of Table 6 with the angles of fold of the conjugated metal rings in the same compounds shows that the conformation of the non-conjugated metal ring depends significantly on the structure of the conjugated rings fused with it. It can be concluded firstly that a stepped structure of the chelate molecule as a whole favours a skew conformation of the ethylenediamine ring and secondly that the distance of the carbon atoms $C_{(1)}$ and $C_{(2)}$ of the ethylene bridge from the CuO_2N_2 plane is determined mainly by the magnitude of the step distortion.

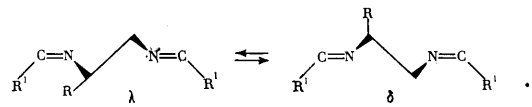

Table 6 shows that these two carbon atoms of the diamine bridge do not usually form an ideally skew conformation, but are situated unsymmetrically with respect to the plane of the chelate group CuO_2N_2. Such lack of symmetry is a consequence of the non-equivalence of the angles of fold of the two conjugated metal rings. From a comparison of the distances l_1 and l_2 of these atoms with the step distortions of the conjugated metal rings it was concluded that the departures of the bridge carbon atoms from the plane of the chelate group diminish with decrease in the angle of fold of the conjugated metal rings. Thus values of l_1 for the chelates (XXIV), (XXIV).$\frac{1}{2}H_2O$, and (XXIV).$[CH_3NH_3]^+[ClO_4]^-$, for which this angle is 13.5°, 3.5°, and 0°, are respectively 0.44, 0.18, and 0.05 Å. Among these compounds the greatest interest attaches to the chelate (XXIV).$[CH_3NH_3]^+[ClO_4]^-$, in which complete coplanarity of the conjugated metal rings leads to formation of the sterically unfavourable completely eclipsed conformation of the ethylene bridge.

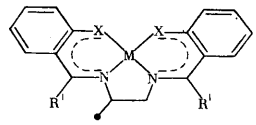
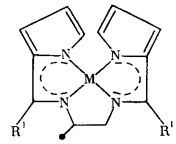
The partly eclipsed *cis* conformation of the ethylene bridge (with the two bridge carbon atoms on the same side of the CuO_2N_2 plane) is found in the chelates (XXIV).H_2O and *NN'*-ethylenebis(trifluoroacetylacetoneiminato)nickel(II)[179] with an umbrella structure of the molecule



The reason for such an uncharacteristic *cis*-eclipsed conformation of the ethylene bridge is that steric interaction of the bridge carbon atoms with the metal rings *a* is less than for a skew conformation. Yet in *NN'*-propylenebis-(*o*-aminobenzylideneiminato)copper(II) (XXXVI) and in *NN'*-ethylenebis(salicylideneiminato)iron(III) chloride (XXXVII), which like the preceding compounds possess an umbrella structure, the ethylene bridge has an eclipsed conformation. Such a conformation of the non-conjugated metal ring in these chelates is determined mainly not by the way in which the metal rings are folded but by the configuration of the chelate group, which has a distorted tetrahedral structure with a relative angle of rotation of the two metal rings of 9° and 10° respectively.

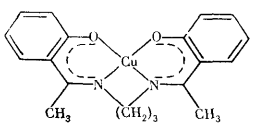
With a skew conformation the ethylene bridge can have either a λ- or δ-conformation, which are enantiomeric:



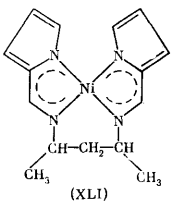
If the substituent R = H, the λ- and δ-conformations of the metal rings are equivalent. With substituted ethylenediamines (e.g. in chelates based on propylenediamine—R = CH_3), however, steric interactions of the radicals R and R^1 should lead to non-equivalence of λ- and δ-conformations, so that one of them will be formed preferentially. Indeed, X-ray results for copper(II) chelates of *NN'*-propylenebis-(*o*-aminobenzylideneimine)[173] and *NN'*-propylenebis(salicylideneimine)[180] show that the propylene bridge has the δ-conformation with an axial methyl group. 1,3-Interaction of R and R^1 is far weaker with an axial than with an equatorial methyl group.

(XXXVIII)

X = O, R^1 = H, CH_3, M = Cu, Ni;
X = N, R^1 = H, M = Cu



(XXXIX)



R^1 = H, CH_3

A δ-conformation of the propylene ring in solution was indicated also by a spectropolarimetric investigation[181,182] of the chelates (XXXVIII). The same conclusion has been reached[183,184] for analogous titanium(IV) monoxide and iron(III) chelates, and also in a study[176] of conformational aspects of the chelates (XXVII: R = CH_3, C_6H_5 and R^1 = H, CH_3).

The chelates (XXXIX: R^1 = H) have the propylene ring in the λ-conformation[185], which was explained by weakening the 1,3-equatorial interactions between the methyl group and the azomethine hydrogen atom in chelates (XXXIX) from Schiff bases of pyrrole-2-aldehyde in comparison with chelates (XXXVIII) from Schiff bases of salicylaldehyde. Such weakening is due to the smaller size of the five-membered metal ring in the former case relative to the six-membered ring in the latter. In chelates (XXXIX) of 2-acetylpyrrole ($R^1 = CH_3$), however, the steric stresses in the molecule due to interaction of the two methyl groups are already quite strong, and the central metal ring has the δ-conformation. A 1,2-diaxial conformation of a five-membered metal ring has been found also in the cobalt(II) chelate of the Schiff base of salicylaldehyde and butane-1,2-diamine[186].

(XL)

(XLI)

Very little information has been obtained on the conformation of non-conjugated central metal rings containing more than two carbon atoms. The central metal ring in the chelate (XL), formed by a trimethylene bridge, has a twisted boat conformation[187], but the analogous metal ring in (XLI) possesses a half-chair conformation with both methyl groups in equatorial positions[188]. X-Ray examination of the chelate (XIII) has established[149] that the tetramethylene bridge has a half-boat conformation. It was suggested[149] that the conformation of the central metal rings in chelates obtained from polymethylenediamines as amino-components will probably be determined by the configuration of the chelate group: a planar or slightly distorted planar chelate group should give a boat conformation, but a tetrahedral or nearly tetrahedral group should yield a chair conformation. However, the literature is devoid of results supporting this hypothesis.

* * *

Thus inspection of the literature shows that the conformation of metal rings, like the configuration of the chelate group, depends on the nature of the central metal atom, the spatial and electronic structure of the ligands, and also the character of the intermolecular interactions. Full information on the stereochemistry of chelate compounds can be obtained only by using a combination of diverse physicochemical methods, enabling the structure of chelates to be characterised not only in the solid state but also in solutions.

Advances in the Chemistry of Organofluorine Hypohalites and Related Compounds

F.M.Mukhametshin

Organofluorine compounds containing the groups O-Hal and O-O-Hal are surveyed. Methods of preparation, physical and chemical properties, structure, and possibilities of practical application are examined. A list of 247 references is included.

I. INTRODUCTION

A major achievement of organofluorine chemistry, based on the use of elementary fluorine, has been the discovery and study of new classes of compounds. Several of them contain functional groups that are essentially strong oxidants, which makes preparation of their hydrocarbon analogues almost impossible. Examples of such compounds are, in particular, many known organofluorine hypohalites and related *O*-halogenoperoxides.

These two groups of compounds owe their existence and relative stability to the alkyl fluorine atoms. This stabilising effect comprises (i) shielding of the carbon skeleton by the fluorine atoms and (ii) the inductive effect of fluoroalkyl groups, which strengthens the oxygen–halogen bond. Among the hypohalites the hypofluorites are more common than the corresponding hypochlorites. The less common peroxides are roughly equally represented by both halogens.

The first results on the synthesis and isolation of organofluorine hypohalites appeared in 1948, when trifluoromethyl hypofluorite CF_3OF was identified[1]; the hypochlorite CF_3OCl was first described in 1968;[2] and the *O*-halogenoperoxides have been characterised quite recently. Methods of preparation and individual properties of hypofluorites have been surveyed in several general[3–5] and specialised[6–8] reviews.

The present Review summarises the vast amount of published information on the preparation and properties of organofluorine hypofluorites and on the related hypochlorites and *O*-halogenoperoxides. It covers publications that had appeared by the end of 1977 inclusive. Perfluoroacyl hypofluorites[8] are not considered.

II. METHODS OF PREPARATION

Existing methods for the directed preparation of organofluorine hypohalites and *O*-halogenoperoxides can be arbitrarily divided into catalytic and non-catalytic. Each group includes various modifications, determined essentially by the type of initial organofluorine or other compound, the type of catalyst, and the experimental conditions. Carbonyl-containing compounds have been most widely used as starting materials for the preparations of organofluorine hypohalites. Reactants for production of the O–Hal group are elementary fluorine to obtain hypofluorites and chlorine monofluoride for hypochlorites. The same reactants are employed in the preparation of organofluorine *O*-halogenoperoxides.

1. Hypofluorites

The chief method for the preparation of organofluorine hypofluorites is the catalysed action of fluorine on perfluoroacyl fluorides[9–19]:

$$R_FC(=O)F + F_2 \xrightarrow{cat.} R_FCF_2OF .$$

Fluorides of sodium, potassium, rubidium, caesium, magnesium, calcium, strontium, barium, lanthanum, iron, copper, nickel, and silver as well as mixed compounds of the type $CsHF_2$ or $KAgF_4$ can be used as fluorination catalysts[9]. Caesium fluoride possesses extremely high catalytic activity: in its presence hypofluorites can be obtained not only from carbonyl difluoride or fluorides of mono- and per-fluorinated dicarboxylic acids[10–16] but also from the unstable peroxy-compounds $(FCOO)_2$,[15] CF_3OOCOF,[17] and $(SF_5OO)_2COF$.[18]

The preparation of hypofluorites in the presence of caesium fluoride is distinguished by simplicity and nearly quantitative yields of the end-products. Fluorine and the acyl fluoride are mixed in a vessel containing the catalyst, evaucated and cooled to −196 °C, which is then warmed to room temperature[11]. A disadvantage is the low ouput due to the need to use static conditions and small quantities of reactants.

Fluorides of alkaline-earth and transition metals are weaker catalysts than caesium fluoride, and require higher reaction temperatures (25–100 °C). Their catalytic activity has been examined in detail only in the conversion of carbonyl difluoride into trifluoromethyl hypofluorite. The reaction can be conducted in a flow system[1].

In general the formation of hypofluorites from acyl fluorides consists essentially in the addition of fluorine at the carbonyl multiple bond. The reaction mechanism has not been finally established: two possible alternatives, determined by the nature of the catalyst, are postulated. In the case of alkali-metal fluorides, especially caesium fluoride, it is assumed[20,21] that an alkoxide (I) is formed, which then reacts with fluorine:

$$R_FC(=O)F + CsF \rightarrow \underset{(I)}{R_FCF_2\bar{O}\overset{+}{C}s}$$

$$(I) + F_2 \rightarrow R_FCF_2OF + CsF .$$

The second stage is classified[22] as nucleophilic substitution S_N2 at the fluorine atom. However, it is more correct to regard it as a one-electron transfer process, as e.g. in the fluorination of the trinitromethyl anion by perchloryl fluoride[23].

In the case of fluorides of metals of variable valency (silver, copper, nickel) the role of the catalyst is essentially[21] to generate fluorine atoms, which initiate a radical process. A mechanism suggested[21] for the fluorination of carbonyl difluoride is

$$F_2 \xrightarrow{cat.} 2\dot{F}$$
$$\dot{F} + COF_2 \rightarrow CF_3\dot{O}$$
$$CF_3\dot{O} + \dot{F} \rightarrow CF_3OF$$
$$2CF_3\dot{O} \rightarrow CF_3OOCF_3 .$$

The chief arguments in favour of such a mechanism are the formation of trifluoromethyl peroxide and the inability of catalysts of this type to form alkoxides with perfluoroacyl fluorides. A heterogeneous mechanism has also been suggested[24], with formation of trifluoromethyl peroxide involving chemisorption processes:

$$AgF_2 + CoF_2 \rightarrow Ag(OCF_3)_2$$
$$Ag(OCF_3)_2 + F_2 \rightarrow [F_2 \cdot Ag(OCF_3)_2] \rightarrow AgF_2 + CF_3OOCF_3 .$$

None of the schemes is entirely satisfactory. The true mechanism of formation of trifluoromethyl hypofluorite and peroxide is probably catalytic, as indicated in particular by results for the activated adsorption of fluorine[25] and the dipole moment of carbonyl difluoride (0.95 D).[4]

Acyl fluorides can be converted catalytically into hypofluorites not only heterogeneously but also homogeneously. Thus at −20 °C carbonyl difluoride and fluorine do not interact, but in the presence of even small quantities of nitrosyl fluoride under the same conditions nearly quantitative yields of trifluoromethyl hypofluorite are formed[10]. The catalytic action of nitrosyl fluoride is attributed to the ease of its addition to the carbonyl bond:

$$COF_2 + NOF \rightleftarrows CF_3ONO$$
$$CF_3ONO + F_2 \rightarrow CF_3OF + NOF .$$

Because the addition of fluorine at the carbonyl bond is so strongly exothermic, catalysis by fluorides of metals of variable valency is in effect limited to the preparation of trifluoromethyl hypofluorite. Since this product has high thermal stability, it can be prepared not only from carbonyl difluoride but also from such compounds as carbon monoxide [24,26], carbon dioxide[26,27], carbonyl dichloride, and methanol† [11,26]. In all the above cases silver fluoride deposited on copper catalyses the formation of both intermediate and final products:

$$CO + F_2 \xrightarrow{cat.} COF_2$$
$$COF_2 + F_2 \xrightarrow{cat.} CF_3OF .$$

Caesium fluoride, which is incapable of sorbing fluorine and carbon monoxide, plays no part at the stage of formation of carbonyl difluoride[24]. Copper fluoride has a weak catalytic effect on both stages. The fluorination of carbon dioxide to trifluoromethyl hypofluorite in the presence of silver fluoride (or difluoride) is a complicated degradative process accompanied by the evolution of oxygen and other products. In the presence of the more active caesium fluoride, however, carbon dioxide is smoothly converted into difluoromethylene bishypofluorite[11,28–30]:

$$CO_2 + 2F_2 \xrightarrow{CsF} CF_2(OF)_2 .$$

† The fluorination of methanol probably involves intermediate formation of carbonyl difluoride.

The high yield of this product and the possibility of obtaining it from fluoroformyl hypofluorite[13]

$$FC(=O)OF + F_2 \xrightarrow{CsF} CF_2(OF)_2$$

suggest that the activation of carbon dioxide by the catalyst is analogous to that of an acyl fluoride or hexafluoroacetone[12]:

$$O{=}C{=}O + CsF \rightleftarrows [O{=}CF\bar{O}\overset{+}{C}s] \xrightarrow{F_2} FC(=O)OF + CsF$$
$$(CF_3)_2C{=}O + CsF \rightleftarrows (CF_3)_2CF\bar{O}\overset{+}{C}s \xrightarrow{F_2} (CF_3)_2CFOF + CsF .$$

Despite unsuccessful attempts to isolate the intermediate fluoroformyl hypofluorite, it is difficult to imagine a different reaction path for carbon dioxide and fluorine in the presence of caesium fluoride.

Non-catalytic methods for the preparation of hypofluorites can be divided into gas-phase, liquid-phase, and solid-phase according to the state of aggregation of the substances to be fluorinated. The first group has been used primarily to obtain trifluoromethyl hypofluorite by the fluorination of carbon monoxide, carbon dioxide, or carbonyl difluoride. The other two groups are suitable with certain limitations for obtaining higher perfluoroalkyl hypofluorites.

In the absence of a catalyst carbon monoxide and fluorine react smoothly at 300–400 °C.[31] A good yield of trifluoromethyl hypofluorite is achieved by the use of two reaction vessels connected in series, the first of which serves for the formation of carbonyl difluoride.

Carbon dioxide reacts with fluorine at 200–300 °C:[32]

$$CO_2 + F_2 \rightarrow CF_3OF + {}^1/_2O_2$$

The reaction is autocatalytic, presumably with regeneration of the fluorooxy-radical OF. Above 350 °C oxygen is accompanied by other products, which have not been identified. In the photochemically initiated reaction detailed investigation[33–35] has revealed the formation of the primary active radicals $O:C(O\dot{F})$ and $O:CF.\dot{O}$. The same radicals probably occur as intermediates in the thermal process.

Ultraviolet irradiation of a mixture of carbonyl difluoride and fluorine gives an approximately 80% yield of trifluoromethyl hypofluorite[36]:

$$F_2 + h\nu \rightarrow 2\dot{F}$$
$$\dot{F} + COF_2 \rightarrow CF_3\dot{O}$$
$$CF_3\dot{O} + F_2 \rightarrow CF_3O\dot{F} + F$$
$$2CF_3\dot{O} \rightarrow CF_3OOCF_3 .$$

The mechanism of this reaction has recently been reinterpreted[37]

$$F_2 + h\nu \rightarrow 2\dot{F}$$
$$\dot{F} + COF_2 \rightarrow \dot{C}F_2OF$$
$$2\dot{C}F_2OF \rightarrow (CF_2OF)_2^*$$

$$(CF_2OF)_2^* \xrightarrow[\text{conversion}]{\text{internal}} (CF_2OF)_2$$
$$(CF_2OF)_2^* \xrightarrow{\text{walls}} CF_3OF + COF_2$$
$$(CF_2OF)_2^* + COF_2 \rightarrow (CF_3O)_2 + COF_2$$
$$(CF_2OF)_2 + F_2 \rightarrow 2CF_3OF$$
$$F \xrightarrow{\text{walls}} {}^1/_2F_2$$

but this is not convincing. In contrast to the photoprocess the thermally initiated reaction is reversible, with equilibrium displaced towards formation of trifluoromethyl hypofluorite below 250 °C.[38]

Among the above methods the fluorination of carbon monoxide has the greatest preparative value. Its advantages consist in comparatively simple apparatus, high purity of the final product (especially in the presence of caesium fluoride),

and the ready availability of carbon monoxide. Among other gas-phase reactions, in which trifluoromethyl hypofluorite has been isolated as a by-product, we may note the ultraviolet-initiated fluorination of hexafluoroacetone[39] and the interaction of chlorotrifluoroethylene with nitrogen fluoride oxide[40], tetrafluoroethylene with dioxygen difluoride[41], and tetrafluoromethane with oxygen under the influence of γ-rays[42]. The formation of trifluoromethyl hypofluorite from methane or fluoroform and oxygen difluoride[43] is of some interest.

In the liquid-phase and solid-phase fluorination of organic compounds hypofluorites have been obtained by treating the starting material with fluorine in a static or flow-type reaction vessel at temperatures between 20° and −78 °C. The fluorine should be diluted with an inert gas; its concentration must be raised from 5–10% at the start of the experiment to 20–50% at the end. The interest taken by research workers in these methods is indicated by examples in which hypofluorites have been obtained from trichloro- and trifluoroethanol, hexafluoroacetone hydrate, trichloronitropropan-2-ol, perfluoro-t-butyl alcohol[44–48], trichloroacetic esters[49], higher polyfluorinated alcohols, salts of trifluoroacetic, oxalic, and higher perfluorinated acids[46,48,50–52], trifluoroacetyl nitrate[45,46], and other compounds[53,54]. Nevertheless, they are ineffective as methods of preparation.

The chief defects of these methods are lack of selectivity and low yields. For example, the sodium salt of hexafluoroacetone hydrate gives four different hypofluorites[45]:

$$(CF_3)_2C\begin{matrix}OH\\ONa\end{matrix} \xrightarrow{F_2,N_2} (CF_3)_2CFOF + (CF_3)_2C(OF)_2 + CF_3CF(OF)_2 + C_2F_5OF\ .$$

Three hypofluorites are formed from sodium trifluoroacetate[50]:

$$CF_3C\begin{matrix}O\\ONa\end{matrix} \xrightarrow{F_2,N_2} CF_2(OF)_2 + C_2F_5OF + CF_3CF(OF)_2\ .$$

Hexafluoroacetone hydrate, in contrast to the sodium salt, gives heptafluoroisopropyl hypofluorite and a large number of by-products[44]:

$$(CF_3)_2C(OH)_2 \xrightarrow{F_2,N_2} (CF_3)_2CFOF + CF_3COF + CF_4 + C_2F_6 + COF_2 + CO_2\ .$$

Trifluoroethanol and trifluoroacetyl nitrite are converted into pentafluoroethyl hypofluorite in at most 20% yield. Under mild conditions sodium oxalate gives difluoromethylene bishypofluorite[55], but with rise in temperature trifluoromethyl hypofluorite and peroxide are obtained[51]:

$$(COONa)_2 \begin{matrix}\xrightarrow{21°C} CF_2(OF)_2\\ \xrightarrow{84°C} CF_3OF + CF_3OOCF_3\end{matrix}\ .$$

Highly selective fluorination occurs only with perfluoro-t-butyl alcohol, which it is advisable to use in the form of an alkoxide[47]:

$$(CF_3)_3CONa \xrightarrow{F_2,N_2} (CF_3)_3COF\ .$$

Attempts have been made to use oxygen difluoride to introduce a fluorooxy-group into an organofluorine molecule. On ultraviolet irradiation, a mixture of dichlorotetrafluoroacetone and the difluoride gives mainly chlorodifluoromethyl hypofluorite[56]. When perfluoroalkenes are treated with the difluoride to obtain the oxides[57], trifluoromethyl and other hypofluorites are formed as by-products.

It has recently been shown that it is fundamentally possible to prepare trifluoromethyl hypofluorite by the electrochemical fluorination of carbon monoxide, carbonyl dichloride and difluoride[58–60], and more complicated compounds[61], but the yields are appreciably inferior to those of chemical fluorination.

2. Hypochlorites

Initial compounds investigated for the catalytic preparation of organofluorine hypofluorites have been carbonyl difluoride[2,62–69], perfluoroacyl fluorides[65,69–73], and perfluoroketones[69–73], with as catalysts potassium, rubidium, and caesium fluorides[2,67,69,70,72], hydrofluoric acid and Lewis acids [boron(III), arsenic(III), arsenic (V), and antimony(V) fluorides][65,66,71,73], nitrosyl fluoride[10,66,71], magnesium fluoride, and fluorinated aluminium oxide[62,68,74]. The first three types of catalysts possess a wide spectrum of action; magnesium fluoride and alumina have been tested only in the chlorofluorination of carbonyl difluoride.

The reaction of carbonyl difluoride with chlorine monofluoride yields trifluoromethyl hypochlorite:

$$COF_2 + ClF \xrightarrow{cat.} CF_3OCl\ .$$

Perfluorinated acyl fluorides and ketones give higher perfluoroalkyl hypochlorites:

$$R_FCOF \xrightarrow{cat.} R_FCF_2OCl$$
$$(R_F)_2CO \xrightarrow{cat.} (R_F)_2CFOCl\ .$$

Catalysis by alkali-metal fluorides is essentially the same as in the preparation of hypofluorites[73]. Owing to the polarity of chlorine monofluoride[75], however, the second stage—attack on the anionoid centre of the alkoxide—is considerably facilitated in comparison with fluorine:

$$R_F-\bar{O}\ ,\ Cs^+ \quad + \quad Cl^{\delta+}\ ,\ F^{\delta-} \rightarrow R_FOCl + CsF\ .$$

This is confirmed by the great selectivity, the mild conditions, and the nearly theoretical yields of hypochlorites.

The effect of polarisation of chlorine monofluoride in the ground state is clearly illustrated by the absence of reaction with carbon dioxide[70]:

$$CO_2 + 2ClF \xrightarrow{CsF} CF_2(OCl)_2\ .$$

A possible reason for the negative result is that the monofluoride (dipole moment 0.88 *D*) is removed from the reaction zone, by forming with the catalyst a complex—caesium difluorochlorate $Cs^+Cl^-F_2$—that is inert towards carbon dioxide[76].

On passing from alkali-metal fluorides to acids the action of the catalyst is directed at chlorine monofluoride. With catalysis by hydrogen fluoride as example it is assumed[73] that activation increases the positive charge on the chlorine atom by protonation:

$$\overset{\delta+\ \delta-}{Cl-F} + H-F \rightarrow \overset{+}{Cl}-\overset{\sim}{F\cdots H\cdots F}\ .$$

This is followed by electrophilic attack on the carbonyl oxygen and stabilisation of the carbocation:

$$\rangle C{=}O + \overset{+}{Cl}-\tilde{F}\cdots H\cdots F \longrightarrow \left[\rangle \overset{+}{C}-OCl\right]\cdot H\bar{F}_2 \longrightarrow \rangle CFOCl + HF\ .$$

In the case of catalysis by boron, arsenic, and especially antimony fluorides the reaction velocity is increased by their tendency to give onium complexes with donors of the fluoride ion, e.g. chloronium hexafluoroantimonate $Cl^+SbF_6^-$.[77]

Nitrosyl fluoride is a homogeneous catalyst in the formation of hypochlorites. As noted above it forms covalent adducts (nitrites) with carbonyl compounds. The ability of such nitrites to be converted into hypochlorite derivatives under the influence of chlorine monofluoride is shown by the

example of perfluoroisopropyl nitrite[10]:

$$(CF_3)_2CONO + ClF \rightarrow (CF_3)_2CFOCl + NOF .$$

It is significant that nitrosyl fluoride not only has a direct catalytic effect but also confers catalytic properties on the surfaces of the reaction vessels: trifluoromethyl hypochlorite is formed no less smoothly in stainless-steel and polychlorotrifluoroethylene reaction vessels that have been treated with nitrosyl fluoride and then evacuated than in the presence of nitrosyl fluoride as catalyst[10,71]. The nature of the activation is unknown, although it is undoubtedly connected with the high sorbability of nitrosyl fluoride.

"Fluorinated aluminium oxide" is a catalyst distinguished by a highly developed specific surface. It is prepared by treating γ-alumina with chlorine trifluoride[62,68,74]. In its presence trifluoromethyl hypochlorite can be obtained from carbonyl difluoride and chlorine trifluoride, although the product is contaminated with tetrafluoromethane and chloryl fluoride[74,78]:

$$COF_2 + ClF_3 \xrightarrow{cat.} [CF_3OClF_2] \xrightarrow{COF_2} CF_3OCl + CF_4 + FClO_2 .$$

Non-catalytic methods for obtaining hypochlorites use hydroxy-compounds—alcohols and ketone hydrates—as starting materials[72,79-82]. *O*-Chlorination is characterised by great selectivity, which enables hydrogen, alkyl, and aryl derivatives to be employed:

$$X(CF_3)_2C{-}OH \xrightarrow[-HF]{ClF} X(CF_3)_2C{-}OCl$$
$$X = H,\ CH_3,\ Ar,\ CF_3 .$$

A bishypochlorite can be obtained from hexafluoroacetone hydrate[72]:

$$(CF_3)_2C(OH)_2 \xrightarrow{2ClF} (CF_3)_2C(OCl)_2 .$$

However, an attempt to apply the reaction to perfluoropinacol was unsuccessful[79]:

$$(CF_3)_2C(OH){-}C(OH)(CF_3)_2 \xrightarrow{2ClF} (CF_3)_2C(OCl){-}C(OCl)(CF_3)_2 .$$

3. Organofluorine Halogenoperoxides

As with the hypohalites, catalytic methods are of the greatest interest for obtaining organofluorine halogenoperoxides. In the presence of caesium fluoride carbonyl and oxygen difluorides readily interact to give a good yield of trifluoromethyl fluoroperoxide[83,84]:

$$COF_2 + OF_2 \xrightarrow{CsF} CF_3OOF .$$

The mechanism is similar to that discussed above for the hypohalites[85].

The mechanism of the formation of trifluoromethyl fluoroperoxide from the hydroperoxide

$$CF_3OOH \xrightarrow{CsF,F_2} CF_3OOF$$

is not entirely clear[86]. Possibly caesium fluoride activates the hydroperoxide by forming the hydrogen bond $CF_3OOH...F^-Cs^+$, which facilitates subsequent attack by the halogen. This view is suggested by the ease with which the same hydroperoxide is converted into the ClO-derivative by chlorine monofluoride in the presence of sodium fluoride[87]:

$$CF_3OO{-}H{\cdots}F{-}Na \cdots Cl{-}F \xrightarrow{-110^\circ C} CF_3OOCl + NaF \cdot HF .$$

According to patent claims[88,89] this is a general method for the production of organofluorine chloroperoxides.

Other methods are the reaction of fluoroalkenes with dioxygen difluoride, demonstrated with hexafluoropropene as example[90,91], and the fluorination of salts of perfluoro-acids, in particular sodium trifluoroacetate[52]:

$$CF_3CF{=}CF_2 + O_2F_2 \xrightarrow{-183^\circ C} \underset{(75\%)}{CF_3CF(OOF)CF_3} + \underset{(25\%)}{CF_3CF_2CF_2OOF}$$
$$CF_3C(=O)ONa + F_2 \rightarrow CF_3OOF + C_2F_5OOF .$$

Because of possible ambiguity in the results very little preparative value attaches to these reaction.

III. PHYSICAL PROPERTIES AND STRUCTURE

Under ordinary conditions the great majority of hypofluorites obtained hitherto are gases having the characteristic odour of fluorine. In relation to physical properties, spectra, and structure the most fully studied of this group is trifluoromethyl hypofluorite. At −95 °C it condenses into a colourless liquid of density 1.9 g cm^{-3}. The heat of evaporation, the standard heat of formation from the elements, and the Trouton constant are respectively 3710 cal $mole^{-1}$, −181.5 kcal $mole^{-1}$, and 20.8.[4] The energy of the oxygen–fluorine bond has been estimated as 43.5 ± 0.5 kcal $mole^{-1}$,[92] and its refraction is 3.89.[93] Components of the dipole moment have been found from data on the rotational spectrum[94]. This compound does not solidify at −215 °C.

The boiling point rises as fluorine atoms in the trifluoromethyl group are replaced by other atoms or groups. For example, chlorodifluoromethyl[56] and dichlorofluoromethyl hypofluorites boil at −25 and 0 °C respectively.

Difluoromethylene bishypofluorite boils at −64 °C. When placed in liquid nitrogen, it is converted into a transparent vitreous material[28]#. The heat of evaporation is 4445 cal $mole^{-1}$, and the standard heat of formation −130.5 kcal $mole^{-1}$. The vapour pressure curve can be calculated by means of the equation[55]§

$$\lg p = 7.530 - 971.6/T .$$

The energy of the oxygen–fluorine bond has not been accurately determined, but is most probably less than in trifluoromethyl hypofluorite.

Among perfluoroalkyl hypochlorites only the first two—trifluoromethyl and pentafluoroethyl—are gaseous under ordinary conditions. The higher hypochlorites are colourless or slightly yellowish liquids. Trifluoromethyl hypochlorite boils at −45.8 [69] or −47 °C,[70] and solidifies at −164 °C.[70] The heat of vaporisation is 4684 [70] or 5090 [69] cal $mole^{-1}$, and the Trouton constant 20.7 [70] or 22.4.[69] The temperature dependence of the vapour pressure between −131 and −54 °C is given by the equation[70]

$$\lg p = 7.413 - 1025/T .$$

The corresponding physical constants for pentafluoroethyl and heptafluoroisopropyl hypochlorites will be found in Refs. 69 and 70.

Some idea of the physical properties of the halogenoperoxides is given by published data on trifluoromethyl fluoroperoxide[86] and chloroperoxide[87]. The former condenses at

---

Another worker[30] obtained a viscous liquid.

§ Here and subsequently *p* represents pressure in mmHg, and *T* K is the temperature.

−69.4 °C to a colourless transparent liquid of density 1.65 g cm^{-3}. The heat of vaporisation is 4360 cal mol^{-1}, and the vapour density equation between −117 and −70 °C is

$$\lg p = 6.8764 - 673.9/T - 28442/T^2 .$$

This peroxide does not solidify in liquid nitrogen. Trifluoromethyl chloroperoxide boils at −22 °C , and its melting point is −132 °C. Other constants for this compound can be found in Ref. 87.

The infrared spectrum of trifluoromethyl hypofluorite contains 12 fundamental absorption bands, among which that in the region of 945 cm^{-1} corresponds to oxygen–fluorine stretching vibrations[95–97]. The molecule has C_S symmetry and is a somewhat distorted tetrahedron. Bond lengths and angles are

C—F 1.319±0.003 Å; C—O 1.395±0.006 Å; O—F 1.421±0.006 Å;

∠FCF 109.4±1°; ∠COF 104.8±0.6°[98, 99].

For analysis of the infrared spectra in terms of absorption by carbon–fluorine bonds see Ref. 100. The infrared spectrum of difluoromethylene bishypofluorite contains 15 main bands, 2 of which in the region of 916 and 933 cm^{-1} have been assigned to absorption by the hypofluorite group (stretching vibrations)[101]. This molecule has C_{2v} symmetry.

Detailed analysis of the infrared spectra of hypofluorites has established that electron-accepting substituents (difluoroamino, nitro, trifluoromethyl)[8] shift the band due absorption by FO-groups to lower wavenumbers, in the limit to 882 cm^{-1}. It is interesting that in the Raman spectrum of trifluoromethyl hypofluorite the ν(O–F) band is more intense than the ν(C–O) band, whereas the opposite relation applies in the infrared spectrum[102]. This was attributed[102] to the more covalent character of the oxygen–fluorine than of the carbon–oxygen bond.

The many papers on the fluorine-19 magnetic resonance spectra of hypofluorites[10,11,28,29,44,45,55,103–105] have established the most important fact of a considerable down-field shift in the fluorine lines due to FO-groups (140–160 ppm relative to the standard fluorochloroform), which indicates a decrease in electron density on the fluorine atom. This should tend to increase the energy of the carbon–oxygen bond in hypofluorites. Indeed, mass-spectrometric measurements of the ionisation of trifluoromethyl hypofluorite[106] and calorimetric determinations on difluoromethylene bishypofluorite[107] show that the energy of this bond exceeds on the average by 10–15 kcal $mole^{-1}$ those in hydrocarbon derivatives of similar structure (alcohol, ethers). Further support is provided by PPDP/2 quantum-chemical calculations on the trifluoromethyl hypofluorite molecule[108].

Investigations have been published[69,70,86,87] on the infrared and nuclear magnetic resonance spectra of organofluorine hypochlorites and halogenoperoxides.

IV. CHEMICAL PROPERTIES

The reactivity of organofluorine hypohalites and halogenoperoxides is determined by the tendency to rupture of the oxygen–halogen bond, the weakest in the molecule. Because of the relatively low energy of rupture of this bond, radical processes are most typical of these two groups of compounds. However, in conformity with the diminished electron density on the halogen atom, the hypofluorites also undergo heterolytic reactions, in which they act as electrophiles.

The highly exothermic character of processes involving these two groups of compounds often leads to the formation of a relatively large number of by-products from direct decomposition of these compounds, interaction of the substrate with the decomposition products, rearrangements, etc. The following discussion of thermolysis and photolysis reveals several views on such reactions.

1. Thermolysis

Trifluoromethyl hypofluorite and difluoromethylene bishypofluorite are thermally the most stable among organofluorine hypofluorites. In an enclosed space the former begins to decompose at ~200 °C, and the rate becomes appreciable above 250 °C. In an already passivated nickel reaction vessel reversible decomposition takes place[109]:

$$CF_3OF \rightleftarrows COF_2 + F_2 .$$

Furthermore, small quantities of trifluoromethyl peroxide are formed. Above 400 °C decomposition becomes irreversible owing to interaction of fluorine with the material of the vessel. Degradation of trifluoromethyl hypofluorite in a cold-glow electrical discharge (quartz vessel) yields tetrafluoromethane, carbon dioxide, oxygen, and silicon tetrafluoride, whereas in a metal vessel the first two products are accompanied by carbonyl difluoride and fluorine[109]. Degradation is retarded by additions of carbonyl difluoride to the hypofluorite.

Difluoromethylene bishypofluorite does not decompose at 150 °C for several hours; at 250 °C after 3 h it is possible to recover 40% of the initial compound. Such slow thermal decomposition is described by the equation[55]

$$CF_2(OF)_2 \xrightarrow{\Delta} COF_2 + {}^1/_2O_2 + F_2 .$$

Under explosive conditions[107] a more complicated mixture is formed:

$$CF_2(OF)_2 \xrightarrow{\text{explosion}} COF_2 + CF_3OF + CF_3OOCF_3 + CF_3OOF + CF_4 .$$

Another stable member of this group is tetrafluoroethylidene bishypofluorite, which at 150 °C is only 5% decomposed after 6.5 h:[45]

$$CF_3CF(OF)_2 \begin{cases} \xrightarrow{\Delta} CF_4 + COF_2 + {}^1/_2O_2 \\ \xrightarrow{\Delta SiO_2} CO_2 + {}^1/_2O_2 + {}^3/_2SiF_4 . \end{cases}$$

Higher perfluoroalkyl hypofluorites are less stable. The decomposition products depend on the structure of the alkyl group: primary derivatives give alkanes and carbonyl difluoride, secondary yield alkanes and acyl fluorides, and tertiary form alkanes and ketones[44]—e.g.

$$CF_3CF_2OF \xrightarrow{\Delta} CF_4 + COF_2$$

$$(CF_3)_2CFOF \xrightarrow{\Delta} CF_4 + CF_3C(=O)F$$

$$(CF_3)_3COF \xrightarrow{\Delta} CF_4 + (CF_3)_2CO .$$

The tendency to form alkanes is due to stabilisation of intermediate alkoxy-radicals by homolytic fission of a carbon–carbon bond:

$$CF_3CF_2OF \xrightarrow{\Delta} CF_3CF_2\dot{O} + F$$

$$CF_3CF_2\dot{O} \rightarrow \dot{C}F_3 + COF_2$$

$$CF_3CF_2OF + \dot{C}F_3 \rightarrow CF_4 + CF_3CF_2\dot{O} \quad \text{etc.}$$

Thermal breakdown of higher perfluoroalkyl hypofluorites is evidently a chain process, in which the presence of traces of hydrocarbons, e.g. methane, may have a similar effect to heating[44]:

$$CF_3CF_2OF + CH_4 \rightarrow HF + \dot{C}H_3 + CF_3CF_2\dot{O}$$

$$CF_3CF_2\dot{O} \rightarrow \dot{C}F_3 + COF_2 \quad \text{etc.}$$

This indicates that hypofluorites are potentially explosive, and requires that appropriate precautions should be observed when working with them.

Perfluoroalkyl hypochlorites are considerably inferior to the corresponding hypofluorites in thermal stability. For example, trifluoromethyl hypochlorite decomposes completely when heated to 165 °C:[69]

$$CF_3OCl \xrightarrow{\Delta} CF_3\dot{O} + \dot{Cl}$$
$$CF_3OCl + \dot{Cl} \rightarrow Cl_2 + CF_3\dot{O}$$
$$2CF_3\dot{O} \rightarrow CF_3OOCF_3$$
$$CF_3\dot{O} \rightarrow COF_2 + F \cdot$$

Products of the thermal breakdown of pentafluoroethyl hypochlorite under still milder conditions are carbonyl difluoride, trifluoroacetyl fluoride, chlorotrifluoromethane, chlorine, and chlorine monofluoride. The thermal stability of the hypochlorites diminishes in the sequence

$$CF_3OCl > C_2F_5OCl > (CF_3)_3COCl \geqslant (CF_3)_2CFOCl.$$

Hydrogen- and alkyl-containing hypochlorites are stable only at room or slightly higher temperatures. Their thermal decomposition yields polyfluorinated derivatives: e.g.

$$CH_3C(CF_3)_2OCl \begin{cases} \rightarrow CF_3COCH_3 + CF_3Cl \\ \not\rightarrow CF_3COCF_3 + CH_3Cl \cdot \end{cases}$$

The relatively high stability of organofluorine halogenoperoxides is somewhat unexpected: trifluoromethyl fluoroperoxide and chloroperoxide can be kept at room temperature for a long time[86,87]. Heating the halogenoperoxide vapours to 100 °C is accompanied by decomposition:

$$CF_3OOF \xrightarrow{\Delta} CF_4 + O_2$$
$$CF_3OOCl \xrightarrow{\Delta, SiO_2} COF_2 + CO_2 + SiF_4 + FClO_2 \cdot$$

2. Photolysis

The character of the breakdown products resulting from the ultraviolet irradiation of organofluorine hypohalites and halogenoperoxides depends on the conditions. Gaseous trifluoromethyl hypofluorite gives a low yield of trifluoromethyl peroxide[36]. Photolysis in an argon matrix[110] (with $\lambda < 400$ nm at 8 K, followed by infrared analysis of the products) yields only carbonyl difluoride. Monitoring photolysis of the hypofluorite by electron spin resonance (e.s.r.) (at −196 °C, mixed with nitrogen trifluoride or carbon tetrafluoride) revealed the peroxy-radical $CF_3O\dot{O}$, whose formation was attributed to the presence of traces of oxygen[111]. Intermediate formation of the radical $CF_3OO\dot{O}$ has been explained[112] by photosensitised oxidation of carbon monoxide to the dioxide on ultraviolet exposure of a mixture of the hypofluorite with the monoxide and oxygen. The quantum yield of carbon dioxide is ~10^4 molecules.

Photodecomposition of trifluoromethyl hypochlorite at room temperature gives a high yield (91%) of trifluoromethyl peroxide, and has been proposed as a method of preparation of the latter[69]:

$$2CF_3OCl \xrightarrow{h\nu} CF_3OOCF_3 + Cl_2 \cdot$$

In an argon matrix ($\lambda < 280$ nm), however, breakdown of the hypochlorite is more complicated[110]:

$$CF_3OCl \xrightarrow{8K, h\nu} CF_3OOCF_3 + CF_3OF + COF_2 + COFCl \cdot$$

In relation to the photodecomposition of organofluorine halogenoperoxides it is known that they serve as sources of perfluoroalkylperoxy-radicals, the products of whose further breakdown depend on the nature of the initial compound[87,113]:

$$CF_3OOF \xrightarrow{h\nu} CF_3O\dot{O} + \dot{F} \rightarrow CF_4 + O_2$$
$$CF_3OOCl \xrightarrow{h\nu} CF_3O\dot{O} + ClO_2 + O_2 \cdot$$

3. Reactions with Inorganic Compounds

Perfluoroalkyl hypofluorites display both fluorinating and oxidising properties towards inorganic compounds. Their fluorinating power is somewhat weaker than that of elementary fluorine; nevertheless, they can replace the latter in many reactions.

Water hydrolyses hypofluorites considerably more slowly than perfluoroacyl fluorides[6]. They react with aqueous alkalis to form perfluorocarboxylates and oxygen[11,44,45]; a *gem*-bishypofluorite yields the carbonate[55]:

$$R_FCF_2OF + 4NaOH \rightarrow R_FCOONa + 3NaF + 2H_2O + {}^1/_2O_2$$
$$CF_2(OF)_2 + 6NaOH \rightarrow Na_2CO_3 + 4NaF + 3H_2O + O_2 \cdot$$

Very dilute aqueous alkalis resemble water in their hydrolytic action. Recommendations[92] for the purification of trifluoromethylhypofluorite from traces of carbonyl difluoride are based on this property.

Like elementary fluorine, hypofluorites readily react with dry alkali-metal halides on being heated, with evolution of the corresponding halogens[6]:

$$CF_3OF + 2NaCl \rightarrow COF_2 + 2NaF + Cl_2 \cdot$$

The redox reaction with aqueous potassium iodide

$$CF_3CF_2OF + 2KI + H_2O \rightarrow CF_3COOK + I_2 + KHF_2$$

has been proposed[6,44,45] for the detection and determination of fluorooxy-groups.

Hypofluorites withstand the action of strong inorganic acids. For example, perfluoro-t-butyl hypofluorite is only 5% decomposed after contact with 98% sulphuric acid for 2 h.[44]

Dry quartz and Pyrex glass do not react with trifluoromethyl hypofluorite at room temperature[6]. Copper, nickel, and stainless steel begin to react only when strongly heated[6]. Alkali metals and mercury interact with hypofluorites on simple contact[114]. In the presence of mercury decomposition is a radical process[44]:

$$(CF_3)_3COF + Hg \rightarrow (CF_3)_3C\dot{O} + {}^1/_2HgF_2$$
$$(CF_3)_3C\dot{O} \rightarrow (CF_3)_2CO + \dot{C}F_3$$
$$(CF_3)_3COF + \dot{C}F_3 \rightarrow (CF_3)_3C\dot{O} + CF_4 \quad \text{etc.}$$

Interaction with ferrocene occurs similarly. Because of the change in colour this reaction can be used to detect fluorooxy-groups[44]:

$$CF_3CF_2OF + 2Fe(C_5H_5)_2 \rightarrow CF_3COF + 2\dot{F}\dot{F}e(C_5H_5)_2 \cdot$$
(orange) (dark blue)

In the absence of impurities trifluoromethyl hypofluorite does not react with hydrogen at room temperature, but a reaction giving carbonyl difluoride and hydrogen fluoride can be initiated by copper powder[6]. The most significant example of the great fluorinating power of this hypofluorite is its reaction with xenon to form the difluoride[115]:

$$2CF_3OF + Xe \xrightarrow{250^\circ C} XeF_2 + CF_3OOCF_3 \cdot$$

The reactions of trifluoromethyl hypofluorite with sulphur and nitrogen derivatives are important. At 0 °C elementary sulphur forms mainly the tetrafluoride, disulphur difluoride, and carbonyl difluoride, presumably contaminated with the unstable trifluoromethyl fluorothiosulphite and bistrifluoromethyl thiosulphite[116]. Addition at the carbon–sulphur multiple bond is observed with thiocarbonyl dichloride[116], when one of the addition products could not be isolated in the free state:

$$Cl_2C{=}S \xrightarrow[-78^\circ C]{CF_3OF} \begin{cases} \rightarrow Cl_2CF{-}S{-}OCF_3 \\ \rightarrow [Cl_2C(OCF_3){-}SF] \xrightarrow{2CF_3OF} SF_4 + COF_2 + CF_3OCFCl_2 \cdot \end{cases}$$

The less reactive carbonyl sulphide reacts with trifluoromethyl hypofluorite to form bistrifluoromethyl sulphite and carbonate together with trifluoromethyl fluoroformate[116]. Electron spin resonance has established[117] that the radicals $(CF_3O)_2S^{\cdot}COOCF_3$ and $(CF_3O)_2S^{\cdot}COF$ are formed as active intermediate species.

Radical reactions include also those of trifluoromethyl hypofluorite with sulphur dioxide and tridoxide and with sulphur tetrafluoride. When heated to 175–185 °C sulphur dioxide is converted into a complicated mixture in which trifluoromethyl fluorosulphate and fluoropyrosulphate have been identified together with bistrifluoromethyl sulphate and pyrosulphate[118].

The reaction with sulphur trioxide is more unambiguous:

$$CF_3OF + SO_3 \rightarrow CF_3OOSO_2F \ .$$

Even in this case, however, trifluoromethyl and fluorosulphonyl peroxides have been isolated among the by-products. Detailed investigations indicate[92] that the reaction mechanism involves the primary stages

$$CF_3OF \rightleftarrows CF_3\dot{O} + \dot{F}$$
$$SO_3 + \dot{F} \rightarrow \dot{S}O_3F$$
$$2\dot{S}O_3F \rightleftarrows FSO_2OOSO_2F$$
$$CF_3\dot{O} + \dot{S}O_3F \rightarrow CF_3OOSO_2F$$
$$2CF_3\dot{O} \rightarrow CF_3OOCF_3 \ .$$

Reaction with sulphur tetrafluoride involves intermediate formation[119,120] of the radical $CF_3OS^{\cdot}F_4$, which under thermal conditions[121] abstracts a fluorine atom from the hypofluorite:

$$CF_3OSF_4 + CF_3OF \rightarrow CF_3OSF_5 + CF_3\dot{O} \ .$$

Ultraviolet exposure produces also bistrifluoromethyl tetrafluorodioxosulphate, in 10% yield[122]. It is significant that the reaction with sulphur tetrafluoride depends appreciably on the presence of particular impurities. For example, dissolved oxygen may be responsible for the formation of peroxy-compounds, and tetrafluorohydrazine for *NN*-difluoroamidosulphates[123]:

$$CF_3O\dot{S}F_4 + O_2 \rightarrow CF_3OSF_4O\dot{O} \xrightarrow{CF_3O\dot{S}F_4} CF_3OSF_4OOSF_4OCF_3$$
$$CF_3O\dot{S}F_4 + N_2F_4 \rightarrow CF_3OSF_4NF_2 + \dot{N}F_2 \ .$$

As a consequence of the ease of fission of the nitrogen–nitrogen bond tetrafluorohydrazine causes decomposition of trifluoromethyl hypofluorite even in the dark at room temperature[124]:

$$CF_3OF + NF_2 \rightleftarrows N_2F_4 \begin{cases} \rightarrow COF_2 + NF_3 \\ \rightarrow NOF + NF_3 + CF_4 \end{cases} .$$

For a similar reason the hypofluorite breaks down in the presence of nitrogen dioxide[125]:

$$CF_3OF + NO_2 \rightleftarrows FONO + CF_3\dot{O} \quad (N_2O_4)$$
$$CF_3\dot{O} + NO_2 \rightarrow FONO + COF_2; \quad FONO \rightarrow FNO_2 \ .$$

However, ultraviolet initiation yields *NN*-difluoro-*O*-trifluoromethylhydroxylamine[124,126–128]:

$$CF_3OF + N_2F_4 \xrightarrow{h\nu} CF_3ONF_2 + NF_3 \ .$$

Formation of similar derivatives from difluoroamine and difluoromethylene bishypofluorite[129] is a heterogeneous process involving an alkali-metal fluoride:

$$CF_2(OF)_2 + HNF_2 \xrightarrow{KF} CF_2(ONF_2)OF + CF_2(ONF_2)_2 \ .$$

Perfluoro-t-butyl hypofluorite reacts with tetrafluorohydrazine in perfluoropentane on ultraviolet irradiation to form a peroxide and nitrogen trifluoride by homolysis of the oxygen–fluorine bond[130]:

$$2(CF_3)_3COF + N_2F_4 \xrightarrow[-60°C]{h\nu} (CF_3)_3COOC(CF_3)_3 + NF_3 \ .$$

It has been stated[131] that the bond undergoes heterolytic fission in the absence of a solvent and radiation, to give a hydrazinium salt as a crystalline adduct:

$$(CF_3)_3COF + N_2F_4 \rightarrow (CF_3)_3C\overset{+}{O}\overset{+}{N}_2F_5 \ .$$

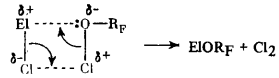
However, this has proved incorrect[247].

Perfluoroalkyl hypochlorites also exhibit strong polarisation of the oxygen–halogen bond and a tendency to undergo electrophilic processes. For example, they are very readily hydrolysed by water, with the rate of hydrolysis decreasing in the sequence[79]

$$(CF_3)_3COCl > CH_3C(CF_3)_2OCl > (CF_3)_2CHOCl > CF_3CH_2OCl \gg (CH_3)_3COCl \ .$$

Hypochlorites react smoothly with sulphur dioxide to form the corresponding alkyl chlorosulphates in theoretical yield[132,133]:

$$R_FOCl + SO_2 \xrightarrow{-20°C} R_FOSO_2Cl \ .$$



The reactions of hypochlorites with compounds containing negatively polarised halogen (boron trichloride, phosphorus chlorotetrafluoride, and hydrogen chloride) are probably of ionic type[134–136]:

$$R_FOCl \begin{cases} \xrightarrow{BCl_3} (R_FO)_3B + 2Cl_2 \\ \xrightarrow{PClF_4} R_FOPF_4 + Cl_2 \end{cases} .$$

Among these the reaction of trifluoromethyl hypochlorite with hydrogen chloride is especially interesting, yielding trifluoromethanol (m.p. −82 °C), which was stable up to −20 °C:[136]

$$CF_3OCl + HCl \xrightarrow[-120°C]{} \begin{cases} CF_3OH + Cl_2 \\ COF_2 + HF \end{cases} .$$

From general considerations it may be suggested that in all three cases positive polarisation of the halogen in the hypochlorite and a deficit of electrons in the other reactant result in a cyclic transition state:

El = H, > B, ≫ P

The reactions of hypochlorites with fluorine on heating and with tetrafluorohydrazine on ultraviolet irradiation are of radical type[69]:

$$CF_3OCl \begin{cases} \xrightarrow[65°C]{F_2} CF_3OF + Cl_2 \\ \xrightarrow[h\nu]{N_2F_4} CF_3ONF_2 + Cl_2 \end{cases} .$$

In contrast to certain organofluorine hypohalites, the halogenoperoxides react only by a radical mechanism. With trifluoromethyl fluoroperoxide products resulting from cleavage at oxygen–fluorine and oxygen–oxygen bonds could be isolated depending on the nature of the substrate. The former bond is broken when the fluoroperoxide is treated with nitrogen dioxide[137]:

$$CF_3OOF + N_2O_4 \rightarrow CF_3OONO_2 + FNO_2 \ .$$

The reactions with sulphur dioxide and tetrafluoride involve fission of the peroxy-bond[138]:

$$CF_3OOF + SO_2 \rightarrow CF_3OSO_2F + CF_3OSO_2OSO_2F$$
$$CF_3OOF + SF_4 \rightarrow CF_3OSF_4OCF_3 + CF_3OSF_5 \ .$$

Attempts to bring trifluoromethyl chloroperoxide into reaction with sulphur dioxide[87] and the hypochlorite into reaction with ozone[139] have been unsuccessful.

4. Reactions with Organic Compounds

The considerable literature on the reactions of organofluorine hypohalites and halogenoperoxides with organic derivatives covers addition at the multiple bonds C:O, C:N, and C:C, as well as the fluorination of various saturated compounds.

Among carbonyl derivatives the fullest information has been obtained for the action of the difluoride on trifluoromethyl hypofluorite, leading to formation of trifluoromethyl peroxide[140–146]:

$$CF_3OF + COF_2 \rightleftarrows CF_3OOCF_3 \ .$$

The reactants are heated in a static reaction vessel[142,143] or in the presence of a catalyst in a flow[24,143]. The optimum temperature of the uncatalysed preparation lies in the range 220–275 °C: up to 250 °C the equilibrium is displaced towards formation of the peroxide, and at higher temperatures slow decomposition of the latter begins. As could be expected, the yield is increased by raising the pressure in the system: thus with 100 atm at 275 °C the yield of the peroxide reaches 91%.[142]

Detailed kinetic investigations have been made[140,145–148] on these processes. The rate-determining stage is breakdown of the hypofluorite with cleavage of the oxygen–fluorine bond:

$$\left.\begin{array}{l} CF_3OF \rightarrow CF_3\dot{O} + \dot{F} \quad \text{slow} \\ \dot{F} + COF_2 \rightarrow CF_3\dot{O} \\ 2CF_3\dot{O} \rightarrow CF_3OOCF_3 \end{array}\right\} \text{rapid}$$

The possibility of the catalytic preparation of trifluoromethyl peroxide was discovered when the hypofluorite conterminated with carbonyl difluoride was stored in a steel vessel for a year[143]. Further investigations showed that the reaction is accelerated by the presence of fluorides of silver, copper, nickel, mercury, cobalt, iron[143,144], and caesium[24]. The fact that the peroxide is formed under mild conditions (at room temperature) casts doubt on the suggested[21] radical initiation of the process. In the presence of the most active catalyst (caesium fluoride) the reaction is probably analogous to the formation of trifluoromethyl hypofluorite from carbonyl difluoride and fluorine:

$$COF_2 + CsF \rightarrow CF_3\bar{O}\overset{+}{C}s$$
$$CF_3\bar{O}\overset{+}{C}s + CF_3OF \rightarrow CF_3OOCF_3 + CsF \ .$$

Activation of carbonyl difluoride by the remaining catalysts is probably not a chemisorption process. According to a patent[149] the peroxide can be obtained by the action of chlorine trifluoride on carbonyl difluoride in the presence of a fluoride of an alkali-earth metal, which is a modification of the method based on the action of fluorine on carbonyl difluoride[143].

Difluoromethylene bishypofluorite, unlike trifluoromethyl hypofluorite, does not give normal addition products at the carbonyl bond[150–153]. As a consequence of degradation the main products are bistrifluoromethyl trioxide and trifluoromethyl fluoroperformate:

$$CF_2(OF)_2 + COF_2 \xrightarrow{CsF} CF_3OOOCF_3 + CF_3OOC(O)F \ .$$

The latter compound on cautious hydrolysis gives the hydroperoxide[154]:

$$CF_3OOC(O)F \xrightarrow{H_2O} CF_3OOH \ .$$

The reaction of trifluoromethyl hypofluorite with difluorocarbamoyl fluoride is also anomalous, with formation of *NN*-difluoro-*O*-trifluoromethylhydroxylamine instead of the expected peroxide[155]:

$$NF_2COF + CF_3OF \rightarrow \begin{cases} NF_2OCF_3 \\ NF_2CF_2OOCF_3 \end{cases}$$

The fluorination of perfluoroglutaryl difluoride yields perfluorofuran, whose precursor is assumed to be an unstable fluorocarbonylperfluoroalkyl hypofluorite[16]:

$$FC(O)(CF_2)_3C(O)F + F_2 \xrightarrow{CsF} \left[FO(CF_2)_4C(O)F\right] \xrightarrow{-COF_2} \begin{array}{c} O \\ CF_2 \quad CF_2 \\ CF_2{-}CF_2 \end{array} \ .$$

The action of fluorine in cyclising copper and nickel hexafluoroacetylacetonates into cyclic peroxides is probably of the same type[53].

Under conditions of thermal and photochemical initiation trifluoromethyl hypofluorite reacts with carbon monoxide to form the fluoroformic and oxalic esters[156–159]. The mechanisms of photolysis and thermolysis differ in the first stage, which serves as source of trifluoromethoxy-radicals:

$$CF_3OF \xrightarrow{h\nu} CF_3\dot{O} + \dot{F}$$
$$CF_3OF + CO \xrightarrow{\Delta} CF_3\dot{O} + \dot{C}OF$$
$$CF_3\dot{O} + CO \rightarrow CF_3O\dot{C}O$$
$$CF_3O\dot{C}O + CF_3OF \rightarrow CF_3OC(O)F + CF_3\dot{O}$$
$$2CF_3O\dot{C}O \rightarrow CF_3OC(O)C(O)OCF_3 \ .$$

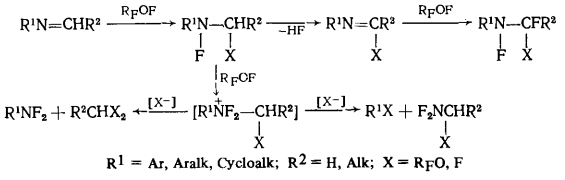
At room temperature in the dark no reaction takes place[159]. As a consequence of degradation, photolysis of a mixture of the hypofluorite with hexafluoroacetone forms small quantities of bistrifluoromethyl carbonate[160]:

$$(CF_3)_2CO + CF_3OF \xrightarrow{h\nu} (CF_3O)_2CO \ .$$

The reaction with carbon monoxide, like that discussed above with sulphur dioxide, provides additional evidence of the differing reactivities of fluorooxy- and chlorooxy-derivatives. Carbon monoxide reacts with the more active hypochlorites under mild conditions to give nearly quantitative yields of perfluoroalkyl chloroformates[61,69,79–81,159,161–163]:

$$R_FOCl + CO \rightarrow R_FOCOCl \ .$$

A kinetic scheme has been suggested[164] for the photochemical process, analogous to the formation of trifluoromethyl fluoroformate; with a pressure of 100 mmHg at 30 °C the quantum yield is 10^4 molecules of the hypochlorite. In the dark, reaction between carbon monoxide and trifluoromethyl hypochlorite probably begins with bimolecular initiation, which is secured by the relatively low energy of the oxygen–chlorine bond (~38 kcal mole^{-1}):[165]



$$CF_3OCl + CO \rightarrow CF_3\dot{O} + \dot{C}OCl \ .$$

The capacity for addition at the carbonyl bond in organofluorine hypochlorites parallels their stability. For example, the very unstable *O*-chlorinated perfluoropinacol obtained *in situ* has only a weak chlorinating and oxidising action on benzaldehyde[166]:

$$(CF_3)_2C(ONa)-C(ONa)(CF_3)_2 \xrightarrow[CFCl_3]{Cl_2} \left[(CF_3)_2C(OCl)-C(OCl)(CF_3)_2\right] \xrightarrow[CCl_4]{h\nu,\ PhCHO}$$
$$\rightarrow PhCOOH + PhCOCl + (CF_3)_2CClCCl(CF_3)_2 \ .$$

The direction of addition of organofluorine hypohalites to compounds containing multiple carbon–nitrogen bonds is consistent with the electrophilic character of the former and

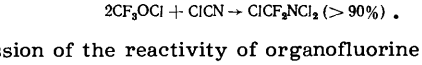
the donor power of the nitrogen atom. Because of the instability of the initial adducts the reaction is usually accompanied by degradation with formation of the corresponding *N*-fluoroamines or fluorination of the carbon–nitrogen bond. It has been shown for Schiff bases as example[167–170] that fluorination occurs mostly when the methine group is unsubstituted, but degradation occurs when alkyl or alkoxyl is attached to the carbon atom:

$R^1 = Ar, Aralk, Cycloalk;\ R^2 = H, Alk;\ X = R_FO, F$

Compounds in which the substituent $X = CF_3O$ are rarely met among the products. If the reaction is conducted in an inert solvent (e.g. fluorochloroform), derivatives with $X = F$ are obtained. If alcohols are added to the reaction mixture, ethers and acetals ($X = AlkO$) are formed.

Because of the good yields of difluoroamines it has been proposed to use the reaction between hypofluorites and Schiff bases as a method of preparation[169]. Hypofluorites prove quite useful also for obtaining azoalkanes[171]:

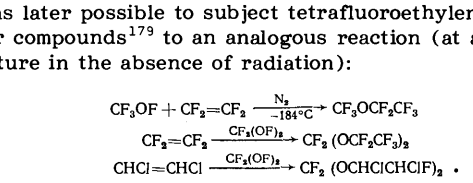
Perfluoroaza-alkenes react with organofluorine hypohalites under more severe conditions:



Nevertheless, even this is characterised by a difference in reactivity: hypochlorites do not require heating, whereas fluorooxy-derivatives have a fluorinating effect at high temperatures. This has been regarded[172] as indicating a transition from an ionic to a radical mechanism.

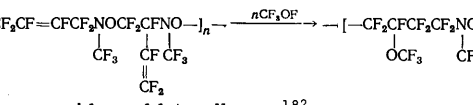
A radical mechanism obviously operates in the reaction between perfluoroguanidine and difluoromethylene bishypofluorite[173,174], from which a large number of products have been isolated. The only case in which a stable *N*-trifluoromethoxy-derivative has been obtained (in 30% yield) is the photochemical reaction between fluorosulphonyl isocyanate and trifluoromethyl hypofluorite[175]:

The reaction between trifluoromethyl hypochlorite and cyanogen chloride reveals the strong chlorofluorinating effect of the former on nitriles[72,176]:



Discussion of the reactivity of organofluorine hypohalites and halogenoperoxides towards compounds containing an ethylenic bond have some bearing on the problem of anomalous electrophilic substitution, which has recently been widely discussed[177]. Since detailed examined in relation to the present compounds would be a major task outside the scope of the present Review, we shall consider only the most important points.

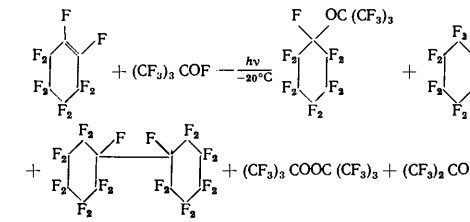
It must first be noted that the main criterion in assessing the nature of processes involving the ethylenic bond is the state of aggregation of the reactants. Reactions between gases usually take place by a free-radical mechanism. In the liquid phase organofluorine hypohalites and halogenoperoxides often exhibit electrophilic properties at the initiation stage, attacking the substrate at the site of maximum electron density.



One of the earliest studies of the chemistry of hypofluorites had shown[178] that ethylene and tetrafluoroethylene react explosively with trifluoromethyl hypofluorite. Only great dilution with nitrogen and ultraviolet irradiation enabled the ethylene addition product to be isolated:

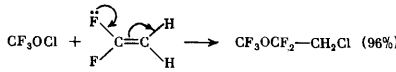
It was later possible to subject tetrafluoroethylene[41] and other compounds[179] to an analogous reaction (at a low temperature in the absence of radiation):

The stabilisation of polymeric materials by trifluoromethyl hypofluorite is a radical process[180,181]:



Fluoroperoxides add to alkenes[182]:

Reaction of the hypofluorite with symmetrical dichlorodifluoroethylene occurs similarly[183].

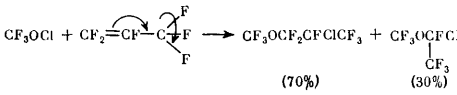


Under poorly controlled temperature conditions hypofluorites and unsaturated compounds form a large number of products, as in radical reactions of elementary fluorine. A similar result can be obtained in the case of intermediate radicals showing little tendency to attack a multiple bond. For example, the photochemical reaction of perfluoro-t-butyl hypofluorite with a perfluorocycloalkene gives a complicated mixture of peroxides, ethers, cycloalkanes, their dimers, hexafluoroacetone, and tetrafluoromethane[184]:

In the absence of ultraviolet radiation at 0 °C only decomposition of the hypofluorite is observed. On the other hand, with trifluoromethyl hypofluorite (ultraviolet exposure at −60 °C) the reaction is highly selective, as is indicated by the theoretical yield of perfluoromethoxycyclohexane.

The change in character of the reactions of organofluorine hypohalites and halogenoperoxides with alkenes from radical to electrophilic largely depends on the nature of the oxygen–halogen and ethylenic bonds. As in certain reactions with inorganic substances, such a change occurs primarily with hypochlorites. It is apparent in intermediate addition of the positively polarised halogen atom to the carbon atom possessing the greatest electron density.

Trifluoromethyl hypochlorite reacts with vinylidene difluoride to form in effect a single isomer[185]:

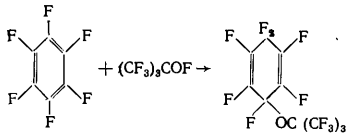


Similar orientation occurs with vinyl chloride[185]¶

Trifluoromethyl chloroperoxide reacts similarly[186]:

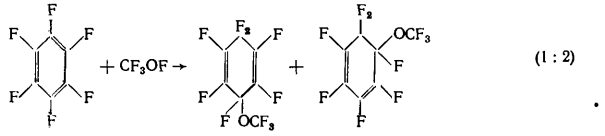
$$CF_2{=}CCl_2 + CF_3OOCl \rightarrow CF_3OOCF_2CCl_3\ (>50\%)$$
$$CH_2{=}CF_2 + CF_3OOCl \rightarrow CF_3OOCF_2CH_2Cl\ (>50\%)$$

with formation of 2,2,2-trichloro-1,1-difluoroethyl trifluoromethyl ether and 2-chloro-1,1-difluoroethyl trifluoromethyl ether (<10%) as by-products. Sometimes both isomers are formed, but with the "normal" addition product predominating[185,187,188]:



This is consistent with views on a radical-ion reaction mechanism, in which polar effects play a leading part.

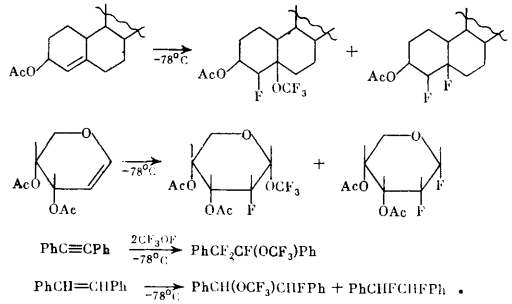
The occurrence of electrophilic attack at the site of greatest electron density in the double bond is confirmed no less convincingly by many reactions involving perfluoroalkyl hypofluorites[47,189-223]. This property has not only theoretical applications but also wide synthetic use for introducing fluorine into biologically active compounds—uracil and cytosine derivatives[194-200], steroids[201-211], sugars[212-220], and aromatic compounds[189-193].



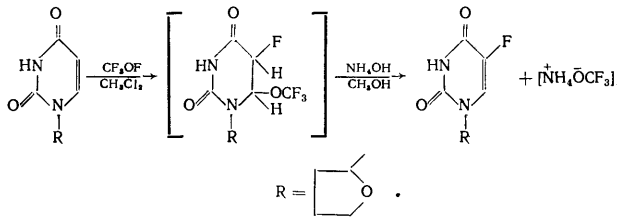
Because of the strong negative inductive effect of the perfluoro-t-butyl group electrophilic properties are most characteristically developed in the corresponding hypofluorite. The latter reacts with hexafluoropropene and with perfluoroalkoxyethylenes[47] to give predominantly the straight-chain isomers:

$$CF_3CF{=}CF_2 + (CF_3)_3COF \rightarrow CF_3CF_2CF_2OC(CF_3)_3$$
$$R_FOCF{=}CF_2 + (CF_3)_3COF \rightarrow R_FOCF_2CF_2OC(CF_3)_3$$

the yield of "anomalous" addition products not exceeding 5%. Hexafluorobenzene gives a substituted cyclohexa-1,4-diene[189]:

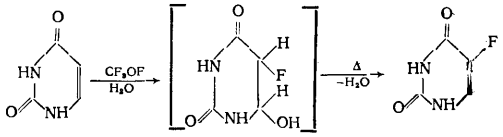


The 1,2-isomer is not formed, although in the case of trifluoromethyl hypofluorite both isomers have been isolated:

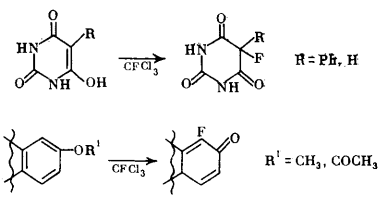


Addition of the latter hypofluorite to octafluorotoluene requires more severe conditions.

These results and the reaction with hexafluoropropene have suggested[189] that the action of hypofluorites on unsaturated compounds can be regarded as "electrophilic addition involving a fluoronium ion". It must be emphasised that this hypothesis applies only to the primary step—attack on the substrate by a polarised halogen atom—whereas the overall process obviously involves electron transfer. This is indicated in particular by the appearance of dimeric products in the reaction of hexafluorobenzene with perfluoro-t-butyl hypofluorite. It is also possible that the formation of isomeric cyclohexadienes from hexafluorobenzene and trifluoromethyl hypofluorite is a result of a cage process[177].

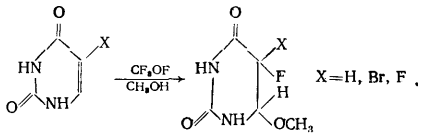


Trifluoromethyl hypofluorite adds at a double bond on reaction with steroids[190,202,204,210,211], anhydro-sugars[214,216,217,219-221], diphenylacetylene[190,204,206], stilbene[223], and uracil derivatives if an inert solvent (fluorochloroform, dichloromethane) is used. In several cases the corresponding difluorides are formed also, as a consequence of the fluorinating power of the hypofluorite:

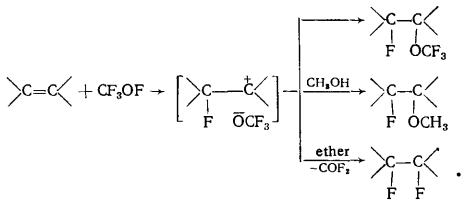


Trifluoromethoxy-derivatives are usually unstable, and pass into hydroxy-derivatives on subsequent treatment (heating) of the reaction mixtures. Treatment of such derivatives with basic reagents leads to elimination of the trifluoromethoxy-group. It is assumed[200] that an unstable alkoxide is formed, e.g. $^+NH_4O^-CF_3$ in the production of Fluorafur, an effective antitumour preparation:

Unstable intermediate products are formed also when unsubstituted uracil is treated with trifluoromethyl hypofluorite in trifluoroacetic acid containing water[195]:

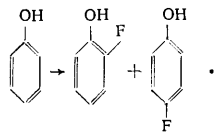


If hydroxyl, alkoxyl, or acetoxyl is present as substituent adjacent to the multiple bond, decomposition terminates in ketonisation[201-204,210,211]:



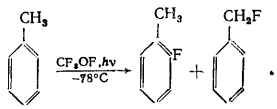
¶ Trifluoromethyl hypochlorite has been subjected to reaction also with ethylene and with tetrafluoroethylene.

If the fluorinating effect of trifluoromethyl hypofluorite is applied in the presence of methanol, the multiple bond undergoes fluoromethoxylation[199,201]:



This extremely important experimental fact, together with other observations, led several authors to consider reactions between hypofluorites and activated unsaturated compounds to be ionic[199,201,203,210,216,217]. The first stage is regarded[199, 210,217] as involving formation of a carbocation, whose subsequent reactions depend on the experimental conditions and the nature of the substituents. In inert solvents the carbocation is stabilised by capture of a trifluoromethoxide anion. Electron-donor solvents (e.g. ether), which tend to stabilise the carbocation, displace the reaction towards formation of the difluoride:

Electron-donor substituents in the unsaturated compound have a similar effect. As the stronger base, methanol when present adds to the carbocation.



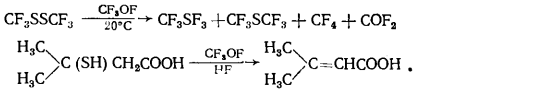
A detailed investigation of the stereochemistry of the processes, made on stilbene[223], showed *cis* addition independently of the nature of the products.

In the fluorination of aromatic compounds the electrophilic properties of hypofluorites are evident as *ortho* and (more rarely) *para* orientation when substituents such as hydroxy, alkoxy, and acylamino are present in the ring[190–193,224]:

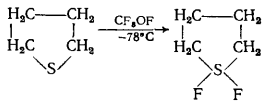
This case of "anomalous electrophilic substitution" has been reviewed[177] in terms of cage and free-radical processes.

Under special conditions (ultraviolet irradiation) hypofluorites react with aromatic compounds probably by a radical mechanism. Thus toluene is fluorinated in the ring and in the side-chain[225]:

Photofluorination has enabled fluorine to be introduced into the ring and the side-chain of other aromatic hydrocarbons [226–229], and many aliphatic compounds to be fluorinated, including such polymeric materials as polycaprolactam and polyethylene[230,231]. The most suitable solvent for photofluorination is liquid hydrogen fluoride, in which the process occurs highly selectively, e.g. without affecting the amino-group[231]. This property has been utilised in the preparation of the antibacterial β-fluoro-α-alanine[232–235]:



The high fluorinating power of hypofluorites is illustrated by their reactions with amines and amides to give *N*-fluorinated products[236–238]:



Amides in which the basicity of the nitrogen atom has been diminished constitute an exception. Thus the relatively inactive *N*-trifluoroacetyladamantylamine is fluorinated by trifluoromethyl hypofluorite at position 3 of the ring system[239].

Organic compounds containing sulphur react variously with hypofluorites. Disulphides and thiols undergo degradation[240, 241]:

Aliphatic and cyclic sulphides form fluorothio-derivatives[242,243]:

Hypofluorites react very readily with compounds containing labile functional groups, e.g. with diazo-ketones[244]:

V. POSSIBILITIES OF PRACTICAL APPLICATION

A survey of published information on the chemistry of organofluorine hypohalites enables us to recommend certain reactions for practical use.

Thus various trifluoromethyl ethers possessing an anaesthetic action can be obtained by addition to halogenated alkenes. Dehalogenation or dehydrohalogenation of such ethers is of interest for the preparation of fluorinated alkyl vinyl ethers. Perfluoromethoxyethylene was first obtained in this way[183].

Hypofluorites, being less active fluorinating agents than elementary fluorine, can be used to obtain biologically active preparations—5-fluorouracil[195], fluorobarbituric acid[201], fluorinated cytosine bases[199], Fluorafur[200], etc.

Organofluorine hypohalites themselves are effective insecticides, fungicides, and brightening agents for paper and textiles[62–64]. Hypofluorites have been recommended for the surface sterilisation of materials that cannot readily be subjected to heat[245]. An important field of application of the hypohalites is the initiation of polymerisation[62–64,246].

However, the high toxicity of organofluorine hypohalites and their reactivity towards non-fluorinated organic compounds make their use potentially dangerous. The precautionary measures usual in work with elementary fluorine must be taken when these compounds are used.

Concentration Methods for the Determination of Trace Elements

Yu.A.Zolotov

Methods of concentrating trace constituents are discussed, and the quantitative parameters used to describe them are defined. The main methods of concentration (extraction, sorption, coprecipitation, evaporation, etc.) are examined and compared. Rational combinations of methods of concentration and methods of determination of trace elements are recommended, and successful examples of such combinations are quoted. Special aspects of concentration methods applicable to the analysis of high-purity materials and of natural waters are discussed. 114 references.

I. INTRODUCTION

Preliminary concentration is used when the relative detection limit of an analytical method is higher than the real concentration of the trace elements in the sample. Concentration allows the matrix (or most of it) to be removed, together with a number of interfering micro-components. The concentrate thus obtained contains a higher relative concentration of the micro-elements than the initial sample. Furthermore the larger sample size made possible by the adoption of concentration methods also ensures that larger absolute amounts of the micro-elements are available for analysis. As a result the detection limit can be lowered by a considerable amount, often 100- or 1000-fold. This is the main (but not the only) reason for the widespread adoption of concentration methods.

Preliminary concentration is almost unavoidable if the trace elements are inhomogeneously distributed in the sample. A representative sample in this case must be large, and direct analysis of such a large sample may be difficult, especially when the chosen method of determination requires a small sample (e.g. mass-spectrometric analysis, or emission spectrometry). The preparation of a small concentrate from a solution or a melt of a relatively large sample often provides a representative sample for analysis: for example, assay melting can be used to concentrate gold and other precious metals unevenly distributed in large samples of naturally occurring materials.

Concentration also facilitates calibration, especially when suitable standard samples are not available. It yields concentrates of a single type for the analysis of different types of material: for example, concentrates on carbon powder for spectroscopic analysis. The reference samples are produced as concentrates in the same form, and special standards for each type of material become unnecessary. Concentration with complete removal of the matrix is very desirable in the analysis of toxic, radio-active, or very expensive materials. Furthermore suitable internal standards can be conveniently introduced (if required) during the decomposition and concentration of the sample. Concentration sometimes extends the range of the trace elements which can be determined by a chosen method of analysis.

Because of all these advantages, concentration is an important step in the determination of trace elements. Its importance has not decreased as a result of the development of new, highly sensitive direct analysis methods. On the contrary, its perspectives are continually expanding, especially in combination with new methods of determination.

On the other hand concentration makes the analysis more laborious and complicated. It can lead to a loss of sample, or to contamination from outside. In some cases fewer micro-elements can be analysed than by direct analysis, and special operating procedures are needed (high-purity reagents, specially equipped laboratories, special materials or apparatus). However the advantages of concentration methods far outweigh their disadvantages.

Concentration methods cover a wide range of variants. It is important to distinguish absolute and relative concentration. Absolute concentration transfers the trace elements from a large mass of sample into a smaller mass, as for example when a solvent is evaporated or when the trace elements are extracted into a small volume of organic phase. Relative concentration increases the ratio of the trace element to the main macro-component (in this case the solvent is not treated as a macro-component). Relative concentration is a separation of components present at very different concentrations; its main aim often is to replace an interfering matrix by a suitable collector (usually of smaller mass). In some cases (e.g. in concentration by zone melting methods) the boundary between absolute and relative concentration is blurred, and concentration of both types is assumed to occur.

Both individual and group concentration of the elements can be carried out as required. Concentration involves either removing the matrix or separating the wanted trace components. Removal of the matrix is convenient for the simultaneous determination of several trace elements (for example, by spectroscopic analysis), but only if the matrix has a simple composition. Removal of the matrix is most frequently used in the analysis of high-purity metals. If the matrix consists of several elements combined as a compound (as in geological and biological samples) it is often simpler to separate the trace elements. Sometimes it is not necessary to remove the matrix completely (in this case we use the term "enrichment"). However in most cases it is best to concentrate the wanted element into a different matrix which satisfies the special requirements of the chosen method of determination, which makes calibration easy, etc. Some of these collectors can be used for determining micro-elements by several methods. For example, graphite powder can be analysed spectroscopically or by flameless atomic absorption.

The general problems underlying the pre-concentration of trace elements have been discussed in a number of review articles and monographs[1-8].

The three quantitative parameters used to describe concentration methods—the extent of extraction, the concentration coefficient, and the separation coefficient—are defined as follows: 1) the extent of extraction $R = Q_T/Q_T^0$, where Q_T and Q_T^0 are the quantities of the micro-element in the concentrate and in the sample respectively; 2) the concentration coefficient $K = (Q_T/Q_M)/(Q_T^0/Q_M^0) = Q_T Q_M^0/Q_M Q_T^0$, where Q_M^0 and Q_M are the amounts of matrix before and after the concentration respectively (obviously, for $R = 100\%$ we have $K = Q_M^0/Q_M$); 3) the separation coefficient $S = (Q_M/Q_T)/(Q_M^0/Q_T^0) = Q_M Q_T^0/Q_M^0 Q_T$ (so that $S = 1/K$).

II. CONCENTRATION METHODS

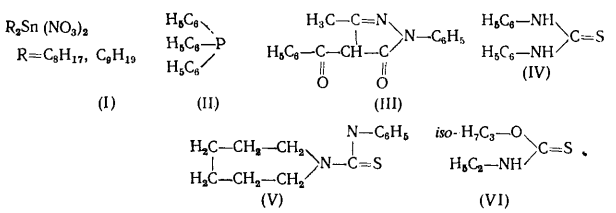
Many different methods are used for analytical concentration. The most rational classification of these methods is in terms of the nature of the separation process used. First of all we distinguish between chemical (or physicochemical) and physical methods of concentration. Among the chemical and physicochemical methods we include extraction and sorption methods, precipitation and coprecipitation, ashing and other methods of decomposing the sample, partial dissolution of the matrix, leaching, and electrochemical methods. The physical group of methods includes evaporation (e.g. distillation, sublimation), directional crystallisation, zone melting, and some other concentration techniques.

Methods can be classified also according to the number and type of phases involved. Among the most important methods of concentration are those based on the distribution of solutes between two immiscible phases, such that one phase becomes a concentrate of the trace element. This classification is expanded in Table 1. However there are also methods based on separation in a single phase (electrodialysis and diffusion methods).

Table 1. Methods of concentrating trace elements based on the distribution of compounds between two phases.

Phases*		Concentration methods
concentrate	matrix	
Liquid	liquid	extraction of trace elements, extraction of the matrix, distribution chromatography
Solid	liquid	sorption of trace elements, coprecipitation of minor constituents, electrolysis and cementation of trace elements
Liquid	solid	sorption of the matrix, precipitation of the matrix, electrolysis of the matrix, leaching of trace elements by solvents, directional freezing and zone melting
Gas	liquid	evaporation of trace elements
Liquid	gas	evaporation of the matrix and wet ashing
Gas	solid	evaporation of trace elements
Solid	gas	sublimation of the matrix, evaporation of the matrix after chemical conversion (dry ashing etc.)

*Phases present during and after concentration are quoted.



Of course, not all the methods are equally important. The IUPAC Commission for Microchemical Methods and Trace Analysis compared the methods of separation and concentration used in 188 laboratories throughout the world to determine impurities in chemical reagents[9]. The methods most generally used were found to be extraction (79 laboratories), ion exchange (21), precipitation of complexes (18), distillation and sublimation (8), and electrolysis (5). We shall discuss these methods in some detail, in approximately the same order.

1. Extraction Methods

Extraction methods are among the most convenient. They can be used either to transfer trace elements into the extract (individually, or in groups) or to remove the matrix. Important advantages of these methods are their universality, simplicity, and speed. Extraction usually offers very efficient concentration. Extraction methods are reviewed in Ref.8.

Various extraction systems are used for trace elements, though chelating agents are the commonest. Extraction of the trace element is possible only if the matrix does not react with the chosen reagent, as in the analysis of waters, acids, alkali, alkali metal salts, and metal compounds, which exist as anions during the extraction. Common reagents for group concentration include hydroxyquinoline, dithizone, and dithiocarbamates (especially diethyl- and pyrrolidinedithiocarbamate). In order to extract the largest possible number of elements extraction with a given reagent can be carried out at several pH values, or alternatively a mixture of different reagents can be used. For example, a method of determining 18 impurities in very pure alkali metal halides by extraction with a mixture of Cupferron, sodium diethyldithiocarbamate, and trioctylphosphine oxide has been reported[10]. All 18 elements are extracted simultaneously, and the extract is evaporated on graphite powder and analysed spectroscopically. Reagents which do not themselves become extracted by the organic phase under the condition of the metal extraction are chosen. Trioctylphosphine oxide goes into the extract, but it does not interfere with the spectroscopic determination of the elements.

Several new reagents for the concentration of trace elements by extraction have been proposed in recent years. The dinitrates of dinonyl- and dioctyltin (I) have a unique capacity for extracting multiply-charged anions. These reagents quantitatively extract phosphate and arsenate; sulphate, selenite, and selenate are removed less completely but still to an acceptable extent, and singly charged anions are only slightly extracted[11,12]. Organotin extractants are unlike any other previously known reagent: by using these materials methods of concentrating phosphorus, arsenic, and selenium have been developed, and in particular an extraction–photometric method of determining phosphorus and arsenic in vanadium[12].

Triphenylphosphine (II) has been recommended for the selective concentration of traces of gold and silver, followed by atomic-absorption analysis of the gold (in minerals and in cyanide solutions[13]) and of the silver (in ores and minerals[14]). A special feature of this reagent is its affinity for metal ions showing weak acid properties (according to Pearson's classification[15]).

1-Phenyl-3-methyl-4-benzoylpyrazol-5-one (III) can be used[16,17] for the group concentration of several elements. Spectroscopic methods of determining impurities in sodium hydroxide and other materials have been developed by applying this reagent. It can be used also for the selective extraction of certain elements before atomic-absorption[18], photometric, or luminescence analysis. The applications of this reagent are discussed in a recent monograph[16].

Diphenylthiourea (IV) and hexamethylenephenylthiourea (V) have been suggested for the concentration by extraction of chalcophilic metals, especially silver and metals of the platinum group. These reagents can be used to concentrate the precious metals and to separate them from non-ferrous metals. For example, a spectroscopic method of determining all the precious metals (except osmium) in solutions of natural or industrial materials containing large amounts of nickel, cobalt, iron, manganese, and zinc, and smaller amounts of copper, has been developed[19]. The method includes a preliminary concentration of the precious metals by extraction as diphenylthiourea complexes after treating the solution with tin(II) chloride: the limit of detection is 10^{-7}–10^{-5}%. Diphenylthiourea has been used to concentrate traces of silver in ores and in mineral concentrates[20], and also traces of copper, silver, and thallium in chemical reagents[21]. In both cases the elements were determined by atomic absorption spectroscopy.

The most important theoretical problems in the extraction of trace elements from a matrix in aqueous solution are the effect of other components of the matrix (salting-out, masking complex formation, etc.) and the concentration dependence of the distribution coefficient of the trace element. These problems offer some interesting topics for research.

Removal of the matrix is also very important in analytical practice. In this case the capacity of the organic phase must be large, and the extraction must be extremely selective (to ensure that the trace elements remain fully in the water phase). Chelates are not so attractive for this type of extraction, because their solubility in organic solvents is limited: the most suitable extraction forms are ionically associated, co-ordination solvated, and molecular compounds. An interesting and important general problem is the effect of the matrix being extracted on the behaviour of the trace element. In many cases undesirable co-extraction of the trace elements is observed. This problem has been studied for several years in the writer's laboratory[22,23]: rational and theoretically sound methods of suppressing co-extraction of trace elements have been developed.

Many different reagents have been used for extracting the matrix. Among the newer extractants we should mention *O*-isopropyl-*N*-ethylthiocarbamate (VI).[24] The extraction properties of this compound have been studied in detail, and several methods of separating and concentrating elements have been developed as a result. The reagent is a liquid, miscible with organic solvents, and therefore its capacity is large. Silver is extracted particularly well by reagent (VI). The only elements co-extracted with silver from a 1 *M* nitric acid solution are mercury, platinum, palladium, and (partly) gold. All the other elements remain in the water phase. A single-stage extraction by a 2 *M* solution of the reagent in chloroform removes 99.98% of the silver: i.e. the extraction is quantitative. This allows the determination of 23 impurities in high purity silver by a spectroscopic method[25]. With a concentration coefficient $K = 50$ the limits of detection are 2×10^{-6}–5×10^{-6}%. *O*-isopropyl-*N*-methylthiocarbamine is even more useful, because it is more easily available.

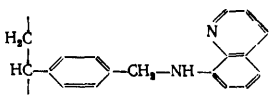
Ordinary extraction methods give a concentration coefficient not greater than 50–100. Improvements in this direction can be expected from current work on extraction chromatography[26], gel extraction (see, for example, Ref.27), and three phase extraction systems[28].

The latter method requires some explanation. In some extraction systems the organic phase separates into two layers, one of which (often very small in volume) contains practically the whole of the extracted element. This phase can be separated and used directly for spectroscopic or atomic absorption analysis. Several methods of this type have been proposed (see, for example, Refs.29 and 30).

2. Sorption Methods

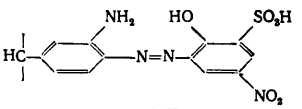
Sorption methods of concentration rely on various types of sorption: physisorption, ion exchange, and chemisorption (with complex formation). The ion exchange methods are particularly important.

The use of conventional synthetic resins for ion exchange is complicated by the need to handle large volumes of solution, but nevertheless the method is used in many laboratories. Static, dynamic, and chromatographic variants of ion-exchange separation can be used to concentrate trace elements. Either the trace element or the matrix can be removed. If the trace elements are sorbed, they can be recovered for analysis by desorption or by ashing the sorbent (if a very high purity sorbent is available). Alternatively, concentrates on very pure sorbents can be analysed directly by spectroscopic or other methods. This approach is favoured in Refs.31–33 for the determination of impurities in boric anhydride[31] and other materials. The boric anhydride is dissolved in a mixture of glycerol and water, and the resulting glycerol complex of boric acid is not sorbed by the resin. The Cu, Ni, Cr, and other impurities are adsorbed on a cation-exchange resin in a micro-column, then the resin is transferred to a Teflon mortar, ground with sodium chloride, and treated with a drop of concentrated sulphuric acid. The decomposed resin is taken up in alcohol and analysed spectroscopically.



Rare-earth element impurities in metallic uranium have been determined by a two-stage ion-exchange concentration method[34]. The impurities were first sorbed (and thus separated from the main bulk of the uranium) from a sulphate solution on a column containing a cation exchanger. The rare earth elements were then eluted with a solution of hydrochloric acid. In the second concentration stage the uranium residues were sorbed as the chloro complex on an anion exchanger, while the rare earth elements were not sorbed. Impurities of gadolinium, europium, and samarium, can be determined in this way (using a luminescence method of end-analysis) at concentrations as low as 2×10^{-6}%.

Complex formation in ion-exchange concentration is used also to prevent unwanted elements from being sorbed, and to convert the wanted elements into an easily sorbed form. In addition to the normal inorganic ligands, many organic chelating reagents are found useful in this work. For example, traces of Cu, Zn, and Cd have been concentrated[35] on an ordinary anion exchanger by first converting them into 2(3'-sulphobenzoyl)-pyridine-2-pyridylhydrazone complexes. A concentration coefficient as high as 300 was obtained in this way.

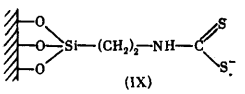


Under certain conditions trace-element complexes are readily sorbed by active carbon. This sorbent is known to behave as an anion exchanger in aqueous solutions: for example, it can selectively absorb anionic complexes of the precious metals. On the other hand oxidised carbon (i.e. carbon treated, for example, with nitric acid) acquires the properties of a cation exchanger and readily sorbs multiply-charged cations. The sorption properties of oxidised carbon towards Ag^+ have been studied in detail[36,37], and it was found that columns packed with oxidised carbon can be used to concentrate alkaline-earth metal impurities from solutions of alkali metal or ammonium salts. Active carbon can concentrate also metal chelates such as diethyldithiocarbamates. This property is used for concentrating traces of chalcophilic metals.

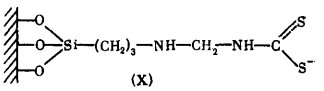
Synthetic chelating resins offer some very attractive possibilities. The existence of a very large number of organic analytical reagents, and the extensive information available on their interaction with various elements, can be used to synthesise resins incorporating special groups of different types,

for both selective and group reactions. Some examples of chelating resins are shown below: the sorbent (VII) takes up palladium and platinum, the sorbent (VIII), copper[38-40].

(VII)

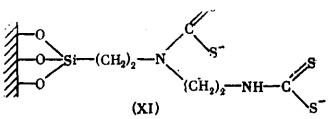


(VIII)

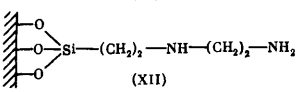


Resins of the Kelex-100,[41] XAD,[42] and other types have been studied and are now being used.

Many inorganic sorbents such as hydroxides, sulphides, and phosphates are being intensively studied. For example, copper and gold can be fully concentrated on copper sulphide from a 6 *M* solution of hydrochloric acid. However very pure inorganic sorbents are needed for the concentration of trace elements, and these materials are not readily available in a very pure form.



Sorbents containing grafted organic functional groups can be treated as a "hybrid" between inorganic sorbents and synthetic chelating resins. Leiden[42-45] has developed methods of concentrating ions on silica gel or on very small glass spheres with complex-forming groups of types (IX)–(XII) immobilised on their surface.



(IX)

(X)

(XI)

(XII)

The diethyldithiocarbamate group in reagents (IX)–(XI) assists the sorption of cations, the diamine group in (XII) the sorption of anions. Trace elements are sorbed fairly quantitatively even in the static variant. When traces have to be separated from a large volume of sample the column variant is used, and in this case the glass micro-spheres are better than silica gel. After sorption the glass of silica gel particles are mixed with an equal volume of powdered cellulose and pressed into a pellet which is analysed by X-ray fluorescence. Elements can be extracted from very dilute solutions: for example, selenium from 2 litre of water at a concentration of 2 ng ml^{-1}.

3. Coprecipitation and Precipitation Methods

The coprecipitation of the trace elements with a collector and the precipitation of the matrix are among the most important methods of pre-concentration of impurities. Trace elements are usually coprecipitated on amorphous precipitates of large surface area (hydroxides, sulphides, etc.). Coprecipitation on these carriers can be treated as a heterogeneous ion-exchange or chemical reaction leading to the formation of a solid solution or of chemical compounds between the trace component and the collector.

The choice of collector is dictated by various factors. It must be pure, and able to carry the wanted trace element on a small mass of the collector. A special requirement for spectroscopic end-determinations is that the emission spectrum must be as simple as possible: thus Al and Zn hydroxides are preferable to Fe and Mn hydroxides. A compound of a metal which can subsequently be removed by evaporation or other simple means makes a very convenient collector. For example, a mercury sulphide collector used for the coprecipitation of trace elements was removed as the bromide[46]. Some trace components are easily reduced to the elemental state and coprecipitated, for example, with elemental tellurium or mercury.
