Stereochemistry of the Reactions of Phosphorus-containing Free Radicals

S.P.Solodovnikov, N.N.Bubnov, and A.I.Prokof'ef

The stereochemical characteristics of phosphoranyl radicals and β-phosphorus-substituted radicals as well as tautomeric transformations involving phosphorus-containing phenoxy-radicals, which reflect the stereochemical properties of quinquevalent phosphorus, are discussed.
The bibliography includes 58 references.

I. INTRODUCTION

Phosphorus-containing free radicals and reactions involving them have been vigorously investigated in recent years. The results of experimental and theoretical studies on the structures and reactivities of numerous phosphorus-radicals published until 1974 have been compiled in two reviews[1,2]†.

In the study of the structures and reactivities of phosphorus-containing free radicals a research field associated with the stereochemistry of the radical reactions of organophosphorus compounds has been established. Ideas have been put forward, according to which the stereochemical transformations occuring in organophosphorus free radicals influence the mode and rate of reaction and also the stereochemical properties of the reaction products.

II. STEREOCHEMICAL CHARACTERISTICS OF PHOSPHORUS-CONTAINING FREE RADICALS

According to the established classification, phosphorus-centred free radicals are divided into phosphinyl, phosphonyl, and phosphoranyl radicals. In these radicals the unpaired electron is either wholly or largely localised at the phosphorus atom. There exists a large class of radicals in which the free valence is located at atoms in the β-positions relative to the phosphorus atom. The radical-anions and radical-cations of organophosphorus compounds are widely known[1,2].

A planar structure with the localisation of the unpaired electron in the *p* orbital of the phosphorus atom has been attributed to the phosphinyl radicals $\dot{P}R_2$.[1] It is believed that

† After the present review had been sent to the printers, the monograph by Ya.A.Levin and E.I.Vorkunova, "Gomoliticheskaya Khimiya Fosfora" (The Homolytic Chemistry of Phosphorus), Izd.Nauka, Moscow, 1978, was published; here the reader will find a more detailed discussion of a number of the problems dealt with in the present review.

the phosphonyl radicals $R_2\dot{P}O$ have a non-planar structure and the unpaired electron is in the 3*s* and 3*p* phosphorus orbitals and the 2*p* oxygen orbital[1]. The greatest amount of data are available on the structures of phosphoranyl radicals of the type $\dot{P}R_4$. Depending on the nature of the substituents, either a trigonal bipyramid (TBP) or a tetrahedral structure is attributed to them.

The non-equivalence of the fluorine atoms in the $\dot{P}F_4$ radical[3,4] or the hydrogen atoms in the $\dot{P}H$ radical[5] and the hydrogen atoms in the methyl groups in the $H_3\dot{P}O$–t-Bu, $Me\dot{P}H_2$–O–t-Bu, and $Me_3\dot{P}O$–t-Bu radicals[6], which follows from the EPR spectra, shows that the radicals have a structure close to that of a TBP, which is characteristic of phosphorus(V) compounds.

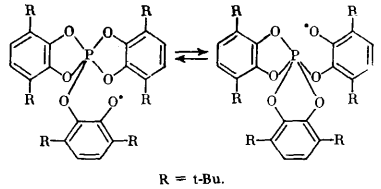
The following stereochemical problems arise in the study of phosphoranyl radicals[7].

(a) Is the formation of a phosphoranyl radical following the addition of an attacking radical (for example in the apical position, as in the nucleophilic attack on PX_4^+, $X_3P=O$, and possibly $:PX_3$) stereoselective?

(b) Is there a possibility of the interconversion of the configurational isomers during the lifetime of the radicals, which naturally can vary as a function of the experimental conditions?

(c) Is the fragmentation of phosphoranyl radicals stereoselective, particularly when the phosphoranyl radical contains a pair of identical ligands, one of which is in the apical position and the other in the equatorial position and which one of them is susceptible to more or less ready α- or β-cleavage?

$$A{-}B^{\cdot} + PX_3 \rightarrow AB{-}\dot{P}X_3 ,$$



$$AB\dot{P}X_3{-}\left|\begin{array}{l}\xrightarrow[\alpha\text{-elimination}]{} A{-}B{-}PX_3 + X^{\cdot} ,\\ \xrightarrow[\beta\text{-elimination}]{} A^{\cdot} + B{=}PX_3 .\end{array}\right.$$

(d) The question arises which isomer of the phosphoranyl radicals recorded or not recorded by EPR undergoes faster fragmentation and which is the main source of the fragmentation products:

(e) Finally it is necessary to establish to what extent the stereochemical characteristics of the disposition of the substituents and the frequency of the interconversions of the stereoisomers of phosphoranyl compounds differ compared with phosphorus(V) compounds.

In the study of radicals where the free valence is localised on atoms in the β-positions relative to the phosphorus atom stereochemical problems associated with the steric requirements of the radical fragments also arise.

Exchange reactions involving radicals of the following type have been discovered recently:

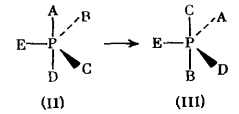
R = t-Bu.

(I)

where the rapid transfer of the unpaired electron between the ligands results in the phosphorus(V) compound having the structure of a hexacoordinate phosphorus compound on the EPR time scale[8]. The study of this reaction led to the problem of the stereospecificity of the substitution reaction involving bonds and radicals with the TBP structure.

The main aspects of the stereochemical problem under consideration is the possibility of the interconversion of the configurational isomers of the radicals, their frequency and activation barriers, the mechanisms of stereochemical transformations, and their role in the overall mechanism of the radical reactions of organophosphorus compounds. The study of the stereochemistry of phosphoranyl radicals is based on the findings obtained in the study of phosphorus(V) compounds with which the radicals have much in common according to experimental data.

X-Ray diffraction and NMR data established that the geometry of these compounds corresponds to either a TBP or a tetragonal pyramid (TP). In agreement with calculations, the energy differences between these conformations are small (~0.5 kcal mol^{-1}). It has come to be assumed that in the liquid phase the majority of phosphorus(V) compounds have the TBP geometry[9].



The so-called polarity rule has been established[9,10], according to which electron-donating substituents occupy equatorial positions in TBP, while electronegative substituents occupy apical positions (the vacant *d* orbitals of the phosphorus atom interact effectively with electron-donating substituents via the formation of dative bonds in the equatorial positions). Apart from the donor–acceptor interactions, steric effects play a major role, the apical position being more shielded. All these features make the apical bonds longer than the equatorial bonds.

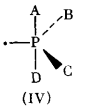
It has been noted that for cyclic ligands, particularly oxygen-containing cyclic ligands, five-membered rings occupy preferentially the equatorial-apical positions because the internal strain is reduced in this configuration. Six-membered rings are located mainly in the equatorial positions[10]. The presence of identical ligands leads to additional stabilisation as a result of the ligand symmetry. It consists in the fact that isomers having identical ligands in either apical or equatorial positions are more stable.

Thus the disposition of the substituents in phosphorus(V) compounds is a complex function of several parameters. The concept of "apicophilicity" of particular ligands, based on empirical data, is used to describe this function[9,10].

The use of NMR made it possible to follow, in an enormous number of examples, the dynamics of the mutual exchange of ligands in a TBP, in which the substituents exchange between the apical and equatorial positions. It was found that the frequencies of such transformations depend significantly on the nature of the ligands and the activation energy varies within wide limits (1.5–25 kcal $mole^{-1}$).[9]

The ligand exchange in the chiral phosphorane

(II) (III)



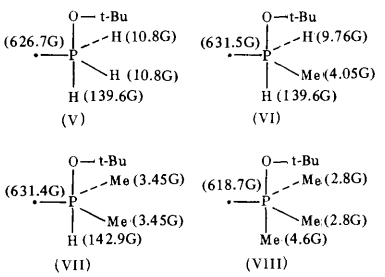
can be explained within the framework of two models: (1) Berry's pseudorotation mechanism[11], taking into account the change in the angles in the TBP, which leads to a TP as an intermediate conformation with formation of a new TBP, and (2) the Ramirez turnstile mechanism[10], which postulates the rotation of three ligands relative to two others and reflects the transposition mechanism of the pseudorotation. The turnstile mechanism is more applicable to the explanation of ligand exchange involving cyclic phosphorus compounds, where Berry's pseudorotation is accompanied by an increase of ring strain when the angles are altered.

Five different types of rearrangements of the TBP of the phosphorane P(ABCDE), denoted by *M*1–*M*5, are distinguished[12]. The rates of different rearrangements and the stability of the conformers depend on the nature of the ligands. In the stereochemistry of nucleophilic substitution at a tetracoordinate phosphorus atom the formation of an

intermediate (or transition state) with a pentacoordinate phosphorus atom, having the TBP geometry, is postulated. The empirical rule that the attacking nucleophile enters the apical position and the substituted ligand leaves the apical position has been established and has been widely confirmed on numerous examples[10]. Hexacoordinate phosphorus species are anions and have the octahedral configuration.

III. STEREOCHEMICAL TRANSFORMATIONS OF PHOSPHORANYL RADICALS

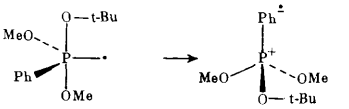
A TBP structure with the free valence located in the equatorial plane has been attributed to phosphoranyl radicals:



(IV)

This geometry has been established on the basis of the study of EPR spectra and theoretical analysis.

The EPR spectra of the simplest phosphoranyl radicals $\dot{P}F_4$ and $\dot{P}H_4$ show a non-equivalent hyperfine interaction (HFI) of the unpaired electron with the fluorine and hydrogen nuclei. In $\dot{P}F_4$ two fluorine atoms have an HFI constant of 259 G, while two others have a constant of 59 G; in $\dot{P}H_4$ two hydrogen atoms have an HFI constant of 198 G and two others have a constant of 6 G. The high HF constants involving the phosphorus atom (a_P), which amount to 1330 G in $\dot{P}F_4$ and 519.3 G in $\dot{P}H_4$, are associated with the appreciable *s* character of the hybrid *spd* orbital of the unpaired electron. Theoretical analysis[13,14] made it possible to assign the higher values of a_F and a_H to the apical positions and the lower values to the equatorial positions.



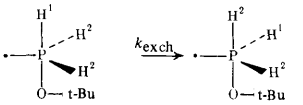
The EPR spectra of $\dot{P}F_4$ and $\dot{P}H_4$ were obtained in solid matrices. However, numerous examples of phosphoranyl radicals with a marked non-equivalence of the apical and equatorial substituents have also been obtained in solution. A number of phosphoranyl radicals in solutions in hydrocarbons have been obtained[6] at a low temperature by the addition of the t-butoxy-radical to the phosphines PH_3, CH_3PH_2, $(CH_3)_2PH$, and $(CH_3)_3P$. The structure of the radicals is shown in the diagram below, the values of the HFI constants being indicated opposite the corresponding atoms:

Thus the structure of phosphoranyl radicals is similar to that of phosphorus(V) compounds (phosphoranes), where the orbital of the unpaired electron acts as one of the substituents. It is therefore of great interest to follow the stereochemistry of the disposition of the substituents in phosphoranyl radicals and to compare it with the stereochemistry of the corresponding phosphoranes.

Roberts and coworkers carried out extensive studies in this field. They established that the chlorine atoms in chlorophosphoranyl radicals occupy apical positions preferentially. The EPR spectra of phosphoranyl radicals of the type t-Bu–O–$(RO)_n\dot{P}Cl_{3-n}$ and t-Bu–O–$R_n\dot{P}Cl_{3-n}$ have been investigated and show electron–Cl HF constants of 30–40 G.[15] In the EPR spectrum of $\dot{P}Cl_4$ the splitting by the apical chlorine atoms is 62 G and that by the equatorial atoms is 7 G.[16]

In the study of phenyl-substituted phosphoranyl radicals the fundamental problem of their structure arose (a TBP or tetrahedral structure). Doubts about the TBP structure of phenyl-substituted phosphoranyl radicals arose in view of the extremely low phosphorus hyperfine interaction constants in the corresponding radicals. Thus $a_P = 9.7$ G for t-Bu–O(Ph)$\dot{P}$·(OMe)$_2$ and we have $a_H^{para} = 9.7$ G, $a_H^{ortho} = 5.5$ G, and $a_H^{meta} = 0.9$ G.[17,18] On the basis of these data, it was suggested that the structure of phenyl-substituted phosphoranyl radicals changes from a TBP to a tetrahedron and that the radical itself acquires the betaine structure:

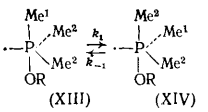
(IX) (X)



Numerous examples of radicals of this type have been presented in reviews[1,2].

Analysis of the hyperfine structure of the EPR spectra of a large number of phosphoranyl radicals established the apicophilicity series for substituents at the phosphorus atom[19,20]:

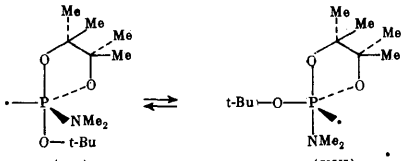
$$F, Cl, RC(O)O > CF_3, \overline{CH_2CH_2CH_2C(O)N}, OCN > RO, R_2N > H > H_3C.$$



This apicophilicity series agrees on the whole with the electronegativities of the substituents and is consistent with the general characteristics established in the study of phosphorus(V) compounds. The study of the EPR spectra of phosphoranyl radicals over a wide temperature range showed that, with increase of temperature, an interchange of the ligand positions at a frequency of 10^6–10^8 s^{-1} is observed in some cases.

Krusic and Meakin[21] measured the frequency of exchange between two types of hydrogen atoms in t-BuO$\dot{P}H_3$ and the corresponding activation barrier and found that $\Delta G^{\neq} = 5.3$ kcal mole^{-1} at −75 °C and $k_{exch} = 3 \times 10^6$ s^{-1} at −80 °C:

(XI) (XII)



A similar example is provided by the t-butoxytrimethylphosphoranyl radical, in which the methyl groups change positions[22]:

(XIII) (XIV)

$k_1 = 4 \times 10^6$ s^{-1} at −70 °C. The temperature dependence of the rate constant is of the form $\lg k_1 = (10.4 \pm 1) - (13 \pm 4)$ kcal mole^{-1} θ^{-1}, where $\theta = 2.3\,RT$ kcal mole^{-1}. The rate of ligand exchange involving methyl groups is independent of the nature of the alkoxy-group (R = Et, t-Bu, or t-pentyl). It has been stated that[18] in certain trimethyl (R,R′) phosphoranes similar methyl exchange frequencies are observed.

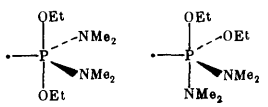
Another example where the ligands change positions is provided by the aminophosphoranyl radical[23]:

(XV) (XVI)

In contrast to the previous case, the states of the radicals (XV) and (XVI) are energetically different. The spectroscopic characteristics of the radicals (XV) and (XVI) differ appreciably:

Radical	(XV)	(XVI)
a_P, G	849	784
a_N, G	8.4	24

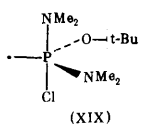
At −120 °C the ratio of the radical concentrations is (XVI)/(XV) = 0.25. With increase of temperature, the rate of interconversion of radicals (XV) and (XVI) increases, which is manifested by a characteristic broadening of the hyperfine structure (HFS) components associated with the nitrogen nuclei. Agreement between the experimental and calculated spectrum was achieved for $k_1 = 2.0 \times 10^7$ s^{-1}, $k_{-1} = 8.0 \times 10^7$ s^{-1}, and (XVI)/(XV) = 0.25 at −120 °C and $k_1 = 10^8$ s^{-1}, $k_{-1} = 3.3 \times 10^9$ s^{-1}, and (XVI)/(XV) = 0.3 at −80 °C.[23]



The following equation holds in the range between −120 °C and −80 °C:

$$\lg k_1 = 10.7 - 2.4/\theta,$$

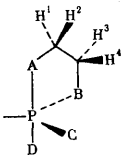
where $\theta = 2.3\,RT$.



The temperature dependence of the equilibrium constant K = (XVI)/(XV) in the range from −160° to −120 °C makes it possible to determine $\Delta H^\circ \cong \Delta G^\circ \cong 0.4$ kcal mol^{-1} and $\Delta S^\circ \cong 0$.

The interaction of EtO· with $EtOP(NMe_2)_2$ gives rise to two radicals, namely (XVII) and (XVIII):

(XVII) (XVIII)

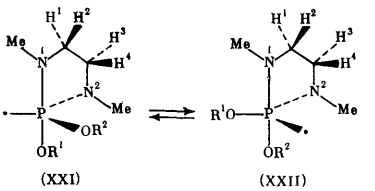


At −126 °C the concentration ratio [XVIII]/[XVII] = 6. At −140 °C each component of the phosphorus doublet in the spectrum of radical (XVIII) is split into a 1 : 1 : 1 triplet ($a_N = 11.5$ G). With increase of temperature to −110 °C, the three lines are replaced by five lines with a splitting of 7.5 G, and at −90 °C their intensity ratios become close to 1 : 2 : 3 : 2 : 1. These changes are attributed to the rapid exchange between the NME_2 groups in the apical and equatorial positions in the radical (XVIII) ($k_{exch} = 10^8$ s^{-1} at −110 °C).[23] In the radical[24]

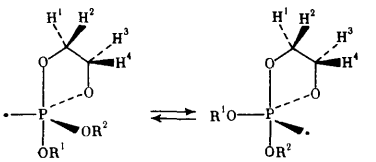
(XIX)

the exchange of the dimethylamino-groups takes place at a rate of 2×10^7 s^{-1}, i.e. is somewhat slower than in the radical $(EtO)_2\dot{P}(NMe_2)_2$.

In the EPR spectra of the radicals of 1,3,2-dioxaphospholane and 1,3,2-diazaphospholane derivatives[23,24]



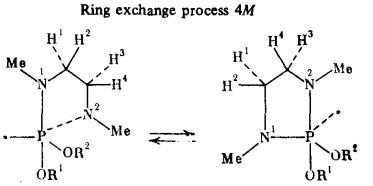
(XX)



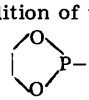
where A = B = O or A = B = N–Me, a hyperfine splitting by the quasi-apical ring protons H^1 or H^2 is observed and can serve as a source of information about the stereochemical mobility of these radicals.

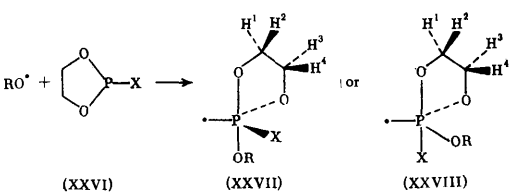
For the above radicals, different stereochemical reactions are possible:

Exocyclic process 4*M*



(XXI) (XXII) (1)



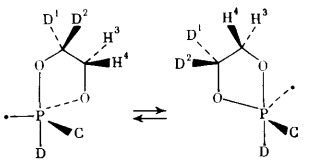


(XXIII) (XXIV) (2)

Ring exchange process 4*M*

(XXI) (XXV)

The addition of the alkoxy-radical RO· to 1,3,2-dioxaphospholane  as well as 1,3,2-diazaphospholane can proceed stereospecifically depending on the electronegativity of X:

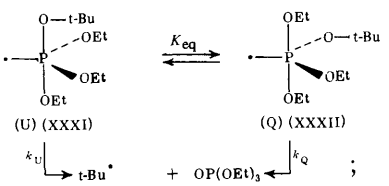


(XXVI) (XXVII) (XXVIII)

At a low temperature hyperfine splitting by one H^1 or H^2 proton is observed in the spectra of radicals formed from 1,3,2-dioxaphospholane when RO and X have markedly different apicophilic properties; the hyperfine interactions with the H^1 and H^2 protons are different owing to the differences between the steric orientations of these protons relative to the unpaired electron. When X and RO are identical, hyperfine splitting by the two equivalent protons ($a_H = 2$ G), caused by by the rapid exchange via reaction (2), is observed.

For C = D = OEt, the exocyclic process 4*M* takes place with $k_{exch} > 6 \times 10^9$ s^{-1} over the entire experimental temperature range. When C = OEt, D = Cl, and Cl is much more apicophilic than OEt, the groups change positions in the ring. The same process is observed for D = $MeCO_2$, CF_3CO_2, BzO, and $(EtO)_2P(O)O$. On the other hand, if D = F, OCN, and $CH_2(CH_2)_2C(O)N$, changes in line form are not observed, which indicates the absence of ligand position interchange[23,24].

The exocyclic 4*M* process and the exchange process in the ring were resolved using 4,4-dideutero-1,3,2-dioxaphospholanes. The resolution was achieved on the basis of the different HFS changes in spectra of the protonated and 4,4-dideutero-derivatives of the radicals when the temperature is varied:



(XXIX) (XXX)

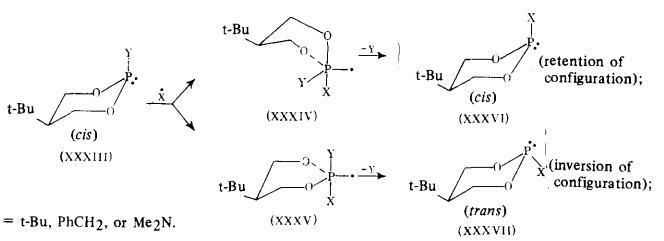
In the interchange of positions in the rings of radicals of 4,4-dideutero-derivatives of 1,3,2-dioxaphospholanes, the spectra are altered; with increase of temperature, there is a transition from the superposition of the doublet due to one proton in one pseudoapical CH_2 group (with a splitting of 4 G) on to a singlet due to one pseudoapical CD_2 group to a doublet with a splitting of 2 G, which corresponds to rapid migrations of the CH_2 and CD_2 groups between the apical and equatorial positions. In the exocyclic 4*M* process involving the protonated form there should be a change from a doublet with a splitting of 4 G to a 1:2:1 triplet with a splitting of 2 G. For the deutero-derivative at a high temperature, a singlet due to the deutero-group should be superimposed on the triplet and the resultant spectrum should have intensity ratios of 1:6:1, which has been observed experimentally[24].

The results show that the ligand positions are interchanged in the phosphoranyl radicals; the rate and nature of these processes are determined by the structural characteristics of the radicals.

The study of ligand exchange processes in phosphoranyl radicals involves the investigation of the chemical reactions of these radicals. Thus the mobility of the leaving group in the apical and equatorial positions is very important for the β-elimination reaction. The equilibrium between the stereoisomers can influence the observed β-elimination rate constant in the following way:

(U) (XXXI) (Q) (XXXII)

$$k_{obs} = (k_U + k_Q K_{eq})/(1 + K_{eq}).$$



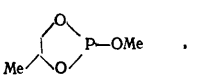
Thus in the elimination of the t-butyl radical with equilibrium between the stereoisomers, cleaved at different rates, will influence significantly the rate of the chemical reaction.

Kinetic studies have revealed definite stereochemical relations for α- and β-elimination reactions involving phosphoranyl radicals[22,25-28]. It has been suggested that in tetraalkoxyphosphoranyl radicals β-elimination takes place preferentially in the equatorial position, while α-elimination in alkoxyalkylphosphoranyl radicals takes place from the apical position[22,25].

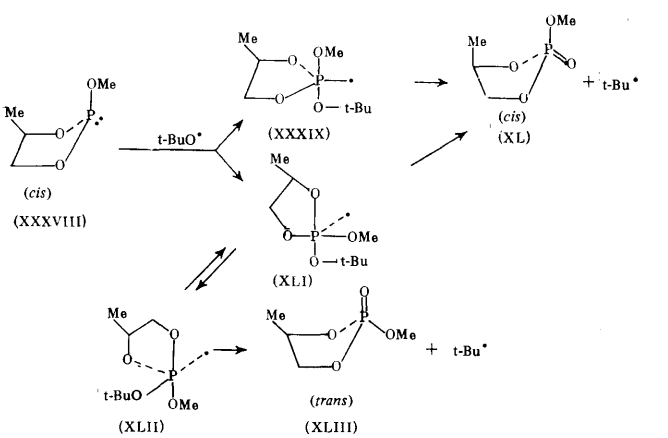
A definite relation has been observed between the stability of phosphoranyl radicals and the change in the number of alkyl and alkoxy-groups in the radical[27]. The maximum stability is observed when the numbers of alkyl and alkoxy-groups are equal. This is attributed to the fact that, in conformity with their more pronounced apicophilic properties, the alkoxy-groups are located in the apical positions, while the alkyl groups are in the equatorial positions[27]. Thus the groups involved in α- and β-elimination are located in chemically inactive positions.

Stereochemical transformations are important in homolytic substitution reactions involving phosphorus(III) compounds. Bentrude and coworkers[29,30] studied the stereochemistry of radical substitution and oxidation of phosphorus(III) compounds[29,30] In the course of the investigation of these reactions the problem arose of the configurational stability of the phosphoranyl radicals formed and of its influence on the yield of the isomers.

The stereochemistry of the substitution reaction was studied in the following example[29];



(*cis*) (XXXIII) (XXXIV) (XXXV) (*cis*) (XXXVI) (retention of configuration); (*trans*) (XXXVII) (inversion of configuration);



Y = t-Bu, $PhCH_2$, or Me_2N.

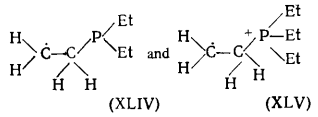
The radical X· was Me_2N·, obtained in the decomposition of the tetrazene $Me_2NN{=}NNMe_2$ under the influence of ultraviolet light. These reactions proceed with a high degree of stereoselectivity and lead mainly to inversion of configuration. It has been suggested that the disposition of X and Y in the apical positions in structure (XXXV) is responsible for the observed inversion of configuration.

The stereochemistry of the oxidation reactions of phosphorus(III) compounds has been studied[30] for the compound

It was found that the reaction is stereospecific and proceeds with retention of configuration. The retention of configuration implies that the β-decomposition of phosphoranyl radicals is faster than the ligand exchange (XLI) → (XLII):

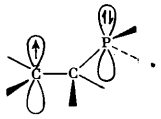
(*cis*) (XXXVIII) (XXXIX) (*cis*) (XL) (XLI) (XLII) (*trans*) (XLIII)

The retention of configuration was observed previously[31] in the study of the oxidation of the following compound:



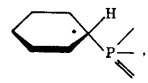
The stereospecificity of the above reactions implies a "memory" of the pathways followed in the formation of the phosphoranyl radical. On the other hand, the intramolecular migrations of the ligands should abolish this effect. In order to observe the "memory" effect, Hay and Roberts[32] obtained radicals of the type $(RO)_2\dot{P}(OR^1)OR^2$ in two ways: by the reaction between $(RO)_2POR^1$ and $R^2O^\cdot$ and by the reaction between $(RO)_2POR^2$ and $R^1O^\cdot$. The relative yields of the radicals $R^{1\cdot}$ and $R^{2\cdot}$, formed as a result of β-elimination, are independent of the source of the intermediate phosphoranyl radicals. It follows from these date that the tetraalkoxyphosphoranyl radicals do not retain a "memory" of their origin. The authors[32] concluded that the high rate of exchange of the alkoxy-ligands in phosphoranyl radicals precludes the observation of a "memory" effect in reactions involving the oxidation of phosphites by alkoxy-radicals. It follows from the above results[32] that the "memory" effects observed previously by Bentrude and coworkers in the oxidation of phosphites by alkoxy-radicals were not confirmed in their repeated investigations.

Thus the influence of the interchange of ligand positions in phosphoranyl radicals on the yield of the stereoisomers of the final products depends on the rates of these processes and on the rate of decomposition of the phosphoranyl radicals.



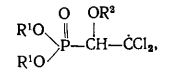
IV. CONFORMATION OF PHOSPHORUS-SUBSTITUTED RADICALS

There exists a wide class of phosphorus-containing radicals in which the unpaired electron is localised at carbon atoms in the β-positions relative to the phosphorus atom. In such radicals the hyperfine interaction of the unpaired electron with the phosphorus nucleus depends significantly on their geometrical structure. Symons and coworkers[33,35] investigated the EPR spectra of the radicals



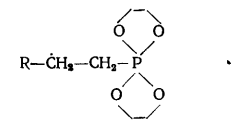
(XLIV) (XLV)

obtained by the γ-irradiation of powdered specimens of the corresponding phosphines and phosphonium salts at 77 K. The isotropic HFI constants calculated from the spectra proved to be $a_P = 251$ G for (XLIV) and $a_P = 120$ G for (XLV). The much higher values of a_P for the former radical can be accounted for by the homoconjugation of the $2p_z$ unpaired electron orbital and the phosphorus orbital occupied by the lone electron pair:

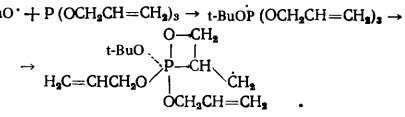


The mechanism of the delocalisation of the unpaired electron over the quadrivalent phosphorus atom in radical (XLV) is not so evident. Presumably the transfer of unpaired electron spin density to the quadrivalent phosphorus atom proceeds via $p_\pi - d_\pi$ conjugation. However, Symons believes[35] that this mechanism is unlikely, since it is inconsistent with the isotropic nature of the HFI constant. As an alternative hypothesis, a hyperconjugation mechanism involving the C–P bond was postulated. The strong hyperfine interaction with the phosphorus nucleus in the cyclohexadienyl radical

obtained by the γ-irradiation of phenylphosphonous acid PhPO(O)H at 77 K, can be accounted for by an analogous mechanism[36]. An isotropic EPR spectrum was observed for this radical and the following HFI constants were calculated from it: $a_H = 40$ G for the methylene proton, $a_H = 10$ G for the *ortho*- and *para*-protons of the benzene ring, and $a_P = 200$ G.

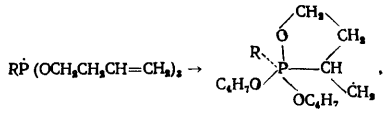


Damerau and coworkers[37–40] obtained radicals of the type



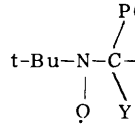
in aqueous solution for which a_P varies from 60 to 69 G, depending on the size of R^1 and R^2, and in addition it depends on temperature. The latter finding is related to the angular dependence of the phosphorus hyperfine interaction constant and constitutes significant evidence in support of the hyperconjugation mechanism[37].

A number of β-phosphorus-substituted alkyl radicals have been obtained in the liquid phase by the addition of phosphorus-centred radicals to unsaturated compounds. For such radicals, the phosphorus hyperfine interaction constant is in the range from 30 to 180 G and is determined mainly by the conformation of the radical. Thus Beckwith[41] investigated the EPR spectra of the radicals formed as a result of the addition of HPO_2, $H\dot{P}O_3$, and $\dot{P}O_3^{2-}$ to unsaturated compounds of the type $R_2C=CR'_2$, where R, R' = H, CH_3, CO_2H, or the aci-anions of nitroalkanes ($H_2C=NO_2$). The phosphorus hyperfine interaction constants in the resulting adducts varied in the range from 60 to 100 G; the phosphorus hyperfine interaction is treated within the framework of the hyperconjugation mechanism with participation of 3*d* orbitals. Radicals of an analogous type were also obtained by Gilbert et al.[42] The phosphorus hyperfine interaction constants in these adducts vary with temperature, which shows that they depend on the conformation.



Davies et al.[43] investigated the EPR spectra of the radicals formed following the addition to the double bond of dialkoxyphosphonyl radicals of the type $(RO)_2\dot{P}O$, for which the phosphorus hyperfine interaction constant in the range 94–112 G and this corresponds to β-phosphorus-substituted alkyl radicals. Radicals have been obtained similarly by the addition of spirophosphoranyl radicals to olefins[44]:

Davies et al.[45] also observed an interesting reaction involving the intramolecular addition of the phosphoranyl radical to the double bond of an olefinic substituent. Phosphoranyl radicals containing 2-alkenyloxy-substituents cyclise to oxaphosphotans, in which the unpaired electron is localised at an exocyclic carbon atom:



Depending on the substituents, a_P varies from 176 to 199 G. On the other hand, if the phosphorus atom is linked to 3-alkenyloxy-groups, cyclic oxaphospholan radicals are formed;

for which the isotropic HFI constant is $a_P = 127-136$ G.[45]

From the standpoint of conformational analysis, more or less stable nitroxy-radicals incorporating phosphorus-containing fragments proved to be very interesting. Il'yasov and coworkers[46] obtained a large number of such radicals using 2-methyl-2-nitrosopropane as the spin-trapping agent and analysed in detail their EPR spectra. The presence of one or two magnetic phosphorus nuclei in nitroxy-radicals of this kind leads to the appearance of hyperfine interaction of the unpaired electron with these nuclei; the HFI constant can serve as a criterion of the conformation of the molecules and of its dependence on the steric and electronic effects of the substituents. Additional information is provided by the hyperfine interaction β-proton constant when a β-proton exists.

Table 1. The HFI constants for radicals of the type

obtained in a 1:3 (by volume) water–alcohol mixture at room temperature.

No.	Y	a_N, G	a_P, G	a_H, G
(XLVI)	$P(O)(OEt)_2$	14.2	42.1; 42.5	1.6
(XLVII)	H	16.3	45.0	10.3 (2H)
(XLVIII)	COOMe	14.3; 14.2	29.2; 28.8	2.0; 2.4
(XLIX)	COOEt	14.3; 14.3	28.7; 28.5	2.3; 2.5
(L)	$COOC_3H_7$	14.3; 14.3	28.8; 28.4	2.4; 2.8
(LI)	COC_6H_5	14.3; 14.3	22.6; 22.5	4.7; 4.8

Table 1, taken from the paper by Il'yasov and coworkers[46], lists the EPR data for nitroxy-radicals with phosphorus-containing fragments. We shall consider the nitroxy-radical (XLVI), which incorporates two phosphorus atoms. The presence of two different ^{31}P hyperfine interaction constants and the low value of the single β-proton hyperfine interaction constant ($a_H = 1.6$ G) are striking. These data agree with the conformation proposed by the authors[46], which has the form, in terms of the Newman projection, illustrated in Fig.1. The low values of the β-proton hyperfine interaction constant shows that the angle between the direction of the C–H bond and the axis of the $2p_z$ orbital of the unpaired electron is close to 90° ($\alpha \to 0$). For the same reason, the difference between the two phosphorus hyperfine interaction constants is only 0.4 G. With increase of temperature, the phosphorus HFI constants become even more similar but the complete equivalence of the two phosphorus nuclei could not be attained up to 100 °C. A further increase of temperature is limited owing to the inadequate stability of the radical.

For the phosphononitroxy-radical (XLVII), which has one phosphorus atom and two β-protons, there is a complete equivalence of the protons even at room temperature. It might have been thought that the equivalence of the two protons is due to the free rotation of the $C(P)H_2$ fragment about the C–N bond. However, the experimental value of the constant $a_H^\beta = 10.3$ G, the lower limit of which is 13 G according to Chapelet-Letournux et al.[47], is inconsistent with this hypothesis. In order to account for the equivalence of the β-protons in radical (XLVII), the authors[46] therefore postulated a rapid transition between two conformations, which would lead to the averaging of the hyperfine interaction with the protons H_a and H_b (Fig.2).

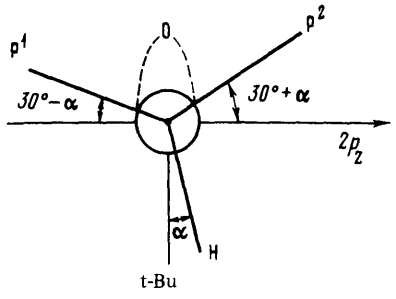


Figure 1. Schematic representation of one of the conformations of the nitroxy-radical (XLVI).

The two conformations are energetically equivalent and the average value of a_H under the conditions of a rapid transition is therefore determined by the simple relation:

$$\langle a_H \rangle = \frac{1}{2} B_2^N \rho_N^\pi (\langle \cos^2 90° \rangle + \langle \cos^2 30° \rangle)$$

where $\beta_2^N \rho_N^\pi = 26 \pm 2$ G is characteristic of the majority of nitroxy-radicals[47].

Stone and Maki[48] developed a theory, according to which the the values of $\langle \cos^2\theta \rangle$ are related to the barrier V_0 to the conformational transitions. Using conclusions from this theory, Il'yasov and coworkers[46,49] showed that the experimental β-proton hyperfine interaction constant in radical (XLVII) $a_H^\beta = 10.3$ G corresponds to the barrier $V_0 = 2$ kcal mole^{-1}.

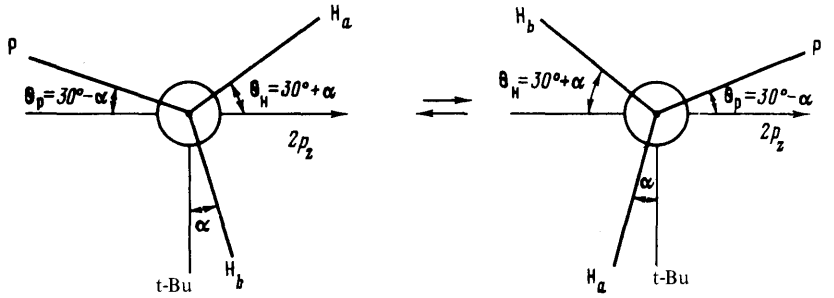
Table 1 shows that a_P for the phosphononitroxy-radicals (XLVIII)–(LI) is greatly reduced compared with the values for radicals (XLVI) and (XLVII), which indicates an increase of the angle θ_P, which can be estimated from the β-proton splitting. For example, $\langle \theta_H \rangle = 80°$ when $V_0 = 3$ kcal mole^{-1} has been found for the nitroxy-radical (L) from the expression

$$a_H^\beta = \rho_N^\pi (B_0 + B_2 \langle \cos^2 \theta_H \rangle)$$

on the assumption that $B_0 \cong 0$ [50] and using the experimental value $a_H^\beta = 2.8$ G. Here it is evident that $\langle \theta_P \rangle = 40°$. The expression

$$a_P^\beta = \rho_N^\pi (B_0 + B_2^P \langle \cos^2 \theta_P \rangle)$$

with $B_0 \cong 0$ and $\rho_N^\pi B_2^P = 56$ G [46] yields $a_P = 31$ G, which is very close to the experimental value $a_P = 28.8$ G.



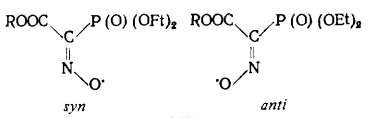


Figure 2. Schematic illustration of the conformational transitions in the nitroxy-radical (XLVII).

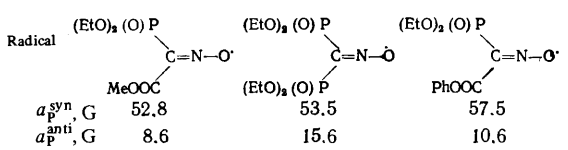
With decrease of temperature, the EPR spectra of the two forms of the nitroxy-radicals (XLVIII)–(LI) are resolved. In their study of the temperature dependence of the concentration of the two forms, Il'yasov and coworkers[46] estimated the difference between the energies of these forms. Thus $\Delta H = -0.36$ and -0.77 kcal mole^{-1} for radicals (XLVIII) and (L) respectively.

The unpaired electron in the nitroxy-radicals examined above is localised mainly in the 2*p* orbitals of the nitrogen and oxygen atoms. The angular dependence of the ^{31}P hyperfine interaction constant shows that the transfer of spin density to the phosphorus atom proceeds via the hyperconjugation mechanism.

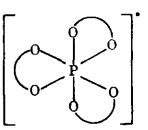


Il'yasov and coworkers[51] obtained phosphorus-containing iminoxy-radicals of another type:

(LII)

A characteristic feature of these radicals is the possibility of spin density transfer to the phosphorus atom via the system of σ bonds, since the unpaired electron is located mainly in the σ plane. The EPR spectra showed that in solution the radicals (LII) exist in the form of stable *syn*- and *anti*-isomers with markedly different HFI constants and *g*-factors. The spectroscopic parameters of some of the radicals investigated are listed in Table 2, which shows that the phosphorus hyperfine interaction constant is much greater for the *syn*-isomers than for the *anti*-isomers. The authors[51] found from the temperature dependence of the relative concentrations of the isomers that the equilibrium is displaced towards the *anti*-isomer, which is thermodynamically more favourable ($\Delta H = -1.1$ kcal mol^{-1}).

It is interesting to compare the influence of the electronic properties of substituents on the phosphorus hyperfine interaction constant in the *syn*- and *anti*-isomers. For this purpose, we shall compare the values of a_P for the following three radicals[49]:



The data show that the electronic properties of the substituents have a greater influence on the a_P constants for the *anti*-isomers. One can therefore postulate that in these isomers the σ–π polarisation and the delocalisation of the unpaired electron over the σ bonds make a significant contribution to the phosphorus hyperfine interaction. In the *syn*-isomers the spin density is largely transmitted via a mechanism involving the direct overlap of the orbitals of the unpaired electron with the σ orbitals of the C–P bond.

Table 2. Parameters of the EPR spectra of radicals (LIII).

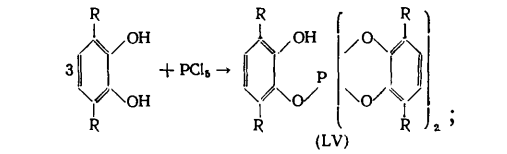
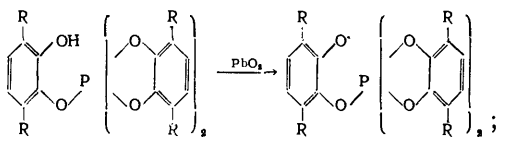
V. TAUTOMERISM OF PHOSPHORANYLPHENOXY-RADICALS

The previous sections dealt with radicals in which the free valence was localised either in the hybrid orbitals of the phosphorus atom (phosphoranyl radicals) or in the *p* orbitals of the carbon or oxygen atoms linked directly to the phosphorus atom. Here we shall deal with radicals where the free valence migrates between the oxygen atoms of catechol ligands attached to the phosphorus atom. In these radicals the phosphorus is formally hexacoordinate[8]:

The arcs drawn between two oxygen atoms represent different *ortho*-phenylene groups[53]. The migration of the free valence in these radicals involves the stereochemical features of quinquevalent phosphorus (see above).



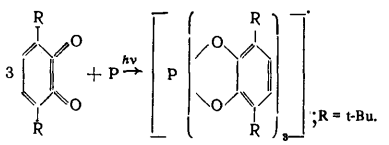
The photoinitiated reaction of 3,6-di-t-butyl-o-quinone with the spirophosphorane (LIII) leads to the formation of an analogue of the phosphate anion (LIV) which carries an unpaired electron instead of a negative charge[8]:



(LIII) (LIV)

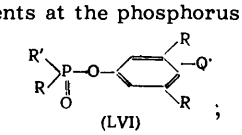
R = t-Bu.

The same free radical can be obtained by the oxidation with lead dioxide of the hydropyrophosphorane (LV), which is synthesised in its turn from 3,6-di-t-butylcatechol and phosphorus pentachloride[58]:



(LV)

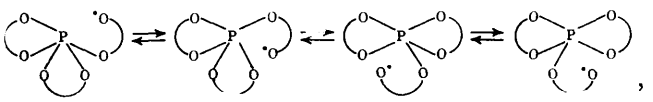
(LIV)



R = t-Bu.

Radical (LIV) is also obtained by the photoaddition of 3,6-di-t-butyl-o-quinone to elemental phosphorus[53]

R = t-Bu.



Solutions of the free radicals (LIV), obtained in different ways, exhibit identical EPR spectra with similar temperature variations. Fig.3 illustrates the EPR spectrum of radical (LIV) in ether. At 20 °C the spectrum consists of a doublet with a phosphorus splitting of 4.0 G; each component of the doublet consists of seven lines with the intensity ratios 1:6:15:20:15:6:1 (the splitting by the six equivalent protons is $a_H = 1.45$ G). Thus the unpaired electron interacts with all six protons of the three benzene rings and with the phosphorus atom. The spin density at the phosphorus atom itself is then low: the splitting constant of 4.0 G can be compared with the splitting in the spectrum of the phenoxy-radical (LVI), which amounts to 6–7 G (depending on the nature of the substituents at the phosphorus atom):[52]

(LVI)

R = t-Bu.

One must assume that the unpaired electron spin density is localised mainly in the catechol fragments. With decrease of temperature, the components are broadened at −80 °C the spectrum is converted into a doublet of triplets (Fig.3)—a doublet due to the phosphorus atom and a triplet with a splitting of 4.35 G due to the two protons of one ring[8,53]. Thus at 20 °C and above the free valence "migrates" between all six equivalent oxygen atoms:

etc., while at low temperatures the EPR spectra reveal the interaction with the protons of only one ring.

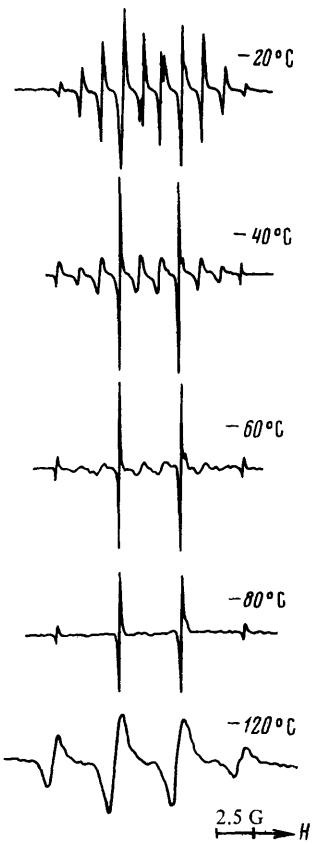


Figure 3. The EPR spectrum of radical (LIV) in ether at different temperatures.

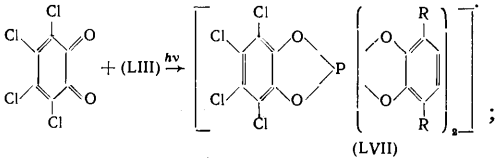


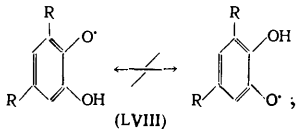
The temperature-induced changes in the spectrum have been studied in greater detail in solution in ether[53]. At low temperatures a quartet splitting was observed (by two protons and a phosphorus atom; 1:3:3:1), but the intermediate spectra are particularly distinct and convenient for the kinetic analysis of the exchange process. It was found that, with decrease of temperature, both interligand and intraligand exchange reactions are retarded to approximately the same extent, but, whereas the interligand exchange is already "frozen", the rapid-exchange spectral conditions are maintained for the intraligand exchange, which

has approximately the same intrinsic frequency, and we observe splitting by two protons. The exchange frequency is

$$\nu_{exch}=3.4\cdot10^{12}\exp[(-4300\pm500)/RT]\ s^{-1}.$$

The frequency of the "migration" of the unpaired electron at 20 °C (toluene) is $2.2\times10^9\ s^{-1}$. Thus at 20 °C the unpaired electron passes through all six oxygen atoms with a jump frequency of 2×10^9 per second.

The interaction of the spirophosphorane (LIII) with *o*-chloranil on irradiation also gives rise to the radical (LVII), which contains a formally hexacoordinate phosphorus atom[8]:

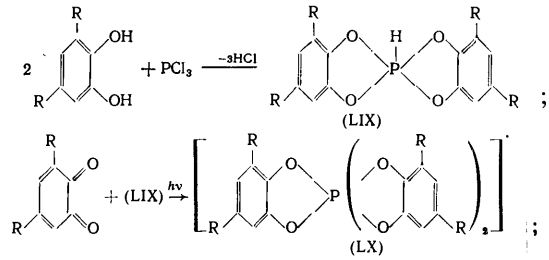


(LVII)

R = t-Bu.

The presence of four chlorine atoms in a single ring suggested that the unpaired electron spin density is preferentially concentrated in two other catechol fragments and at the phosphorus atom. Indeed the 1:3:3:1 quartet is observed in the EPR spectrum at −80 °C (splitting by the phosphorus atom and the two protons—interaction of the unpaired electron with the protons of a single ring), while on increase of temperature the spectrum is transformed into a doublet of 1:4:6:4:1 quintets corresponding to four equivalent protons. The splitting by phosphorus is 4.35 G and that in the quintet is 2.18 G#. It is remarkable that the splitting in the quintet is 1.5 times greater than that (1.45 G) in the septet and the symmetrical radical (LIV). The explanation is that the same spin density in the former case is distributed over six protons, while in the latter case it is distributed over four protons. Hence the entire spin density, previously distributed over three ligands, is now concentrated in two ligands, i.e. we have a "four-well" system[8].

Hitherto we have considered only radicals with a symmetrical ligand—the 3,6-di-t-butylphenylenedioxy-group. A series of studies have been carried out with an asymmetric ligand—the 3,5-di-t-butylphenylenedioxy-group. In the first place one should note that neither hydrogen nor deuterium migrate in the corresponding semiquinone radical—the 4,6-di-t-butyl-2-hydroxyphenoxy-radical (LVIII)—up to 200 °C:[54]

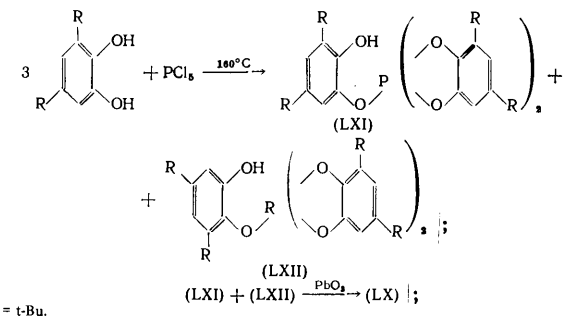


(LVIII)

R = t-Bu.

From our point of view, this can be explained by the non-equivalence of the oxygen atoms; the transfer of the proton to the oxygen atom adjoinging the t-butyl group actually becomes relatively unfavourable owing to the steric shielding by this group§. One could therefore assume that there is no intramolecular exchange in "multiwell" systems containing this fragment.

The photoinitiated reaction of 3,5-di-t-butyl-*o*-quinone with the spirophosphorane (LIX), obtained from 3,5-di-t-butylcatechol and phosphorus trichloride, leads to the formation of the free radical (LX) with three 3,5-di-t-butylphenylenedioxy-ligands[56]:

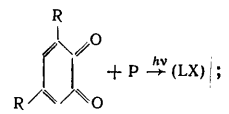


(LIX)

(LX)

R = t-Bu.

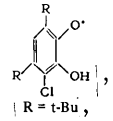
The same radical is formed in the oxidation with lead dioxide of a mixture of the spirophosphoranes (LXI) and (LXII) obtained from 3,5-di-t-butylcatechol and phosphorus pentachloride. When these reactants are fused together, a mixture of the isomers (LXI) and (LXII) is produced; on oxidation, both isomers give rise to the same three-ligand radical (LX):[56]



(LXI)

(LXII)

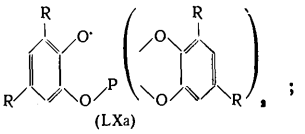
R = t-Bu.



The same radical is formed in the photoinitiated reaction of elemental phosphorus with 3,5-di-t-butyl-*o*-quinone[53]:

R = t-Bu.

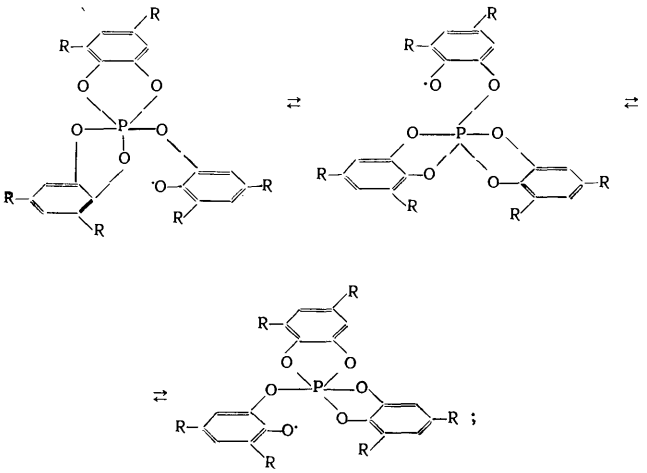
At a low temperature (−100 °C, toluene) the EPR spectrum of this radical consists of a triplet due to the hyperfine interaction with the proton in the 5-position and the phosphorus



§ This does not imply that the absence of symmetry in the radical inevitably leads to the absence of migration. This happens only for large energy differences between different forms. In other cases, for example, for the 4,6-di-t-butyl-3-chloro-2-hydroxyphenoxy-radical

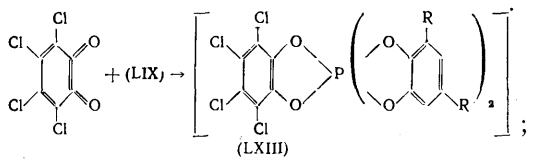
all the characteristics of hydrogen-tropic tautomerism[55] (non-degenerate!) are observed.

Radical (LVII) is unstable and disproportionates even at −40 °C, which complicates the spectrum.



atom ($a_H^5 = a_P = 4.35$ G). Under these conditions, the structure (LXa), with the unpaired electron localised at one of the oxygen atoms of one of the ligands, should be assigned to this radical:

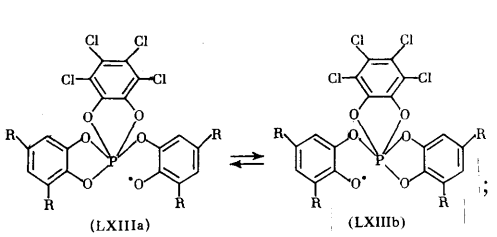
(LXa)



R = t-Bu.

With increase of temperature, additional broad lines appear and at −40 °C a doublet of 1:3:3:1 quartets arises (a_H = 1.45 G)—the unpaired electron interacts with three equivalent protons of three benzene rings; this is a "three-well" system, with one well for each ligand, and only interligand exchange takes place[56]:

R = t-Bu.



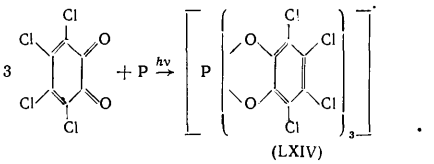
If *o*-chloranil is involved in the reaction with the spirophosphorane (LIX) instead of di-t-butyl-*o*-quinone, a new three-ligand radical (LXIII) is formed[56]:

(LXIII)

R = t-Bu.

As noted previously, the *o*-chloranil ligand is in this case excluded from the exchange. The EPR spectrum at −100 °C in toluene therefore shows a 1:2:1 triplet ($a_H^5 = a_P = 4.35$ G) and at −40 °C a doublet of 1:2:1 triplets ($a_H = 2.17$ G). In the first case there is a "frozen" structure (LXIIIa) or (LXIIIb), while in the second case there is rapid interligand exchange with splitting by one proton in each ligand:

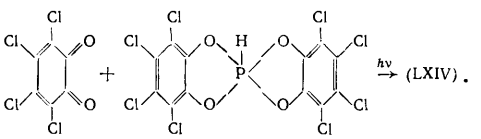
(LXIIIa) (LXIIIb)



R = t-Bu.

For the low-temperature spectrum (splitting by one proton), the splitting constant is 4.35 G and in the "two-well" system at −40 °C it amounts to 2.17 G, i.e. the splitting by each proton is smaller by a factor of two, while in the "three-well" system the contant is 1.45 G, i.e. the splitting is smaller exactly by a factor of three[56].

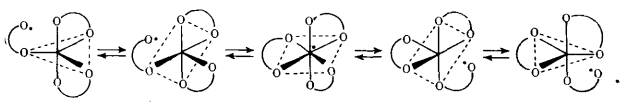
The exchange process involving thse radicals belongs to the category of rapid processes. At 20 °C the exchange frequency is 1.2×10^9 s^{-1} for the "three-well" system and 4×10^9 s^{-1} for the "two-well" interligand system[56]. The kinetic parameters of the exchange reactions (s^{-1}) are as follows:



$$\nu_{(LX)} = 4.8 \cdot 10^{12} \exp\{-(4800 \pm 500)/RT\}\ s^{-1};$$
$$\nu_{(LXIII)} = 2 \cdot 10^{14} \exp\{-(6300 \pm 500)/RT\}\ s^{-1}.$$

The reaction of white phosphorus with *o*-chloranil under irradiation gives rise to the highly chlorinated three-ligand radical (LXIV):[53]

(LXIV)



The same radical is formed in the photochemical reaction of *o*-chloranil with a perchlorospirophosphorane:

The EPR spectrum of this radical naturally contains only one doublet with a splitting of 3.4 G by the phosphorus atom, because the hyperfine interaction with the chlorine nuclei is not manifested. Nothing can be said about the characteristic features of this radical.

The examples of the free valence and bond exchange reactions examined involve intramolecular radical substitution at a pentacoordinate phosphorus atom of the "synchronous" type[57]. The instantaneous structure of the given radicals, with the localisation of the unpaired electron at one oxygen atom, consists of a trigonal bipyramid. The pseudorotation characteristic of pentacoordinate phosphorus compounds, as a result of which the apical and equatorial positions change places, has a broad frequency spectrum which depends on the nature of the substituents in these compounds. In particular, the pseudorotation frequencies for hydroxyspirophosphoranes are $>10^5$ s^{-1} and the energy barrier is <8 kcal mole^{-1}.[10]

Thus the kinetic equivalence of the intra- and inter-ligand exchange processes can be indissolubly linked to pseudorotation. When the trigonal bipyramid passes through the stage of a tetragonal pyramid on pseudorotation, it is attacked from the "rear" (from the side of the base) by an oxygen atom with an unpaired electron. The intermediate octahedral structure constitutes in this case a transition state[53]:

bipyramid pyramid octahedron pyramid bipyramid

If the pseudorotation frequency is higher than the rate of intramolecular exchange, then any oxygen atom can be located at the apical positions of the bipyramid or at the

vertex of the tetragonal pyramid (positions subjected to radical attack). Evidently the intra- and inter-ligand exchange reactions should be indistinguishable from this point of view. However, it can be assumed that the octahedral configuration constitutes a transition state in which all the oxygen atoms become equivalent and the loss of any of them is equally probable, which is consistent with experimental data; the requirement for high pseudorotation frequencies of the bipyramid then loses significance. Both concepts are evidently fairly speculative in view of the lack of correct pseudorotation frequencies for pentacoordinate phosphorus compounds (above 10^5 s^{-1}). One can only say that the low phosphorus HFI constant and the similarity of the unpaired electron density distribution in the radicals under consideration (when the interligand exchange is "frozen") to that in semiquinone radical-anions with a similar structure indicates the localisation of the unpaired electron almost entirely in the catechol ligand. This constitutes important evidence in support of an octahedral transition state in the intramolecular free valence and bond exchange reactions considered.

The above mechanism apparently determines the nature of the exchange involving radicals containing non-equivalent and asymmetric ligands. The intra- and inter-ligand exchange processes are then manifested as a result of radical attack on the phosphorus atom and the equal probabilities of the appearance of a free valence at any of the oxygen atoms (for symmetrical and identical ligands).

Catalytic Amination of Alcohols, Aldehydes, and Ketones

M.V.Klyuev and M.L.Khidekel'

Data on the catalytic amination of alcohols and carbonyl compounds are examined, the catalysts for these processes are described, and the problems of their effectiveness, selectivity, and stability are discussed. The possible mechanisms of the reactions indicated are presented.
The bibliography includes 266 references.

I. INTRODUCTION

Amines are the most important products of basic and fine organic syntheses. They are used extremely widely and for different purposes in the national economy. Amines and their derivatives are employed, in particular, as antioxidants in fuel oils and as rubber stabilisers, in the manufacture of water-impermeable fabrics and effective medicinal drugs, in road building, in the manufacture of detergents, as extractants of rare metals (U, Th, Pu, Au, Zr, V. Pa, and others), and in the manufacture of herbicides. They have found applications in the synthesis of dyes and accelerators of the polymerisation of rubber. A wide variety of plastics are obtained from alicyclic and aromatic amines.

Amines are obtained by the amination of saturated and unsaturated hydrocarbons, alcohols, halogeno-compounds, and carbonyl compounds, by the reduction of a wide variety of nitro-compounds, and by the Hofmann, Curtius, and other reactions. The synthesis of amines from alcohols was first achieved by Sabatier and Mailhe[1] in 1909 and the reductive amination of aldehydes and ketones was first carried out by Mignonac[2] in 1919. Since then, numerous studies on particular aspects of the above reactions as well as a number of reviews have been published[3-7], the results of pre-war investigations (particularly those of Emerson[3]) being surveyed most completely.

This review is devoted to the literature on the synthesis of amines by the catalytic amination of alcohols and carbonyl compounds. An attempt is made to reflect the achievements and trends in the study of these reactions.

II. CATALYTIC AMINATION OF ALCOHOLS

The modern industrial method for the preparation of primary, secondary, and tertiary aliphatic amines consists in passing the vapour of the corresponding alcohol and ammonia over oxide catalysts such as Al_2O_3, ThO_2 etc. heated to 350–450 °C. Apart from amines, unsaturated and saturated hydrocarbons, water, nitriles, aldehydes or ketones, hydrogen, and ethers are detected in the reaction products. The presence of these substances in the reaction medium has been explained in different ways by various investigators. There is as yet no unanimous view concerning the mechanism of the amination of alcohols.

The original discoverers of the reaction assumed that[8] the alcohol initially reacts with the catalyst (thorium oxide) and forms an unstable ester—alkyl thorate [reaction (1)], which then reacts rapidly with ammonia [reaction (2)]. The authors assumed that the olefins obtained are the products of secondary reactions. Secondary and tertiary amines are formed by the interaction of alkyl thorate with primary [reaction (3)] and secondary [reaction (4)] amines:

$$ROH + ThO_2 \rightarrow ThO(OR)_2 + H_2O\,, \quad (1)$$

$$ThO(OR)_2 + NH_3 \rightarrow RNH_2 + ThO_2 + H_2O\,, \quad (2)$$

$$ThO(OR)_2 + RNH_2 \rightarrow R_2NH + ThO_2 + H_2O\,, \quad (3)$$

$$ThO(OR)_2 + R_2NH \rightarrow R_3N + ThO_2 + H_2O\,. \quad (4)$$

Baum[9] assumed that the ethers formed from the alcohols via reaction (5) are intermediates in the synthesis of amines in the presence of alumina [reaction (6)–(8)]:

$$RCH_2OH \rightarrow (RCH_2)_2O + H_2O\,, \quad (5)$$

$$(RCH_2)_2O + NH_3 \rightarrow RCH_2OH + RCH_2NH_2\,, \quad (6)$$

$$(RCH_2)_2O + RCH_2NH_2 \rightarrow (RCH_2)_3NH + RCH_2OH\,, \quad (7)$$

$$(RCH_2)_2O + (RCH_2)_3NH \rightarrow (RCH_2)_3N + RCH_2OH\,. \quad (8)$$

Schwegler and Adkins[10] suggested that the alcohols are initially dehydrogenated via reaction (9) to aldehydes or ketones, which react with ammonia to form imines [reaction (10)]. The latter are then reduced with hydrogen to primary amines via reaction (11). While reacting with fresh molecules of the carbonyl compounds via reactions (12)–(14), the primary amines give rise in their turn to secondary and tertiary amines via the intermediate Schiff bases:

$$RCH_2OH \rightarrow R-C\begin{matrix}O\\ \diagdown H\end{matrix} + H_2\,, \quad (9)$$

$$R-C\begin{matrix}O\\ \diagdown H\end{matrix} + NH_3 \rightarrow RCH{=}NH + H_2O\,, \quad (10)$$

$$RCH{=}NH + H_2 \rightarrow RCH_2NH_2\,, \quad (11)$$

$$RCH_2NH_2 + RC\begin{matrix}O\\ \diagdown H\end{matrix} \rightarrow RCH_2N{=}CHR + H_2O\,, \quad (12)$$

$$RCH_2N{=}CHR + H_2 \rightarrow (RCH_2)_2NH\,, \quad (13)$$

$$RCH_2N{=}CHR + RC\begin{matrix}O\\ \diagdown H\end{matrix} \xrightarrow{+H_2} (RCH_2)_3N + H_2O\,. \quad (14)$$

Popov[11] assumed that the first stage in the amination process is reaction (15) involving the dehydration of alcohols with formation of olefins, which then react with ammonia, primary, and secondary amines to form primary [reaction (16)]. secondary [reaction (17)], and tertiary [reaction (18)] amines respectively:

$$RCH_2CH_2OH \rightarrow RCH{=}CH_2 + H_2O\,, \quad (15$$

$$NH_3 + RCH{=}CH_2 \rightarrow RCH_2CH_2NH_2\,, \quad (16$$

$$RCH{=}CH_2 + RCH_2CH_2NH_2 \rightarrow (RCH_2CH_2)_2NH\,, \quad (17)$$

$$RCH{=}CH_2 + (RCH_2CH_2)_2NH \rightarrow (RCH_2CH_2)_3N \ . \qquad (18)$$

It has been shown[12-14] that amines are formed in the amination of alcohols by direct substitution of the alcoholic hydroxy-group by the amino-group [reaction (19)]. Secondary [reaction (20)] and tertiary [reaction (21)] amines are obtained similarly:

$$RCH_2OH + NH_3 \rightarrow RCH_2NH_2 + H_2O \ , \qquad (19)$$

$$RCH_2OH + RCH_2NH_2 \rightarrow (RCH_2)_2NH + H_2O \ , \qquad (20)$$

$$RCH_2OH + (RCH_2)_2NH \rightarrow (RCH_2)_3N + H_2O \ . \qquad (21)$$

The alcohols, unsaturated hydrocarbons, carbonyl compounds, and ethers formed in the amination process were regarded[13] as the products of the dehydration and dehydrogenation [side reactions (5), (9), and (15)] occurring on the surface of the catalysts at elevated temperatures.

In contrast to this view, Bashkirov and coworkers showed in relation to the amination of deuteroalcohols[15-20] that the reaction proceeds via the mechanism proposed by Schwegler and Adkins[10]. In their study of the interaction of labelled ethanol with ammonia, they noted[15-20] that the ethanol is initially dehydrogenated, the abstraction of hydrogen atoms from the α-position in the alcohol molecule being the rate-limiting stage of the process. The β-hydrogen atoms in the alcohol are not involved in the rate-limiting stage. It was found that this stage proceeds with participation of two active centres of the catalyst. Secondary amines are formed in consequence of the addition of primary amines to the double bonds of aldimines. On raising the temperature and at a low hydrogen partial pressure, aldimines can be dehydrogenated to nitriles. It was established that ammonia and primary and secondary amines as well as the saturated hydrocarbons produced do not influence the rate of reaction. The addition of water greatly lowers the rate of amination. The authors[15-20] proposed the following reaction mechanism (Z is a catalyst active centre):

$$RCH_2OH + Z \rightleftarrows RCH_2OHZ \ , \qquad (22)$$

$$H_2 + Z \rightleftarrows H_2Z \ , \qquad (23)$$

$$NH_3 + Z \rightleftarrows NH_3Z \ , \qquad (24)$$

$$RCH_2OHZ + Z \rightarrow RCHOZ + H_2Z \ , \qquad (25)$$

$$RCHOZ + NH_3Z \rightarrow RCH{=}NHZ + H_2OZ \ , \qquad (26)$$

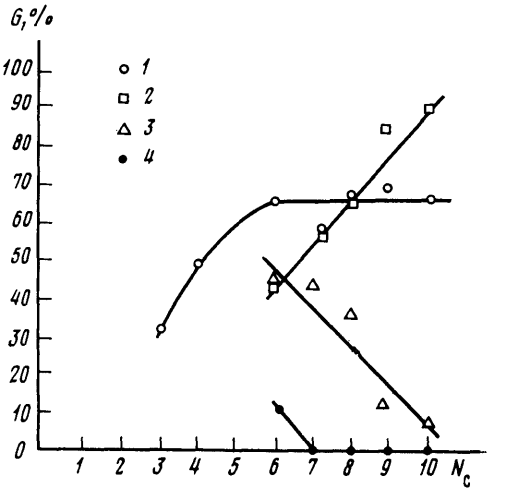
$$RCH{=}NHZ + H_2Z \rightleftarrows RCH_2NH_2Z + Z \ , \qquad (27)$$

$$RCHOZ + RCH_2NH_2Z \rightarrow RCH{=}N{-}CH_2RZ + Z \ , \qquad (28)$$

$$RCH{=}N{-}CH_2RZ + ZH_2 \rightarrow (RCH_2)_2NHZ + Z \ , \qquad (29)$$

$$RCH_2NH_2Z \rightleftarrows RCH_2NH_2 + Z \ , \qquad (30)$$

$$(RCH_2)_2NHZ \rightleftarrows (RCH_2)_2NH + Z \ , \qquad (31)$$



$$H_2OZ \rightleftarrows H_2O + Z \ . \qquad (32)$$

Stage (25) is slow, while all the remaining stages are fast or correspond to equilibrium. We believe that this mechanism is the most probable.

1. The Synthesis of Aliphatic Amines

(a) The Synthesis of Aliphatic Amines in the Presence of Dehydrating Catalysts

The principal disadvantage of the synthesis of amines from alcohols is the occurrence of a number of side reactions, particularly the dehydration of the initial alcohols. One of the ways of suppressing the dehydration involves the use of a high ammonia pressure in the reaction zone. With the aid of this method, Kozlov and coworkers established[21,22] that with increase of ammonia pressure the yield of amines rises. With increase of the molecular weight of the alcohol, the yield of amines falls (Table 1, Nos.1–7). For alcohols having the same molecular weight[22], the yield of amines depends on the degree of branching of the carbon chain, other conditions being equal. Indeed the yield of amines obtained from 1-butanol was 89.9% while that from triethylmethanol was only 25.5% with respect to the alcohol which has reacted (Table 1, Nos.1 and 8). It is noteworthy that secondary and tertiary amines are obtained with lower yields than primary amines. This probably occurs because a transamination reaction takes place when amines are passed over heated oxide catalysts, i.e. ammonia and two new amines are obtained from the initial amine[23,24]. It has been established[25] that the predominance of the primary amine in the products is associated with the fact that an increase of ammonia pressure greatly displaced the reaction equilibrium between the alcohol and ammonia towards the formation of the primary amine. This was confirmed in a study of the thermodynamics of the reaction[26].

Dependence of the yield of amines G on the number of carbon atoms in the alcohol N_C (according to the data of Kozlov and Kirichenko[27]); 350–400 °C; $p_{NH_3} = 7$–11.5 atm; Al_2O_3–SiO_2 catalyst: 1) overall yield of amines; 2) primary amines; 3) secondary amines; 4) tertiary amines.

Another approach to the problem of improving the selectivity in the amination of alcohols involved the promotion of alumina by other metal oxides. It has been shown[27] that a mixed aluminosilicate catalyst dehydrogenates alcohols to a lesser extent, so that C_3–C_{10} straight-chain aliphatic alcohols can be converted into amines in yields up to 70%. The Figure shows that, with increase of the length of the carbon chain of the alcohol, there is not only an increase of the yield of amines in the presence of this catalyst under conditions analogous to the use of activated alumina but there is also an increase of selectivity in relation to primary amines

Table 1. Catalytic amination of aliphatic alcohols in the presence of dehydrogenating catalysts.

The decrease of the yield of secondary amines and the disappearance of tertiary amines from the reaction mixture are probably associated either with a decrease in the surface area of the catalyst or with steric hindrance. However, the aluminosilicate catalyst was less active and the yield of amines in its presence was lower than in the presence of alumina. From earlier studies[21-22,27-29], Kozlov et al.[30] suggested that the catalysts described be used to synthesise amines from the waste in the manufacture of synthetic methanol and ethanol.

Catalysts based on Al_2O_3 and SiO_2, promoted with chromium, nickel, vanadium, molybdenum, magnesium, iron, titanium, and other oxides, have been investigated[13,31-38]. Typical examples of the conditions in the amination processes in their presence as well as the yields of products are listed in Table 1 (Nos. 9–13).

Natural aluminosilicates (bauxites, gumbrin, mordenite, etc.) have been studied as amination catalysts[39-44]; even under fairly severe conditions, the yield of amines is as a rule low (Table 1, Nos. 14 and 15). We may note that in the presence of H-substituted mordenite ($Na_2Al_2Si_{10}O_{24}.7H_2O$), only the formation of primary and secondary amines is observed[40]. The author[40] believes that the reaction selectivity depends on the pore size in the catalyst and the associated steric hindrance to the formation of tertiary amines.

It has been suggested that methylamines be synthesised in the presence of various mixtures of H_3BO_3 and H_3PO_4 on kieselguhr or pumice[45,46] or in the presence of pure Al_2O_3.[47-49] It is of interest that, when acid-treated alumina was employed, the preferential formation of secondary amines was observed[50], other conditions being equal. Alumina[51] or thorium sulphate[52] have been used in the amination of alcohols by primary or secondary amine. A particularly high yield of *N*-alkylated amines (95%) was obtained in the presence of a catalyst containing 12% $Th(SO_4)_2$ on kieselguhr[53] (Table 1, Nos. 16).

(b) The Synthesis of Aliphatic Amines in the Presence of Hydrogen

Dehydration and hydrogenation[54] or dehydrogenation and hydrogenation[55] catalysts have been used in succession to synthesise amines in a number of studies. Thus a mixture of alcohol vapour with ammonia was passed initially[54] over an iron catalyst at 300–470 °C and the resulting condensate was then hydrogenated on a nickel catalyst at 80–160 °C and a hydrogen pressure of 100–150 atm, the product consisting mainly of primary amines. Up to 100% of amines was obtained[55] when nickel on kieselguhr at 200 °C (a dehydrogenation catalyst) and copper at 180 °C or nickel at 100 °C (hydrogenation catalysts) were used in succession.

Very many studies have been devoted to the amination of alcohols on hydrogenation catalysts. Raney nickel has been widely used; with its aid, amines have been alkylated by alcohols[56,57], aminoalcohols have been synthesised[58], and amines have been obtained from butyl[59] and isooctyl[60] alcohols. Raney nickel proved to be a non-selective catalyst and in addition it must be consumed in large amounts for high yields of amines to be attained. Other nickel-containing catalysts[61-67] suffer from the same disadvantages (Table 2, Nos. 1 and 2). When nickel and Cr_2O_3 on kieselguhr were used (Table 2, No. 1), water was continuously removed from the reaction mixture, which made it possible to displace the equilibrium towards the formation of the tertiary amine[61].

Catalysts containing cobalt[68-70] or noble metals[71-73] proved to be much more active than nickel catalysts; up to 97% of amines has been obtained in their presence (Table 2, Nos. 3–5). Their high selectivity, the relatively mild conditions required for their application, and their low cost make cobalt catalysts extremely promising for the amination of alcohols.

Bashkirov and coworkers[74] suggested that fused Fe_3O_4, promoted by acid and amphoteric oxides, be used for the amination of alcohols. This catalyst has been employed in a number of subsequent studies[15-20,75-89]. The authors found the optimum conditions for the synthesis of butylamines[76] (Table 2, No. 6) and investigated in detail the amination of octyl alcohols with a wide variety of structures[77]. It was shown that the branching of the carbon skeleton entails a sharp increase in the yield of side products. At the same time the branching of the carbon chain of the initial alcohol lowers its capacity for the formation of secondary and tertiary amines, probably owing to the increasing steric hindrance.

In the amination of various aliphatic alcohols (C_5–C_{18}) the authors[79] found that, with increase in the length of the carbon chain of the alcohol, its capacity for the formation of

secondary amines also increases. Subsequently Bashkirov and coworkers showed that it is possible to obtain preferentially either primary[80], or secondary[81], or tertiary[82] amines by altering the reaction conditions. By using an optimisation method, the authors[83–86] determined the best conditions for the synthesis of normal primary, secondary, and tertiary amines as well as branched amines (Table 3). If the alcohol is in the liquid state then, other conditions being equal, the amount of secondary amines obtained increases by a factor of 1.5.

The kinetics of the amination of 1-octanol have been studied in detail[88]. In particular, it was shown that the addition of water lowers the rate of reaction, while the addition of hydrogen and the concentrations of other reactants do not influence the rate of amination.

Using primary amines (CH_3NH_2, $C_4H_7NH_2$, $C_7H_{10}NH_2$) as the aminating agents, Bashkirov and coworkers[89] obtained between 60 and 85% of secondary amines (with respect to the alcohol which has reacted). They used Fe_3O_4 with added 0.8–1.0% of beryllium or vanadium oxide as the catalyst at 230–240 °C and a hydrogen pressure of 20 atm.

The catalytic properties of the fused iron catalyst[74], iron ε-nitride (ε-Fe_2N), and iron carbonitride ($Fe_2C_{0.29}N_{0.71}$) were compared[90] in the amination of butanol. It was found that mainly primary amines are obtained in the presence of ε-Fe_2N, secondary amines are the main products in the presence of $Fe_2O_3 + V_2O_5$, while the carbonitride can serve as a catalyst for the synthesis of butyronitrile.

2. The Synthesis of Alicyclic Amines

There are very few data on the amination of alicyclic alcohols, although this reaction has much in common with the amination of aliphatic analogues and proceeds in the presence of similar catalysts.

Thus Al_2O_3 has been used[91] (Table 4, No.1). The authors found that the application of an increased ammonia pressure suppresses (as for aliphatic alcohols[21]) the dehydration of cyclohexanol and drives the process towards the formation of cyclohexylamines.

Subsequently the amination of cyclohexanol and cyclopentanol was investigated[92] over Al_2O_3, Al_2O_3–SiO_2, Al_2O_3 activated with 2% KOH or 2% LiOH, Cu/Al_2O_3, and Ni/Al_2O_3. It was found that, for a copper content above 0.5%, cyclohexylamine was obtained with a maximum yield (76.5%); with increase of the copper content to 20%, the main amination product became dicyclohexylamine.

When Ni/Al_2O_3 was used, aniline and *N*-cyclohexylaniline as well as pyridine and 2-methylpyridine were detected in the reaction products. It is noteworthy that the formation of pyridines was observed also in the presence of copper catalysts. It had been suggested earlier[93] that 2-methylpyridine may be obtained from cyclohexylamine. This was subsequently confirmed by Kozlov et al.[92] Under the conditions of the amination of alicyclic alcohols, these workers obtained 52–70% of 2-methylpyridine and 5–10% of pyridine respectively from cyclohexyl- and cyclopentyl-amines. It

has been suggested that alicyclic alcohols be aminated in the presence of aluminosilicates[94-97]. The yield of the corresponding amines was 51–90% (Table 4, Nos.2–4).

Catalysts working under hydrogenation conditions have been investigated[93-104]. Whereas in the presence of nickel or iron catalysts the amination products are the corresponding amines (Table 4, No.5), in the presence of noble metals anilines are obtained (Table 4, Nos.6–8). Richardson and coworkers believe[101] that the reaction proceeds in the presence of these catalysts via the intermediate cyclohexylamine, which is strongly retained and is then dehydrogenated with the desorption of aniline.

3. The Synthesis of Aromatic Amines

In industry aromatic amines are obtained mainly by the reduction of the corresponding nitro-compounds. Together with the wide-scale development of this method, reports have appeared of the synthesis of aniline and its homologues by the catalytic amination of phenol and its analogues:

It has been found[21,105] that industrial activated alumina catalyses the conversion of phenol, *o*- and *p*-cresols, and *m*-xylenol into the corresponding primary amines. The highest yield (88% of aniline) was obtained in the amination of phenol (Table 5, No.1). The effectiveness of Al_2O_3 increases after its preliminary treatment with alkali and a carboxylic acid[106] or H_3BO_4 [107] (Table 5, Nos.2 and 3). The same catalysts have been proposed also for the synthesis of *m*- and *p*-toluidines, diphenylamine, β-naphthylamine, etc. The above amines are also obtained when (2–10% $AlCl_3$)/Al_2O_3 or Al_2O_3–SiO_2 are used under analogous conditions (365 °C, $p_{NH_3} = 16$ atm).[108] In addition, other oxide catalysts have been proposed[109-115]. The yield of aniline is 80–99% (Table 5, Nos.4–6).

The properties of mixed oxide catalysts in the amination of phenol have been studied in detail[116-119] and it has been established that SiO_2–TiO_2, TiO_2–WO_3, TiO_2–Nb_2O_5, TiO_2–ZrO_2, ZrO_2–Nb_2O_5, and other mixtures of oxides showed a higher catalytic activity and selectivity in this reaction than SiO_2–Al_2O_3. It has been found with the aid of thermogravimetric analysis[119] that the amination proceeds via the adsorption of phenol on the acid centres of the catalyst and that the more acid centres of the mixtures of oxide proved to be more effective than the less acid centres of SiO_2–Al_2O_3. It is noteworthy that phenol and aniline poison catalysts containing highly acid and therefore highly active centres.

Yamamoto et al.[120] investigated the amination of phenol in the presence of type Y zeolites at 350–380 °C. In terms of their catalytic activity, the zeolites can be arranged in the following sequence: HY > CaY > CuY. The yield of aniline is 11–14 mol.%. In addition, the influence of the amount of Cu^{2+} in the zeolite on the yield of products has been studied. The maximum yield of aniline was obtained in the presence of 80% of the metal. It is noteworthy that, when aniline or pyridine is added to CuY, the yield of aniline falls, while in the presence of added HCl it increases. This suggests that amination proceeds in this case via the adsorption of phenol on the acid centres of the zeolites.

Hydrogenation catalysts have been used to aminate benzyl and β-phenylethyl alcohols as well as phenol[69,121-123] (Table 5, Nos.7–9). When catalysts based on noble metals

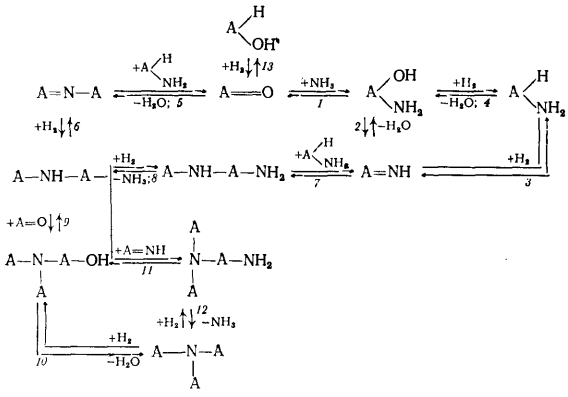
were used, the hydrogenation of the aromatic ring was observed and cyclohexylamines and cyclohexanol were obtained from phenol[124,125]. It was found[126] that the addition of 0.015–10 wt.% of sodium phenoxide lowers the fraction of cyclohexanol in the product and that cyclohexylamine is obtained in 85.2% yield (Table 5, No.10). In the presence of (5% Pd)/C phenol is converted preferentially into dicyclohexylamine[127] (Table 5, No.11).

We shall consider separately data for the alkylation of aniline by alcohols and for the amination of phenol–aliphatic alcohol mixtures. Evans and Bours[128] postulated that the best catalyst for the gas-phase alkylation of aniline by methanol is activated alumina; it has been established[39] that natural aluminosilicates can also be used to alkylate aniline by alcohols. Thus, in the presence of bauxite containing 6% Fe_2O_3 at 275 °C, at atmospheric pressure, and for the ratio ethanol : aniline = 1.45, 83.9% of ethylaniline and 3.3% of diethylaniline were obtained. It has been shown[129] that, when aniline and ethanol are passed over Nb_2O_5 heated to 350–408 °C, 10% of *N,N*-dimethylaniline and 20–25% of *N*-ethylaniline are obtained during one pass.

Alumina, various aluminosilicates, as well as Al_2O_3 promoted by other metal oxides and hydroxides have been investigated[130–133] in the amination of the phenol–aliphatic alcohol system. The best catalyst proved to be the Al_2O_3 + 1% LiOH mixture[132]. The yield of arylamines in the presence of this catalyst at 450 °C and $p_{NH_3} = 12$ atm was in excess of 60%. With increase of the LiOH content, the yield of amines fell to 28%, probably owing to the blocking action of the lithium cations, which covered a proportion of the aprotic centres of Al_2O_3 responsible for the amination reaction. It has also been found that, with increase of the molecular weight of the alcohol, the yield of arylamines falls from 69% (for CH_3OH) to 18% (for C_4H_9OH) and that for branched alcohols the yield is smaller by a factor of two than for normal alcohols.

It has been suggested[134–136] that aniline be alkylated by alcohols in the presence of acids. Thus using H_2SO_4, 99% of *N,N*-dimethylaniline was obtained on heating a methanol–aniline mixture to 190–210 °C under a pressure of 5 atm.[135]

A number of studies[57,137–140] have been devoted to the synthesis of mixed amines by the reaction of aromatic amines with aliphatic alcohols in the presence of Raney nickel. The yield of amines is fairly high (41–90%) and the alkylation conditions in the presence of Raney nickel are comparatively mild. The main disadvantage of the method is the high consumption of the catalyst.



It has been found[141] that phenylacetylmethanols can be alkylated by primary amines also by a non-catalytic procedure, in the presence of sodium tetrahydroborate. The main disadvantage of this method is the high cost of $NaBH_4$.

III. CATALYTIC REDUCTIVE AMINATION OF CARBONYL COMPOUNDS

The catalytic reductive amination of carbonyl compounds is usually carried out in the presence of catalysts based on transition metals. Studies on the use of complex catalysts have been carried out recently. In addition, there have been reports of the electrocatalytic synthesis of amines from ketones and by non-catalytic amination with the aid of tetrahydroborates.

We shall consider certain general postulates underlying the reductive amination of carbonyl compounds. The synthesis of amines by this procedure (Scheme 1) consists in the addition of ammonia to a carbonyl compound with subsequent reduction of the adduct (pathway *1*, *4*)

Scheme 1

where A=O represents R–C(=O)–R′ and R, R′ = alkyl, aryl, or H.

It may be that the adduct is initially dehydrated and the dehydration product is subsequently reduced (pathway *1–2–3*). The primary amine formed ultimately can also behave as an aminating agent for carbonyl compounds, forming Schiff bases, which are reduced to secondary amines (pathway *5–6*). The addition of a primary amine to imines with subsequent reduction of the adduct also leads to secondary amines (pathway *7–8*). Secondary amines react similarly in their turn with carbonyl compounds (pathway *9–10*) or with an imine (pathway *11–12*), forming tertiary amines. The principal side reactions involve the formation of an alcohol (pathway *13*) and aldol condensation. In order to prevent the formation of an alcohol, it has been recommended in a number of studies that ammonium[6,147–148] or sodium[149] acetates or chlorides be added to the reaction mixture. The aldol condensation is retarded or is not observed at all when the reaction mixture is cooled before hydrogenation[6] or when the contact time between the carbonyl compound and ammonia is reduced[150]. The kinetics of the reductive amination of aldehydes and ketones have been studied in detail[142–146] and we shall not consider them in the present review.

Numerous catalysts for the reductive amination of carbonyl compounds have now been investigated. From these, Freifelder[6] selected nickel catalysts, believing them to be the most effective and most readily available. Together with nickel catalysts, Augustine[151] recommends also platinum catalysts for this reaction. The use of catalysts containing platinum group metals has been most fully described by Rylander[7]. This review covers studies which are not included in the books by Freifelder[6] and Rylander[7] and in Augustine's review[151].

(a) Reductive Amination of Aliphatic Aldehydes and Ketones

Nickel catalysts have been used in many studies on the synthesis of amines from aliphatic carbonyl compounds. Raney nickel has been investigated[152–160]. Table 6 (Nos.1–11) shows that the yield of amines depends on the structure of the carbonyl compound. The rate of reaction also depends on the structure of the substrate employed. Thus it has been established[155] that the rate of amination decreases in

the sequence ethyl methyl ketone > isobutyl methyl ketone > diethyl ketone. The advantages of Raney nickel as a catalyst include ready availability, the possibility of carrying out experiments under mild conditions, and fairly high selectivity, while its main disadvantages are high consumption and lack of safety. These disadvantages can be eliminated by employing catalysts containing nickel on various carriers.

Nickel deposited on alumina proved to be an effective catalyst for the amination of carbonyl compounds[161-174]. Analysis of the literature data showed that the conditions under which Ni/Al_2O_3 is used are as a rule similar to those employed for Raney nickel (Table 6, Nos.12–14), but, in contrast to the latter, it is more active and stable in the reaction under discussion. Thus it has been shown[164] that Ni/Al_2O_3 is three times more active than freshly prepared Raney nickel and it has been reported[161] that Ni/Al_2O_3 is stable for 2000 h.

In some cases, when the amination reaction was carried out in the presence of Ni/Al_2O_3, nitriles were detected in the reaction mixture. Popov and Shuikin[168] suggested that the amination proceeds via the formation of nitriles and put forward the following reaction mechanism:

$$R{-}CHO + NH_3 \rightarrow R{-}C(H)(OH)(NH_2) \xrightarrow[-H_2O]{} R{-}C(H)=NH \xrightarrow[-H_2]{} RC{\equiv}N \xrightarrow{+2H_2} RCH_2NH_2 .$$

Next the primary amine is converted into a secondary amine and the secondary amine is converted into a tertiary amine.

Among other carriers, kieselguhr has been widely used. Thus, considerable amounts of ethylamines have been obtained[175] by the amination of acetaldehyde in the presence of a catalyst containing 52.2% Ni, 14% Cu, 2% Mo, and 31.5% of kieselguhr (Table 6, No.15); the synthesis of tertiary amines by the reaction of ketones with secondary amines in the presence of a catalyst consisting of 50% Ni and 2% Zr on kieselguhr has been reported in a number of patents[176,177].

Analysis of studies in which cobalt catalysts for reductive amination have been used[178-180] shows (Table 6, Nos.16–18) that these catalysts give rise to a high yield of amines, but require more severe conditions than nickel catalysts. Copper catalysts have been studied in a number of investigations[181-183]. Among these, the greatest interest attaches to the hydroamination of ketones by benzonitrile in the presence of $(20\%\ Cu)/Al_2O_3$. Various *N*-alkylated benzylamines have been obtained by this method. It has been reported in a patent[184] that alkylidenealkenylamines are obtained in yields up to 98% when a mixture of the corresponding aldehyde and ammonia is passed through a column heated to 150–400 °C and filled with pumice containing 7.5% Zn and 1.5% Cr. Catalysts based on platinum[148,185,186] work under milder conditions (20–100 °C, $p_{H_2} = 1$–4 atm), but the yield of amines is as a rule low (10–65%). With increase of hydrogen pressure to 50–125 atm, the use of PtO_2,[187] Pd/C,[188,189] and Rh/Al_2O_3 [190] gives rise to 81–95% of secondary amines (Table 6, Nos.19–21).

There is very little information about the electrocatalytic amination of carbonyl compounds. It has been reported[191,192] that, using electrodes activated by Raney nickel, it was possible to convert acetone into isopropylamine in 78% yield. On these electrodes, ketones with identical hydrocarbon groups are aminated more readily than those with different hydrocarbon groups[149]. When a porous palladium electrode was used[193], the opposite behaviour was noted: the yield of the primary amine from ethyl methyl ketone was higher than that from diethyl ketone.

(b) Reductive Amination of Alicyclic Carbonyl Compounds

Nickel catalysts have been widely investigated, most studies being devoted to the synthesis of cyclohexylamine. Analysis of the literature data on the use of reduced nickel and Raney

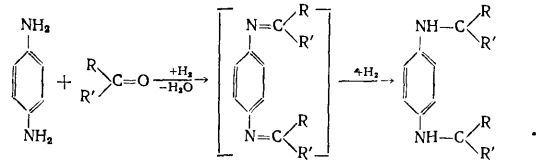
nickel[194-199] shows that these catalysts proved to be extremely selective and effective in the synthesis of cyclohexylamine (Table 7, Nos.1–3). In the reductive amination of more complex alicyclic compounds it is impossible to achieve a high yield of amines even under severe conditions (Table 7, No.4). It has been established[196] that the yield of amines depends on the solvent employed and falls in the sequence ethanol > water > methanol > isopropyl alcohol. The authors suggest that in alcoholic solution the reaction proceeds via the intermediate cyclohexanone–cyclohexylimide. Cyclohexylamine is obtained also in the electrocatalytic reduction of cyclohexanone[200] in the presence of Raney nickel electrodes.

Other nickel-containing catalysts are also known. It is suggested in a patent[201] that nickel be modified by the addition of H_3PO_4 or H_3BO_3 for the synthesis of cyclohexylamine. A number of studies have been made[202-204] on nickel–chromium catalysts. They do not require high pressures and are more stable than Raney nickel, although they are inferior to it as regards selectivity (Table 7, No.5).



Nickel on alumina proved to be a less effective catalyst[205], but in its presence certain aliphatic ketones have been aminated[206] by pyridine bases, while dicyclohexylamine has been obtained from cyclohexanone and aniline at $p_{H_2} = 20$ atm at 250 °C.[207] We may note that, in the presence of Cu/Al_2O_3, *N*-cyclohexylaniline was obtained under the same conditions. Aliphatic cyclic amines have been synthesised using a catalyst containing Ni, MgO, and kieselguhr[208], and 1-*N*-cycloalkylaminocyclododecene which has been obtained[209] from cyclododecanone and morpholine, piperidine, and pyrrolidine in the presence of $TiCl_4$.

Table 7 (Nos.6–11) shows that catalysts based on noble metals[148,185,186,188,190,210,213] proved to be effective, with the exception of the study of Popov and Shuikin[185], only for the synthesis of secondary and tertiary amines. We may note that, when platinised quartz or certain other catalysts are used, mainly aniline is obtained from cyclohexanone[214].

(c) Reductive Amination of Aromatic Carbonyl Compounds

Raney nickel proved to be extremely suitable for the amination of aromatic carbonyl compounds[153,215-219]. Examples of its use (Table 8, Nos.1–5) shows that the yield of amines is fairly high and depends on the structure of the initial carbonyl compounds and on the reaction conditions.

As in the reductive amination of aliphatic and alicyclic carbonyl compounds, catalysts based on noble metals[148,190,220-228] proved to be effective only for the synthesis of secondary and tertiary aromatic amines (Table 8, Nos.6–8). The use for this purpose of platinum group metal sulphides[229-233] or catalysts based on these metals with added sulphur-containing compounds[234,235] (Table 8, Nos.9–11) proved to be particularly successful. It has been suggested[232] that the alkylation of *p*-phenylenediamine proceeds via the intermediate formation of Schiff bases:

In another study by the same workers[236] it was shown that, in the presence of the same catalysts and under similar conditions, the reduction of Schiff bases does indeed occur.

Among non-noble metal sulphides, rhenium sulphide proved to be the most active catalyst[232,237] (Table 8, No.12). The sulphides of basic metals proved to be relatively insensitive to poisons and in their presence virtually no hydrogenation of the benzene ring was observed and in many instances the initial carbonyl compound was not reduced to the corresponding alcohol.

Copper catalysts modified with barium sulphate[182] or chromium oxide[238,239] have been used[182,238,239] to synthesise secondary aromatic alkylamines. The yield of amines under conditions close to those employed for sulphide catalysts is appreciably lower (38–74%).

(d) Reductive Amination of Carbonyl Compounds in the Presence of Tetrahydroborates

Lane[240] believes that the reductive amination of an aldehyde or ketone is possible when the carbonyl compound interacts with an amine or ammonia at pH 6–8 in the presence of $NaCNBH_3$. The explanation is that the imino-group is reduced much faster than the carbonyl group. It has been suggested[241-245] that $LiCNBH_3$ in methanol at pH 5–6 and 25 °C be used together with $NaCNBH_3$ for reductive amination. However, lithium cyanotrihydroborate proved to be

Table 7. Reductive amination of alicyclic carbonyl compounds.

No.	Carbonyl compound	Catalyst	*t*, °C	*p*, atm	Product	Yield, %	Remarks	References
1	Cyclohexanone	Ni	140	28	cyclohexylamine	98.5	—	194

a milder reductant than $NaBH_4$ and reductive amination did not go to completion in its presence. This may be associated with the choice of solvent. It is known[246] that $NaBH_4$ reduces the $>C=N$ bond more readily in dimethyl sulphoxide than in alcohols.

Using sodium cyanotrihydroborate, Borch and coworkers aminated cyclohexanone with methyl- and propyl-amines[243], methyl phenyl ketone with ammonia[242], and formaldehyde with aniline[245]. This yielded 78.5% of cyclohexylpropylamine, 53% of cyclohexyldimethylamine, 76% of 1-phenyl-1-aminoethane, and 92% of dimethylaniline. Together with the examples described, a considerable number of analogous syntheses of primary, secondary, and tertiary amines have been carried out[241-245] at room temperature and atmospheric pressure. This undoubtedly demonstrates the importance of the synthetic application of tetrahydroborates in the reductive amination of aldehydes and ketones. At the same time, in view of the high cost of tetrahydroborates, the large scale industrial production of amines by this procedure is not very promising.

(e) Reductive Amination of Carbonyl Compounds in the Presence of Complex and Catalysts

The reductive amination of carbonyl compounds in the presence of complex catalysts has been so far inadequately investigated. In a number of studies[247-252] the reductant was the complex tetracarbonylhydroferrate $[HFe(CO)_4]^-$ in an equimolar amount relative to the carbonyl compound. The reaction was carried out in an atmosphere of CO at room temperature in alcohol; $[HFe(CO)_4]^-$ was obtained *in situ* by the reaction of $Fe(CO)_5$ with alkali. Under these conditions, Watanabe et al. synthesised *N*-alkyl- and *N*-aryl-glycines from glyoxylic acid[249] and *N*-substituted piperidines from glutaraldehyde[250] and also carried out the amination[247] of acetone by isopropylamine (Table 9, No.1), of butanol by aniline (Table 9, No.2), and of cyclohexanone by cyclohexylamine (Table 9, No.3). *N,N*-Dimethyl-, *N,N*-diethyl, *N,N*-dipropyl-, *N,N*-dibutyl-, *N,N*-ethylmethyl-, and other *N,N*-substituted anilines have been obtained from aniline and the corresponding aldehydes in quantitative yields[248]. The reaction has been shown to proceed via *N*-substituted anilines[251].

Certain aromatic amines have been alkylated by formaldehyde under analogous conditions[252]. The yield of the corresponding secondary and tertiary amines was ~80%. The authors suggested that the reaction proceeds via the formation of intermediate Schiff bases, which are reduced irreversibly by $[HFe(CO)_4]^-$ to the corresponding amines. The $[HFe(CO)_4]^-$ ion cannot be regarded as a catalyst, since it is active only in stoichiometric amounts.

The reductive amination of aldehydes and ketones by ammonia and primary and secondary amines has been investigated[253] in the presence of catalytic amounts of cobalt and rhodium carbonyls at 100–160 °C and $p_{H_2} = 100$–300 atm. Amines were obtained in very high yields in this homogeneous process. Thus (2-ethylhexyl)isopropylamine (Table 9, No.4), cyclohexylisopropylamine (Table 9, No.5), and benzylmethylamine (Table 9, No.6) have been obtained from α-ethylhexanal and isopropylamine, from cyclohexanone and isopropylamine, and from benzyl methyl ketone and ammonia respectively.

A cobalt cyanide complex has been used[254,255] as a catalyst of the homogeneous reductive amination of benzylacetone (Table 9, No.7) and benzylacetophenone (Table 9, No.8). Previously aminoacids had been obtained[256-258] from α-hydroxyacids with the aid of this catalyst.

In enzymatic catalysis reductive amination constitutes the main pathway for the conversion of ammonia into compounds with α-amino-groups[259]. It is to be expected that compounds which are models of enzymes will prove active in the reductive amination reaction. Indeed it has been reported[260] that *N*-methylaniline can be obtained from aniline and formaldehyde under mild conditions in the presence of vitamin B_{12r} or its model—diaquocobaloxime(II).

It has been found[261] that hydridobis(dimethylglyoximato)-aquorhodium(III) is a catalyst of the reductive amination of formaldehyde by aniline and of cyclohexanone by ammonia (Table 9, No.9). At the same time, in contrast to claims by Schrauzer and Windgassen[260], it has been shown[261] that in the presence of diaquocobaloxime(II) the process is not catalytic and stops at the stage involving the formation of the complex

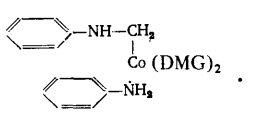

Table 8. Reductive amination of aromatic carbonyl compounds.

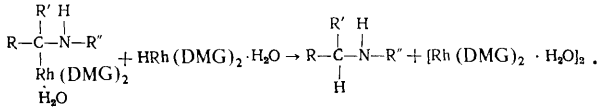
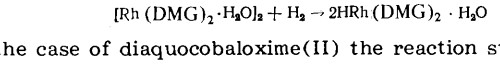
9	Cyclohexanone	$HRh(DMG)_2.H_2O$	45	1	cyclohexylamine, dicyclohexylamine	74 9	yield w.r.t. cyclohexanone employed	261



It has been postulated[261] that the reaction proceeds via the following mechanism: there is initial condensation of the carbonyl compound with ammonia or the amine:



The resulting imine or Schiff base reacts with the catalyst to form an intermediate complex:

The complex reacts with a new catalyst species and forms amines:

The resulting dimer is reduced in its turn by hydrogen with formation of two molecules of the initial catalyst:

In the case of diaquocobaloxime(II) the reaction stops in the second stage. In this connection one may note that, in a number of other reduction reactions, rhodium complexes proved to be more active than the corresponding cobalt analogues[262].

---o0o---

It is seen from the data presented that considerable advances have been made in recent years in the catalytic amination of carbonyl compounds and alcohols. Thus, on the basis of developments in recent years, a large-scale industrial production of aniline from phenol has been established in the USA;[263] many valuable medicinal drugs have been obtained[6] by the reductive amination of various carbonyl compounds.

Despite the fact that the vast majority of amines are obtained nowadays by traditional methods (from alcohols or halogeno-compounds or by the reduction of nitro-compounds), in the immediate future the reductive amination of carbonyl compounds may become one of the main procedures for the synthesis of amines. This appears possible primarily because of the considerable advances in the field of oxo synthesis (see, for example, Alekseeva et al.[264]), which made it possible to reduce the cost of carbonyl compounds. Many aldehydes and ketones are now cheaper than the corresponding alcohols[265].

The most important task at the present time is the selection of highly effective and selective catalysts for the reductive amination of carbonyl compounds, because only on the basis of such catalysts is it possible to set up a modern waste-free industry. Great expectations are associated with the employment of the principles of molecular catalysis[266]. The first studies on the use of complex catalysts for reductive amination give rise to the hope that in their presence it will be possible to carry out the process under mild conditions and extremely selectively.

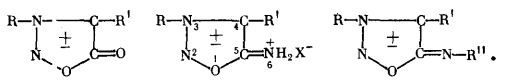
The Chemistry of Sydnone Imines

V.G.Yashunskii and L.E.Kholodov



All the available data on the structures, physicochemical properties, reactivities, reactions, and biological activities of sydnone imines—representatives of the class of the so-called mesoionic heterocycles—are surveyed and described systematically.
The bibliography includes 166 references.

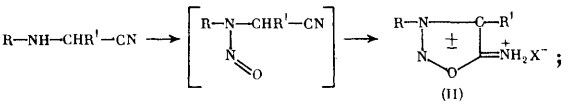
I. INTRODUCTION

Among the so-called mesoionic heterocyclic compounds[1-4], sydnones (I), which are derivatives of anhydro-1,2,3-oxadiazol-5-one, are best known and have been most thoroughly investigated. Their exocyclic nitrogen analogues—the sydnone imines (II) and (III)—were discovered only 20 years ago, but during these years many interesting data have been obtained on the structures, reactivities, physicochemical properties and biological activities of these compounds.

(I) (II) (III)

Certain representatives of sydnone imines have found application as medicinal drugs. Soviet and Japanese investigators have made the greatest contribution to the development of this interesting field of the chemistry of heterocycles.

While the chemistry of sydnones has been fairly widely described in the review literature[2,3], only brief information is available concerning their nitrogen analogues—sydnone imines. This article is the first attempt at a survey and systematic account of data on the synthesis, structures, and chemical, physical, and biological properties of sydnone imines available in the periodical and patent literature (up to 1978 inclusive).

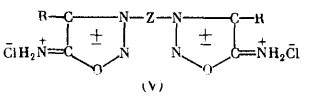


II. THE SYNTHESIS OF SYDNONE IMINES

Sydnone imines exist in the form of salts, as a rule hydrochlorides (II, X = Cl), or exocyclic derivatives ($N_{(6)}$-derivatives) (III), where R" are the residues of various organic acids (carboxylic, carbamic, arenesulphonic etc.) or inorganic acids (nitrous, nitric etc.). With the exception of special cases (see below), sydnone imines have not been isolated in the form of the free base.

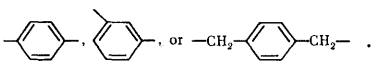
1. Sydnone Imine Salts

Although the possibility of the existence of nitrogen analogues of sydnones was predicted as early as 1949,[5] the first sydnone imines were synthesised in 1957 independently by Japanese[6] and English[7] chemists.



Having treated *N*-nitroso-*N*-phenylaminoacetonitrile (IVa) and its *C*-phenyl analogues (IVb) with hydrogen chloride, Kato et al.[6] obtained the hydrochlorides of 3-phenylsydnoneimine (IIa) and 3,4-diphenylsydnoneimine (IIb). When the *N*-methyl derivatives of isobutyronitrile and isovaleronitrile were treated with nitrogen oxides, the corresponding sydnone imines (II, c and d) were isolated in the form of the hydrogen nitrates (X = NO_3), which were then converted into the hydrochlorides (X = Cl):[7]

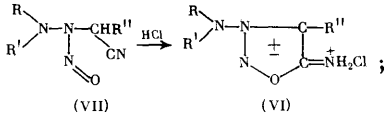
(II)



(a) R = C_6H_5, R' = H; (b) R = R' = C_6H_5;
(c) R = CH_3, R' = iso-C_4H_9; (d) R = CH_3, R' = iso-C_5H_{11}.

A large number of sydnone imine salts with various substituents in the 3- and 4-positions in the ring have been synthesised by the cyclisation of *N*-substituted *N*-nitroso-α-aminonitriles (IV) in an acid medium (the only known method hitherto). Derivatives of sydnones themselves and their exocyclic hydrogen analogues with an unsubstituted third nitrogen atom do not exist. The majority of the known sydnone imines contain hydrocarbon substituents in the 3-position: alkyl,[7,8-18] cycloalkyl,[9,10,19,20] arylalkyl,[9,11-15,17,21-23,25,26] and aryl.[6,9,11,17,27] Polymethylene-3,3'-bis-sydnone imines[9,28,29] and phenylene-3,3'-bis-sydnone imines (V)[9,16,30] have been described:

(V)

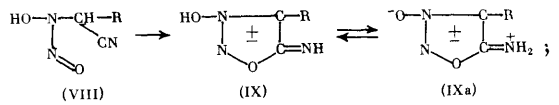


Z = $(CH_2)_n$ (*n* = 2-10), $(CH_2)_2$—O—$(CH_2)_2$,

Sydnone imines containing various functional and other groups in the hydrocarbon substituent have been synthesised, for example: 3-hydroxyethyl[14], 3-chloroethyl[14], 3-carboxylalkyl[31,32], 3-alkoxycarbonylalkyl[33], 3-dialkylaminoalkyl[34], and dinitromethyl-3,3'-bisethyl[35] derivatives. The presence of powerful electronegative substituents (for example, three nitro-groups[35]) in the β-position of the hydrocarbon chain attached to the nitrogen atom prevents cyclisation with formation of a mesoionic heterocycle.

N-nitrosoaminoacetonitriles with an arylacetyl or sulphogroup at the amino-nitrogen atom do not enter into the cyclisation reaction[6].

In recent years much attention has been devoted to the synthesis of sydnone imine salts (VI) with a dialkylaminogroup in the 3-position, which are obtained by the cyclisation of *N*-nitroso-derivatives of various *N*,*N*'-dialkyl and *N*,*N*'-cycloalkyl-hydrazinoacetonitriles (VII) under the influence of hydrogen chloride[36–47]:

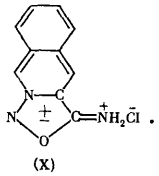


(VII) (VI)

R, R' = alkyls or X, where X = CH_2, O, or NH.

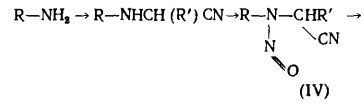
Among sydnone imines of this type, compounds containing the morpholino-,[36–38,44,45] piperidino-,[36,37,40,41,45] piperazino-,[36,45] and *N*'-substituted piperazino-groups[36,38,39,46,47] have attracted most attention.

It has recently proved possible to cyclise derivatives of *N*-nitrosohydroxylaminoacetonitrile (VIII),[48] which yielded 4-alkyl-substituted 3-hydroxysydnoneimines (IX), to which the betaine structure (IXa) was ascribed:



(VIII) (IX) (IXa)

R=C_3H_7, $PhCH_2$, or $PhCH_2CH_2$.



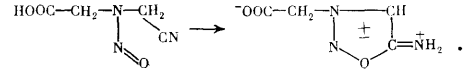
The cyclisation of *N*-nitrosoaminoacetonitriles can give rise to sydnone imine salts containing, apart from hydrogen, hydrocarbon substituents in the 4-position of the ring, namely alkyl[7,9,11–13,16,18,26,31,36,39], arylalkyl and aryl[9,11,12,16,17,25,36], chloromethyl[18,44], and dialkylaminomethyl[44] groups in the 4-position of the ring.

The synthesis of a single representative of the tricyclic series—3,4-dihydroisoquinolinyl[1,2-*c*]sydnone imine hydrochloride—has been described:

(X)

The synthesis of sydnone imine salts is fairly simple and consists in general of three stages: (1) the formation of an *N*-substituted α-aminonitrile having at least one hydrogen atom at the α-carbon atom; (2) the nitrosation of the α-aminonitrile; (3) the cyclisation of the resulting *N*-nitroso-derivative to the sydnone imine:

(IV)



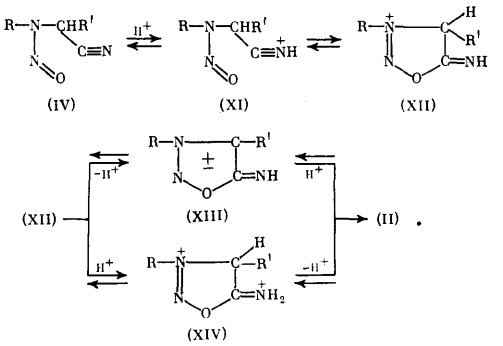
Sometimes the isolation of one or both intermediates is difficult and the synthesis of sydnone imines is converted into a single-stage process; this requires a more careful purification of the final product.

α-Aminoacetonitriles are usually obtained by the cyanomethylation of primary amines. The use of glycolonitrile as the cyanomethylating agent has been described[8]. Acetone cyanohydrin can be conveniently used as the cyanating agent under laboratory and industrial conditions[11,22–24]. Cyanomethyl derivatives of aminoacids can be obtained smoothly in an alkaline medium[14,31–33].

The nitrosation of aminoacetonitriles is carried out in most instances with sodium nitrite in the presence of inorganic acids. When an excess of sodium nitrite in an acid is used, cyclisation can take place in the course of the nitrosation with formation of sydnone imine nitrite or nitrate salts[7,14]. The *N*-nitroso-derivatives (IV) are sometimes obtained in a non-aqueous medium by treating aminotriles with nitrogen oxides.

Other inorganic acids, for example sulphuric, as well as organic carboxylic acids, such as succinic and picric, can be used for the cyclisation of nitrosoaminonitriles (IV) to sydnone imine salts, in addition to hydrogen chloride in varous organic solvents (lower alcohols, ether, tetrahydrofuran, dichloroethane, methylene chloride, chloroform, ethyl acetate, and acetone)[37].

Nitrosoaminoacetonitriles can also be cyclised in an aqueous medium[9,45]. The cyclisation in acetic acid has recently been described[49] and it has been possible for the first time to demonstrate, in relation to *N*-nitroso-*N*-carboxymethylaminoacetonitrile, the feasibility of self-cyclisation catalysed by the protons of the carboxy-group[50]:

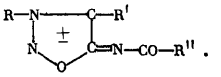


The formation of sydnone imines under the influence of HCl can be accompanied by a side reaction—the denitrosation of *N*-nitrosoaminoacetonitriles with elimination of nitrosyl chloride[14,15,18,26,29]. Thus, despite the variation of the conditions[14], it has not been possible to cyclise *N*-nitroso-*N*-t-butylaminoacetonitrile[14]. The low yields of sydnone imine in the cyclisation of *N*-nitroso-*N*-methylaminoacetonitrile in the presence of an excess of HCl have been noted[18].

It has been suggested[26] that the denitrosation can be avoided by carrying out the cyclisation in solvents without oxygen, for example in methylene chloride; however, it has been shown[15] that the cleavage of nitroso-derivatives and the low yield of sydnone imines are due to the use of an excess of HCl and the increase of temperature above 10 °C rather than the choice of a particular solvent.

A spectrophotometric study of the kinetics of the acid cyclisation of *N*-nitrosoaminoacetonitriles[5] showed that in the case of non-aromatic substituents at the nitrogen atom their reaction is of first order with respect to the nitroso-derivative and of second order with respect to protons. The rate of cyclisation depends significantly on the nature of the substituents at the nitrogen atom of the nitrosoaminoacetonitrile and increases with increasing inductive effect and bulk of the radical. Thus, one passing from the methyl to the cyclohexyl substituent, the rate of cyclisation increases by more than two orders of magnitude. Analysis with the aid of correlation equations made it possible to estimate the electronic and steric effects of the substituents. The equation obtained ($\lg k = -3.2 - 3.6\sigma^* - 1.2E_S^C$) agrees satisfactorily with the experimental cyclisation rate constants. It has been suggested that in the course of this reaction "steric acceleration" takes place with increasing bulk of the substituent at the amino-nitrogen and after the introduction of substituents at the α-carbon atom in the nitrosoaminoacetonitrile. The cyclisation takes place most readily for *N*-nitrosoadamantylaminoacetonitrile: the rate of formation of the sydnone imine ring is in this case more than 1500 times higher compared with the methyl analogue.

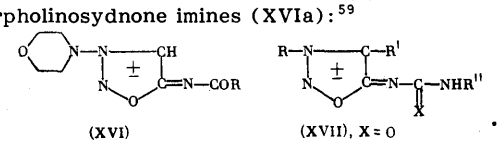
From these results, a mechanism of the formation of the sydnone imine ring, illustrated in the scheme below, has been put forward[51]:



The first stage of the process is in all probability the protonation of the nitrile group in (IV) which is followed by the conversion of the protonated product (XI) into the cyclic iminoester diazotate (XII), which can give rise to the cation of the sydnone imine (II) either via the stage of the sydnone imine base (XIII) or via the dication (XIV).

2. *N*-Exocylic ($N_{(6)}$) Derivatives of Sydnone Imines

The exocyclic *N*-derivatives of the heterocycles, which are synthesised from the corresponding salts, have perhaps attracted no less attention than the sydnone imine salts.



While manifesting properties typical for strong amines, sydnone imine salts interact with carboxylic acid anhydrides and chlorides in the presence of basic agents under mild conditions to form the corresponding $N_{(6)}$-acylsydnone imines (XV):

(XV)

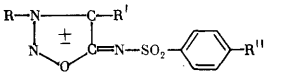
Apart from the $N_{(6)}$-acetyl derivatives (XV, $R = CH_3$),[6,7,10,11,14,21,25,30,32,36,41,48,52-57] which can be prepared by treatment with acetic anhydride in the absence of a base[52], compounds have been synthesised with other alkanoyl[15,53-55] and aroyl[6,10,11,14-16,21,25,36,52,56-58] substituents as well as halogenoacetyl,[53-56] isonicotonyl[15,59], and alkoxycarbonyl[10,11,15,27,36,52,56] groups.

$N_{(6)}$-Acyl derivatives have been obtained not only for sydnone imines with hydrocarbon substituents in the 3- and 4-positions in the ring, but also for 3-hydroxy-,[48] 3-carboxyalkyl-,[32-58] and 3-dialkylamino-derivatives[36,40,41,44,59-63]. By treatment with formic anhydride or *p*-nitrophenyl formate, it has been possible to synthesise the $N_{(6)}$-formyl derivative of 3-morpholinosydnone imines (XVIa):[59]

(XVI) (a) R = H

(XVII), X = O

(XVIII), X = S



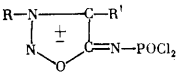
Apart from compound (XVIa), mono-, di-, and tri-chloroacetyl, trifluoroacetyl, phenoxyacetyl, trimethoxybenzoyl, benzyloxycarbonylalanyl, nicotinoyl, and other $N_{(6)}$-acyl derivatives of this sydnone imine have been obtained[59]. The interaction of sydnone imine hydrochlorides with diketen in the presence of sodium dicarbonate yielded $N_{(6)}$-acetoacetylsydnone imines (XV, $R'' = CH_3COCH_2$).[52,54,59]

Sydnone imine salts react smoothly with aliphatic and aromatic isocyanates in the presence of bases—pyridine and sodium acetate or bicarbonate—in aqueous and alcoholic media, forming $N_{(6)}$-carbamoyl derivatives (XVII).[13,15,16,21,32,53-55,58,64-70] Among these, compounds containing carboxy-substituents in the 3-position of the ring have been described[32,58,64].

When the reaction is carried out in an aqueous medium, the corresponding diarylureas are formed by a side reaction in the case of aryl isocyanates. Di-(*o*-chlorophenyl)urea proved to be the only reaction product for *o*-chlorophenyl isocyanate[15]. The reaction takes place most smoothly in alcohols[53,54]. Unsubstituted carbamoyl derivatives (XVII, $R'' = H$) have been synthesised by treating sydnone imine hydrochlorides with sodium cyanate[15,32,64,71,74].

Sydnone imine isothiocyanates react similarly to the isocyanates, giving rise to the corresponding $N_{(6)}$-thiocarbamoylsydnone imines (XVIII).[11,15,52,65] The reaction proceeds under the same conditions as with the oxygen analogues. Unsubstituted thiocarbamoyl derivatives could not be synthesised by treating sydnone imine hydrochlorides with ammonium thiocyanate[15,25,71]. The corresponding sydnone imine hydrogen thiocyanates proved to be the only reaction product.

Several studies have been devoted to the synthesis of $N_{(6)}$-arenesulphonyl derivatives (XIX), which are formed under fairly severe conditions (heating in the presence of aqueous alkali) when sydnone imine salts are acted upon by the corresponding arenesulphonyl chlorides[10,11,59,72,75]:

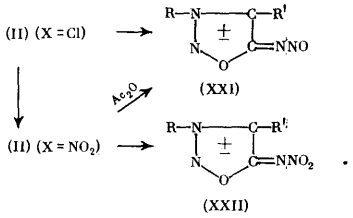


(XIX)

$R'' = H$, $NHCOCH_3$, or NH_2.

The sydnonyl analogues of sulphonamide preparations with the amino-group in the *p*-position in the benzene ring (XIXa, $R'' = NH_2$) have been synthesised in this way[10,72].

When the hydrochlorides of 3-isopropyl-, and 3-phenyl-4-methylsydnone imines were heated cautiously with phosphoryl chloride in dichloroethane solution, the corresponding $N_{(6)}$-dichlorophosphino-derivatives (XX) were synthesised[14]:



(XX)

$R = C_3H_7$, $R' = H$; $R = Ph$, $R' = CH_3$.

The presence of the exocyclic imino-group is confirmed by the ready formation of $N_{(6)}$-nitroso-derivatives (XXI) when sydnone imine salts are acted upon by sodium nitrite[6,25,32,33,53,73]. A number of $N_{(6)}$-nitroso-derivatives with alkyl, arylalkyl, and aryl substituents in the ring have been synthesised in this way. It has been observed that in certain cases the formation of $N_{(6)}$-nitroso-derivatives requires an acid medium and the introduction of an excess of sodium nitrite in order to avoid the formation of the nitrite of the corresponding sydnone imine[73]. The latter can be converted into $N_{(6)}$-nitrososydnone imine by treatment with acetic

anhydride[73]. The $N_{(6)}$-nitro-derivative (XXII) can be obtained analogously from the sydnone imine nitrite[7]:

(II) (X = Cl) → (XXI)

(II) (X = NO_2) → (XXII)

III. PHYSICOCHEMICAL PROPERTIES AND ELECTRONIC STRUCTURE

Numerous studies have been made on the physicochemical properties of sydnone imines. Investigation of the ultraviolet, infrared, NMR, and mass spectra, polarographic studies, etc. yielded data which can be used to explain the characteristics of the structures and a number of chemical and physical properties of these heterocyclic compounds. On the other hand, effective methods for the investigation of the kinetics and mechanisms of the chemical reactions of sydnone imines and for the identification of the resulting products have been developed on the basis of the study of certain physicochemical properties.

1. Electronic Spectra

Sydnone imines absorb intensely in the ultraviolet[9,15,27,32,48,52,56,72,73,76-79] and their $N_{(6)}$-nitroso-derivatives have absorption maxima also in the visible part of the spectrum[73]. Alkylsydnone imine salts have two intense absorption maxima in the region of 270–306 and 200–208 nm; the latter has been observed and described quite recently[78].

The bands have been assigned[80] on the basis of quantum-mechanical calculation by the Pariser–Parr–Pople (PPP) method and it has been shown that the long-wavelength maximum is a $\pi-\pi^*$ band corresponding to the $S_0 \rightarrow S_1^*$ transition, while the short-wavelength band corresponds to the $S_0 \rightarrow S_3^*$ transition. Calculations predict[80] the existence of yet another band corresponding to the $S_0 \rightarrow S_2^*$ transition, but, owing to its low intensity, it has not been possible to observe it. The absorption bands of $N_{(6)}$-exonitroso-derivatives of sydnone imines in the visible region have been assigned[73] to the $n \rightarrow \pi^*$ transition.

The nature of the substituents in the 3- and 4-positions in the ring and of the exocyclic group has almost no influence on the position of the short-wavelength maximum, in contrast to the long-wavlenegth absorption, whose shifts reach considerable magnitudes[78]. Thus the introduction of an aryl substituent in the 3- or 4-position in the sydnone imine ring[27] or the substitution of the hydrogen at the exocyclic nitrogen by an aryl residue[27,56] lead to a bathochromic shift of the absorption band and to the appearance of a new band at 222–260 nm. On protonation of $N_{(6)}$-acylsydnone imines, the opposite hypsochromic shift of the long-wavelength band from 308–342 nm to 278–306 nm was observed, which made it possible to measure the pK_a spectrophotometrically[56].

The great similarity of the ultraviolet spectra of sydnone imine salts and correspondingly substituted sydnones, indicating the similarity of the strctures of the electronic shells in these compounds, is striking[76]. A satisfactory correlation of the frequencies of the long-wavelength $\pi \rightarrow \pi^*$ transition with the energy difference between the highest occupied and lowest vacant molecular orbitals (calculation by the Hückel molecular orbital method) has been demonstrated[81] for the series of sydnone imines:

$$\nu_{\pi\rightarrow\pi^*} = 23\,241 + 8366\,(m_{m+1} - m_m)\,(r = 0.938)\,.$$

On passing from non-polar to polar solvents, the long-wavelength absorption of sydnone imines, like that of sydnones, shifts towards shorter wavelengths, in full agreement with calculations[80]. Owing to the formation of hydrogen bonds, in hydroxylated solvents a pronounced hypsochromic shift of the absorption bands of $N_{(6)}$-nitrososydnone imines is observed in the visible region[73].

The $N_{(6)}$-nitrosoaminoacetonitriles, formed by the opening of the sydnone imine ring, absorb at much shorter wavelengths (approximately 230 nm for the 3-alkyl-substituted derivatives); on the basis of this difference, the kinetics of the ring opening process[82] and the reverse cyclisation reaction[51] of sydnone imine have been investigated spectrophotometrically.

A weak pale-yellow luminescence (with a maximum at approximately 510 nm) has been observed recently[82] for solid solutions of sydnone imine salts in water; a pronounced bathochromic shift of the luminescence bands relative to the corresponding absorption bands has been noted.

2. Vibrational Spectra

Characteristic intense bands due to the stretching vibrations of the exocyclic $\rangle C{=}N-$ bond (1671–1700 cm^{-1}) and deformation vibrations of the immonium group $=\overset{+}{N}H_2-$ (1588 to 1606 cm^{-1}) have been observed in the infrared spectra of sydnone imine salts[83,84]. These bands were assigned by comparing the spectra with those of the salts of iminoesters and deuterated derivatives of sydnone imines[83,84].

A low-intensity band due to the stretching vibrations of the $C_{(4)}-H$ bond has been observed in the region of 3110 to 3205 cm^{-1} in the spectra of sydnone imines unsubstituted in the 4-position[32,68]. Other systematically observed absorption bands (at 742–810 and 1160–1216 cm^{-1}) are probably associated with the deformation vibrations of the sydnone imine ring[83,84]. The positions of the characteristic frequencies depend little on the type of substituents in the 3- and 4-positions in the ring. It has been noted that the presence of a substituent at a ring carbon atom diminishes somewhat the intensity of the vibrations of the $\overset{+}{N}H_2$ group.

The band due to the stretching vibrations of the carbonyl group in $N_{(6)}$-acylsydnone imines (1620–1670 cm^{-1})[84] is displaced towards lower frequencies, compared with acyclic *N*-acylamines (1660–1680 cm^{-1}). This shift can be accounted for by the electron-donating properties of the sydnone imine ring relative to the imino-group[56]. Owing to its conjugation with the carbonyl group, the C=N bond in the $N_{(6)}$-acylsydnone imines has a stretching vibration band in the region of lower frequencies (1546–1608 cm^{-1})[56,69] than the C=N bond in the corresponding $N_{(6)}$-unsubstituted sydnone imine salts. As a result of the exclusion from conjugation of the electron pair of the exocyclic nitrogen atom, the spectra of the salts of $N_{(6)}$-acylsydnone imines[32,56,69] exhibit an appreciable shift of the carbonyl band to the $\nu(C{=}O) = 1722$–1739 cm^{-1} and of the C=N bond stretching vibration band to $\nu(C{=}N) = 1615$–1635 cm^{-1}. The study of the infrared spectra showed that in $N_{(6)}$-acylsydnone imines the proton adds to

the exocyclic nitrogen and not to the oxygen of the carbonyl group[56].

The vibration frequencies of the carbonyl groups in $N_{(6)}$-acylsydnone imines are weakly correlated with the calculated C=O bond orders[85] (the calculation was performed[86] by the Hückel molecular orbital method with parameters obtained by the PPP method).

The infrared and Raman spectra of $N_{(6)}$-carbamoylsydnone imines have been studied in detail[69] in the region of the characteristic vibrations of the $>C{=}N{-}\overset{\overset{O}{\|}}{C}{-}NHR$ group; the following assignments have been made: $\nu(C{=}O) = 1640–1660\ cm^{-1}$; $\nu(C{=}N) = 1580–1600\ cm^{-1}$; $\delta(NH) = 1510–1540\ cm^{-1}$. The bands were found[69] to have high integral intensities ($A_{C=O} = 3.1 \times 10^{4}–5.0 \times 10^{-4}$ cm^2 litre mole^{-1} and $A_{C=N} = 2.4 \times 10^{-4}–3.1 \times 10^{-4}$ cm^2 litre mole^{-1}); comparison with the spectroscopic characteristics of other $N_{(6)}$-acyl derivatives indicates an effective electronic interaction of the atoms in the group investigated. It has been shown by infrared spectroscopy[69] that the proton adds to the exocyclic nitrogen atom in the $N_{(6)}$-carbamoyl derivatives.

The value of $\nu(C{=}N)$ in the spectra of 3-hydroxysydnone imines (1680 cm^{-1}) led to the conclusion that these compounds have the zwitter-ionic (*N*-oxide) structure (IXa).[48]

Two intense bands at 1335–1355 and 1408–1421 cm^{-1}, assigned to the stretching vibrations of the N=O bond in the associated and non-associated molecules respectively, are characteristic[73] of $N_{(6)}$-nitrososydnone imines; the band at 1503–1599 cm^{-1} corresponds[73] to the exocyclic C=N bond and that at 1090–1111 cm^{-1} corresponds to the N–N bond in the $>C{=}N{-}N{=}O$ group.

The characteristic vibration frequencies of various groups attached to substituents in the 3- and 4-positions in the sydnone imine ring have been quoted in a number of investigations, namely carboxy-,[32] ester, hydroxy-, and other groups[84,87]. When the groups are close to the ring, the characteristic frequencies undergo a shift due to the electronegative properties of the mesoionic ring.

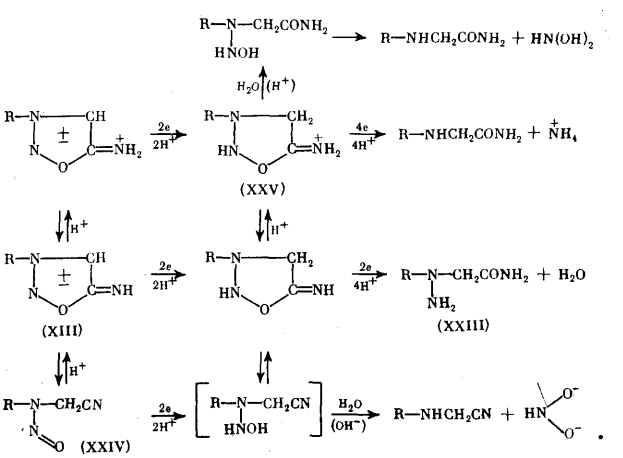
3. Nuclear Magnetic Resonance Spectra

There can be only one hydrogen atom at the carbon atom in the 4-position in the sydnone imine ring. The chemical shifts of this proton have been quoted in a number of reports as a function of the substituents at the $N_{(3)}$ and $N_{(6)}$ atoms[9,33,52,68,88]. The chemical shifts of the protons in the sydnone imine salts ($\delta = 7.4–8.1$ p.p.m.†) are located in a lower field[9,23] than for sydnones ($\delta = 6.2–6.8$ p.p.m.).[33] In $N_{(6)}$-acylsydnone imine salts the signal due to the proton at $C_{(4)}$ is displaced downfield even more ($\delta = 8.3–8.8$ p.p.m.).[52] Owing to the combination of the anisotropic effects of the two rings in the 3-aryl derivatives of sydnone imines, the signal due to the proton at $C_{(4)}$ is displaced downfield[88].

The signal due to the protons of the methyl group in 3-methyl-substituted sydnone imines is located in a very low field (5.5–5.9 p.p.m.), which indicates an appreciable positive charge on the $N_{(3)}$ atom.

† Here and henceforth the chemical shifts are relative to tetramethylsilane.

The positions of the substituents entering the molecule in electrophilic substitution (nitration and bromination) reactions involving certain $N_{(6)}$-arylcarbamolysydnone imines have been determined with the aid of the analysis of the ^{1}H NMR spectra[68].

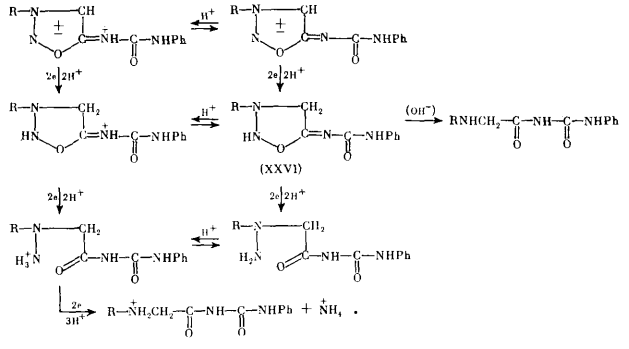


The ^{13}C NMR spectrum of 3-methylsydnone imine hydrochloride has been recently investigated and it has been shown that the $C_{(4)}$, $C_{(5)}$, and $C_{(CH_3)}$ atoms have chemical shifts of 97.3 170.4 and 40.1 p.p.m. respectively. Thus the signals due to the ring carbon atoms are located in a very high field compared with those of the carbon atoms in many other heterocycles, which in general agrees[89] with the higher effective charges on the carbon atoms in the sydnone imine ring (calculation by the CNDO/2 method).

4. Polarography

Like the sydnone ring, the sydnone imine ring is polarographically active; sydnone imine derivatives are very readily reduced at a dropping mercury electrode[27,90–98]. The influence of pH, temperature, drop period, and the addition of alcohol and the surfactants on the polarographic behaviour of sydnone imines has been investigated[90,92,94,95]. Coulometric measurements have been made to determine the number of electrons consumed at the anode[90,94,95] and it has been found that in an acid medium sydnone imine salts give rise to a single six-electron reduction wave[90,94], while in an alkaline medium $N_{(6)}$-acylsydnone imines give a four-electron wave[90,93].

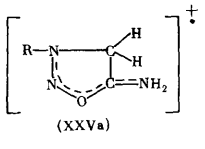
Two waves are characteristic of $N_{(6)}$-acyl derivatives in the pH range 8–11: one corresponds to the reduction of the cation and the other, at more negative potentials, corresponds to the reduction of the base[92,95]. Two waves have been observed in the polarography of 3,3′-dimethylene-, trimethylene, and *p*-phenylene-3,3′-bis-sydnone imines—the reduction of the first heterocycle is facilitated under the influence of the second[98].



A mechanism has been proposed for the polarographic reduction of the sydnone imine cation[90]. For 3-alkyl derivatives, this mechanism has been revised[94] and can be represented schematically as follows#:

The vertical arrows in the above scheme indicate the chemical processes accompanying the reduction reactions represented horizontally.

After the electrolysis of sydnone imines in a neutral medium (four electrons are consumed), the polarogram shows the anodic wave due to the oxidation of the hydrazine (XXIII); the anodic peak due to the oxidation of (XXIII) is observed likewise in cyclic voltamperometric measurements[92]. In unbuffered solutions the sydnone imine ring is partly cleaved to the *N*-nitroso-derivative (XXIV) in the region near the electrode. In the reduction of the sydnone imine ring ($c = 0.86 \times 10^{-3}$ M) in 0.1 M KCl with added 0.5×10^{-3} M HCl the splitting of the wave was observed—as a result of the increase in the alkalinity of the space near the electrode, the sydnone imine base (XIII) is formed and is involved in the production of the second wave at more negative potentials[94].



A similar mechanism has been proposed[92] for the reduction of $N_{(6)}$-carbonyl derivatives of sydnone imines and was subsequently revised and extended[95]. For example, for $N_{(6)}$-phenylcarbamoyl derivatives, it can be represented by the following scheme:

(XXVI)

In solutions with insufficient buffer capacity it was possible to observe the reduction wave of the dihydrosydnone imine (XXVI).

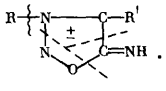
The proposed mechanisms agree with quantum-chemical calculations on certain possible intermediates[96]. From the standpoint of these calculations, the capture of the first potential-determing electron followed by the addition of a proton to the $C_{(4)}$ atom with formation of the radical-cation (XXVa)

(XXVa)

is most probable. The addition of a second electron and a proton to the $N_{(2)}$ atom of this radical-cation leads to the dihydro-compound (XXV).

3-Aryl derivatives of sydnone imines have a number of characteristic features in their polarographic behaviour and their reduction mechanism is somewhat different[88].

On the basis of calculations, it has been suggested[94] that the reduction of the sydnone imine cation is greatly facilitated as a result of the gain of hydration energy on passing from the cation to the corresponding radical-cation (XXVa), which is formed following the addition of the first electron.



The values of $E_{1/2}$ for sydnone imines are proportional to the energies of the lowest vacant molecular orbitals calculated by the Hückel method with the parameters of Pullman and Pullman[81]. When the energies of the lowest vacant molecular orbitals calculated by the Hückel molecular orbital method are used together with the parameters obtained by the PPP method, such proportionality is observed simultaneously for sydnones and sydnone imines[86].

The validity of the Hammett and Taft equations for the sydnone imines reduction half-wave potentials $E_{1/2}$ has been demonstrated: $E_{1/2} = -0.93 + 0.37\sigma^*$ for 3-alkyl-substituted derivatives (pH 7.4);[90] $E_{1/2} = -0.63 + 0.17\sigma$ for 3-aryl-substituted derivatives[27,77] (pH 7.4);[27,93] $E_{1/2} = -0.305 \pm 0.14\sigma$ for $N_{(6)}$-methoxycarbonyl-3-aryl-substituted derivatives[27,93] (0.1 *N* HCl).

The polarographic method has been used to investigate the kinetics and equilibria in the alkaline opening of the sydnone imine ring[97,99,100]. The dynamics of the changes in the concentration of $N_{(6)}$-phenylcarbamoyl-3-phenylisopropylsydnone imine (the medicinal drug sydnocarb) in the blood of experimental animals has been followed with the aid of oscillographic polarography[101].

5. Mass Spectrometry

The most intense peak in the mass spectra of sydnone imine hydrochlorides corresponded[102] to the base (M–HCl). The heterocyclic ring of the base is cleaved preferentially into three fragments (NO, C=NH, and NCR') in accordance with the scheme

The mass spectra confirmed[48] the mode of methylation of 3-hydroxysydnone imine—both methyl groups are directed to the $N_{(6)}$ atom.

6. Quantum-Chemical Calculations of the Electronic Structure of Sydnone Imines

Quantum-chemical calculations on sydnone imines (and sydnones) have been carried out by various methods (see Tables 1 and 2).

The calculations were performed by the Hückel method using the parameters of Pullman and Pullman[81,103] and a self-consistent system of parameters computed from data evaluated by the PPP method[85]. The electron density distributions obtained were qualitatively independent (as regards the signs of the effective charges) of the parametrisation, but the quantitative differences between them were fairly marked. The most equalised charges were obtained using parameters calculated by the PPP method[85]. The influence of substituents in the 3-, 4-, and 5-positions has been calculated[81,85,104]. Analysis of the results shows that the sydnone imine ring (like the sydnone ring) is a weak "transmitter" of π-electronic effects from the 3-position to the 1- and 5-positions and to the exocyclic nitrogen atom and also from the 4-position to the 1- and 5-positions and from the 5-position to the 3-position; the charges on the $N_{(2)}$ and $C_{(4)}$ atoms are most sensitive to the influence of substituents in sydnone imine[85,105].

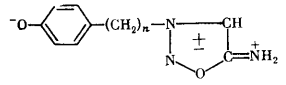
*Notation: 1) Hückel molecular orbital method, parameters of Pullman and Pullman; 2) Hückel molecular orbital method, parameters calculated by the PPP method; 3) PPP.

Calculations have been made by the Hückel method on sydnone imines, sydnones, and certain other mesoionic heterocycles using the ω-technique[88,106].

The first calculation on sydnone imine in terms of the π-electron approximation by the LCAO-MO SCF method was performed[107] using a modified PPP method. Calculations have been made[108,109] on sydnone imine and sydnone by the PPP method and the influence of the initial system of parameters was analysed. In contrast to the results obtained by the simple Hückel molecular orbital method, the PPP method predicts a much higher effective charge on the $N_{(2)}$ atom than on the $C_{(4)}$ atom.

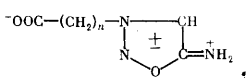
Calculations have been carried out[110] on the 3-methylsydnone imine cation and its base by the LCAO-MO SCF method in terms of the CNDO/2 valence approximation and the dipole moment of the hypothetical 3-methylsydnone imine base has been calculated ($\mu = 6.39$ *D*). A comparative calculation has been performed recently by the same method[111] on sydnone imine in which protons have been added to different atoms. Comparison of the total energies of the resulting cations showed that protonation at the exocyclic nitrogen atom is energetically most favourable. Calculations have been made in the same study[111] on certain possible intermediates in the acid cyclisation of *N*-nitrosaminoacetonitrile and the reverse reaction involving the alkaline opening of the sydnone imine ring. The calculations permitted certain hypotheses concerning the mechanisms of these reactions.

A number of studies demonstrated a fair agreement of the results of the calculations with experimental physicochemical characteristics[86,96,105,109] and the fundamental chemical properties, which will be dealt with below.



IV. CHEMICAL PROPERTIES

Like sydnone, sydnone imines are extremely reactive; reactions occurring with both retention and opening of the heterocyclic ring are characteristic of these compounds and the majority of reactions take place under fairly mild conditions.



1. Reactions with Retention of the Ring

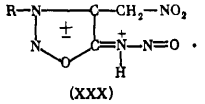
(a) *Reactions involving the exocyclic group.* The synthesis of $N_{(6)}$-exocyclic derivatives of sydnone imines, obtained by the electrophilic substitution of the hydrogen at the exocyclic nitrogen atom, was examined in detail above. These reactions take place readily and smoothly, which makes it possible to characterise the exocyclic imino-group as highly basic.

Frequent attempts to isolate the free sydnone imine bases have been unsuccessful, except for 3-hydroxy-derivatives (IX),[48] which exist as a result of betaine stabilisation. The strong base formed on neutralisation apparently undergoes autocatalytic tautomerisation to the initial nitrosoaminoacetonitrile (for further details, see below). The high basicity of the hypothetical sydnone imine base is also indicated by other facts, such as the ability to form salts with weak acids (carbonic or thiocyanic) and to form inner salts as a result of the involvement in the betaine structure of the phenolic hydroxyl of (XXVII) [9] and (XXVIII) [21] or the carboxy-group in a series of free-carboxyalkyl-substituted sydnone imines (XXIX):[32]

(XXVII) $n = 0$
(XXVIII) $n = 2$

(XXIX) $n = 1, 2$

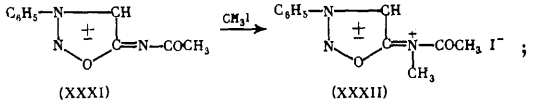
The pK_a values have been determined for certain 3-dialkylaminosydnone imines (VI) and were found to be ~8.15–8.85,[36] i.e. are similar to, for example, the pK_a for morpholine (8.7). According to Gotz and Grozinger[36], this shows that the exocyclic nitrogen atom is protonated in these compounds, since its acylation leads to a decrease of pK_a by 4–5 orders of magnitude.



The capacity of $N_{(6)}$-acyl derivatives for protonation, which likewise confirms the high basicity of the sydnone imine "base", has been observed not only for 3-dialkylaminosydnone imines but also for compounds with hydrocarbon substituents in the 3-position[15,27,52,56]. $N_{(6)}$-Carbamoylsydnone imines possess similar properties[52]. The hydrochlorides, sulphates, and nitrates of a series of compounds of this type has been isolated in the solid state.

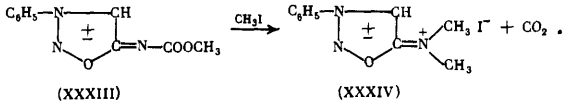
The basicity of $N_{(6)}$-acyl- and $N_{(6)}$-carbamoyl-sydnone imines depends significantly on the nature of the substituent in the 3- and 4-positions and in the acyl residue. The pK_a values for $N_{(6)}$-acyl derivatives vary in the range 2.5–4.6. Compounds with alkyl substituents in the 3-poisition are more basic than their aryl analogues. The substitution of the hydrogen atom at the carbon atom in the 4-position of the ring by the methyl or phenyl group leads to a decrease of capacity for salt formation.

Comparison of the pK_a values for compounds with the same exocyclic substituent, for example, the methoxycarbonyl group, reveals an increase in the basicity of the exocyclic nitrogen following the enhancement of the electron-donating properties of the substituent in the 3-position[27]. As was to be expected, in compounds with the same substituent in the 3-position, a decrease of the electronegativity of the substituent at the $N_{(6)}$ atom increases significantly the basicity for the following series of substituents: $CCl_3CO < C_6H_5CO < CH_3OCO < CH_3CO$.[56]



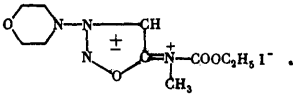
The carbamoyl analogues of $N_{(6)}$-acylsydnone imines are somewhat less basic than the latter compounds[52,101]. Benzenesulphonyl and thiocarbamoyl derivatives exhibit weak basic properties; the pK_a of the latter compounds cannot even be measured[52].

A single instance of the protonation of $N_{(6)}$-nitroso-derivatives has been described, namely of compound (XXX) having in the 4-position the nitromethyl group, which apparently stabilises the molecule[49]:

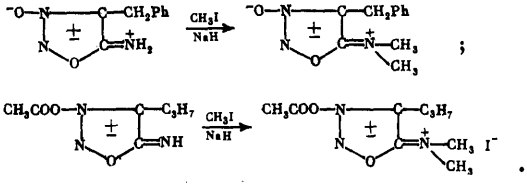


(XXX)

Evidence additional to the spectroscopic data quoted above, confirming that the protonation of $N_{(6)}$-acylsydnone imines proceeds at the exocyclic nitrogen atom, comes from the ability of these compounds to form quaternary salts[56]. Thus, when $N_{(6)}$-acetyl-3-phenylsydnone imine (XXXI) was heated with methyl iodide in acetone, the methiodide (XXXII) was obtained:

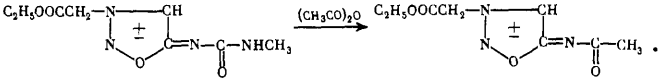


(XXXI) (XXXII)



(XXXIII) (XXXIV)

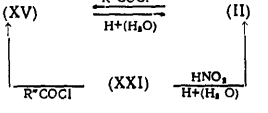
Under analogous conditions, the $N_{(6)}$-methoxycarbonyl derivative (XXXIII) is converted into the quaternary salt (XXXIV).[56] Evidently the methiodide of type (XXXII) formed in the latter reaction is readily decarboxylated.



Decarboxylation was not observed in the methylation of $N_{(6)}$-ethoxycarbonyl-3-morpholinosydnone imine[59] and the final product had a structure similar to that of (XXXII):

Quaternary salts of type (XXXIV) have been obtained from 4-benzyl-3-hydroxysydnone imine and 3-acetoxy-4-propylsydnone imine by treatment with methyl iodide in the presence of sodium hydride[48]:

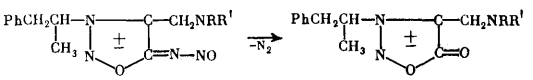
Other types of reactions of the exocyclic group in $N_{(6)}$-substituted sydnone imines have also been described. Thus, in the presence of boron trifluoride etherate, the $N_{(6)}$-methylcarbamoyl derivative (XXXV) is smoothly converted under the influence of acetic anhydride into the corresponding acetyl derivatives (XXXVI):[112]



(XXXV) (XXXVI)

Certain $N_{(6)}$-acyl-3-arylsydnone imines split off the acyl group under the influence of 1 *N* HCl even at room temperature, giving rise to sydnone imine salts[41,48,52,59]. On the other hand, this reaction for the majority of other acyl derivatives requires fairly severe conditions (for example, 1 *N* HCl, 1 h, 100 °C).[52] The phenylcarbamoyl group is not eliminated under analogous conditions[52].

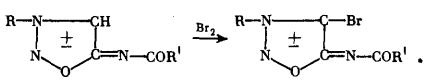
The acid elimination of the acyl group could be used to obtain other $N_{(6)}$-derivatives of 4-substituted sydnone imines when a sydnone imine salt cannot be used. For example, on heating the $N_{(6)}$-methoxycarbamoyl-4-bromo-3-phenylsydnone imine (XV, $R = C_6H_5$, $R' = Br$, $R'' = OCH_3$) with 2.7 *N* H_2SO_4 and subsequent nitrosation of the reaction mixture, the $N_{(6)}$-nitroso-derivative of this sydnone imine (XXI, $R = C_6H_5$, $R' = Br$) was synthesised[73].



$N_{(6)}$-Nitrososydnone imines (XXI) exhibit a high reactivity. Under the influence of carboxylic acid chlorides, they are converted smoothly into the corresponding $N_{(6)}$-acylsydnone imines (XV):[25]

When the $N_{(6)}$-nitroso-derivative is treated with hydrogen chloride in alcohol, the nitroso-group is eliminated as nitrosyl chloride with formation of the sydnone imine hydrochloride[25]. This reaction also proceeds smoothly with sulphuric or hydrochloric acid, giving an almost quantitative yield. Its detailed kinetic study established[25] that the nitroso-group in compound (XXI) hydrolyses extremely readily. The reaction is catalysed by acids and proceeds via the S_N2 mechanism. Under identical conditions, $N_{(6)}$-nitrososydnone imines hydrolyse at a rate faster by several orders of magnitude than the usual *N*-nitrosoamines[25].

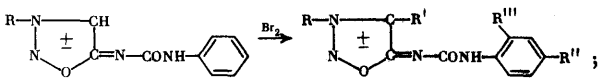
When $N_{(6)}$-nitroso-derivatives are heated in inert solvents, they are converted into the corresponding sydnones (I) with evolution of nitrogen[25,73]. It has been observed[25] that in alcohols and dichloroethane the reaction is slow and the yield of sydnones is frequently 25–50%; in boiling dimethylformamide (DMF) the process also proceeds partly with liberation of nitrogen oxides. On moderate heating in DMF (at approximately 90 °C), the reaction proceeds rapidly and sydnone is formed almost quantitatively[113]. This transformation is observed for compounds with aliphatic, alicyclic, and aliphatic-aromatic substituents in the 3-position and also for 4-benzylsydnone imines. The kinetic studies have led to the conclusion that the reaction is a unimolecular process, which can be classified as an S_Ni intramolecular substitution reaction.



A new method of synthesising sydnones[114] can be more convenient in some cases than the usual procedure; it leads to higher yields and makes it possible to synthesise sydnones which cannot be obtained by the cyclisation of the corresponding *N*-nitrosoaminoacids. Thus the $N_{(6)}$-nitroso-derivative of 4-dimethylamino-3-phenylisopropylsydnone imine (XXXVIIa) and 3-phenylisopropyl-4-piperidinosydnone imine (XXXVIIb) are converted in almost quantitative yields into the corresponding sydnones (XXXVIIIa) and (XXXVIIIb) on heating in DMF:[49]

(XXXVII) (XXXVIII)

(a) R, $R^1 = CH_3$, (b) $RR^1 = -(CH_2)_5-$.



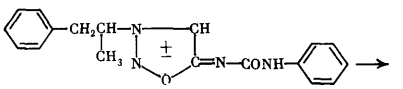
(b) Reactions involving substitution in the 4-position and transformation of side groups. By analogy with sydnones, $N_{(6)}$-acyl derivatives of sydnone imines enter into electrophilic substitution reactions involving the fourth carbon atom. Under mild conditions, the hydrogen at the $C_{(4)}$ atom is replaced by the mercuriacetate group[6]. The bromination of $N_{(6)}$-acylsydnone imines proceeds smoothly[6,9,20,42,76,115] and the reaction takes place most readily in ether in the presence of an excess of sodium bicarbonate[9,20]; the use of dibromodioxan and bromosuccinimide[20,41] leads to much lower yields:

It has been noted that substitution of 3-alkyl derivatives takes place much more readily than that of their aryl analogue[20]. Like the $N_{(6)}$-acylsydnone imines, their $N_{(6)}$-sulphonyl derivatives undergo the bromination reaction[75].

On bromination of $N_{(6)}$-carbamoylsydnone imines containing alkyl substituents in the exocyclic group, substitution by bromine, as in the $N_{(6)}$-acyl analogues, takes place at the $C_{(4)}$ atom of the sydnone imine ring[68].

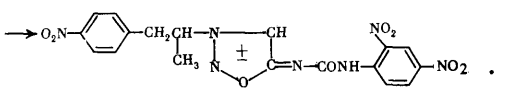
In the course of the bromination of $N_{(6)}$-phenylcarbamoyl-3-butylsydnone imine (XXXIX, $R = C_4H_9$), it was observed[41] that bromine enters the benzene ring and not the sydnone imine ring and it was postulated that this leads to the formation of the *p*-bromo-derivative (XL, $R = C_4H_9$):

(XXXIX)



(XL): $R^1 = R''' = H$, $R'' = Br$;
(XLI): $R''' = H$, $R^1 = R'' = Br$;
(XLII): $R^1 = R'' = R''' = Br$.

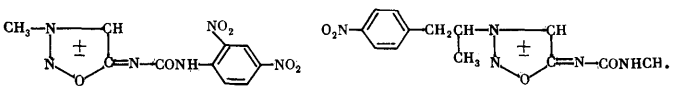
A detailed study of the bromination of $N_{(6)}$-phenylcarbamoylsydnone imines showed[68] that, when equimolar amounts of bromine are used, *p*-bromophenyl derivatives (XL) are indeed formed. An increase of the amount of bromine to 2 moles leads to the substitution of both the benzene and sydnone imine rings in (XLI). When the reaction was carried out in the presence of a large excess of bromine, the tribromo-derivative (XLII) was obtained.



The introduction of chlorine and iodine atoms into the 4-position of $N_{(6)}$-acyl-3-morpholinylsydnone imines with the aid of chloro- and iodo-succinimide has been described[41,115].

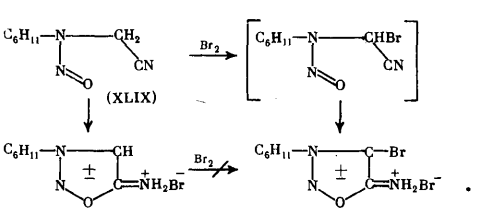
The attempt to substitute at the $C_{(4)}$ atom by treatment with chlorine or sulphuryl chloride led only to the cleavage of the sydnone imine ring[116]. In contrast to sydnones, the bromine in $N_{(6)}$-acyl-4-bromosydnone imines could not be substituted by lithium[75].

Nitration of $N_{(6)}$-phenylcarbamoyl-3-arylalkylsydnone imines with a mixture of nitric and acetic acid at room temperature gives rise, in contrast to sydnones, to the corresponding nitrate salts only[68]. Under more severe conditions (treatment with a mixture of nitric and sulphuric acid), $N_{(6)}$-phenylcarbamoyl-3-phenylisopropylsydnone imine (XLIII) is converted into a trinitro-derivative, to which structure (XLIV) was attributed:



(XLIII)

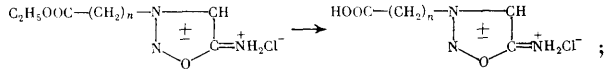
(XLIV)



$N_{(6)}$-Phenylcarbamoyl-3-methyl- and $N_{(6)}$-methylcarbamoyl-3-phenylisopropyl-sydnone imines give rise under these conditions, to the nitro-derivatives (XLV) and (XLVI) respectively without a nitro-group in the sydnone imine ring:

(XLV) (XLVI)

In the bromination and nitration reactions a decrease of the nucleophilic activity of the $C_{(4)}$ atom of the sydnone imine ring is observed relative to the phenylcarbamoyl group.

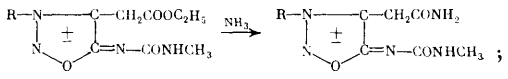


The impossibility of introducing the nitro-group into the sydnone imine ring is apparently due to the sharp decrease of the nucleophilic activity of the entire molecule and in the first place of the carbon atom in a strongly acid medium owing to the protonation of the exocyclic nitrogen atom. For the same reason, it is impossible to brominate 3-cyclohexylsydnone imine hydrobromide (XLVII) by treatment with bromine in chloroform[20]. The expected product (XLVIII) was obtained by allowing a solution of *N*-nitroso-*N*-cyclohexylaminoacetonitrile (XLIX) in bromine-containing methylene chloride to stand for a long time, whereupon compound (XLVII) was isolated together with compound (XLVIII). Apparently there is initially substitution of the hydrogen at the α-carbon atom by bromine, which results in the evolution of hydrogen bromide, under the influence of which both nitrosonitriles cyclise;

(XLVII) (XLVIII)

Thus exocyclic derivatives of sydnone imines can enter into electrophilic substitution reactions involving a ring carbon atom, provided that the formation of the cationic form of the molecule is excluded during the process.

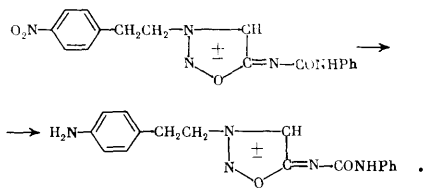
Apart from the examples of the involvement of the side groups of sydnone imines in bromination and nitration reaction quoted above, a number of other instances are also known were side groups react, while the mesoionic ring remains unaffected. Thus 3-carboxymethylsydnone imine hydrochloride (La), which could not be obtained by direct synthesis, has been prepared by the hydrolysis of the corresponding ethyl ester (LIa) (which is available) with hydrochloric acid at room temperature[64]:



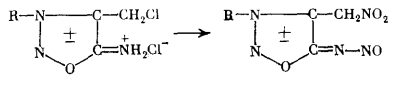
(LI) (a) $n = 1$. (L)

The hydrochlorides of other carboxylalkylsydnone imines (L) [33] have been synthesised analogously and the esters of $N_{(6)}$-carbamoyl and $N_{(6)}$-thiocarbamoyl-3-carboxymethylsydnone imines have been converted into the corresponding acids[64].

Under the influence of aqueous ammonia at room temperature, the ester group in the 3- or 4-positions in $N_{(6)}$-methylcarbamoylsydnone imines is smoothly converted into the amide group[58,117].



In contrast to the compound with the methyl substituent in the 3-position (LIIa), its phenyl analogue (LIIb) undergoes ring cleavage with further rearrangement under these conditions, in addition to the formation of the amide:

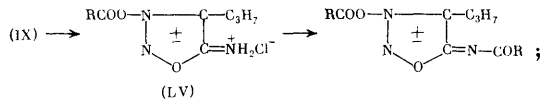


(LII)

(a) R = CH_3, (b) R = Ph.

By virtue of the considerable stability of the $N_{(6)}$-carbamoyl derivatives, it was possible to reduce the nitro-group in the benzene ring of the substituent with the aid of iron in acetic acid[68]:

Interesting reactions are observed for 4-chloromethylsydnone imines (LIII).[49] On treatment with sodium nitrite in water or methanol, a reaction involving both the exocyclic group and the side chain takes place. The reaction products were found to be $N_{(6)}$-nitroso-derivatives of 4-nitromethylsydnone imines (LIV):

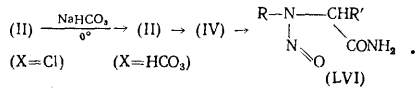


(LIII) (LIV)

This indicates a high mobility of the chlorine atom in the chloromethyl group.

Incidentally, attempts to obtain 4-chloro- or 4-bromomethyl derivatives of sydnone imines by substituting the hydrogen atom by a halogen in *N*-acyl-4-methylsydnone imines under various conditions were unsuccessful[49].

The simultaneous involvement in the reaction of the exocyclic nitrogen atom and the side chain was observed also in the acetylation or carbamoylation of 3-hydroxy-4-propylsydnone imine[33] (IX). In the first place the reaction involves the oxygen atom, as shown by the formation of the monosubstituted product (LV):



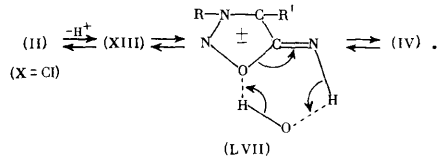
(LV)

R = CH_3, or NHPh.

2. Reactions with Opening of the Ring

The high reactivity of sydnone imines is manifested particularly strikingly in reactions leading to the opening of the heterocyclic ring. Ring cleavage can take place at different bonds under the influence of various reagents.

(*a*) *The action of alkalis and bases.* When sydnone imine hydrochlorides are treated cautiously with sodium bicarbonate at 0 °C, it is possible to isolate acid carbonate salts, but even at room temperature the ring opens under these conditions with formation of the initial *N*-nitrosoaminonitrile[9]:

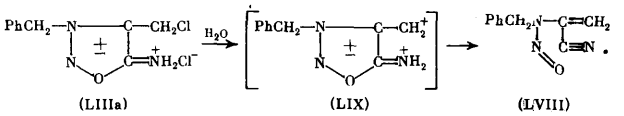


(LVI)

When sydnone imine salts are treated with a solution of sodium carbonate or caustic alkalis and also on being passed through an anion-exchanger, saturated with hydroxide ions, the reaction products are the corresponding *N*-nitrosoaminoacetamides (LVI), probably obtained as a result of the hydrolysis of the nitriles produced initially[7,9,97,118].

The formation of *N*-nitrosoacetamide has been observed also on treating sydnone imine hydrochloride with piperidine[119]. It has been shown by a polarographic procedure for a series of 3-alkylsydnone imine hydrochlorides[99] that they are rapidly converted in a weakly alkaline medium (pH 11) into *N*-nitrosoaminoacetonitriles (IV), which give rise to the corresponding amides (LVI) at higher pH values.

The kinetics of the alkaline opening of the ring in 3-isopropylsydnone imine hydrochloride has been studied spectrophotometrically[120] and it has been established that the process is reversible in the pH range 7.15–8.60 and is of first order with respect to the sydnone imine and of second order with respect to hydroxide ions. The authors[120] suggest that the first stage involves the elimination of a proton from the salt, leading to the formation of the base (XIII), which is a cyclic tautomer of the final cleavage product—*N*-nitrosoaminoacetonitrile (IV). The rate-limiting stage of the process is a bimolecular reaction involving the attack on the base (XIII) by a hydroxide ion. The resulting reaction complex, which may have the bicyclic structure (LVII), is converted into (IV) either directly with elimination of a hydroxyl or via an intermediate:



(LVII)

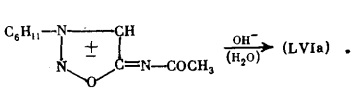
It has been observed that in the case of 3-arylsydnone imines the reaction is of first order with respect to both the heterocycle and the hydroxide ion[97]. Apparently here too

the first stage involves the elimination of a proton from the sydnone imine cation with formation of a base, which undergoes spontaneous ring opening to give compound (IV) without the involvement of the OH^- ion or an activated complex. This difference in the mechanism can probably be accounted for by the conjugation between the sydnone imine and benzene rings in the 3-arylsydnone imine base.

In the series of 3-arylalkylsydnone imines there is also a possibility of ring opening not catalysed by hydroxide ions. Thus, it has been noted that the hydrochloride of 3-benzyl-4-chloromethylsydnone imine (LIIIa, $R = C_6H_5CH_2$) undergoes ring cleavage even under the influence of water[49]. α-(*N*-Nitrosobenzylamino)acrylonitrile (LVIII) was isolated as the final product:

(LIIIa) (LIX) (LVIII)

The process probably involves the initial elimination of a chloride ion from the chloromethyl group with formation of the unstable dication (LIX), which is stabilised with elimination of two protons and the opening of the ring to give the unsaturated nitrile (LVIII).

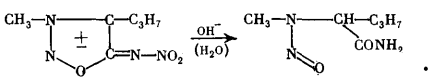


The determination of the rate and equilibrium constants made it possible to elucidate the effect of substituents on the stability of the sydnone imine ring in an alkaline medium[90,107]. Electron-donating substituents in the 3- and 4-positions, which lower the electrophilic activity of the entire molecule and of the reaction centre in relation to the reaction catalysed by hydroxide ions, increase the stability of the ring. It has been shown recently[121] that even the carboxy-group in 3-carboxyalkylsydnone imines promotes an increase of the stability of the ring compared with the 3-methyl derivative.

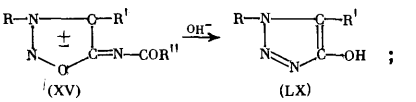
A detailed study of the alkaline opening of the ring in the hydrochloride of 3-morpholinosydnone imine[122] showed that this process has the general characteristic observed for sydnone imines with hydrocarbon substituents in the 3-position.

All the available data permit the conclusion that the opening of the ring in sydnone imine salts is not a result of hydrolysis but constitutes a tautomeric ring–chain reversible transformation: sydnone imine base ⇋ *N*-nitrosoaminoacetonitrile.

N-Exocyclic derivatives of sydnone imines are much more stable in relation to alkalis and bases, like sydnones[46].



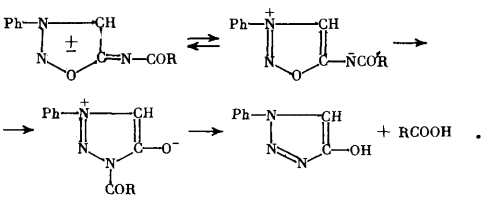
While the majority of $N_{(6)}$-acylsydnone imines are resistant to the action of alkalis at room temperature, they are cleaved on raising the temperature. Thus heating of $N_{(6)}$-acetyl-3-cyclohexylsydnone imiine for 10 min with a 10% solution of sodium hydroxide gives an almost quantitative yield of *N*-cyclohexyl-*N*-nitrosoaminoacetamide (LVIa):[52]



(LVIa).

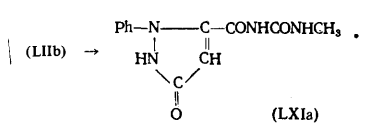
It has been shown in relation to $N_{(6)}$-ethoxycarbonyl-3-morpholinosydnone imine[122] that the first stage of the alkaline cleavage of $N_{(6)}$-acylsydnone imines involves the formation of the "base", as for sydnone imine salts, which is subsequently converted into a nitrosonitrile and a nitrosoamide.

$N_{(6)}$-Nitro-derivatives undergo an alkaline decomposition analogously for $N_{(6)}$-acylsydnone imines[7]:



When $N_{(6)}$-acylsydnone imines are treated with a methanol solution of potassium hydroxide, the formation of *N*-nitrosoaminoacetamides, which are obtained also in an aqueous medium, can be accompanied by other reactions[52]. Thus $N_{(6)}$-acyl-3-butyl- and $N_{(6)}$-acyl-3-phenyl-sydnone imines (XV, a and b) give rise to the corresponding nitrosoamides (LVI) even at room temperature. In the latter case the main reaction product proved to be 4-hydroxy-3-phenyl-1,2,3-triazole (LXb), which is obtained with a high yield on heating (XVb) with a 10% potassium hydroxide solution in methanol:

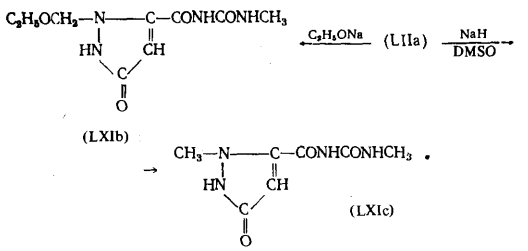
(XV) (LX)



(a) $R = C_4H_9$, $R' = H$, $R'' = CH_3$, C_2H_2Ph;
(b) $R = Ph$, $R' = H$, $R'' = CH_3$, C_2H_5, or Ph;
(c) $R = R' = Ph$, $R'' = C_2H_5$.

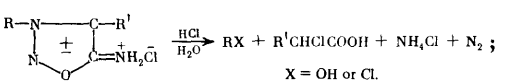
The reaction involving $N_{(6)}$-propionyl-3,4-diphenylsydnone imine (XVc) also proceeds analogously. It is believed[52] that under these conditions ring opening is accompanied by a rearrangement which can be represented by the following scheme:

$N_{(6)}$-Carbamoylsydnone imines are more resistant to alkalis than the corresponding acyl derivatives, but, on heating with an alcoholic solution of potassium hydroxide, their heterocyclic ring is opened[52]. Urea derivatives were isolated among the cleavage products.



It was mentioned above[117] that, in contrast to the 3-methyl analogue, $N_{(6)}$-methylcarbamoyl-4-ethoxycarbonylmethyl-3-phenylsydnone imine (LIIb) undergoes preferential cleavage on treatment with aqueous ammonia at room temperature, forming a rearrangement product—5-pyrazolinone (LXIa):

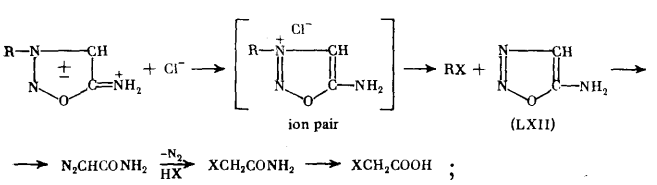
(LXIa)



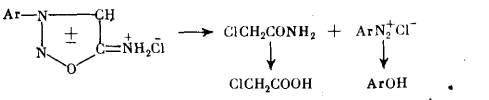
Derivatives of 5-pyrazolinone (LXI, b and c) have been isolated and identified after treating $N_{(6)}$-methylcarbamoyl-4-ethoxycarbonylmethyl-3-methylsydnone imine (LXIIa) with

sodium ethoxide[117] or hydride[123]:

These reactions apparently involve the simultaneous or successive rupture of the $N_{(2)}-O_{(1)}$ bond in the ring and the intramolecular acylation of the unsubstituted nitrogen atom by the carboxymethyl group.

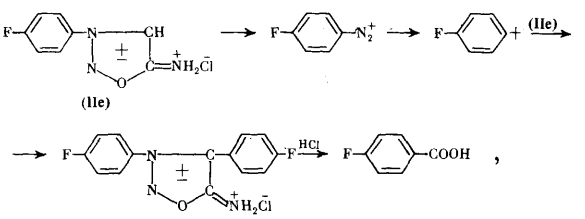


(*b*) *The action of acids*. It was believed initially that, in contrast to sydnones, sydnone imine salts are resistant to the action of acids even on raising the temperature[6,11]. However, a detailed study showed that, on heating with hydrochloric acid, sydnone imines are cleaved with liberation of nitrogen and formation of the corresponding halogeno- or hydroxy-derivatives, substituted chloroacetic acids, and ammonium chlorides[9,123,125]:



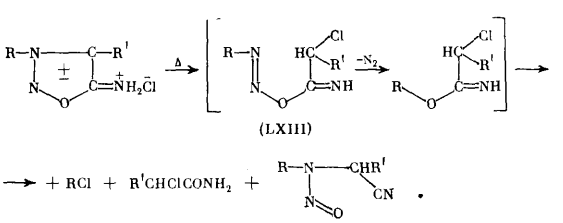
The study of the kinetics of the cleavage of sydnone imine hydrochlorides with aryl substituents in the 3-position showed[125,126] that nitrogen is evolved via a first-order reaction and that the pseudo-unimolecular rate constant is directly proportional to the HCl concentration but is independent of that of H_2SO_4. This confirms that the reaction is catalysed by chloride ions and not protons.

The rate of hydrolysis of sydnone imine salts increases with enhancement of the electron-donating properties of the substituents or with increase of their bulk[125,127]. It has been suggested[125] that the acid hydrolysis of 3-alkylsydnone imine salts is an S_N1 reaction, the first rate-limiting stage of which involves dissociation of the $R-N_{(3)}$ bond with formation of the carbonium ion R^+ and the unstable 5-amino-1,2,3-oxadiazole molecule (LXII). The latter decomposes with evolution of nitrogen and the formation of the amide of glycolic acid. In hydrochloric acid the hydroxy-group is replaced by chlorine and the amide group is converted into a carboxy-group. The R^+ cation reacts instantaneously with water to form the alcohol ROH, while in the presence of chloride ions the chloride RCl is formed.

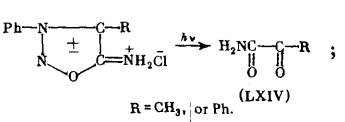


The specific effect of HCl can apparently be explained by the ability of the sydnone imine cation to form ion pairs with Cl^-:

Another mechanism of the acid cleavage has been established for 3-arylsydnone imines[128]. In this case an arenediazonium chloride and chloroacetamide are formed and are subsequently converted into phenol and chloroacetic acid:

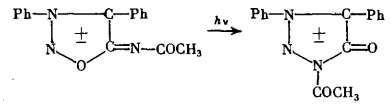


Direct confirmation of the intermediate formation of an arenediazonium compound in this reaction has been obtained[119] by employing the hydrochloride of 3-(4′-fluorophenyl)sydnone imine (IIe). *p*-Fluorobenzoic acid, whose formation has been explained[120] by the mechanism



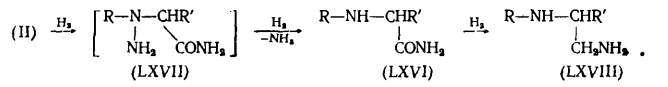
was then detected in the reaction mass.

(*c*) *Thermal and photochemical cleavage*. Sydnone imine salts with non-aryl substituents have been found to undergo thermal as well as hydrolytic cleavage, the former beginning to predominate at high chloride ion concentrations[125,127]. A detailed study of this process led to the hypothesis that in the given instance, when the concentration of the ion pair is high, the first reaction stage involves the dissociation of the $N_{(3)}-C_{(4)}$ bond with formation of the unstable diazoiminoester (LXIII), which is subsequently converted into the corresponding alkyl chloride and amide via the iminoester[125,127]:



The thermal cleavage of the sydnone imine ring can occur on heating sydnone imine salts in non-aqueous solvents, for example in DMF and in butyl alcohol[127]. Together with the products formed on thermal decomposition of the salts in water, the corresponding *N*-nitrosoaminoacetonitrile is obtained. An exception is 3-benzyl derivative, from which benzyl chloride is apparently initially split off, as in an aqueous medium, while 5-amino-1,2,3-oxadiazole (LXII) is cleaved further with participation of yet another sydnone imine molecule to give the final products[128].

Examples of the photochemical cleavage of the sydnone imine ring have been described. Thus, on irradiation of aqueous solutions of the hydrochlorides of 4-methyl-3-phenyl- and 3,4-diphenyl-sydnone imines with light from a mercury lamp for 20–40 h, the corresponding dicarbonyl compounds (LXIV) are formed in 8–9% yield[129]:

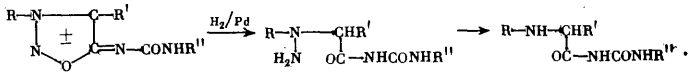


Morpholine, glycolic acid, and nitrogen were identified among the products of the photochemical decomposition of the hydrochloride of 3-morpholinosydnone imine[122]. After ultraviolet irradiation of $N_{(6)}$-acetyl-3,4-diphenylsydnone imine, it was possible to detect the mesoionic triazolone (LXV) among the decomposition products[130]:

(LXV)

Morpholine, chloroacetic acid, ethyl alcohol, and carbon dioxide were found among the products of the photolysis of $N_{(6)}$-ethoxycarbonyl-3-morpholinosydnone imine in 0.1 *N* HCl solution[122].

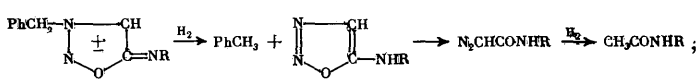
(d) Other ring cleavage reactions. The sydnone imine ring is opened also in catalytic hydrogenation. In an early study Brookes and Walker[7] observed that, when the hydrochlorides of 4-isopropyl-3-methyl- and 4-isobutyl-3-methylsydnone imines are reduced over a platinum catalyst, the corresponding aminoacetamides (LXVI) are formed and ammonia is evolved;



(LXVII) (LXVI) (LXVIII)

Since in the reduction of a sydnone imine salt over a palladium catalyst the first two moles of hydrogen are absorbed rapidly, the authors[9] suggested that a hydrazinoamide (LXVII) is formed initially and is then deaminated on further reduction to give (LXVI). They showed that, in the reaction of the hydrochloride of 3,4-diphenylsydnone imine (IIb), the formation of an amide of type (LXVI) is accompanied under these conditions by the formation of a product of further hydrogenation—*N*,*C*-diphenylethylenediamine.

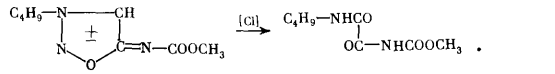
It was mentioned above that, when $N_{(6)}$-phenylcarbamoylsydnone imines are reduced with iron, ring cleavage is not observed[68], but hydrogenation over palladium black leads to ring opening in these compounds[52].



The main product of the reductive cleavage of $N_{(6)}$-carbamoylsydnone imines is the hydrazine derivative (LXIX):

(LXIX) (LXX)

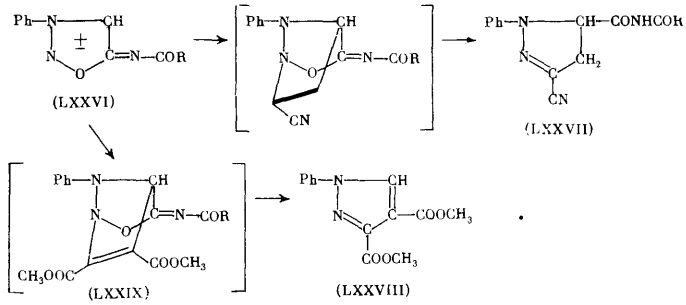
In an acid medium or on hydrogenation of the hydrochlorides of $N_{(6)}$-carbamoyl derivatives, the deamination product (LXX) is formed preferentially.



As in thermal cleavage, hydrogenolysis of sydnone imines with a benzyl substituent in the 3-position (LXXI) takes place differently. It has been shown[131] that under these conditions the primary step is debenzylation with successive formation of unstable oxadiazoles (LXXII) and acetyldiazoacetamides (LXXIII). The latter can be partly hydrogenated to the corresponding acetamides:

(LXXI) (LXXII) (LXXIII)

R = H · HCl, $COCH_3$ or CONHPh.



Yet another example of the oxidative cleavage of the sydnone imine ring has been described[116]. In contrast to sydnones, which are chlorinated fairly smoothly in the 4-position in the ring, when sydnone imine salts were acted upon by chlorine their decomposition was observed and the individual products could not be isolated. On treatment of $N_{(6)}$-methoxycarbonyl-3-butylsydnone imine (LXXIV) with chlorine in dichloroethane in the presence of sodium dicarbonate or with sulphuryl chloride in dichloroethane and subsequent treatment of the reaction mixture with water, the cleavage product was isolated to which the structure (LXXV) was attributed:

(LXXIV) (LXXV)

Like sydnones, $N_{(6)}$-acylsydnone imines enter into 1,3-dipolar addition reactions with unsaturated compounds[132]. Thus, when $N_{(6)}$-methoxycarbonyl- and $N_{(6)}$-benzoyl derivatives of 3-phenylsydnone imines (LXXXVI, a and b) are heated with an excess of acrylonitrile, the sydnone imine ring is opened with formation of a new ring (the pyrazoline ring). In contrast to sydnones, the ring oxygen and the exocyclic group are not then eliminated and the final reaction product is a derivative of 1-phenylpyrazoline-5-carboxylic acid (LXXVII, a and b), i.e. 1,3-addition with a subsequent rearrangement takes place.

On the other hand, the reaction with dimethyl acetylenedicarboxylate proceeds via a "sydnone" type mechanism[133]: on prolonged heating with $N_{(6)}$-benzoyl-3-phenylsydnone imine (LXXVIb), the main reaction products isolated were dimethyl 1-phenylpyrazole-3,4-dicarboxylate (LXXVIII) and dibenzoylurea:

(LXXVI) (LXXVII) (LXXIX) (LXXVIII)

The authors[133] suggest that the latter is formed as a result of the elimination of benzoyl isocyanate from the intermediate (LXXIX), analogous to the elimination of CO_2 when the similar reaction is carried out with sydnones.

3. Characteristics of the Reactivity of Sydnone Imines

It follows from the examination of the chemical behaviour of sydnone imines that these compounds exhibit a high and many-faceted reactivity due to a number of their structural features, primarily the unusual distribution of electron density in the unsaturated heterocyclic system, including the exocyclic group.

The relative reactivities of sydnone imines are on the whole consistent with the calculations of the distribution of electron density. The ease of their hydrolytic and thermal decomposition is consistent with the presence of a large positive charge on the $N_{(3)}$ atom in sydnone imine salts. The enhanced electron density at the exocyclic nitrogen atom in

$N_{(6)}$-acyl and $N_{(6)}$-carbamoyl derivatives is confirmed by the high basicity of these compounds. The excess electron density at the $C_{(4)}$ atom in $N_{(6)}$-acylsydnone imines determines the mode of the electrophilic substitution reaction. The large negative charge on the exocyclic nitrogen atom in the sydnone imine base is consistent with the ease of the electrophilic substitution at and addition to this atom. As already mentioned above, calculations indicate a fair agreement with the values of $E_{1/2}$ for the polarographic reduction of sydnone imines[81,86].

Quantitative analysis of the reactivity of sydnone imines with the aid of equations based on the principle of the linearity of free energies (LFE), namely in terms of the influence of substituents on the kinetics and equilibria in certain reactions, made it possible to deduce the properties of the sydnone imine ring as a transmitter of the electronic effects of both the reaction centre and the substituent[58,87,97,99,100].

Substituents in the 3-position exhibit an inductive effect in relation to reactions involving the exocyclic group and the influence of these substituents is correlated satisfactorily with the Taft inductive constants (σ^*) of non-aryl substituents and the σ^0 constants of aryl substituents.

In view of the identical order of magnitude of the constants σ^* and σ^0 ($\sigma^* = 0.600 + \sigma^0$), the data for 3-substituted derivatives can be combined into a single reaction series. Thus a single straight line has been obtained for the basicities of $N_{(6)}$-methoxycarbonyl-3(R)-sydnone imines[100]:

$$pK_a = 3.50 - 0.65\,\sigma^* \quad (r = 0.990),$$

and two virtually parallel straight lines have been obtained for the kinetics of the acid hydrolysis of the nitroso-group in $N_{(6)}$-nitroso-3(R)-sydnone imines[87,135]:

$$\lg k = -3.84 + 0.39\,\sigma^* \quad \text{(for non-aromatic R)},$$
$$\lg k = -4.06 + 0.39\,\sigma^* \quad \text{(for aromatic R)}.$$

The distance between these straight lines along the ordinate axis ($\psi = -0.22$) is determined by the non-polar conjugation of the exocyclic N=O group with the benzene ring in the 3-position; the calculated energy of this conjugation is low[87,135]: $E_\psi = 2.3RT\psi = 0.3$ kcal.

Reactions involving the exocyclic group are also satisfactorily correlated with the σ^0 constants of 4-aryl substituents, as shown in the conversion of $N_{(6)}$-nitroso-4-aryl-3-benzylsydnone imines into the corresponding sydnones ($\rho^0 = 0.18$) and in the acid hydrolysis ($\rho^0 = 0.24$) and polarographic reduction of the nitroso-group ($\rho^0 = 0.025$) in these compounds[87].

The sydnone imine ring is a reaction centre in polarographic reduction[90,93]; the correlation analysis of the half-wave potentials $E_{1/2}$ in accordance with the LFE principle has already been described. For the alkaline opening of the sydnone imine ring[82,97,100], which in this case also behaves as a reaction centre, the equilibrium constant for derivatives with non-aromatic substituents in the 3-position is described satisfactorily by the equation[99,100]

$$\lg K = -6.63 + 2.44\sigma^* + 0.46E_S^c, \qquad (1)$$

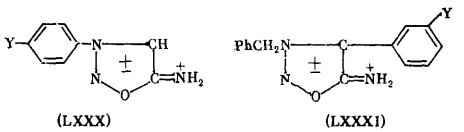
where E_S^c is the steric constant of the substituents. The steric hindrance in the ring opening reaction can apparently be accounted for by the "expansion" of the substituents at the $N_{(3)}$ atom on passing from the sp^2 hybridisation of this atom in the sydnone imine to the p^3 state in *N*-nitrosoaminoacetonitrile. The equilibrium constant for this reaction involving 3-(R)-aryl derivatives is described by the equation[27,99,100]

$$\lg K = -6.16 + 2.44\,\sigma^0. \qquad (2)$$

Comparison of Eqns.(1) and (2), taking into account the fact that $\sigma^* = 0.600 + \sigma^0$ and $E_S^c \cong 0.25$ for R = aryl, led to the calculation[99,100] of the effect of the non-polar conjugation of the benzene and sydnone imine rings ($\psi = -1.2$) and of the energy of this conjugation: $E_\psi = 1.6$ kcal. The energy of the non-polar conjugation with the sydnone imine ring for the phenyl substituent in the 4-position is[87] $E_\psi \cong -2.0$ kcal. These values of E_ψ are smaller by a factor of approximately four than the energy of the conjugation of the two benzene rings in biphenyl.

The following equations have been obtained for the kinetics of the alkaline ring opening (pH 8.75):

$$\lg k = -2.374 + 1.00\,\sigma^0 \quad (3(R) = Ar)^{27,100},$$
$$\lg k = -3.19 + 1.86\,\sigma^* \quad (3(R) = Alk)^{91}.$$



The absence of a steric effect in the latter case can serve as evidence in support of the view that the activated complex in this reaction has a geometry closer to that of the initial sydnone imine than that of *N*-nitrosoaminoacetonitrile[97]. On the other hand, as stated above, a considerqble "steric acceleration" effect was observed in the acid cyclisation reaction[51].

The rate-limiting stage in the thermal cleavage of the hydrochlorides of 3-alkyl- and 3-aryl-sydnone imines (except 3-benzylsydnone imine) involves the interaction of the chloride ion with the $C_{(4)}$ atom and subsequent rupture of the $N_{(3)}-C_{(4)}$ bond. The substituent at $N_{(3)}$ is in the *ortho*-position with respect to the ring $C_{(4)}$ atom and therefore exhibits a considerable steric as well as electronic effect[127]:

$$\lg k = -3.21 + 0.90\sigma^* + 1.00E_S^c \text{ (DMF, 89°)}.$$

The retardation of the reaction as the bulk of the substituent increases and its electron-donating capacity is diminished supports an S_N2 mechanism for this reaction, since a steric acceleration of the reaction might have been expected for an S_N1 mechanism[127].

The Hammett constants σ for the sydnone imine ring have been calculated from the half-wave potentials $E_{1/2}$ for the polarographic reduction of the Y group in compounds of the type (LXXX) and (LXXXI):[98]

(LXXX) (LXXXI)

The results are presented below; the σ constants of the sydnone ring and of the *N*-nitrosoaminoacetonitrile group, from which sydnone imine groups are synthesised, are included for comparison:

Substituent	σ
p-(3-sydnone iminyl)	+1.1
m-(3-benzyl-4-sydnone iminyl)	+0.40
p-[N(N=O)CH$_2$CN]	+0.5
p-(3-sydnonyl)	+1.0
p-(3-benzyl-4-sydnonyl)	+0.3

The values of σ indicate strong electron-accepting properties of the 3-sydnone iminyl substituent; the addition of a heterocycle to the 4-position entails an appreciable weakening of these properties. Sydnones and sydnone imine cations proved to have similiar σ constants, while the opening of the sydnone imine ring leads to a decrease of the electronegativity by a factor greater than two.

V. BIOLOGICAL PROPERTIES OF SYDNONE IMINES

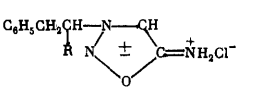
Like sydnones, sydnone imines are not found in nature and have no analogues among the known natural and synthetic biologically active substances. However, the high and varied reactivity of sydnone imines as well as the possibility of converting them under mild conditions into *N*-nitroso-compounds and aminoacid derivatives led investigators to study their biological activity. Data have now been obtained on the antibacterial, antitumour, pharmacological, and biological activities of a number of sydnone imine derivatives[88,135]. By analogy with sulphonamide preparations, incorporating a five-membered nitrogen-containing heterocycle with an exocyclic amino-group (ethazole, norsulphazole, etc.), a study was made of the antimicrobial activity of $N_{(6)}$-*p*-aminobenzenesulphonyl derivatives of sydnone imines (XIX, $R'' = NH_2$).[10,72] However, like the hydrochlorides of 4-alkyl-3-methylsydnone imines[7], these compounds proved to be relatively inactive in relation to various experimental infections. Among 3-piperonylsydnone imines, substances with antimalarial activity were discovered[26].

The antiblastic activity of a number of mono- and bis-sydnone imines has been investigated on small laboratory animals[8,136]. Among the lower alkyl derivatives, compounds with antitumour activity were not discovered[8]. On the other hand, it has been shown that[136] 3-isopropyl-, 3-cyclohexyl-, 3-piperidinylethyl-, and a number of alkylene-bis-sydnone imines are able to inhibit at least one of the five grafted tumours employed. The dichloride of ethylenebis-3,3'-sydnone imine [V, $Z = (CH_2)_2$] and its $N_{(6)}$-bismethoxycarbonyl derivative proved to be the most active in relation to sarcoma 45 and M-1 in rats and sarcoma 180 in mice. In one of the experiments 80% inhibition of the growth of sarcoma 45 was noted. It has been observed that in the general case the salt form of sydnone imines has a favourable influence on the antiblastic activity and that, with increase of the length of the hydrocarbon chain in polymethylenebis-3-sydnone imines, the antiblastic activity falls. It has been suggested that the antitumour activity of sydnone imines is associated with their conversion into *N*-nitrosoaminoacid derivatives, some of which have an inhibiting effect on tumour growth.

Interesting results have been obtained in the study of the pharmacological activity of sydnone imine derivatives. As a result of extensive research by Soviet and Japanese scientists, substances which have found applications as medicinal drugs have been found among compounds of this series. It has been discovered that many salts of 3-aryl-,[9] 3-benzyl-,[16] and 3-ethoxycarbonylmethyl-sydnone imines[17] as well as their $N_{(6)}$-acyl[53-55,57] and $N_{(6)}$-carbamoyl[53-55,58,64,65,74,112] derivatives exhibit analgesic and antipyretic activities. Together with the analgesic and antipyretic activities, certain hydrochlorides of 3-arylsydnone imines show an anti-inflammatory action[17,64,65,74,112]. It has been stated[53-55] that certain 3-aryl- and 3-benzyl-sydnone imines can be used in the treatment of rheumatism.

It has been found[137] that, among the series of sydnone imine salts with hydrocarbon substituents investigated, only the 3,4-diaryl derivative shows a spasmolytic activity. An analogous activity is also exhibited by certain 3-amino-sydnone imines[45].

Pharmacological studies have shown that many sydnone imine salts and their exocyclic derivatives exhibit a hypotensive activity. A fairly prolonged effect has been observed for compounds containing the benzyl group in the 3-position[16]. In experiments on cats the hydrochloride of 3-phenoxyethyl-sydnone imine reduced the arterial pressure by 30–50 mm for 1–2 h.[13] The hydrochlorides of 3-cyclobutyl- and 3-cyclopentyl-sydnone imines have been patented as vasodilators[49]. Sydnone imine salts containing 4-benzyl, 4-*o*-methoxyphenyl-, 4-piperonyl-, and 4-α-pyridylpiperazinoalkyl substituents in the 3-position show antianginal and hypotensive activities.



However the hypotensive activity is exhibited most strikingly by 3-amino-derivatives[138]. In small doses, the hydrochlorides of 3-dimethylamino-,[37,38,44] 3-dibutylamino-,[37,45] 3-piperidino-,[37,38,43,45] 3-(α-pipecolinyl)-,[38,43,45] 3-pyrrolidino-,[37,38,43,45] 3-morpholino-,[37,38,43,45,118,139,140] and 3-(4'-methylpiperazino)-sydnone imines[38,45] reduce blood pressure for a long time.

The salts of 3-aminosydnone imines containing in the 4-position chlorine or bromine atoms[41,42,45] or alkyl substituents[43] as well as the dihydrochloride of 3,3'-(1'',4''-piperazino)bis-sydnone imine[37,38,45] have a dilating effect on the coronary artery. The $N_{(6)}$-acyl derivatives of 3-aminosydnone imines containing the benzoyl[44,61], cyclohexanecarbonyl[44,115], and ethoxycarbonyl[62,63] residues at the exocyclic nitrogen atom proved to be still more effective.

From compounds of this type, Japanese investigators selected one substance—$N_{(6)}$-ethoxycarbonyl-3-morpholinosydnone imine—which was subjected to an extensive pharmacological study[141-143]. Under the names SIN-10, morsydomine, or morial[144], this sydnone imine has found application as a hypotensive drug. The use of a specimen labelled at the $C_{(5)}$ atom[145] made it possible to investigate in detail the pharmacokinetics and metabolism of this preparation[146]. It has been suggested[143] that the mechanism of its hypotensive action based on its ability to block α-adrenergic receptors.

In the series of sydnone imines substances acting on the central and peripheral nervous systems have been discovered: these are the salts of certain 3-aminosydnone imines[39] and their $N_{(6)}$-acyl derivatives[60] as well as various 3-phenylalkylsydnone imines[12,13,21,147]. It has been shown that the salts of a number of sydnone imines exhibit an adrenopositive peripheral activity and exert a stimulating influence on the central nervous system[12,147]. The inhibiting effect of these compounds on the enzyme monoamine oxidase has been studied in detail[12,33,147]. It has been shown the sydnone imine salts inhibit the oxidative deamination of a number of biogenic amines and that the majority of the compounds cause reversible competitive inhibition of enzymes. Among a whole series of the sydnone imine salts investigated with different substituents in the 3- and 4-positions, the most effective inhibitors in relation to tyramine and serotonine as substrates *in vitro* proved to be the hydrochlorides of 3-phenylethylsydnone imine (LXXXII) and 3-phenylisopropylsydnone imine (LXXXIII), whose activity [$I_{50} = (1.8–6.6) \times 10^{-5}$ M] is comparable to that of iproniazid. An increase of the bulk of the group in the 3-position [$(C_6H_5)_2CHCH_2$ and $(C_6H_5CH_2)_2CH$] and the replacement of hydrogen in the 4-position by the CH_3 or C_6H_5 group lowers the inhibiting effect[12,148].

The hydrochloride of 3-phenylisopropylsydnone imine showed a high activity also in *in vivo* experiments on rats and it was demonstrated that the inhibiting effect is exhibited by the sydnone imine itself and not by products of its metabolism:

(LXXXII), R = H
(LXXXIII), R = CH_3

The results of biochemical studies permitted a specific investigation of the pharmacological activities of the compounds which enhance the activity of biogenic amines[12,147]. It was found that the intensity of pharmacological effects in this series of compounds is more notable the higher the ability of the sydnone imine salts to inhibit the oxidation of biogenic imines, which serve in the organism as chemical mediators in nervous excitation.

Among alkyl- and aryl-sydnone imines, substances were discovered which influence the central nervous system and exhibit a peripheral sympathomimetic activity[147-149]. They diminish somewhat the sedative and hypothermal activity of reserpine, enhance the convulsant effect of tryptamine and 5-hydroxytryptophan, and intensify the motor activity of animals. Among them, the highest pharmacological activity was shown by the hydrochloride of 3-phenylisopropylsydnone imine (LXXXIII), which under the name sydnophen has found applications in psychiatric practice as a medicinal drug acting both as a psychostimulator and antidepressant[22,23,24,150-153].

An interesting pharmacological activity is manifested by $N_{(6)}$-phenylcarbamoyl-3-phenylazopropylsydnone imine (XLIII), which is an effective psychostimulator. In experiments on animals this compound increases motor activity, shortens the latent period in conditioned reflexes, has an activating effect on the bioelectric processes in the cortex and subcortical structures of the brain, weakens the effect of hypnotic substances, and increases the body temperature. This relatively non-toxic substances has found applications as a medicinal drug (under the name sydnocarb) stimulating the central nervous system in the treatment of various mental illnesses and in other cases, and it has many advantages over other preparations with similar activities[67,154-160]. A similar study of the pharmacokinetics of sydnocarb by chromatographic[161] and polarographic[101] methods and a procedure using synthetic [^{14}C]sydnocarb specimens labelled in different sites within the molecule[162] made it possible to establish clearly the characteristics of the action of this preparation, its metabolism, its distribution in the organism[163], and its elimination from the latter.

During the preparation of the manuscript for the press, several reports on the chemistry of sydnone imines were published. It has been shown[163] that the sydnone imine ring can be formed not only under the conditions of acid catalysis but also under the conditions of base catalysis; the intermediate cyclisation product, formerly regarded as the hypothetical base of the sydnone imine (XIII), has been detected spectroscopically.

Infrared spectroscopic data have led to the conclusion that the side chain in $N_{(6)}$-carbamoylsydnone imines has a planar structure and an inference has been drawn about its conformation[164]. A number of $N_{(6)}$-aminoalkylacyl derivatives of sydnone imines have been synthesised by the method of polymeric activated esters[165].

Phosphinates ("Hypophosphites") and Their Reactivity

V.I.Yudelevich, L.B.Sokolov, and B.I.Ionin

Results are given on the preparation, structure, and physicochemical properties of phosphinates, and their reactivity is discussed. A list of 234 references is included.

CONTENTS

I. Introduction 46
II. Structure, physicochemical properties, and methods of preparation 46
III. Chemical properties 49

I. INTRODUCTION

Simple compounds containing an active phosphorus–hydrogen bond can be used in general methods for preparing phosphines and phosphonic acids, phosphonous acids, and their derivatives. Various homolytic and heterolytic reactions yielding compounds containing a phosphorus–carbon bond have been applied to various phosphines, as well as phosphonic and phosphinic acids, derivatives, and analogues. However, the chemistry of phosphinates and their reactivity have hitherto been little studied, although research in this field was begun as early as the end of the nineteenth century[1] and various lines have been actively followed up to the present time. Esters[2] and organic ammonium salts[3,4] of phosphinic acid containing a four-coordinated phosphorus atom (phosphinates) are known already. A novel group of compounds having a three-coordinated phosphorus atom—full esters (dialkoxyphosphines)[5-7], diamides[8], and amidoesters[9] of phosphonous acid—have been obtained recently.

Table 1. Change in ^{31}P chemical shifts on the protonation of phosphoryl compounds[37].

Phosphoryl compound	Chemical shift, ppm	Phosphoryl compound	Chemical shift, ppm
Phosphinic acid	-24.0	Methylphosphonic acid	-15.0
Phosphonic acid	-13.6	Phosphonates and phosphonamides	-8.0--12.0
Phosphoric acid	-2.3	Trialkyl phosphates	0

However, only phosphinates have yet found extensive practical application, not only as initial reactants for the preparation of various organophosphorus compounds but also as reductants in the protective coating of metals[10-12], in analytical chemistry[13,14], in the chemical modification of antibiotics[15,16], as inhibitors of certain enzymes[17], and in other most diverse applications. Practical interest attaches also to many compounds obtainable from phosphinates: they possess biological activity[18-20], are surface-active agents, antioxidants, and flotation agents[21], find application in photography for the preparation of developers that do not darken with time[22], and enter into the composition of fluxes for low-temperature soldering[23].

The present Review discusses methods of preparation and the physicochemical and chemical properties of phosphinates. A considerable number of interesting papers of fundamental character have appeared in this field during recent years. However, among the reviews that have appeared[24-28] only three early publications—a short chapter in van Wazer's monograph[26] and Frank's[24] and Kosolapoff's[25] general surveys of the chemistry of organophosphorus compounds—devote an extremely modest space to the reactions of phosphinates. The present paper makes an attempt to fill in some measure the gap existing in the review literature on the chemistry and the reactivity of phosphinates.

II. STRUCTURE, PHYSICOCHEMICAL PROPERTIES, AND METHODS OF PREPARATION

1. Structure, Physicochemical Properties, and Method of Preparation of Phosphinic Acid and its Inorganic Salts

Phosphinic ("hypophosphorous") acid was first obtained in 1816 by Dulong[29], who identified it as containing a minimal number of oxygen atoms (two). This acid, in which phosphorus is in a lower oxidation state (+1) than in its other acids[30], corresponds to the formula H_3PO_2.

Physicochemical data indicate that the two hydrogen atoms are covalently bound to the phosphorus. Thus the phosphorus-31 nuclear magnetic resonance spectrum of aqueous phosphinic acid is a triplet having intensities 1:2:1, with a chemical shift of -13.0 ppm.[31-35]. The ^1H n.m.r. spectrum of the protons attached to phosphorus is a doublet: the chemical shift is 7.14 ppm, and the spin–spin coupling constant $J_{HP} = 566$ Hz (solution in perdeuteroacetone)[36]. Protonation of phosphinic acid is accompanied by an appreciable change in the phosphorus-31 chemical shift (Table 1).[37]

The vibrational infrared and Raman spectra of the free acid and its salts indicate four-coordinated phosphorus[38-40]. Comparison of experimental spectra with parameters of a calculated vibrational model showed that the phosphinate ion corresponds to a model with equalised phosphorus–oxygen bonds[40]. The phosphorus–hydrogen frequencies correspond to vibrations of the phosphino-group of characteristic frequency and form. Detailed study of the infrared spectra of phosphinic acid and several of its inorganic salts[41,42] also showed appreciable lowering of phosphorus–hydrogen stretching frequencies on passing from the acid to its inorganic salts (Table 2).

Results of X-ray structural investigations correlate with the spectroscopic data. The former indicate[43,44] that the $H_2PO_2^-$ ion is a tetrahedron having C_{2v} symmetry: one axis passes through a phosphorus–hydrogen bond, and another

through a phosphorus–oxygen bond. Comparison of interatomic distances and bond angles in ions of the free acid and of ammonium phosphinate shows (Table 3) that the state of the bonds with oxygen atoms remains unchanged within the limits of error in the measurements, whereas the phosphorus–hydrogen bonds, which determine the reactivity of phosphinates, are appreciably longer in the ammonium salt, with a smaller angle between the bonds. This indicates a diminution in the polarity of the phosphorus–hydrogen bond. Hence not only ammonium phosphinate but also other salts of phosphinic acid should be less reactive than the acid itself in heterolytic reactions.

Table 2. Infrared spectral data on phosphinic acid and its inorganic salts[41].

Compounds	ν_{P-H}, cm^{-1}	ν_{PO_2}, cm^{-1}

Considerable difficulties arise in obtaining pure phosphinic acid[45]; among numerous methods of preparation described in reviews[26–28] only a few, giving good yields of the pure acid, are of interest. Hitherto a method of practical value has involved treating white phosphorus with a boiling lime slurry[46] and other alkali[47]. Pure phosphinic acid can be obtained by oxidising phosphine in an aqueous suspension of iodine[48]: phosphine obtained from calcium phosphide and dilute hydrochloric acid is passed into the stirred suspension of iodine in a flask until the solution becomes colourless; hydrogen iodide and water are removed under reduced pressure (40 mmHg), after which pure phosphinic acid remains. The safest laboratory method for obtaining the acid involves passing an aqueous solution of an alkali-metal phosphinate through an ion-exchange resin, then concentrating the acid on a water-bath, and drying over phosphorus pentoxide in a high vacuum[49].

It was suggested[50] that chemically pure phosphinic acid could be isolated in crystalline form by continous extraction with diethyl ether. Quite recently three methods have been described for obtaining the crystalline acid from accessible inorganic salts[36]. Double decomposition between barium phosphinate and sulphuric acid followed by removal of water by low-temperature high-vacuum sublimation (lyophilic drying) gives a product which retains its physicochemical characteristics when kept in hermetically sealed vessels for a long time. However, prolonged storage of the contaminated liquid acid is not possible even when all precautionary measures are taken (cold, hermetic sealing, storage in an atmosphere of an inert gas).[51]

Decomposition of impure phosphinic acid by disproportionation can take place in the absence of air:

$$2H_3PO_2 \rightarrow H_3PO_4 + PH_3 .$$

In the presence of water hydrogen is evolved:

$$H_3PO_2 + H_2O \rightarrow H_3PO_3 + H_2\uparrow .$$

At elevated temperatures decomposition is more fundamental in character, with the formation of red or yellow phosphorus[45]. The instability of phosphinic acid in air is attributed to its strong reducing properties, which are used both in organic synthesis, e.g. for the reduction of acids[52], and in industry—to obtain chemical protective coatings (nickel and chromium plating) of better quality than electroplating[53,54].

Pure phosphinic acid comprises white crystals in the form of lobes, melting at 26.5 °C. It is a strong monobasic acid (pK 1.1).[55] Its monobasicity indicates that phosphorus has coordination number 4 in this structure. Phosphinates of alkali and alkaline-earth metals are obtained both by trivial processes (double decomposition)[45,56] and by specific methods involving change in the coordination of the phosphorus atoms[57–60].

Phosphinates are produced industrially by the action of hydroxides of alkali and alkaline-earth metals on white phosphorus: e.g.

$$8P + 3Ca(OH)_2 + 6H_2O \rightarrow 3Ca(H_2PO_2)_2 + 2PH_3$$
$$Ca(H_2PO_2)_2 + Na_2CO_3 \rightarrow 2NaH_2PO_2 + CaCO_3 .$$

Phosphinates of rare-earth metals $M_n(H_2PO_2)_3$ have been prepared in which M = Sc, Y, La, as well as double phosphinates $CeM'(H_2PO_2)_6$ with M' = Er, Tm, Yb, Lu.[61–65] Their physicochemical characteristics have been studied[66].

2. Structure, Physicochemical Properties, and Methods of Preparation of Organic Derivatives of Phosphinic Acid

Organic derivatives of phosphinic acid were first obtained in 1948[3]. Very little is known about the organic salts[3,4,67,68] (Table 4), only two of which have been isolated in pure form

and characterised[3]. Dialkylmetal salts of general formula $(CH_3)_2MPH_2O_2$ (where M = Al, Ga, In) have been reported comparatively recently[69].

Many attempts to obtain phosphinic esters have proved unsuccessful[70-72]. In 1960 Kabachnik et al.[2] were the first to accomplish the direct esterification of phosphinic acid with diazoalkanes to obtain monoalkyl phosphinates (Table 5):

$$RCHN_2 + HOP(O)H_2 \rightarrow ROP(O)H_2 + N_2.$$

This reaction confirms the suggestion that the acid is monobasic. Later several alkyl phosphinates were prepared from phosphinic acid and orthocarbonyl compounds (acetals)[73]. This is less important than the previous method for preparative purposes, since it yields a difficultly separable mixture of compounds formed by interaction between the esters and carbonyl by products:

$$(RO)_2CR'R'' + HOP(O)H_2 \rightarrow ROP(O)H_2 + O{=}CR'R'' + ROH$$
$$ROP(O)H_2 + O{=}CR'R'' \rightarrow ROP(O)\underset{H}{\underset{|}{CR'R''}}\underset{OH}{\underset{|}{}}$$

Table 5. Esters of phosphinic acid*.

* Table 5 omits several phosphinic esters for which constants have not been given—6-hydroxyhexyl phosphinate[87], poly(allyl phosphinate)[87], and cellulose phosphinate[79].

** Temperature of bath.

Nifant'ev et al. proposed a simpler and more convenient method for obtaining alkyl phosphinates[74-76]:

$$HOP(O)H_2 + ROH \xrightarrow{-H_2O} ROP(O)H_2 .$$

The reaction is accomplished by azeotropic distillation of water using a Dean and Stark trap. It can be conducted either in the absence or in the presence of a catalyst such as zinc chloride, aluminium chloride, sodium acetate, etc.; excess of one of the reactants is used to accelerate the reaction. Several lower alkyl phosphinates are very unstable when purified by vacuum distillation. If the products are contaminated with the alcohol or phosphinic acid, however, they can be stored and are convenient for use. Many alkyl phosphinates have been obtained by this method[77] (Table 5); the products were freed from unchanged acid and excess of the alcohol by vacuum treatment in molecular distillation apparatus. However, after many redistillations they could not be isolated in analytically pure form.

An interesting process for obtaining phosphinic esters consists[78] in the hydrolysis of dialkoxyphosphines. Fundamentally novel alkyl phosphinates—alkyl phosphinothionates $ROPH_2S$ (Table 5)—have been obtained by essentially the same method, by oxidising dialkoxyphosphines with hydrogen sulphide:

$$(RO)_2PH \xrightarrow{+H_2S} ROP(S)H_2 .$$

Not only monohydric alcohols but also glycols react readily[5] with phosphinic acid, to form hydroxyalkyl phosphinates and alkylene bisphosphinates:

$$HOROH + HOP(O)H_2 \begin{cases} \xrightarrow{1:1} HOROP(O)H_2 \\ \xrightarrow{1:2} H_2(O)POROP(O)H_2 \end{cases} .$$

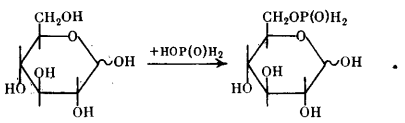
Alkylene bisphosphinates, like esters of phosphinic acid with monohydric alcohols, are unstable in pure form. In contrast, hydroxyalkyl phosphinates are stable on storage, probably as a consequence of their specific structure[5].

Phosphinic esters are formed also by the phosphorylation of certain high-molecular polyhydroxy-compounds, peptides, and monosaccharides[79-84]. The action of phosphinic acid on cellulose yields phosphinates[80] containing up to 14% of phosphorus:

$$Cell\text{-}OH + H_3PO_2 \xrightarrow{-H_2O} Cell\text{-}O\text{-}P(O)H_2 .$$

The degree of esterification of the cellulose increased steadily with rise in temperature from 80 to 120 °C. With further rise in temperature (under otherwise similar conditions), however, the phosphorus content of the reaction product diminished. This was attributed[80] to partial decomposition of phosphinic acid above 120 °C, to give phosphine, removed from the sphere of reaction[85], and phosphonic acid, which is also an esterifying reagent[86-88]:

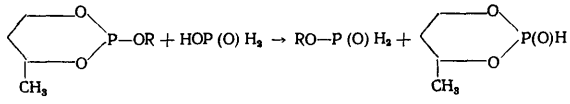
$$3H_3PO_2 \xrightarrow{>120°} PH_3 + 2H_3PO_3 .$$



The phosphorylation of cellulose with ammonium phosphinate[79,80] showed the latter to be a more active esterifying agent than in phosphinic acid. However, the reaction products contain not only chemically bound phosphorus but also a greater or smaller quantity of nitrogen.

Research on the phosphorylation of polyols was continued with the acylation of polyvinyl alcohol by phosphinic acid[82,83]:

$$-CH_2-\underset{\displaystyle OH}{\underset{|}{CH}}- + H_3PO_2 \rightarrow -CH_2-\underset{\displaystyle O-P(O)H_2}{\underset{|}{CH}}- .$$



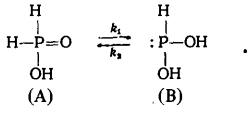
The resulting high-molecular polyphosphinate was quite stable in comparison with the unstable lower alkyl phosphinates, which break down into the initial reactants.

Study of the acylation of phosphinic acid of polyallyl alcohol and its low-molecular analogues (isobutyl alcohol and hexamethylene glycol)[84] has received a second-order reaction. Monosaccharides—glucose[76] and xylitol[81]—also react with phosphinic acid:

With xylitol the process is complicated: the formation phosphorylation products is accompanied by partial dehydration of the xylitol.

The above method of preparing phosphinic esters, though simple and convenient, is unsuitable for obtaining the simplest alkyl phosphinates. Great practical interest attaches to the dealkylation of cyclic full esters of phosphorus acid with phosphinic acid, by a modification of the Arbuzov reaction[89]:

This method gives a somewhat higher yield of ethyl phosphinate than does the process suggested by Fitch[73] (Table 5). The lower phosphinates obtained are very unstable, and can be stored only in an inert gas at temperatures below 0 °C: in air they ignite. Paper chromatography and ^{31}P n.m.r.spectra have established that the products contain the corresponding dialkyl phosphites, whose quantity increases during storage. Formation of the latter is due to disproportionation of the alkyl phosphinates, which gives also phosphine:

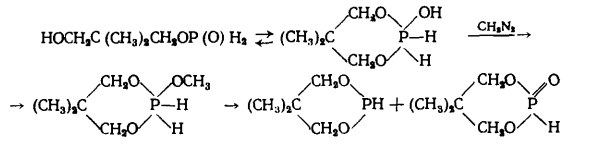


$$2RO{-}P(O)H_2 \rightarrow PH_3 + (RO)_2P(O)H_2 .$$

Organosilicon esters of phosphinic acid—trialkylsilyl phosphinates—have recently been obtained[90] by the alcoholysis of bistrialkylsilyl phosphonites:

$$(R_3SiO)_2PH + C_2H_5OH \rightarrow R_3SiOP(O)H_2 + R_3SiOC_2H_5 .$$

3. Tautomerism of Phosphinates



Although all the inorganic and organic phosphinates mentioned in the preceding subsections indicate that phosphinic acid is monobasic, many investigations show the occurrence of tautomerism:

Kinetic examination of the oxidation of phosphinic acid showed[91-100] that the active form is present in extraordinarily small quantities, only one-billionth (10^{-12}) part of $(HO)_2PH$ in $HOPH_2O$. As van Wazer[26] maintains, the rate-determining stage in the oxidation of phosphinic acid in acid medium by various reagents[101-105] in moderate or considerable concentrations is probably conversion of the "passive" form (A) into the "active" form (B). The rate is essentially unaffected by the nature or the concentration of the oxidant, but increases with increase in acidity. Other kinetic investigations—study of hydrogen[106,107] and oxygen[108] isotope exchange and also of the reaction mechanism[109]—confirm the tautomerism of phosphinic acid. A monograph[110] also regards the acid as tautomeric: the negative results of attempts to detect the "active" form $(HO)_2PH$ in certain spectroscopic investigations[111] are attributed to its low content in the equilibrium mixture.

The tautomerism of phosphinic acid and several other acids of phosphorus[112-114] provides an explanation of their nucleophilic reactions. The rate of conversion of "passive" into "active" form is small, so that it was difficult to count on obtaining from ordinary phosphinic acid (with the object of a final proof of tautomerism) esters of its "active" form, i.e. dialkoxyphosphines. Attempts to obtain dichlorophosphine $PHCl_2$—the initial acid chloride for the synthesis of dialkoxyphosphines—were also unsuccessful[115].

In 1969, however, appeared the first paper[5] on the preparation of a member of this class of compounds—2,2-dimethyltrimethylene phosphonite—from the phosphinic monester—3-hydroxy-2,2-dimethylpropyl phosphinate:

This was followed by the publication of several fundamental researches on this problem[6,8,9,78,116-119]. Lutsenko et al.[6] suggest obtaining dialkoxyphosphines by the reduction of dialkyl phosphorochloridites with di- and tri-alkylstannanes:

$$(RO)_2PCl + R_3SnH \rightarrow (RO)_2PH + R_3SnCl .$$

Bistrialkylsilyl phosphonites have been prepared[7,120] from ammonium phosphinate and trialkylsilylamines:

$$NH_4OP(O)H_2 + 2R_3SiNR_2 \rightarrow (R_3SiO)_2PH + NH_3 + 2HNR_2$$
$$NH_4OP(O)H_2 + (R_3Si)_2NH \rightarrow (R_3SiO)_2PH + 2NH_3 .$$

Reaction with trialkylchlorosilanes in the presence of a secondary or tertiary amine B gives the same products[121]:

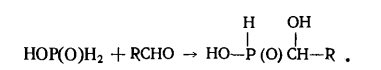
$$NH_4OP(O)H_2 + 2R_3SiCl + : B \rightarrow (R_3SiO)_2PH + NH_4Cl + : B \cdot HCl .$$

The yield reaches 35–45%. High yields (80–90%) are obtained by another method[121], based on the reaction of phosphinic acid with *NN*-dialkyltrialkylsilylamines:

$$HOP(O)H_2 + 2R_3SiNR_2 \rightarrow (R_3SiO)_2PH + 2HNR_2 .$$

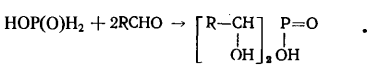
The formation of dialkoxyphosphines, together with the kinetic results, enables us to postulate the existence of an "active" form of phosphinic acid as the principal motive force of the nuclephilic reactions, which will be discussed in Section III.

The tautomerism of organic salts of phosphinic acid has not been studied, although its presence is suggested by studies of chemical properties.



III. CHEMICAL PROPERTIES

Study of the reactivity of phosphinic acid and its inorganic salts had already begun by the end of the past century. The preparation of organic phosphinates (esters and organic salts) during recent years has given a fresh impetus to the intensive study of various reactions involving phosphinates. The present Section is devoted to a comparative analysis of the reactivity of phosphinic acid, its salts, and its esters.

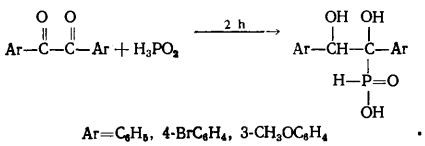


1. Reactions with Aldehydes and Ketones

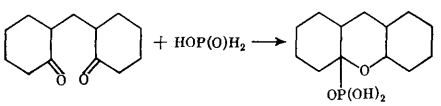
Most reactions of phosphinates with aldehydes (ketones)* lead to the formation of phosphinic acids. The addition of phosphinic acid to aromatic, aliphatic, and unsaturated aldehydes (ketones) was first accomplished during 1888–1904 by Ville and by Marie[1,122,123,24-26]. Since then the reactions have aroused theoretical interest[109,124-126], and the possibility of practical utilisation of the adducts has emerged[127-131].

Depending on the molar proportions of phosphinic acid and aldehyde or ketone two series of derivatives may be formed[15, 124, 132–147]. Equivalent proportions give 1-hydroxyalky (or aryl) phosphinic acids:

When excess of the carbonyl compound is present, a second molecule of the latter is added:

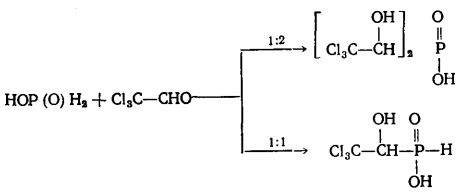


Reaction between phosphinic acid and aldehydes or ketones takes place with some difficulty, requiring heating for many hours. With benzaldehyde, for example, reaction occurs at 60–108 °C:[109]

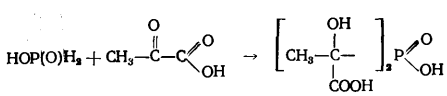


Since the equilibrium is shifted towards the initial reactants in such reactions[47], and also because of the tendency of phosphinic acid to undergo disproportionation on prolonged heating, the yields are low.

Phosphinic acid reacts considerably more rapidly with 1,2-diketones, and as a consequence the yields of condensation products—1,2-diaryl-1,2-dihydroxyethylphosphinic acids—reach 70–80%:[140]



Ar=C_6H_5, 4-BrC_6H_4, 3-$CH_3OC_6H_4$



The readier addition of ketones in this case is due to the presence of two neighbouring electron-accepting (carbonyl) groups, which promote the nucleophilic addition of reactants containing phosphorus–hydrogen bonds. The action of phosphinic acid on the 1,5-diketone, methylene-2,2′-bis-cyclohexanone, is unusual[147] in that heating in acetic acid gives a 50% yield of a product regarded as a phosphonate:

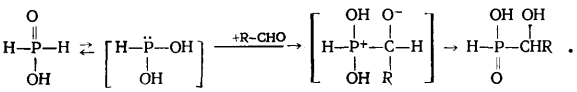
Compounds containing a polarised group react considerably more readily, i.e. at lower temperatures and with high yields. The action of anhydrous phosphinic acid on chloral in an inert solvent gives a mixture of di- and mono-substituted phosphinic acids in yields of 80% and 65% respectively[137,138]:

Pyruvic acid reacts after 2 h, to give a 46% yield of di-(1-carboxy-1-hydroxyethyl)phosphinic acid[141]:

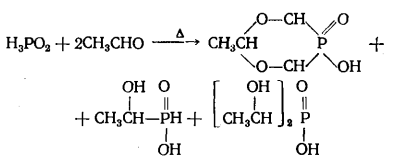
A substituted phosphinic acid is obtained also with dichloroacetaldehyde, but a period of 18 h is required and the yield is much lower (21%):[136]

Thus reaction is hindered with less strongly electrophilic reagents (dichloroacetaldehyde), in contrast to chloral: prolonged heating is necessary, and a lower yield of the desired product is obtained.

The reaction mechanism of the condensations has been studied with the action of phosphinic acid on formaldehyde and on benzaldehyde as examples[109]. These reactions are catalysed by hydrochloric acid, but their rate is independent of the hydrogen-ion concentration. They are first order with respect to the carbonyl component and to phosphinic acid in its undissociated form.



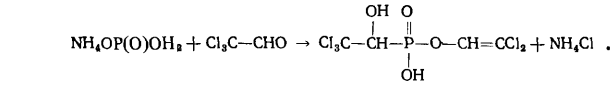
According to Kirby[110] tautomeric conversion in compounds containing a phosphinylidene group under conditions of acid catalysis corresponds to a two-stage process:



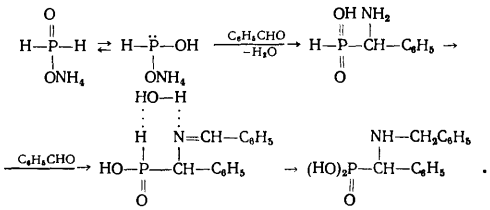
Such catalysts can apparently activate not only the phosphorus component but also the carbonyl reagent:

In view of recent studies on the mechanism of tautomeric transition of certain phosphinates into the active state with a lone pair of electrons on the phosphorus atom, and all the above considerations in relation to this problem, the addition of phosphinic acid to aldehydes can be represented by the scheme

In the cases of acetaldehyde and paraldehyde the usual adducts with phosphinic acid are accompanied by aldol condensation products, and the presence of at least two stereoisomers of the six-membered rings is postulated[125]:



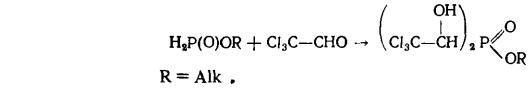
The reactivity of salts of phosphinic acid towards aldehydes has been little studied. Replacement of the acid by its potassium salt on reaction with chloral in hydrochloric acid enables the expected condensation product to be obtained[139], but the process is very slow, requiring several weeks, and gives a low yield (29%) apparently because of mutual insolubility:



Reaction between salts of phosphinic acid and carbonyl compounds can be conducted successfully only at higher temperatures than those for the acid itself, and for a prolonged time, though in many cases the yield is high. This supports the view that the salts are more stable than phosphinic acid. Thus good yield (respectively 71% and 93%) are

obtained in the action of sodium phosphinate on 1,2,5,6-tetrahydrobenzaldehyde[135] and on paraform[148].

Unexpected results were obtained by Taube et al.[4,149], who used the little studied ammonium phosphinate as phosphorylating agent. Thus condensation of the latter with chloral gave not the expected substituted ammonium phosphinate, whatever the proportions of the reactants, but 2,2-dichlorovinyl hydrogen 2,2,2-trichloro-1-hydroxyethylphosphonate[149]:

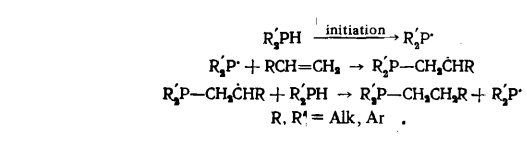


α-Benzylaminobenzylphosphonic acid was obtained by the reaction between ammonium phosphinate and benzaldehyde[4]:

The formation in the latter reaction of a phosphonic acid instead of the expected α-aminobenzylphosphinic acid is attributed to an intramolecular redox process.

The use of phosphinic esters in such reactions is of undoubted theoretical interest. It will permit comparison of the effect of replacing the acidic hydrogen by an alkyl radical: increasing the acidity of the phosphorus–hydrogen bond should favour nucleophilic addition. Indeed, the reaction of phosphinic esters with several carbonyl compounds (e.g. chloral) is exothermic and considerably more rapid than in the case of phosphinic acid[150]:

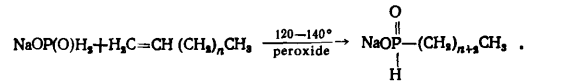
R = Alk .



Thus the results reported in this subsection suggest the sequence of phosphinates

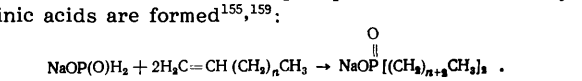
$$ROP(O)H_2 > HOP(O)H_2 > MOP(O)H_2,$$
R = Alk; M = Metal or NH_4

of diminishing reactivity in nucleophilic addition (to aldehydes and ketones).

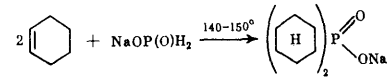


2. Reactions with Unsaturated Compounds

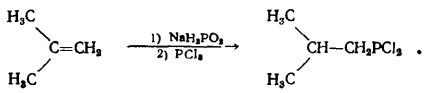
Free-radical addition to alkenes is a general reaction of compounds containing a phosphorus–hydrogen bond (phosphines, phosphonates, and phosphinates):



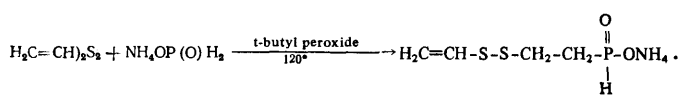
The reactions are initiated by ultraviolet irradiation or the usual sources of free radicals (organic peroxides), and take place by a radical–chain mechanism contrary to Markovnikov's rule.



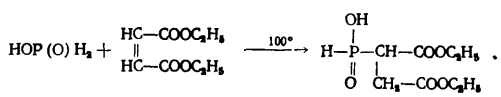
The reactions of inorganic phosphinates with unsaturated compounds usually give high yields[152–159]. For example, sodium phosphinate when heated to 120 °C with oct-1-ene in methanol in the presence of a peroxide gives a 100% yield of the salt of octylphosphonous acid[156]. Other alkylphosphonous acids have been obtained similarly from compounds having a terminal double bond:



When the molar ratio of alkene to phosphinate is 2: 1, dialkylphosphinic acids are formed[155,159]:

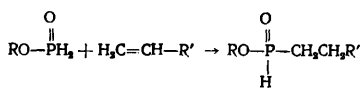


Sodium phosphinate reacts with allyl alcohol also in the presence of a peroxide[160,161]. Isolation of the reaction products presents considerable difficulties, probably owing to the occurrence of secondary processes. For the same reason individual addition products of the phosphinate to allyl cyanide and allyl acetate could not be isolated[162]. The resulting mixture was identified as the chlorides of 3-acetoxypropylphosphinic acids. The action of cyclohexene on sodium phosphinate in the presence of t-butyl peroxide gives a 77.5% yield of dicyclohexylphosphinic acid[83,163]:

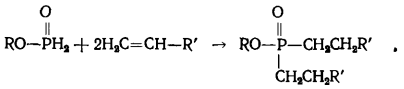


These reactions cna be used to obtain various alkyldichlorophosphines. A convenient procedure consists in initial preparation from an alkene and sodium phosphinate of the monosodium alkyl phosphinate, which is then treated with phosphorus trichloride or thionyl chloride[152]:

The above account shows clearly that all investigators have chosen sodium phosphinate to study the reactivity of salts of phosphinic acid, probably because of its better solubility in various solvents on heating. Only a British Patent[157] chose ammonium phosphinate, which on reaction with divinyl disulphide gave ammonium 3,4-dithiahex-5-enylphosphinate:



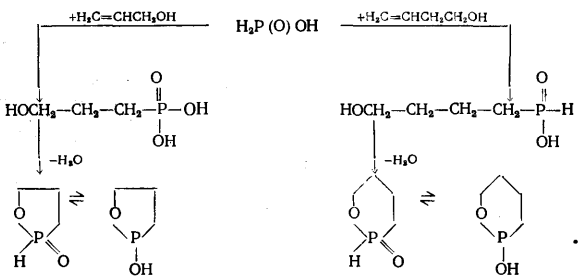
Phosphinic acid reacts with unsaturated compounds to from analogous products[164–167], but the yields are considerably lower, varying in the range 9–40%.[166,167] Reaction occurs with ethyl maleate in the absence of a catalyst to give a 65% yield[168], possibly by an ionic mechanism:



Attempts to catalyse the process with alkali-metal alkoxides or triethylamine did not increase the yield.

Alkyl phosphinates also add to alkenes in the presence of peroxides[76,169]:

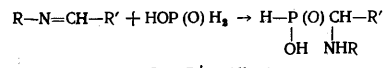
R = Alk; R′ = Alk .



Cyclohexene reacts with greater difficulty. Phosphinic esters are formed with excess of the alkenes at a higher temperature:

The reactions of methyl phosphinate with acrylonitrile and with methyl acrylate follow a similar course; in the latter case the main product is accompanied by a dimethyl phosphonate[170]:

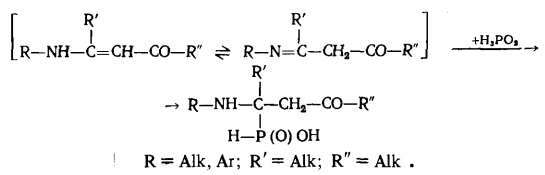
$$CH_3OP(O)H_2 + H_2C{=}CH\text{-}C(O)OCH_3 \rightarrow$$
$$CH_3OP(O)HCH_2CH_2C(O)OCH_3 + (CH_3O)_2P(O)CH_2CH_2C(O)OCH_3 .$$



The synthetic possibilities of the reactions of phosphinic acid and its derivatives with unsaturated compounds are confirmed by a publication[161] on the action of allyl alcohols on phosphinates. Aliphatic phosphinic acids containing a hydroxy-group in position 3 or 4 of the alkyl radical, obtained from phosphinates and aliphatic alcohols having a terminal ethylenic bond, undergo cyclisation when heated to 100–150 °C, with formation of 2-oxaphospholan-1-ones and 2-oxaphosphan-1-ones (γ- and δ-phostones):

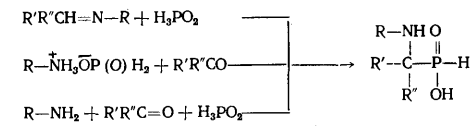
Owing to the inadequacy of published results it is fairly difficult to compare the reactivities of phosphinates in these reactions. There is no doubt, however, that the use of phosphinate salts instead of the acid itself in reactions with unsaturated compounds is entirely justified. The high yields obtainable are attributable to the greater stability of the salts under the severe conditions of addition at double bonds.

3. Reactions with Azomethines



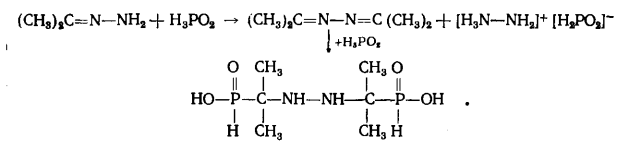
The addition to azomethines of reactants containing an active phosphorus–hydrogen bond provides a method for obtaining aminoalkyl (or aryl)phosphinic acids, interest in which is increasing in view of the physiological activity possessed by compounds of this type[171–176] and their detection in naturally occurring products of biological origin[177–180]. Substituted acids of this type were synthesised from phosphinic acid by Schmidt[3,181,182]. These reactions give good yields under mild conditions, with azomethines obtained from acetone reacting more readily:

R = Alk, Ar, Het; R′ = Alk, Ar .



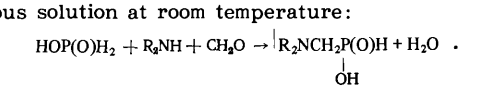
Various Schiff bases obtained from primary amines (aromatic, aliphatic, heterocyclic) and carbonyl compounds (aliphatic and aromatic aldehydes and ketones) have been used[3,182–190].

Certain enamines of β-dicarbonyl compounds react[189]:

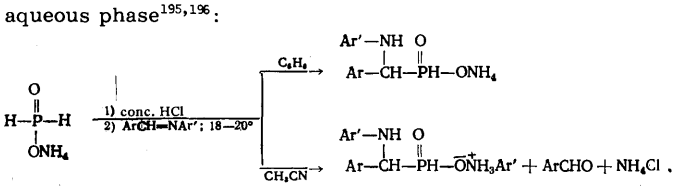


R = Alk, Ar; R′ = Alk; R″ = Alk .

Most of the investigators note[3,67,191] that 1-aminoalkyl(aryl) phosphinic acids can be obtained not only from azomethines but also by other methods, including placing all three components—amine, aldehyde (ketone), and phosphinic acid—together in the reaction vessel, but data on yields are contradictory[67,186]. A third variant—bringing a phosphinate, the amine, and the aldehyde into reaction—has been tested on several examples[3,4,185], but diminished yields of aminophosphinic acids are obtained[185]. Thus *N*-aryl(alkyl)-1-aminoaryl(alkyl)phosphinic acids can be synthesised in three ways:

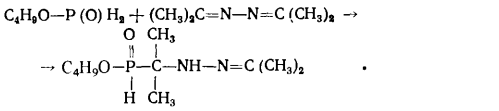


If an unsubstituted hydrazone is used as azomethine, the course of the process is anomalous[67]. Reaction between an equivalent quantity of acetone hydrazone and phosphinic acid gives a quantitative yield of acetone azine and hydrazinium phosphinate:

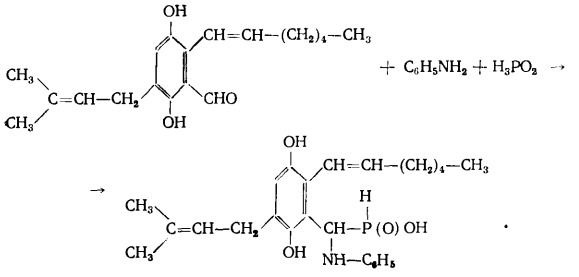


Azines can be obtained also from the hydrazones of benzaldehyde, acetophenone, and butan-2-one. Difunctional amino-acids are formed by the action of phosphinic acid on azines: a diphosphinic acid is obtained in good yield from acetone azine and two equivalents of phosphinic acid.

Secondary amines are more reactive than primary amines[192,193]. Dialkylaminomethylphosphinic acids are formed exothermally from secondary amines, formaldehyde, and phosphinic acid in aqueous solution at room temperature:



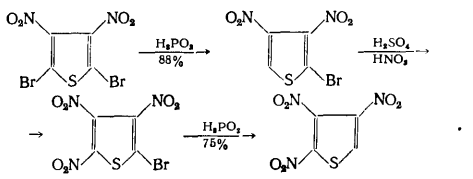
This process, which resembles formally the Mannich reaction, can be more far reaching: with excess of amine and formaldehyde bis(dialkylaminoalkyl)phosphinic acids are formed. With primary amines, however, only phosphinic acids are obtained.



Quite recently phosphinic acid has been replaced by its salts and esters in such reactions. A series of *N*-substituted 1-aminoaralkylphosphinic acids have been obtained from ammonium phosphinate[194]. The latter reacts with azomethines in the presence of an equivalent quantity of hydrochloric acid in benzene and acetonitrile to form arylammonium 1-aryl-1-arylaminomethylphosphinates[195,196]; when benzene is used, ammonium salts of the same acids are formed in the aqueous phase[195,196]:

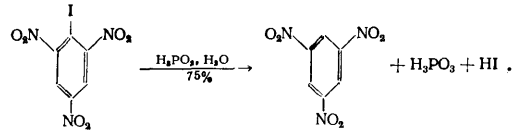
Treatment of alkyl phosphinates with azines[197,198] yields 1-aminoalkylphosphinic esters. The reaction studied in greatest detail is that between butyl phosphinate and acetone azine, in which heat is evolved and a 1:1 adduct is formed:

Reactions between phosphinates and azomethines (or their components) have already found practical application. Interest undoubtedly attaches to the selective modification of antibiotics by phosphorus-containing agents with the aim not only of practical application of novel semi-synthetic preparations (the possibility of obtaining forms suitable for injection) but also of their theoretical study, of the effect of introducing phosphorus grouping on the biological properties of the resulting organophosphorus antibiotics. Thus a water-soluble form of the antibacterial antibiotic aspergin has been obtained as 1-*N*-phenylaminoasperginphosphinic acid[15]:

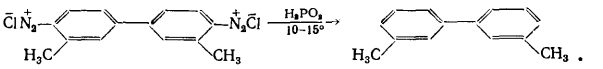


A medical form for parenteral introduction can be obtained by converting the hydrogen form into the sodium salt.

A series of phenothiazinylaminoalkylphosphinic acids have been obtained as potential medicinals[191]. Interesting complexones have been prepared by means of Schiff bases obtainable from ethylenediamine[188]:

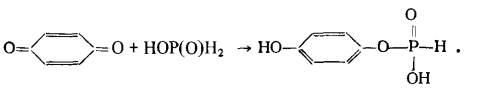


4. Other Reactions of Phosphinates

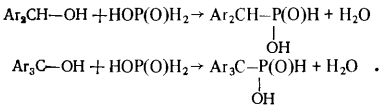


As already noted, the practical application of phosphinates is largely due to their reducing properties[10-12], which are responsible for the use of phosphinic acid in organic synthesis. 2,3,4-Trinitrothiophen can be obtained by means of this acid[199]:

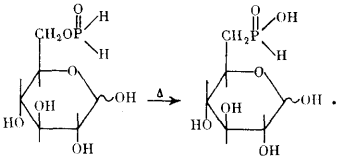
The latter effects reductive elimination also in the formation of trinitrobenzene from picryl iodide[200]:



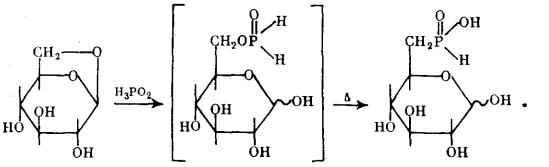
The acid was suggested also for reductive deamination by replacement of a diazonium group by hydrogen[201]:



A sixfold excess of 30% phosphinic acid was used to reduce bisdiazotised o-tolidine[202]. The acid has been used also to obtain 2,4,6-tribromobenzoic from *m*-aminobenzoic acid[203].



Several studies have been made of the mechanism of the reduction of organic compounds by phosphinates[204-208]. Reduction products—quinhydrone and quinol—are formed by the action of 50% phosphinic acid on *p*-benzoquinone. However, when this reaction is conducted in anhydrous medium or in the presence of a small quantity of water, an addition product—*p*-hydroxyphenyl hydrogen phosphonate—is also formed (in yields up to 46%):[209]



An interesting recent method for obtaining alkylphosphinic acids is the isomerisation of alkyl phosphinates. As early as 1910 Fosse[210], and later other workers[211,212], obtained alkylphosphinic acids by the action of secondary and tertiary arylcarbinols on phosphinic acid in the absence of a catalyst:

However, the mechanism of these reactions was not studied. Nifant'ev, who has detected isomerisation, considers[213] that initial esterification of phosphinic acid is followed by isomerisation of the resulting ester into the substituted phosphinic acid:

When sugars were treated with phosphinic acid, the initially formed phosphinic esters were isolated, and their structure was proved by oxidation to the corresponding phosphates or hydrolysis to the original products. The structure of glucose 6-phosphinate was proved more rigorously by the methods of carbohydrate chemistry. The same compound was obtained from phosphinic acid and levoglycosan[76,214]:

Heating levoglycosan with a mixture of phosphinic acid and sodium phosphinate gives sodium 6-glucophosphinate, whose structure has been confirmed by cross-synthesis[215]. The possibility of such intramolecular rearrangement was further postulated by Plets[216] when investigating the reactions of

sodium phosphinate with methyl iodide and with ethyl chloroacetate:

$$NaOP(O)H_2 + H_2 + CH_3I \xrightarrow{-NaI} CH_3OP(O)H_2 \rightarrow HO-\underset{\displaystyle CH_3}{\underset{|}{P(O)H}}$$

$$NaOP(O)H_2 + ClCH_2COOC_2H_5 \xrightarrow{-NaCl} \rightarrow H_2P(O)-OCH_2COOC_2H_5 \rightarrow \underset{\displaystyle OH}{\underset{|}{HP(O)}}CH_2COOC_2H_5 .$$

Phosphinate salts react vigorously with acetic anhydride. In concentrated media violent reaction occurs with formation of disproportionation products. In extremely dilute solutions (0.2M) high yields of potassium acetylphosphinate have been obtained[217,218]:

$$KOP(O)H_2 + (CH_3CO)_2O \rightarrow KO-\underset{\displaystyle H_3C-\underset{\displaystyle O}{\underset{\|}{C}}}{\underset{|}{P(O)}}H + CH_3COOH .$$

This reaction has been accomplished with various phosphinates—those of sodium, lithium, nickel, barium, and zinc—and other anhydrides of carboxylic acids react similarly. The process probably involves a Michaelis–Arbuzov reaction:

$$H-\underset{\displaystyle OH}{\underset{|}{P}}-OK + (R-\underset{\displaystyle O}{\underset{\|}{C}}-)_2O \rightarrow \left[\left(R-\underset{\displaystyle O}{\underset{\|}{C}}-\overset{\displaystyle OK}{\overset{|}{\underset{\displaystyle OH}{\underset{|}{P^+}}}}-H\right)R-COO^-\right] \rightarrow R-\underset{\displaystyle O}{\underset{\|}{C}}-\overset{\displaystyle OK}{\overset{|}{\underset{\displaystyle O}{\underset{\|}{P}}}}-H + RCOOH .$$

The aminomethylation of alkyl phosphinates

$$ROP(O)H_2 + (C_2H_5)_2NCH_2X \begin{cases} \rightarrow [(C_2H_5)_2NCH_2]_2P(O)OR + HX \\ \rightarrow (C_2H_5)_2NCH_2P(O)(OR)_2 + HX \end{cases}$$

is of theoretical interest[77]. In the first stage the phosphorus in the phosphinates is probably electrophilic with respect to the amines[76]. The reaction was conducted at 130–160 °C, and nearly always gave a mixture of products containing aminoalkyl-phosphinic and -phosphonic esters and the corresponding amides.

The Todd–Atherton reaction has been successfully extended to phosphinates[68,76,169,219]: alkyl phosphinates react readily with alcohols and tetrachloromethane in the presence of triethylamine. Depending on the proportions of the reactants either phosphonates or phosphates are formed[76,169]:

$$ROP(O)H_2 + CCl_4 + ROH + N(C_2H_5)_3 \begin{cases} \xrightarrow{1:1:1:1} (RO)_2P(O)H \\ \xrightarrow{1:2:2:2} (RO)_3PO \end{cases} .$$

Phosphinates of glycols are converted into cyclic phosphonates:

$$HO-R-O-P(O)H_2 + CCl_4 + N(C_2H_5)_3 \rightarrow R\begin{cases} O \\ O \end{cases}P(O)H .$$

If alcohols are replaced by secondary amines, phosphorodiamidates are formed:

$$ROP(O)H_2 + 4HNR'_2 + 2CCl_4 \rightarrow ROP(O)(NR'_2)_2 .$$

The Todd–Atherton reaction has been accomplished also with phosphinic acid[68,219]: thus with tetrachloromethane, triethylamine, and water the acid is converted into phosphorous acid. With tetrachloromethane and aniline the dianilide of phosphoric acid is formed. Aliphatic secondary amines behave similarly. Phosphinic acid on treatment with alcohols, tetrachloromethane, and triethylamine is converted into dialkyl phosphates.

Thus the great activity of phosphinates has permitted their use in many heterolytic and homolytic reactions. Although the range of reactions studied has hitherto been narrowly restricted, the above results demonstrate the wide opportunities open to the use of phosphinates for the preparation of diverse organophosphorus compounds.

---o0o---

Several publications on the preparation and the chemical properties of phosphinates have appeared while this Review was being prepared for the press. The action of water and hydrogen sulphide on dialkoxyphosphines yields alkyl phosphinates and phosphinothionates respectively[220]. Several inorganic salts of phosphinic acid have been prepared and their physicochemical properties have been studied[221,222].

The thermolysis of *p*-acetylanilinium phosphinate reflects the highly reactive character of the arylammonium salts[223]. A method has been suggested for the phosphorylation of allylcellulose with alkali-metal phosphinates[224]. Ion-exchange resins of polycondensation type, containing phosphorus and nitrogen, have been obtained from various di- and poly-amines, aqueous formaldehyde, and phosphinic acid[225,226]. The condensation of oximes with phosphinic acid yields 1-aminoalkyl-phosphinic and -phosphonic acids[227]. 1,5-Diketones react with phosphinic acid to give hydroxyalkylphosphinic or tetrahydropyranylphosphonic acids and their analogues depending on the structure of the ketone and the acidity of the medium[228–231]. The structure of the reaction product reported in Ref.231 has been refined[228–230]. Several macrocycles[232] and arenediazonium compounds[233] have been reduced with phosphinic acid. Homolytic reactions of phosphinates have been described in a monograph[234].

Problems of the Theory of Transport Processes in Systems with Intensive Mass Exchange

V.S.Krylov

The principles of the macroscopic theory of processes of convective heat and mass transfer in systems with mass exchange, taking place under conditions of large concentration gradients, have been presented. For these systems, the structure of the hydrodynamic fluxes (in particular the velocity profile in the boundary layer next to the wall) shows a marked dependence on the concentration field of the substance being transferred. Studies in which the effect of the interaction between the processes of mass transfer and momentum transfer has been analysed quantitatively in relation to problems of chemical and electrochemical technology have been reviewed. The bibliography contains 68 references.

I. INTRODUCTION

Present-day chemical and electrochemical technology, and many other fields of science and technology (for example thermophysics, hydrometallurgy, nuclear and electrochemical energetics, purification of gases, etc.) are engaged in the search for methods of intensifying interphase heat and mass transfer. Extensive possibilities in this connection are being opened up by the development of effective methods of dispersing and mixing, and the use of hydrodynamically non-stabilised conditions of convective transport and input regions of heat and mass exchange. High rates of the processes of interphase exchange are realised when these processes are carried out under markedly non-equilibrium conditions, that is with high temperature and concentration gradients.

Traditional methods of mathematical description, based on the separate solution of the equations of hydrodynamics and convective heat and mass transfer, are not applicable to systems in which transfer processes are taking place under conditions of intense mass exchange. In the traditional approach, the distribution of hydrodynamic velocities is found first (for example by solving the Navier–Stokes equations in the case of laminar flow conditions), after which this distribution is substituted in the equation of convective heat or mass exchange and solved for specific boundary conditions to determine the rate of interphase exchange. When applied to systems having large concentration gradients, however, this method of solution is not correct, since convective motion induced by mass exchange takes place[1,2]. The velocity of the induced movement is at right angles to the interphase boundary and the movement takes place in the direction of mass transfer. The physical factor responsible for this movement is the mechanical momentum, which is transferred from one phase to the other by the particles responsible for mass exchange. Since the transmitted momentum is proportional to the diffusion flow of the particles involved is mass transfer, the velocity field close to the interphase boundary depends on the concentration field. The specific form of this dependence is determined by the system of equations for the simultaneous transfer of momentum and mass, and also by the boundary conditions relating the fluxes of momentum and mass at the interphase boundary.

II. CHARACTERISTIC FEATURES OF THE HYDRODYNAMIC CONDITIONS OF INTENSIVE MASS EXCHANGE

The mechanical momentum, proportional to the velocity of interphase mass exchange, influences primarily the boundary conditions for the equations of hydrodynamics and mass transfer: these equations, unlike the case of systems with low velocities of interphase mass exchange, cannot be solved separately. To establish the relationship between the local velocity of movement of a continuous medium (liquid or gas) at the phase interface and the rate of interphase mass exchange, it is possible to take as an example the isothermal transfer of a solute from phase 1 to phase 2. For simplicity it will be assumed that each of the phases is a two-component liquid mixture (a solution of substance m in the corresponding solvent), and that the solvents are immiscible. The diffusion flux $j_m^{(i)}$ of the substance m at any point in space within the phase i is defined as follows[3]:

$$j_m^{(i)} = M_m c_m^{(i)} (\mathbf{v}_m^{(i)} - \mathbf{v}^{(i)}). \quad (1)$$

Here, $c_m^{(i)}$ is the molar concentration of the substance being transferred in the phase i; M_m the molecular mass of this substance; $\mathbf{v}_m^{(i)}$ the mean statistical velocity of the movement of the particles of the substance m in an arbitrary but fixed system of coordinates; and $\mathbf{v}^{(i)}$ the velocity of movement of the centre of mass of the entire liquid mixture in the same system of coordinates.

The velocity $\mathbf{v}^{(i)}$ is described by the system of equations of hydrodynamics (in the case of laminar flow conditions by the Navier–Stokes system of equations). At the same time, this velocity, by definition, is related to the velocities of the movement of the components of the mixture by

the relationship

$$\rho^{(i)}\mathbf{v}^{(i)} = M_m c_m^{(i)}\mathbf{v}_m^{(i)} + M_0 c_0^{(i)}\mathbf{v}_0^{(i)}, \qquad (2)$$

where the quantities having the subscript "0" refer to the corresponding solvent, and $\rho^{(i)} = M_m c_m^{(i)} + M_0 c_0^{(i)}$ is the total density of the solution in the phase i (in the general case this density is a function of the spatial coordinates and time). Each velocity in Eqn.(2) is represented as the sum of the velocity of movement of the interphase surface $d\mathbf{r}_s/dt$ ($\mathbf{r}_s$ is the radius vector of an arbitrary point at the phase interface) and the velocity relative to this surface $\mathbf{v}_{rk}^{(i)}$ ($k = m, 0$). Since the solvents are immiscible, the normal components of the velocities $v_{r0}^{(1)}$ and $v_{r0}^{(2)}$ at the interphase boundary should be equal to zero. Thus Eqn.(2), projected on to the direction of the normal n to the interphase boundary, has at each point on this boundary the following form:

$$\rho^{(i)}(\mathbf{v}_r^{(i)}, \mathbf{n}) = M_m c_m^{(i)}(\mathbf{v}_{rm}^{(i)}, \mathbf{n}); \quad i = 1, 2. \qquad (3)$$

The analogous operation of projecting Eqn.(1) on to the direction of the normal n leads, with allowance for Eqn.(3), to the equation

$$(\mathbf{v}_s^{(i)}, \mathbf{n}) = \left(\frac{d\mathbf{r}_s}{dt}, \mathbf{n}\right) + \frac{(\mathbf{j}_{ms}^{(i)}, \mathbf{n})}{\rho_s^{(i)} - M_m c_{ms}^{(i)}}, \qquad (4)$$

applicable for any point on the interphase surface. The subscript "s" in this equation indicates that the corresponding quantity refers to the interface between the phases. If the form of the interface is given by one of the equations

$$y = f_1(x, t), \; z = f_2(r, t), \; r = f_3(\vartheta, t),$$

the following expressions give the first term on the right-hand side of Eqn.(4)

$$\left(\frac{d\mathbf{r}_s}{dt}, \mathbf{n}\right) = \begin{cases} \left[1 + \left(\frac{\partial f_1}{\partial x}\right)^2\right]^{-1/2} \frac{\partial f_1}{\partial t} & \text{(in a rectangular system of coordinates);} \\ \left[1 + \left(\frac{\partial f_2}{\partial r}\right)^2\right]^{-1/2} \frac{\partial f_2}{\partial t} & \text{(in a cylindrical system of coordinates);} \\ \left[1 + \left(\frac{\partial f_3}{f_3 \partial \vartheta}\right)^2\right]^{-1/2} \frac{\partial f_3}{\partial t} & \text{(in a spherical system of coordinates).} \end{cases}$$

The condition (4) can readily be generalised to the case where several substances are transferred simultaneously through the interface. According to this condition, the normal component of the velocity of the movement of a continuous medium close to the interphase boundary is determined by the rate of displacement of the boundary itself, the rate of interphase mass exchange, and the surface values of the concentrations of the substance, responsible for mass exchange. It follows from Eqn.(4) that in the case of sufficiently high rates of mass exchange, the hydrodynamic problem cannot be solved independently of the problem of convective diffusion.

A large number of examples of systems of practical interest have been described, in which intensive mass exchange leads to a significant change in the hydrodynamic conditions of heat and mass transfer[4-13]. The most typical examples in this connection are the condensation of a mixture of vapours on a cooled wall[4], the evaporation of a liquid on the surface of drops and bubbles[8,9], and the crystallisation and dissolution of salts[10-13]. One of the theoretical problems in which the velocity field being calculated is found to depend on the concentration field of the particles responsible for mass exchange is the problem of the anodic dissolution of a metal surface in a stream of electrolyte solution at a high electrical current density. This problem is directly related to the theory of the technique of three-dimensional electrochemical machining of metals and alloys which has wide practical uses[14-19]. Existing approaches to the analyses of the processes of intensive anodic dissolution are examined in the next section.

III. ANODIC DISSOLUTION OF METALS IN A STREAM OF ELECTROLYTE

The mathematical description of the macrokinetics of the processes of anodic dissolution, used in practice for the three-dimensional machining of metals, is usually based on the so-called model of the "ideal" electrochemical process[20-22]. This model assumes that: 1) Ohm's law applies throughout the entire space occupied by the solution, as far as the actual electrode surfaces; 2) the distribution of electrical potential in solution is everywhere described by the Laplace equation (in other words, the existence of regions of bulk charge close to the electrodes is not taken into account); and 3) the ionisation of the atoms of the dissolving metal takes place at a constant current efficiency (generally 100%). This means that calculations within the framework of the model of the "ideal" process can lead to satisfactory results only for systems in which the effects of chemical and concentration overvoltage do not play a significant role, and the basic electrical resistance is determined by the bulk properties of the solution, which are constant at all points in the gap between the electrodes.

Mathematically, the problem of the "ideal" process of anodic dissolution does not differ in principle from the problem of the filtration of liquids through porous media under conditions in which the hydrodynamic resistance of the medium is described by Darcy's law[23]. The main difficulty in this case lies in finding the solution of the Laplace equation for the region, the boundaries of which are related to this solution by a familiar differential equation. Even in this simplified formulation, the problem of determining the form of the gap between the electrodes is still extremely complex, and its solution usually requires the use of numerical methods. The problem can be solved in analytical form only in individual cases, mainly for regions having two-dimensional geometry, to which the methods involving the theory of the functions of a complex variable are applicable[24-28]. An elegant analytical method, based on the establishment of the relationship between the components of the complex potential being sought and the solution of the characteristic hypergeometric equation, was developed by Polubarinova-Kochina[23] for application to problems of the theory of filtration. This method can be used without any modification to solve the stationary problems of electrochemical machining within the framework of the model of the "ideal" process (the given values of the flux at the boundaries of the filtration region, the configuration of which is to be determined, are direct analogues of the given values of the potential at the electrodes of the electrochemical cell).

Since in practice it is necessary to deal with non-ideal processes, the calculations carried out on the basis of the "ideal" model generally do not give satisfactory results. It has been shown[18] that Ohm's law cannot be extrapolated from the bulk of the solution to the region of the diffusion boundary layer next to the anode. The results[18] indicate that the true value of the electric potential gradient next to the anode at current densities of the order of 10 A cm^{-2} and electrolyte concentrations of the order of 1 M may differ by several factors of tens from the value obtained without allowance for the effect of concentration overvoltage. For this reason, published methods[17,29,30] for solving the problems of electrochemical machining can hardly be regarded as corresponding to the actual conditions. This statement will be illustrated below by a specific example.

1. Electrochemical Dissolution of a Surface Uniformly Accessible for Ionic Mass Exchange

The problem of the anodic dissolution of a metal in a solution of its own salt (for example the dissolution of iron in iron chloride solution) can be considered. To obtain the analytical solution of this problem, the following simplifying assumptions are made[31-33].

1. The dissolving surface is uniformly accessible with respect to diffusion.

2. The dissolution process is stationary, that is the concentration of each component of the solution at any fixed distance from the surface of the anode (this surface will be regarded as planar) is independent of time.

3. Ionic mass transfer in the solution takes place at very large Schmidt numbers, so that the velocity profile within the diffusion boundary layer may be approximated by a uniform distribution with a constant velocity, equal to the velocity of the movement of the solution directly at the anode surface.

4. The ratio of the effective thicknesses of the diffuse and diffusion boundary layers next to the anode is negligibly small, so that the solution can be regarded as electrically neutral at all points up to the interphase boundary.

5. The physical and transport properties of the solution are independent of the local concentration of cations of the dissolving metal.

6. Dissolution takes place under isothermal conditions.

The condition of uniform accessibility with respect to mass exchange means that the local concentration of each component of the solution depends only on the distance to the surface of the anode:

$$c_k = c_k((\boldsymbol{r} - \boldsymbol{r}_s), \boldsymbol{n}).$$

The stationary form of the equation for the differential mass balance of the kth component of the solution is as follows:

$$\operatorname{div} \boldsymbol{j}_k + M_k(\boldsymbol{v}, \nabla c_k) = 0,$$

where the quantities $\mathbf{j}_k$, $\mathbf{v}$, and c_k are functions of the spatial coordinate $\boldsymbol{r}$. The replacement of $\boldsymbol{r}$ by the new independent variable $x = (\boldsymbol{r}, \boldsymbol{n}) - (\boldsymbol{r}_S, \boldsymbol{n})$ gives

$$\left\{(\boldsymbol{v}, \boldsymbol{n}) - \left(\frac{\mathrm{d}\boldsymbol{r}_s}{\mathrm{d}t}, \boldsymbol{n}\right)\right\}\frac{\mathrm{d}c_k}{\mathrm{d}x} + \frac{1}{M_k}\frac{\mathrm{d}}{\mathrm{d}x}(\boldsymbol{j}_k, \boldsymbol{n}) = 0.$$

The assumption that the velocity field next to the anode is uniform makes it possible to replace the expression in braces by the right-hand side of Eqn.(4):

$$\frac{M_k(\boldsymbol{j}_1^{(s)}, \boldsymbol{n})}{\rho^{(s)} - M_1 c_1^{(s)}}\frac{\mathrm{d}c_k}{\mathrm{d}x} + \frac{\mathrm{d}}{\mathrm{d}x}(\boldsymbol{j}_k, \boldsymbol{n}) = 0; \quad k = 1, 2, 3. \tag{5}$$

Here, the subscripts $k = 1,2,3$ refer to the cations of the dissolving metal, the anions of the salt, and the solvent molecules respectively.

From the definition of the diffusion flux (1) and the mass-average hydrodynamic velocity (2) it follows that the vector sum of the diffusion fluxes of all the components present in the solution is equal to zero:

$$\sum_k \boldsymbol{j}_k = 0.$$

This means that in the three-component system being considered here, only two fluxes are independent. Subsequently, therefore, the mass transfer problem will be solved only for two components of the solution (for example 1 and 2).

In the formulation of the boundary conditions for Eqns.(5) it will be assumed that at a certain fixed distance $x = \delta$ from the surface of the anode, the ion concentrations c_1 and c_2 take their constant bulk values $c_1^{(0)}$ and $c_2^{(0)}$. The quantity δ in this approach is equivalent to the effective thickness of the diffusion boundary layer.

If the only electrochemical reaction taking place at the anode is the ionisation of the metal atoms, the normal component of the total mass flux of the metal cations at the surface of the anode

$$(\boldsymbol{j}_1^{(s)}, \boldsymbol{n}) + M_1 c_1^{(s)}\left\{(\boldsymbol{v}^{(s)}, \boldsymbol{n}) - \left(\frac{\mathrm{d}\boldsymbol{r}_s}{\mathrm{d}t}, \boldsymbol{n}\right)\right\},$$

should be proportional to the anodic current density i with proportionality coefficient equal to M_1/z_1F (F is the Faraday number):

$$\frac{iM_1}{z_1F} = (\boldsymbol{j}_1^{(s)}, \boldsymbol{n}) + M_1 c_1^{(s)}\left\{(\boldsymbol{v}^{(s)}, \boldsymbol{n}) - \left(\frac{\mathrm{d}\boldsymbol{r}_s}{\mathrm{d}t}, \boldsymbol{n}\right)\right\}.$$

Allowance for Eqn.(4) gives

$$(\boldsymbol{j}_1^{(s)}, \boldsymbol{n}) = \frac{iM_1}{\rho^{(s)}z_1F}(\rho^{(s)} - M_1 c_1^{(s)}). \tag{6}$$

The normal n in the last expression, and subsequently throughout, is assumed to be directed from the anode towards the solution, and the current density is assumed to be positive.

When an analogous expression is written for the total mass flux of the electrochemically inert anion and this flux is put equal to zero at the anode surface, the following relationship is obtained:

$$(\boldsymbol{j}_2^{(s)}, \boldsymbol{n}) = -M_1M_2ic_2^{(s)}/\rho^{(s)}z_1F. \tag{7}$$

Eqns.(6) and (7) can be regarded as the boundary conditions for Eqns.(5). According to condition (7), the diffusion flux of an electrochemically inert anion at the interphase boundary is nonzero. The physical factor responsible for this fact is the existence of a nonzero normal component of the rate of movement of the centre of mass of the solution at the anode surface; this component leads to a diffusion of the anion from the solution to the surface.

Single integration of Eqn.(5) with boundary conditions (6) and (7) gives:

$$(\boldsymbol{j}_k, \boldsymbol{n}) = \frac{iM_1}{\rho^{(s)}z_1F}(\rho^{(s)}\delta_{1k} - M_k c_k); \quad k = 1, 2, \tag{8}$$

where δ_{1k} is the Kronecker symbol.

The fluxes $\mathbf{j}_k$ are related to the ionic concentration gradients by the following expressions[18]:

$$\boldsymbol{j}_1 = -\frac{D_{\mathrm{eff}}M_1M_3c}{\rho}\zeta(c_1, c_2)\nabla c_1 + \frac{M_1D_{13}\boldsymbol{i}}{F(z_2D_{23} - z_1D_{13})}\left[\frac{c_1}{\rho D_{13}}(M_1D_{13} - M_2D_{23}) - 1\right], \tag{9}$$

$$\boldsymbol{j}_2 = -\frac{D_{\mathrm{eff}}M_2M_3c}{\rho}\zeta(c_1, c_2)\nabla c_2 - \frac{M_2D_{23}\boldsymbol{i}}{F(z_2D_{23} - z_1D_{13})}\left[\frac{c_2}{\rho D_{23}}(M_1D_{13} - M_2D_{23}) + 1\right]. \tag{10}$$

Here, $\mathbf{i} = F[(z_1\mathbf{j}_1/M_1) + (z_2\mathbf{j}_2/M_2)]$ is the vector of the electric current density, related to the scalar current density i by the relationship $(\mathbf{i},\mathbf{n}) = i$, $\rho = M_1c_1 + M_2c_2 + M_3c_3$ is the local density of the solution, $c = c_1 + c_2 + c_3$ the total concentration of the liquid phase, D_{ik} the coefficients of mutual diffusion in the corresponding binary mixtures, and D_{eff} the effective coefficient of ionic mass transfer, defined by the expression

$$D_{\mathrm{eff}} = \frac{\rho(z_2 - z_1)D_{13}D_{23}}{(z_1c_1 + z_2c_2)(M_1D_{13} - M_2D_{23}) + \rho(z_2D_{23} - z_1D_{13})}. \tag{11}$$

The function $\zeta(c_1, c_2)$ is expressed in terms of the mean activity coefficient of the electrolyte γ_{12} by the relationship

$$\zeta(c_1, c_2) = 1 + \frac{\mathrm{d}\ln\gamma_{12}}{\mathrm{d}\ln(c_1/c_1^{(0)})}. \tag{12}$$

Using the fourth simplifying assumption above, which postulates that the condition of local electrical neutrality is fulfilled, the mass transfer problem will subsequently be examined only for the cations "1" (the concentration of the anions c_2 in this case is determined directly from the electrical neutrality condition). Substitution of Eqn.(9) in Eqn.(8) and simple transformation give:

$$\left(1+\frac{d\ln\gamma_{12}}{d\ln(c_1/c_1^{(0)})}\right)\frac{dc_1}{dx}+\frac{i}{F(z_1-z_2)M_3D_{23}c}\times$$
$$\times\left\{\frac{M_1D_{13}-M_2D_{23}}{D_{13}}c_1-\rho\left[1-\frac{(z_1-z_2)D_{23}}{z_1D_{\text{eff}}}\left(1-\frac{M_1c_1^{(s)}}{\rho^{(s)}}\right)\right]\right\}=0. \quad (13)$$

If the functional form of the relationship $\gamma_{12}=\gamma_{12}(c_1, c_2)$ is known, it follows that Eqn.(13), together with the condition of local electrical neutrality and the boundary condition (6), determines completely the solution of the problem posed. Since however the published[34] empirical correlations for the relationships $\gamma_{12}(c_1, c_2)$ have an extremely complex form, the rigorous integration of Eqn.(13) is impossible without using numerical methods.

To analyse the most characteristic features of ionic mass exchange under conditions of intensive anodic dissolution, a number of further simplifications can be carried out. Thus it is possible to examine the particular case of a solution composition at which, on the one hand, the local concentrations of the ions are low compared with the concentration of the solvent ($c\cong c_3$) and on the other hand, as a consequence of the high molecular mass of the dissolving metal, the local density of the cations M_1c_1 is comparable with the local density of the solution ρ. Putting $c=c_3=$ const. in Eqn.(13) gives

$$\left(1+\frac{d\ln\gamma_{12}}{d\ln(c_1/c_1^{(0)})}\right)\frac{dc_1}{dx}-\frac{iM_1c_1}{Fz_1\rho^{(s)}D_{\text{eff}}}=$$
$$=\frac{i}{F(z_1-z_2)D_{23}}\left[1-\frac{(z_1-z_2)D_{23}}{z_1D_{\text{eff}}}\left(1-\frac{M_1c_1^{(s)}}{\rho^{(s)}}\right)\right]. \quad (14)$$

If the influence of the mass flux of the cations on the hydrodynamics [this influence is described by the boundary conditions (6) and (7)] were not taken into account, the transfer equation would have the form

$$\left(1+\frac{d\ln\gamma_{12}}{d\ln(c_1/c_1^{(0)})}\right)\frac{dc_1}{dx}=\frac{z_2i}{Fz_1(z_1-z_2)D_{12}}. \quad (15)$$

Comparison of Eqns.(14) and (15) shows that the effect of the mutual influence of the processes of momentum and mass transfer begin to be observed under conditions of intensive anodic dissolution, when the partial density of the cations $M_1c_1^{(s)}$ in the layer next to the anode becomes comparable with the density of the solution next to the anode $\rho^{(s)}$.

The quantitative assessment of the contribution of this effect can be carried out, without loss of generality, by examining a restricted range of concentrations close to the minimum of the function giving the dependence of $\ln\gamma_{12}$ on c_1 (for most aqueous electrolyte solutions this minimum lies at concentrations of ~1 M,[34] that is in the range where the ratio $M_1c_1^{(s)}/\rho^{(s)}$ may amount to several tens %). In this case, putting $d\ln\gamma_{12}/d\ln(c_1/c_1^{(0)})=0$ in Eqn.(14) and integrating gives

$$c_1=(c_1^{(0)}+\chi)\exp\left[-\frac{iM_1(\delta-x)}{z_1F\rho^{(s)}D_{\text{eff}}}\right]-\chi, \quad (16)$$

where

$$\chi=c_1^{(s)}+\frac{z_2\rho^{(s)}D_{23}}{M_1(z_1D_{13}-z_2D_{23})}. \quad (17)$$

Eqns.(16) and (17) can be used to obtain an equation for determining the concentration of cations $c_1^{(s)}$ next to the anode:

$$[2z_1M_1D_{13}-(z_1M_2+z_2M_1)D_{23}]c_1^{(s)}+z_2M_3D_{23}c=$$
$$=[(z_1D_{13}-z_2D_{23})M_1c_1^{(0)}+z_1(M_1D_{13}-M_2D_{23})c_1^{(s)}+z_2M_3D_{23}c]\times$$
$$\times\exp\left(-\frac{z_2iM_1\delta(z_1D_{13}-z_2D_{23})}{z_1(z_1-z_2)FD_{13}D_{23}[(z_2M_1-z_1M_2)c_1^{(s)}+z_2M_3c]}\right). \quad (18)$$

If the diffusion flux had no influence on convective ion mass transfer from the anode surface, it follows from Eqn.(15) that the equation for $c_1^{(s)}$ would have the form

$$c_1^{(s)}=c_1^{(0)}-\frac{z_2i\delta}{z_1(z_1-z_2)FD_{13}}. \quad (19)$$

Analysis of Eqn.(18) shows that the value of $c_1^{(s)}$ which it gives, for any fixed current density i, is less than the corresponding value determined by Eqn.(19). The $c_1^{(s)}(i)$ relationship described by Eqn.(18) is monotonic, and for a formally unrestricted increase in current, in contrast to Eqn.(19), it gives not an infinitely large value of $c_1^{(s)}$ but a finite asymptotic value, defined by the equation

$$c_{1\max}^{(s)}=-\frac{z_2D_{23}\rho^{(s)}}{2M_1(z_1D_{13}-z_2D_{23})}. \quad (20)$$

Fig.1 gives the $c_1^{(s)}(i)$ relationship for the dissolution of bivalent iron in aqueous 1 *N* $FeCl_2$ at $\delta=10^{-3}$ cm, and for comparison the linear graph corresponding to the absence of mass flux at the anode surface. Fig.1 shows that for a given anodic current density, the true value of the concentration of cations in the layer next to the anode is always lower than the value calculated without allowance for the mutual influence of the processes of mass and momentum transfer. An important conclusion from this result is the prediction of the possibility of achieving higher current densities (compared with those obtained within the framework of the traditional theory of convective diffusion, applicable for systems having low rates of interphase mass exchange) for a given "critical" value of the concentration of metal cations next to the anode. The existence of this "critical" value under real conditions may be related either to supersaturation of the solution or to other restrictions, for example complex formation or bulk chemical reactions, the formation of passivating films, etc.

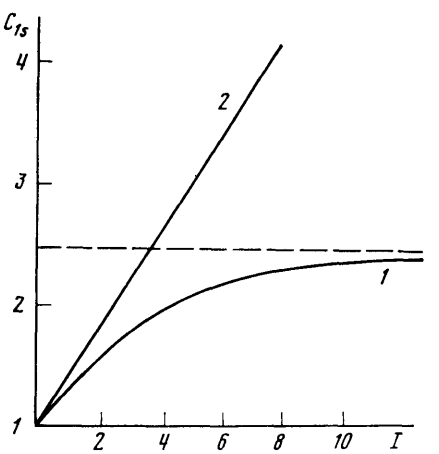

Figure 1. Dependence of the concentration of iron cations next to the anode (curve *1*) on the dimensionless current density $I=i\delta/Z_1FD_{13}c_2^{(0)}$ under the conditions of the dissolution of iron in 1 *N* aqueous $FeCl_2$ solution for $\delta=10^{-3}$ cm; the straight line corresponds to the conditions in which there is no mass flux at $x=0$ and no translational movement of the anode; $C_{1S}=c_1^{(s)}/c_2^{(0)}$.

Thus the above analysis indicates that it is necessary to take account of the interaction of the processes of mass and momentum transfer in the mathematical description of intensive electrochemical mass exchange. Estimates show that this interaction has a significant influence on the accuracy of the calculations at current densities of the order of 10 A cm^{-2} or more in molar (or more concentrated) solutions.

2. Macrokinetics of Intensive Electrochemical Mass Exchange in Solutions Containing Three Kinds of Ion

In many cases of practical interest, the process of anodic dissolution takes place in solutions containing ions of three kinds: the cations of the dissolving metal and the ions of the indifferent electrolyte. The latter is used to ensure that the electrical conductivity of the solution is sufficiently high. Since the intensive mass exchange accompanying the dissolution process can make the concentration of the cations of the dissolving metal close to the anode surface comparable with the local concentration of the ions of the indifferent electrolyte, it follows that in the equations for ionic mass transfer, even within the electricially neutral diffuse layer, it is necessary to consider the mechanism of electromigration.

It is appropriate to use the Nernst diffusion model[35] as a completely satisfactory approximation for application to the processes involved in the steady-state dissolution of surfaces uniformly accessible for mass exchange, when the local concentrations c_k and mass diffusion–migration fluxes j_k of all the ionic components of the solution depend only on the distance x to the anode surface. This model postulates the existence of a layer of a certain thickness δ next to the anode, in which the main change in the concentration of the components of the solution, limiting the rate of mass exchange, occurs.

The results obtained within the framework of the Nernst model show good agreement with the results of a theoretical analysis, based on the correct non-model allowance for the hydrodynamic conditions of mass transfer, if it is assumed that the effective thickness of the diffusion layer δ depends, in a definite manner, on the coefficient of molecular diffusion of the component being transferred. This relationship is a power dependence with exponent varying from 0.33 to 0.25 with change from laminar to turbulent mixing conditions[36]. Estimates based on the published equations[36] show that in the case of turbulent mixing conditions, the values of the thickness δ corresponding to different ionic components of the solution differ from one another by not more than 20%, if the coefficients of molecular diffusion of these components differ by a factor of not more than three. For this reason, in the examination of mass transfer in solutions containing ions of three kinds, it has been assumed[37–40] that the thickness δ is the same for all three kinds.

In the case of steady-state conditions of dissolution of a surface uniformly accessible for mass exchange, the system of equations of ionic mass transfer can be represented as follows[18]:

$$j_k = \frac{M_1 i}{z_1 F}\left(\delta_{1k} - \frac{M_k c_k}{\rho^{(s)}}\right); \quad k = 1, 2, 3. \tag{21}$$

Here, the subscript "1" for all quantities refers to the cations of the dissolving metal, and the subscripts "2" and "3" to the anions and cations respectively of the indifferent electrolyte. As before, the fluxes j_k are assumed to be positive if they are directed from the anode to the solution.

The fluxes j_k are related to the gradients of the ionic concentrations c_k and the electric potential ϕ by Onsager's equations[41]. In the case of solutions containing ions of three kinds, however, these equations contain the coefficients of mutual diffusion D_{12}, D_{13}, and D_{23}, which cannot be calculated theoretically or determined experimentally. It is therefore appropriate to examine as a first approximation the case of a sufficiently dilute solution, when it is possible to neglect the mutual influence of the ion fluxes and to approximate these fluxes by the expression

$$j_k = -M_k D_k \frac{dc_k}{dx} - \frac{z_k M_k D_k c_k F}{RT}\frac{d\varphi}{dx}; \quad k = 1, 2, 3, \tag{22}$$

where D_k is the diffusion coefficient of the ions of type k in the pure solvent, and z_k the valency of the ions. Substituting Eqn.(22) in Eqn.(21) gives the set of equations

$$\frac{dc_k}{dx} + \left(\frac{z_k F}{RT}\frac{d\varphi}{dx} - \frac{M_1 i}{z_1 F \rho^{(s)} D_k}\right) c_k + \frac{i\delta_{1k}}{z_1 D_1 F} = 0. \tag{23}$$

This set must be supplemented by the equation for the electric potential ϕ and by boundary conditions defining the values of the ion concentrations and the potential in the bulk of the solution (more accurately, beyond the limits of the diffusion layers). In the case of sufficiently high concentrations of the indifferent electrolyte, when the ratio of the effective thicknesses of the diffuse and diffusion boundary layers next to the anode is small, the Poisson equation describing the electrical field distribution can be replaced by the condition for local electrical neutrality of the solution:

$$\sum_{k=1}^{3} z_k c_k = 0. \tag{24}$$

It will be assumed that beyond the limits of the diffusion layer, the concentrations of the ions of the indifferent electrolyte are uniform, and that the concentration of the ions of the dissolving metal is equal to zero. Since outside the diffusion layer the electric field is purely ohmic, the potential can be measured from the plane $x = \delta$ (the value of the potential in the region next to the cathode can be determined if the magnitude of the ohmic electric field and the thickness of the gap between the electrodes are known). Thus the boundary conditions for the system of equations (23) and (24) can be formulated as follows:

$$c_1 = 0, \; c_2 = c_2^{(0)}, \; c_3 = -\frac{z_2}{z_3} c_2^{(0)}, \; \varphi = 0 \text{ for } x = \delta.$$

It is convenient to look for solutions using the following dimensionless variables:

$$y = x/\delta, \; C_k = c_k/c_2^{(0)}, \; \psi = F\varphi/RT, \; I = i\delta/z_1 F D_1 c_2^{(0)}, \; \xi_k = M_1 D_1 c_2^{(0)}/D_k \rho^{(s)}.$$

In these variables, the system of equations (23) and (24) has the form

$$\frac{dC_k}{dy} + \left(z_k \frac{d\psi}{dy} - \xi_k I\right) C_k + \delta_{1k} I = 0, \tag{25}$$

$$\sum_{k=1}^{3} z_k C_k = 0, \tag{26}$$

with boundary conditions

$$C_1 = 0, \; C_2 = 1, \; C_3 = -z_2/z_3, \; \psi = 0 \text{ for } y = 1. \tag{27}$$

The system of equations (25) and (26) has an analytical solution when the diffusion coefficients of all types of ion present in the solution are equal ($D_1 = D_2 = D_3 = D$). In this case, the following expressions are obtained for the distributions of the ionic concentrations and the electric potential:

$$C_1 = \frac{1}{2\xi Y}\left\{\frac{4 z_2 z_3 Y^2}{(z_1 - z_2)(z_2 - z_3)} + \frac{\xi^2 (z_1 - z_2)(z_2 - z_3)}{z_1^2}\exp\left[-2\xi I (1 - y)\right]\right\}, \tag{28}$$

$$C_2 = -\frac{2 z_1 z_3 Y}{\xi (z_1 - z_2)(z_2 - z_3)}, \tag{29}$$

$$C_3 = -\frac{\xi (z_1 - z_2)(z_2 - z_3)}{2 z_1 z_3 Y}\exp\left[-2\xi I (1 - y)\right], \tag{30}$$

$$\psi = \frac{z_2 - z_3}{2z_2z_3}\left\{\xi I(1-y) + \frac{1}{2}\ln\frac{a_1\exp[-2\xi I(1-y)] + a_2\exp[-\xi I(1-y)] + a_3}{a_1 + a_2 + a_3}\right\}. \quad (31)$$

Here, the following symbols are introduced:

$$Y = 1 - \left[1 - \xi\left(1 - \frac{z_2}{z_3}\right)\right]\exp[-\xi I(1-y)];$$

$$\xi = \frac{M_1 c_2^{(0)}}{\rho^{(s)}};$$

$$a_1 = 2 + \frac{z_3}{\xi(z_2 - z_3)} + \frac{\xi(z_2 - z_3)}{z_3}\left[1 + \frac{z_3(z_1 - z_2)(z_1 - z_3)}{4z_1^2 z_2}\right];$$

$$a_2 = -\frac{2}{\xi(z_2 - z_3)}[\xi z_2 + z_3(1 - \xi)];$$

$$a_3 = \frac{z_3}{\xi(z_2 - z_3)}.$$

When the charges of all the ions are the same ($z_1 = z_3 = -z_2 = z$). Eqns.(28)–(31) are transformed into the corresponding equations obtained in Ref.38.

As noted above, the chief difference between the equations describing the transfer phenomena in electrolyte solutions under conditions of intensive interphase mass exchange and the traditional equation of ionic mass transfer, which assumes that the hydrodynamics are independent of mass exchange, lies in the allowance for additional convective transfer, associated with the existence of the normal component of the hydrodynamic velocity at the interphase surface. The additional convective flux arises as a consequence of the influence of mass exchange on the hydrodynamics, and this process is more intense, the higher the value of the parameter ξ. To illustrate quantitatively the effect brought about by the influence of ionic mass exchange on hydrodynamics, it is possible to compare the values of the concentrations, next to the anode, of the ions of the dissolving metal $C_1(0)$ and $C_1^*(0)$ determined by Eqn.(28) for a certain finite value of ξ and for $\xi = 0$ (that is under conditions where the solution "adheres" to the anode) respectively. Table 1 gives the values of these concentrations as functions of the current density for the cases of the dissolution of bivalent iron in 1 M and 5 M aqueous solutions of a 2–2-valent indifferent electrolyte.

Table 1. Dependence of the quantities $C_1(0)$ and $C_1^*(0)$ on the anodic current density and the concentration of the indifferent electrolyte.

I	$C_1^*(0)$	$C_1(0)$		I	$C_1^*(0)$	$C_1(0)$	
		$c_2^{(0)}$=1 M	$c_2^{(0)}$=5 M			$c_2^{(0)}$=1 M	$c_2^{(0)}$=5 M
0	0	0	0	10	5.83	4.29	1.74
1	0.833	0.802	0.716	15	8.38	5.46	1.77
5	3.21	3.06	1.56	20	10.9	6.30	1.79

Table 1 shows that the existence of a mass flux of solution to the anode surface decreases the concentration gradient of the ions of the dissolving metal next to the anode. Eqns.(28) to (31) lead to the predicted[38] effect of increase in the electric field intensity close to the anode compared with conditions in which dissolution is not accompanied by the transfer of the mechanical momentum of the solution. In fact, the extent of the increase in the intensity can be characterised by the parameter τ, given by

$$\tau = (d\psi/dy)_{x=0}/(d\psi^*/dy)_{x=0},$$

where $\psi^*(y)$ is the distribution of the potential, calculated without allowance for the influence of mass exchange on hydrodynamics. In the particular case where the charges of all the ions are equal ($z_1 = z_3 = -z_2 = z$), this distribution has the form[38]:

$$\psi^* = \frac{1}{z}\ln\left[1 + \frac{1}{2}I(1-y)\right].$$

It can readily be shown that the parameter τ is always greater than unity, and with an unrestricted increase in the current density it increases according to the law $\tau = \xi I$. Table 2 gives the numerical values of the parameter τ, calculated for the dissolution of nickel in a 2 *N* aqueous solution of a 2–2-valent indifferent electrolyte.

Table 2. Influence of the mass flux of the solution at a nickel surface dissolving in 2 *N* aqueous $CuSO_4$ solution on the electric field intensity next to the anode.

I	0	1	5	10	15	20	40
τ	1.00	1.12	1.41	1.80	2.21	2.68	4.70

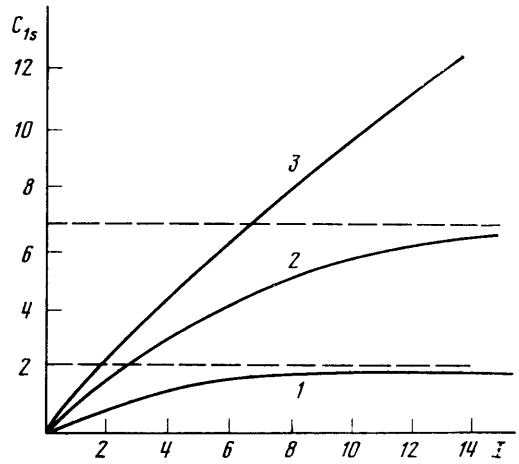

Figure 2. Concentration of nickel cations next to the anode during the dissolution of nickel in 5 *N* (curve *1*) and 1 *N* (curve *2*) aqueous $CuSO_4$ solutions; curve *3* was calculated without allowance for the influence of mass exchange on hydrodynamics; $C_{1S} = c_1^{(s)}/c_2^{(0)}$; $I = i\delta/z_1FD_1c_2^{(0)}$.

Eqn.(28) leads to the effect, described in the previous section, of "saturation" of the layer next to the anode by cations of the dissolving metal. Fig.2 gives graphs showing the change in the value of C_{1S} with change in the current density for the system $Ni^{2+}/CuSO_4$. These graphs were calculated with the assumption that the density of the solution is constant ($\rho = \rho^{(s)} = 1$ g cm^{-3}) for $\delta = 10^{-3}$ cm. According to the results obtained[32,38], the maximum deviation of the value of the concentration of nickel cations next to the anode is independent of the concentration of the indifferent electrolyte and amounts to ~9 M. Calculations show that for $\delta = 10^{-3}$ cm, the limiting value of the cation concentration can be achieved only at current densities greater than 100 A cm^{-2}. At current densities less than 10 A cm^{-2}, however, the concentration of nickel cations close to the anode, according to estimates carried out, does not exceed 0.8 M for $c_2^{(0)} = 1$ M, and 3.6 M for $c_2^{(0)} = 5$ M.

The physical factor responsible for the effect of "saturation" of the layer next to the anode is that at high anodic current densities, the rate of removal of cations from the anode by a convective transport mechanism, associated with the influence of mass exchange on hydrodynamics, becomes equal to the rate of accumulation of cations close to the anode as a result of dissolution.

3. Dissolution of the Wall of a Plane-Parallel Channel

The problem of intensive mass exchange between the wall of a circular or plane-parallel channel and a liquid flux moving along this channel is of interest from the viewpoint of the quantitative description of the elementary act of processes of dissolution and precipitation, which find extensive application in chemical and electrochemical technology. Problems of analogous type have been examined in the thermophysical literature[42–45] in connection with the analysis of systems in which gas is blown in or sucked out via a porous wall in order to intensify heat transfer. An analysis of this kind is applicable to osmotic membranes[46]: in all these cases, at the interphase boundary, there is a normal component of the hydrodynamic velocity, related either to the pressure drop on different sides of the permeable wall or to the diffusion flux of substance responsible for mass exchange. The difference between the problem of intensive electrochemical dissolution in a stream of electrolyte and the problem in which an inert medium is blown into the main stream lies in the fact that the mechanical momentum transferred to the liquid phase on dissolution is not independent of the conditions of mass exchange, as in the case where an inert medium is blown in, but is determined by the solution of the convective–diffusion problem.

A typical example of systems in which there is intense electrochemical dissolution of a metal in a stream of electrolyte is a plane-parallel channel, along which a concentrated electrolyte solution is flowing, where one of the walls of the channel (the anode) is dissolving under the influence of an electric current of high density. The dissolving surface in this case is not uniformly accessible for mass exchange, and the Nernst diffusion model is not applicable to it. Correct allowance for the contribution of convective mass transfer to the resulting rate of interphase mass exchange in this system is possible only by simultaneous solution of the system of equations of hydrodynamics and convective diffusion[47].

A plane-parallel channel $-a \leqslant x \leqslant a$ can be considered, along which a laminar flow of a solution of an indifferent electrolyte is moving in the positive direction of the z axis (the ions of this electrolyte do not take part in heterogeneous processes at the walls of the channel). It is assumed that the following quantities are given at the inlet to the channel (at $z = 0$): the average rate of flow of the electrolyte u_0, the pressure $p = p_0(x)$, the longitudinal pressure gradient $(\partial p/\partial z)_0 = \gamma_0$, and the average bulk concentration of the indifferent electrolyte c_0. It is also assumed that the wall $x = a$ consists of a metallic anode, which is dissolving under the influence of an electric current of density $i(z)$. Under real conditions, the average density $\bar{i}$ of the current flowing through the gap between the electrodes is usually fixed:

$$\bar{i} = \frac{1}{l}\int_0^l i(z)\,dz,$$

where l is the length of the channel.

It will be assumed that the concentration of the cations M^{z_1+} of the dissolving metal (z_1 is the charge of the cations) is equal to zero at the inlet to the channel, and that at the cathode surface ($x = -a$) the liquid adheres to the surface ($v_x = v_z = 0$) and there is no mass flux of the cations M^{z_1+}. It will also be assumed that in the dissolution process, the anode is kept in a fixed position (at $x = a$) by means of a special regulating device. In accordance with condition (4), the x component of the velocity of the liquid v_x at $x = a$, in the case of a stationary anode, is related to the current density i by the expression

$$v_x = -\frac{M_1 i}{z_1 \rho^{(s)} F}, \qquad (32)$$

where M_1 is the atomic mass of the dissolving metal, and $\rho^{(s)}$ the local density of the solution at $x = a$.

The steady-state conditions for the transfer of the momentum and mass of the metal cations within the channel is described by the system of Navier–Stokes, continuity, and convective diffusion equations. It is convenient to write this system of equations using the following dimensionless variables:

$$X = \frac{x}{a}, \quad Z = \frac{D_1 z}{a^2 u_0}, \quad V_x = \frac{a}{D_1} v_x, \quad V_z = \frac{v_z}{u_0},$$
$$P = \frac{D_1 p}{\mu u_0^2}, \quad C = \frac{c}{c_0}, \quad \mathrm{Re} = \frac{a u_0 \rho}{\mu}, \quad \beta = \frac{D_1}{a u_0}.$$

Here, c is the local concentration of ions of the dissolving metal, and μ the dynamic viscosity of the solution. In dimensionless variables, the system of transfer equations has the form

$$\beta^3 \mathrm{Re}\left\{V_x \frac{\partial V_x}{\partial X} + V_z \frac{\partial V_x}{\partial Z}\right\} = -\frac{\partial P}{\partial X} + \beta^3\left\{\frac{\partial^2 V_x}{\partial X^2} + \beta^2 \frac{\partial^2 V_x}{\partial Z^2}\right\},$$
$$\beta \mathrm{Re}\left\{V_x \frac{\partial V_z}{\partial X} + V_z \frac{\partial V_z}{\partial Z}\right\} = -\frac{\partial P}{\partial Z} + \frac{\partial^2 V_z}{\partial X^2} + \beta^2 \frac{\partial^2 V_z}{\partial Z^2},$$
$$\frac{\partial V_x}{\partial X} + \frac{\partial V_z}{\partial Z} = 0,$$
$$V_x \frac{\partial C}{\partial X} + V_z \frac{\partial C}{\partial Z} = \frac{\partial^2 C}{\partial X^2} + \beta^2 \frac{\partial^2 C}{\partial Z^2}.$$

This system does not take account of the influence of the gravitational field.

The mathematical analysis of the problem is simplified considerably by examining a region of the channel separated by a sufficient distance from the inlet section $z = 0$; it can be shown that for the region $z \geqslant a^2 u_0/D_1$, where D_1 is the diffusion coefficient of the ions of the dissolving metal, it is possible to omit terms containing second derivatives with respect to the coordinate Z in the original system of transfer equations. Moreover, according to condition (32), the x component of the velocity can be represented in the form

$$v_x = \frac{\bar{i} M_1}{z_1 \rho^{(s)} F} V_x = \beta \varepsilon u_0 V_x,$$

where $\varepsilon = a\bar{i}M_1/z_1 F \rho^{(s)} D_1$.

The boundary conditions for this system are:

$$V_x = -(i/\bar{i}) = -W(Z) \quad \text{for } X = 1; \qquad (33)$$

$$V_z = 0 \text{ for } X = \pm 1; \; V_x = 0 \text{ for } X = -1; \qquad (34)$$

$$P = P_0' = \frac{D_1 p_0}{\mu u_0^2}, \quad \frac{\partial P}{\partial Z} = \Gamma_0 = \frac{a\gamma_0}{\mu} \quad \text{for } Z = 0; \qquad (35)$$

$$C = 0 \text{ for } Z = 0; \qquad (36)$$

$$\frac{\partial C}{\partial X} = 0 \text{ for } X = -1; \qquad (37)$$

$$\frac{\partial C}{\partial X} = \frac{a\bar{i}}{z_1 F D_1 c_0}\left(1 - \frac{M_1 c_0}{\rho^{(s)}} C_s\right) \quad \text{for } X = 1. \qquad (38)$$

Since by definition[18] the current density i is related to the diffusion flux of the cations M^{z_1+} by the expression

$$j_1^{(s)} = -D_1\left(\frac{\partial c}{\partial x}\right)_s = -\frac{i}{z_1F}\left(1-\frac{M_1c_s}{\rho^{(s)}}\right) = \frac{\rho^{(s)}D_1}{aM_1}V_x^{(s)}\left(1-\frac{M_1c_s}{\rho^{(s)}}\right),$$

it follows that conditions (33) and (38) are essentially identical and give the relationship between the velocity and concentration profiles.

The parameter β is inversely proportional to the Peclet number, and for many systems of practical interest it is negligible compared with unity. For example, for the flow of pure water at an average velocity of 1 m s^{-1} along a channel of width 1 mm, this parameter is of the order of 10^{-6}. It is therefore possible to neglect terms containing the parameter β in the original system of equations, and to write this system in the following simplified form:

$$\frac{\partial P}{\partial X} = 0,\ \frac{\partial P}{\partial Z} = \frac{\partial^2 V_z}{\partial X^2},\ \frac{\partial V_x}{\partial X} + \frac{\partial V_z}{\partial Z} = 0,$$
$$V_x\frac{\partial C}{\partial X} + V_z\frac{\partial C}{\partial Z} = \frac{\partial^2 C}{\partial X^2}. \qquad (39)$$

To simplify the problem further and obtain a solution in analytical form, it will also be assumed that the parameter ε is small.

The numerical value of this parameter depends to a significant extent on the average anodic current density $\bar{i}$. Thus in the case of the dissolution of bivalent iron for a width of the gap between the electrodes equal to 1 mm, the parameter ε satisfies the relationship $\varepsilon \cong 0.3\,\bar{i}$, where the current density is expressed in units of A cm^{-2}; this means that for $\bar{i} < 1$ A cm^{-2}, the parameter ε can in fact be regarded as small. By representing the functions being sought in the form of the expansions

$$V_x = V_x^{(0)} + \varepsilon V_x^{(1)} + \ldots$$
$$V_z = V_z^{(0)} + \varepsilon V_z^{(1)} + \ldots$$
$$P = P^{(0)} + \varepsilon P^{(1)} + \ldots$$
$$C = C^{(0)} + \varepsilon C^{(1)} + \ldots$$

and using the boundary conditions (33)–(38), it is possible to obtain in the zeroth approximation the following solution of the hydrodynamic problem:

$$P^{(0)} = P_0^{(0)} + \Gamma_0^{(0)}Z,\ V_x^{(0)} = 0,\ V_z^{(0)} = -\frac{1}{2}\Gamma_0^{(0)}(1-X^2), \qquad (40)$$

where the quantities $P_0^{(0)}$ and $\Gamma_0^{(0)}$ are the first nonzero terms of the expansions

$$P_0 = P_0^{(0)} + \varepsilon P_0^{(1)} + \ldots,\quad \Gamma_0 = \Gamma_0^{(0)} + \varepsilon\Gamma_0^{(1)} + \ldots$$

Equating the terms linear with respect to the parameter ε in Eqns.(39) and in the boundary conditions (33)–(35) gives

$$P^{(1)} = P_0^{(1)} + \Gamma_0^{(1)}Z - \frac{3}{2}\int_0^Z d\xi \int_0^\xi W(\xi')\,d\xi',$$
$$V_x^{(1)} = -\frac{1}{2}W(Z)\left(1+\frac{3}{2}X-\frac{1}{2}X^3\right), \qquad (41)$$
$$V_z^{(1)} = (1-X^2)\left[\frac{3}{4}\int_0^Z W(\xi)\,d\xi - \frac{1}{2}\Gamma_0^{(1)}\right].$$

Analysis of Eqns.(41) shows that, for sufficiently large values of Z at least, the existence of the normal component of the hydrodynamic velocity at the surface of the anode leads to an increase in the velocity of the flux in the direction Z.

With the assumptions made, the concentration field is described by the equations

$$V_z^{(0)}\frac{\partial C^{(0)}}{\partial Z} - \frac{\partial^2 C^{(0)}}{\partial X^2} = 0, \qquad (42)$$

$$V_z^{(0)}\frac{\partial C^{(1)}}{\partial Z} - \frac{\partial^2 C^{(1)}}{\partial X^2} = -V_x^{(1)}\frac{\partial C^{(0)}}{\partial X} - V_z^{(1)}\frac{\partial C^{(0)}}{\partial Z} \qquad (43)$$

with boundary conditions

$$C^{(0)} = 0,\ C^{(1)} = 0 \quad \text{for } Z = 0; \qquad (44)$$

$$\frac{\partial C^{(0)}}{\partial X} = 0,\ \frac{\partial C^{(1)}}{\partial X} = 0 \quad \text{for } X = -1; \qquad (45)$$

$$\frac{\partial C^{(0)}}{\partial X} = J_0(Z),\ \frac{\partial C^{(1)}}{\partial X} = -C_s^{(0)}(Z) \quad \text{for } X = 1, \qquad (46)$$

where $J_0(Z) = a\bar{i}W(Z)/z_1FD_1c_0$.

The function $J_0(Z)$ in the general case cannot be regarded as small, since for any fixed value of Z it is proportional to the product of two parameters, ε and $\rho^{(s)}/M_1c_0$. The latter, even for extremly concentrated solutions (1 M and above), may be significantly greater than unity.

The extreme problems defined by Eqns.(42)–(46) are solved by the standard methods of mathematical physics. The solution obtained is very cumbersome, however, and it is not appropriate to give it here. Nevertheless, it is appropriate to analyse the asymptotic behaviour of the concentration profile for large values of the longitudinal coordinate Z under conditions of uniform distribution of the current density at the anode (J_0 = const). Using the published method[43], the solution of Eqn.(42) can be sought in the form

$$C^{(0)} = A^{(0)}Z + B^{(0)}(X), \qquad (47)$$

where $A^{(0)}$ and $B^{(0)}(X)$ are the unknown constant and function. It can readily be seen that the first boundary condition (44) cannot be satisfied by Eqn.(47). Thus the boundary condition (44) is replaced by the condition

$$J_0Z = \int_{-1}^{1} C^{(0)}V_z^{(0)}\,dX. \qquad (48)$$

This condition means that in the zeroth approximation with respect to the parameter ε, the quantity of metal cations entering the channel in unit time as a result of the dissolution of its wall is equal to the quantity of cations transferred by the flux through a given transverse cross section in the same time interval.

Substituting Eqn.(47) in Eqn.(42), integrating the latter twice with respect to X, and using the boundary conditions (45), (46), and (48) give:

$$C^{(0)} = \frac{1}{2}J_0\left\{-\frac{3}{\Gamma_0^{(0)}}Z + X + \frac{3}{4}X^2\left(1-\frac{1}{6}X^2\right) - \frac{117}{280}\right\}. \qquad (49)$$

Sine $\Gamma_0^{(0)} < 0$, the concentration $C^{(0)}$ increases linearly with distance from the channel inlet.

The correction to the concentration, associated with the existence of the normal component of the hydrodynamic velocity at the anode surface, can be found analogously. For large values of the argument Z, this correction can be sought in the form

$$C^{(1)} = A^{(1)}Z^2 + B^{(1)}(X)\,Z + G^{(1)}(X). \qquad (50)$$

Here, instead of the second boundary condition (44), it is necessary to use the condition

$$-C_s^{(0)}Z = \int_{-1}^{1}(C^{(0)}V_z^{(1)} + C^{(1)}V_z^{(0)})\,dX, \qquad (51)$$

which has the same physical significance as condition (48), but is written in a higher linear approximation with respect to the parameter ε.

Simple but cumbersome operations give the expression

$$C^{(1)} = -\frac{9}{4}\frac{J_0}{(\Gamma_0^{(0)})^2}Z^2 + \frac{3}{4}\frac{J_0}{\Gamma_0^{(0)}}Z\left\{\frac{3}{4}X^2\left(1-\frac{1}{6}X^2\right)+X-\frac{39}{280}\right\}+ \\ +\frac{1}{64}J_0\left\{-\frac{1}{8}X^8+\frac{3}{2}X^6-\frac{4}{5}X^5-\frac{669}{140}X^4-12X^3- \right. \\ \left. -\frac{443}{70}X^2+\frac{568}{35}X+\frac{519919}{333400}\right\}. \quad (52)$$

From this expression it follows that at a sufficient distance from the channel inlet, the additional convective transfer induced by interphase mass exchange leads to a decrease in the concentration of the ions of the dissolving metal next to the anode. This is illustrated by Fig.3, where the broken line corresponds to the solution of the problem of ionic mass transfer with allowance for the convective flux described above.

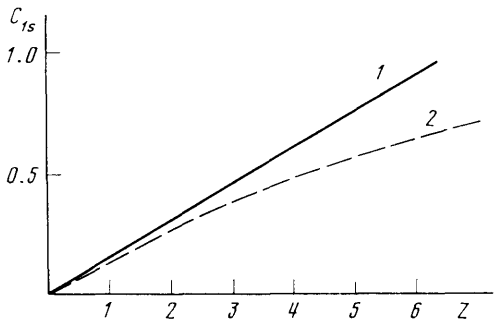

Figure 3. Theoretical profiles of the concentration of the cations of a dissolving metal next to the anode as a function of distance from the inlet to the gap between the electrodes at a given anodic current density: *1*) assuming that the liquid adheres to the anode surface; *2*) with allowance for the normal component of the hydrodynamic velocity, induced by the mass exchange.

The above analysis confirms the results obtained in the two previous sections for the dissolution of surfaces uniformly accessible with respect to mass exchange. They lead to the conclusion, important in practice, that it is possible to achieve higher current densities under conditions in which the concentration of the cations of the dissolving metal cannot, for various reasons, exceed a particular value.

IV. INFLUENCE OF DIFFUSION OF HYDRODYNAMICS UNDER CONDITIONS OF MASS TRANSFER TO THE SURFACE OF A ROTATING DISC

A disc rotating in a laminar liquid represents a typical example of a surface uniformly accessible with respect to mass exchange. Surfaces of this kind are often examined using the Nernst diffusion model[35], which makes it possible to obtain clear and simple expressions for describing the kinetics of mass transfer. In many cases, however, this model cannot reflect the quantitative aspect of the relationship between the processes of mass and momentum transfer. The reason for this is that convective mass transfer, which is essentially not included in the equations postulated by this model, not only leads to a change in the dependence of the thickness of the diffusion layer on the transport properties of the solution but also leads to a change in the actual type of mass transfer equations. For this reason, attempts have been made to develop a method which on the one hand would make it possible to take correct account of the contribution of convective mass transfer to the resulting rate of interphase mass exchange, and on the other hand could be used to estimate the accuracy of the results given by the Nernst model.

The equations of hydrodynamics for a rotating disc with allowance for the mass flux, induced by mass exchange, and the variable transport properties, have been formulated and solved for various specific cases[10–13,16,43,44,45]. The most general method of solution, based on a procedure involving "splicing" of the asymptotic expansions for the velocity field, was developed in Refs.13 and 16. The application of this method to the case of mass exchange limited by the resistance of convective diffusion in a liquid phase for large Schmidt numbers is examined below.

The Navier–Stokes equations are written in a cylindrical system of coordinates with a polar axis x passing through the centre of the disc. The property of uniform accessibility of the surface of the disc with respect to diffusion makes it possible to assume that the density ρ and kinematic viscosity ν of the solution, which depend on the concentration of the substance responsible for mass exchange, are functions only of the coordinate x. The coordinate x is replaced by the new independent variable ζ, defined by the expression

$$\zeta = \sqrt{\omega}\int_0^x \frac{dx'}{\sqrt{\nu(x')}},$$

where ω is the angular velocity of rotation of the disc. The distributions of the velocities v_r, v_ϑ, and v_x are represented in the form

$$v_r = r\omega F(\zeta),\quad v_\vartheta = r\omega G(\zeta),\quad v_x = \sqrt{\nu\omega}\,H(\zeta).$$

Substitution of these expressions in the system of Navier–Stokes equations, and simple transformations, give[49]:

$$F^2 - G^2 + HF' - F'' = F'\left(\ln\sqrt{\frac{\rho^2\nu}{\rho_0^2\nu_0}}\right)', \\ 2FG + HG' - G'' = G'\left(\ln\sqrt{\frac{\rho^2\nu}{\rho_0^2\nu_0}}\right)', \quad (53) \\ 2F + H' = -H\left(\ln\sqrt{\frac{\rho^2\nu}{\rho_0^2\nu_0}}\right)',$$

where ρ_0 and ν_0 are the values of the density and viscosity at a distance from the disc (as $x \to \infty$); the primes denote the corresponding derivatives with respect to ζ. Since the transfer equations do not contain derivatives of the function $H(\zeta)$ higher than the first derivative, it follows that one boundary condition is sufficient for the determination of this function. With allowance for the mass flux of the solution at $x = 0$, due to the movement of the centre of mass of the liquid phase as a consequence of mass exchange (see Eqn.(4)), the boundary conditions for the functions F, G, and H take the form

$$F(0) = 0,\ G(0) = 1,\ H(0) = -\sigma^3 M\left(\frac{\partial c}{\partial\zeta}\right)_s \frac{1}{\rho^{(s)} - Mc^{(s)}}, \quad (54)$$

$$F(\infty) = 0,\ G(\infty) = 0. \quad (55)$$

Here, $\sigma = (D/\nu_0)^{1/3}$, M and D are the molecular mass and diffusion coefficient of the substance being transferred, c is its local concentration, and the symbol "s" refers to the conditions at the surface of the disc.

The boundary conditions (54) show that to solve the hydrodynamic problem it is necessary to know the distribution of concentration close to the surface of the disc. At the same time, the equation of convective diffusion, which in the case of stationary conditions of mass transfer has the form

$$(\mathbf{u}, \nabla c) = D \operatorname{div} \nabla c, \qquad (56)$$

contains the hydrodynamic velocity **v**, and therefore cannot be solved independently of Eqns.(53). To find the simultaneous solution of the problem of the transfer of mass and momentum close to the rotating disc it is necessary to substitute the boundary conditions for the concentration field. It is assumed that the values of the concentration at the surface of the disc ($c^{(s)}$) and in the bulk of the solution (c_0) are given. In the case of large Schmidt numbers ($Sc = \nu_0/D \gg 1$), Eqn.(56) can be simplified by making use of the condition that the parameter σ be small. If this parameter is small compared with unity, it can be shown[49] that the concentration c depends only on the single coordinate ξ. Eqn.(56) then takes the form

$$H(\zeta)\frac{dc}{d\zeta} = \sigma^3 \frac{d^2 c}{d\zeta^2},$$

which, with allowance for the above boundary conditions, gives:

$$c(\zeta) = c^{(s)} - (c^{(s)} - c_0)\int_0^{\zeta} \exp\left\{\sigma^{-3}\int_0^{\zeta'} H(\zeta'')\,d\zeta''\right\} d\zeta' \Big/ \int_0^{\infty} \exp\left\{\sigma^{-3}\int_0^{\zeta'} H(\zeta'')\,d\zeta''\right\} d\zeta'. \qquad (57)$$

The determination of the derivative $(dc/d\zeta)_S$ from Eqn.(57) gives for the third boundary condition (54):

$$H(0) = \frac{\sigma^3 (c^{(s)} - c_0) M}{\rho^{(s)} - Mc^{(s)}} \left\{\int_0^{\infty} \exp\left[\sigma^{-3}\int_0^{\zeta} H(\zeta')\,d\zeta'\right] d\zeta\right\}^{-1}. \qquad (58)$$

The analytical solution of the system of equations (53) can be obtained by the method of "spliced" asymptotic expansions, which represent a generalisation of the boundary layer method and has been described in detail[50]. According to this method, the functions F, G, and H are sought in the form of the following expansions:

$$F = F_0(\zeta) + \sigma F_1(y) + \ldots,$$
$$G = G_0(\zeta) + \sigma G_1(y) + \ldots,$$
$$H = H_0(\zeta) + \sigma^2 H_1(y) + \ldots,$$

where $y = \zeta/\sigma$, and the functions F_0, G_0, and H_0 represent the solution of the hydrodynamic problem in the absence of mass exchange, that is for $H(0) = 0$. For $\zeta \ll 1$, these functions are given by the expressions[51]:

$$F_0 = a\zeta,\ G_0 = 1 - b\zeta,\ H_0 = -a\zeta^2,\ a = 0.51,\ b = 0.62.$$

By substituting the expansions introduced above in Eqn. (53) and equating terms with identical powers of σ, it is possible to obtain equations for the functions F_1, G_1, and H_1. These functions should satisfy the following boundary conditions for $y = 0$:

$$F_1(0) = 0,\ G_1(0) = 0,\ H_1(0) = \frac{(a/3)^{1/3} M (c^{(s)} - c_0)}{\Gamma\left(\frac{4}{3}\right)(\rho^{(s)} - Mc^{(s)})},$$

where $\Gamma(4/3)$ is the gamma function. As $y \to \infty$, the "splicing" conditions should be satisfied:

$$\lim_{y\to\infty}[F_0(\sigma y) + \sigma F_1(y)] = a\zeta,$$
$$\lim_{y\to\infty}[G_0(\sigma y) + \sigma G_1(y)] = 1 - b\zeta,$$
$$\lim_{y\to\infty}[H_0(\sigma y) + \sigma^2 H_1(y)] = -a\zeta^2.$$

Simple mathematical operations give the following result[16]: with an accuracy corresponding to terms of order σ^2, the function $H(y)$ is given by

$$H(y) = \sigma^2\left\{H_1(0) - 2a\rho_0\int_0^y\int_0^{y'} \frac{\rho(y')\sqrt{\nu(y')}}{\rho(y'')\sqrt{\nu(y'')}}\,dy''\,dy'\right\}. \qquad (59)$$

Substitution of Eqn.(59) in Eqn.(57) gives the solution to the problem of convective mass transfer. Since the quantity $H_1(0)$ is proportional to the difference $\Delta c = c^{(s)} - c_0$, that is the driving force of mass transfer, it follows from Eqns.(57) and (59) that under the conditions of intensive mass exchange, the rate of mass transfer is not a linear function of the driving force. When the values of the difference Δc are not too large, the diffusion flux $j^{(s)} = -D(dc/dx)_S$ can be represented, using Eqns.(57) and (59), as a power series in Δc. In the particular case where the physical properties are constant ($\rho = \rho_0 = \text{const}$, $\nu = \nu_0 = \text{const}$), this series has the form[13]:

$$j^{(s)} = \frac{(a/3)^{1/3}}{\Gamma\left(\frac{4}{3}\right)} MD^{2/3}\nu_0^{-1/6}\sqrt{\omega}\,\Delta c\left(1 - \frac{0.57M\Delta c}{\rho_0 - Mc^{(s)}} + \ldots\right).$$

The resulting rate of mass transfer w is determined by the sum of the contributions of the diffusion and convective mechanisms of mass transfer:

$$w = j^{(s)} + Mc^{(s)}v_x^{(s)}.$$

Use of the expressions given above for $j^{(s)}$ and $v_x^{(s)}$ gives, with an accuracy corresponding to terms quadratic in the difference Δc:

$$w = 0.62MD^{2/3}\nu_0^{-1/6}\sqrt{\omega}\,\Delta c\,\frac{\rho_0 - 0.57M\Delta c}{\rho_0 - Mc^{(s)}}. \qquad (60)$$

In the particular case where $c_0 = 0$, Eqn.(60) becomes

$$w = 0.62MD^{2/3}\nu_0^{-1/6}\sqrt{\omega}\,\Delta c\left(1 + 0.43\frac{M\Delta c}{\rho_0}\right).$$

It follows from Eqn.(60) that the existence of additional convective movement, induced by mass exchange, leads, for a given value of the driving force of mass transfer Δc, to an increase in the rate of interphase mass exchange. A measure of this increase is provided by the ratio $(\rho_0 - 0.57M\Delta c)/(\rho_0 - Mc^{(s)})$.

V. MUTUAL INFLUENCE OF THE COMPONENTS OF A GASEOUS MIXTURE ON CONDENSATION FROM A TURBULENT STREAM

Convective fluxes induced by mass exchange may also arise in systems with mass transfer in multicomponent gaseous mixtures (for example in condensation, evaporation, or rectification). These are usually called "Stefan" fluxes[2]. When Stefan fluxes are present, there is a significant change in the nature of the interaction between the components being transferred in gaseous mixtures, since this interaction may take place through the velocity field, modified by mass exchange. To illustrate this effect, it is possible to examine a multicomponent gaseous phase containing components which differ sharply in their molecular transport properties. Since the transfer of all components of this system takes place under identical hydrodynamic conditions, it is possible in principle, by obtaining quantitative information on the magnitude of the individual mass fluxes, to establish an unambiguous correlation between the effective coefficients of mass transfer for each component of the mixture and the molecular properties of all the other components. This correlation represents a

measure of the mutual influence of the substances being transported[52].

The process involved in the condensation of one component from a fully developed turbulent stream of a three-component ideal gaseous mixture on to the surface of a planar hard wall can be examined. The molecular properties of the component condensing will be denoted by the symbol "1". It will be assumed that the rate of condensation is determined entirely by the resistance of the gaseous phase. It will also be assumed that the surface of the film of condensate is uniformly accessible with respect to mass transfer and that the process of interphase mass exchange takes place under stationary conditions, that is that the concentration of each component of the gaseous phase at any fixed distance from the surface of the film is independent of time. With these conditions, the equation of convective mass transfer for any ith component of the mixture will have the following form:

$$\frac{d}{dx}\left(j_i - M_i D_t \frac{dc_i}{dx}\right) + M_i(v - V)\frac{dc_i}{dx} = 0; \quad i = 1, 2, 3. \tag{61}$$

Here, j_i is the molecular-diffusion flux of the ith component, M_i its molecular mass, c_i the molar concentration, $D_t = D_t(x)$ the coefficient of turbulent diffusion, $v = v(x)$ the velocity of the turbulent stream, averaged over the period of turbulent pulsations, and V the velocity of translational movement of the surface of the film of condensate relative to the solid wall, that is the linear velocity of growth of the condensate film. The coordinate x is measured from the surface of the film in the direction of the gaseous phase.

The relationship between the fluxes j_i and the gradients of the concentrations c_i in the case of ideal mixtures is described by the familiar Stefan–Maxwell equations. In the particular case when one of the inert, that is non-condensing, components of the mixture (for example component 3) is present in excess and it can be assumed that the conditions $c_1 \ll c_3$ and $c_2 \ll c_3$ are fulfilled, there is no direct diffusion interaction between components 1 and 2, determined by the laws of the thermodynamics of irreversible processes. In this case, the simple expressions corresponding to Fick's first law are applicable for the fluxes j_1 and j_2:

$$j_1 = -D_{13}M_1\frac{dc_1}{dx}, \quad j_2 = -D_{23}M_2\frac{dc_2}{dx}.$$

Here, D_{13} and D_{23} are the coefficients of mutual molecular diffusion in the corresponding binary mixtures.

The above-mentioned particular case of an excess of one of the inert components of the mixture will subsequently be examined, and it will be assumed that the mass transfer of components 1 and 2 takes place in a turbulent diffusion boundary layer $0 \leq x \leq d$, beyond which the concentrations of the components being transferred are distributed uniformly:

$$c_1 = c_1^{(0)}, \; c_2 = c_2^{(0)} \text{ for } x \geqslant d. \tag{62}$$

On the surface of the film of condensate, the total mass flux of the component condensing should be equal to the rate of interphase mass exchange. If the latter is denoted by I and it is assumed that the fluxes directed from the surface of the film in the direction of the gaseous phase are positive, the boundary condition for component 1 at $x = 0$ will have the form:

$$\frac{1}{M_1}j_1^{(s)} + c_1^{(s)}(v^{(s)} - V) = -I, \tag{63}$$

where the symbol "s", as before, refers to the values of the liquid–gas interface. The boundary condition for the inert component 2 is formulated analogously:

$$\frac{1}{M_2}j_2^{(s)} + c_2^{(s)}(v^{(s)} - V) = 0. \tag{64}$$

The rate of convective mass transfer, brought about by the Stefan flux, is determined by Eqn.(4) given above:

$$v^{(s)} = V + \frac{j_1^{(s)}}{\rho^{(s)} - M_1 c_1^{(s)}}.$$

Allowance for Eqns.(63) and (64) gives the following boundary conditions for the diffusion fluxes:

$$j_1^{(s)} = -M_1 I\left(1 - \frac{M_1 c_1^{(s)}}{\rho^{(s)}}\right), \tag{65}$$

$$j_2^{(s)} = \frac{M_1 M_2 c_2^{(s)}}{\rho^{(s)}} I. \tag{66}$$

It may be noted that, according to Eqn.(66), the diffusion flux of the inert component at the interphase boundary is non-zero. The physical reason for this is the existence of a non-zero normal component of the rate of movement of the centre of mass of the gaseous mixture at the interphase boundary: this component, in the case where the surface of the film is not permeable to the inert component, brings about diffusion of this component in the direction away from the surface.

To analyse Eqns.(61) it is necessary to obtain the form of the relationship $D_t(x)$ more accurately. According to general theoretical considerations[53] and published[54–58] experimental data on transport phenomena in turbulent streams, the intensity of convective mass transfer brought about by turbulent pulsations of the velocity field decreases with decrease in the distance from the solid interphase boundary approximately according to a power law with exponent lying in the range between 3 and 4. In the case of a mobile interface (liquid–gas and liquid–liquid), the effect of damping of the turbulent pulsations is much less marked: the role of stabilising factor bringing about damping in this case is played by the interphase surface tension. Experimental data[59–62] indicate that the decrease in the effective coefficient of turbulent diffusion as the mobile interphase boundary is approached, as in the case of a solid wall, takes place according to a power law, but with a smaller exponent (equal to approximately two). If allowance is made for the fact[36] that beyond a viscous hydrodynamic sub-layer of thickness δ_0 (in the range $x > \delta_0 \cong \nu/u^*$, where u^* is the characteristic velocity of turbulent pulsations in the direction perpendicular to the interphase boundary), the relationship $D_t(x) \sim x$ should be fulfilled, it is possible to write for $D_t(x)$ the following interpolation equation:

$$D_t(x) = \frac{\varkappa_1 u^* x^n}{x^{n-1} + \varkappa_2 \delta_0^{n-1}}, \tag{67}$$

where $\varkappa_1$, $\varkappa_2$, and n are empirical constants.

Estimation of the relative contribution of the terms of Eqn. (61) responsible for different transfer mechanism shows that in the layer directly adjoining the surface of the film and having a thickness δ_i defined by the expression

$$D_{i3} = D_t(\delta_i) = \frac{\varkappa_1 u^* \delta_i^n}{\delta_i^{n-1} + \varkappa_2 \delta_0^{n-1}}, \tag{68}$$

turbulent mass transfer does not play a significant role, and the rate of convective transfer brought about by the averaged velocity field in a direction perpendicular to the film surface can be approximated with a high degree of accuracy by the velocity of the Stefan flux (4). Thus within the range $0 \leq x \leq \delta_i$, the mass transfer equations (61) can be simplified considerably and written in the form

$$\frac{d}{dx}\left(j_i + \frac{M_i c_i j_1^{(s)}}{\rho^{(s)} - M_1 c_1^{(s)}}\right) = 0; \quad i = 1, 2.$$

With allowance for the boundary conditions (65) and (66), the first integral of these equations has the form

$$\frac{dc_i}{dx} = \frac{M_1 I}{M_i D_{i3}}\left(\delta_{i1} - \frac{M_i c_i}{\rho^{(s)}}\right),$$

where δ_{i1} is the Kronecker symbol. Subsequent integration gives the expression

$$c_i = \frac{1}{M_i}\rho^{(s)}\delta_{i1} + A_1^{(i)} \exp\left(-\frac{M_1 I x}{\rho^{(s)} D_{13}}\right); \quad i = 1, 2, \tag{69}$$

where $A_1^{(i)}$ represents the constants of integration.

In the ranges $\delta_i \leq x \leq d$, molecular diffusion plays no part, and convective mass transfer is brought about chiefly by turbulent pulsations, so that the transfer equations (61) can be approximated as follows:

$$\frac{d}{dx}\left\{D_t(x)\frac{dc_i}{dx}\right\} = 0; \quad i = 1, 2.$$

With allowance for Eqn.(68) and the boundary conditions (62), the following concentration profiles are obtained for the regions $\delta_i \leq x \leq d$:

$$c_i = c_i^{(0)} + \frac{A_2^{(i)}}{\varkappa_1 u^*}\left\{\ln\left(\frac{x}{d}\right) + \frac{\varkappa_2 \delta_0^{n-1}}{n-1}\left(\frac{1}{d^{n-1}} - \frac{1}{x^{n-1}}\right)\right\}, \tag{70}$$

where $A_2^{(i)}$ represents arbitrary constants, which can be found from the conditions for smooth linking of the profiles (69) and (70) at $x = \delta_i$:

$$\left(\frac{dc_i}{dx}\right)_{\delta_i - 0} = \left(\frac{dc_i}{dx}\right)_{\delta_i + 0}, \quad (c_i)_{\delta_i - 0} = (c_i)_{\delta_i + 0}.$$

Simple calculations give the following result:

$$A_1^{(i)} = \left(c_1^{(0)} - \rho^{(s)}\frac{\delta_{i1}}{M_i}\right)\exp\left(\frac{M_1 I \delta_1}{\rho^{(s)} D_{i3}}\right) \times$$
$$\times\left\{1 + \frac{M_1 I}{\rho^{(s)}\varkappa_1 u^*}\left[\ln\left(\frac{\delta_i}{d}\right) - \frac{\varkappa_2 \delta_0^{n-1}}{n-1}\left(\frac{1}{\delta_i^{n-1}} - \frac{1}{d^{n-1}}\right)\right]\right\}^{-1}. \tag{71}$$

Eqns.(69) and (71) can be used to obtain the relationship between the rate of condensation I and the concentration of the component condensing on the surface of the film $c_1^{(s)}$ (if condensation is to take place, this concentration must be equal to the saturation concentration):

$$\frac{c_1^{(s)} - \rho^{(s)}/M_1}{c_1^{(0)} - \rho^{(s)}/M_1} = \exp\left(\frac{M_1 I \delta_1}{\rho^{(s)} D_{13}}\right) \times$$
$$\times\left\{1 + \frac{M_1 I}{\rho^{(s)}\varkappa_1 u^*}\left[\ln\left(\frac{\delta_1}{d}\right) - \frac{\varkappa_2 \delta_0^{n-1}}{n-1}\left(\frac{1}{\delta_1^{n-1}} - \frac{d}{d^{n-1}}\right)\right]\right\}^{-1}. \tag{72}$$

If the molecular masses of all the components of the mixture are identical and $\delta_1 = d$ (that is within the framework of the film model), Eqn.(72) becomes the familiar Stefan equation[2] for the rate of condensation in the presence of non-condensing gases.

The nature of the "hydrodynamic" interaction between components 1 and 2 can be analysed by comparing the surface ($x = 0$) values of the concentration of the inert component 2 in the presence and absence of condensation. According to Eqns.(69) and (71), the surface concentration of component 2 is given by

$$c_2^{(s)} = c_2^{(0)} \exp\left(\frac{M_1 I \delta_2}{\rho^s D_{23}}\right) \cdot \left\{1 + \frac{M_1 I}{\rho^{(s)}\varkappa_1 u^*}\left[\ln\left(\frac{\delta_2}{d}\right) - \frac{\varkappa_2 \delta_0^{n-1}}{n-1}\left(\frac{1}{\delta_2^{n-1}} - \frac{1}{d^{n-1}}\right)\right]\right\}^{-1} \tag{73}$$

and increases sharply with increase in the rate of condensation (in the absence of condensation, that is for $I = 0$, the concentration profile $c_2(x)$ would be completely uniform). It follows from Eqns.(72) and (73) that the driving force for the transfer of component 2 from the surface of the film into the depth of the gaseous phase (proportional to the difference $c_2^{(s)} - c_2^{(0)}$) depends to a significant extent on the molecular transport properties of the condensing component 1. The nature of this relationship can be analysed for the case of the condensation of ethanol from a vapour–air mixture, formed during the convective drying of the polymer carboxymethylcellulose. The main components of the mixture are ethanol ($C_1^{(0)} = 0.1$), oxygen ($C_2^{(0)} = 0.1$), and nitrogen ($C_3^{(0)} = 0.8$). The concentrations $C_i^{(0)}$ are given in mole fractions. The temperature of the surface on which condensation takes place is 20 °C. This temperature corresponds to a saturation concentration $C_1^{(s)} = 0.058$ at atmospheric pressure[63].

The Reynolds number Re for the stream of vapour–gas mixture is 10^4 for an average linear velocity $u_0 = 10$ m s^{-1}. The coefficients of mutual diffusion of the components of the mixture are (m^2 s^{-1}): $D_{13} = 0.10 \times 10^{-4}$, $D_{23} = 0.15 \times 10^{-4}$, $D_{12} = 0.10 \times 10^{-4}$. The rate of condensation I and the difference $c_2^{(s)} - c_2^{(0)}$ were calculated using Eqns.(72) and (73) for the chosen real mixture and four hypothetical mixtures. The only difference between the latter and the real mixture was that the coefficient D_{13} was given the arbitrary values 0.06, 0.08, 0.12, and 0.14 cm^2 s^{-1}. The Schmidt numbers in all cases had an order of magnitude of unity (from 1 to 2.5). In the calculations, the parameter n was put equal to 2.

Table 3 gives the calculated values of the rate of condensation I, the concentration $c_2^{(s)}$, and the driving force of mass transfer $c_2^{(s)} - c_2^{(0)}$.

Table 3. Dependence of the kinetic characteristics of the transfer of an inert component on the coefficient of molecular diffusion of a condensing component.

D_{13}, cm^2 s^{-1}	0.06	0.08	0.10	0.12	0.14
$10^4 I$, kg mole m^{-2} s^{-1}	4.8	5.5	6.0	6.3	6.3
$10^3 c_2^{(s)}$, kg mole m^{-3}	4.73	4.77	4.80	4.82	4.84
$10^3(c_2^{(s)} - c_2^{(0)})$, kg mole m^{-3}	0.27	0.31	0.34	0.36	0.38

Table 3 shows that the difference $c_2^{(s)} - c_2^{(0)}$ increases approximately linearly with increase in the diffusion coefficient D_{13}.

VI. ELECTRODEPOSITION OF METALS FROM CONCENTRATED SALT SOLUTIONS

In the cathodic deposition of metals (in electroplating, the development of electrochemical information transformers, etc.) it is often necessary to predict the magnitude of the limiting diffusion current with respect to the discharging metal cations. This calculation is also of interest for the determination of the mechanism of the electrochemical deposition of a metal; in this case the values of the limiting current calculated for the assumed mechanism, and the experimentally measured values,

should be compared. An analogous calculation is also necessary to determine the concentration dependence of the diffusion coefficient for a known mechanism of the electrochemical reaction.

At diffusion current densities close to the limiting value, the local values of the viscosity and density of the solution, and also of the ionic diffusion coefficients close to the cathode surface, in the diffusion boundary layer, correspond to the conditions of ionic mass transfer in infinitely dilute solutions. With increase in the distance from the cathode surface, however, the local transfer coefficients and the physical properties of the solution, particularly in concentrated solutions, may differ significantly from the values next to the electrode, and this should be reflected in the profiles of the ion concentrations and the electric potential close to the electrode, and also in the magnitude of the limiting diffusion current.

The numerical calculation of the limiting current has been carried out[49] for the electrochemical deposition of copper from copper sulphate solution with allowance for the empirical concentration dependence of the diffusion coefficient of the salt. In a theoretical examination of the same process[64], but under non-stationary conditions, a linear concentration dependence of the diffusion coefficient was postulated. The calculations showed that the theoretical concentration profiles next to the electrode are in much better agreement with the experimental profiles, determined by an optical method, than the relationship given by Sand's familiar equation[65].

To derive an analytical relationship which would make it possible to carry out a more detailed comparison of theory and experimental data and to use this equation to obtain information on the effective transfer coefficients in concentrated electrolyte solutions, it is appropriate to examine the problem of ionic mass transfer to a rotating disc electrode (in this case the problem has one-dimensional geometry) with possibly a more general form of concentration dependence of the transfer properties of the solution. From an analysis of available experimental data on the viscosity ν, density ρ, and activity coefficient g of the salt, the following relationships can be postulated[66–68]:

$$\nu = \nu^s \exp\left[\frac{n}{c_2^{(0)}}(c_1 - c_1^{(s)})\right], \quad \rho = \rho^s \exp\left[\frac{m}{c_2^{(0)}}(c_1 - c_1^{(s)})\right], \quad g = g^s \exp\left[-\frac{k}{c_2^0}(c_1 - c_1^{(s)})\right]. \tag{74}$$

Here, $c_2^{(0)}$ is the bulk concentration of the anions of the salt, c_1 the local concentration of cations, the superscript "s" refers to the conditions at the interphase boundary, and n, m, and k are positive empirical constants.

Equations and boundary conditions have been derived[18], describing the transfer of cations close to the surface of a rotating disc under the conditions of the dissolution of the metal in a concentrated solution of its own salt (for example iron in $FeCl_2$ solution). The problem of the mass transfer of cations, accompanying the cathodic deposition of a metal from a binary electrolyte solution, is formulated analogously, the only difference being that there is a change in the direction of the mass flux of the particles being transferred[67]. If the cathodic current density is denoted by i, and it is assumed that $i < 0$, the equation for the transfer of the cations will have the form

$$(v - V)\frac{dc_1}{dy} - \frac{D_{eff}t(M_1D_1 - M_2D_2)}{(z_1 - z_2)FD_1D_2}\frac{d}{dy}\left(\frac{c_1}{\rho}\right) = \frac{D_{eff}M_3\nu_0^{1/6}\sqrt{\omega}}{D_1^{1/3}}\frac{d}{dy}\left(\frac{cg}{\rho\sqrt{\nu}}\frac{dc_1}{dy}\right). \tag{75}$$

Here, v is the component of the velocity of the liquid at right angles to the surface of the disc; y the dimensionless distance from the surface of the disc, related to the effective thickness of the diffusion boundary layer; V the linear rate of increase in the thickness of the deposited layer of metal; c the total molar concentration of the solution (as before, the subscript "3" refers to the solvent molecules); and D_1 and D_2 the ionic diffusion coefficients in an infinitely dilute solution.

The boundary conditions for this equation are:

$$\frac{dc_1}{dy} = \frac{z_2 i\rho^s\sqrt{\nu^s}}{z_1(z_1 - z_2)F\sqrt{\omega}D_1^{2/3}M_3c^{(s)}g^{(s)}} \quad \text{for } y = 0; \tag{76}$$

$$c_1 = -\frac{z_2}{z_1}c_2^{(0)} \quad \text{for } y = \infty. \tag{77}$$

The integration of Eqn.(75) with boundary conditions (76) and (77) can be carried out in analytical form by expanding the concentration profile as a power series in the distance y. The additional condition that $c_1 = 0$ for $y = 0$ makes it possible to obtain an expression for the limiting diffusion current i_{lim}. This expression has the form[66]:

$$i_{lim} = i_{lim}^{(0)}L, \tag{78}$$

where $i_{lim}^{(0)}$ is the value of the limiting current for the electrochemical deposition of the metal, calculated without allowance for the concentration dependence of the physical properties of the solution:

$$i_{lim}^{(0)} = z_1FD_1\left(1 - \frac{z_1}{z_2}\right)\frac{c_1^{(0)}\sqrt{\omega}}{1{,}61D_{eff}^{1/3}\nu_0^{1/6}}.$$

The coefficient L is given by the expression

$$L = \left\{1 + [0.418m + 0.089n + 0.258k + 0.281B]\frac{z_2}{z_1}\right\}\cdot\left(\frac{\nu_0\rho_0}{\nu^s\rho^s}\right)^{1/3}, \tag{79}$$

where

$$B = \sqrt{\frac{\nu^s}{\nu_0}}\frac{(z_1M_2 - z_2M_1)c_2^{(0)}}{(z_1 - z_2)\rho^s}. \tag{80}$$

Eqn.(79) shows that for $m = n = k = 0$, the coefficient L is not equal to zero, but makes a correction to $i_{lim}^{(0)}$ which is independent of the changes in the physical properties of the solution as the concentration varies and which arises as a result of the more accurate solution of the equation of convective diffusion, which includes terms quadratic in the driving force of ionic mass transfer.

Since one of the most important directions in present-day chemical and electrochemical technology is the development of the theoretical principles of transport phenomena in highly non-equilibrium systems with mass and heat fluxes which are not linear functions of the corresponding driving forces, a rigorous and systematic mathematical theory of processes of intensive mass exchange is undoubtedly urgently required. From the examples examined in the present review it is possible to obtain a picture of the fields of science and technology in which the effects of the interaction between the processes of mass and momentum transfer play the most important role, and the magnitude of these effects. Moreover, the examples given demonstrate the weakness and unsystematic character of the traditional theory of convective diffusion, developed for systems with low rates of interphase mass exchange, for the description of systems in which the hydrodynamic conditions are not an external factor, but are established under the influence of the technological conditions of the process of mass transfer.

Extraction Polarography and Its Analytical Applications

G.K.Budnikov and N.A.Ulakhovich

The review is devoted to extraction polarography as a method for the determination of microelements. The possibilities of polarography in combination with a preliminary chemical separation of the elements by extraction are discussed. The types of extraction-polarographic systems known at present are described. It is shown that the selectivity of extraction separations increases if the reagents form complexes with the ions to be determined, which are manifested by effects on the polarisation curves at different potentials. The influence of extracting and ionising solvents on the analytical signal is examined from the standpoint of modern ideas of the chemistry of coordination compounds in non-aqueous media. Examples of the use of extraction polarography for the determination of microelements are presented.
The bibliography includes 116 references.

I. INTRODUCTION

The usefulness of the preliminary concentration, by extraction in the form of complexes of the metal ions to be determined, has begun to attract attention recently. The metals are determined directly in the organic extracts[1-4]. The combination of separation and concentration with subsequent determination by physicochemical methods has proved to be one of the most promising fields in chemical analysis. In many instances such combination has become so intimate that it is possible to distinguish a new category of analytical methods which have been called hybrid[3].

Extraction-photometric, extraction-spectroscopic, extraction-polarographic and extraction-radioactive methods as well as extraction chromatography and extraction emission and atomic-absorption flame photometry can be included among the hybrid methods. The simultaneous application of concentration by extraction and of a sensitive apparatus greatly extends the scope of analytical methods. The selectivity of the analysis can be varied both as a function of the type of extraction system (reagent, acidity of the phase, etc.) and as a function of the method of measurement of the analytical signal. The use of a hybrid method in which preliminary extraction determines the absolute and relative concentrations of microelements in combination with an appropriate detection method permits in certain cases the analysis of multicomponent systems. Extraction polarography is one such method.

The present review surveys the results of studies in the field of extraction polarography during the last five years. The first investigations up to 1971 have been summarised in a familiar monograph[1] and also in a review[5]†. Since then the number of publications on extraction polarography has increased continuously. The interest in this method is explained by its universality, simplicity, the rapidity of analysis, the possibility of the simultaneous determination of a group of elements, and the lack of the need for re-extraction with associated inevitable losses.

The polarography is carried out by different methods. The use of versions such as oscillographic and a.c. polarography and catalytic hydrogen currents greatly enhances the scope of the extraction-polarographic methods. In examining the possibilities and advantages of the direct polarography of the extracts, one should note the first studies carried out by amalgam polarography with accumulation[11-15]. In this case concentration of the metal on the stationary electrode was achieved by electrolysing the solution of the test metal (in the form of a complex in an organic solvent). The essential feature of the method of extraction polarography with accumulation consists in the determination of traces of elements directly in the extracts. In this case one carries out a double concentration—by extraction and electrochemically[16-20].

However, the possibilities of the extraction-polarographic methods have been by no means exhausted—one should note in the first place an empirical approach to the selection of both the reagents for the binding of the metal in a complex and of the polarographic conditions as well as the method of recording the polarisation curves itself. The medium in which the polarography is carried out consists of at least two solvents. One of these is used to extract the metal in the form of a complex and the other to ensure the solubility of the supporting electrolyte and the conductivity of the medium. Consequently the second component must have a fairly high dielectric constant. The ratio of these components influences the analytical signal.

The combination of extraction and polarography gives rise to new possibilities and advantages. For example, the employment of non-aqueous solvents for polarography extends the range of potentials in which experiments can be performed as well as the range of values of $E_{1/2}$ for the reduction of ions bound in complexes. Hence it follows that the study of the influence of the nature of the solvent is an essential stage in the development of extraction-polarographic methods.

A conscious choice of rational conditions for extraction-polarographic determinations is impossible without knowing the electrochemical properties of the corresponding complexes. The knowledge of the mechanism of the electrode process permits rational extraction-polarographic determinations with recording of the maximum possible analytical signal. It is then possible to employ specifically polarographic characteristics such as the reversibility of the reduction, the maximum number of electrons involved in a particular stage, the adsorbability and associative accumulation of the substance on the surface of the electrode, and other ways of increasing the sensitivity and selectivity.

†The work of the Kiev School of Analytical Chemistry[6-10] has made a definite contribution to the development of the extraction-polarographic methods.

Only after such studies is a foundation laid for the selection of the optimum polarographic conditions ensuring a fairly low concentration limit in the determination and a high selectivity of extraction-polarographic analyses.

II. THE ROLE OF THE ORGANIC SOLVENT IN EXTRACTION POLAROGRAPHY

The solution for polarography must have a fairly high conductivity. However, extracts are not as a rule electrolytes. It is therefore necessary to add to the extract solvents with a high dielectric constant containing a specific amount of supporting salts, ensuring a high conductivity. Thus homogeneous mixtures of extracting and ionising solvents are used in extraction polarography. The ratio of the mixture components is determined by the solubility of the extracted complex and of the supoorting salt. In terms of their electrical conductivity, such systems are not inferior to the traditional polarographic electrolytes[1].

The nature of both the extracting and ionising organic solvents can influence the stability of the complexes formed in the "metal ion–organic reagent" system. However, in most cases the depolariser is the metal chelate with a fairly high stability. The complex formation equilibrium and hence the question of the predominance of a particular complex species in the polarographed extract are not of decisive importance. This is particularly valid in relation to a large group of the so-called inert complexes. In order to solve problems associated with the increase of the selectivity and sensitivity of the analysis, it is necessary to make a rational choice of the extracting solvent, since it influences the parameters of the polarographic waves and hence the analytical signal. The most important factor for the analytical chemist is information about the properties of the limiting current recorded on the voltamperograms as a function of the nature of the organic solvent.

Table 1. The properties of extracting and ionising solvents at 20 °C.

Solvent	ε	η, cP	DN($SbCl_5$)[28]	Solvent	ε	η, cP	DN($SbCl_5$)[28]
Extracting solvents				Extracting solvents			
Benzene	2.28	0.70	4.9	Ethyl acetate	6.40	0.47	17.1
Toluene	2.38	0.63	—	Butyl acetate	5.01	0.73	—
m-Xylene	2.36	0.62	—	Pentyl acetate	4.75	0.92	—
Chloroform	4.80	0.59	—	Isopentyl alcohol	15.64	4.8	—
Carbon tetrachloride	2.24	—	—	Ethyl methyl ketone	18.51	0.42	—
				Butyl alcohol	17.0	3.37	29.0
Ionising solvents				Ionising solvents			
Acetonitrile	38.80	0.34	14.1	Methyl alcohol	33.60	0.54	19.0
Acetone	21.24	0.30	17.0	Ethyl alcohol	25.80	1.09	—
Dimethylformamide	37.65	0.79	26.6	Formamide	111.50	3.76	39.1
Dimethyl sulphoxide	48.90	1.96	29.8				

The physical constants of the most important solvents of both types are listed in Table 1. The influence of the nature of the extracting solvent on the height of the polarographic waves (i_{lim}) has been studied in relation to hydroxyquinolinates[7], benzoylphenylhydroxylaminates (BPHA),[9] *N*-cinnamoylphenylhydroxylaminates (CAPHA),[21] 4-benzoyl-3-methyl-1-phenyl-5-pyrazolonates[22], dithiocarbamates (DTC),[23–27] ethylxanthates (EXT),[25,26] dithiophosphates (DTP),[26,27,29] 8-mercaptoquinolinates[30,31], and tri-n-octylaminates (TOA).[32]

Useful information about the influence of the solvent on the reduction process can be obtained by comparing the polarographic characteristics of the complexes in aqueous (whenever possible) and non-aqueous media. The height of the reduction wave of copper(II) ions in the presence of 8-hydroxyquinoline in a non-aqueous solution (a mixture of toluene and methanol) is almost twice as high as in an aqueous solution[6]. The change in the limiting current in non-aqueous solvents compared with water is attributed to the change in the viscosity of the solution, which influences the diffusion coefficient of the depolariser[6]. However, such a difference between the values of i_{lim} is not always a consequence of the influence of the viscosity of the medium alone. Whereas in an aqueous solution copper(II) is reduced in the form of the aquo-ion, in the toluene–methanol system being compared it is reduced as the 8-hydroxyquinoline complex. One cannot agree with the postulate[6] that the complex dissociates prior to the electrode process: like other chelate complexes, the 8-hydroxyquinolinates usually do not dissociate in organic solvents[34]. It is therefore also impossible to account for the difference between the diffusion current constants by the non-identical electrochemical behaviour of the depolariser in aqueous and non-aqueous media, which should be reflected, like the viscosity of the solution, in the diffusion coefficient. For this reason, the use of non-aqueous media can apparently entail in many instances a decrease of i_{lim} compared with an aqueous medium[12,13].

In order to elucidate the influence of the nature of the organic solvent, it is more useful to investigate the same complex in different extracting solvents. The viscosities of the pure extracting solvents can be used to establish the relation between the viscosity of the solution and the limiting current for the reduction of the complex. The ionising solvent must be the same under these conditions and the ratio of the extracting and ionising solvents must be constant. Such a study has been made by Pyatnitskii and Ruzhanskaya in relation to copper, lead, and iron hydroxyquinolinates[7] and copper, iron, and indium benzoylphenylhydroxylaminates[9]. The results showed that the nature and properties of the solvent (Table 1) have a considerable influence on the height of the polarographic waves and hence also on the lower limit of the determination. In the general case the wave height diminishes with increasing viscosity of the solvent, which is due to the familiar inverse proportionality between the diffusion coefficient and the viscosity of the medium (η). On the other hand, the viscosity factor is not always decisive, because the product $i_{lim}\eta^{1/2}$ is not constant in many instances. A similar phenomenon has been observed, for example, in the reduction of metal complexes of CAPHA in mixed organic solvents[21]. Data concerning the influence of the nature of the extracting solvent on i_{lim} for the waves due to the metal complexes of dithiocarbamic, dithiophosphoric, and xanthic acid derivatives[23–27] show that the change in i_{lim} is related not only to the viscosity of the solvent but also to its capacity to solvate the depolariser species. The change in the degree of solvation of the complexes leads to the formation of solvates whose diffusion coefficients differ greatly and this is also reflected in the values of i_{lim}. The decrease of the limiting current for the reduction of iron(III) and zinc(II) dimethyldithiocarbamates in the sequence ethyl acetate > butyl acetate > pentyl acetate is probably associated with the fact that the complex solvated by ethyl acetate molecules is smaller than in pentyl acetate[23]. The increase of the size of the solvate in the above sequence entails a decrease of the diffusion coefficient of the complex. The highest limiting

current in the determination of metals as their complexes with organic ligands can be attained in the polarography of benzene extracts.

On passing to chelates of metals whose ions are more highly solvated (copper and cadmium), the change in i_{lim} with the change in the nature of the solvent is more distinct. For example, cadmium complexes of DTC in solutions in aromatic hydrocarbons in the presence of 0.2 M lithium perchlorate in methanol as the supporting electrolyte are reduced reversibly, whereas in acetate esters and in dimethylformamide (DMF) the reduction is irreversible[24] (Fig. 1). The tendency towards an increase of i_{lim} on passing from DMF to aromatic hydrocarbons is observed also for other dithiocarbamate complexes, but in the case of cadmium chelates the difference between the currents i_{lim} is particularly notable. This behaviour is associated with the strong solvating capacity of DMF.

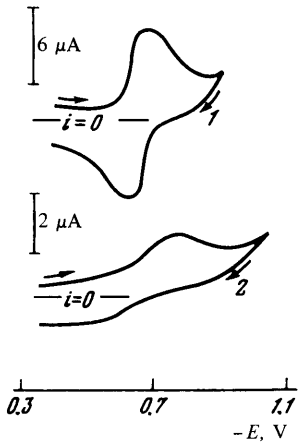

Figure 1. Oscillopolarograms of a 5×10^{-4} M solution of cadmium dibutyldithiocarbamate in an ethanol–benzene mixture (curve *1*) and dimethylforamide (curve *2*); supporting electrolyte—0.2 M lithium perchlorate[24].

Another parameter of the voltamperogram to which attention should be paid in selecting the solvent, the type of reagent for chelating the metal, and other analytical conditions is the velocity constant for charge transfer k_S, which determines the reversibility of the electrochemical system[35]. When $k_S > 10^{-2}$ cm s^{-1}, the electrochemical equilibrium at the electrode is fairly mobile during the recording of the voltamperogram. If there are no intermediate chemical stages, deactivating the electron addition product, then under these conditions the discharge is reversible. By selecting the appropriate organic solvent, it is possible to increase the stability of the electron transfer products and to ensure suitable conditions for the recording of curves with the aid of a.c. polarography. It is impossible to extend greatly the number of reversible electrochemical reactions at the electrode compared with an aqueous medium.

The different degrees of reversibility of the waves due to the complexes are caused by the nature not only of the central atom but also the ligand. Thus in the reduction of iron(III) dithiocarbamates[23] and xanthates[28] in aromatic hydrocarbons the wave corresponding to the transfer of the first electron to the complex species is reversible only in the former instance. The polarographic waves of metal xanthates obtained under the same conditions are as a rule less reversible than those for the dithiocarbamates. The differences in the reversibility of the reduction waves of metal dithiocarbamates and xanthates can be explained by the more marked ability of the xanthates to form comparatively stable solvates for which a slow charge transfer in the electrochemical stage proper is observed. The reduction of the copper(II) complex of CAPHA in oxygen-free extracting solvents is also reversible; in isopentyl and hexyl alcohols the process is irreversible[21]. The irreversible reduction of the complex in carbon tetrachloride is an exception. It has been noted that, on passing to ethyl acetate, the reduction takes place with consumption of one electron. The slow electron transfer has been explained[21] by the adsorption of organic solvent molecules on the surface of the electrode.

The choice of a suitable ionising solvent to increase the sensitivity of the metal also merits attention. Various ionising solvents have been compared[7] (for the same extracting solvent) in relation to 8-hydroxyquinolinates: methanol, DMF, dimethyl sulphoxide (DMSO), and formamide; they differ from one another by their dielectric constants (ε) and viscosities. Analogous studies were made later for metal xanthates[28]. The replacement of methanol by another ionising solvent with a greater solvating capacity leads to a decrease in the height of the wave. On passing to solvents with a greater solvating capacity (DMF, DMSO), the change in i_{lim} becomes more appreciable. The fact that in solvents with similar viscosities the limiting current for the reduction of metal chelates is greater for the solvent with a lower donor number is striking[24]. Furthermore, when ethanol, the viscosity of which is greater than that of DMF (Table 1), is used as the ionising solvent, the i_{lim} observed for the xanthates is approximately twice as great as the current obtained in DMF.

Attempts have been made to explain from different standpoints the influence of the solvent on the parameters of the electrode process[36]. The replacement of one solvent by another can entail an appreciable change in the energy of the activated state, while the energy of the initial state of the chelate remains almost the same. This situation leads to an increase in activation energy for the reaction, i.e. to a decrease of the rate of charge transfer (a decrease of k_S).

On solvation, solvent molecules can enter the inner coordination sphere (particularly for a coordination-unsaturated complex) or remain bound to the complex, occupying a second coordination sphere[36]. In the former case the reduction of the complex is apparently less reversible than in the latter.

In studies of the influence of the organic solvent, both extracting and ionising, on the ease of reduction of complexes attempts have frequently been made to establish a correlation between $E_{1/2}$ and the dielectric constants[7,9,23]. The results of the study of hydroxyquinolinates[6], benzoylphenylhydroxylaminates[9], and dithiocarbamates[23] have shown that, when the solvent is changed, the values of ε are altered somewhat, but a consistent relation between them and the dielectric constants ε (Table 1) is not observed. Nor is there an appreciable change in the differences between the reduction potentials of the metal ions and their sequence. One should note that the displacement of the half-wave potential $E_{1/2}$ along the potential axis when the solvent is altered can be associated with the change in the interphase potential. In estimating the half-wave potential shift under the influence of the solvent, one must also take into account the adsorption of the depolariser[37].

It is of interest to examine the influence of the ratio of the volumes of the extracting and ionising solvents on the characteristics of the polarographic waves. The change in the

volume of the extracting solvent with a low viscosity and a slight solvating capacity (toluene, *m*-xylene, benzene) has almost no influence on the height of the polarographic waves of metal 8-hydroxyquinolinates[7,9], while the increase of the fraction of the extracting solvent with a greater viscosity and a satisfactory solvating capacity (butyl and isopentyl alcohols and cyclohexanone) leads to a decrease of i_{lim}. In order to ensure a better conductivity of the solution, it is sometimes necessary to increase the fraction of the ionising solvent, as happened in the reduction of the indium(III) complex of TOA,[32] the copper(II) complex of dithizon[38], and the molybdenum(VI) complex of BPHA.[39] The influence of η and ε of the extracting solvent is hardly manifested in this instance. The application of the method of differential oscillographic polarography makes it possible to do without ionising solvents altogether. In this method there is no need for a high conductivity of the solution. The low solubility of the supporting electrolyte in the extracts used in the study[40] (butyl and isobutyl alcohols, ethyl methyl ketone, and butyl methyl ketone) nevertheless proved sufficient to permit measurements.

From a practical point of view, solvents with high viscosities and high donor numbers are less convenient, since a rigorous control of the ratio of their volumes is then essential.

III. TYPES OF EXTRACTION-POLAROGRAPHIC SYSTEMS

An effective combination of extraction and voltamperometric methods necessitates a comprehensive knowledge of the characteristics of the electrochemical reactions of metal chelates in the extracting solvents or their mixtures. The general principles by which one must be guided in choosing the polarographic conditions for the solution of chemical-analytical problems can be easily examined in relation to the reduction of a large number of metal complexes with reagents containing different donor atoms in functional-analytical groups.

It is preferable to extract elements in the form of inner complexes and chelates, for which electrochemical processes are less complicated by the preceding and subsequent chemical reactions which influence both on the shape of the waves and their position along the potential axis. Furthermore, chelates are uncharged, which reduces the degree of their solvation and creates suitable conditions for increasing the analytical signal. This is why there is no slackening of interest at the present time in the traditional chelating extractants.

Among the metal chelates extracted by organic solvents, derivatives of dithio-acids and 8-hydroxyquinoline are used most frequently, in practice, as already mentioned. This is associated not only with the ready availability of the reagents but also with the fact that a very wide range of metals generate a current proportional to the metal concentrations in their presence during both electrochemical reduction and oxidation. The conditions for the electrode reactions can then be modified by varying the ratio of the extracting and ionising solvents and by slecting the supporting electrolyte, which makes it possible to apply different versions of polarography for the recording of the analytical signal.

The possibility of the polarography of certain metal dialkyldithiocarbamates in the chloroform–methylcellosolve–water ternary mixture was noted above. Methylcellosolve functions in this instance as a homogeniser for the system, chloroform is the extractant, and water creates conditions suitable for conductimetric measurements[41-43]. However, the use of this system is limited by the comparatively narrow region corresponding to the polarisation of the mercury dropping electrode (m.d.e.)—below −0.8 V relative to the saturated calomel electrode (sat.c.e.). The use of dioxan, dichloroethane, and formamide, in which there is a wide range of cathodic polarisations, in polarographic analysis of chelates involves certain difficulties. In electrochemical reduction in these solvents and their mixtures one frequently records rather indefinite voltage–current curves, which are unsuitable for analysis[7,9]. For many 8-hydroxyquinoline[7] and benzoylphenylhydroxylamine[9] complexes, it has been impossible to observe reduction waves under these conditions.

This is the reason why a search has been made for a solvent system which should not be inferior to chloroform in its capacity to dissolve chelates but would ensure the recording of readily reproducible voltage–current curves, suitable for the measurement of the potential and the current. Such a system is apparently provided by a mixture of aromatic hydrocarbons or acetate esters with methanol, which is added to dissolve the electrolyte salt (ionising solvent). Solvents of the benzene and acetate ester series dissolve readily the majority of complexes with organic ligands, are infinitely miscible with ionising solvents[1,7,13], and are polarographically inactive over a wide range of potentials[7-9]. Furthermore benzene and its analogues have a low solvating capacity (see above), which increases the reversibility of the process and makes it possible to increase the sensitivity of the determination by employing a more effective apparatus. The shape of the voltage–current curves depends significantly also on the concentration of the depolariser, in consequence of its adsorption activity. It has been established for metal complexes of dithiocarbamic acid derivatives that the adsorption phenomena observed in the polarography of such systems are determined by the solubility of the chelates in the given solvent and the position of the polarisation curve relative to the potential axis. The electrochemical reduction of complexes of a large group of metals (Tl, Pb, Cu, Hg, Cd, and Bi) takes place at the m.d.e. near the electrocapillary zero, where complex species with organic ligands are adsorbed to the greatest extent.

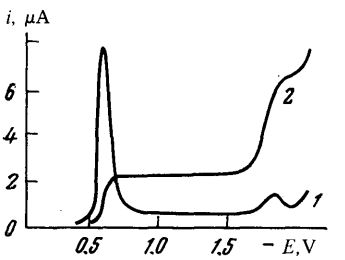

Figure 2. A.c. (curve *1*) and classical (curve *2*) polarograms of a 5×10^{-4} M solution of iron dimethyldithiocarbamate in a benzene–ethanol mixture; supporting electrolyte—0.2 M lithium perchlorate[23].

Thus, in selecting the extraction-polarographic system preference should be given to chelating agents and solvents which would make the electrochemical process reversible to the maximum extent. The presence of at least one reversible stage in the electrode reaction makes it possible to use a.c. polarography for the recording of the analytical signal[23].

The set of the data available at present permits a well-founded approach to the selection of not only the solvent but also of the extraction reagents. The choice of the ligand depends on the problem formulated and the objects of the analysis. If there is a need for an increased sensitivity of the analysis one can recommend dithiocarbamates as extraction reagents, because their complexes are reduced irreversibly in most instances, which makes it possible to employ a.c. polarography for the recording of voltage–current curves[23]. The analytical signals recorded with the aid of classical and a.c. polarography are compared in Fig.2. For extraction from hydrochloric acid solutions, dithiophosphates, which are stable under the given conditions in contrast to dithiocarbamates, are of greatest interest. This is especially important for the determination of elements such as bismuth, antimony, and arsenic, which are almost completely bound in complexes with dithiophosphates only when the acidity of the solution is high[29]. The extraction and hence the polarographic process can be made selective under these conditions by choosing an appropriate pH. Fig.3 presents the dependence of the extractability of metal dithiophosphates on pH in extraction with toluene.

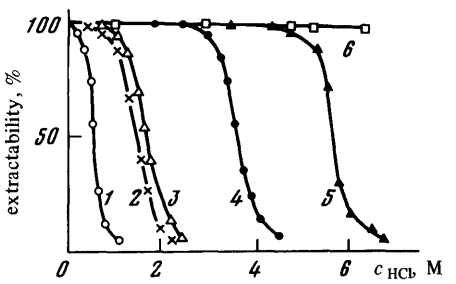

Figure 3. Dependence of the extractability of metal diethyl dithiophosphates on the acidity of the medium: 1) cadmium; 2) cobalt; 3) nickel; 4) lead; 5) bismuth; 6) arsenic[29].

When the complexes are extracted jointly, the polarographic method permits a separate determination of the elements in the same solution. For example, in the extraction of cobalt(II), nickel(II), and zinc(II) dithiophosphate complexes it is impossible to select a pH range where they would be separated, but the polarograms of the solutions in benzene (toluene)–ethanol mixtures shows distinct waves of the metal complexes at different potentials[29] (Fig.4).

Another way of increasing the selectivity in the determination of metals involves the use of metal complexes as extractants. There are very few examples of this type of application of complexes and these refer mainly to dithiocarbamates. The stability of metal complexes of DTA decreases in the sequence Hg(II) > Pd(II) > Ag(I) > Cu(II) > Tl(III) > Ni(II) > Bi(III) > Pb(II) > Co(III) > Cd(II) > Zn(II) > Tl(I) > Sb(III) > Fe(III) > Te(IV) > Mn(II).[44,45] With the aid of this stability series, it is possible to select a complex capable of participating in the extraction exchange with the metal to be determined[46]. Such an extractant complex can consist of a metal complex less stable than the complex of the element to be determined. A necessary condition governing the choice of the extractant is also its ability to be reduced or oxidised in a potential range different from the corresponding range for the dithiocarbamate of the element to be determined. In the determination of palladium(II) this requirement is met by copper(II) dithiocarbamate[47], which is reduced in a 2 : 3 toluene–ethanol mixture at a potential of −0.3 V relative to liquid mercury at the bottom of the cell. When a toluene solution of copper(II) diethyldithiocarbamate is added to an aqueous solution containing palladium(II) ions as well as ions of other elements, palladium(II) is almost completely extracted; other elements are not extracted, which is established on the basis of the absence of the waves of their dithiocarbamates from the polarograms. The copper(II) diethyldithiocarbamate complex has been used as the extractant in the determination of palladium(II) in a combined metallation electrolyte[47].

Zinc(II) diethyldithiocarbamate has been used as an extractant to determine microamounts of copper[48]. Down to 8.5 μg kg^{-1} of mobile copper in the soil can be determined from anodic voltamperograms obtained at a rotating graphite disc electrode in a 2 : 3 toluene–acetone mixture[48]. In procedures based on extraction-exchange reactions the determination is not always carried out directly in the organic extracts. Thus the extraction exchange between the bismuth(III) diethyldithiocarbamate complex in carbon tetrachloride and mercury(II) in an aqueous bromide solution is completed by the equivalent transfer of bismuth(III) to the aqueous phase. Its subsequent determination by inversion voltamperometry ensures a lower limit of detection down to 0.003 μg ml^{-1}.[49]

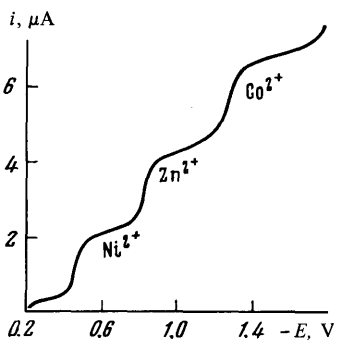

Figure 4. Polarograms of a benzene extract containing 10^{-3} M nickel(II), zinc(II), and cobalt(II) in 0.2 M lithium perchlorate in ethanol as the supporting electrolyte; extractant—diethyl dithiophosphate[44].

An essential requirement which must be made by the extraction-polarographic system is the purity of all its components. Apparently one must not accept without question the stated grade of commercial reagents. Studies have shown[23,24,31] that they require careful purification by repeated recrystallisation from alcohols, acetone, etc. Studies where the choice of rational conditions for the extraction-polarographic determinations based on specially synthesised, purified, and identified complexes, in the form of which the elements are extracted merit attention[50–52]. As regards the purification of solvents, the latter are subjected to fractional distillation in almost all cases. However, since the solvents are added to aqueous solutions in the extraction process, it is not always essential to dry them carefully. This is necessary only in those cases where the solvent hydrolyses when stored in the presence of an admixture of water with formation of polarographically active compounds. Table 2 presents the most typical extraction-polarographic systems used for the analysis of various elements.

Table 2. Types of extraction-polarographic systems.

Reagent	Solvent mixture	Method of recording	Polarisation potential of electrode	Elements determined	References
1. Sodium diethyl dithiocarbamate	chloroform – methylcellosolve – 0.1 M $HClO_4$ ($KClO_4$)	I, II	0.0 – –0.8 V	Bi(III), Cu(I), Cu(II), Tl(I), Pb(II), Hg(II)	41–43,50,51
2. Dithiocarbamates ($R_2NCS_2^-$, R = CH_3, C_2H_5, or n-C_4H_9) (n = 4, 5)	benzene, toluene, *m*-xylene, ethyl acetate, butyl acetate, pentyl acetate—0.2 M $LiClO_4$ ($NaClO_4$) in methanol or ethanol	I–III	+0.2 – –1.8 V**	Pb(II), Cd(II), Sn(II), Cu(II), Bi(III), Tl(I), Fe(III), Zn(II), Mn(II)	23,24,52,55
	benzene, toluene, chloroform, carbon tetrachloride—0.2 M $LiClO_4$ in acetone	IV	0.0 – +1.9 V**	Cu(II), Ni(II), Zn(II), Tl(I), Pb(II)	48,58,59
3. Alkyl xanthates ($ROCS_2^-$, R = CH_3, C_2H_5, n-C_3H_7, or iso-C_3H_7)	benzene, toluene, *m*-xylene, ethyl acetate, butyl acetate, pentyl acetate, pentyl and isopentyl alcohols, heptane—0.2 M $NaClO_4$ in ethanol	I, III	+0.3 – –2.0 V***	Fe(II), Fe(III), Ni(II), Zn(II), Cd(II), Pb(II), Sn(II), Tl(I), Bi(III), Sb(III), As(III)	25–28
($ROCS_2^-$, R = n-C_4H_9, iso-C_4H_9, n-C_5H_{11}, or iso-C_5H_{11})	toluene (chloroform)—0.2 M $LiClO_4$ in acetone	V	0.0 – +1.9 V**	Ni(II)	59
4. Diethyl hydrogen dithiophosphate	toluene (benzene)—0.2 M $LiClO_4$ in ethanol	I, III	+0.1 – –2.0 V***	V(IV), Cr(III), Mn(II), Co(II), Fe(II), Fe(III), Ni(II), Zn(II), Cd(II), Pb(II), Bi(III), As(III), Sb(III), Tl(I)	26,27,29
5. 8-Mercaptoquinoline	benzene, toluene, *m*-xylene, pentyl acetate, isopentyl alcohol—0.1 M LiCl in ethanol	I	–0.2 – –2.0 V***	Hg(II), Cu(II), Cr(III), Mo(VI), Zn(II)	30
6. 8-Hydroxyquinoline	benzene, toluene, *m*-xylene, pentyl acetate, butyl acetate, chloroform, dichloroethane, pentyl and butyl alcohols, cyclohexanone—0.1 M LiCl in methanol	I	–0.2 – –1.2 V	Cu(II), Pb(II), Fe(III), Cd(II), Bi(III)	7
	fused naphthalene-DMF—0.1 M $HClO_4$ + 0.1 M NaClO	I	0.0 – –1.0 V	Mo(VI), Cd(II), Pb(II), In(III)	61,62
	isobutyl methyl ketone, supporting electrolyte—0.1 M $(C_4H_9)_4NClO_4$	I	0.0 – –1.3 V	Cu(II)	63
7. *N*-Benzoylphenyl-hydroxylamine	benzene, *m*-xylene, butyl, pentyl, and isopentyl alcohols—0.1 M $(C_4H_9)_4NClO_4$ in methanol, DMF, formamide, and DMSO	I	-0.2 – -1.6 V (pH of aqueous phase 5 – 10); -0.2 – -0.9 V (pH of aqueous phase 3)	Pb(II), Cu(II), Cd(II), Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Zn(II), Pd(II), Bi(III), Ti(IV)	70,71
8. *N*-Cinnamoylphenyl-hydroxylamine	pentyl alcohol, ethyl acetate, benzene—0.1 M LiCl in methanol	I	0.0 – –1.2 V	Cu(II), Cd(II), Pb(II), Ga(III), In(III), Tl(III), Fe(III), Bi(III), Ti(IV), V(V), W(VI), Mo(VI)	72–75
9. Salicylaldoxime	toluene—0.1 M LiCl in methanol	I	–0.2 – –1.5 V	Cu(II), Pd(II), Pb(II), Cd(II), Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Zn(II), Bi(III), Ti(IV)	8
10. Phenoyltrifluoro-acetone	benzene—0.1 M LiCl in methanol and butanol—acetophenone mixt.	I	-0.2 – -0.75 V (pH 4.1); -0.2 – -0.6 V (5 *N* HCl)	Cu(II), Tl(I), Pb(II)	8
	isobutyl methyl ketone—0.1 M acetylacetone – acetate buffer at pH 5.8	I	0.0 – –1.5 V	Fe(III)	100
11. 4-Benzoyl-3-methyl-1-phenyl-5-pyrazolone	cyclohexanone, dichloroethane, ethyl acetate, chloroform, toluene, benzene—0.75 M NH_4Br in ethanol	I	0.0 – –1.2 V	In(III)	22
12. Dimethyl-α-furyl-, and α-benzyl-glyoximes	toluene, 1 M ammonia buffer in ethanol	I–III	–0.2 – –1.8 V*	Ni(II)	85
13. Acetylacetone, phenoyl-trifluoroacetone	isobutyl methyl ketone, supporting electrolyte—0.1 M $(C_4H_9)_4NClO_4$	I	—	Fe(III)	95,96
14. Diantipyrinylmethane	chloroform—1 M LiCl in ethanol	III	0.0 – –1.0 V	Sb(III), V(V), As(III)	92,93,96
15. Catechol	dichloroethane – diphenylguanidinium acetate	I	0.0 – –1.2 V		116

IV. THE USE OF EXTRACTION POLAROGRAPHY IN THE DETERMINATION OF METALS

The method of extraction polarography has come to be used comparatively widely in recent years. There has been an increase of the range of reagents investigated and studies have been made on extraction polarography using solid reagents. Among the metal chelates extracted by organic solvents at the present time, dithiocarbamates[18,23–27,47–60], hydroxyquinolinates[6–8,10,15,17,61–69], and substituted hydroxylaminates[9,70–82] have been most fully investigated. There have been reports also of the other reagents; oximes[8,83–85],

xanthates[25-28,56-60,86-91], dithiophosphates[25-27,29,56,60], pyrazolone derivatives[22,92-94], etc.[95-103].

8-Hydroxyquinoline is widely used for concentration by extraction in combination with different versions of polarography. Pyatnitskii and Ruzhanskaya investigated the influence of the nature and properties of organic solvents (benzene, toluene, *m*-xylene, pentyl acetate, chloroform, dichloroethane, pentyl, isopentyl, and butyl alcohols, and cyclohexanone) on the polarographic characteristics of the reduction waves for certain metal hydroxyquinolinates[6,7,10]. On the basis of the results, methods have been devised for the determination of copper in ferrotitanium, titanium-based alloys, alloyed steels, and babbitts[6,10]. Apart from 8-hydroxyquinoline, its various derivatives have been used. Cadmium, cobalt, and iron have been extracted quantitatively with butyl alcohol in the form of their complexes with 8-hydroxyquinoline-5-sulphonic acid with subsequent determination of the metals in the extract down to a lower limit of 7.5×10^{-8} g-ion litre^{-1}.[68]

Studies have been made on the extraction of metal hydroxyquinolinates by extraction amalgam polarography with accumulation using solvents of the benzene series[15,17]. The sensitivity of the determination of the elements by this method is in most cases not less than the sensitivity of the amalgam-polarographic analysis of impurities in aqueous media. The method of extraction polarography with accumulation is promising for the study of the extraction of substances present at low concentrations. The scope of this method has been investigated in the extraction of chelates in relation to the distribution of copper and cadmium *O*-hydroxyquinolinates in systems comprising water and solvents of the benzene series[15,17] and also copper diethyldithiocarbamate in the water–chloroform system[18]. The kinetics of the extraction of complexes with organic solvents and the influence of the pH of the aqueous phase on the extraction have been investigated, the extraction constants for the complexes have been calculated, and the composition of the complexes has been determined. It has been shown that the metal can be concentrated at the electrode either as a result of its transfer to the amalgam in the electrolysis of the solution of the chelate in the extracting mixture (chelate complexes of bismuth, cadmium, lead, thallium, copper, indium, and certain other metals[19]) or as a result of the formation of a colloid metal–mercury system (iron, nickel, manganese, cobalt, etc. compounds).

Extraction polarography with accumulation has been used to determine antimony in solutions of sodium chloride and specially pure hydrochloric acid[54] with the aid of chloroform and sodium diethyldithiocarbamate in the presence of EDTA and potassium iodide. The lower limit of the detection is 5×10^{-6}%. The use of 8-hydroxyquinoline in polarographic analysis has been described by Fujinaga and Puri[65]. Zinc, cadmium, manganese, and magnesium have been determined by an indirect method based on the decrease on the height of the reduction wave for 8-hydroxyquinoline itself in the presence of these metals.

The possibility of employing solid but readily fusible organic substances for extraction had been reported previously[104-106]. Such extraction is carried out in slightly heated solutions where the extractant is fused. After extraction and cooling, the extract solidifies rapidly and the aqueous layer is separated by simple decantation. Extraction by readily fusible substances does not require a separating funnel. A set of readily fusible extractants, permitting the extraction of elements from solutions with different acidities, has been published[106]; these are mainly paraffins in mixtures with various oxygen-containing solvents or with *N*,*N*-dimethyl- and *o*-chloro-aniline. Lobanov et al.[107] studied the possibility of the group concentration of metal ions by an 8-hydroxyquinoline melt. However, extractants of this class are still hardly used.

Several communications have been published recently[61,62,64,65] on the isolation of metal hydroxyquinolinates by extraction into fused naphthalene with subsequent polarography of the dimethylformamide solution of the extract. The use of such extraction-polarographic systems has definite advantages: simplicity of operation, faster attainment of equilibrium as a result of heating, the absence of risk of emulsification, and the disappearance of the need to dilute the solution with an ionising solvent when, for example, dimethylformamide is used, etc. The conditions for the extraction-polarographic determinations of Be, Bi, Mo, Cd, Hg, Ni, Pb, Pd, Sn, Ti, U, V, W, Ce, Cu, Tl, In, Mn, Sr,[65] Mo,[61] Pb and Cd,[63] and In [64] have been investigated. Waves suitable for analytical purposes have been obtained only for Mo, Pb, In, Bi, U, Cu, Pd, and Fe.[65] Other metals investigated do not give rise to reduction waves in the accessible range of potentials, since at potentials more negative than −1.1 V the organic reagent is reduced under these experimental conditions. Evidently it would be useful to find a supporting electrolyte other than pyridine + $HClO_4$ and $NaClO_4$ + $HClO_4$ mixtures, as a result of which the range of potentials for polarography would be narrowed down still further. The number of ions determined in the presence of the above supporting electrolytes is very small. Polarographic activity is not shown by 8-hydroxyquinoline alone. Substituted hydroxylamines and the oximes of certain aldehydes and ketones, which are reduced at an m.d.e., have been used in extraction-polarographic analysis. For example, *N*-benzoylphenylhydroxylamine (BPHA) permits studies in the range from −0.2 to −1.6 V. An increase of the acidity of the aqueous phase narrows down the range in the cathodic region to −0.9 V (pH 3), which can apparently be accounted for by the facilitation of the reduction of the protonated form of the reagent. The polarographic study of the reduction of the complexes was begun by Hudbard and Gernon[70], and thenumber of polarographically active complexes under the conditions employed by them is small: those of Sb, Bi, Cu, In, Fe, Pb, and V. Copper ($E_{1/2} = -0.28$ V relative to the sat.c.e.), iron ($E_{1/2} = -0.56$ V), and lead ($E_{1/2} = -0.62$ V) waves and to a lesser extent antimony ($E_{1/2} = -0.27$ V) and vanadium ($E_{1/2} = -0.62$ V) waves (because their heights are small), are suitable for analytical purposes[70]. Pyatnitskii and Ruzhanskaya[9] investigated the polarographic behaviour of lead(II), copper(II), cadmium(II), nickel(II), zinc(II), iron(III), gallium(III), indium(III), thallium(I), bismuth(III), cobalt(II), titanium(IV), vanadium(V), molybdenum(VI), tungsten(VI), manganese(II), chromium(III), and palladium(II) benzoylphenylhydrozylaminates in isopentyl alcohol and *m*-xylene. The influence of the solvent has been studied for copper(II), iron(III), and indium(III) complexes. It follows from the results that, with decrease of the dielectric constant, the reduction potentials are in most cases displaced to the negative region, but there is no clear-cut regular variation in this instance. The greatest sensitivity of the determinations has been obtained in extraction by weak polar solvents of the benzene series. They also have the advantage that waves with a more definite shape are obtained.

The results of a study of the same metal benzoylphenylhydroxylaminates have been published by Pilipenko et al.[71]; in this case the influence of the solvents was investigated (in contrast to Pyatnitskii and Ruzhanskaya[9]) also for all the remaining benzoylhydroxylaminates. The BPHA complexes of many metals are reduced in benzene, toluene,

dichloroethane, carbon tetrachloride, butyl, pentyl, isopentyl, and hexyl alcohol, ethyl acetate, and ethyl methyl ketone extracts in the presence of 0.1 M LiCl supporting electrolyte and methanol. It was established that the values of $E_{1/2}$ for metal *N*-benzoylphenylhydroxylaminates in organic solvents are displaced towards more negative potentials compared with the $E_{1/2}$ of the metal ions in aqueous solutions as a result of complex formation or solvation. The cathodic shift of the waves in ethyl acetate and pentyl alcohol relative to benzene and chloroform has been explained[72] by the solvating capacity of oxygen-containing organic solvents. In terms of their reduction potentials at the m.d.e., metal *N*-benzoylphenylhydroxylaminates can be arranged in the following sequence (polarographic spectrum)[71]: Cu(II) < V(V) < Tl(I) < Bi(III) < Fe(III) < Pb(II) < Cd(II) < Mo(VI) < W(VI) < Ga(III). In some cases the values of $E_{1/2}$ for metal ions in the aqueous medium are very close, while in organic solvents they differ significantly. Thus in an aqueous medium the values of $E_{1/2}$ for the copper(II)–bismuth(III), indium(III)–cadmium(II), copper(II)–lead(II), copper(II)–cadmium(II), and indium(III)–lead(II) systems are less than 0.1 V which makes it difficult to determine the above components in mixtures.

The application of extraction polarography makes it possible to determine certain elements when these are present jointly. For example, in a benzene extract the values of $\Delta E_{1/2}$ are as follows: 0.19 V for copper(II) and bismuth(III), 0.29 V for copper(II) and lead(II), 0.30 V for copper(II) and cadmium(II), 0.13 V for lead(II) and thallium(I), 0.30 V for indium(III) and cadmium(II), 0.35 V for indium(III) and lead(II), and 0.48 V for indium(III) and thallium(I). A similar observation has been made for extracts in isopentyl alcohol and ethyl acetate. The values of $E_{1/2}$ in these solvents are sufficient for the joint polarographic determination of the above pairs of ions even when one is present in a considerable excess. The possibility of the polarographic determination of molybdenum in the presence of other metals after extraction of its BPHA complex with chloroform has been noted[39].

The results of the polarographic study of *N*-cinnamoylphenylhydroxylamine (CAPHA) and its metal complexes have been published[72–81]. In organic solvents CAPHA is reduced at −1.2 V relative to the saturated calomel electrode, so that the limit of the polarographic determination is 0.0 to −1.2 V. The CAPHA complexes of thallium(I), lead(II), copper(II), cadmium(II), zinc(II), nickel(II), iron(III), gallium(III), bismuth(III), indium(III), titanium(IV), vanadium(V), zirconium(IV), tungsten(VI), and molybdenum(VI) have been investigated in pentyl alcohol, ethylacetate, benzene, and chloroform with added methanol.

The dependence of the height of the wave for the copper, indium, and iron complexes of CAPHA in the benzene extract on the initial metal concentration in aqueous solution is linear and indicates the possibility of the determination of these elements by the extraction-polarographic method. Since this entails an increase of the selectivity of the elements as a result of the different polarographic behaviour of the CAPHA complexes of metals in organic solvents, indium(III) can be determined in the presence of copper(II) and lead(II) and in mixtures with cadmium(II) and gallium(III), copper(II) can be determined in the presence of bismuth(III), thallium(I) can be determined in the presence of indium(III) and gallium(III), etc. Furthermore, the selectivity of the determination increases owing to the unequal capacities of the metal complexes of CAPHA for extraction under the conditions of different acidities of the aqueous solution. Thus the lead, zinc, nickel, and cadmium complexes are not extracted μat pH 3 and in the extraction polarographic method do not therefore interfere in the determination of molybdenum, tungsten, gallium(II), iron(III), titanium(IV), vanadium(V), and indium. It is possible to determine indium and copper in the presence of various elements.

It has been observed that metal *N*-cinnamoylphenylhydroxylaminates give rise to the following polarographic spectrum in benzene extracts in terms of their ability to be reduced at the m.d.e.: Cu(II) < Tl(I) < Bi(III) < Mo(VI) < V(V) < Fe(III) < Cd(II) < Pb(II) < W(VI) < Ti(IV) < In(III).[74] By introducing tartaric acid and sodium fluoride into the aqueous phase before extraction, the interfering influence of tin, vanadium, titanium, molybdenum, and iron is eliminated. An extraction-polarographic method has been developed on the basis of experimental studies for the determination of copper and lead in various materials; it is distinguished by a high sensitivity and a fairly high selectivity[74].

Various oxime derivatives have found applications in extraction polarography[83–85]. The possibility of the extraction-polarographic determination of microgram amounts of nickel after its concentration in the form of the dimethylglyoximate has been investigated[85]. The method is based on the use of the catalytic hydrogen wave and is therefore one of the most sensitive polarographic procedures for the determination of nickel. When dimethylglyoxime is added to a solution containing nickel, the height of the nickel reduction wave increases by a factor of approximately 6. The lower limit of the determination of nickel under the recommended conditions is 1×10^{-6} M at a m.d.e. and 1×10^{-7} at a stationary mercury electrode. The sensitivity increases appreciably when oscillographic polarography is used (as far as 1.5×10^{-8} M).

A study of the possibility of using α-furylglyoxime and α-benzylglyoxime showed[85] that it is better to employ dimethylglyoxime, since it dissolves more readily than α-benzylglyoxime, and the wave heights do not differ quite so much (in the case of α-furylglyoxime the wave height is much smaller). Copper and cobalt are extracted together with nickel from ammonia solutions in the form of hydroxyquinolinates. Although the extraction is not quantitative, copper and cobalt nevertheless interfere with the photometric determination of nickel. On the other hand, the proposed extraction polarographic method makes it possible to determine nickel quantitatively in the presence of amounts of copper and cobalt in the extract greater by a factor of 100.

Polarographic data for metal *salicylaldoximates* and *thenoyltrifluoroacetonates* in toluene and benzene extracts and in butanol–acetophenone mixtures have been published[8]. In toluene polarographic waves were observed for copper, iron, cobalt, nickel, palladium, and titanium salicylaldoximates, i.e. a much greater number of metal compounds of this reagent are reduced in toluene than in the case of hydroxyquinolinates[6].

Among the thenoyltrifluoroacetonates (TTA), only copper, lead, thallium, and uranyl complexes are reduced polarographically[8]. This makes it possible to determine copper and lead in the presence of much greater amounts of bismuth, which does not give rise to a wave. The use of isobutyl methyl ketone (IBMK) as the extracting solvent makes it possible to include iron ions among those of the elements investigated[100]. When iron(III) is extracted in the form of a complex with TTA, the extraction is carried out from an acetate buffer solution at pH 5.8; a complex anodic-cathodic wave is observed in the organic phase at a potential characteristic of the reduction of $Fe(TTA)_3$, which indicates the presence of iron(III) and iron(II) complexes in the organic phase. A polarographic determination of thallium(III), which is difficult to determine in aqueous media, is also possible.

TTA is unsuitable for extraction polarography as a result of the narrow range of polarisations. With increase of the acidity of the medium, the comparatively narrow range of m.d.e. cathodic polarisations (−0.20 – −0.75 V) becomes narrower still (is reduced to −0.60 V).

Phosphorus dithio-acids are widely used as analytical reagents in separations by the extraction method, mainly with spectrophotometric detection. However, not all complexes formed by phosphorus dithio-acids with metal ions absorb in the accessible region of the spectrum. This imposes certain limitations on extraction-photometric determinations. Extraction polarography is more promising in such cases. There are few literature data concerning the use of this method for the determination of metals in the form of dithiophosphate complexes. The polarographic properties of a number of transition and non-transition metal diethyl dithiophosphates and their extractability by certain aromatic hydrocarbons have been investigated[26,27,29]. Under the conditions used, the electrochemical reduction of thallium, lead, and copper diethyl dithiophosphates is inhibited by the reduction product adsorbed on the electrode[29].

Diethyl dithiophosphate complexes in another group, including vanadium(IV), chromium(III), nickel(II), cobalt(II), zinc(II), manganese(II), and cadmium(II) compounds, are reduced with fnrmation of waves uncomplicated by adsorption phenomena[29], which is due primarily to the fact that the reduction occurs in the range of potentials more negative than the electrocapillary zero potential[29].

Dithiocarbamates are used in extraction-polarographic analysis mainly for the determination of elements which do not form coloured complexes and which cannot be determined spectrophotometrically.

The extraction of lead(II) by benzene in the form of $Pb(R_2NCS_2)_2$ and $Pb[(CH_2)_nNCS_2]_2$ ($R = C_2H_5$ or C_4H_9; $n = 4, 5$) has been investigated polarographically. The distribution of the chelates between water and the organic phase was followed by oscillographic polarography[55]. The presence of nickel(II), chromium(III), zinc(II), aluminium(III), molybdenum(VI), tungsten(VI), vanadium(V), and titanium(IV) in the test solution does not interfere with the determination of lead(II), because the chelates of the first four metals are reduced at more negative potentials than $Pb(R_2NCS_2)_2$; the chelates of the remaining elements are hardly extracted at pH >7. The high resolving power of oscillographic polarography makes it possible to determine lead(II) in the presence of comparable amounts of bismuth(III) and thallium(I).

Taking into account data for the extraction of zinc(II) as $Zn(R_2NCS_2)_2$ by pentyl acetate at pH 3, a method has been developed for the extraction-polarographic determination of zinc(II) in the blood of animals[55]. The concentration of zinc(II) was found from the limiting current for the wave with $E_{1/2} = -1.45$ V (relative to s.c.e.). In order to eliminate the interference by cobalt(II) and manganese(II), sodium thiosulphate was added. The optimum conditions for the distribution of $Zn(R_2NCS_2)_2$ in the benzene–water system obtain at pH 10–11.

The possibility of the selective extraction of copper(II), lead(II), zinc(II), manganese(II), cadmium(II), nickel(II), and bismuth(III) in the form of their dithiocarbamate complexes has been investigated[52]. Best results are achieved in in a 1:1 benzene–methanol medium (an emulsion is formed in toluene). The values of $E_{1/2}$ for these complexes are similar. In order to determine the metal ions present jointly in the same solution, use was made of extraction at different pH in conjunction with masking reagents.

Other aspects of the electrochemical behaviour of metal chelates in relation to derivatives of dithiocarbamic, xanthic, and dithiophosphoric acids were discussed in detail in previous sections of the review.

Dithizone is used to a lesser extent as an extractant in extraction polarography. A method has been developed for the determination of copper in natural waters based on the concentration of copper by extraction in the form of a dithizonate and the polarography of the toluene extract in the presence of a hydrochloric acid buffer solution as the supporting electrolyte[38].

Extraction polarography can prove to be irreplaceable in those cases where the technological processes are carried out in non-aqueous media, for example in polymerisation in the presence of catalysts. The concentration of a copper catalyst has been determined[99] directly in the reaction mixture. In such cases re-extraction is impracticable in view of the long duration and laborious nature of the operations, and extraction polarography therefore significantly simplifies and facilitates analysis.

Among different electrochemical analytical methods, particular interest attaches to anodic extraction voltamperometry at solid electrodes, which involves a preliminary extraction of the complexes into a diluent and the measurement of their oxidation current. In a 2:3 toluene–acetone mixture in the presence of 0.1 M $LiClO_4$ supporting electrolyte chromium(III), manganese(II), iron(III), cobalt(II), cobalt(III), nickel(II), copper(II), zinc(II), cadmium(II), lead(II), bismuth(III) and thallium(I) dithiocarbamate, xanthate, and dithiophosphate complexes are oxidised at graphite and platinum disc electrodes with formation of diffusion waves whose positions along the potential axis are determined by the nature of the central ion and the ligand[57–59]. The results make it possible to select the extractant as a function of the object of the analysis. For example, in the determination of nickel(II) and zinc(II) extraction should be carried out with dithiocarbamates, since the dithiophosphate complexes of the above metals are oxidised virtually at the same potential (1.13 and 1.08 V respectively). In extraction from strongly acid media preference should be given to dithiophosphates. Account must be taken also of the electrode. In the oxidation of dithiophosphate complexes at a platinum electrode no waves were observed on voltage–current curves.

Anodic voltamperometry makes it possible to extend the range of extracting solvents compared with polarography. Apart from toluene, chloroform and carbon tetrachloride have been used in the determination of copper(II).[48,59] The extraction of metal dithiocarbamates by these solvents has been thoroughly investigated[108]. However, their use in polarography encounters difficulties owing to the narrow range of cathodic polarisation potentials. The oxidation of copper(II) dithiocarbamate at graphite in mixtures of acetone with $CHCl_3$ and CCl_4 gives rise to a single distinct diffusion wave at a potential of 0.6 V. The oxidation current at a rotating electrode in a 2:3 carbon tetrachloride–acetone mixture is several times higher than in a 2:3 toluene–acetone mixture at the same concentration. The lower limit of the detection of copper(II) is 0.5 – 0.7 μg ml^{-1}.[59]

Anodic extraction voltamperometry has a somewhat higher detection limit than polarography; the error of the determination is also increased (from 3–6% to 8–12%). Nevertheless this method also has undoubted advantages. Firstly, mercury as the electrode material is eliminated. Secondly, the duration of analysis is greatly reduced, because there is no need to remove the dissolved oxygen from the electrolyser (this is particularly important in routine analyses). Finally, it is possible to eliminate highly toxic solvents such as benzene and its analogues.

Together with the extraction of inner complexes, procedures based on the extraction of elements into an organic solvent in the form of thiocyanate complexes[109] or metal halide acids[22,32,110,111] have become common in voltamperometry.

In the determination of antimony and arsenic in industrial objects, they were extracted with benzene in the form of bromide complexes[112] and the extracts were polarographed in

a LiCl solution in ethanol or glacial acetic acid as the supporting electrolyte. The oscillopolarogram of the arsenic(III) extract shows two peaks at potentials of −0.3 and −0.8 V (relative to the mercury at the bottom of the cell). The second peak is suitable for the determination of arsenic(III) in the presence of antimony and tin in proportions of 1 : 100. In these supporting electrolytes antimony(III) is reduced at a potential of −0.2 V with formation of a distinct peak. Antimony(III) has been determined in objects free from arsenic(III).

Among the new extractants used for concentration and determination mention should be made of α-dibutylphosphinyl-α-hydroxypropionic acid (DPHP) with added isopentyl alcohol. This system has been recommended for the determination of cadmium(II) on the basis of the limiting current for the reduction of its complex with DPHP in the presence of copper(II).[101] The reaction of copper(II) with DPHP is masked by the addition of ethylenediamine.

The conditions for the extraction of indium(III) and tin(IV) ionic association complexes with tri-n-octylamine (TOA) in dichloroethane and the polarography of the extract in methanol in the presence of NH_4Br as the supporting electrolyte have been used to determine indium and tin in the $CdSiAs_2$ semiconducting compound alloyed with indium[102]. The change in the TOA concentration from 0.25 to 1.25 M increases the percentage extraction of indium from 54 to 99%. The composition of the extracted ionic association complex $(TOAH)_2SnCl_2$ was determined from the bilogarithmic plot of the partition coefficient against the amine concentration. A lower limit of $(2–5) \times 10^{-8}$ M in the detection of the indium impurity in $CdSiAs_2$ has been achieved as a result of a combination of extraction by concentration with polarographic accumulation of indium[103].

The principal results of the extraction-polarographic determinations of metals in various objects are summarised in Table 3. The Table does not include the results of studies involving re-extraction before polarography[113–116].

Table 3. Extraction-polarographic determination of elements in various objects.

Element	Reagent	Object of study	Conditions of extraction-polarographic determination	Remarks	References
Copper	8-hydroxy-quinoline	alloyed steels, babbitts	pH 3–14, toluene : methanol = 2 : 3; supporting electrolyte—0.1 M LiCl; Fe^{3+} ions masked by sodium fluoride	measurable concentration limits 4×10^{-6}–5×10^{-5} M	6,10
Copper	8-hydroxy-quinoline	petroleum	pH 2.4–12.0; benzene : methanol = 1 : 1; supporting electrolyte–NH_4NO_3 + NH_4SCN; accumulation potential = –0.4 V	relative error of extraction-polarographic determination 5.6%	17
Copper	dithizone	natural waters	extracted with 0.001% solution of dithizone in toluene at pH 2.15; polarographed mixture: toluene–acetone–hydrochloric acid buffer (1 : 19 : 5)	wave height proportional to concentration in the range 1×10^{-6}–8×10^{-5} M; 0.12 mg litre^{-1} determined in the water of Belaya River with a relative error of 3.7%	38
Copper and lead	CAPHA	silts and natural waters	pH 5.6–6.0; benzene (chloroform) : methanol = 2 : 3; supporting electrolyte—0.1 M LiCl	limits of proportionality of i_{lim} for a lead complex 1×10^{-5}–6×10^{-4}M and for a copper complex 1×10^{-5}–8×10^{-4} M; Ni, Co, Zn, Mn, In, Ga, Fe, and Cd do not interfere with determinations; sensitivity 5×10^{-4}% in silts and 10 mg litre^{-1} in water; relative error not exceeding 5%	74
Copper and lead	CAPHA	sedimentary rocks and minerals	pH 5.6–7.7; benzene : methanol = 2 : 3; supporting electrolyte—0.1 M LiCl	simultaneous determination based on difference in $E_{1/2}$ ($\Delta E_{1/2}$ = 0.25 V); sensitivity of method 5×10^{-4}%; relative error not exceeding 5%	73
Lead	sodium dialkyl-dithiocarbamates	heat resistant EI-437B nickel alloy	pH 8.5; benzene : ethanol = 2 : 3; supporting electrolyte—0.1 M $NaClO_4$	upper limit of proportionality 7×10^{-4}M (R = C_2H_5) and 1×10^{-3} M (R = C_4H_9); Ni, Cr, Zn, Al, Mo, V, Ti, Bi, and Tl do not interfere with determination; lower limit of determination 1×10^{-6} M (oscillopolarography)	55
Lead	8-hydroxy-quinoline	–	pH 9–12; extractant—fused naphthalene; supporting electrolyte—0.1 M pyridine + 0.1 M $HClO_4$; extract dissolves in dimethyl-formamide	limits of calibration graph 0–112 μg/10 ml; Pd, Cd, and Hg interfere with determination	61
Lead and zinc	xanthates	standard specimens and industrial objects	pH 3–5; extractant—benzene (CCl_4 or $CHCl_3$); supporting electrolyte—LiCl in ethanol	tenfold amounts of Fe, Ni, and Cu interfere with determination (oscillopolarography)	86
Zinc	sodium diethyl-dithiocarbamate	animal blood	pH 3; pentyl acetate : ethanol = 2 : 3; supporting electrolyte— 0.2 M $NaClO_4$; optimum conditions for zinc: benzene–ethanol at pH 10–11	interference by Co and Mn is eliminated with sodium thiosulphate; lower limit of determination 8×10^{-6}M	55
Iron, manganese, and zinc	sodium dimethyl-dithiocarbamate, ethylenebis-dithiocarbamate	residual amounts of ferbam, ziram, and maneb	benzene : methanol = 2 : 3; supporting electrolyte—0.2 M $LiClO_4$	lower limit of determination for Fe and Mn 1×10^{-7} M (a.c. polarography)	23
Iron	acetylacetone, thenoyltrifluoro-acetone	–	extractant—isobutyl methyl ketone; supporting electrolyte—0.1 M $(C_4H_9)_4NClO_4$; pH 8.8–9.1	quantitative extraction with acetylacetone; iron can be determined in the concentration range 8×10^{-5}–1×10^{-3} M	96

Table 3 (contd.)

Element	Reagent	Object of study	Conditions of extraction-polarographic determination	Remarks	References
Nickel	dimethylglyoxime	sea water	pH 9-10; ammonia buffer solutions; polarographed mixture: toluene—1 M ammonia buffer-ethanol	down to 1×10^{-8} M Ni determined from catalytic hydrogen wave; hundred-fold amounts of Cu and Co in extract do not interfere (oscillographic differential polarography)	85
Indium	4-benzoyl-3-methyl-1-phenyl-5-pyrazolone	doped semiconducting alloys	pH 1.2-1.3; polarographed mixture: chloroform—1 M LiCl or 0.75 M NH_4Br in methanol (1:4)	sensitivity of determination much higher when NH_4Br is used than for LiCl; accompanying elements (Cd, Sb, As) do not affect peak height	94
Indium	8-hydroxyquinoline	–	extractant—fused naphthalene; pH 3-12; supporting electrolyte—0.1 M pyridine + 0.1 M $HClO_4$ in dimethylformamide	i_{lim} proportional to metal concentration in the range 0.7-21.5 $\mu g\ ml^{-1}$; error of determination 1.1% majority of cations and anions do not interfere with determination; complexone III interferes	62
Molybdenum	8-hydroxyquinoline	alloys and other complex materials	extractant—naphthalene; extraction temperature ~ 60 °C; pH 2.25-5.30; supporting electrolyte—0.1 M $NaClO_4$ + 0.1 M $HClO_4$ in DMF	citrates, oxalates, tartrates, $PdCl_2$, and $FeCl_3$ interfere with determination; the majority of ions do not interfere	
Molybdenum	BPHA	steel	Mo extracted from hydrochloric acid solution with 2 ml of 1% BPHA solution in $HClO_4$; LiCl in methanol also added	the majority of metals and complex-forming substances do not interfere with determination	39
Cadmium	α-dibutylphosphinyl-α-hydroxypropionic acid	aluminium alloys	isopentyl extract polarographed in the presence of 0.1 M LiCl in ethanol as supporting electrolyte; pH of aqueous phase 6	minimum measurable amount of cadmium 5.6×10^{-4} mg ml^{-1}	101
Antimony	diantipyrinylmethane	steels	1 M LiCl in ethanol added to extract before oscillopolarographic measurements	linear relation between peak height and Sb^{3+} concentration holds between 1×10^{-7} and 1×10^{-3} M; Cu for a 20:1 ratio, Bi for a 3:1 ratio, and Sn for all ratios interfere with determination; relative error <10%	92
Arsenic	–	steels	As^{3+} extracted from 11.5 *N* HCl with carbon tetrachloride and butanol is added	error +0.4-2.0% (oscillopolarography)	96
Gallium	salicylic acid	metallic aluminium	pH 3; homogeneous mixture; butyl acetate–aqueous 0.5 M LiCl solution and 0.1 M sodium salicylate—ethanol (1:1:2)	range of proportionality of gallium concentration 5.4×10^{-4}-2.2×10^{-3} M	97

*Extraction in the form of halide complexes.

Thermodynamic Treatment of the Polarity and the Selectivity of Sorbents in Gas Chromatography

R.V.Golovnya and T.A.Misharina

Existing methods for assessing the polarity and the selectivity of sorbents in gas chromatography are examined. The recently developed thermodynamic treatment of the polarity and the selectivity of stationary phases is shown to have several advantages over the Rohrschneider-McReynolds system. Attention is paid mainly to the quantitative characterisation of the energy of sorbate-sorbent intermolecular interactions on the basis of retention indices. A universal system is proposed for assessing polarity and selectivity in gas chromatography in terms of the energy of intermolecular interaction.
A list of 83 references is included.

I. INTRODUCTION

The widespread use of gas-chromatographic methods of analysis in science and technology makes it necessary to assess as fully as possible the properties of stationary phases and adsorbents, which would permit the choice of optimum conditions for analysis. The problem of classifying stationary phases in gas chromatography and assessing their polarity and selectivity has already been the subject of research for more than twenty years. Empirical methods for such assessment have been surveyed[1].

Before passing to a thermodynamic consideration of the problem of polarity and selectivity, we shall briefly consider existing methods of determination. According to Littlewood polarity is determined by the enhanced affinity of the given substance for a polar compound ("the stationary phase is the more polar the longer it retains a polar substance in comparison with the retention of a non-polar substance"[2]). The polarity of a compound is attributed to the presence of a dipole moment; the magnitude of the orientation (dipole–dipole) interaction is regarded as decisive in assessing the polarity of a stationary phase[3,4]. Several attempts have been made to relate polarity to the electrostatic and structural properties of stationary phases and substances analysed. Careful analysis of these results[5-7] has shown that only when both structures are comparatively simple, while the proportion of polar groups in the stationary phase is not too large, do relative retentions clearly depend on polarisability, the dipole moments of the interacting molecules, and the dielectric constant of the stationary phase. It is especially difficult to establish any dependence with stationary phases and compounds whose molecules have no dipole moment but are capable of forming hydrogen bonds (such stationary phases are usually regarded as polar[8,9]). Substances that have no dipole moment but are capable of complex formation are retained better by polar than by non-polar phases. The results that have accumulated have made it necessary to interpret the polarity of stationary phases somewhat more broadly, as the capability of such phases for electron-donor–acceptor interaction with a substance being analysed[10].

Numerous attempts have been made to assess the polarities of stationary phases, adsorbents, and carriers empirically in terms of the retention of polar and non-polar substances. Kovats and Wehrly developed[11,12] the idea of estimating the polarities of stationary phases from the retention indices I of a series of compounds of general formula RX, where R represents an n-alkyl radical containing at least six carbon atoms, and X various functional groups. Selectivity was measured by the difference ΔI between the retention indices for each of the substances RX on the given stationary phase and on Apiezon L. The range of ΔI values was termed the "retention dispersion". Despite the great quantity of information which this parameter gave on the ability of stationary phases to retain substances containing various functional groups, it did not become widely used because of the large amount of experimental work required. Bayer[13] suggested that selectivity could be determined from the relative retention of two substances having similar boiling points, one of these compounds being an n-alkane. Rohrschneider[14] used the relative butane–butadiene retention to assess polarity; he chose squalane and oxy-$\beta\beta'$-dipropionitrile as extreme points of the polarity scale, with that for squalane equated to zero. Later suggestions for determining the polarity of stationary phases have included the use of two[15-19], three[20-23], and five[24] compounds.

The well known Rohrschneider–McReynolds system[25-27] has become the most widely used, in which the main compounds for testing stationary phases are benzene, butanol, pentan-2-one, nitropropane, and pyridine, supplemented by 2-methylpentan-2-ol, 1-iodobutane, oct-2-yne, 1,4-dioxan, and *cis*-hydrindane. The indices I for the first five test compounds serve for the assessment of polarity, and the differences ΔI for assessing the selectivity of stationary phases.

It is interesting that the suggestion has been made repeatedly that the polarity of stationary phases should be assessed from the relative retention of adjacent n-alkane homologues[28-31]. It was first proposed[28] that the polarity should be defined by

$$\lg \alpha = \lg V_{g(n+1)} - \lg V_{gn},$$

where $V_{g(n+1)}$ and V_{gn} are the retention volumes of n-alkanes containing respectively $n+1$ and n carbon atoms. It was assumed that the more polar the stationary phase the shorter the retention time of n-alkanes. The one-sidedness of assessing the polarity of stationary phases with respect to n-alkanes has been stressed[32,33].

The problem of determining the polarity of stationary phases in terms of the differential molar free energy per mole of methylene groups in n-alkanes has been discussed[34-36]. Developing these ideas, Novak suggested[10] that the polarity should be determined from the excess energies of mixing of a mole of methylene groups. He obtained these values by measuring the retention times of acetates forming a homologous series and the vapour pressures of the homologues at the analysis temperature and a pressure of 1 atm. The idea of assessing the polarity of stationary phases solely on the basis of the change in the retention parameters of n-alkanes or their thermodynamic characteristics is somewhat illogical, since this involves an attempt to determine polarity by testing compounds for which polar interactions with stationary phases are uncharacteristic. The decrease in energy of dispersion interaction during analysis on a polar phase is thus assumed to be directly proportional to the capacity of the phase for polar interactions. This hypothesis requires proof: it cannot be assumed *a priori*. In any case the polarity scale based on capacity for dispersion interaction is uninformative. It has been suggested[36,37] that the polarity and the selectivity of stationary phases should be estimated from the differential molar enthalpies of the dissolution of compounds containing a series of functional groups. Enthalpies were determined from the temperature dependence of the specific retention volume of the test substances. However, an approach to the assessment of ability to retain polar substances that disregards the change in entropy is not rigorous. The analysis of polar substances on polar stationary phases involves not only a change in the heat of dissolution but also a decrease in the degree of freedom of the molecule analysed, so that retention is determined by the overall differential molar free energy of dissolution. Neglect of the entropy contribution may lead to erroneous conclusions. The need to allow for the entropy contribution in assessing polarity has been noted[38,39] with the suggestion that the polarity of stationary phases should be estimated from the energy contributions by various functional groups.

A tendency has appeared recently for the concepts of "polarity" and "selectivity" to be equated[40,41], which introduces still greater confusion into an understanding of the physical significance of these terms. Thus the concept of polarity and selectivity in gas chromatography has hitherto remained indeterminate. Inspection of published results reveals ambiguity in the treatment of this concept.

The present Review is concerned mainly with the thermodynamic assessment of polarity and selectivity. These concepts are interpreted in terms of various types of intermolecular interactions governing retention in gas chromatography. Systematic regard for the thermodynamic characteristics of processes involved in the interaction between the sorbent and the substances undergoing analysis enables a simple method to be recommended for the quantitative estimation of polarity and selectivity from thermodynamic quantities.

II. INTERMOLECULAR INTERACTIONS GOVERNING RETENTION IN GAS CHROMATOGRAPHY

Retention in chromatography is determined mainly by the energy of intermolecular interactions between the substances undergoing analysis and the stationary liquid phase or the adsorbent. The differential molar free energy of dissolution or adsorption is the sum of the energies of the intermolecular interactions—non-specific, due to physical forces, and specific electron-donor–acceptor interactions, which are chemical in nature.

Physical forces of interaction between two molecules (van der Waals forces) comprise dispersion, induction, and orientation interactions, the total energy of which is for diatomic molecules 1–3 kcal mole^{-1}.[42] The energy of dispersion interaction to the London approximation E_d is the main component of the physical forces:

$$E_d = -\frac{3}{2}\frac{\pi h}{R^6}\alpha_1\alpha_2\frac{J_1 \cdot J_2}{J_1 + J_2}, \quad (1)$$

where α is the static polarisability of the molecules, the J are their ionisation potentials, and R is the intermolecular distance.

If the molecules have non-zero dipole moments μ_1 and μ_2, the contribution of the energy of orientation interaction E_0 may be very substantial:

$$E_0 = -\frac{2}{3kTR^6}\mu_1^2\mu_2^2, \quad (2)$$

where k is Boltzmann's constant and T K is the temperature. In some cases E_0 may reach 50% of the energy of the physical forces[42-44].

The energy of induction interaction E_i usually introduces a small fraction to the total energy; it is expressed by the Debye formula[43]

$$E_i = -\frac{1}{R^6}(\mu_1^2\alpha_2 + \mu_2^2\alpha_1). \quad (3)$$

Thus the energy of the physical forces of interaction of the molecules depends on their static polarisability α, ionisation potentials J, and dipole moments μ. The polarisability can be calculated by means of the formula[42]

$$\alpha = \frac{3}{4}\frac{MR_\infty}{\pi N} \approx \frac{3}{4}\frac{MR_D}{\pi N}.$$

Since $n_\infty^2 \cong 1.1 n_D^2$, we find that

$$\alpha = \frac{3}{4\pi N}\frac{n_D^2 - 1}{n_D^2 + 2}\tilde{V}_m \quad (4)$$

where MR_D is the molecular refraction for the sodium D-line, MR_∞ the molecular refraction for light of zero frequency[42], i.e. at infinite wavelength, n_D the refractive index for the sodium D-line, N Avogadro's number, and $\tilde{V}_m$ the molar volume. We shall examine the cases encountered in gas chromatography.

1. In the analysis of a non-polar molecule (subscript "T") on a non-polar stationary phase (subscript "Ph") the differential molar free energy of dissolution is determined by the energy of dispersion interaction: i.e. $E = E_d$. Hence the greater the molecular refraction the more strongly will the substance be retained by the column sorbent. This was first verified experimentally by Littlewood[2].

2. In the analysis of a non-polar substance on a polar phase or of a polar substance on a non-polar phase the interaction energy is determined by the sum of the contributions:

$$E = E_d + E_i; \quad (5)$$

in which E_i, calculated by means of Eqn.(3), will have a single component. If the dipole moment of the test substance $\mu_T = 0$, we have

$$E_i = -\frac{1}{R^6}\mu_{Ph}^2\alpha_T; \quad (6)$$

if, however, $\mu_{Ph} = 0$, then

$$E_i = -\frac{1}{R^6}\mu_T^2\alpha_{Ph}. \quad (7)$$

It must be borne in mind that, if the substance is capable of donor–acceptor interaction (DA) with the stationary phase, the energy of such specific interaction is added:

$$E = E_d + E_i + E_{DA}. \quad (8)$$

For example, benzene and *p*-dinitrobenzene have zero dipole moments, but with several polar phases they give π-complexes; the donor–acceptor interaction energy of aromatic hydrocarbons with the ether groups of polyethylene glycols (PEG) reaches ~1.8 kcal mole^{-1},[45] and must be taken into account.

3. In the analysis of a polar substance on a polar stationary phase all types of physical interaction occur, and interactions of chemical nature—complex formation, hydrogen bonding, etc.—are often added. The total interaction energy is

$$E = E_d + E_i + E_o + E_{DA}. \quad (9)$$

The concept of physical interactions has been developed and tested experimentally for diatomic molecules. Applied to gas chromatography, therefore, it merely enables us to understand on what the energy of physical forces of interaction depends, what is the contribution by each component to the total free energy. It makes possible prediction of the sequence in which substances of similar structure are eluted from a column in the absence of specific donor–acceptor interactions with the sorbent. Actually, the interaction energy is considerably greater, and an accurate calculation must take into account the influence on the test molecule of the surrounding medium, the molecular weight, the number of contacts with the stationary phase, etc; an attempt can be made to use for this purpose one of the theories of solutions[46,47]. Experimental data indicate that the energy of interaction of non-specific physical forces in gas–liquid chromatography may reach ~10 kcal mole^{-1}. When the methyl ester of an aliphatic acid containing 24 carbon atoms undergoes analysis on SE-30, for example, the differential molar free energy is 8.34 kcal mole^{-1}.[48]

The differential molar free energy of sorption, which determines the retention of a substance in a column, is in general the sum of energies of both physical and chemical types of interaction; this sum is determined solely by experiment. According to views developed by Zhukhovitskii, furthermore, the free energy probably includes also the energy consumed by the substance in penetrating the stationary phase[3,5,49,50]. The contribution by the energy of donor–acceptor interactions, which are chemical in nature, may be significant in the analysis of polar substances on polar stationary phases. Such interactions probably involve at least partial delocalisation of electrons and the formation of electron-donor–acceptor bonds. The energy of weak donor–acceptor interactions usually varies in the range 1–3 kcal mole^{-1}. In the case of hydrogen bonds it may reach 3–8 kcal mole^{-1}.[51,52]

Experimental investigation of donor–acceptor interactions began at the start of the 1960s. The properties of many such interactions and their energies of formation have been given in a monograph[53]. Several determinations of the energy of weak hydrogen bonds have been made by the methods of infrared spectroscopy and gas chromatography[54,55]. There is no doubt that donor–acceptor interactions occur widely. Published data[56] enable us to assess between what classes of substances they are possible and what is the heat of formation of the complexes. Benzene, for example, is active in forming complexes with aromatic compounds—benzene, phenol, aniline—and also with dioxan and hydrogen cyanide. Complex formation of similar type probably occurs in the analysis of benzene and other aromatic compounds on silicone phases containing phenyl and nitrile groups, as well as on phases containing ether groups (polyethylene glycols, Tritons, Carbowaxes, etc.). Complex formation with alcohols can occur during analysis on stationary phases containing nitrile and ester groups. During gas-chromatographic analysis the energy contribution by donor–acceptor interactions to the free energy may be substantial[45,51–56].

Thus the differential molar free energy of dissolution of a substance in a stationary phase is the sum of non-specific energies of intermolecular interactions amounting to ~1–10 kcal mole^{-1}, due to physical forces, and the energy of specific donor–acceptor interactions of chemical nature, including hydrogen bonding (~1–8 kcal mole^{-1}).

III. THERMODYNAMIC TREATMENT OF THE POLARITY AND SELECTIVITY OF STATIONARY PHASES AND ADSORBENTS IN GAS CHROMATOGRAPHY

It has already been remarked that the concepts of polarity and selectivity are very indefinite in gas chromatography, and are interpreted differently by different investigators[2–40]. In the opinion of the Reviewers gas-chromatographic polarity must be interpreted as *the capacity of a sorbent for various types of intermolecular interactions,* which is assessed from the differential molar free energy respectively of dissolution and of adsorption ΔG and ΔG_A in gas–liquid and gas–adsorption chromatography: the higher is ΔG, the more polar the sorbent. The selectivity of two comparable stationary phases or adsorbents represents *the difference in ability to retain* the compound analysed, and is expressed quantitatively by the difference in excess energies of mixing $\delta(\Delta G^E)$[57]: the greater the value of $\delta(\Delta G^E)_{2,1}$, the greater the selectivity of sorbent *2* in comparison with *1*.

The polarity of a sorbent cannot be assessed by analysing only one substance, since it is impossible to choose a compound capable of all types of intermolecular interactions on contact with the sorbent. A series of test substances must be selected that model possible intermolecular interactions most closely and completely. They should include those that will reveal the capacity of the sorbent for dispersion, orientation (dipole–dipole), and induction interactions, and permit determination of electron-donor–acceptor properties, as well as the ability to form hydrogen bonds.

Determination of the polarity of stationary phases or adsorbents requires the use, not of a single scale for one test substance, but of a set of scales for all the test substances. The reason is that each sorbent has a different capacity for intermolecular interactions during an analysis, and it is advisable to compare all free energies for all test substances. But the sum of the values

$$\sum_1^i \Delta G_i,$$

like the sum[24,58]

$$\sum_{i=1}^{i} \Delta I_i,$$

does not indicate individual features of a sorbent because of possible compensation effects. For example, a stationary phase with a large energy of dispersion interaction and hence a small energy of orientation interaction may have the same sum

$$\sum_{i=1}^{i} \Delta G_i,$$

as a phase having moderate energies of dispersion and electron-donor–acceptor interactions; therefore assessing polarity from the sum of the differential molar free energies of dissolution of all the test substances will not enable the optimum phase to be chosen for separating a specific mixture.

In every case the experimenter who has a mixture of compounds should envisage the intermolecular interactions of which they are capable, and then select a stationary phase or an adsorbent that will realise these possibilities. If, for example, compounds having a large dipole moment, unsaturated or hydroxylated, are to be separated, polarity scales are to be compared on the basis of free-energy values for substances that test the capacity of stationary phases for orientation interaction, π-complex formation, and hydrogen bonding.

The choice and the number of test substances have been the subject of study by many investigators for more than a decade[20-27]. The difficulty is that it is impossible to select test substances capable of only a single type of interaction—orientation, induction, or donor–acceptor interaction—for usually two or more types function simultaneously. Researches to find the necessary and sufficient number of test substances, made by Tacats[59], Hartkops[60], and de Clercq[61] with mathematical assessment of the weighting of each of a long series of proposed substances used to characterise stationary phases, have shown that Rohrschneider and McReynolds' five compounds are quite sufficient to assess the polarity of stationary phases in gas–liquid chromatography. Other substances will give little additional information on the properties of sorbents.

In the Reviewers' opinion the assessment of polarity can usefully be expressed in terms of six parameters[62-64] based on the differential molar free energies of dissolution ΔG^{CH_2} of a methylene unit of an n-alkane (or of a methyl ester of an aliphatic acid) and the five well known test substances[24,27,58]—benzene (x), butan-1-ol (y), pentan-2-one (z), 1-nitropropane (u), and pyridine (s)—which model the chief types of intermolecular interactions with stationary phases during analysis (Table 1). Some changes in this list of test substances may be required to estimate the polarity of adsorbents in gas–adsorption chromatography, but at present this is difficult to verify, since sufficient published data are not available.

If gas-chromatographic polarity is regarded as the capacity of sorbents for various intermolecular interactions (physical and chemical in nature) with substances undergoing analysis, it can be determined numerically from the differential molar free energies of sorption of the test substances. Retention of a compound in a column is always due to intermolecular forces of interaction. On this view there are in gas chromatography no stationary phases or adsorbents that are absolutely incapable of intermolecular interactions. In the old terminology non-polar solvents are those that are capable mainly of dispersion interaction with a substance to be analysed. Such stationary phases include, for example, squalane, Apiezons, Kovats' hydrocarbon, etc. These phases are characterised by large differential molar free energies of dissolution of the methylene group. According to the thermodynamic treatment of polarity they possess a large "dispersion polarity"[62]. Stationary phases and adsorbents that possess a minimal capacity for all types of intermolecular interactions, i.e. that have minimal values of ΔG for all test substances, must be included among non-polar sorbents[63,64].

Thus the thermodynamic interpretation of gas-chromatographic polarity attributes to this term a quite different significance from that accepted hitherto. Such a definition of polarity makes it easy to avoid the ambiguity in understanding the nature of sorption forces in gas chromatography and brings published results into an orderly system, avoiding the confusion that had arisen from a different interpretation of this concept.

The energy of the dispersion, orientation, induction, and donor–acceptor interactions responsible for the retention of a substance in a column depends on the temperature of analysis. Hence the polarity, defined by the energy of intermolecular interaction, will also depend on the temperature. Therefore the polarities of different stationary phases and adsorbents can be compared only under isothermal conditions at the same analysis temperature by comparing values of ΔG or specific retention volumes. It is incorrect to determine the polarities of different sorbents from the retention indices, and the selectivities from ΔI, as is widely done at the present time for stationary phases[58], since the energy value of an index unit changes from one sorbent to another (see Section IV). As a consequence, different sorption energies correspond to the same values of the retention index or of ΔI.

Recent publications have suggested[38,39] that the polarities of stationary phases should be determined from the differential molar free energies of dissolution of functional groups—hydroxyl, formyl, carbonyl, formyloxy, acetoxy, oxy—for homologous series of organic compounds. Firstly the dependence of the specific retention volume on the reciprocal of the temperature is plotted from two or three points, ΔH and ΔS are determined graphically, the total energy of dissolution ΔG is calculated, and then the energy contributions by individual fragments of the molecules, including functional groups, are determined[39]. However, the authors disregard the effect of the position of a functional group in a molecule on its energy contribution. For example, the contribution by a carbonyl group is greater in the homologous series of alkan-2-ones than in alkan-3- and -4-ones[65]; the same applies to the oxy-group, which is analogous to the thio-group[66] in its gas-chromatographic behaviour. Hence the estimation of polarity from the contributions by various functional groups[39] is quite complicated and does not give a true picture because of inaccurate calculation and a simplified treatment of the results.

Thus in the strict thermodynamic sense the capacity of a sorbent for various intermolecular interactions with a substance undergoing analysis (its polarity) is determined by the differential molar free energies of sorption. Selectivity represents a difference in the capacity of comparable sorbents for intermolecular interactions with the substance analysed, and is determined by the quantity $\delta(\Delta G^E)$.

IV. UNIVERSAL SYSTEM FOR ASSESSING POLARITY AND SELECTIVITY OF STATIONARY PHASES

1. Assessment of Polarity

Before considering a universal system for assessing the polarity of sorbents in gas chromatography we can usefully examine in greater detail the Rohrshchneider–McReynolds estimation of the polarity and selectivity of stationary phases[24-27,58], which has been widely used by research workers. By now more than 200 stationary phases have been classified according to this system[27,58], which diminishes the number of experiments in the selection of stationary phases for gas–liquid chromatography.

A detailed account of the principle underlying the characterisation of stationary phases will be found in a review[1]. According to Rohrschneider polarity and selectivity are characterised by five ΔI values, each the difference between the retention indices of a standard test substance x, y, z, u, or s (Section III) on the given stationary phase and on squalane regarded as a phase of "zero polarity".

In order to describe theoretically the relation between the ΔI values and the thermodynamic characteristics of the gas-chromatographic process Rohrschneider suggested the empirical equations[24]

$$\lg V_g = -\Delta G + \text{const}, \qquad (10)$$

$$-\frac{\Delta G^{CH_2}}{100} = B = b/100, \quad (11)$$

$$\Delta I = I_{Ph} - I_{Ph_1} = 100\frac{\Delta G_{Ph} - \Delta G_{Ph_0}}{\Delta G^{CH_2}_{Ph}}, \quad (12)$$

in which b is the coefficient in the dependence of the logarithm of the specific retention volume of an n-alkane on the number of carbon atoms

$$\lg V_{gn} = a + bn, \quad (13)$$

or

$$b = \lg V_{g(n+1)} - \lg V_{gn}; \quad (14)$$

$\Delta G^{CH_2}_{Ph}$ is the differential molar free energy of dissolution of a methylene group of the n-alkane in Ph, the polar phase, I_{Ph} and I_{Ph_1} are the retention indices of the substance on the phases Ph and Ph_1, the latter representing squalane, and ΔG_{Ph_0} is the energy of dissolution in the polar phase Ph of the hypothetical hydrocarbon containing $n = I_{Ph_1}/100$ carbon atoms.

Equation (10) shows the dependence of the specific retention volume V_g on the differential molar free energy of dissolution ΔG. Equation (11) represents the dependence of the differential molar free energy of dissolution of a methylene unit of an n-alkane ΔG^{CH_2} on the coefficient b. According to the fundamental empirical equation (12) the quantity ΔI is directly proportional to the difference between the free energies of dissolution on the given phase Ph and the phase of "zero polarity" Ph_1. Actually, Eqn.(10) is valid only when specific volumes of substances V_g are compared on the same stationary phase at the same temperature. According to other workers[67]

$$\Delta G = -2.3RT \lg \frac{V_g T\rho}{273}, \quad (15)$$

$$\lg V_g = -\frac{\Delta G}{2.3RT} - \lg \frac{T\rho}{273}, \quad (16)$$

where ρ is the density of the stationary phase at the analysis temperature T K. Hence Eqn.(16)—not Eqn.(10) as in Ref.24—must be used to classify different stationary phases.

A rigorous deduction of Eqns.(11) and (12) could be made after the relation between the retention index and the free energy ΔG had been established. In 1971 Golovnya and Arsen'ev showed[68] that

$$\Delta G = -2.3RT\left[\frac{I - 100n}{100}b + \lg\frac{V_{gn}T\rho}{273}\right], \quad (17)$$

which revealed discrepancies in Rohrschneider's thermodynamic treatment of ΔI and also ΔG^{CH_2}. Thus, when we use Eqn.(17) to express the differential molar free energies of dissolution of two n-alkane homologues ΔG_{n+1} and ΔG_n and take their difference, we obtain[62]

$$\Delta G^{CH_2} = -2.3RTb. \quad (18)$$

Hence calculation of the differential molar free energy of dissolution of a methylene unit of an n-alkane, or other homologous compounds in which the difference in the index per methylene unit is 100, requires the use of Eqn.(18), not Eqn.(11), which is not even dimensionally correct.

Use of Eqn.(17) to compare the gas-chromatographic behaviour of a given substance on the two phases Ph and Ph_0 yields for the difference in the differential molar free energies of dissolution the expression[63]

$$\delta(\Delta G)_{Ph,Ph_0} = \Delta G_{Ph} - \Delta G_{Ph_0} = \quad (19)$$
$$= \frac{1}{100}(I_{Ph}\Delta G^{CH_2}_{Ph} - I_{Ph_0}\Delta G^{CH_2}_{Ph_0}) - 2.3RT(a_{Ph} - a_{Ph_0}) + 2.3RT\lg\rho_{Ph}/\rho_{Ph_0},$$

where a_{Ph} and a_{Ph_0} are determined for n-alkanes by the application of Eqn.(13) to analytical results on these phases. Equation (19) shows that the difference in the free energies of dissolution in the two phases is a complicated function of the indices I_{Ph} and I_{Ph_0}, which is not consistent with the empirical equation (12) previously used to assess the polarity and the selectivity of stationary phases[24-27,58]. Analysis of Eqn.(19) reveals that the free-energy difference cannot be directly proportional to ΔI. The same conclusion can be reached by using the well known relation[44,48,69] $\Delta G = A + BI$ to express ΔI. The resulting formula

$$\Delta I_{Ph,Ph_0} = \frac{\Delta G_{Ph} - A_{Ph}}{\Delta G^{CH_2}_{Ph}} - \frac{\Delta G_{Ph_0} - A_{Ph_0}}{\Delta G^{CH_2}_{Ph_0}},$$

is not equivalent to Rohrschneider's equation (12). The Rohrschneider–McReynolds assessment of polarity distorts the real picture more strongly the greater the difference in the gas-chromatographic behaviour of n-alkanes on the stationary phases under comparison, and hence the difference in the quantities $\Delta G^{CH_2}_{Ph}$ and $\Delta G^{CH_2}_{Ph_0}$.

It follows from Eqn.(19) that the energy value of one index unit differs on different stationary phases. Therefore the same index on different stationary phases corresponds to different free energies. The energetic importance of unit retention index on a given stationary phase can be determined by means of Eqn.(18), since ΔG^{CH_2} correspond to 100 index units (i.u.), and $\Delta G_{i.u.} = \Delta G^{CH_2}/100 = -0.023RTb$ cal mole^{-1} is the energy value of one index unit. According to the thermodynamic treatment (Section III) the polarity of a stationary phase must be determined from ΔG values calculated from retention indices by means of Eqn.(17).[63] At the present time it is probably advisable to use the compounds listed in Table 1 as test substances for the assessment of polarity.

Table 1. Test species for assessment of phase polarities.

Species	Type of interaction with sorbent tested*
Methylene in n-alkane or methyl aliphatic ester	dispersion
Benzene	π-complex formation
Butan-1-ol	hydrogen bonding with electron-donor groups
Pentan-2-one (weak electron-donor)	donor–acceptor complex formation
1-Nitropropane	orientation, since dipole moment $\mu = 3.6$; donor–acceptor complex formation
Pyridine (base)	hydrogen bonding with hydrogen donors; donor–acceptor complex formation

*Only the retention of methylene groups is determined by the energy of dispersion interaction. Retention of the remaining test species, unfortunately, depends on the character of the sorbent as a consequence of the total energy of the dispersion, orientation, induction, and donor–acceptor interactions (Section II); the type of interaction which they test is a component of the total energy of sorption.

The capability of a sorbent for dispersion interaction with a substance undergoing analysis is determined from the differential free energy of sorption of a methylene group ΔG^{CH_2} in the homologous series of n-alkanes, or in methyl esters of aliphatic acids in the case of very polar sorbents.

It has recently been established[70] that these esters have a homologous difference of 100 index units per methylene group even on such polar phases as Silar 5CP and Silar 10C,[70] whereas the series of alkyl acetates suggested previously for this purpose[10] exhibits a variation in the homologous difference with the polarity of the phase, as follows from a comparison of the indices for homologues tabulated in Ref.71. Hence acetates cannot be recommended as test substances for the classification of sorbents according to their ΔG^{CH_2} values.

As example of the assessment of dispersion polarity Table 2 lists values of ΔG^{CH_2} for several stationary phases, calculated by means of Eqn.(18).[63] Comparison of the capacities of these phases for dispersion interaction, assessed from the ΔG^{CH_2} values (Table 2) shows that SE-30, which is non-polar in the old terminology, is less capable of dispersion interaction than are the moderately polar OV-17 and Chalcomide M-18 OL, and is close to the more polar Triton X-305. Hence the decrease in the capacity for dispersion interaction is not proportional to the increase in polarity of the stationary phases[62,63]. Maximum dispersion polarity, i.e. capacity for dispersion interaction with a substance, is exhibited by such phases as squalane, the Kovats hydrocarbon $C_{87}H_{176}$,[72] and the Apiezons. The greatest dispersion polarity among the stationary phases in Table 2 is exhibited by squalane, which has the highest free energy of dissolution of n-alkanes.

Table 2. "Dispersion polarity"* of some stationary phases at 120 °C, estimated from the differential molar free energies of dissolution of a methylene unit of an n-alkane ΔG^{CH_2}.[63]

*Results from Ref.63 supplemented by calculations of ΔG^{CH_2} for several stationary phases taken from tables[27,71].

The capacity of stationary phases for other types of intermolecular, including dispersion, interaction is determined from the differential molar free energies of dissolution of the five test substances (Table 1), which are calculated by means of Eqn.(17). Indices of the test substances, specific retention volumes V_{gn} of n-alkanes, and values of the coefficient b, which are required for the calculation, can be taken from Reynolds' tables[27,71]. Density data for stationary phases at the temperature of analysis cannot usually be found in the literature, and must be determined specially. If the density ρ is unknown, values of ΔG can be calculated[63] to within 10% by means of the formula

$$\Delta G + 2.3RT \lg \rho = -2.3RT\left[\frac{I - 100n}{100} b + \lg \frac{V_{gn}T}{273}\right]. \qquad (20)$$

This does not affect the general picture in the estimation of polarity.

Table 3 gives as example the estimation of polarity for several stationary phases from the ΔG values of the five test substances[63]. Comparison of ΔG^{CH_2} and of the five ΔG values permits numerical assessment of the capacity of the stationary phases for intermolecular interactions—dispersion, orientation, induction and donor—acceptor—including hydrogen bonding. The larger the value of ΔG for a given test substance the greater the capacity of the phase for those intermolecular interactions that are tested by this substance (Table 1). Thus in the thermodynamic treatment of polarity the most polar stationary phase will be that exhibiting the highest ΔG values for every test substance among comparable stationary phases, and the most non-polar that with which all five ΔG values are least. Inspection of Table 3 on this basis indicates SE-30 to be the most non-polar, and Oronite N1W the most polar. Table 3 indicates also that each stationary phase has its individual features. For example, the retention of alcohols on Oronite N1W, Poly-Tergent J-300, and Chalcomide M-18 OL, and that of organic bases on Oronite N1W, are greater than on polyethylene glycols. Aromatic compounds are retained most strongly by Oronite N1W, dioctyl sebacate, Chalcomide M-18 OL, Flexol 8N8, and Poly-Tergent J-300 (Table 3). The contribution of dispersion interaction to the total ΔG value can be determined as in Ref.62.

*Results from Ref.63 supplemented by calculation for stationary phases from Refs.27 and 71.

The system proposed[62-64] for assessing polarity from the ΔG^{CH_2} values and the five ΔG values of the Rohrschneider–McReynolds test substances is universally applicable. It does not require the "zero polarity" phase necessary in other methods for estimating the polarity of stationary phases[24,27,58], and can be extended to determination of the polarity of adsorbents in gas chromatography if values are included for

the differential molar free energies of adsorption ΔG_A of the test substances. The polarity of adsorbents can be calculated by means of the equations[63]

$$\Delta G_A^{CH_2} = -2.3RTb_A = -2.3RT\,[\lg V_{g(n+1)} - \lg V_{gn}], \quad (21)$$

$$\Delta G_A = -2.3RT\left[\frac{I-100n}{100}b + \lg V_{gn} - \lg RTS\right], \quad (22)$$

$$\delta(\Delta G)_{A_1A_2} = \frac{1}{100}(I_{A_1}\Delta G_{A_1}^{CH_2} - I_{A_2}\Delta G_{A_2}^{CH_2}) - 2.3RT\,(a_{A_1} - a_{A_2}) + 2.3RT \lg S_{A_1}/S_{A_2}, \quad (23)$$

in which a is the constant and b the coefficient in the relation $\lg V_{gn} = a + bn$ for n-alkanes analysed on an adsorbent A, where $b_A = \lg V_{g(n+1)} - \lg V_{gn}$, while I_{A_1} and I_{A_2} are the retention indices of the substance on adsorbents A_1 and A_2, with $\Delta G_{A_1}^{CH_2}$ and $\Delta G_{A_2}^{CH_2}$ the differential molar free energies of adsorption of a methylene unit in n-alkanes on these adsorbents, and S_{A_1} and S_{A_2} (in $cm^2\ g^{-1}$) their specific surfaces.

The single method of using free energies of sorption for quantitative assessment of the capability of stationary phases and adsorbents for intermolecular interactions with substances undergoing analysis makes it possible to characterise every sorbent individually.

2. Assessment of Selectivity

The term "selectivity" is widely used in gas chromatography, but it is often applied without regard to its thermodynamic basis, consequently with different and occasionally incorrect interpretations. For example, selectivity and column efficiency have been identified in one book[74]. Several papers regard selectivity as synonymous with polarity[38,40] or as the ability to separate two substances of closely similar boiling points, and distinguish three types of selectivity defined in different ways[75].

Actually the separating ability of a column is a result of its selectivity and efficiency. The former depends solely on the equilibrium characteristics in the sorbent–gas system; it indicates the difference in retention of the substances undergoing analysis, and is assessed in terms of the relative retention. Selectivity can be expressed quantitatively in terms of thermodynamic quantities. Efficiency depends on kinetic processes occurring in the column and influencing the peak widths; it is estimated as the height of a theoretical column H. It follows from van Deemter's rate theory[76] that H depends on the velocity of the carrier gas, diffusion, and resistance to mass exchange. The separation of two substances depends both on the selectivity and on the efficiency of the column, and is measured by the separation factor R,[43] which includes the distance d between the retention times of the substances and the widths w of their peaks:

$$R = 2d/(w_1 + w_2). \quad (24)$$

It is evident from this formula that the larger is d the higher the selectivity, and that the wider the peaks the lower the efficiency and hence the overall separation.

A thermodynamic examination of comparable gas-chromatographic processes will help to introduce complete clarity into an understanding of selectivity, which is used in two cases—to compare the abilities of (i) a given sorbent to retain two substances, and (ii) two sorbents to retain a given substance—as a characteristic of the properties of a sorbent. Both cases have been considered in terms of thermodynamics, and selectivity has been determined quantitatively from differences in differential molar free energy of mixing $\delta(\Delta G^E)$.[57,77]

The selectivity of a stationary phase in the separation of two substances is defined by the factor

$$\alpha_{ij} = \frac{\gamma_j^\infty p_j^0}{\gamma_i^\infty p_i^0} = (e^{\Delta G_j^E/RT}/e^{\Delta G_i^E/RT})\frac{p_j^0}{p_i^0}, \quad (25)$$

in which γ_i^∞ and γ_j^∞ are the activity coefficients of substances i and j at infinite dilution, p_i^0 and p_j^0 are their saturated vapour pressures under 1 atm at the column temperature, and ΔG_i^E and ΔG_j^E their excess free energies of mixing on the given stationary phase. After rearranging Eqn.(25) we obtain a quantitative assessment of the selectivity of a stationary phase in terms of the difference in excess free energies of dissolution of the two substances:

$$\delta(\Delta G^E)_{ij} = \ln \alpha_{ij} = \Delta G_i^E - \Delta G_j^E. \quad (26)$$

Since[68,77–79]

$$\delta(\Delta G^E)_{ij} = 2.3RT \lg \gamma_i/\gamma_j. \quad (27)$$

the selectivity of a given stationary phase with respect to two substances, i.e. the difference in its ability to retain them at a given temperature, is determined by the difference in the excess energies of mixing: it can be found from the polarity expressed in terms of ΔG by means of the equation[63,64]

$$\delta(\Delta G^E)_{ij} = \delta(\Delta G)_{ij} - 2.3RT \lg p_i^0/p_j^0. \quad (28)$$

The calculation of selectivity by means of this formula requires knowledge of the vapour pressures of the pure substances p_i^0 and p_j^0 under 1 atm at the analysis temperature. When the polarity of the phase expressed in free energies is unknown, the first term in Eqn.(28) can be calculated from the difference in the retention indices of i and j by means of the equation[44]

$$\delta(\Delta G)_{ij} = -2.3RTb\frac{\delta I_{ij}}{100}. \quad (29)$$

It follows from (28) and (29) that the selectivity of one stationary phase with respect to substances i and j can be calculated by means of the formula[63,64]

$$\delta(\Delta G^E)_{ij} = -2.3RT\left[b\frac{\delta I_{ij}}{100} + \lg p_i^0/p_j^0\right]. \quad (30)$$

The second case—the selectivity of two stationary phases Ph_2 and Ph_1 with respect to a given substance a—is expressed quantitatively by the formula[77]

$$\delta(\Delta G^E)_{Ph_2Ph_1} = 2.3RT \lg \gamma_{Ph_2}/\gamma_{Ph_1}, \quad (31)$$

in which γ_{Ph_2} and γ_{Ph_1} are the activity coefficients of i at infinite dilution in the two phases. Recently it has been shown[63,64] that selectivity can easily be determined quantitatively from the polarities of the phases expressed in terms of free energies. Thus at a given temperature the excess energy of i on the phases will be given by the classic equations

$$\Delta G_{Ph_2}^E = \Delta G_{Ph_2} + \Delta G_e, \quad (32)$$

$$\Delta G_{Ph_1}^E = \Delta G_{Ph_1} + \Delta G_e, \quad (33)$$

where ΔG_e is the differential molar free energy of evaporation of the pure substance i under 1 atm at the analysis temperature, and ΔG_{Ph_2} and ΔG_{Ph_1} are the differential molar free energies of dissolution of i in the phases Ph_2 and Ph_1. From (33) and (32) we obtain for selectivity the thermodynamic formula

$$\delta(\Delta G^E)_{Ph_2Ph_1} = \Delta G_{Ph_2} - \Delta G_{Ph_1} = \delta(\Delta G)_{Ph_2Ph_1}. \quad (34)$$

Thus the selectivity of two stationary phases towards a substance analysed at a given temperature is determined quantitatively from the difference in its free energies of

dissolution on the phases and can be calculated from a table of estimated polarities of stationary phases (Table 3).

A single system for assessing selectivity can be obtained by selecting one of the stationary phases as reference, which should satisfy certain requirements. According to the thermodynamic treatment of polarity and selectivity the reference phase should have minimal ΔG values for all test substances and minimal differences between them: i.e.it should have minimal selectivity. Furthermore, it should be chemically homogeneous and should withstand high temperatures. These demands are met neither by squalane (whose disadvantages, including irreproducibility of the indices, have been criticised by Ettre[1] and by Supina[80]) nor by the hydrocarbon 24,24-diethyl-19,29-dioctadecylheptatetracontane, proposed by Kovats[72,73] to replace squalane, as is evident from Table 4.

Table 4. Choice of reference phase for assessing the selectivity of stationary phases on the thermodynamic criterion[64] $\delta(\Delta G)_{max}$.

Phase	Retention index for test cpd.*					ΔI_{max}	Energy of 1 i.u., cal mole^{-1}	$-\delta(\Delta G)_{max}$,
	benzene	butan-1-ol	pentan-1-ol	nitropropane	pyridine			
Squalane	653	590	627	652	699	109	—5.20	567
$C_{87}H_{176}$	674	600	630	664	724	124	—5.11	634
SE-30	668	643	671	716	740	97	—4.49	435
Hydrogenated Apiezon-30	671	599	632	667	736	137	—	—

*Underlining denotes indices of compounds for which ΔI_{max} and $\delta(\Delta G)_{max} = -0.023RTb\Delta I_{max}$ have been calculated.

Recently a comparison has been made[73] of the phases—hydrogenated Apiezon M, the hydrocarbon $C_{87}H_{176}$, and SE-30—with respect to their ability to reproduce the retention indices of the five test-substances, with the aim of seeking a null phase for the determination of selectivity by the Rohrschneider–McReynolds method. Prolonged operation over the range 120–200 °C showed that the indices at 120 °C remained almost unchanged for a year on SE-30, in contrast to the Kovats hydrocarbon. Since the reference phase should possess outstanding reproducibility of indices, and also satisfy the thermodynamic criterion, i.e.have a minimal difference in the free energies of dissolution of the test substances, we have made an estimate of ΔG values. Table 4 lists indices of the test substances for the four phases proposed as reference phases[27,72,73], the energy value of one index unit on each of the stationary phases, and values of the differences $\delta(\Delta G)_{max}$ in the free energies of dissolution of two substances, one of which is retained the longest in the column, whereas the other is eluted first from the column. Among the four stationary phases compared the Kovats hydrocarbon has the maximum selectivity and is therefore least suitable as reference phase for the assessment of selectivity. Minimal selectivity is exhibited by SE-30, which is recommended as reference phase[63,64].

A quantitative assessment of the selectivity of a stationary phase for a given test substance is a measure of its specific interaction with the latter in comparison with SE-30. Table 5 shows as example the selectivities of several stationary phases in terms of $\delta(\Delta G^E)_{Ph,SE}$. It includes for comparison selectivity estimates according to McReynolds[27] based on ΔI values†. It is evident that the former method of assessment is far more informative. As example we compare two phases—Triton X-305 and Igepal CO-880—that are identical on the Rohrschneider–McReynolds view, since their ΔI values differ by 20 index units: actually they exhibit differences in practical gas chromatography, which can be clearly traced in the $\delta(\Delta G^E)$ data, for Igepal CO-880 is three times as selective as Triton X-305 towards aromatic compounds, and twice as selective in the separation of carbonyl compounds. Although the Rohrschneider–McReynolds method shows identity of XF-1150 and Carbowax-20M in the separation of aromatic compounds, alcohols, and amines, the $\delta(\Delta G)_{Ph,SE}$ values indicate that the latter phase has an advantage for the separation of all three classes of compounds. The phases EGA and XF-1150 are also identical according to their ΔI values in the analysis of carbonyl compounds and nitroderivatives, whereas the $\delta(\Delta G^E)$ values indicate that XF-1150 is four times as selective towards the former compounds, and 50% more selective towards the latter, which is confirmed by experiment[63]. Another pair—tritolyl phosphate and Poly-Tergent—have the same selectivity in the separation of aromatic compounds and amines according to ΔI data, but differ sharply according to the $\delta(\Delta G^E)$ values. The choice of optimum conditions for gas-chromatographic analysis of a mixture on the basis of the latter type of data has been described in detail[81] for analysis of a mixture of saturated and unsaturated aldehydes and ketones.

Table 5. Comparison of selectivities of stationary phases based on $\delta(\Delta G^E)_{Ph,SE-30}$ values and on McReynolds constants (at 120 °C).[63]

†It has already been mentioned that comparison based on values of $\Delta I = I_{Ph} - I_{sql}$ is incorrect because of different energy equivalents of an index unit of different stationary phases (Section IV).

The above results provide clear evidence that the proposed thermodynamic assessment of the selectivity of stationary phases[63,64] is definitely superior to the McReynolds system and reveals most fully the gas-chromatographic possibilities of a sorbent. It can be extended to gas-adsorption chromatography, since Eqns.(30)–(34) for estimating selectivity from $\delta(\Delta G^E)$ data are still valid[63].

Thus the rigorous thermodynamic treatment of polarity and selectivity in gas chromatography and the availability of equations enabling these properties of sorbents to be determined from thermodynamic functions quantitatively in terms of retention indices enable a single, universally applicable system to be constructed, which will make it possible to find the optimum form of gas-chromatographic analysis to solve a specific problem.

V. CALCULATION OF ENERGY CONTRIBUTIONS BY FRAGMENTS OF MOLECULE ANALYSED

The use of retention indices as gas-chromatographic parameters makes it possible for a qualitative analysis to yield also data for thermodynamic calculation of the contributions, by individual groups in the compounds analysed, to the differential molar free energy of dissolution. For this purpose the formula

$$\delta(\Delta G) = -2.3RTb\frac{\delta I_{ij}}{100}, \qquad (35)$$

is used[44], in which δI_{ij} is the difference between the retention indices of two comparable compounds analysed under the same conditions. Equation (35) has been employed in a comparison of the methyl esters of aliphatic and monounsaturated acids i and j to determine the change in free energy of dissolution on introduction of a double bond into the molecule. On the non-polar phase SE-30 the presence of a double bond diminishes this free energy by 80–120 cal mole^{-1}, but on a polar phase (Silar 5CP) an average increase of 80 cal mole^{-1} is evident at 200 °C.[48]

In analogous heteroatomic compounds the replacement of oxygen by sulphur increases the differential molar free energy of dissolution by 1020 ± 30 cal mole^{-1} independently of the character of the stationary phase[44]. Such an increase is observed on passing from aliphatic ethers, furan, oxolan, dioxan, and their substituted derivatives to sulphides, thiophens, thiolans, and dithians[44]. Calculation based on the application of formula (35) to the difference in retention indices between sulphur- and oxygen-containing compounds of analogous structure indicates that on the non-polar Apiezon M and the polar polyethylene glycol 1000 the retention of both types of compounds is a consequence mainly of dispersion interaction[44].

Equation (35) can be used also to determine the contribution by a functional group in metameric compounds, i.e. compounds of the same class containing the same number of carbon atoms but differing in the position of the functional group. This would indicate whether it is legitimate to assume, when the contribution by a functional group to the free energy of dissolution of one homologous series is known, that this contribution will be the same in another homologous series. We have used earlier results on thiatridecane metamers[82] to trace the variation in the energy contribution by the functional thio-group as it moves deep into an unbranched aliphatic chain[84]. If the contributions to the free energy ΔG by fragments of a molecule are additive[10] the metameric sulphides should be described by the single equation

$$\Delta G = 2\Delta G^{CH_3} + (n-2)\Delta G^{CH_2} + \Delta G^{-S-}. \qquad (36)$$

Analysis of the results[82] shows that the energy contributions ΔG^{CH_3} and ΔG^{CH_2} of the metamers are the same, whereas ΔG^{-S-} changes, decreasing as the sulphur atom moves along the chain. This is readily seen from Table 6, which gives the differences in free energy of dissolution of the thiatridecane metamers relative to 2-thiatridecane. As the sulphur atom is displaced from position 2 to position 7 ($K = 2$ and 7 respectively), the differential molar free energy of dissolution diminishes by 234 and 308 cal mole^{-1} on Apiezon M and polyethylene glycol 1000 respectively. Hence additive equations analogous to (36) can be used only for specific homologous series. The position of a functional group in the molecule must be indicated in a statement of the contribution by the group.

Table 6. Retention indices I and free energies of dissolution ΔG of metameric thiatridecanes on Apiezon M and on PEG-1000 at 130 °C.

	PEG-1000	130	97	377
Octan-1-ol-heptan-1-ol	PEG-1000	130	108	420
Hept-2-enal-hex-2-enal	XF-1150	125	112	402
Hept-2-enal-hex-2-enal	oxy-ββ'-dipropionitrile	50	84	377
Heptan-2-one-hexan-2-one	oxy-ββ'-dipropionitrile	50	83	373

Previous results[65,82,83] can be used to calculate the energy contribution by a methylene unit in various homologous series analysed under identical conditions. Table 7 shows that $\Delta I^{CH_2} = 100$ does not apply to all homologous series: it is observed only with straight-chain aldehydes and methyl ketones on Apiezon M and PEGA, whose differential molar free energy for dissolution of a methylene group is the same as with n-alkanes. For homologous series in which

$\Delta I^{CH_2} = 100$, Eqn.(35) can be used to calculate the energy contribution due to specific interaction of the functional group with the stationary phase, from the difference between the retention indices of the given substance and the n-alkane containing the same number of carbon atoms. For αβ-unsaturated aldehydes on XF-1150 and on oxy-ββ′-dipropionitrile $\Delta I^{CH_2} \neq 100$ and ΔG^{CH_2} differs substantially from the values obtained for n-alkanes (Table 7). A similar pattern is observed for dithiols and other compounds.

Hence the energy contribution whether of a methylene or of a functional group depends on the homologous series and the character of the stationary phase. It is thus inadvisable to use energetic contributions to the free energy of dissolution of functional groups, to estimate the polarity of a stationary phase[39], in isolation from the total differential molar free energy of dissolution of the test substance.

The Present State of the Problem of the Identification of Kinetic Models

V.V.Kafarov and V.N.Pisarenko

The present state of the problem of the identification of kinetic models and the principal methods of solution are described. The principles of the estimation of the constants for non-linear kinetic models are examined and the properties of the resulting estimates are specified. Methods for the determination of the adequacy of single-response models, the statistical significance of their individual components, and the accuracy of the estimates of kinetic parameters are analysed. The Bayes methods and probability ratios, used in tests of hypotheses concerning the mechanism of a complex chemical reaction, as well as methods for the determination of the causes of a possible inadequacy of kinetic models and procedures for the specific construction of an adequate model are described. The importance of an active design of a kinetic experiment for the effective solution of the problem of the identification of models is demonstrated.
The bibliography includes 80 references.

I. INTRODUCTION

The problem of the identification of kinetic models is one of the most important in any branch of chemistry—physical, organic, and biological. The reason for this is, in particular, that the solution of the problem in many respects determines the state and level of development of the theory of reactivity of the chemical compounds, which makes it possible in its turn to predict the course of various processes and to establish pathways for the specific synthesis of new chemical substances with specified properties. The problem of the identification of kinetic models is also of practical importance, because both rapid and effective incorporation of new processes in industry and the planning of individual chemical industries are impossible without the determination of the nature and dynamics of a chemical reaction and, the more detailed the investigation of the kinetics of the chemical reaction, the more precise are the results of all subsequent industrial predictions. However, despite its importance for the determination of the mechanism of the chemical reaction, this problem has still not been ultimately resolved.

At the present time the rapid development of computational mathematics, computer technology, and the cybernetics of chemical engineering processes has led to fundamentally new possibilities for the solution of the problem of the identification of kinetic models. In recent years a number of theoretical studies have been carried out in this field[1-5] on the development of methods for the identification of kinetic models and, particularly, statistical methods for the design and analysis of experiments, tests of hypotheses concerning the mechanism of the given chemical process, the establishment of an adequate kinetic model, and an accurate estimation of its parameters. The application of these methods leads to fundamentally new possibilities for the study of complex physicochemical phenomena, since it becomes possible to discover effectively finer details of the reaction mechanisms than in determinations by traditional classical methods.

To simplify the description of the relevant data, the general solution of the problem of the identification of the kinetic model for a complex chemical reaction has been divided in the present review into four consecutive stages.

1. A system of hypotheses concerning the chemical reaction mechanism, which must be tested against the corresponding experimental data, is put forward. Each hypothetical mechanism is represented by a set of elementary reactions (states).

2. Using the available information about the chemical system investigated, sometimes taking into account the selected criterion of optimum conditions, one constructs a "starting" experimental design; the constants for the kinetic models are estimated from the results of measurements.

3. Estimates of kinetic constants obtained at this stage do not usually satisfy the essential requirements as regards accuracy and are therefore revised with the aid of consecutive methods for experimental design.

4. One constructs a consecutive design for a discriminating experiment in such a way that in each single observation the competing models exist under certain critical conditions (from the standpoint of their descriptive power). The suitability of a particular model is decided on the basis of the agreement with experimental data. This leads to the selection of a single model which reflects the given experiment better than any other; the reaction mechanism corresponding to this kinetic model is assumed to be the most fully representative of the structure of the chemical reaction.

II. THE CONSTRUCTION OF A SYSTEM OF COMPETING HYPOTHESES CONCERNING THE REACTION MECHANISM

The role of the first stage in the overall scheme for the solution of the problem of the identification of kinetic models is exceptionally important. Practice shows that the experimenter cannot as a rule choose correctly, on the basis of intuitive considerations, a sufficiently complete system of competing hypotheses, particularly when one is dealing with multistage reactions.

When a multistage chemical reaction takes place, there are both qualitative and quantitative changes in the compositions of the reactants owing to the redistribution of their constituent atoms and individual molecular structures, which remain unaltered in the process (such atoms and molecular structures are referred to as atomic varieties). All chemical reactants can be represented by integral associations of atomic varieties. In view of the necessity to satisfy the law of conservation of mass in the reacting system, it is possible to develop a formalised method for the construction of a system of competing hypotheses, based on the stoichiometric analysis of the reacting system.

The problem of the stoichiometric analysis of the reacting system can be formulated as follows: it is assumed that the initial reactants, intermediates, and reaction products, which are referred to as molecular varieties $M_i^B (i = 1,2,\ldots,N)$ are known (or postulated) from theoretical considerations and also from physical measurements. It is necessary to determine the possible chemical reactions $\mathscr{R}_r (r = 1,2,\ldots,Q)$, among the N molecular varieties M_i^B and to construct a system of competing hypotheses concerning the reaction mechanism. In order to solve this problem, each of the N chemical reactants M_i^B is brought into correspondence with an M-dimensional vector $\alpha_i = (\alpha_{i1},\ldots,\alpha_{ij},\ldots,\alpha_{iM})T$ and each of the Q reactions $\mathscr{R}_r$ is brought into correspondence with an N-dimensional vector $\beta_r = (\beta_{r1},\ldots,\beta_{ri},\ldots,\beta_{rN})T$ [6-13]:

$$M_i^B = \sum_{j=1}^{M} \alpha_{ij} M_j^A, \tag{1.1}$$

$$\mathscr{R}_r = \sum_{i=1}^{N} \beta_{ri} M_i^B, \tag{1.2}$$

where α_{ij} are non-negative integers, $M_j^A (j = 1,\ldots,M)$ are atomic varieties, and β_{ri} are rational numbers, referred to as stoichiometric coefficients. It is assumed that any molecular variety having a positive stoichiometric coefficient is a reaction product and a molecular variety with a negative stoichiometric coefficient as an initial reactant[7].

To chemical reactions $\mathscr{R}_r = \sum_{i=1}^{N} \beta_{ri} M_i^B = 0$ and $\mathscr{R}_r' = \sum_{i=1}^{N} \gamma \beta_{ri} M_i^B = 0$ are identical for any rational γ. Hence it follows that, for any chemical reaction, the ratio of stoichiometric coefficients is of decisive importance. Among the overall set of reactions $\{\mathscr{R}_r\}$ the reactions $\mathscr{R}_l (l = l_1,\ldots l_R)$ are assumed to be independent, provided that there are no non-zero multipliers $\gamma_l (l = l_1,\ldots,l_R)$ such that

$$\sum_{l=l_1}^{l_R} \gamma_l \mathscr{R}_l = 0.$$

Evidently the total number of independent reactions is determined by the rank of the matrix of stoichiometric coefficients $B = \{\beta_{ri}\}$ for the set of reactions $\{\mathscr{R}_r\}$.

The reaction $\mathscr{R}_{r_1}$, occurring among the molecular varieties $M_1^B,\ldots,M_k^B$, is defined as stoichiometrically simple if no reactions of the specified set $\{\mathscr{R}_r\}$ takes place between the molecular varieties.

A number of useful relations can be derived from Eqns.(1.1) and (1.2). On substituting Eqn.(1.1) into the Eqn.(1.2), we obtain

$$\mathscr{R}_r = \sum_{i=1}^{N} \beta_{ri} \sum_{j=1}^{M} \alpha_{ij} M_j^A = \sum_{j=1}^{M} \left(\sum_{i=1}^{N} \beta_{ri} \alpha_{ij} \right) M_j^A = 0.$$

Consequently

$$\sum_{i=1}^{N} \beta_{ri} \alpha_{ij} = 0 \tag{1.3}$$

for all $r = 1,\ldots,Q$; $j = 1,\ldots,M$. Or in a matrix form, we have

$$BA = 0, \tag{1.4}$$

where $A = \{\alpha_{ij}\}$ is the molecular matrix and $B = \{\beta_{ri}\}$ is the matrix of stoichiometric coefficients. One should note that this system of equations characterises none other that the law of conservation of matter in the reacting system.

Since the elements of the molecular matrix A are known, any of the possible reactions can be obtained by solving the homogeneous linear system of equations (1.3), which is called the fundamental system of equations (FSE); the converse assertion is also valid, namely each solution of the FSE represents a possible reaction. Suppose that the rank of the maxtrix A is u_A. Then the maximum number of independent reactions which can occur in the given reaction system is, according to the Gibbs rule, $u_B = N - u_A$.

In order to calculate the stoichiometric coefficients β_{ri} for the independent reactions, we shall find in the molecular matrix A a minor A of rank u_A and shall correspondingly reindex the columns and rows of the matrices B and A so that the indices of the rows of the minor of A vary from 1 to u_A inclusive. Eqns.(1.3) can then be written in the following form:

$$\sum_{i=1}^{u_A} \beta_{ri}\alpha_{ij} = -\sum_{i=u_A+1}^{N} b_{ri}\alpha_{ij}, \quad \begin{matrix} r = 1, \ldots, u_B; \\ j = 1, \ldots, u_A, \end{matrix} \qquad (1.5)$$

where $\beta_{ri}(i = 1,\ldots,u_A)$ are the required unknowns and b_{ri} are stoichiometric coefficients whose values are specified arbitrarily. Any solution of Eqns.(1.5) is specified to within linear combinations of a parameter b_{ri}. The solution is referred to as a basis solution if the parameters b_{ri} are chosen in the following way.

$$b_{ri} = \delta_{u_A+r,i} = \begin{cases} 0, & \text{if } i \neq u_A + r; \\ 1, & \text{if } i = u_A + r. \end{cases} \qquad (1.6)$$

Eqns.(1.5) are then transformed as follows:

$$\sum_{i=1}^{u_A} \beta_{ri}\alpha_{ij} = \sum_{i=u_A+}^{N} \delta_{u_A+r,i}\alpha_{ij}. \qquad (1.7)$$

It is easy to show that each basis solution of the FSE defines a stoichiometrically simple reaction. Consequently, if all the basis solutions have been determined, all the stoichiometrically simple chemical reactions possible in the given reacting system have been thereby found. In order to find all the basis solutions, it is necessary to solve the FSE subject to the limitations defined by Eqns.(1.6) for each non-singular minor of A rank u_A. Naturally, the stoichiometrically simple reactions determined in this way will be linearly dependent. From the set of stoichiometrically simple reactions obtained, one rejects reactions which are absurd from the standpoint of chemical theory and one introduces individual supplementary elementary reactions, which cannot be determined with the aid of the above procedure without a significant increase in complexity but which evidently follow from the set of stoichiometrically simple reactions (usually the number of such supplementary elementary reactions does not exceed 1–2).

To achieve further clarification, consider the following example. Suppose that one investigates a reaction system in which the following elementary reaction takes place:

$$I_2 + M \rightleftarrows 2I^{\cdot} + M,$$

Where I_2, $I^{\cdot}$, and M are respectively the iodine molecule, the iodine atom (a radical species), and a neutral molecule. The procedure described above defines the stoichiometrically simple reaction

$$I_2 \rightleftarrows 2I^{\cdot}.$$

Knowing that the iodine atom is formed in the gas phase when I_2 collides with a neutral molecule, it is possible to formulate the first reaction on the basis of the second.

One must note that the procedure under consideration is relatively ineffective if the reactants in elementary chemical reactions are isomeric and stereoisomeric molecules.

The determination of the possible mechanisms of the process on the basis of the set of elementary reactions (stages) obtained reduces to the selection of the corresponding sets of stoichiometric numbers[14]. The numerical values of the latter are not arbitrary and are subject to a series of limitations. Thus the sum of the equations for the elementary chemical stages, multiplied by the stoichiometric numbers of the corresponding stages, should yield the overall reaction (the final equation)[15–18]. Consequently if the stoichiometric analysis showed that the S elementary reactions involving I intermediates and P reactants and reaction products, then, for example for a single-pathway reaction there exist S stoichiometric numbers ν_r satisfying Eqns.(1.8) and (1.9):

$$\sum_{r=1}^{S} \beta_{rs}\nu_r = 0, \; s = 1, \ldots, I, \qquad (1.8)$$

$$\sum_{r=1}^{S} \beta_{rs}\nu_r = b_{s'}, \; s' = 1, \ldots, P', \qquad (1.9)$$

where b_s' is the stoichiometric coefficient of the s'th reactant or product in the final equation.

Naturally any set of stoichiometric numbers $\{\nu_r\}$ satisfying Eqns.(1.8) and (1.9) corresponds to a specific reaction mechanism. Since there are usually more stoichiometric numbers than independent linear equations (1.8) and (1.9), there exist large sets of hypothetical single-pathway reaction mechanisms. The necessary limitations can be obtained by resorting to additional *a priori* information about the reaction system, for example, the occurrence of a specific limiting elementary reaction or a sequence of specific stages[19]. The extensions to the case of multipathway reactions are self-evident.

For each hypothetical mechanism of a chemical reaction, one constructs the corresponding kinetic model. The methods of construction of such models have been fairly satisfactorily developed[16,18] and will not therefore be considered in the present review.

III. ESTIMATION OF THE CONSTANTS FOR KINETIC MODELS

The kinetic models obtained, which consist of systems of differential, algebraic, or differential-algebraic equations, contain unknown constants, which must be estimated from experimental data. In those cases where one employs empirical models or theoretical kinetic models linear in terms of the parameters, the methods of linear regression analysis, which have been developed in detail, are used to obtain point and interval estimates of the parameters. The theory of linear regression analysis has been described in a number of monographs[20–24].

However, the vast majority of the models are non-linear in terms of the parameters and the procedure for their estimation is much more complex. We shall consider it in greater detail. Suppose that m kinetic models for each of the m kinetic hypotheses M_j $(j = 1,\ldots,m)$ can be put in the form

$$\frac{d\eta^{(j)}}{dt} = \varphi(x_u, \theta_j); \; y_u^{(j)} = \eta_u^{(j)} + \varepsilon_u \text{ or } y_u^{(j)} = f(x_u, \theta_j) + \varepsilon_u, \qquad (2.1)$$

where $f(x_u, \theta_j) = \eta^{(j)}(0) + \int_{\tau_0}^{\tau} \phi(\bar{x}_u, \theta_j)dt$, t is the reaction time, θ_j the p_j-dimensional vector for the space of unknown parameters, x_u the q-dimensional vector of the space of the controllable variables, ε_u the error in the irreproducibility of the observations, and u the number of the

experiment. For simplicity, we shall confine ourselves initially to the analysis of single-response models; the generalisations required for the multiresponse models are self-evident.

In kinetic studies involving the estimation of unknown parameters for the model, the method of maximum probability is most widely used. When it is employed, one normally assumes in addition that the form of the distribution density of the errors of the observations is known. The unknown parameters of the probability distribution density can then be estimated together with the unknown parameters of the models. However, joint estimation of the parameters as a function of the distribution density and in terms of the kinetic model is significant only for single-, two-, and at most three-response models, since otherwise the search for the estimates of the constants correlated with one another would be prosecuted in the space with a very large number of dimensions, which precludes a solution even with the aid of a third generation computer.

We shall now assume that the estimates of θ_j^+ have been obtained in some way for the model M_j; Eqn.(2.1) can then be written as in the following form:

$$e_u^{(j)} = y_u^{(j)} - f^{(j)}(x_u, \theta_j^+), \tag{2.2}$$

where $e_u^{(j)}$ are estimates of the experimental errors ε_u for the given θ_j^+ and M_j.

Suppose that n experiments have been carried out. We shall denote by $P(\varepsilon_u, \psi)$ the distribution density of the probabilities of a random quantity and by $P(\varepsilon, \psi)$ the joint distribution density of a random vector $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)^T$, where ψ is the vector of the space of the distribution density parameters containing, in particular, the mathematical expectations and variances of the reproducibility. The function of the probability of the selection of $L^{(j)}(\theta_j^+, \psi^+)$, obtained as a result of the substitution of $e_u^{(j)}$ from Eqn. (2.2) in the expression for $P(\varepsilon, \psi)$, has the following form:

$$L^{(j)}(\theta_j^+, \psi^+) = P(e^{(j)}, \psi^+). \tag{2.3}$$

For independent random quantities ε_u $(u = 1, \ldots, n)$, we have

$$L^{(j)}(\theta_j^+, \psi^+) = \prod_{u=1}^{n} P(e_u(\theta_j^+), \psi^+). \tag{2.4}$$

According to the method of maximum probability, the best estimates of parameters are those attributing the maximum probabilities to the observations obtained in reality. Consequently, the problem of the estimation of the parameters reduces to the determination of the values of $\theta_j^\times$ and $\psi^\times$, which satisfy the condition

$$L^{(j)}(\theta_j^\times, \psi^\times) = \max_{\theta_j^+, \psi^+} L^{(j)}(\theta_j^+, \psi^+). \tag{2.5}$$

The specific form of the function $L^{(j)}(\theta_j, \psi)$ depends on the distribution density of the probabilities of ε. In particular, if the random quantities ε_u $(u = 1, \ldots, n)$ are independent and normally distributed with a zero average and known variances σ_u^2, then,

$$L^{(j)}(\theta_j^+, \psi^+) = \frac{1}{(2\pi)^{n/2}\left(\prod_{u=1}^{n}\sigma_u^2\right)^{1/2}} \exp\left(-\frac{1}{2}\sum_{u=1}^{n}\frac{(y_u - f^{(j)}(x_u\theta_j^+))^2}{\sigma_u^2}\right). \tag{2.6}$$

Then the estimates obtained using the principle of maximum probability are equivalent to the estimates minimising the weighted sum of squares (the estimates obtained by the method of least squares):

$$\Phi^{(j)}(\theta_j^\times) = \min_{\theta_j^+}\Phi^{(j)}(\theta_j^+) = \min_{\theta_j^+}\sum_{u=1}^{n}\frac{e_u^{(j)}(\theta_j^+)^2}{\sigma_u^2}. \tag{2.7}$$

For unknown but equal variances of the observations, Eqn.(2.7) transforms into

$$F^{(j)}(\theta_j^\times) = \min_{\theta_j^+} F^{(j)}(\theta_j^+) = \min_{\theta_j^+}\sum_{u=1}^{n}[e_u^{(j)}(\theta_j^+)]^2. \tag{2.8}$$

We may note in conclusion that, for normally distributed errors of the observations, the estimates obtained by the methods of maximum probability and least squares θ_j are identical. They have a number of optimum properties if the models $f^{(j)}(\bar{x}, \bar{\theta}_j)$ are linear in terms of the parameters regardless of whether or not the quantities ε_u $(u = 1, \ldots, n)$ are normally distributed[24,25].

For multiresponse kinetic models, the probability function of the selection of $L^{(j)}(\theta_j^+, \psi^+)$ for independent normally distributed errors of the observations can be written as follows:

$$L^{(j)}(\theta_j^+, \psi^+) = \prod_{u=1}^{n} P(e_u^{(j)}(\theta_j^+, \psi^+)) =$$

$$= (2\pi)^{-Qn/2}\det(\Sigma)^{-n/2}\exp\left[-\frac{1}{2}\sum_{k=1}^{Q}\sum_{l=1}^{Q}\sigma^{kl}\sum_{u=1}^{n}e_{uk}^{(j)}e_{ul}^{(j)}\right] = \tag{2.9}$$

$$= (2\pi)^{-Qn/2}\det(\Sigma)^{-n/2}\exp[-{}^1/_2\,\mathrm{Sp}\,(\Sigma^{-1}A(\theta_j^+))],$$

where $e_u^{(j)}(\theta_j^+) = y_u - f^{(j)}(x_u, \theta_j^+) = [e_{u1}^{(j)}(\theta_j^+), \ldots, e_{uQ}^{(j)}(\theta_j^+)]^T$ is a Q-dimensional vector of the measurements, $f^{(j)}(\bar{x}_u, \theta_j^+)$ a Q-dimensional vector function—the kinetic model of the chemical reaction corresponding to the hypothesis M_j, $\Sigma = \{\sigma_{kl}\}$ the variance-covariance matrix of the measurements, T the transposition index, and

$$A(\theta_j^+) = \sum_{u=1}^{n} e^{(j)}(\theta_j^+)\, e_u^{(j)}(\theta_j^+)^T;\ \Sigma^{-1} = \{\sigma^{kl}\}.$$

According to the method of maximum probability, the estimates of $\theta_j^\times$ for known Σ maximise $L^{(j)}(\theta_j^+, \psi^+)$, provided that they minimised quantity

$$SS_1^{(j)}(\theta_j^\times) = \mathrm{Sp}\,(\Sigma^{-1}A(\theta_j^\times)) = \min_{\theta_j^+}\mathrm{Sp}\,[\Sigma^{-1}(A(\theta_j^+))]. \tag{2.10}$$

If the matrix Σ^{-1} is diagonal, then $\mathrm{Sp}[\Sigma^{-1}A(\theta_j^+)]$ is the weighted sum of the squares of the residues. Evidently, for $Q = 1$, Eqn.(2.10) is identical with Eqn.(2.7).

On the other hand, if the variance–covariance matrix of the errors of the observations Σ is unknown *a priori*, then, it has been shown[26] with the aid of the Bayes ion approach to the estimation of the parameters that the estimates of the maximum probability of $\theta_j^\times$ are obtained by minimisation with respect to the parameter $\det A(\theta_j^+)$:

$$SS_2(\theta_j^\times) = \det A(\theta_j^\times) = \min_{\theta_j^+}\det A(\theta_j^+). \tag{2.11}$$

It has been noted[27] that, in order to eliminate the possible errors, one includes in Eqn.(2.11) only responses which are linearly independent. The authors[27] quote the required mathematical procedure for the determination and elimination of linearly dependent responses.

In many instances, particularly for non-normal distributions of errors of observations, the use of the principle of maximum probability leads to relations characterising the closeness of the calculated and experimental data other than Eqns.(2.7), (2.8), (2.10), and (2.11). In particular, if the error has a Laplace distribution, it is necessary to use the method of least moduli for single-response situations and the corresponding relation.

$$SS_3(\theta_j^\times) = \sum_{u=1}^{n}|e_u(\theta_j^\times)| = \min_{\theta_j^+}\sum_{u=1}^{n}|e_u(\theta_j^+)|. \tag{2.12}$$

Evidently, the determination of estimates of the maximum probabilities does not by itself guarantee that an adequate model will be obtained; the latter is tested additionally

against statistical criteria governing the agreement with experimental data[28,29].

IV. TEST OF THE ADEQUACY OF THE KINETIC MODELS

The principal methods for testing the adequacy of kinetic models, most widely used in experimental research, are based largely on the procedures of variance analysis and the analysis of residues.

The variance analysis of models is used to compare the differences $e_u^{(j)} = y_u - f^{(j)}(x_u, \theta_j)$ with the quantities ε_u characterising the error of the measurements. By means of such a comparison, it is possible to establish both the overall adequacy of the model and methods for its further simplification, by rejecting the statistically insignificant individual terms of the model or its kinetic parameters.

For this purpose, one calculates the sums of squares

$$SS(1) = \sum_{u=1}^{n} y_u^2 \text{ and } SS(2) = \sum_{u=1}^{n} \hat{\eta}_u^{(j)2} = \sum_{u=1}^{n} f_u^{(j)2}$$

characterising respectively the scatter of experimental data and the scatter of the responses calculated on the basis of the model. The differences $e_u^{(j)} = y_u - f_u^{(j)}$, called residuals, constitute a measure of the inability of the model to describe accurately the experimental data. Evidently, if the model tested is true, then the residues are in fact the estimates of the errors of the measurements. Hence the overall measure $SS(3)$ of the discrepancy between the model and experimental results can be put in the form

$$SS(3) = \sum_{u=1}^{n} (y_u - f_u^{(j)})^2.$$

In the literature $SS(1)$ is called the overall sum of squares, $SS(2)$ is called the sum of squares due to regression, and $SS(3)$ is referred to as the residual sum of squares. Then

$$SS(1) = SS(2) + SS(3),$$

which is a direct consequence of the properties of the method of least squares.

In variance analysis a single degree of freedom is assigned to each individual measurement of the response. Consequently, when n experiments are set up, the overall sum of squares $SS(1)$ for a single-response situation has n degrees of freedom: $SS(3)$ has $n - p_j$ degrees of freedom and $SS(2)$ has p_j degrees of freedom [p_j is the number of parameters of the model with the aid of which one calculates $SS(2)$].

When several replicate measurements are made for identical experimental conditions, the sum of squares $SS(4) = \sum_{u=1}^{n} (y_u - \bar{y})^2$, where $\bar{y} = \sum_{u=1}^{N} y_u/N$ contains all the necessary information about errors of the measurements, since it is proportional to the variance σ^2_{exp}. The quantity

$$SS(5) = \sum_{u=1}^{n} (y_u - f_u^{(j)})^2 - \sum_{u=1}^{n} (y_u - \bar{y})^2,$$

equal to the difference between $SS(3)$ and $SS(4)$, therefore defines the measure of the inability of the test model to reflect the experimental results, i.e., in other words, the sum of squares $SS(5)$ characterises the degree of inadequacy of the model.

If $\tilde{n}$ replicate experiments have been carried out for each of the q different experimental conditions, then the sum of squares $SS(4)$ has $\tilde{n} - 1$ degrees of freedom (one degree of freedom is used to estimate $\bar{y}$), while the sum of squares $SS(5)$ has $n - p_j - q(\tilde{n} - 1)$ degrees of freedom; the latter number is defined as the difference between the number of degrees of freedom of the residual sum of squares and the sum of squares of the errors of the measurements.

The sums of squares arising from different sources define the average squares after division by the corresponding numbers of degrees of freedom. Since the average square of the error of the measurements is an estimate of the variance of the errors of the measurements, evidently the adequacy of the model can be determined in terms of the ratio of the average square of the inadequacy of the model to the average square of the error of the measurements (the F-statistic). If this ratio is large (at least much greater than unity), there is good reason to suppose that the model tested does not reflect the experimental results.

The F-statistic is defined as the ratio of the sum of squares of independent normal random quantities and the test of the adequacy of kinetic models actually reduces to a test of the validity of the inequality

$$\frac{SS(5)/(n - p_j - q(\tilde{n} - 1))}{SS(4)/(q(\tilde{n} - 1))} < F_\alpha[n - p_j - q(\tilde{n} - 1), q(\tilde{n} - 1)]$$

for a level of significance α specified beforehand. The F statistics for the specified level of significance α and the numbers of degrees of freedom in the numerator and denominator have been tabulated and published[24,29].

To illustrate the application of the procedures of variance analysis in the determination of the adequacy of kinetic models, we shall consider the results of a kinetic study of the isomerisation of pentane[30-32]. The authors tested two reaction mechanisms and obtained two corresponding competing kinetic models. The parameters of the models were estimated from experimental data and variance analysis was carried out to test the adequacy of the models. The principal results of this test are presented in Table 1, which shows, in particular, that the first model reflects adequately the experimental results, while the second is at the "limit of adequacy". The latter does not permit either the adoption of the second model with confidence or its rejection as inadequate. Further statistical tests of the second model are therefore necessary.

The procedure described above for the testing of the adequacy of the model nevertheless does not guarantee a statistical significance of its individual terms. Consequently it is necessary to carry out a more detailed analysis of the components of the model, which is achieved by a direct extension of the methods of variance analysis. For this purpose, one carries out an additional expansion of the sum of squares, due to regression, into a series of components. To simplify the analysis, one then usually calculates the sums of squares due to the general regression model and the simplified model in which one term of a group of terms is rejected. The difference between these two sums of squares is the sum of squares characterising the influence of the tested component of the kinetic model. Since it is known that, for adequate models, the average square of residues characterises the variance of the reproducibility, the condition

$$\overline{SS}(6)/\overline{SS}(5) > F_\alpha(1, n - p_j), \qquad (3.1)$$

where $\overline{SS}(6)$ is the average square due to the tested component of the model and $\overline{SS}(5)$ the average square of the residues, determines the significance of the tested component. Evidently such tests must be carried out for all the terms (components) of the kinetic model[33].

An example of such analysis of the significance of one of the terms of the first kinetic model for the isomerisation of pentane is presented in Table 1, which shows that, in view of the considerable difference between the average squares

of the overall and simplified models, inequality (3.1) holds: consequently the tested term is significant and must be retained in the model.

Table 1. Results of the variance analysis of kinetic models of the isomerisation of pentane.

Source of scattering	Sum of squares	No. of degrees of freedom	Average squares	Ratio of average squares	*F* statistic	
					95%	97,5%
		First model				
Overall	763.54	24	—	—	—	—
Regression	754.29	4	188.6	—	—	—
Deviation from regression equation (for the model)	9.25	20	0.462	—	—	—
Inadequacy of the model	8.58	17	0.528	5.9	8.7	14.3
Deviations of repeated observations	0.27	3	0.090			
Elimination of one constant of the model	123.2	1	123.2	1370	246	985
		Second model				
Overall	28894.0	24	—	—	—	—
Regression	26896.8	4	6724.2	—	—	—
Deviation from regression equation (for the model)	1997.20	20	99.86	—	—	—
Inadequacy of the model	1964.56	17	115.5	10.62	8.7	14.3
Deviations of repeated observations	32.65	3	10.88			

Finally, we may note that the results of the variance analysis permit a conclusion only about the overall suitability of the model or the significance of its individual terms. Nevertheless a model can be inadequate even if criteria such as the Fischer criterion show that the model is consistent with experimental data. It is therefore necessary to carry out a more detailed test on the models by the method involving the analysis of residues.

The residues $e_u = y_u = f^{(j)}(x_u, \theta_j)$, being random quantities, are known to have a fully defined probability distribution function. In the majority of cases encountered in practice this is a normal distribution function with a mathematical expectation of zero and a variance σ^2_{exp}. Evidently the determination of the adequacy of the kinetic model on the basis of any one characteristic of the distribution function (for the Fisher criterion , this characteristic is $\sigma^2_{non\text{-}add}$) cannot give a complete guarantee of the adequacy of the model. In view of the foregoing considerations, in a combined test of the agreement between the kinetic model and experimental data, one must employ either entirely the probability distribution function, which requires a large number of experiments, or its principal characteristics. Among these the following may be noted[24,34–36].

1. Analysis of the normality of the distribution. For this purpose, one plots histograms for the distribution of the normalised appearance frequencies of the residues on a function of their numerical values. Such histograms should correspond approximately to the normal distribution law. The hypothesis of the normality can then be tested in terms of difference statistics. Together with this hypothesis, additional tests are also carried out of the hypothesis that the mathematical expectation of the selective distribution is zero, which is done using both graphical methods and the methods of linear or non-linear regression analysis.

2. Analysis of the absence of non-random components in the residues. The first stage of such analysis is carried out by plotting and investigating the graphical dependence of the residues on the predicted responses, which makes it possible to establish a correspondence between the model and experimental data. In particular, the results of variance analysis carried out for the first kinetic model of the isomerisation of pentane, indicate a complete adequacy of the model, while the plot of the residues (Fig.1) shows clearly that the overall adequacy of the model is achieved as a result of the balancing of the residue e_u for low and large responses when the latter vary consistently, with increase of their values. Consequently the first model must be rejected as inadequate.

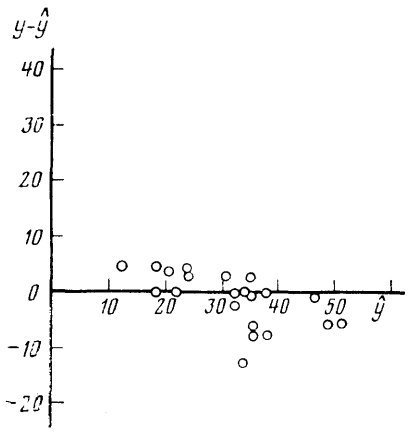

Figure 1. Dependence of the residuals on the predicted response.

Analysis of the graphical dependence of the residues on the predicted responses makes it also possible to obtain additional information about the validity of a number of initial statistical postulates in terms of the characteristics of the errors of the measurements, particularly in terms of the validity of the condition of a constant reproducibility variance in the selected experimental region (Fig.2). If, for example, the scatter of the residues in such plots increases or decreases monotonically, then evidently the variance of the reproducibility error is a variable quantity. In this case the parameters of the models must be estimated by the method of least squares with variable weighting factors or, in order to maintain the constancy of the variance σ^2, the dependent variable $\eta = f^{(j)}(x, \theta_j)$ must be transformed.

Plots of the residues against the controllable variables and time and of the estimated parameters against the controllable variables make it impossible to obtain similarly important information about the possible latent inadequacies in the model, which are established by observing trends in the residues relative to the levels of independent controllable variables. A detailed study of such relations permits a

qualitative analysis of the agreement between the competing models and experimental data and enables one to outline ways for the elimination of possible inadequacies.

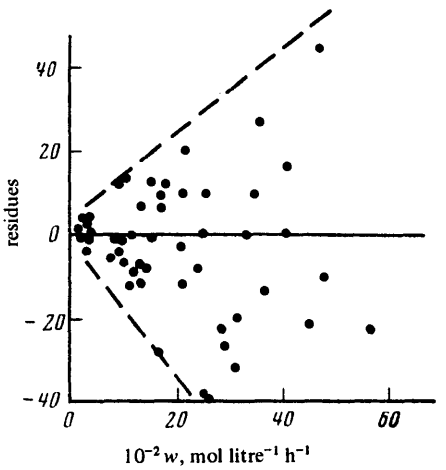

Figure 2. Dependence of the residuals on the predicted reaction rate w.

The establishment of the adequacy of multiresponse models involves a more complex procedure and requires the use of a large amount of experimental information, because, in contrast to the case of the single-response model, one has to test the hypothesis of the equality of two covariance matrices Σ_1 and Σ and not the equality of two variances. Here $\Sigma_1 = A(\theta_j)/(n - p_j)$, where n is the total number of measurements, p_j the minimum number of experiments necessary for the estimation of the kinetic parameters, $A(\theta_j = \sum_{u=1}^{n} e_u(\theta_j)e_u(\theta_j)^T$, and $\Sigma = \sum_{u=1}^{n_2} (y_u-\bar{y})(y_u-\bar{y})^T/(n_2-1) = A_2/(n_2-1)$ is the selective covariance matrix of the measurements, where $y_1,\ldots,y_{n_2}$ represent the reselection of the volume n_2 and $\bar{y} = \sum_{u=1}^{n_2} y_u/n_2$.

To test the hypothesis that

$$\Sigma_1 = \Sigma$$

use is made of the T_4 statistic[28]:

$$T_4 = \frac{1}{2}\left\{(n-p_j)\,\mathrm{Sp}\left[\Sigma_1\left(\frac{A(\theta_j)+A_2}{n-p_j+n_2-1}\right)^{-1} - I\right]^2 + n_2\,\mathrm{Sp}\left[\Sigma\left(\frac{A(\theta_j)+A_2}{n-p_j+n_2-1}\right)^{-1} - I\right]^2\right\}, \quad (3.2)$$

where I is a unit matrix with dimensions $Q \times Q$ and Q is the dimension of the observations vector $y_u (u = 1,\ldots,n_2)$.

Assuming that the hypothesis is correct, the distribution of the T_4 statistic, expressed as a linear combination of χ^2 distributions with different degrees of freedom, assumes the following form for large selections:

$$P(T_4 \leqslant x) = P_f + m^{-1}\left[\frac{1}{12}\{\tilde{\rho}Q(4Q^2+9Q+4) - 12Q(Q+1)^2 + 4Q(Q^2+3Q+4)\}P_{f+2} + \frac{1}{8}\{-\tilde{\rho}Q(6Q^2+13Q+9) + 16Q(Q+1)^2 + 3Q(2Q^2+5Q+5)\}P_{f+4} + \frac{1}{4}(2\tilde{\rho}+2)Q(Q+1)^2 P_{f+2} + \frac{1}{24}(1-\tilde{\rho})Q(2Q^2+3Q-1)P_f + O(n^{-2}), \quad (3.3)$$

where

$$\tilde{\rho} = \frac{n+n_2-p_j-1}{n-p_j}\cdot\frac{n+n_2-p_j-1}{n_2-1},\quad m = n+n_2-p_j-1,\quad P_f = P(\chi_f^2 \leqslant x)$$

with $f = Q(Q+1)$ degrees of freedom.

Consequently, if the observed quantity T_4, treated as a measure of the deviation from the zeroth hypothesis, is not significant according to distribution (3.3), one adopts the hypothesis that $\Sigma_1 = \Sigma$.

V. DESIGN OF PRECISION EXPERIMENTS

The estimation of the parameters of kinetic models must usually satisfy the essential requirements of accuracy in order that the model constructed should have a sufficient predictive power making it suitable for the design, optimisation, and control of processes. It is therefore as a rule necessary to carry out an additional consecutively designed experiment in order to revise the parameters. Numerous studies of this problem[37,38] have been limited mainly to linear models; much less attention has been devoted to non-linear models. It is therefore quite natural that the problem of experimental design for the estimation of the parameters of non-linear models has so far not been ultimately investigated and the methods employed for its solution constitute in essence a generalisation of experimental design methods for linear models.

The procedure used to devise a strategy for consecutive experimentation is determined by the specific tasks of the kinetic study at the given stage. Among these, the following are the most important: (1) estimation with a specified accuracy of the single parameter or subvector of the space of parameters, which is necessary, for example, to confirm the reaction mechanism or to characterise the individual stages of the chemical reaction; (2) the minimisation of the correlation coefficients between two parameters or a group of parameters. The correlation coefficients have an appreciable influence on the rate of convergence of the iterative methods for the estimation of parameters and on the extrapolated properties of the models obtained; (3) estimation of the vector of the space of parameters in the models.

For the solution of such problems, it is sufficient to analyse certain functionals of the information matrix as well as its individual elements and submatrices. Thus it is suggested that the determinant of the information matrix $\Delta = \det X^T X$, whose square root is inversely proportional to the volume $V_{c.e.}$ of the confidence ellipsoid, be used as a functional characterising the accuracy of the estimates of the parameters of single-response models[39]. Indeed,

$$V_{c.e.} = C\prod_{i=1}^{p}\left(\frac{\beta}{\lambda_i}\right)^{1/2} = C\frac{\beta^{p/2}}{(\det X^T X)^{1/2}}, \quad (4.1)$$

where $\lambda_i (i = 1,\ldots,p)$ are the eigenvalues of the matrix X^TX:

$$X_{nxp} = \{x_{ul}\} = \left\{\frac{\partial f(x_u, \theta)}{\partial \theta_l}\right\};$$

C is a constant which depends on the dimension p of the space of parameters, and β a constant which depends on the reproducibility variance σ^2, the number of degrees of freedom $n - p$, and the level of significance α.

The problem of experimental design in the selection of the statistic Δ involves a consecutive determination of experimental conditions such that the maximum decrease of the volume of the confidence region (and the corresponding maximum increase of det X^TX) is observed. The experimental design cycle is continued until the parameters reach the required degree of accuracy. Naturally, since the model is non-linear in terms of the parameters, they must be re-estimated after each new experiment.

There have been numerous modifications of the Box-Lucas criterion for various practical situations, in particular:

(a) For multiresponse models in the absence of *a priori* information about the parameters[40]:

$$\Delta = \sum_{i=1}^{Q}\sum_{j=1}^{Q} \sigma^{ij} (X^{(i)})^T X^{(j)}, \qquad (4.2)$$

where Δ is the information matrix of the Q- response system;

$$X^{(i)} = \{x_{ul}^{(i)}\} = \left\{\frac{\partial f^{(i)}(x_u, \theta_l)}{\partial \theta_l}\right\} \quad (i = 1, \ldots Q;\ l = 1, \ldots p);$$

i, l, and u are indices which determine the number of the response, the parameter, and the experiment.

(b) For multiresponse models in the presence of *a priori* information about the parameters[41]:

$$\Delta_k = \sum_{i=1}^{Q}\sum_{j=1}^{Q} \sigma^{ij} (X^{(i)})^T X^{(j)} + \Omega^{-1}, \qquad (4.3)$$

where Ω is the covariance matrix of the estimates of the para-parameters, known beforehand before the formulation of the refining experiments:

(c) For the estimation of the specified subset of parameters[42]:

$$\Delta_s = \det (Y_{11} - Y_{12}Y_{22}^{-1}Y_{21}), \qquad X^TX = \begin{bmatrix} Y_{11} & Y_{21} \\ Y_{12} & Y_{22} \end{bmatrix}, \qquad (4.4)$$

where Y_{11} is a submatrix with dimensions $s \times s$ of the matrix X^TX with dimensions $p \times p$ and s is the number of estimated parameters ($s < p$).

Further generalisations have been made[43,44] for discontinuous measurements, for the simultaneous design of models of m ($m > 1$) experiments, and for the design of an experiment characterised by a variance matrix, which depends on the experimental conditions.

Criteria of type (4.2)–(4.4) are known as determinant criteria. Box[45] analysed the principal advantages and disadvantages of determinant criteria and discussed many of their properties. Their practical employment, particularly for the estimation of parameters in multiresponse models and in carrying out a small number of experiments, has demonstrated their exceptional effectiveness even in fairly complex cases[46].

However, the structure of kinetic models is as a rule such that the estimates of kinetic parameters are highly correlated with one another, as a result of which the functions characterising the agreement between experimental and calculated data show the presence of "ravines" in the space of parameters in the vicinity of the minimum, which hinder point estimates of the constants. The determinant criteria greatly decrease the volume of the confidence ellipsoid without, however, altering the correlation coefficients and hence without correcting the "ravine" situation.

In this respect the shape criteria†, maximising the minimum eigenvalue of the information matrix X^TX, are preferable, since they tend to impart a greater sphericity to the confidence region by minimising the length of the major half-axis of the confidence ellipsoid. One should also note that the practical employment of the shape criterion makes it possible also to achieve an increase of the determinant of the information matrix because

$$\det X^TX = \prod_{i=1}^{p} \lambda_i, \qquad (4.5)$$

where $\lambda_i (i = 1,\ldots,p)$ are the eigenvalues of X^TX; an increase of the minimum eigenvalue entails an increase of det X^TX. Consequently the two statistics are not entirely independent.

The efficiences of the above criteria have been compared[47,48]. It has been shown for a number of examples that the determinant criterion decreases the volume of the confidence region mainly as a result of its compression along the minor half-axes of the hyperellipsoid, which are significantly smaller, as regards order of magnitude, than the major half-axes. On the other hand, the shape criterion tends to make the joint confidence region spherical. However, a true sphericity cannot be attained, mainly owing to the different sensitivities of the model to a change in the parameters and the limited dimensions of the experimental region.

Table 2. The results of the design of a refining experiment.

Constants to be estimated	Estimates of the constants	Standard deviation $\sqrt{\sigma_{k_l}^2}$	Determinant criterion: estimates of constants	Determinant criterion: standard deviation $\sqrt{\sigma_{k_l}^2}$	Shape criterion: estimates of constants	Shape criterion: standard deviation $\sqrt{\sigma_{k_l}^2}$
	After the starting experiment		After 23 refining experiments			
k_1	4.61	1.16	2.89	0.09	2.97	0.06
k_2	92.29	24.41	57.47	1.94	58.94	1.56
k_3	16.04	4.22	9.23	0.54	9.24	1.07
k_4	33.89	8.58	18.88	0.86	21.24	1.50
Correlation matrices of the estimates	1 0.99 0.98 0.99 0.99 1 0.97 0.99 0.98 0.97 1 0.37 0.99 0.99 0.37 1		1 0.98 0.56 0.66 0.98 1 0.48 0.60 0.56 0.48 1 0.46 0.66 0.60 0.46 1		1 0.96 0.13 0.11 0.96 1 0.06 0.02 0.13 0.06 1 0.01 0.11 0.02 0.01 1	

To illustrate the foregoing considerations, we shall examine the following example[47]. In the study of the enzymatic hydrolysis of sucrose[14] a kinetic equation [Eqn.(4.6)] was obtained in which the kinetic constants were estimated:

$$R_s^{iw} = -\frac{k_1 k_2 c_s}{1 + k_2 c_s + k_3 c_g + k_4 c_f}, \qquad (4.6)$$

† The shape criterion is referred to in the literature as the *E*-criterion of the optimum nature of the design and the determinant criterion is referred to as the *D*-criterion.

where R_S^W is the rate of consumption of sucrose and c_s, c_g, and c_f are the concentrations of sucrose, glucose, and fructose respectively. Their initial concentrations were used as independent controllable variables. Fig.3 illustrates the starting experimental design as well as the conditions of 23 experiments designed additionally on the basis of the determinant and shape criteria. The results of the interpretation of these experiments are presented in Table 2, which shows that the shape criterion makes it possible to estimate more accurately the constants k_1 and k_2 than k_3 and k_4.

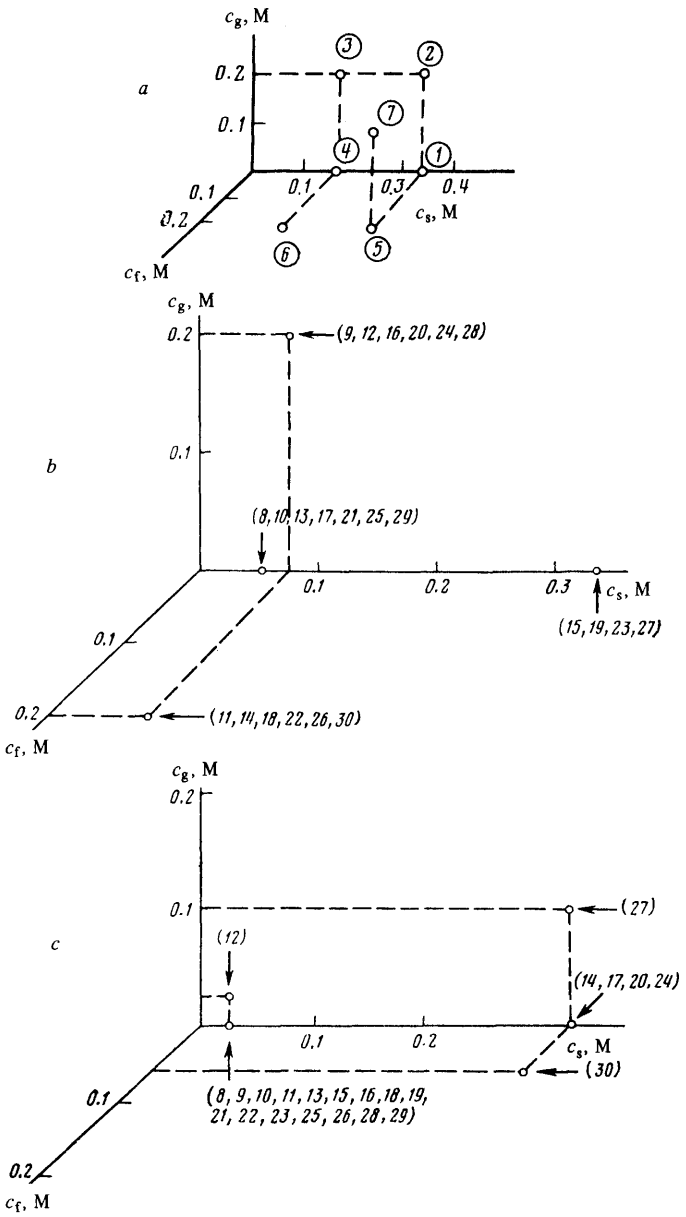

Figure 3. The starting experimental design (*a*) and the conditions of additional planned experiments determined from the determinant criterion (*b*) and the shape criterion (*c*). The coordinates of the points in Figs.3*a*–3*c* correspond to the initial concentrations of fructose, sucrose, and glucose (c_f, c_s, and c_g) in the periodic action reactor. The numerals in brackets are the ordinal numbers of repeated experiments carried out under the conditions indicated by the arrow.

This is apparently because, among the set of the constants estimated, k_1 and k_2 exhibit a greater parametric sensitivity. On the other hand, analysis of the pair correlations of the estimates shows that the correlations are significantly greater in absolute magnitude for the determinant criteria. Consequently, overall, when one considers a given specific example, the shape criteria is preferable.

The results of the comparison of these criteria[47] are not general and one should not expect to obtain analogous results in all cases. The results depend greatly on the type of kinetic model, on the specific numerical estimates of the constants and their parametric sensitivity, and on the length of the intervals corresponding to the variation of different controllable variables. The choice of a particular criterion is therefore determined by the aim of the kinetic study and also by the overall balance of the time allowed for the experiments and for the necessary computer calculations.

Naturally the experimental design which is optimum in relation to a given criterion may be significantly non-optimum in relation to any other. It is therefore useful to characterise the optimum properties of the design using not one criterion but a broad class of fundamental criteria. It is frequently convenient, by analogy with statistical theory of acceptable solutions, to allow a diminution of the optimum properties of the design in relation to the selected criterion, improving significantly at the same time the optimum properties of designs estimated on the basis of other criteria. Consequently, instead of using specific criteria, it is desirable to devise a single complex criterion.

Kiefer[49] suggested that the family of functionals of the information matrix be used to estimate the extent to which the designs approach an optimum:

$$\Phi_k(\xi) = \{p^{-1}\,\mathrm{Sp}\,[\Delta^{-k}(\xi)]\}^{1/k} = \left\{p\sum_{i=1}^{p}\lambda_i^{-k}\right\}^{1/k},$$
$$\Phi_0(\xi) = \lim_{k\to+0}\Phi_k(\xi) = \{\det\Delta(\xi)\}, \qquad (4.7)$$
$$\Phi_\infty(\xi) = \lim_{k\to+\infty}\Phi_k(\xi) = \max\{\lambda_i^{-1}\},$$

which include three of the most general criteria of an optimum, A, D, and E, obtained, in particular, when $k = 1, 0,$ or ∞. The properties of the family of functionals (4.7) have been analysed in detail by Kiefer; he interprets many of them as different characteristics of the dimensions of the confidence ellipsoid.

There are self-evident examples where the family of functionals Φ_k ($k = 0,1,\ldots\infty$) may not correct particular disadvantages of the design procedures. However, the employment of Φ_k is undoubtedly useful in most cases in characterising the properties of designs. Here one should note that the efficiency of the procedure used to design the refining (precision) experiment for models non-linear in terms of parameters will depend also on the initial parameters being estimated, which need to be refined, and hence also on the starting experimental design.

Practice has shown that, as a rule, the intuitively selected starting experiments in the possible region of experimentation lead to unsatisfactory (degenerate or almost degenerate) experimental designs; we may note that a virtually degenerate experimental design# can lead in many instances to incorrect results. It is known[50,51] that the strategy for the

A non-degenerate experimental design is understood to be one whose information matrix determinant is significantly non-zero.

starting experimentation depends both on the specific type of model and on the numerical values of its parameters. The dependence of the strategy on the first factor is significantly greater, so that the design of starting experiments is desirable even in those cases where the experimenter has *a priori* extremely approximate estimates of the model parameters. Naturally, in the complete absence of *a priori* information about the parameters, the traditional approach, in which the experiment is designed intuitively, is the only one possible.

We shall consider the situation where there is some *a priori* information about the parameters and the cost of a single observation is fairly high, so that one needs to construct an exact D-optimum experimental design for a number of experiments N, specified beforehand, which exceeds only slightly the number of parameters p to be estimated. In the latter case the theorem of equivalence for locally optimum exact designs does not hold and only the following system of inequalities is valid:

$$\det(x, \varepsilon'_N) \leqslant \det(x, \varepsilon_N) \leqslant \frac{Np}{N+1-p}, \qquad (4.8)$$

where ε'_N and ε_N are respectively the experimental designs minimising the response variance $d(x, \varepsilon_N)$ and maximising the determinant of the information matrix $M(\varepsilon_N)$. Under these conditions, the procedure used to construct locally optimum exact designs for single-response models can be carried out in the following particular way:

(1) p kinetic parameters θ are specified for the kinetic model being tested;

(2) the design $\varepsilon_N^{(1)} = (x_1, \ldots, x_N)$ with $\det M(\varepsilon_N) \neq 0$ is chosen in the experimentation region G.

(3) the conditions for the $(N+1)$th experiment, maximising $d_N(x, \varepsilon_N^{(1)})$, are calculated;

(4) the design $\varepsilon_{N+1}^{(1)} = \varepsilon_N^{(1)} \cup x_{N+1}$ is formulated;

(5) on the basis of the $\varepsilon_{N+1}^{(1)}$ design, the $\varepsilon_N^{(1)}$ design, for which the determinant of the information matrix is a maximum, is found by consecutive sorting in the $(N+1)$th N-point design.

In the sth step of the construction of the exact design the inequality

$$\det\{M(\varepsilon_N^{(s)})\} > \det\{M(\varepsilon_N^{(s-1)})\} \qquad (4.9)$$

always holds, provided that

$$\sup_{x \in G} d(x, \varepsilon_N^{(s)}) = d(\varepsilon_N^{(s)}) > \frac{Np}{N+1-p}. \qquad (4.10)$$

The construction of the design is repeated until it is found that, for a specified value of δ at some step,

$$d(\varepsilon_N^{(k)}) \leqslant \frac{Np}{N+1-p} + \delta$$

for all $k > s$.

The procedure examined above converges fairly rapidly to the exact locally optimum design. Thus five interactions are usually sufficient for the construction of the exact design.

One should note that the most significant factor determining the optimum strategy for the starting (and subsequent refining) experiments involves the determination of the number of constants in the kinetic model capable of being estimated. To a first approximation, it is equal to the rank of the information matrix $M(\varepsilon_N)$ of the ε_N design; the rank depends both on the numerical values of θ and on the experimental design ε_N. The number of constants capable of being estimated is then usually less than the total number of parameters of the model, because some of them are determined in the form of certain combinations, for example, because of the use of approximations postulating a quasi-stationary reaction or a quasi-equilibrium in the rapid stages. The total number of parameters does not include those whose statistical insignificance has been established by methods of variance analysis in testing the adequacy of the kinetic models.

In the consecutive design of refining experiments one must maximise, together with the selected criterion for an optimum design, also the rank of the information matrix in order not to lose information about the numerical parameters and in order not to reach incorrect conclusions in selecting a kinetic model adequate for the process.

VI. DISCRIMINATION BETWEEN MODELS

Before the concluding stage of the determination of the probable mechanism of a chemical reaction, it is usually found that several kinetic models are consistent with the available experimental data and the problem of discrimination between them therefore arises. There exist two main methods for testing kinetic models—the method of the probability ratio and Bayes' method. Although they are in many respects similar, nevertheless there are fundamental differences.

The method of the probability ratio[52] is effective in testing kinetic hypotheses, particularly when the probability function is know, i.e. when the density of the distribution of the errors of the measurements and the numerical parameters of both the kinetic models and of the distribution function are known. The probability ratio

$$u_{ij} = L_i / L_j \qquad (5.1)$$

then serves as a measure of the advantage of the ith model compared with the jth model. Evidently, if $u_{ij} > 1$, then $L_i > L_j$ and the experimental results are therefore better reflected by the ith model than by the jth model. For $u_{ij} > 10$ and even more so for $u_{ij} > 100$, there exists sufficient evidence in support of the ith model.

However, the parameters θi and θj, on which the probability ratio $u_{ij}(\theta_i, \theta_j)$ depends, are usually unknown. One of the possible ways of eliminating "interfering" parameters consists in the employment of estimates of maximum probability as a function of the probability ratio

$$u_{ij}(\theta_i^{\times}, \theta_j^{\times}) = \max_{\theta_i} L_i(\theta_i) / \max_{\theta_j} L_j(\theta_j). \qquad (5.2)$$

In this case $u_{ij}(\theta_i^{\times}, \theta_j^{\times})$ represents the ratio of the probabilities for two individually best models. When the parameters estimated from the experimental data are not known beforehand, interpretation of the probability ratio and a decision in favour of a particular model become much more arbitrary. For the same number of parameters of the models, the probability ratio $u_{ij}(\theta_i, \theta_j)$, for which preference is given to the ith model compared with the jth model, is selected in the range from 10 to 100.

If $u_{ij}(\theta_i, \theta_j)$ includes the vectors θ_i and θj of different dimensions, the model containing a greater number of parameters is usually found to be superior in the test. This finding must be taken into account in testing kinetic hypotheses.

If the number of tested hypotheses is greater than two $(m > 2)$, they are checked in pairs for all possible pairs. However, it is better to employ the general probability ratio[53]

$$u_j = \frac{L_j(\theta_j)}{\left(\prod_{k=1}^{m} L_k(\theta_k)\right)^{1/m}}. \qquad (5.3)$$

as the criterion. As described above, in this case the pth model is thought to have been proved best in the tests if the values of u_j ($j = 1,\ldots,p-1, p+1,\ldots,m$) do not exceed $0.01-0.1$; here it is assumed that $u_p > 0.1$.

It is nevertheless most useful to employ the criterion (5.3) in a consecutive procedure for the determination of the best kinetic model, the essential features of which are as follows. The experiment is carried out consecutively until the probability ratio for one of the models, for example the lth model, is in the range $0.01-0.1$; the lth model is then discarded and the number of models is reduced by unity. Tests are continued until only one model remains and is adopted as most consistent with the experimental data.

The Bayes ion approach to the solution of the problem of discrimination between models is based on the Bayes theorem and a subjective interpretation of the *a priori* information. In the Bayes ion approach the solution of the discrimination problem begins with the determination of the *a priori* distribution density of the probabilities $P(M_j)$, $j = 1,\ldots,m$, constructed for a set of m competing hypotheses M_j. It is specified on the basis of previous experimental studies or literature data and constitutes a subjective interpretation of the available information by the investigator. The distribution density of the probabilities $P(M_j)$ is usually discrete in view of the finite nature of the set of tested hypotheses and its form has no influence on the result of the final solution of the test of the hypotheses although both the duration of the discrimination procedure and the number of necessary experiments depend on its selection.

Since it is difficult to construct the loss function corresponding to the adoption of an incorrect solution, one usually maximises the *a posteriori* distribution density of $P(M_j|y)$, which is determined from the results of the experiment y and from the *a priori* distribution density of $P(M_j)$ on the basis of Bayes' theory:

$$P(M_l|\mathbf{y}) = \frac{P(\mathbf{y}|M_j)P(M_j)}{P(\mathbf{y})} = \gamma P(\mathbf{y}|M_l)P(M_l), \qquad (5.4)$$

where $P(\mathbf{y}|M_j)$ is the distribution density of the selection obtained on the assumption that the hypothesis is valid and $P(\mathbf{y})$ is the partial distribution density of the selection. The proportionality constant γ in Eqn.(5.4) is determined from the condition that the sum of the *a posteriori* probabilities is equal to unity for all the models.

If the probability function $P(\mathbf{y}|\theta_j, M_j)$ contains "interfering" parameters θ_j, the latter must be excluded from consideration by averaging the function $P(\mathbf{y}|\theta_j, M_j)$ over all possible values of θ_j:

$$P(\mathbf{y}|M_l) = \gamma \int P(\mathbf{y}|\theta_j, M_j)\,P(\theta_j|M_j)\,\mathrm{d}\theta_j, \qquad (5.5)$$

where $P(\theta_j|M_j)$ is the *a priori* distribution density of the parameters θ_j. Similarly $P(M_j)$ is selected from the available information about the values of θ_j.

We may note that, when the Bayes ion approach to the problem of discrimination between the hypotheses is used, the parameters θ_j are regarded as random quantities with a certain probability distribution density.

There exist several ways of achieving the Bayes ion approximation in practice for the solution of the problem of discrimination between models which are non-linear in terms of the parameters. The most general is based on the expansion of non-linear models in Taylor's series in the space of parameters in the vicinity of earlier estimates of θ_j. Restricting the treatment to only the first terms of the expansion, we then have

$$\mathbf{d}_j = X_j(\theta_j - \theta_j^+) + \varepsilon, \qquad (5.6)$$

where $\mathbf{d}_j = (d_{j1},\ldots,d_{jn})^{\mathrm{T}}$, $d_{ju} = y_u - f^{(j)}(x_u, \theta_j^+)$, and $u = 1,\ldots,n$ are indices characterising the number of the experiment. $\theta_j = (\theta_{j1},\ldots,\theta_{jpj})$ is the vector of the space of parameters with the dimensions $pj \times 1$, $\varepsilon = (\varepsilon_1,\ldots,\varepsilon_n)^{\mathrm{T}}$ for the vector of the reproducibility errors, and $X_j = \{x_{ul}^{(j)}\}$ a matrix with the dimensions $n \times p_j$ whose u, l-th element can be put in the form

$$x_{ul}^{(j)} = \left\{\frac{\partial f^{(j)}(x_u, \theta_j)}{\partial \theta_{jl}}\right\}_{\theta_j = \theta_j^+}. \qquad (5.7)$$

It is assumed in addition that (1) the vector of the reproducibility error ε is a normal random vector with a zero vector of mathematical expectations and a covariance matrix Σ, i.e. $\varepsilon \cong N(0,\Sigma)$, and (2) the *a priori* distribution density of the probabilities of Θ_j is also normal with the vector of means $\tilde{\theta}_j$ and a known covariance matrix Ω_j with the dimensions $p_j \times p_j$.

It is readily seen that, for the given assumptions, the random vector d_j is distributed normally with $\mathrm{E}\,d_j = X_j(\theta_j - \theta_j^+)$ and the covariance matrix $D\,d_j = X_j\Omega_j X_j^{\mathrm{T}} + \Sigma$, where E is a symbol representing the mathematical expectation. Eqn.(5.5) then becomes

$$P(\mathbf{y}|M_j) = \frac{\exp\left\{-\frac{1}{2}[\mathbf{d}_j - X_j(\tilde{\theta}_j - \theta_j^+)]^{\mathrm{T}}(X_j\Omega_j X_j^{\mathrm{T}} + \Sigma)^{-1}[\mathbf{d}_j - X_j(\tilde{\theta}_j - \theta_j^+)]\right\}}{(2\pi)^{n/2}[\det(X_j\Omega_j X_j^{\mathrm{T}} + \Sigma)]^{1/2}}. \qquad (5.8)$$

Although Eqn.(5.8) was derived without using Eqn.(5.5), it is fully equivalent to the latter[52].

The *a posteriori* probabilities of the validity of the hypotheses are calculated from Eqn.(5.4). Consequently, we have

$$P(M_j|\mathbf{y}) = \frac{P(M_j)P(\mathbf{y}|M_j)}{\sum_{k=1}^{m} P(M_k)P(\mathbf{y}|M_k)}. \qquad (5.9)$$

At a specific step in the experimentation process one assumes that the lth model has withstood best the tests among the set of competing models if $P(M_l|\mathbf{y})$ assumes values fairly close to unity.

Analogously the Bayes method of selecting the best solutions can be used to estimate the kinetic parameters. In this case the *a posteriori* distribution of the parameter θ is also determined from the Bayes theorem:

$$P(\theta_j|y) = \frac{P(\mathbf{y}|\theta_j)P(\theta_j)}{\int_{\Omega} P(\mathbf{y}|\theta_j)P(\theta_j)\,\mathrm{d}\theta_j} = \frac{P(\mathbf{y}|\theta_j)P(\theta_j)}{P(\mathbf{y})}, \qquad (5.10)$$

where $P(\mathbf{y})$ and $P(\theta_j)$ are the partial distribution densities of the random vectors $\mathbf{y}$ and θ_j. As before, $P(\theta_j)$ contains the initial information about the values of θ_j. If $P(\mathbf{y}|\theta_j)$ and $P(\theta_j)$ are the normal distribution densities of the probabilities, then $P(\theta_j|\mathbf{y})$ is the conventional *a posteriori* distribution density of the parameters θ_j, which is also normal with

$$E(\theta_j) = (X_j^{\mathrm{T}}\Sigma^{-1}X_j + \Omega_j^{-1})(X_j^{\mathrm{T}}\Sigma^{-1}X_j\theta_j^+ + \Omega_j^{-1}\tilde{\theta}_j) \qquad (5.11)$$

and with the covariance matrix

$$D(\theta_j) = [(X_j^{\mathrm{T}}\Sigma^{-1}X_j + \Omega_j^{-1})]^{-1}.$$

In kinetic studies on complex chemical systems the confirmation of the reaction mechanism frequently requires the estimation with a specified accuracy of only some of the constants in the overall set, for example, in order to be able to compare subsequently their values with the constants

obtained from earlier independent measurements. Consequently, one has to estimate only a subvector of the vector of the parameters θ_j, the *a posteriori* distribution density of which is equal to the partial *a posteriori* distribution density of the subvector of the parameters relevant to the given case. For normal $p(\theta_j|y)$, the latter is also normal with the vector of mathematical expectations equal to the corresponding subvector of the specified parameters of the vector $E(\theta_j)$ and with a covariance matrix made up of the elements $D(\theta_j)$ located at the intersections of the columns and rows of the corresponding specified parameters.

We may also note that the use of the *a posteriori* distribution density of the kinetic parameters as a characteristic of the accuracy of their estimates yields incomparably more information about the parameters than the point and interval estimates, which is a characteristic advantage of the Bayesion approach.

The Bayesion procedure for testing kinetic hypotheses, discussed above, which provides for the linearisation of the kinetic models with respect to parameters, is correct only when the models tested for consistency with experimental results are linear in terms of the parameters and the fundamental statistical postulates, concerning the nature of the distribution density of the errors of the measurements and the validity of the employment of the methods of regression analysis, are correct. The application of such procedures in order to discriminate between models which are significantly non-linear in terms of the parameters is legitimate only when the non-linear models can be fitted fairly satisfactorily by linearised models.

In order to improve the reliability of the Bayes methods, which involves the linearisation of the kinetic models, it is necessary to improve in the first place the linearisation procedure itself. This can be achieved, in particular, by a suitable selection of the estimates of θ_j^+ in the vicinity of which the models can be fitted by a truncated Taylor series. It is usually desirable to employ as such estimates the estimates of the maximum probability or estimates which are respectively equal to the vector of the mathematical expectations of the *a posteriori* distribution density of the parameters.

Another method for improving the linearisation procedure consists in a preliminary reparametrisation of the models and their reduction to a form which no longer involves a significant non-linearity. The kinetic models transformed in this way are more covenient for subsequent linearisation. Thus it has been shown in relation to a number of examples[54] that the direct application of Bayes discrimination methods to non-parametrised models leads to contradictory results, while preliminary reparametrisation of the competing models eliminates the possible errors. The algorithms proposed for the reparametrisation of kinetic models were in many respects analogous to the algorithms of Box et al.[55] and Box and Tidwell[56], which were developed to replace dependent and independent variables in regression equations.

One should note that reparametrisation makes it possible to increase appreciably not only the reliability of the Bayes procedures for discrimination between models but also the accuracy of the calculation of the variance matrices and hence the confidence intervals and confidence regions for the estimation of the parameters[57].

A method for the testing of kinetic hypotheses, which does not involve a procedure for the linearisation of models and employs the kinetic models as such in the selection of solutions, has been proposed[58]. In this method the continuous region of parametric space for each competing model, in which the best estimates of the model parameters are sought, is covered by a finite set of discrete points equidistant from one another. An *a priori* probability $P(\theta_j|M_i)$ is assigned to each l_j-th parametric point θ_j and the expression for the *a posteriori* probabilities of acceptable hypotheses (5.9) is replaced by its discrete analogue

$$P(M_j|\mathbf{y}) = \frac{P(M_j)\sum_{l=1}^{s_l} P(\theta_{l_j}|M_j)P(\mathbf{y}|\theta_{l_j}, M_j)}{\sum_{i=1}^{m} P(M_i)\sum_{l=1}^{s_i} P(\theta_{l_i}|M_i)P(\mathbf{y}|\theta_{l_i}, M_i)}, \quad (5.12)$$

where s_i is the total number of parametric points θ_{li} covering the region of the parametric space for the ith model.

The *a posteriori* probabilities

$$P(\theta_{l_j}|\mathbf{y}) = \frac{P(\theta_{l_j}|M_j)P(\mathbf{y}|\theta_{l_j}, M_j)}{\sum_{i=1}^{m}\sum_{l=1}^{s_i} P(\theta_{l_i}|M_i)P(\mathbf{y}|\theta_{l_i}, M_i)}. \quad (5.13)$$

are estimated from the selected y and the *a priori* probabilities $P(\theta_{li}|M_j)$. In the next step of the test of competing kinetic models, i.e. before setting up a new series of experiments and before a new selection of y, the *a posteriori* probabilities $P(\theta_{lj}|y)$ and $P(M_j|y)$ are assumed to be *a priori* probabilities and the cycle of investigations is repeated until the *a posteriori* probability $P(M_k|y)$ of a kth model is close to unity; the kth model is assumed to be most consistent with the experimental results.

The practical application of the method proposed by Hsiang and Reilly[58] presupposes the obligatory use of modern high speed computers with a large memory. Indeed, if, for example, the kinetic model contains five parameters and each parameter has ten discrete values, then 10^5 values of the probability function must be stored in the computer memory. Consequently the method[58] is effective, owing to the so called "dimensional curse", only in those cases where the number of parameters in the competing models is small and the preliminary estimates are known with a sufficiently high accuracy, which makes it possible to select a fairly narrow range of the possible variation of the parameters and in testing the hypotheses one can confine the treatment to a small number of discrete values of the kinetic parameters.

In conclusion we shall examine a useful discrimination method based on the χ_c^2 criterion[59]; the method cannot be in essence classified as a Bayes method or as a probability ratio method. The fundamental idea of the method under consideration is that the ratio of the weighted sum of the squares of the residues to the corresponding number of degrees of freedom for single-response models is an undisplaced estimate of the reproducibility error only for the true kinetic model; for all the remaining models the estimate is displaced. The method tests the homogeneity of the estimates of the reproducibility variances for all the competing models using the Bartlett distribution:

$$\chi_c^2 = \frac{(\ln \bar{s})^2 \sum_{i=1}^{m} p_{s_i} - \sum_{i=1}^{m} p_{s_i} \ln s_i^2}{1 + \frac{1}{3(m-1)}\left[\sum_{i=1}^{m}\frac{1}{p_{s_i}} - \frac{1}{\sum_{i=1}^{m} p_{s_i}}\right]}, \quad (5.14)$$

where m is the number of competing models, s_i^2 the estimates of the reproducibility variances calculated for the ith model, p_{s_i} the number of degrees of freedom of the estimate, and $\bar{s}^2$ the average estimate of the reproducibility error. If, on testing m hypotheses, it is found that χ_c^2 exceeds the tabulated value, the model yielding the maximum variance of the

reproducibility error is rejected. The number of hypotheses is reduced by unity and χ_c^2 is recalculated.

When this criterion is used to solve the problem of discrimination between hypotheses, one should bear in mind that χ_c^2 is extremely sensitive to the deviation of the data from normality and requires the statistical independence of the estimates of the variance against which the hypothesis of homogeneity is tested. It is frequently impossible to establish to what extent such hypotheses hold. However, practical examples of the use of the χ_c^2 criterion in chemical research have demonstrated its effectiveness and reliability[59].

VII. DESIGN OF DISCRIMINATING EXPERIMENTS

In the procedures described above tests of kinetic hypotheses were used to discriminate between models in relation to the results of an experiment, particularly a passive experiment. However, the efficiency of testing procedures greatly increases if the experiment is carried out actively. The problem of the design of discriminating experiments, in contrast to that of the design of precision experiments, is characterised by the absence of uniformity in the criteria employed.

However, they can be subdivided into two categories: the first includes criteria based on various measures of information and the second includes empirical criteria[60,63].

In kinetic experimental studies the entropic criterion, used as a measure of the information entropy S, is most frequently employed among the criteria of the first category. The information entropy can be defined as follows for all $P(M_j) \neq 0$ $(j = 1,\ldots,m)$:

$$S = -\sum_{j=1}^{m} P(M_j) \ln P(M_j), \qquad (6.1)$$

where $P(M_j)$ is the *a priori* probability of the suitability of the M_j-th hypothesis. If $P(M_i) = 0$ for a certain value of i, the product $P(M_i) \ln P(M_i)$ is set equal to zero.

Evidently, if $P(M_k) = 1$ for the kth model, then $P(M_j) = 0$ for $j = 1,\ldots, k-1, k+1,\ldots,m$. Then the entropy S assumes the smallest of the possible values, which is zero. On the other hand, for equal $P(M_j) = 1/m$ $(j = 1,\ldots,m)$, the value of S reaches a maximum. Consequently S characterises a measure of the information obtained about the test system and an increase of the amount of information is accompanied by an obligatory decrease of entropy.

Since in research it is desirable to reduce to the maximum extent the degree of uncertainty in the ideas about the chemical system, one should endeavour to pass from a non-informative situation [$P(M_j) = 1/m$, $j = 1,\ldots,m$; the information is scanty and it is impossible to give preference to any one model] to the most informative situation [$P(M_k) = 1$, $j = 1,\ldots, k-1,\ldots, k+1,\ldots,m$; there is sufficient information to demonstrate in the "statistical sense" the validity of the kth model]. For this purpose, in the region G, corresponding to the experimental conditions, one must carry out only experiments which reduce the entropy S to the maximum extent.

In order to establish the conditions for such experiments, Box and Hill[60] proposed two single-response models based on the criteria $D(\boldsymbol{x})$, which determine the upper limit of the expected decrease of entropy in the design and formulation of the experiment at point $\boldsymbol{x}$ in the experimental region G:

$$D(\boldsymbol{x}) = \frac{1}{2}\sum_{j=1}^{m}\sum_{i=j+1}^{m} P(M_i)P(M_j)\left\{\frac{(\sigma_i^2-\sigma_j^2)}{(\sigma^2+\sigma_i^2)(\sigma^2+\sigma_j^2)}\times \right.$$
$$\left.\times [\hat{\eta}_i(\boldsymbol{x}) - \hat{\eta}_j(\boldsymbol{x})]^2\left(\frac{1}{\sigma^2+\sigma_i^2}+\frac{1}{\sigma^2+\sigma_j^2}\right)\right\}, \qquad (6.2)$$

where $\boldsymbol{x}$ is the vector of the space of independent controllable variables, $\hat{\eta}_i(\boldsymbol{x})$ the response at point $\boldsymbol{x}$ predicted on the basis of the ith model, σ^2 the variance of the reproducibility error, and σ_i^2 the variance of the predicted response i.

In terms of the $D(\boldsymbol{x})$ criterion, an experiment $\boldsymbol{x}^{\times}$ which maximises $D(\boldsymbol{x})$ i.e. for which the conditon

$$D(\boldsymbol{x}^{\times}) = \max_{\boldsymbol{x}\in G} D(\boldsymbol{x}). \qquad (6.3)$$

holds, is most convenient. The entropic criterion[60] has been extended[5] to multiresponse models. Subsequently Reilly[52] again improved the $D(\boldsymbol{x})$ criteria by divising an algorithm for the direct calculation of the expected decrease of the entropy S.

Another important measure of information used in discrimination between models is a function of the general probability ratio. In this case the equality of the generalised probability ratios corresponds to the minimum amount of information about the system of hypotheses, while the maximum difference between them corresponds to the maximum amount of information. Hence it follows directly that, for the attainment in the course of the selection of the solution corresponding to the most favourable informative situation, one must design the experiment in such a way that the expected average increment in the sum of the logarithms of the general probability ratios from experiment to experiment is maximised[12,53]:

$$\Delta L(\boldsymbol{x}_{N+1}) = \sum_{j=1}^{m}\int_{-\infty}^{+\infty}[\ln u_j(N+1) - \ln u_j(N)]\,P_j(y_{N+1}|\,\boldsymbol{x})\,\mathrm{d}\,\boldsymbol{y}_{N+1} =$$
$$= \frac{1}{2m}\left\{\sum_{j=1}^{m}\sum_{k=1}^{m}\mathrm{Sp}\,(\Sigma+S_j)(\Sigma+S_k)^{-1} - m\,\mathrm{Sp}\,I + \right.$$
$$\left. + \sum_{j=1}^{m}\sum_{k=1}^{m}(\hat{\eta}_{N+1}^{(k)} - \hat{\eta}_{N+1}^{(j)})^{\mathrm{T}}[(\Sigma+S_j)^{-1}(\hat{\eta}_{N+1}^{(k)} - \hat{\eta}_{N+1}^{(j)})]\right\}, \qquad (6.4)$$

where $D_j(N)$ is the covariance matrix of the estimates of the constants of the jth model calculated on the basis of N experiments, $P_j(y_{N+1}|x_{N+1})$ is the distribution density of the $(N+1)$th result of the measurement of the response at the point $\boldsymbol{x}_{N+1}$ predicted on the basis of the jth model, $L_j(N)$ the general probability function given by

$$L_j(N) = \frac{\det \Sigma^{-N/2}\det D_j(N)^{1/2}}{(2\pi)^{nN/2-p_j/2}}\cdot\exp\left\{-\frac{1}{2}\left[\sum_{r=1}^{n}\sum_{s=1}^{n}\sigma^{rs}\sum_{l=1}^{N}\times\right.\right.$$
$$\left.\left.\times(y_{rl}^{(j)} - \hat{\eta}_{rl}^{(j)})(y_{sl}^{(j)} - \hat{\eta}_{sl}^{(j)})\right]\right\};$$
$$u_j(N) = \frac{L_j(N)}{\left(\prod_{k=1}^{m} L_k(N)\right)^{1/m}},$$

$S_j = X_j D_j(N) X_j^{\mathrm{T}}$, X_j an $n \times p_j$ matrix with a general element of the type $x_{ri}^{(j)} = \partial\eta_{r,N+1}^{(j)}/\partial\theta_i^{(j)}$, $\hat{\eta}^{(j)}$ the $n \times 1$ vector of the predicted values of the response based on the jth model, $\Sigma = \{\sigma_{ij}\}$ the covariance matrix of the measurements, $\Sigma^{-1} = \{\sigma^{rs}\}$, and the indices j, i, and r characterise respectively the numbers of the model, the parameter, and the response.

Application of criterion (6.4) to the solution of a number of practical problems in chemical kinetics demonstrated its effectiveness and reliability[64,65]. In particular, the use of criterion (6.4) in tests for consistency with experiment of two competing hypotheses about the mechanism of the toluene disproportionation reaction on zeolite catalysts showed that

two consecutive experimental designs are sufficient to demonstrate the superiority of one hypothesis. A similar situation arises in discrimination between multiresponse models, while for single-response models the necessary number of discriminating experiments is usually significantly greater.

Fig. 4 illustrates graphically the function of the general probability ratio ΔL obtained in calculations of the conditions for the first discriminating experiment. The large number of extrema and "ravines" in the plot of the function ΔL against controllable variables indicates computational difficulties in the solution of problems involving discrimination between multiresponse models non-linear in terms of parameters. One should note that discriminating experiments are usually located at the boundary of the region of possible experimentation.

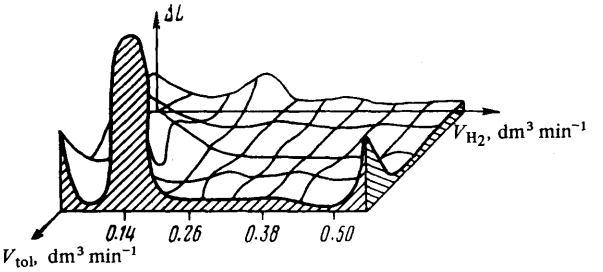

Figure 4. Variation of the response surface of the function of the probability ratio ΔL with controllable variables—the volume flow rates of hydrogen and toluene; the volume flow rate of benzene was constant at 0.05 dm^3 min^{-1}.

Other criteria for the design of discriminating experiments, based on other measures of information, are also known. Thus it has been suggested[66] that the Kullbakov measure be employed, while Borth[67] suggested that one use the increment in the maximum *a posteriori* probability of the suitability of models. The criteria have been compared and their efficiences estimated[68]. However, in practical kinetic research the criteria proposed in the above investigations[66,67] have not so far been used.

All the criteria examined above[69] make it possible to formulate experiments in the experimentation region which permit the establishment of competing models under critical conditions from the standpoint of their descriptive power. One then as a rule takes into account the uncertainty in the predicted responses; preference can be given to experimental conditions characterised by small discrepancies in the predicted responses with small error corridors compared with conditions accompanied by large discrepancies between the predicted responses with large error corridors.

In practice the variances of the predicted responses are calculated with much difficulty and in devising empirical criteria they are therefore as a rule neglected. The $C(x)$ criterion is most widely used[67]:

$$C(x) = \sum_{i=1}^{m} \sum_{j=i+1}^{m} |\hat{\eta}_i(x) - \hat{\eta}_j(x)| , \qquad (6.5)$$

as well as the $B(x)$ criterion[58]:

$$B(x) = \sum_{i=1}^{m} \sum_{j=i+1}^{m} |P(M_i) + P(M_j)| \cdot |\hat{\eta}_i(x) - \hat{\eta}_j(x)|. \qquad (6.6)$$

In applying criteria (6.5) and (6.6) the discriminating experiments are usually located in a single adequately bounded subregion of the experimentation region G. A complex criterion, which provides, together with the maximisation of $C(x)$, also for the maximisation of the distance between the new discriminating point produced by the design and all the remaining points of the design found previously, has therefore been proposed[70]. This principle has been realised in practice[70].

There are now already numerous publications in which the methods for the design and analysis of kinetic precision and discriminating experiments have found practical applications. Most of them describe real practical situations[61–63,71–78], while others deal solely with situations simulated on computers. These publications describe mainly the results of comparisons of different criteria and give estimates of their efficiencies[76–80].

The Basicity of Transition Metal Complexes in Reactions with Aprotic Acids

B.V.Lokshin, A.G.Ginzburg, and E.B.Nazarova

Data for the interaction of transition metal complexes (TMC) with aprotic acids, in which the TMC play the role of bases, are examined and reactions, in which the centre of the basicity of the TMC is the transition metal atom, and the ligands are discussed. The influence on the basicity of the central atom of its position in the Periodic System and of its ligand environment as well as the influence of the structure of the complex and the nature of the aprotic acid and the medium on the formation of donor-acceptor complexes between TMC and electron acceptors are considered. A systematic account is given of data for the interaction of TMC with various classes of acceptors: metal and non-metal halides, halogens, alkyl halides, metal cations, π-acids, and one-electron oxidants.
The bibliography includes 136 references.

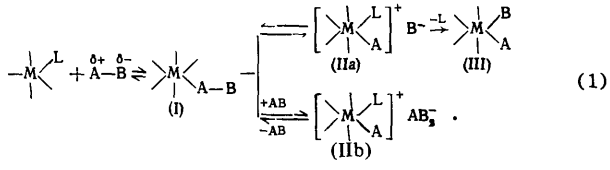
I. INTRODUCTION

It is well known that many transition metal complexes (TMC) have nucleophilic properties and can play the role of bases in an acid–base interaction. The metal in such complexes is in a low oxidation state and can be attacked by various electrophiles. The basic properties of TMC were demonstrated for the first time in 1955 when the reversible protonation of π-complexes at the transition metal atom was discovered[1]. Studies in this field subsequently developed greatly and the infrared spectroscopic and NMR methods played a decisive role in the study of protonation[2-6].

The study of protonation yielded important data on the basicity of the metal atom and complexes, since the basicity of the central metal atom can be inferred qualitatively from the ease of protonation. In particular, a relation has been established between the ease of protonation and the position of the metal in the Periodic System. In series of isostructural compounds with the same ligands, differing only in the central transition metal atom, the basicity of the latter increases with increase of its atomic number within the limits of a single Group. In this sense, transition metal compounds differ sharply from bases containing elements of the main groups of the Periodic System, whose basicity diminishes on passing to heavier atoms within the limits of the same Group. The reason for this is in the difference between the properties of the orbitals involved in the formation of the donor–acceptor bonds. For main Group elements, the lone pair of n electrons of the sp^2- or sp^3-hybridised heteroatoms is involved in the interaction, i.e. the corresponding compounds are n-bases. For TMC, the highest occupied molecular orbital is a virtually pure d orbital of the metal and is occupied by d electrons, i.e. these complexes behave as d-bases.

The basic properties of TMC are shown not only in protonation reactions but also in reactions with many aprotic acids. The basicity of TMC can be shown in two aspects of their reactivity: (a) the interaction with an acceptor suitable as regards the symmetry and energy of the vacant orbital, leading to the formation of a new donor–acceptor chemical bond; (b) oxidation of the TMC involving the abstraction of one electron from the highest occupied molecular orbital without the formation of a new chemical bond. Such oxidation can proceed both chemically under the influence of a suitable oxidant (Ag^+, NO^+) and electrochemically. The study of these reactions greatly extends the scope of research into the basicity of TMC. These data are also important for the understanding of the mechanisms of many reactions of TMC, for example, reactions in the presence of Lewis acids and oxidative addition reactions.

In the present review an attempt is made to achieve a systematic arrangement of the extensive experimental data, which are available for the interaction with aprotic acids, from the standpoint of the basicity of the TMC. In this case we understand by basicity the ability of the TMC to form donor–acceptor (D–A) complexes (adducts) with electron acceptors involving an increase of the coordination number (C.N.) of the donor atoms. The possibility of the formation of an adduct depends not only on the properties of the donor molecules but also on the type of acceptor used. The strength of the D–A bond is determined by the relative energies and symmetries of the D and A orbitals involved in the formation of the bond and also by steric factors. The properties of the same TMC as a base can therefore be different in relation to different acceptors. The interactions of TMC with the following classes of electron acceptors have been considered: aprotic acids—metal and non-metal halides; halogens and alkyl halides; metal cations; π-acids; one-electron oxidants.



There are several possible basicity centres in the molecules of the TMC considered to which attack by the electrophile can be directed: the central metal atom, the O, S, or N atoms or ligands such as CO, CS, NO, N_2 or CN, halogen ligands, and finally π-ligands. It is shown below that the reactions with aprotic acids can lead to the formation of adducts not only via the metal atom but also via the ligand and that, depending on the type of complex, the aprotic acid, and the reaction conditions, the complexes can behave as d-bases, n-bases, or π-bases. Sometimes these possibilities are realised simultaneously.

A number of reviews devoted to the basicity of transition metal complexes have already been published, but some of these[6,7] cover only the literature up to 1970 and one[8] is concerned mainly with the basicity of carbonyl ligands and is incomplete.

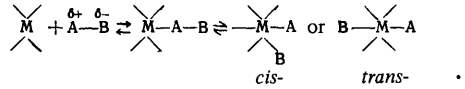
Reactions via the central metal atom and via the ligand will be considered separately below.

II. INTERACTION VIA THE METAL ATOM

For five-ccordinate and six-coordinate complexes, the reactions via the metal atom can be represented by the following mechanism, where A–B is a conventional representation of a molecule of the Lewis acid:

(1)

The electron acceptor can add to the metal to give a neutral adduct (I), which can then be converted into an ionic compound (IIa) or (IIb) with dissociation of the A–B bond. The latter compounds should be electrically conducting in solutions. However, in the majority of cases the structure of the adduct cannot be establsihed exactly in solution, since conductimetric data are not always reliable or are not available. Owing to the reversibility of the formation reactions of compounds (I) and (II), an equilibrium is established in the solution as a result of which the observed conductivities can be low.



Adducts with two or several molecules of the Lewis acid frequently contain involved complex anions (for example, $SnCl_5^-$, $HgCl_3^-$, $Hg_2Cl_5^-$, etc.). The structure of the adduct in solution and in the crystal can be various. Thus polar solvents promote the conversion of adducts of type (I) into compounds of type (II).

The structure of complexes with Lewis acids has not always been established with sufficient reliability. For solid adducts, X-ray diffraction data are available in many instances, but the evidence for the structure has usually been reached solely on the basis of spectroscopic data. The equilibrium between the adduct and the initial compounds in solutions has been studied even less. The equilibrium position can be inferred, at least qualitatively, from such data for the relative basicities of the complexes. In other cases, the relative basicities of series of complexes can be established in accordance with the occurrence or non-occurrence of an interaction with a standard Lewis acid under identical conditions.

In the absence of structural data, the main criterion of the formation of adducts via the metal is provided by spectroscopic measurements. Complexes containing the CO ligand have been most widely investigated, because the CO stretching vibration frequencies are extremely sensitive to changes in the formal oxidation state of the metal. The interaction of the acceptor molecule with the central metal atom leads to an increase of the stretching vibration frequencies of the CO groups, which is associated with the decrease of the electron density at the metal atom and this entails a weakening of the $d_\pi(M) \rightarrow p_{\pi^*}(CO)$ dative bonds and an increase of the CO bond orders in the complex $\overline{M}-C\equiv\overset{+}{O}\leftrightarrows M=C=\ddot{O}:$. As in protonation involving the metal atom, such a frequency shift is believed to be a characteristic feature of the involvement of the metal atom in coordination to the Lewis acid. As will be shown below, other types of coordination of the acceptor lead to quite different changes in the spectra. It is not always possible to state with confidence which type of adduct has been obtained—(I) or (II). It is usually assumed that, in the formation of type (II) adducts, the formal positive charge on the metal atom increases by unity and the CO frequency shift should be the same as in protonation (100–150 cm^{-1}).

The electron density on the metal atom in adduct (I) should also be reduced but to a smaller extent; consequently the observed hypsochromic shift should be smaller. For example, complexes of the type $L_2Fe(CO)_2$ form 1:1 or 1:2 adducts with $HgCl_2$. The ν(CO) frequency shift is 70–80 cm^{-1} for the first type and 100–120 cm^{-1} for the second. Accordingly, the structures $L_2(CO)_3Fe \rightarrow HgCl_2$ and $[L_2(CO)_3FeHgCl]^+HgCl_3^-$ have been attributed to these adducts[9], which has been confirmed by conductimetric measurements.

The final product (III) of reaction (1) is formed by the elimination of a neutral ligand molecule, usually CO (the so-called oxidative elimination). This stage of the reaction is irreversible. In the present review reactions of this type will not be considered in detail (see the previous reviews[10,11]). In the case of tetracoordinate complexes reactions can proceed without the elimination of ligands, involving an expansion of the coordination sphere and an increase of the coordination number by two (oxidative addition reactions):

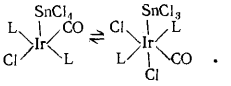
(2)

We may note that the basicity of the central metal atom is one of the main factors which determine the course of such reactions. This can be seen from the following reaction as an example[12]:

$$(bipy)M(CO)_4 + 2HgCl_2 \rightleftharpoons (bipy)M(CO)_4 \cdot 2HgCl_2 \xrightarrow{-CO} (bipy)M(CO)_3Cl(HgCl) + HgCl_2$$

(M = Mo or W; bipy = 2,2'-bipyridyl).

For M = W, it is possible to isolate an unstable intermediate adduct $(bipy)W(CO)_4.2HgX_2$ (X = Cl or Br), which rapidly evolves CO and gives rise to the stable tricarbonyl derivative $(bipy)W(CO)_3X(HgX)$. For the corresponding molybdenum complex, the intermediate adduct is so unstable that one obtains immediately the tricarbonyl derivative $(bipy)Mo(CO)_3X(HgX)$. The reaction with $SnCl_4$ yields in both cases the oxidative addition product $(bipy)M(CO)_3.Cl(SnCl_3)$, where M = Mo or W.[12,13]



The interaction of phosphine derivatives $(diphos)M(CO)_4$ (diphos = $Ph_2PCH_2CH_2PPh_2$) with $HgCl_2$ proceeds without the evolution of CO and the adducts $(diphos)M(CO)_4.HgCl_2$ are formed[12]. The infrared spectra of these adducts in solution contain the ν(CO) bands of the initial complexes and in addition higher-frequency bands, corresponding to an increase of the oxidation state of the metal atom, appear, i.e. the adducts are in equilibrium with the initial substances in solution. The conductances Λ_M of solutions of the adducts in acetonitrile are low, but the addition of an excess of $HgCl_2$ lowers the degree of dissociation of the adduct and increases Λ_M. On this basis, it is postulated that the adducts have the structure $[(diphos)M(CO)_4.HgCl]^+Cl^-$.

It is seen from the examples presented that, depending on the nature of the reactants, reaction (1) can give rise to different products.

The interaction with aprotic acids is extremely characteristic of square planar rhodium and iridium complexes. Here there is a possibility of a donor–acceptor adduct (C.N. = 5

for M) or of oxidative addition (C,N. = 6).[6,14] For example, *trans*-$L_2Ir(CO)Cl$ ($L = PPh_3$) reacts with HgX_2 to give the oxidative addition products $L_2(CO)ClIr\begin{matrix}\nearrow X\\ \searrow HgX\end{matrix}$.[15] The same complex forms 1:1 and 1:2 adducts with BF_3 in solution. The 1:1 adduct[16] is a simple adduct with an Ir–B donor-acceptor bond whose (CO) frequency has been increased by 100 cm^{-1} compared with the carbonyl frequency of the initial complex. For the 1:2 adduct, ν(CO) does not differ appreciably from the value for the 1:1 adduct. The structure of the 1:2 adduct is obscure. It has been suggested that its second BF_3 molecule is not linked to the Ir atom but is connected to the first BF_3 group via a bridge of fluorine atoms[5].

The reaction of *trans*-$L_2Ir(CO)Cl$ with $SnCl_4$, leading to the formation of $L_2(CO)ClIr.SnCl_4$, is extremely interesting[17]. The resulting complex is monomeric and non-conducting. The infrared spectrum shows two bands in the carbonyl region, at 2080 and 2020 cm^{-1} in the solid state and at 2080 and 2041 cm^{-1} in chloroform. The presence of the two ν(CO) bands can be explained by the presence of isomers which undergo a rapid interconversion:

This is an unusual type of isomerism involving a change in the formal oxidation state of the central metal atom. The higher-frequency band corresponds to the oxidative addition product and the lower-frequency band is associated with the donor–acceptor adduct.

Thus the acid–base interaction of the metal atom in the complex L_nM with the aprotic acid AB can lead to several types of compounds: neutral adducts $L_nM \rightarrow AB$ and salt-like compounds $[L_nM-A]^+B^-$ or $[L_nM-A]^+AB_2^-$. The mode of reaction depends on a number of factors: the nature of the metal, the nature of the ligands surrounding it, the type of Lewis acid, and the solvent. Although the available data are non-systematic, they nevertheless make it possible to trace a number of regularities.

1. The Influence of the Nature of the Central Metal Atom

The dependence of the basicity of the complex on the nature of the central metal atom can be established by comparing the behaviour of complexes differing solely by the central atom in reactions with the same electron acceptor.

It was already noted above that, on treatment with BF_3, the complex $L_2Ir(CO)Cl$ ($L = PPh_3$) forms adducts via the metal atom, which contain the $Ir \rightarrow B$ bond.[16] The analogous rhodium complex $L_2Rh(CO)Cl$ does not form adducts with BF_3, which leads to the conclusion that the Ir atom is more basic than the Rh atom. In contrast to the rhodium complex, the iridium complex is also capable of forming a compound with O_2.[14] Thus, atoms with a higher atomic number proved to be more basic in the given Group of the Periodic System. This behaviour, which agrees with that found in the study of protonation[3–5,18–21], is extremely general; it holds also in other Groups of the Periodic System.

Thus cyclopentadienyltricarbonylmanganese $CpMn(CO)_3$ (CTM) does not interact with $TiCl_4$, while the addition of $TiCl_4$ to the corresponding rhenium complex $CpRe(CO)_3$ (CTR) in CH_2Cl_2 gives rise to a spectrum, where, apart from the ν(CO) bands of the initial substance, there are also bands of the adducts displaced towards higher wavenumbers by more than 100 cm^{-1},[22] which is characteristic of adducts formed via the metal atom.

After the addition of an excess of $SnCl_4$ in CH_2Cl_2, the infrared spectrum of the phosphite derivative of CTM, i.e. $CpMn(CO)_2P(OPh)_3$, contains the ν(CO) frequencies of both the initial complex and the adduct[23]. For $CpRe(CO)_2P(OPh)_3$ under the same conditions, the equilibrium is almost wholly displaced towards the formation of the adduct[22]. These data indicate more pronounced basic properties of rhenium compared with manganese.

The arene complexes of Group VI transition metals behave similarly. Thus $MsCr(CO)_3$ (Ms = mesitylene) is in equilibrium with the addition product in CH_2Cl_2 in the presence of an excess of $SnCl_4$. The equilibrium involving the corresponding Mo and W compounds is wholly displaced towards the adduct. Analysis of the available data shows[22] that the basicity of the metal increases in the sequence Cr < Mo < W. An analogous conclusion was reached for the triad Co < Rh < Ir.[14,24]

2. The Influence of the Ligand Environment on the Basicity of the Metal in the Complex

The basicity of the transition metal atom in the complex depends very markedly on the nature of the surrounding ligands. The replacement of ligands by species with more marked electron-donating properties, for example, tertiary phosphines, leads to an increase of basicity and, conversely, the introduction of electron-accepting ligands suppresses basicity.

CTM does not interact with $SnCl_4$ in solutions[23], but the addition of five electron-donating ethyl groups in the Cp ring enables the complex $(Et_5C_5)Mn(CO)_3$ to form an adduct with $SnCl_4$ in solution, although the equilibrium is in this case displaced towards the formation of the initial substances. The replacement of one CO group by a phosphine ligand PR_3, with more pronounced electron-donating properties, increases the basicity of the Mn atom to an even greater extent. The basicity then depends on the electron-donating properties of the group R in the ligand PR_3, increasing sharply in the sequence OPh ≪ Ph < alkyl. Like CTM, CTR does not interact with $SnCl_4$, but the replacement of CO by PR_3 sharply increases the basicity and makes the complex capable of forming adducts; the reaction proceeds readily in solution and goes almost to completion[22].

The complex $MsCr(CO)_3$ (Ms = mesitylene) is in equilibrium with the adduct molecules in the presence of an excess of $SnCl_4$. The phosphine derivative $MsCr(CO)_2PPh_3$ is almost completely converted into an adduct in the presence of an excess of $SnCl_4$.[22]

The substitution of two CO groups in $CpMn(CO)_3$ by two phosphine ligands is accompanied by an even greater increase of the basicity of the manganese atom. Diphosphine complexes of the type $CpMn(CO)L_2$ [$L_2 = (PPh_3)_2$ or the bidentate diphosphines $Ph_2P(CH_2)_nPPh_2$ ($n = 1–3$)] react in solution not only with $SnCl_4$ but also with weaker aprotic acids $SbCl_3$, $HgCl_2$, and $GeCl_4$.[23] In all cases the single ν(CO) frequency then increases by 100–110 cm^{-1} and, depending on the ratio of the amounts of the initial reactants, the spectrum contains the bands of both forms or only of the adducts. In the presence of an excess of $SnCl_4$, $SbCl_3$, or $HgCl_2$ only the bands of the adducts were observed in the infrared spectrum of the solution. For $GeCl_4$, both bands were observed even when the compound was present in a large excess in solution, and their intensity ratio indicates a shift of the equilibrium towards the initial compound.

3. Dependence of the Nature of the Interaction on the Aprotic Acid

The mode of reaction of TMC in many respects depends on the type of acceptor molecule. Certain Lewis acids are capable of interacting with complexes not only via the metal atom but also via the ligands. These instances will be examined separately below. This section deals solely with interactions via the metal.

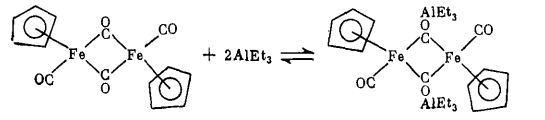
The higher the basicity of the metal atom in the complex, the greater the range of aprotic acids with which it can interact. Thus $(Ph_3P)_2Rh(CO)Cl$ does not interact with BF_3 but does so with BCl_3 and BBr_3, the adduct with BBr_3 being most stable[25,26], which agrees with the usual sequence based on the variation of the Lewis acidity: $BF_3 < BCl_3 < BBr_3$.[27] The complex $CpMn(CO)_2PPh_3$ forms adducts with $SnCl_4$, but does not react with the weaker aprotic acids $GeCl_4$ and $SbCl_3$. The complexes $CpMn(CO)L_2$, where $L_2 = (Ph_3P)_2$ or bidentate diphosphine ligands, form adducts with weak Lewis acids, and the latter can be arranged in the following sequence in terms of the ease of interaction: $SnCl_4 \gg SbCl_3 \cong HgCl_2 > GeCl_4$.[23] The sequence $TiCl_4 > SnCl_4 > SnBr_4$ has been established for $CpRe(CO)_2L$.[22]

$AlCl_3$, which is capable of forming adducts via both the metal and the ligands (see below), occupies a special place among Lewis acids.

III. INTERACTION OF LEWIS ACIDS WITH TRANSITION METAL COMPLEXES VIA THE LIGANDS

Another type of interaction of Lewis acids with TMC involves the formation of adducts with participation of the lone electron pair of one of the ligand atoms. This can be the oxygen atom in the CO and NO groups, the sulphur atom in CS, the nitrogen atom in the N_2 and CN ligands, and a halogen atom.

For complexes containing halogen or nitrile ligands at the transition metal atom, the reaction with Lewis acids proceeds as a rule via an *n*-electron pair of the ligand. If the complex contains, together with halogen or nitrile ligands, carbonyl or nitrosyl ligands, then the shift of the vibration frequencies of the latter can be a sign of the formation of donor–acceptor adducts. The coordination of Lewis acids (A) to halogen or nitrile ligands (X) $(O\equiv C-\overset{\frown}{M}-\overset{\curvearrowright}{X}: \rightarrow A)$ leads to a slight increase of the ν(CO) or ν(NO) frequency—by 15–25 cm^{-1}. Such interaction entails a weakening of the M–CO dative bonds and correspondingly, within the framework of the mechanism $M^- - C\equiv O^+ \leftrightarrow M=C=O$, an increase of the CO bond orders. However, this influence of the acceptor is significantly weaker than in the direct interaction with the metal atom: $O\equiv C-\overset{\frown}{M}\rightarrow A$ [$\Delta\nu$(CO) ≅ 100–150 cm^{-1}. As an example[28] one can quote the ν(CO) frequencies (cm^{-1}) in the spectra of the complexes $CpRe(CO)_2Br_2$ (2005, 2068), $CpRe(CO)_2Br(Br \rightarrow AlCl_3)$ (2022, 2083), and $CpRe(CO)_2 .Br(Br \rightarrow AlCl_3)$ (2022, 2083), and $CpRe(CO)_2(Br \rightarrow AlCl_3)_2$ (2031, 2096).



The donor–acceptor interaction of Lewis acids with the CN group leads to an increase of the stretching vibration frequency of the latter. The CN group behaves analogously in any nitrile and not only in transition metal complexes. It is believed that the increase of the ν(CN) frequency on coordination is associated with the increase of the force constant of the CN bond and with the change in the mechanism of the vibrations of the molecule when it is bound in a complex[29–31].

When the complex $CpFe(CO)_2(CN)$ is coordinated to Lewis acids ER_3 (E = Al or Ga; R = Me or Cl) or BX_3 (X = H, F, Cl, Br, or Me), the stretching vibration frequencies of all three groups (two CO groups and one CN group) increase[32]. The frequency shifts (Table 1) lead to the conclusion that the acceptor is coordinated to the CN group.

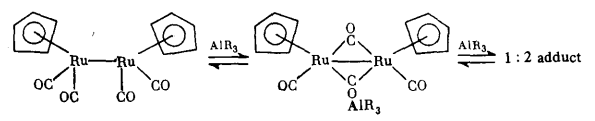
Table 1. The stretching vibration frequencies of the CN and CO groups in the adducts of $CpFe(CO)_2(CN)$ with Lewis acids.

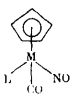
Complex	ν_{CN}, cm^{-1}	ν_{CO}, cm^{-1}
$CpFe(CO)_2(CN)$	2120	2055 2007
$CpFe(CO)_2(CN\rightarrow AlCl_3)$	2168	2068 2026
$CpFe(CO)_2(CN\rightarrow BF_3)$	2201	2073 2031

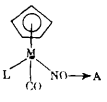
The interaction of the complex with the carbonyl ligand is characteristic of the strongest Lewis acids—boron and aluminium derivatives. The possibility of the addition of a Lewis acid to the oxygen atom of the carbonyl ligand in the complex was first observed for bridging CO groups in the dimeric complex $[CpFe(CO)_2]_2$, which forms an adduct with two $AlEt_3$ molecules[33,34]:

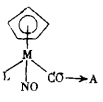
The structure of the adduct was established by X-ray diffraction[33]. Its formation leads to an appreciable decrease of the ν(CO) frequencies of the bridging groups involved in the interaction with aluminium and to an increase of the stretching vibration frequencies of the terminal carbonyl ligands. The decrease of the stretching vibration frequencies of the CO groups linked to aluminium is caused by the weakening of the CO bonds owing to the shift of electron density towards the acceptor molecule. This entails a strengthening of the $M \rightarrow C$ dative bonds in the $MCO \rightarrow Al$ fragments and their weakening for the CO groups not coordinated to aluminium, which leads in its turn to an increase of the terminal CO bond orders and an increase of their vibration frequencies.

The study of the interaction of complexes containing both bridging and terminal CO groups with Lewis acids derived from aluminium showed that the bridging carbonyl groups are more basic and that the basicity of the oxygen atom in the CO groups increases in the following sequence: terminal groups < double bridge groups < triple bridge groups[8]. The difference between the basicity of the bridging and terminal CO groups can be used to displace the equilibrium and to convert terminal groups into bridging groups, for example[35,36]:









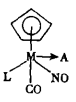


Table 2. The stretching vibration frequencies of the CO and NO groups (cm^{-1}, in CH_2Cl_2) of the complexes $CpM(CO)_2NO$ and $CpM(CO)(NO)PPh_3$ (M = Mo or W) and their adducts with Lewis acids[22].

Note. v.s = very strong (intense), s = strong, m = medium, and sh = shoulder.

Interaction with CO, N_2, and NO terminal ligands leads, as for the coordination with bridging CO groups, to a significant decrease of the stretching vibration frequency of the coordinated group and to an increase of the stretching vibration frequencies of ligands not linked to the aprotic acid. For example[37], the ν(CO) frequencies are 1904, 1808, and 1791 cm^{-1} for $CpylidMo(CO)_3$ and 1932, 1845, and 1665 cm^{-1} for $CpylidMo(CO)_2(CO \rightarrow AlMe_3)$:

The same transition metal complexes with different Lewis acids can react in different ways—either via the metal atom or via the ligands (CO, NO). For example, $CpylidMo(CO)_3$ interacts with H^+, BF_3, $TiCl_4$, and $AlCl_3$ via the Mo atom and with $AlMe_3$ via the CO group[19,22,37].

The simultaneous formation in solution of adducts both via the metal atom and via the terminal CO or NO groups has been observed in some cases. Section IV deals in detail with factors influencing the mode of reaction in competitive coordination.

IV. COMPETITIVE COORDINATION

As shown above, transition metal complexes can react with aprotic acids to form adducts via both the metal and via the ligands. The mode of reaction depends on the relative basicities of the metal atom and the lone electron pairs of the ligands and on the nature of the acceptor and the solvent. Depending on these factors, the same complex can interact differently with different Lewis acids and sometimes there is a possibility of the simultaneous formation of adducts of different types.

This is clearly seen from the example of the complexes $CpM(CO)_2(NO)$ and $CpM(CO)(NO)(PPh_3)$ (M = Mo or W).[22] They are capable of forming three different types of adducts: via the metal and via the oxygen atoms of the carbonyl or nitrosyl ligand. The most basic centre in the $CpM(CO)_2(NO)$ molecule is the nitrosyl oxygen atom. Thus the formation of adducts via the NO groups with complexes of the type Cp_3Ln, where Ln = lanthanide, has been described[38]. $TiCl_4$ and $SnCl_4$, which usually interact with *d*-bases and are coordinated to the metal atom, in this case also interact with the oxygen atom of the NO group[22]. Under these conditions, $SnCl_4$ does not interact with $CpMo(CO)_2(NO)$, but forms an adduct with $CpW(CO)_2(NO)$. The higher basicity of the nitrosyl oxygen atom in the tungsten derivative compared with the molybdenum compound is caused by the more marked shift of electron density from the W atom ($d_\pi - p_\pi$ interaction); an analogous conclusion follows from spectroscopic data[39].

The phosphine derivatives $CpM(CO)(NO)(PPh_3)$, in which the basicity of the M atom is greatly enhanced, form adducts with $SnCl_4$ via the metal atom. The differences between the reactions can be clearly followed on the basis of the infrared spectra. In the adducts via the NO group the ν(NO) frequencies are reduced by more than 200 cm^{-1} compared with the initial comlexes, while the ν(CO) frequencies are increased by 40–70 cm^{-1}. In the adducts formed via the metal atom, both ν(CO) and ν(NO) are displaced towards higher frequencies by ~150 cm^{-1} (Table 2). The increase of the basicity of the central atom after the introduction of the phosphine ligand makes complex formation via the metal atom energetically more favourable than coordination via the nitrosyl group.

The complex $CpW(CO)_2(NO)$ forms an adduct with $AlCl_3$ in CH_2Cl_2 via the oxygen atom of the NO ligand. The behaviour of the molybdenum compound $CpMo(CO)_2(NO)$ in relation to $AlCl_3$ is interesting. The somewhat reduced basicity of the nitrosyl oxygen atom, compared with the corresponding tungsten complex, leads to competition between the oxygen atoms of the carbonyl and nitrosyl groups, although here coordination via the nitrosyl group predominates (Table 1).

In the triphenylphosphine derivatives $CpM(CO)(NO)(PPh_3)$ (M = Mo or W) the basicity of the metal atom is increased, which leads to competition between the metal and the nitrosyl

oxygen atom in the reaction with $AlCl_3$. The tungsten complex forms adducts via both the nitrosyl group and the metal atom. Whereas coordination to the metal only is observed in the interaction with $SnCl_4$, in the interaction with $AlCl_3$ the formation of an adduct via the oxygen atom of the nitrosyl group predominates, which is indicated by the ratio of the intensities of the corresponding infrared bands (Table 2). The situation is similar for the molybdenum complex, but the content of the adduct formed via the metal atom is increased relative to the tungsten complex, which may be associated with a somewhat lower basicity of the nitrosyl oxygen atom in the molybdenum derivative.

Thus, depending on the relative basicities of the metal and the carbonyl and nitrosyl oxygen atom and also on the nature of the acceptor, there is a possibility of donor–acceptor interactions of different types for carbonyl nitrosyl complexes: with participation of the transition metal atom as the centre of basicity, with participation of the oxygen atom of the carbonyl or nitrosyl ligand, or with the simultaneous formation of both types of adducts.

The influence of the solvent on the nature of the donor–acceptor interaction has been observed in the study of the reaction of $CpMn(CO)_3$ with $AlCl_3$.[28] It has been shown by infrared spectroscopy that in benzene the Lewis acid is coordinated to the carbonyl group, while in CH_2Cl_2 an adduct is formed via the metal atom, i.e. $Cp(CO)_3Mn \rightarrow AlCl_3$, in addition to the adduct $CpMn(CO)_2.(CO \rightarrow AlCl_3)$. The introduction of donor ligands facilitates the interaction via the metal. In benzene the complex $CpMn(CO)_2(PPh)_3$ gives rise to a mixture of adducts via the oxygen atom of the CO group and via the manganese atom; in CH_2Cl_2 the formation of an adduct via the metal atom only was observed. Other complexes behave analogously in their reactions with $AlCl_3$ (see below). Examples of different types of reactions as a function of the acceptor are presented in Table 3.

Table 3. Dependence of the mode of coordination of the Lewis acid to the transition metal complex on the nature of the acid.

Transition metal complex base	Acceptor	
	bond with M atom	bond with ligand*
$(Ph_3P^+—C_5H_4^-)Mo(CO)_3$	H^+, BF_3, $TiCl_4$, $AlCl_3$	$AlMe_3$
$CpW(CO)_3^-$	H^+, $InPh_3$	$AlPh_3$, $MgPy_4^{2+}$, $Al(THF)_3^{3+}$
$CpM(CO)(NO)(PPh_3)$ (M = Mo, W)	$SnCl_4$, $AlCl_3$	$AlCl_3$
$CpRe(CO)_3$	$TiCl_4$, $AlCl_3$	$AlCl_3$
Arene $M(CO)_3$ (M = Cr, Mo, W)	H^+, $HgCl_2$, $TiCl_4$, $SnCl_4$, $AlCl_3$	$AlCl_3$
$[CpFe(CO)_2]_2$	H^+	AlR_3, BCl_3, BBr_3

*Py = pyridine.

On the other hand, the same Lewis acid can interact in different ways with the complex depending on its structure. Thus $SnCl_4$ is coordinated via the metal atom to the complexes $AreneM(CO)_3$† (M = Cr, Mo, or W), $CpM(CO)(NO)PPh_3$ (M = Mo or W), $CpM(CO)_2L$ (M = Mn or Re; L = PR_3), *trans*-$IrCl(CO)(PPh_3)_2$, and Cp_2Ru. However, one should note that the coordination of $CpW(CO)_2(NO)$ involves the nitrosyl oxygen atom and that of $CpCr(NO)_2Cl$ involves the chlorine atom. Compounds of the type AlR_3 form adducts via the metal atom with the complexes $CpM(CO)_nL_{3-n}$ (M = Mn, $n = 1–3$; M = Re, $n = 2, 3$; L = PR_3), $AreneM(CO)_3$ (M = Cr, Mo, or W), $(C_6H_6)Cr(CO)_2PPh_3$, $CpM(CO)_4$ (M = V or Nb), $CpV(CO)_3PPh_3$, $Fe(CO)_n(PPh_3)_{5-n}$ ($n = 3, 4$), CpReH, and Cp_2WH. In the case of $[CpFe(CO)_2]_2$ and a number of other complexes with bridging carbonyl ligands the coordination involves the oxygen atom of the bridging CO groups. The compounds $CpM(CO)_3$ (M = Mn or Re), $CpMn(CO)_2PPh_3$, $AreneM(CO)_3$ (M = Cr, Mo, or W), $CpV(CO)_n(PPh_3)_{4-n}$ ($n = 3, 4$), and $Mo(phen)(PPh_3)_2(CO)_2$ react with AlR_3 via the terminal CO groups, $CpM(CO)_n.(NO)L_{2-n}$ (M = Mo or W; $n = 1, 2$) are coordinated via the oxygen of the NO ligand, $CpRe(CO)_2Br_2$ and $CpCr(NO)_2Cl$ are coordinated via the halogen atom, and $CpFe(CO)_2CN$ is coordinated via the nitrogen atom of the cyano-group.

†Here and henceforth Arene = η^6-C_6H_6 and its homologues (mesitylene and hexamethylbenzene).

V. REACTIONS OF TRANSITION METAL COMPLEXES WITH ACCEPTORS OF DIFFERENT TYPES

1. Reactions with Derivatives of Group I–V Elements

(*a*) *Derivatives of Group I elements (Cu and Ag) as acceptors.* There are few examples of the interaction of TMC with acceptors derived from Group I elements. Thus $(diphos)_2.W(CO)(CS)$ reacts with $AgBF_4$ to form the product $\{[(diphos)_2W(CO)CS]_2Ag\}^+BF_4^-$, in which the acceptor is coordinated to the S atom of the CS ligand[40]. The compound $CpCoL_2$ interacts with $[L_2CuCl]_2$ via the metal atom, forming $CpL_2Co \rightarrow CuL_2Cl$ (L = PMe_3).[41]

(*b*) *Group II metal (Zn and Hg) halides.* Data for the interaction of EX_2 (E = Zn or Hg; X = halogen) with different complexes are presented in Table 4. There are no examples of coordination via the lone electron pairs of ligands such as CO, NO, N_2, CN or halogen for mercury or zinc derivatives, but coordination of HgX_2 to the sulphur atom of the CS ligand is known[40].

The Lewis acids HgX_2 are capable of forming adducts of different compositions (ranging from 1:1 to 1:7), and this behaviour is in fact extremely characteristic of these compounds. As mentioned above, 1:1 adducts can be either donor–acceptor complexes with $M \rightarrow HgX_2$ linkages or salts $[M–HgX]^+X^-$. In the solid state additional acceptor molecules sometimes occupy sites in the crystal lattice without forming a direct bond with the donor molecule but participating in intermolecular coordination. This is particularly characteristic of the adducts with HgX_2. For example, the crystal lattice of $Cp_2Ru.3HgCl_2$[42] contains the $Cp_2Ru \rightarrow HgCl_2$, $[Cp_2RuHgCl]^+Cl^-$, and $HgCl_2$ molecules.

X-Ray diffraction analysis of the complexes $CpCo(CO)_2.HgCl_2$[43,44] and $Cp_2Ru.HgX_2$ (X = Cl or Br)[45] indicates the formation of a metal–metal covalent bond. The Co → Hg bond length in the donor–acceptor adduct is 2.578 Å; the formation of this adduct increases ν(CO) by 75 cm^{-1}.[44,46] According to X-ray diffraction data, the 1:3 adduct has a CO–Hg bond with a length of 2.504 Å, i.e. shorter than in the 1:1 adduct. A crystal of the 1:3 complex contains the $[CpCo(CO)_2HgCl]^+$ cations, Cl^- anions, and two $HgCl_2$ molecules[47]. The formation of this complex causes a large shift of ν(CO) (by 90 cm^{-1}). The frequency shifts agree with the values quoted above for the adducts $L_2Fe(CO)_3.HgX_2$.[9]

Together with an intense ν(Cp–Ru)(symm.) line, yet another intense line appears in the Raman spectra of the adducts $Cp_2Ru.HgX_2$ (X = Cl or Br),[45] whose intensity does not change significantly on passing from the $HgCl_2$ adduct to the $HgBr_2$ adduct. This line (137 cm^{-1} for Cl and 130 cm^{-1} for Br) has been assigned to the vibration of the Ru–Hg bond. The Cp–Ru–Cp stretching vibration bands change slightly on coordination to a Lewis acid (by +5 cm^{-1}). The interaction of HgX_2 with Cp_2Ru has apparently little influence on the bonds between ruthenium and Cp rings, since the ruthenium atom uses non-bonding d electrons in the formation of a donor–acceptor bond with HgX_2.

Table 4. The interaction of transition metal complexes with Group II metal halides.

Initial substances	Compn. of adduct	Proposed structure	Refs.
$(Me_3C_6H_3)$ Cr $(CO)_3$ + $HgCl_2$	1:2	$(Me_3C_6H_3)$ Cr $(CO)_3 \cdot 2HgCl_2$	12

*The structure of the reaction product was established by X-ray diffraction.

In contrast to ruthenocene, the interaction of ferrocene with mercury halides is more complex. Regardless of the reactant ratio, the same product, having the 1:7 composition, has been obtained for mercury(II) chloride[45]. A red precipitate is formed initially, turning blue on standing.

The red compound formed with $HgBr_2$ has not been isolated. The red compound $Cp_2Fe.7HgCl_2$ is diamagnetic at room temperature, while the blue compound is paramagnetic and has a magnetic moment close to that for ferrocenium salts. On heating, the red product becomes blue. On the basis of these data, it has been suggested that the red compound contains the Fe–Hg bond and is an adduct of Cp_2Fe with $HgCl_2$, while the blue compound consists of $CpFe^+$ and a complex anion. The above structure of the blue product is also supported by the finding that, after the addition of NH_4PF_6 to its aqueous solution, $[Cp_2Fe]^+PF_6^-$ is formed as a result of anion exchange. Thus the reaction of Cp_2Fe with HgX_2 (X = Cl or Br) ultimately involves the oxidation of ferrocene, in contrast to ruthenocene, which forms adducts with HgX_2.

When π-complexes with aromatic ligands are acted upon by HgX_2 salts, there is also a possibility of the mercuration of the π-ligand with formation of the C–HgX bond, which is characteristic of ferrocene[48] and $CpM(CO)_3$ (M = Mn or Re).[49,50]

(c) *Derivatives of Group III elements* EX_3 (*E = B, Al, Ga, In, or Tl; X = halogen or organic group*). Examples of the interaction of Lewis acids derived from Group III elements with transition metal complexes via both the metal and via the ligands (bridging and terminal CO groups, N_2, NO, CN and halogens) are known. The interaction with the oxygen atoms of the briding ligands is more characteristic of aluminium derivatives than of other Lewis acids. This leads to interesting features of the behaviour of transition metal complexes in reactions with aluminium compounds, which will be discussed below.

Numerous reactions of transition metal complexes, containing bridging carbonyl groups, with Lewis acids have been investigated: $[CpFe(CO)_2]_2$ with BX_3 (X = Cl or Br);[35] $[CpFe(CO)]_4$ with $AlBr_4$ and BX_3 (X = F, Cl, or Br);[35] $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, $Co_2(CO)_8$, and $Ru_3(CO)_{12}$ with $AlBr_3$;[35,60] $[CpNi(CO)]_2$ and $Cp_3Ni_3(CO)_2$ with AlR_3 (R = Et or iso-C_3H_7) and BF_3.[7,35] It has been shown by infrared spectroscopy and in a number of instances also by X-ray diffraction that the bond in the resulting donor–acceptor adducts is formed via the bridging CO groups. The American chemist Schriver, whose studies have been surveyed in a review[8], has made a considerable contribution to the study of the basicity of bridging carbonyl groups.

Table 5. The stretching vibration frequencies of the CO groups [ν(CO), cm^{-1}] in the adducts of $[CpFe(CO)_2]_2$ with Lewis acids[35]

Complex	Terminal CO groups	Bridging CO groups	
		free	coordinated
$[CpFe(CO)_2]_2$	1971; 1930	1797; 1765	—
$[CpFe(CO)_2]_2AlEt_3$	1993; 1985	1828	1682
$[CpFe(CO)_2]_2 \cdot BCl_3$	2038; 2020	1845	1463

It is noteworthy that, when Lewis acids are coordinated to bridging CO groups, the shifts of the ν(CO) stretching vibration frequencies are significantly different for adducts with different Lewis acids (Table 5).[35] Apparently the difference in the frequency shifts reflects qualitatively the strength of the donor–acceptor bond formed. The greater the degree of charge transfer and correspondingly the more stable the complex formed, the greater should be the changes in the vibration frequencies of the CO groups resulting from coordination to the Lewis acid.

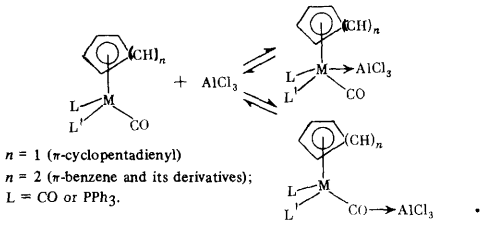
However, estimation of the strength of the donor–acceptor interaction solely from the vibration frequency shifts is not always legitimate. The vibration frequencies can be influenced significantly also by other factors, which have no direct bearing on the change in the electronic structure of the donor molecules as a result of charge transfer on coordination. Thus an increase in vibration frequency can be caused also by kinematic factors. For carbonyl compounds, where coordination takes place via the oxygen atom of the CO group, estimation of the strength of the donor–acceptor bond from the ν(CO) frequency shifts can constitute a fair approximation, since the stretching vibrations of the carbonyl groups are highly localised and the changes in the vibration frequencies are predominantly caused by charge transfer from the oxygen atom to the acceptor molecule, i.e. by electronic effects.

Thus, according to infrared spectroscopic data, the compounds BX_3 are stronger acceptors than AlX_3. The replacement of the halogen in Al derivatives by electron-donating organic groups (Me, Et, Ph) weakens the acid properties. The observed regular variation of the ν(CO) and $\nu(N_2)$ frequency shifts in the spectra of the complexes *trans*-$ReClL_4X$ (X = CO or N_2) on coordination to aluminium derivatives as a function of R in AlR_3 is consistent with this observation[61]:

Complex	ν(CO), cm^{-1}	$\Delta\nu$(CO), cm^{-1}
trans-ReCl(CO)($Ph_2PCH_2CH_2PPh_2$)$_2$	1803	—
trans-ReCl($Ph_2PCH_2CH_2PPh_2$)$_2$(CO → $AlMe_3$)	1677	−126
trans-ReCl($Ph_2PCH_2CH_2PPh_2$)$_2$(CO → $AlPh_3$)	1653	−150
trans-ReCl($Ph_2PCH_2CH_2PPh_2$)$_2$(CO → $AlCl_3$)	1630	−173

Thus the shift increases with enhancement of the electron-accepting properties of the Lewis acid.

There are many examples in the literature indicating the possibility of the coordination of the terminal CO, N_2, and NO ligands in transition metal complexes to aluminium derivatives: *trans*-$ReClL_4X$ (X = CO or N_2) with AlR_3 (R = Me, Ph, or Cl);[61] ML_4X_2 (X = CO or N_2; M = Mo or W) with AlR_3 (R = Me, Et, or Ph) and $GaMe_3$;[61–63] $OsCl_2L_3(N_2)$ with $AlMe_3$ [61] (L = phosphine ligands; L_2 = chelating diphosphine ligands); (π-$Ph_3P^+-C_5H_4^-$)Mo(CO)$_3$ with $AlMe_3$;[37] $[CpW(CO)_3]^-Na^+$ with $AlPh_3$;[64] $W(CO)_5L$ (L = PPh_3, $P(OPh)_3$, or $P(n\text{-}C_4H_9)_3$] with $AlEtCl_2$ in the presence of O_2;[65] CpM(CO)(NO)L (M = Mo or W; L = CO or PPh_3) with $AlCl_3$;[22] $CpM(CO)_3$ (M = Mn or Re), π-AreneM(CO)$_3$ (M = Cr, Mo, or W), $CpV(CO)_4$, and some of their derivatives with $AlCl_3$.[25]



The study of the basicity of the atom Y or the coordinated ligand XY (CO or N_2) in the complexes *trans*-ReCl(XY)L_4 (L = PMe_2Ph) [61] relative to $AlMe_3$ solution in benzene showed that the N_2 ligand is more basic than the CO ligand in these compounds. Comparison of the equilibrium constants for the reactions

$$AlMe_3 \cdot Et_2O + ReCl(XY)L_4 \underset{80°}{\overset{C_6H_6}{\rightleftharpoons}} Et_2O + ReCl(XY \rightarrow AlMe_3)L_4$$

led to this conclusion.

The complexes CpIr(CO)(PPh_3) with $TlCl_3$,[59] Cp_2MH_2 (M = Mo or W) with BX_3 (X = F or Cl) and AlR_3 (R = Me, Et, or Ph),[66,68] Cp_2ReH with BF_3 [66] and $AlMe_3$,[67] and Cp_2Ti with $AlEt_3$ [69] give rise to 1:1 adducts, in which the presence of M–M′ bonds is postulated.

Lokshin et al.[28] made the first systematic study of the interaction of a large number of carbonyl π-complexes of Group V–VII transition metals with $AlCl_3$. Investigation of a series of complexes of the same metal with different ligands or of isotypical complexes with different central metal atoms made it possible to determine the influence of the nature of the ligands and the central metal atom in the complex or the reactivity and the mode of reaction with $AlCl_3$. It has been shown that, depending on the nature of the complex itself and on the solvent, $AlCl_3$ can be coordinated either via the metal atom or via the CO group, or via both centres simultaneously:

n = 1 (π-cyclopentadienyl)
n = 2 (π-benzene and its derivatives);
L = CO or PPh_3.

This leads to completely different changes in the carbonyl region of the infrared spectrum, so that the formation of adducts of a particular type can be deduced spectroscopically. For example[28], the ν(CO) frequencies are 1931 and 2027 cm^{-1} for $CpRe(CO)_3$, 1740, 1991, and 2054 cm^{-1} for $CpRe(CO)_2$(CO → $AlCl_3$), and 2055, 2074, and 2130 cm^{-1} for $Cp(CO)_3Re \rightarrow AlCl_3$.

As mentioned above (Section IV), the mode of reaction depends on the solvent employed. Coordination via the metal atom and via the CO group was promoted by carrying out the reaction in CH_2Cl_2 and in benzene respectively. Thus the formation of adducts via the CO group in CH_2Cl_2 solution was observed only for $CpM(CO)_3$ (M = Mn or Re) and ring-substituted CTM derivatives: $(PhCH_2C_5H_4)Mn(CO)_3$ and $(Et_5C_5)Mn(CO)_3$. Apart from these complexes, in benzene solutions simultaneous interaction via both the oxygen atom of the CO ligand and the metal atom was observed also for $CpMn(CO)_2PPh_3$, $(Et_5C_5)Mn(CO)_2PPh_3$, $(C_6H_6)Cr(CO)_3$, $(1,3,5\text{-}Me_3C_6H_3)Cr(CO)_3$, $(Me_6C_6)Cr(CO)_3$, $(C_6H_6)W(CO)_3$, $CpV(CO)_4$, and $CpV(CO)_3PPh_3$.[28]

Competition between these two reactions is probably determined by the relative basicities of the metal and the oxygen in the complex and the relative strengths of the resulting bonds, the difference between the energies being evidently small. The weaker the basic properties of the metal atom in the complex the greater the predominance of the coordination via the CO group and, conversely, the more basic the metal atom, the more characteristic is the interaction via this centre. Complexes in which the metal atom is most basic do not give rise to adducts via the CO ligand in either CH_2Cl_2 or in benzene: CpMn(CO)(diphos), $CpRe(CO)_2PPh_3$, $CpNb(CO)_4$, $(C_6H_6)Cr(CO)_2PPh_3$, $Fe(CO)_4PPh_3$, and $Fe(CO)_3(PPh_3)_2$.[28]

The interaction of the cyanide complexes $K_4[Fe(CN)_6]$, $K_2[Ni(CN)_4]$, $Fe(phen)_2(CN)_2$ (phen = 1,10-phenanthroline), and $Fe(CNR)_4(CN)_2$ (R = H, Me, or Et) with boron halides has been investigated[70,71] and it has been shown that the adducts formed contain cyanide bridges between the transition metal and BX_3 (for example, $-\overset{|}{\underset{|}{Ni}}-C\equiv N-BF_3$), each CN group being linked to the Lewis acid.

A complex pattern in the carbonyl region of the spectrum (Table 6) is observed for the interaction of *trans*-RhX(CO).$(EPh_3)_2$ with BX_3 (X = halogen; E = P or As).[25,26] As mentioned above, different cases are possible, involving the formation of a donor–acceptor adduct or oxidative addition; nor can one rule out the possibility of interaction via the halogen ligand. In all these cases, the spectral changes in the region of the vibrations of the CO group are different. The most marked changes in ν(CO) apparently occur in oxidative addition and smaller changes correspond to the formation of a donor–acceptor adduct. The hypsochromic

shifts of the signal frequencies on coordination to a halogen are usually small (15–20 cm^{-1}).

It is believed that *trans*-$RhCl(CO)(PPh_3)_2$ forms a donor–acceptor adduct with BCl_3 via the rhodium atom[26]. However, $\nu(CO)$ for the adduct is displaced only by 23 cm^{-1} (Table 6); for such a small shift, coordination of the acid to a chlorine atom is more probable.

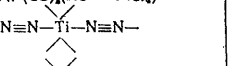


Table 6. Infrared spectra (in the region of the stretching vibrations of the CO group) of the adducts of the complexes *trans*-$[RhCl(CO)(EPh_3)_2]$ with BX_3.

Complex	Lewis acid	Compn. of adduct	ν(CO), cm^{-1}	$\Delta\nu$(CO), cm^{-1}
trans-$[RhCl(CO)(PPh_3)_2]$	—	—	1968	—
Ditto	BCl_3	1:1	1991	+23
	BBr_3	1:1	2098 w, 1990 s	+130, +22
trans-$[RhBr(CO)(PPh_3)_2]$	—	—	1969	—
Ditto	BBr_3	1:1	2102 w, 2049 m, 1998 w, 1985 s	+133, +80, +29, +16
trans-$[RhCl(CO)(AsPh_3)_2]$	—	—	1967	—
Ditto	BBr_3	1:1	2101 m, 2047 s	+130, +80

The infrared spectra of other adducts of rhodium complexes with BX_3 contain two or more bands in the region of the CO vibrations. There is apparently a possibility of the formation of different products simultaneously. Judging from the infrared spectra, the adduct *trans*-$RhBr(CO)(PPh_3)_2$ can contain molecules of the rhodium complex coordinated to the Lewis acid via the halogen ligand (1998, 1985 cm^{-1}), a donor–acceptor adduct (2049 cm^{-1}), and the oxidative addition product (2102 cm^{-1}).[25,26]

As mentioned above, the corresponding iridium complex *trans*-$IrCl(CO)(PPh_3)_2$ interacts with BF_3 via the metal atom, as shown by the hypsochromic shift of $\nu(CO)$ by 100 cm^{-1} (from 1967 to 2067 cm^{-1}).[16] The interaction of the same complex with $AlMe_3$ leads to an increase of the stretching vibration frequency of the CO group by 12 cm^{-1}. The formation of an adduct via the iridium atom has been postulated[61]. However, the above value of $\Delta\nu(CO)$ is more likely to indicate the coordination of $AlMe_3$ via the chlorine atom. The interaction of the same complex with $SnCl_4$ (see above, Section II). leads to $\Delta\nu(CO)$ or 113 cm^{-1} for the oxidative addition product and 74 cm^{-1} for the donor–acceptor adduct[17].

Complexes containing halogen ligands as a rule react with Lewis acids via the halogen atom. Adducts of this type have been obtained for the following complexes: $Mn(CO)_5X$, $(PMe_3)_2Fe(CO)_2X_2$ (X = Cl, Br, or I), and $(PMe_3)_2Ni(CO)I_2$ with AlX_3 (X = Cl or I), $FeCl_3$, and $SbCl_5$;[72] $RuCl_2(CO)_2.(PMe_3)_2$ with $FeCl_3$;[73] $MoCl_2(NO)_2(PMe_3)_2$ with $FeCl_3$;[73] $CpRe(CO)_2Br_2$ with $AlCl_3$;[28] $CpCr(NO)_2Cl$ with $AlCl_3$, $SnCl_4$,[22] and FeCl;[73] $CpFe(CO)_2X$ (X = Cl, Br, or I) with a large set of Lewis acids[73].

According to the shifts of the $\nu(CO)$ frequencies for the adducts compared with the initial complex, in the case of $CpFe(CO)_2$ (X→M′X) the Lewis acids investigated can be arranged in the following sequence in terms of their electron-accepting properties: $SbCl_5 \cong AlCl_3 \cong FeCl_3 > MoCl_5 \cong GaCl_3 \cong AlBr_3 > FeBr_3 \cong AlI_3 > GaI_3 > NbCl_5 > SnCl_4 > InCl_3 \cong TiCl_4 > HgCl_2 \cong Cl_2 > I_2 > Br_2$.[73]

(*d*) *The halides MX_4 of Group IV elements (M = Ti, Ge, or Sn).* Numerous reactions of transition metal complexes with Lewis acids derived from Group IV elements and leading to the formation of oxidative elimination products have been described in the literature[12,13,74–78]. However, in the present review only those reactions are considered in which the initial complex enters wholly into the composition of the adduct. Data for the reversible formation of TMC adducts with Lewis acids $M'X_4$ are presented in Tables 7 and 8.

Table 8. Examples of the interaction of MX_4 with complexes via the transition metal atom.

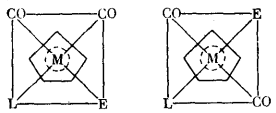
Cp_2Ru	$SnCl_4$, $SnBr_4$	56
$(Ph_3P^+—C_6H_4^-)M(CO)_3$(M = Cr, Mo, W)	$TiCl_4$	22

In the majority of the cases investigated the interaction of the Lewis acids $M'X_4$ with complexes takes place via the transition metal atom and coordination via the ligand lone electron pair has been observed in only a few instances (Table 7). The adducts $[(PMe_2Ph)_4ReClL]_2.TiCl_4$ or more involved compounds containing solvent molecules, for example, $[ReCl(N_2)(PMe_2Ph)_4]_2.TiCl_4.THF$ (THF = tetrahydrofuran), and $[ReCl(N_2)(PMe_2Ph)_4]_2.TiCl_4.(C_6H_6)_n$ (n = 1–5), have been isolated[79] after the interaction of the compounds *trans*-$(PMe_2Ph)_4ReClL$ (L = CO or N_2) with $TiCl_4$. The decrease of the stretching vibration frequencies of the CO and N_2 groups indicates the coordination of $TiCl_4$ via these groups:

trans-$(PMe_2Ph)_4ReCl(N_2) + TiCl_4 \xrightleftharpoons{C_6H_6}$ *trans*-$[(PMe_2Ph)_4ClRe—N\equiv N—Ti—N\equiv N—ReCl(PMe_2Ph)_4].(C_6H_6)_{1-5}$. The $\nu(N_2)$ frequency of the initial complex (1925 cm^{-1}) shifts to 1814 cm^{-1} in the spectrum of the reaction product. This is the first example of a complex containing two nitrogen bridges.



The cyclopentadienyl and arene derivatives of manganese, rhenium, chromium, molybdenum, and tungsten carbonyls [$CpM(CO)_3$, M = Mn or Re; $(Arene)M(CO)_3$, M = Cr, Mo, or W; and their various derivatives] in solutions combine reversibly with Lewis acids derived from Group IV elements

($SnCl_4$, $SnBr_4$, $TiCl_4$, $GeCl_4$) via the transition metal atom[22,23]. The characteristics of the influence of the nature of the metal (see Section II, 2) and the ligands (Section II, 3) on the basicity of the complexes have been examined in relation to these complexes. Solid adducts, having the 1:2 composition, of a series of complexes $CpMn(CO)_2L$ (where $L = PPh_3$, trialkylphosphines, $AsPh_3$, or $SbPh_3$) with $SnCl_4$ have been isolated[23]. X-Ray diffraction studies showed that, for $L = PPh_3$, the adduct has the ionic structure $[(C_5H_5)Mn(CO)_2(PPh_3)SnCl_3]^+SnCl_5^-$ and contains the Sn–Mn bond (with a length of 2.589 Å). The coordination environment of the manganese atom consists of a distorted square pyramid with the C_5H_5 ligand apical. Two CO groups (the OC–Mn–CO angle is 115°), the $SnCl_3$ group, and the PPh_3 ligand are located in the base of the pyramid *trans* to one another[80] (see Figure).

The structure of the cation $[C_5H_5Mn(CO)_2(PPh_3)(SnCl)]^+$.[80] Bond lengths (Å): Mn–P = 2.367, Mn–Sn = 2.589, Mn–C(1) = 1.82, Mn–C(2) = 1.83; valence angles: C(1)–Mn–P = 80.0°, C(2)–Mn–P = 79.6°, C(1)–Mn–C(2) = 115.1°, C(2)–Mn–Sn = 74.4°, C(1)–Mn–Sn = 74.9°, and P–Mn–Sn = 131.1°.

We may note that the addition of the acceptor E to the pseudotetrahedral complexes $(C_5H_5)M(CO)_2L$ can give rise to two isomers with the geometry of a square pyramid, which differ by the *cis*- or *trans*-disposition of the CO groups (or phosphorus nuclei, see below) in the base of the pyramid:

It has been shown by ^1H, ^{13}C, and ^{31}P NMR that, particularly in the protonation (E = H^+) of the complexes $CpM(CO)_2L$ and $CpM(CO)L_2$ (M = Mn or Re; L and L_2 are mono- and bi-dentate phosphines), the products are both *cis*- and *trans*-isomers[81–83]. The infrared spectra of the adducts $[(C_5H_5)Mn(CO)_2(L).SnCl_3]^+SnCl_5^-$ in CH_2Cl_2 as a rule exhibit four and not two ν(CO) bands; the solutions apparently contain a mixture of isomers[23,80].

For $CpRe(CO)_2L$ [$L = PPh_3$, $P(OEt)_3$, or $P(OPh)_3$], the interaction with SnX_4 (X = Cl or Br) leads to the appearance of two new ν(CO) bands in the infrared spectra of the solutions in each case, i.e. only one isomer is formed in this instance. At the same time, a sharp change in the ratio of the ν(CO) band intensity ratios for the adducts is observed compared with initial compounds; this corresponds to an appreciable increase of the angle between the carbonyl groups (from ~100° to ~125°), which is possible only for the *trans*-isomer[22]. On the other hand, the reactions of these complexes with $TiCl_4$ apparently lead to the formation of a mixture of isomers [four ν(CO) infrared bands are observed][22].

There is a further series of examples of the reversible addition of Lewis acids $M'X_4$ to transition metal complexes (Table 8). In particular, the addition of $(Cpylid)M(CO)_3$ ($Cpylid = Ph_3P^+-C_5H_5^-$, M = Cr, Mo, or W) to $TiCl_4$,[22] of *trans*-$(PPh_3)_2Ir(CO)Cl$ to $SnCl_4$,[17] and of $CpM(CO)(NO).PPh_3$ (M = Mo or W) to $SnCl_4$ [22] involves interaction via the metal atom.

The reactions of ferrocene with SnX_4 and TiX_4 (X = Cl or Br) have been investigated. It is suggested that they involve the formation of salt-like products containing the ferrocenium cation and the $Sn_2X_9^-$ and $Ti_3X_{12}^-$ counterions[84]. In contrast to Cp_2M (M = Fe or Ni), ruthenocene is not oxidised under the influence of SnX_4 (X = Cl or Br) but gives rise to yellow products having the composition $2Cp_2Ru.3SnX_4$,[56] for which the structure $[Cp_2Ru–SnX_2–RuCp_2]^{2+}(SnX_5^-)_2$ has been proposed.

Table 9. The interaction of transition metal complexes with metal ions.

Transition metal complex	Reagent	Reaction product*	Refs.

*The structures of the reaction products have been confirmed[89,91] by X-ray diffraction; $M' = Mn(CO)_4$ in the case of $[Mn(CO)_5]_2$.

2. Reactions with Metal Cations

Metal cations can play the role of electrophiles in relation to TMC (Table 9). The nature of the infrared spectra of the salt-like complexes $M^+[Mn(CO)_4L]^-$ [IV, M = Li or Na; L = CO, PMe_2Ph, PPh_3, or $P(OPh)_3$] [84,85] and $M^+[Fe(CO)_3(NO)]^-$ [V, M = Na, K, or $(Ph_3P)_2N$] in the carbonyl region in THF shows that they exist in two forms in equilibrium—contact ion pairs, where the alkali metal cation interacts with the oxygen atom of the CO ligands of complex (IV) or the NO ligand of complex (V), and ion pairs separated by the solvent. For complexes (IV), the existence of contact ion pairs in solution also follows from conductimetric and kinetic data for their reactions with alkyl halides[86]. When reagents binding alkali metal cations, namely crown-ethers or hexamethylphosphoramide, are added to solutions of the complexes in THF, the ν(CO) bands of the contact ion pairs (M–X≡O.....M', where X = C or N) disappear and only the bands of the free ions remain. Iron pentacarbonyl, which is a weak base, reacts in liquid SO_2

with strong acids—$Cd(AsF_6)_2$, $Sn(SbF_6)_2$, and $Fe(SbF_6)_2$.[88] On the basis of Mössbauer and infrared spectroscopic data, the following structure of the reaction product has been postulated: $[-\underset{/\backslash}{\overset{\backslash/}{Fe}}-M-\underset{/\backslash}{\overset{\backslash/}{Fe}}-]^{2+}.2(EF_6)^-$, where E = As or Sb; thus Lewis acids interact with $Fe(CO)_5$ via the metal atom.

Under the influence of magnesium amalgam, the dimeric complexes $[Mn(CO)_5]_2$, $[CpMo(CO)_2L]_2$, $[CpFe(CO)_2]_2$, and $[Co(CO)_3L]_2$ (L is a phosphine ligand) undergo reductive cleavage in the presence of bases such as pyridine, THF, and tetramethylethylenediamine with formation of the compounds $B_xMg(m)_2$ (B = base, m = group containing a transition metal, and $x = 2$ or 4 depending on the nucleophilic properties of the metal carbonyl group)[89,90]. In tetracoordinate complexes ($x = 2$) the transition metal can be linked to the Mg^{2+} ion both via CO bridging groups (Mg–O≡C–M) and directly (M–Mg). The interaction of groups containing a transition metal with Mg^{2+} in hexacoordinate complexes ($x = 4$) always proceeds via the oxygen atoms of the CO groups[90].

According to X-ray diffraction data[89], the adduct $[CpMo(CO)_3]_2Mg(Py)_4$ has an octahedral structure, the Mg atom being coordinated to four pyridine molecules in the equatorial plane and to the oxygen atoms of two metal carbonyl groups—one from each $CpMo(CO)_3$ residue.

3. Reactions with Halogens, Antimony Pentachloride, and Alkyl Halides

When TMC react with halogens, the X_2 molecules are polarised and the positively charged cation X^+ always adds to the transition metal atom, the coordination number of the central atom increases by unity, and ionic compounds $[L_nMX]^+$ are formed via the mechanism:

$$L_nM + \overset{\delta+}{X}-\overset{\delta-}{X} \rightarrow [L_nMX]^+X^- \text{ or } [L_nMX]^+X_3^- .$$

In a number of cases nucleophilic attack by the X^- anion in the second stage of the reaction leads to the formation from these ionic compounds of oxidative addition or oxidative elimination products, for example[92,93]:

$$Mo(CO)_3(diphos)_2 + I_2 \rightarrow [Mo(CO)_3(diphos)_2I]^+I^- \rightarrow Mo(CO)_2(diphos)_2I_2$$
$$CpRe(CO)_3 + Br_2 \rightarrowtail [CpRe(CO)_3Br]^+Br^- \rightarrow CpRe(CO)_2Br_2 + CO .$$

The reactions with the halogens are known for the octahedral derivatives of chromium, molybdenum, and tungsten hexacarbonyls of the type $M(CO)_{6-n}L_n$ (where L are electron-donating ligands: amines, phosphines, and arsines; $n = 2-4$): $M(CO)_2(L_2)_2$ (L_2 = bidentate phosphine or arsine)[92,94,95]; $(CO)_3M(L_2)_3M(CO)_3$ (L_2 = bridging bidentate phosphine)[95]; $Mo(CO)_4L_2$;[96] $Mo(CO)_3(Amine)_3$ and $Mo(CO)_3Q$ (Q = tridentate amine)[97]; $M(CO)_3Q'$ [M = Mo or W; Q' = polydentate phosphine ligands $PhP(C_6H_4PPh_2\text{-}o)_2$ or $P(C_6H_4.PPh_2\text{-}o)_3$].[98] The addition of halogens has been described for the following π-complexes: (π-Arene)$M(CO)_3$ (M = Mo or W; Arene = $Me_nH_{6-n}C_6$);[99]# $CpMn(CO)_3$;[100] $CpIr(CO)(PPh_3)$;[59] Cp_2Ru.[101]#

When TMC are acted upon by $SbCl_5$, Cl_2 is apparently formed initially as a result of the reaction $SbCl_5 \rightarrow SbCl_3 + Cl_2$ and then Cl^+ adds to the metal atom in the complex and Cl^- adds to a second $SbCl_5$ molecule. For example, the interaction of $CpRe(CO)_3$ with $SbCl_5$ leads to the formation of $[CpRe(CO)_3Cl]^+SbCl_6^-$.[102] The interaction of (π-Arene).$M(CO)_3$ (M = Mo or W),[103] Cp_2Ru,[56] and $[Re(CO)_3]_2$(porphyrin)[104]# with $SbCl_5$ leads to analogous products.

#The structure of the reaction products has been confirmed by X-ray diffraction analysis.

The reaction of $Mo(CO)_3L_3$ with $SbCl_5$ and $FeCl_3$ results in the formation of $[Mo_2(CO)_4L_4(\mu\text{-}Cl)_3]^+X^-$ ($X^- = SbCl^-$ or $FeCl_4^-$).[105]

The positive species adds to the central metal atom when TMC are acted upon by alkyl halides or stronger alkylating agents—trialkyloxonium salts and dialkyl sulphates. These reactions proceed via the mechanism $L_nM + \overset{\delta+}{R}-\overset{\delta-}{X} \rightarrow [L_nM-R]^+X^-$. Depending on the nature of the central atom M, the ligand environment, and X^-, the second reaction stage may involve the migration of R to CO with simultaneous attack by X^-, for example:

$$\underset{L=PPh_3}{CpM(CO)L} + MeI \rightarrow \underset{M=Ir}{[CpM(CO)(L)Me]^+I^-} \rightarrow \underset{M=Co,\ Rh}{CpM(COMe)(L)I} . \quad (3)$$

In relation to this reaction, it is possible to follow the influence of various structural factors[24]. The dicarbonyl complexes $CpM(CO)_2$ do not interact with MeI, since the basicity of the central atom is in this case insufficient. The rate of the bimolecular reaction (3) increases in the sequence Co < Rh ≪ Ir, the rate constants 10^4k amounting to 25.7, 35.0, and 210 litre mol^{-1} s^{-1} respectively. For M = Co and Rh, the reaction does not stop at the first stage and neutral acyl complexes are formed immediately. However, in the case of M = Ir, where the basicity of the central atom is extremely high, the final product is an ionic complex. The rate of reaction depends greatly on R and L: for CpCo(CO)L and MeI, the relative rate increases with enhancement of the electron-donating properties of L in the sequence PPh_3 (25.7) < PPh_2Me (150) < $PPhMe_2$ (330). The dependence of the rate on the solvent in the sequence THF < acetone < CH_2Cl_2 < MeCN shows that there is appreciable charge separation in the transition state.

It is possible to quote a further series of examples of similar reactions of transition metal complexes with alkylating agents: of $W(CO)_2(diphos)_2$ with $[Et_3O]^+BF_4^-$;[106] of $CpM(CO)(PPh_3)$ (M = Co, Rh, or Ir) with MeI and EtI;[24] of $CpIr(CO)(PPh_3)$ with MeCl, MeBr, $C_6H_{13}I$, $C_6H_5CH_2I$, and C_3H_7I;[59] of $CpCoL_2$[107] and FeL_5[108] [L = $P(OMe)_3$] with MeI.

4. Oxidation under the Influence of Electrophiles

When the transition metal atom in the complex is sufficiently basic (in the presence of strong electron-donating ligands), the influence of certain electrophiles can lead to oxidation with electron transfer to the acceptor and the formation of a donor radical-cation: $(L_nM)^0 \overset{-e}{\rightarrow} (L_nM)^{\ddagger}$. There is then a possibility of two cases: (a) the neutral acceptor A accepts an electron and gives rise to the radical-anion A^-, i.e. the reaction product is the radical-ion pair $(L_nM^{\ddagger})(A^-)$; (b) the cationic acceptor A^+ accepts an electron and is converted into a neutral molecule A ("one-electron oxidation"). The formation of radical-ion pairs is characteristic of the most basic complexes in reactions with π-acids (tetracyanoethylene and others). These reactions will be considered in detail below.

In one-electron oxidation reactions the oxidants are usually $NO^+PF_6^-$, diazonium salts, and the silver salts $AgPF_6$ and $AgBF_4$. They accept an electron from the TMC with formation of compounds or species which leave the reaction sphere, displacing thereby the equilibrium in the direction of the formation of the products [$NO^+ \rightarrow NO$; $Ag^+ \rightarrow Ag$ (metallic); diazonium salts → $Ph^{\cdot} + N_2$]. 18-Electron transition metal complexes are converted into 17-electron paramagnetic radical-cations, which give rise to well resolved EPR spectra and possess a magnetic moment corresponding to a single

unpaired electron. We may note that electrochemical as well as chemical oxidation is possible. Measurement of the half-wave potential $E_{1/2}$ permits hypotheses concerning the possibility of the chemical oxidation of the same substrates.

The conversion of the diamagnetic 18-electron complexes into radical-cations is always accompanied by an increase of the ν(CO) infrared frequencies, on average by 100–140 cm^{-1}. There are data[109] showing that the ferrocenium ion can also serve as a one-electron oxidant. It is then converted into ferrocene. We may note in this connection that, among the reactions of metallocenes with various electron acceptors, ferrocene and nickelocene are distinguished by their ability to give up readily one electron with formation of salts of the cations Cp_2Fe^+ and Cp_2Ni^+.

The reactions of Cp_2Fe with metal halides such as MX_4 (M = Ti or Sn; X = Cl or Br), $VOCl_3$, and $SbCl_5$ lead to the formation of the solid salts $Cp_2Fe.3TiX_4$, $Cp_2Fe.2SnX_4$, $Cp_2Fe.VOCl_3$, and $2Cp_2Fe.SbCl_5$, which always contain the Cp_2Fe^+ cation.[84] The compound Cp_2Ni is oxidised under the influence of $TiCl_4$ to $Cp_2Ni^+TiCl_4^-$.[84] On reaction with the sandwich-type acceptor Cb_2Ni, where $Cb = (3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-}$,[84] ferrocene gives rise to a charge-transfer complex (CTC), which is gradually converted into the salt $Cp_2Fe^+.Cb_2Ni^-$. The reaction of Cp_2Ni with Cb_2Ni leads to complete electron transfer and the formation of an ionic compound in which both the cation and anion are sandwich complexes with a central Ni^{3+} ion.

Chemical oxidation reactions have been studied for the following complexes: $(C_6Me_{6-n})Cr(CO)_2(PhC{\equiv}CPh)$ (n = 0, 1);[110] CpFe(diphos)R (R = Me, H, Cl, Br, I, or $SnMe_3$);[111] $CpFe(CO)_nL_{2-n}X$ [n = 0, 1, L = $P(OPh)_3$ or CNPh];[111] $CpMn(CO)L_2$ [L_2 = diphos or $(PPh_3)_2$];[111] $CpV(CO)_2$(diphos) and $CpV(CO)_3L$ (L = PPh_2Me);[112] $Fe(CO)_2L$(diene) [L = CO, PPh_3, or $P(OCH_2)_3CH$)];[113] $Fe(CO)_3L_2$ (L = PPh_3, PPh_2Me, $P(OPh)_3$, or $P(NMe_2)_3$, L_2 = diphos);[114] $CpMn(CO)_2L$ (L = phosphines);[115] $[HCoL_4]^+PF_6^-$;[109] $Cr(CO)_4$(diphos) and $[Cr(NO)(MeCN)_3(diphos)]^+$.[116]

5. Reactions with π-Acids

When transition metal π-complexes react with π-acids, there is a possibility of the formation of charge-transfer complexes with complete electron transfer from the donor to the π-acid in the ground electronic state and the formation of salts of radical-anions.

$$D + A \rightleftarrows D \cdot A\ (CTC) \rightleftarrows D^+ + A^- \rightarrow \text{secondary products}$$

(radical-anion salt)

For weakly bound CTC, the transfer of electron density from the donor to the acceptor in the ground electronic state is slight, while the excited states are structures with complete electron transfer from D to A (i.e. are ionic). When a light quantum $h\nu_{CT}$ is absorbed, the CTC passes from the ground to an excited state and a charge transfer band (CTB) appears in the electronic spectrum. The formation of CTC leads to hardly any changes in the infrared spectra of the donor and acceptor, which is due to the fact that the shift of electron density fron the donor to the acceptor in the ground state is slight. Thus an appreciable displacement of the absorption bands of $(Arene)Cr(CO)_3$ and 1,3,5-trinitrobenzene (TNB) was not observed in the infrared spectra of their CTC.[117] When the electron transfer in the ground electronic state is complete, significant changes in the vibrational and electronic spectra are observed; one may then expect the appearance of an EPR signal.

The spectral changes when the transition metal π-complexes interact with π-acids can be illustrated in relation to the reactions of the manganese complexes $CpMn(CO)_3$, (Et_5C_5).$Mn(CO)_2(PPh_3)$, and CpMn(CO)(diphos) with tetracyanoethylene (TCE) and tetracyanoquinodimethane (TCQD).[118] The interaction of $CpMn(CO)_3$ and $(Et_5C_5)Mn(CO)_2(PPh_3)$ with TCE in CH_2Cl_2 does not lead to changes in the infrared spectra either in the carbonyl region [although the ν(CO) frequencies are extremely sensitive to changes in the distribution of electron density in the molecule] or in the region corresponding to the ν(CN) vibrations of TCE; nor do signals appear in the EPR spectra. New CTB bands, which are absent from the spectra of the initial compounds, appear in the electronic spectra (at 790 and 740 nm respectively).

When a solution of TCQD was added to one of CpMn(CO).(diphos) in CH_2Cl_2, a sharp colour change from yellow to emerald green and the appearance of an EPR signal were observed. At −150 °C the EPR spectrum of the complex CpMn(CO)(diphos).TCQD (VI) in CH_2Cl_2 showed two signals superimposed on one another: one broad signal, apparently due to $[CpMn(CO)(diphos)]^+$, and another, narrow signal due to the presence of TCQD. The electronic spectra of a solution of (VI) also indicate the presence of the TCQD radical-anion. The infrared spectrum of (VI) differs significantly from the spectra of the initial components: the frequencies ν(CO) are displaced by ~100 cm^{-1} towards higher values (as in oxidation by the Ag^+ ion and other oxidants), while the ν(CN) bands of TCQD are displaced towards lower values by ~50 cm^{-1}. These data lead to the conclusion that CpMn(CO)(diphos) undergoes one electron oxidation under the influence of TCQD.

The kinds of products formed in the reactions of transition metal π-complexes with π-acids (CTC or radical-anion salts) depend on the polarity of the solvent and on the relative strength of the donor and the π-acids involved in the interaction. Polar solvents should promote electron transfer and the formation of CTC is more likely in a medium with a low dielectric constant. For example, the CTC $Cp_2Fe.TCE$, which exists in the solid state and in solution in cyclohexane, dissociates in acetonitrile[119,120]:

$$Cp_2Fe \cdot TCE \rightleftarrows Cp_2Fe^+ + TCE^-$$

The complexes $(Arene)Cr(CO)_3$ form CTC with TNB, p-benzoquinone, TCE, and chloranil (CA),[117,121–123] the most stable CTC being formed with TNB.[117,121] The stronger π-acids may promote a more complete electron transfer. In solution the starting materials and the reaction products are involved in an equilibrium whose position depends on the concentration; in dilute solutions the equilibrium is displaced towards the starting materials.

In benzene solutions EPR signals due to mixtures of $(Arene)Cr(CO)_3$ with π-acids (TNB, CA, and TCE) have not been observed, while in nitromethane the signals due to radicals have been noted[121]. Thus the chromium complex is oxidised in a polar solvent.

Solid adducts with π-acids have been obtained for a number of π-complexes. Thus $(C_6H_6)_2Cr$, which is very readily oxidised to $(C_6H_6)_2Cr^+$, like ferrocene, gives rise to solid 1:1 salts with TCE, TNB, CA, and p-quinone, which are stable in air[124]. The oxidation of $(C_6H_6)_2Cr$ by π-acids has been demonstrated convincingly by various methods—EPR, infrared spectroscopy, and electronic spectroscopy. The EPR spectrum of each adduct contains two signals corresponding to $(C_6H_6)_2Cr^+$ and the radical-anions of the π-acids.

Solid adducts of Cp_2Co and Cp_2Ni with CA^- and TNB have been isolated: $Cp_2Co.CA$, $Cp_2Co.2CA$, $Cp_2Ni.2CA$, and $Cp_2Co.TNB$. The 1:1 adducts are CTC, in contrast to the

1:2 adducts, which are salt-like[125]. The above adducts of the complexes Cp_2M are relatively stable in air compared with the initial Cp_2Co or Cp_2Ni, which are unstable as regards oxidation. Ferrocene also forms complexes in solution with *p*-benzoquinone[125], CA,[125] TCQD,[126] TCE,[119,120,123] tetrachlorophthalic anhydride[125], and TNB.[127] The complexes Cp_2M (M = Ru or Os) are oxidised by TCE in acetonitrile with formation of salts of Cp_2M^+.[123]

The solid complex CpMn(CO)(diphos).TCQD, which, as in solutions, has the structure of the salt $[CpMn(CO)(diphos)]^+$. $.TCQD^-$ (EPR and infrared spectra), has been isolated from benzene solution[118].

The problem of the relative orientations of the donor and acceptor molecules in the CTC has been discussed in some studies. According to X-ray diffraction data[122], the TNB molecules in the adduct $(MeC_6H_5)Cr(CO)_3$.TNB are located in planes which are approximately parallel to the planes of the arene rings and the planes passing through the oxygen atoms of the CO groups in the chromium complex. The distance between the planes of the cyclic ligand and the TNB molecule is 3.41 Å, while the plane of the oxygen atoms of the CO groups is separated from the plane of the other acceptor molecule by 2.97 Å. Thus both the arene ring and the CO groups should be involved in the formation of the complex. (2,5-Dimethyldecamethylene-*ansa*-benzene)tricarbonylchromium also forms a complex with TNB.[123] It is postulated in this case that the acceptor molecules form a bond with the CO groups of the chromium complex, since the π-ring is blocked by the bridge with ten CH_2 units. However, this evidence is not convincing, because the decamethylene ring, being fairly long, can bend away and need not block the benzene ring.

The nature of the influence of substituents in the arene ring of the complexes $Arene(CO)_3$ on the frequencies of the charge-transfer bands in the spectra of CTC with TCE has been investigated[128]. The satisfactory correlation between the position of the CTB and the σ^+ constant of the substituent in the aromatic ring led the authors to postulate that, in the formation of the CTC, TCE interacts with the aromatic ring of the arenechromiumtricarbonyl derivatives,

VI. CONCLUSION

It has been shown from extensive experimental data that the TMC possess distinct basic properties and readily interact with a wide range of aprotic acids. The interaction can be both via the central metal atom and via the ligands.

One of the main centres where the acid–base interaction takes place is the transition metal atom. The manifestation of basic properties has been noted for virtually all Group V–VIII transition metals. There are not data for the basic properties of Group III and IV metal (Sc, Y, lanthanides, and titanium and its analogues) complexes as well as complexes in which the metal has the d^{10} configuration and which contain Cu^+, Ag^+, Zn^{2+}, Cd^{2+}, and Hg^{2+}. Thus basic properties are most characteristic of the complexes of metals with partially filled *d*-orbitals containing not less than four *d* electrons.

Allowance for the possibility of the interaction via the metal atom permits a new approach to the problem of the study of the mechanisms of the reactions of TMC, particularly the reactivity of π-complexes containing cyclic π-ligands. Evidently, one cannot regard the reactions of these compounds with electrophiles simply by analogy with the reactions of the free ligands without taking into account the role of the central atom and its ligand environment. Such reactions include the so-called aromatic substitution reactions [characteristic of ferrocene, $(C_5H_5)Mn(CO)_3$ derivatives, and certain other π-complexes]: isotope exchange between hydrogen and acids, acylation, alkylation, mercuration, etc. Throughout the initial period of these studies, it was traditional to compare the rates of these reactions and the properties of the π-complexes and the corresponding benzene derivatives. However, such comparison is apparently not legitimate. Although many reactions of π-complexes and aromatic compounds proceed under similar conditions, their mechanisms can be significantly different.

It was demonstrated above with numerous examples that aprotic acids (aluminium, tin, and iron halides) form adducts with many π-complexes via the central atom or via the ligands. The same halides catalyse Friedel–Crafts alkylation and acylation—reactions characteristic of many π-complexes (ferrocene, cymantrene, etc.). In considering the mechanisms of such reactions, it would therefore be incorrect to ignore the possibility of adduct formation; despite the similarity of conditions, the mechanism of the acylation of organometallic π-complexes can differ significantly from the mechanism of the acylation of benzene and its analogues. It would be no exaggeration to state that, as data on the basicity of TMC accumulate, demonstration is obtained the "ricochet" substitution mechanism, proposed more than 20 years ago by Nesmeyanov and coworkers[129,130], according to which the attack by the reagent is directed initially to the central metal atom, after which there is a change of direction from the metal to the cyclic π-ligand. Many examples of reversible rearrangements of this type with migration of a proton[131–133] as well as alkyl and other groups[134,135] have been found recently. The ricochet substitution mechanism has been used to account for the mechanism of the acid exchange of hydrogen in cyclic π-ligands (cyclopentadienyl, benzene) in iron, manganese, chromium, and rhenium complexes[136]. The ideas concerning the basicity of the complexes and the important role of the central metal atom can be used to explain the specificity, kinetics, and nature of the products of many other reactions of π-complexes with electrophiles, for example, the cleavage of the M–C σ-bonds and metal–metal bonds under the influence of hydrogen halides, halogens, and mercury salts HgX_2.

In conclusion, at present the extensive data concerning the basicity of the TMC contain virtually no quantitative data based on the study of the kinetics and thermodynamics of the interaction of the TMC with various electrophiles and that the entire data available are so far purely qualitative.

Photochemical Reactions of Free Radicals in the Solid Phase

M.Ya.Mel'nikov and N.V.Fok

The photochemical reactions of free radicals of different classes in the solid phase (solids, low-molecular-weight organic compounds, and polymers) are examined and data characterising the absorption spectra of the radicals are presented. The role of free radicals in processes involving the breakdown of substances under the action of light is discussed. The bibliography includes 299 references.

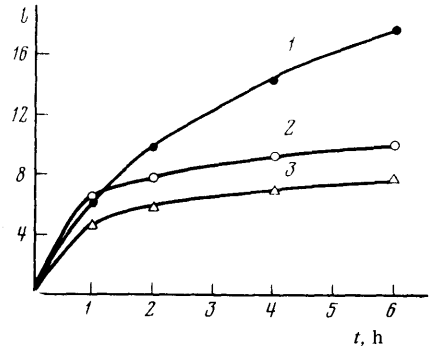
I. INTRODUCTION

The photochemical reactions of free radicals are varied and numerous published reports have presented experimental evidence confirming their occurrence. However, their mechanism is in many instances still unestablished.

The study of the general features of the photochemical reactions of free radicals is important for the determination of the relation between the nature of the excited state and the mode of chemical reactions, and also in connection with the role which these processes play in the breakdown of substances under the action of light.

The absorption spectra of free radicals formed in solid-phase photolysis and radiolysis at relatively high concentrations are characterised by a bathochromic shift relative to the spectra of the initial compounds and fairly high extinction coefficients. On irradiation, more active species are formed from the radicals, unstable under these conditions and regenerating the initial radicals in reactions with water molecules. As a result, radical photochemical chain processes arise in the system and lead to an appreciable decomposition of the medium:

$$\dot{\text{C}}\!-\!\Phi \xrightarrow{h\nu} \text{M}_1 + \dot{\text{R}}$$



$$\dot{\text{R}} + \text{M}_0 \rightarrow \text{M}_2 + \dot{\text{C}}\!-\!\Phi,$$

where Φ is a functional group, M_0 a molecule of the medium and M_1 and M_2 are reaction products. The Figure presents experimental relations characterising the development of photochemical radical chains in methylamine, ethanol, and acetic anhydride. The average photochemical radical chain length $l = [M_1]/[\dot{C}\!-\!\Phi]_0 = [M_2]/[\dot{C}\!-\!\Phi]_0$ in the test systems did not exceed 20 and the main factor limiting it is radical recombination processes.

In order to determine the mechanisms of photochemical reactions, studies were made on the nature and kinetics of the formation of free radicals in the solid phase by ultraviolet and infrared spectroscopy, etc., and also on the nature of the stable reaction products—by gas–liquid chromatography, mass spectrometry, etc.

Reviews have been published recently in which the optical properties of free radicals are discussed[2], the available information about the photochemical reactions involving them is compiled[3-5], and attempts are made at a general survey and the determination of several general characteristics of these processes[6,7].

In the present review we confined ourselves to an examination of the photochemical reactions of certain free radicals and their role in solid-phase photolytic processes.

Variation of the photoradical chain length l in the photolysis of radicals by light at a wavelength $\lambda \geq 300$ nm at 77 K in different solvents: 1) methylamine; 2) ethanol; 3) acetic anhydride[1].

II. PHOTOCHEMICAL REACTIONS OF ALKYL RADICALS

ESR data have shown that the unpaired electron in alkyl radicals is in the p_z orbital of the carbon atom. Alkyl radicals are formed in a chemically excited state as a result of the transfer of the unpaired electron from the p_z orbital to an antibonding σ-orbital and from a bonding σ-orbital to a non-bonding orbital (σ–π^* transition). These transitions are symmetry-forbidden, but analysis of literature data nevertheless shows that alkyl radicals absorb light at wavelengths $\lambda \leq 300$ nm and have fairly high extinction coefficients. A short-wavelength absorption corresponds to π–σ^*

transition. The absorption associated with the $\sigma-\pi^*$ transition could not be observed experimentally. It follows from the analysis of the vibrational structure of the absorption spectra of methyl radicals in the gas phase that, on transition to an electronically excited state[8], the geometry of the methyl radical does not change significantly.

Table 1 presents the available literature data for the absorption spectra of alkyl radicals.

*Notation: f.p. = flash photolysis; p.r. = pulse radiolysis; p. = photolysis; r = radiolysis; py = pyrolysis (flame).
**G = radiation-chemical yield.

Excited alkyl radicals can be involved in reactions of various types: isomerisation, substitution, and dissociation. We shall examine a number of specific examples of such reactions. Following irradiation at $\lambda = 260$ nm of t-butyl radicals, obtained in isobutyl bromide γ-irradiated at 77 K, the 10-line ESR spectrum of the t-butyl radical with a binomial distribution of intensities and a splitting of 23 G is transformed into a 5-line spectrum with intensity ratios 1:2:2:2:1 and a splitting of 21 G, which is due to the isobutyl radical[50]. The reaction is reversible and the reverse process occurs in various systems after the latter have been kept for a long time at 77 K:[51-54]

$$CH_3-\dot{C}(CH_3)_2 \overset{h\nu}{\rightleftarrows} \dot{C}H_2-CH(CH_3)_2.$$

The action of the total radiation of a high-pressure mercury lamp on t-butyl radicals obtained in isobutene γ-irradiated at 77 K leads to the formation of isobutyl and methylallyl radicals[54]. The authors attribute the appearance of isobutyl radicals to the possibility of isomerisation reactions, the dissociation of t-butyl radicals, or their reactions with the molecules of the medium.

Analogous photochemical processes take place under the influence of ultraviolet radiation in γ-irradiated n-, s-, iso-, and t-butyl chlorides, where the conversion of s-butyl radicals into n-butyl radicals and of t-butyl radicals into isobutyl radicals was observed by ESR.[55] When isotactic polypropylene (PP) γ-irradiated at 77 K is acted upon by radiation with $\lambda = 253.7$ nm, the resolution of the ESR spectrum is improved and a 4-line spectrum with the intensity ratios 1:3:3:1 and a splitting of 25.5 G appears. It has been attributed[56,57] to the isomerisation reaction

$$\sim CH_2-\dot{C}CH_3-CH_2\sim \overset{h\nu}{\rightleftarrows} \sim CH_2-CH(\dot{C}H_2)-CH_2\sim.$$

At the same time, a singlet line with $\Delta H \cong 17$ G was noted in the ESR spectra when deuteropolypropylene (DPP) was γ-irradiated at 77 K. The absence of hyperfine structure (HFS) components from the ESR spectrum of DPP suggested that the singlet spectrum is due to allyl radicals. Subsequent exposure to ultraviolet radiation leads to the disappearance of the singlet line and the appearance of an ESR spectrum consisting of 15 HFS lines with a splitting of 3.7 G, corresponding to the radical $\sim CD_2-\dot{C}(CD_3)-CD_2\sim$. These radicals are stable with respect to irradiation and do not undergo further photochemical reactions. The data obtained by Klinshpont et al.[58] suggest that the changes observed by Iwasaki et al.[56] are associated with the reactions of allyl and not alkyl radicals.

The action of ultraviolet radiation on the radical $\sim CF_2-\dot{C}(CF_3)-CF_2\sim$, obtained in the tetrafluoroethylene (TFE)–hexafluoropropylene copolymer γ-irradiated at 77 K, leads to the formation of the radicals $\sim CF_2-\underset{\dot{C}F_2}{CF}-CF_2\sim$, detected by their characteristic ESR spectrum[49].

Following γ-irradiation of polyisobutylene (PIB) at 77 K, a doublet with a splitting of 22 G was recorded in the ESR spectrum and was assigned to the radical $\sim C(CH_3)_2-\dot{C}H-C(CH_3)_2\sim$. When the specimens are heated to 213 K for 5 min, cooled to 77 K, and exposed to light with $\lambda \leqslant 303$ nm, the initial doublet is rapidly converted into a spectrum consisting of 15 lines[59]. These changes can be explained by the isomerisation

$$\sim \dot{C}H-CH(CH_3)_2 \overset{h\nu}{\rightleftarrows} \sim CH_2-\dot{C}(CH_3)_2.$$

On the basis of the change in the ESR spectra, it has been suggested that, after exposure to radiation with $\lambda = 253.7$ nm, the alkyl (n-propyl and t-butyl) radicals, formed on γ-irradiation of propene and isobutene at 77 K in an argon matrix,

may be converted into the corresponding allyl radicals[60,61]:

$$CH_3-CH_2-\dot{C}H_2 \xrightarrow{h\nu} CH_2 \cdots CH \cdots CH_2 + 2H(H_2) \ .$$

However, the absence of an analysis of the stable reaction products makes this hypothesis questionable. We believe that the mechanism proposed by Shamonina and Krotov[54] and involving the reaction of the excited alkyl radical with a molecule of the unsaturated compounds, for example

$$CH_3CH_2\dot{C}H_2 + CH_3CH=CH_2 \xrightarrow{h\nu} C_3H_8 + CH_2 \cdots CH \cdots CH_2 \ ,$$

is more probable.

It is important to note that the yields of the majority of the radicals quoted above are based solely on the analysis of the changes in the ESR spectra, which involves serious difficulties under the conditions of the solid-phase photolysis and radiolysis, particularly in polymeric matrices. Furthermore, in radiolysis there is a possibility of the formation of allyl radicals, whose photochemical reactions, which have been examined in detail in a number of reviews[3,6,7], can mask the reactions of alkyl radicals, as shown for DPP.[58]

When 0.01 M solutions of t-butyl chloride in 3-methylpentane (3-MP), γ-irradiated at 77 K, were irradiated in the wavelength range $240 \leq \lambda \leq 270$ nm, t-butyl radicals disappeared and 3-methylpentyl radicals appeared. The total number of free valences does not change under these conditions. The quantum yield Φ of the reaction in 3-MP was determined as 0.5 ± 0.15 from the initial sections of the kinetic curves for the disappearance of t-butyl radicals[30]. In this case there is apparently a reaction between the excited t-butyl radicals and the matrix molecules. The isomerisation of alkyl radicals in γ-irradiated frozen alkyl halides and other systems, observed previously[49,50,55,60,61], can also be explained by the reactions of excited alkyl radicals with matrix molecules:

$$\dot{R}^* + R_1-X \rightarrow R-X + \dot{R}_1 .$$

The formation of 3-methylpentyl radicals when alkyl radicals, obtained on γ-irradiation of 1 M solutions of alkyl chlorides in 3-MP, are exposed to radiation with $\lambda = 253.7$ nm at 77 K, was observed also in another study[62]. The fact that t-butyl radicals are partly converted into isobutyl radicals in solutions of t-butyl chloride in 3-MP is apparently associated with the high concentration of the solutions and the possibility of reactions involving associated species. According to Burbo's results[63], the formation of associated species from alkyl halide molecules in hydrocarbon matrices is observed at concentrations above 0.01 M.

By analysing the reaction products and the changes in the ESR spectra, it has been shown in a number of studies that alkyl radicals can dissociate on excitation. Thus, after photolysis of a solid solution of n-butyl iodide in argon at 4 K by radiation with $\lambda = 246$ nm, methyl radicals and hydrogen atoms appear, which the authors attribute to the dissociation of n-butyl radicals[64]. The rate constant for the abstraction of a hydrogen atom from the electronically excited radicals can reach approximately 10^9 s^{-1}:[65]

$$CH_3CH_2CH_2CH_2 \xrightarrow{h\nu} \begin{cases} \rightarrow CH_3CH_2CH=CH_2 + H \\ \rightarrow \underline{-CH_2CH_2CH_2-} + \dot{C}H_3 \end{cases} .$$

The formation of methyl radicals when isobutyl vinyl ether γ-irradiated at 77 K was exposed to ultraviolet light was recorded by ESR:[66]

$$\dot{C}H_2CH(CH_3)CH_2OCH=CH_2 \xrightarrow{h\nu} \dot{C}H_3 + CH_2=CHCH_2OCH=CH_2 \ .$$

The study of the kinetics of the accumulation of gaseous products in the photolysis of isotactic PP by the total radiation of the high-pressure mercury lamp showed[67] that the observed rates of gas evolution in photolysis are greater by 3–5 orders of magnitude than the rates which would be expected if the macroradicals underwent thermal decomposition. According to the authors[67], this implies that the macroradicals are to a large extent decomposed on electronic excitation. The study of the kinetics of the accumulation of gaseous products of the photolysis of PP in the presence of 2,2′,6,6′-tetramethylpiperidine 1-oxide showed that the yield of methane then increases almost by a factor of 250, while the yield of the remaining photolysis products hardly changes. Since methyl radicals and hence methane could not be formed from nitroxy-radicals, it was suggested[68] that the vigorous formation of methane is a consequence of the photochemical decomposition of the central PP macroradicals, arising in the reaction of excited nitroxy-radicals with the macromolecules:

$$\dot{R}^* + \sim CH_2-CH(CH_3)-CH_2\sim \rightarrow RH + \sim CH_2-\dot{C}(CH_3)-CH_2\sim \ ,$$
$$\sim CH_2-\dot{C}(CH_3)-CH_2\sim \xrightarrow{h\nu} \dot{C}H_3 + \sim CH_2\sim\ddot{C}-CH_2\sim \ .$$

The biradicals arising in the photolysis react with the polymer, which leads to the regeneration of the central PP macroradicals.

Irradiation of PP in the presence of an added aromatic sensitiser (hexahydropyrene) at 77 K by light at wavelengths in the range $260 \leq \lambda \leq 380$ nm, corresponding to the sensitiser absorption band, leads to the appearance of a 4-line ESR spectrum with nearly binomial intensity ratios, which was assigned to the radical $\sim CH(CH_3)\dot{C}HCH(CH_3)\sim$. On subsequent irradiation of the same specimens with radiation at wavelengths in the range $240 \leq \lambda \leq 270$ nm, which is hardly absorbed by the sensitiser so that there is virtually no sensitised radical formation, components due to the methyl radical are clearly manifested in the ESR spectrum. The action of light at wavelengths of $240 \leq \lambda \leq 270$ nm on the radicals $\sim CMe_2-\dot{C}H-CMe_2\sim$, formed in PIB on photolysis and radiolysis sensitised by aromatic compounds at 77 K, also leads to the formation of methyl radicals. These processes in PP and PIB take place without a change of the total number of free valences. The formation of methyl radicals under the influence of ultraviolet radiation on the macroradicals in PP and PIB apparently proceeds via the reactions[69,70]

$$\sim CH(CH_3)\dot{C}HCH(CH_3)\sim \xrightarrow{h\nu} \sim CH(CH_3)CH=CHCH_2\sim + \dot{C}H_3 \ ,$$
$$\sim C(CH_3)_2\dot{C}HC(CH_3)_2\sim \xrightarrow{h\nu} \sim C(CH_3)_2CH=C(CH_3)\sim + \dot{C}H_3 \ .$$

The numerous instances of the formation of methyl radicals when PP is exposed to radiation with $\lambda \leq 300$ nm can in fact be accounted for by the photolysis of alkyl macroradicals[71–77]. It has been shown that the additional action of radiation at wavelengths in the range $240 \leq \lambda \leq 270$ nm does not entail significant changes in the molecular weight of PP and PIB. Evidently the reactions

$$\sim CH(CH_3)\dot{C}HCH(CH_3)\sim \rightarrow \sim CHCH_3-CH=CHCH_3 + \dot{C}H_2CH(CH_3)CH_2\sim \ ,$$
$$\sim C(CH_3)_2\dot{C}HC(CH_3)_2\sim \rightarrow \sim (CH_3)_2CH=C(CH_3)_2 + \dot{C}H_2C(CH_3)_2CH_2\sim$$

which lead to the dissociation of the polymer chain, take place with low quantum yields if at all and do not cause an appreciable change in molecular weight[69,70].

At the same time, analysis of the composition of the products (methane, ethane, and ethylene), resulting from the exposure to light of alkyl radicals in γ-irradiated polyethylene (PE) at 77 K, led to the following reaction mechanism[78]:

$$\sim CH_2-\dot{C}H-CH_2\sim \xrightarrow{h\nu} \sim CH_2-\dot{C}H-CH_3 + CH_2=CH\sim \ ,$$
$$\sim CH_2-\dot{C}H-CH_3 \xrightarrow{h\nu} \begin{cases} \rightarrow \sim CH=CH_2 + \dot{C}H_3 \\ \rightarrow \sim CH_2-\dot{C}H-CH_3 + C_2H_4 \end{cases} ,$$

incorporating processes leading to the decomposition of the main polymer chain.

Significant changes occur in the ESR spectra of γ-irradiated branched aliphatic hydrocarbons at 77 K, following exposure to short-wavelength ultraviolet radiation. Thus the action of ultraviolet radiation on 3-MP γ-irradiated at 77 K leads, according to the authors[79,80], to the formation of methyl radicals:

$$C_2H_5\dot{C}(CH_3)C_2H_5 \xrightarrow{h\nu} C_2H_5C(CH_3)=CH_2 + \dot{C}H_3 \ .$$

However, one should note that the study of the structure of the radicals in branched aliphatic hydrocarbons γ-irradiated at 77 K established[81-84] that in this case the radicals $CH_3\dot{C}HR$, arising on dissociation of a secondary C–H bond, are formed preferentially. The mechanism of the formation of methyl radicals, proposed in the studies mentioned above[79,80], therefore requires revision. Analogous changes in the ESR spectra of 3-MP and deuterated 3-MP γ-irradiated at 77 K, have been observed after irradiation in another investigation[85].

Analysis of the changes in the ESR spectra occurring under the influence of radiation at wavelengths in the range $240 \leq \lambda \leq 270$ nm on 3-MP and 3-ethylpentane γ-irradiated at 77 K suggested that the photolysis of the corresponding hydrocarbon radicals proceeds with formation of ethyl radicals[35,36]. Ethane was detected among the gaseous reaction products, which constitutes additional confirmation of this conclusion:

$$CH_3\dot{C}HCH(CH_3)C_2H_5 \xrightarrow{h\nu} \dot{C}_2H_5 + CH_3CH=CHCH_3 \ .$$

When hydrogen sulphide and alkanethiols are photolysed in a 2-MP matrix at 77 K by radiation with $\lambda = 253.7$ nm, the changes in the ESR spectrum of 3-methylpentyl radicals are evidently associated with the appearance of small amounts of ethyl radicals as a result of the photolysis of the 3-methylpentyl radicals[86].

Table 2. Absorption spectra of alkoxy-radicals.

Radical	λ_{max}	$10^{-3}\varepsilon_{\lambda max}$, litre mol^{-1} cm^{-1}	Conditions of generation*	Refs

*The notation is the same as in Table 1.

The exposure to radiation with $\lambda = 254$ nm of γ-irradiated polycrystalline n-hexane[87], 3-methylheptane, and 4-methylheptane[36] at 77 K led to the observation of changes in the ESR spectra, which could be attributed to the isomerisation of alkyl radicals:

$$\sim CH_2\dot{C}HCH_2\sim \xrightarrow{h\nu} \sim CH_2\dot{C}HCH_3 \ .$$

At the same time the observed reactions can be accounted for fully by the reaction of the excited alkyl radicals with matrix molecules.

*The notation is the same as in Table 1.

The reactions of radicals in 3-MP, 3-ethylpentane, and 3-methylheptane γ-irradiated at 77 K, observed after exposure to ultraviolet radiation, were explained by the conformational transitions in the radicals, which take place on local heating of the matrix in consequence of the dissipation

of the energy of the light quantum absorbed by the radical[88]. Estimates based on the data of Vasil'ev and Tal'roze[89] have shown that the temperature rise can reach several tens of degrees.

The study of the photochemical reactions of the radicals $(CH_3)_2\dot{C}CH(CH_3)_2$, formed on γ-irradiation and hexahydropyrene-sensitised photolysis of 2,3-dimethylbutane at 77 K, not only established that the reaction product is methyl radicals but also led to the determination of the quantum yield in the accumulation of methane under the influence of radiation having a wavelength in the range $240 \leq \lambda \leq 270$ nm, which proved to be 0.01.[30]

Thus it can now be regarded as established that alkyl radicals can undergo photochemical substitution and dissociation reactions. The question of the possible isomerisation and the explanation of the observed changes in the ESR spectra by conformational transitions occurring on local heating of the matrix require further confirmation.

III. PHOTOCHEMICAL REACTIONS OF ALKOXY- AND PEROXY-RADICALS

The alkoxy-radicals RȮ are formed as intermediates when many organic compounds are irradiated, but their high reactivity makes their direct experimental detection extremely difficult. The rate constants for the reactions of RȮ with alcohol, ester, and aldehyde molecules at 20 °C are in the range 10^5–10^6 litre mol^{-1} s^{-1}.[90,91] The RȮ radicals are usually detected by the spin-trapping method, which makes it possible to reach a conclusion, by analysing the ESR spectrum of the resulting radical adduct, concerning the presence or absence of alkoxy-radicals among the reaction products[92].

The ESR spectra of alkoxy-radicals consist of singlet lines with a *g*-factor in the range 2.0065–2.008 [93,94] or 2.015 ± 0.02 [95] and a half-width in the range 3–6 G.[95,96] The ESR spectra of the radicals ȮH and ȮD are well known in the literature[97]. Table 2 shows that the optical absorption spectra of alkoxy-radicals have been studied inadequately.

The observed photochemical reactions have been attributed to alkoxy-radicals in a number of investigations. However, this is a consequence of an inaccurate identification of the singlet ESR spectra (see for example, Lenci and Neubacher[113] and Moan[114]), observed in the course of the low-temperature photolysis and radiolysis, and is as a rule associated with the photochemical reactions of acyl radicals.

On irradiation in the presence of oxygen or on interaction of irradiated substances with oxygen, a characteristic signal, consisting of a single asymmetric line due to peroxy-radicals, appears in the ESR spectra.

Electronically excited states of peroxy-radicals arise as a result of electron transfer from the n-orbital of the oxygen atom to the antibonding π-orbital. Table 3 presents data characterising the absorption regions and the extinction coefficients of peroxy-radicals.

In γ-irradiated PP the peroxy-radicals obtained as a result of the oxidation of alkyl radicals (heating to 173–193 K after γ-irradiation at 77 K) and allyl radicals (irradiation at room temperature) are converted into the corresponding alkyl radicals under the influence of ultraviolet radiation with $\lambda \geq 280$ nm.[140] Analogous reactions under the influence of light with $\lambda \leq 370$ nm are undergone by the peroxy-radicals obtained as a result of the oxidation of polyene radicals in PP.[141] The action of radiation with $\lambda \geq 280$ nm on peroxy-radicals in PP is not accompanied by a change in the total number of free valences. It has been suggested that the excited peroxy-radicals formed under the influence of light react with matrix molecules to form hydroperoxides:

$$R\dot{O}_2^* + RH \rightarrow \dot{R} + ROOH .$$

The decomposition of the hydroperoxide under the influence of radiation with $\lambda \leq 280$ nm can lead to the development of a chain process with photochemical chain branching[142]:

$$ROOH \xrightarrow{h\nu} R\dot{O} + \dot{O}H ,$$
$$\dot{O}H + RH \rightarrow \dot{R} + H_2O ,$$
$$R\dot{O} + RH \rightarrow \dot{R} + ROH .$$

A three-fold increase of the number of free valences is then observed.

The time variation of the overall radical concentration under the influence of light on peroxy-radicals, obtained by the oxidation of allyl radicals in PP, is described by the equation

$$[\dot{R}] = \left[1 + 2\left(1 + \frac{I}{\alpha - I}e^{-\alpha\tau} - \frac{\alpha}{\alpha - I}e^{-\tau}\right)\right],$$

where $\alpha = k_2/k_1$, k_1 is the rate constant for the conversion of peroxy-radicals into alkyl radicals, k_2 the rate constant for the decomposition of hydroperoxides, $\tau = k_1 It$, I is the light intensity, and t the irradiation time. The experimental values agree satisfactorily with the curve calculated for $\alpha = 2.1$, determined from linear logarithmic modifications of the curves describing the disappearance of peroxy-radicals on irradiation at wavelength $\lambda \geq 280$ nm and the accumulation of radicals on subsequent ultraviolet irradiation light at wavelength $\lambda \leq 280$ nm.[141]

However, it was established that the rate of accumulation of radicals in the photolysis of oxidised PP exceeds approximately by a factor of 7 the rate of decomposition of hydroperoxy-groups[143]. The study of the rate of accumulation of 3-methylpentyl radicals under the influence of light at a wavelength in the range $240 \leq \lambda \leq 270$ nm at 77 K on peroxy-radicals in 3-MP (at a concentration of approximately 0.001 M) and in solutions of t-butyl hydroperoxide in 3-MP at the same concentration showed that in the latter case the rate of accumulation is smaller almost by an order of magnitude[144]. Together with data for the extinction coefficients of the hydroperoxides (for example, $\varepsilon_{260} = 6$, $\varepsilon_{240} = 16$, and $\varepsilon_{200} = 70$ litre mol^{-1} cm^{-1} for t-butyl hydroperoxide[145]), these results show that, under the conditions of simultaneous absorption of radiation by alkyl radicals ($\lambda_{max} = 220$–240 nm, $\varepsilon \approx 10^3$ litre mol^{-1} cm^{-1}) and peroxy radicals [$\lambda_{max} = 250$–260 nm, $\varepsilon \cong (2$–$3) \times 10^3$ litre mol^{-1} cm^{-1}], present at comparable concentrations, the decomposition of hydroperoxide molecules is greatly hindered. Furthermore, one should note that the threefold increase of the number of free valences observed by Klinshpont et al.[141] is difficult to explain by the decomposition of the hydroperoxide formed in the reaction of the electronically excited peroxy-radical with matrix molecules, because "quasi-cage" radical recombination processes and radical recombination processes within the cage should then play a major role. The quantum yield of free radicals in the photolysis of hydrogen peroxide solutions in reactive and inert matrices at 77 K is known to be in the range from 10^{-4} to 0.3,[146,147] i.e. is less than unity.

At the same time, when peroxy-radicals derived from PP are irradiated at a wavelength $\lambda \leq 300$ nm in methyl methacrylate (MMA) vapour, the concentration of peroxy-radicals diminishes and the number of radicals of the growing polymeric PMMA chain increases, the overall radical concentration increasing under these conditions by a factor of 2–3.[148,149]

Under the influence of irradiation in the wavelength range $240 \leq \lambda \leq 270$ nm, the dissociation of peroxy-radicals plays an important role in processes involving them[69,144]. Thus the photolysis of peroxy-radicals (77 K), obtained by the γ-irradiation of solutions of butyl chlorides in 3-MP, leads to the formation of 3-methylpentyl radicals from n-, s-, and t-butyl chlorides, while isobutyl chloride gives rise to isobutyl radicals. It is believed that both substitution reactions and peroxy-radical dissociation reactions can occur:

$$R\dot{O}_2 \xrightarrow{h\nu} \dot{R} + O_2 \ .$$

The quantum yields in the consumption of peroxy-radicals, measured in PE, DPE, PP, and DPP, are presented in Table 4. Evidently, with increase of temperature from 77 to 300 K, the quantum yield increases significantly, the increase occurring over a narrow temperature range above 170 K, because, for example, in PP, the rate of the photochemical reaction of peroxy-radicals does not change in the temperature range from 77 to 170 K.[141]

Table 4. The quantum yields of photochemical reactions of peroxy-radicals[150-151] (ROȮ → Ṙ).

Polymer	Quantum yield		Polymer	Quantum yield	
	77 K	300 K		77 K	300 K
PE	0.3±0.1	—	PP	0.1±0.03	—
DPE	0.2±0.07	0.7±0.3	DPP	0.04±0.01	0.7±0.3

The ESR spectra of peroxy-radicals in γ-irradiated PTFE, obtained by the reaction with oxygen of the terminal and central macroradicals, are identical and consist of an asymmetric signal with $g_\perp = 2.007$ and $g_\parallel = 2.038$.[152] The action of radiation at a wavelength $\lambda \leq 280$ nm on the central radicals ~$CF_2C(O\dot{O})FCF_2$~ induces their conversion into terminal fluoroalkyl radicals[152-156]. CF_2O and CO were detected among the reaction products by mass spectrometric and infrared spectroscopic methods[152]. It has been suggested that the photolysis proceeds as follows:

$$\sim CF_2\underset{\underset{O\dot{O}}{|}}{CF}CF_2 \sim \xrightarrow{h\nu} \sim CF_2\dot{C}F_2 + CF_2O + CO + CF_3{-}CF_2\sim .$$

The action of light on the terminal peroxy-radicals in PTFE at temperatures below 170 K leads to the formation of terminal fluoroalkyl radicals and oxygen[152]:

$$\sim CF_2CF_2O\dot{O} \xrightarrow{h\nu} \sim CF_2\dot{C}F_2 + O_2 \ .$$

The results presented agree satisfactorily with data obtained in the study of the thermal decomposition of peroxy-radicals in PTFE *in vacuo* at 473 K.[157,158] It was observed that the decomposition of the peroxy-radicals obtained from the central and terminal macroradicals leads to the appearance in the ESR spectra of signals due to the central and terminal macroradicals. At the same time, the formation of considerable amounts of CO, CO_2, and CF_2O among the gaseous reaction products has been observed, which indicates the dissociation of the C–C bonds in the polymer chain. It is important to note that the decomposition of the peroxy-radicals obtained from the central macroradicals leads to a significant decrease of the molecular weight, while the decomposition of the peroxy-radicals obtained from the terminal macroradicals hardly changes this quantity.

The photolysis of the peroxy-radical ~$CF_2\underset{\underset{{}^{18}O{}^{18}\dot{O}}{|}}{CF}CF_2$~, labelled with the ^{18}O isotope, leads to the formation of considerable amounts of $C^{18}OO$ and $C^{18}O$, which the authors[158] attribute to the occurrence of the following reactions:

$$\sim CF_2C(^{18}O{}^{18}\dot{O})FCF_2 \sim \xrightarrow{h\nu} [\sim CF_2CF^{18}O{}^{18}OCF_2\sim] \rightarrow \sim CF_2\underset{\underset{{}^{18}O}{\|}}{CF} + {}^{18}\dot{O}CF_2\sim \ ,$$

$$^{18}\dot{O}CF_2\sim \rightarrow CF_2{}^{18}O + \dot{C}F_2\sim \ ,$$

$$CF_2{}^{18}O + H_2O \rightarrow HF + C^{18}OO \ .$$

At temperatures above 170 K, the photodissociation of the peroxy-radicals obtained from the terminal macroradical proceeds via the reaction

$$\sim CF_2CF_2O\dot{O} \xrightarrow{h\nu} \sim CF_2\dot{C}F_2 + 2CF_2O \ .$$

In each decomposition step the free valence migrates via the polymer chain over a distance equal to two C–C bond lengths, which leads to the photorecombination of the radicals in the system[149,159]. Analysis of the amounts of fluoride ions obtained by the hydrolysis of the gaseous products evolved on photolysis shows that between 50 and 90 fluoride ions are produced for each disappearing peroxy-radical, which confirms the chain mechanism of the photochemical reactions of peroxy-radicals in PTFE. The quantum yields in the consumption of peroxy-radicals in PTFE are 0.015 ± 0.005 at 77 K and 0.1 ± 0.03 at 300 K.[150]

Thus the mode of photodissociation of peroxy-radicals in PTFE depends on their nature and is accompanied by the dissociation of C–C or C–O bonds. The peroxy-radicals obtained in hydrocarbon matrices can apparently undergo dissociation and substitution reactions.

IV. PHOTOCHEMICAL REACTIONS OF ACYL RADICALS

The study of the mechanisms of the low-temperature photolysis and radiolysis of various classes of oxygen-containing compounds by ESR led to the observation of radicals giving rise to spectral lines with a *g*-factor smaller than for the free electron. The absence of HFS in the ESR spectra made it difficult to explain the nature of the radical species and initially many investigators attributed the singlet line either to alkoxy-radicals RȮ[160-165] or to the radicals RCOȮ.[166]

Analysis of the literature data shows that the singlet lines in the EPR spectra with $\Delta H \cong 10$–16 G and $g \cong 2.0010$ are due to the acyl radicals RĊO. In certain cases HFS is observed with a splitting of approximately 5 G,[167-171] which is confirmed by the theoretical calculation for the acetyl radical[172]. Acyl radicals can be formed in photochemical processes either as a result of the photolysis of molecules[173-179] or as a result of secondary photochemical reactions of radicals.[180-182]

Data for the absorption spectra of acyl radicals are presented in Table 5. The unpaired electron is located in acyl radicals in the sp^2-orbital. The absorption in the range 500 to 550 nm is associated with the transfer of the unpaired electron to the π*-orbital (the C–CO angle then changes from 120° to 180°, i.e. the radical acquires a linear structure). The absorption in the range 450–500 nm is associated with the transfer of the lone electron pair in the *p*-orbital of the oxygen atom to the π*-orbital[7].

The excitation of acyl radicals leads to their dissociation (the dissociation energies of these radicals are low and are in the range 5.4–11 kcal mol^{-1} [195-197]). The dissociation of acyl radicals with the formation of the corresponding alkyl radicals and carbon monoxide under the influence of radiation at the wavelength corresponding to the absorption band has been observed in many systems (see, for example, Refs.198

to 201). The reverse process, involving the addition of CO to radicals, takes place effectively in the dark.

At the same time it has been noted[178] that the action of ultraviolet radiation on acyl radicals at 77 K in di-n-heptadecyl ketone results in the disappearance of the singlet line with $\Delta H \cong 15$ G from the ESR spectrum and the appearance of a multiplet spectrum with an overall width of approximately 170 G, which the authors assigned to the radical $\sim CH_2\dot{C}HCHO$. These changes were explained by the isomerisation of the acyl radicals:

$$\sim CH_2CH_2\dot{C}O \overset{h\nu}{\rightleftarrows} \sim CH_2\dot{C}HCHO \ .$$

The hypothesis of the isomerisation reactions also served as the basis of an explanation of the results obtained in the photolysis of PE and PP.[176,177]

Analogous changes in the ESR spectra were observed in the photolysis of acyl radicals in isobutyraldehyde at 77 K. However, mass spectrometric analysis of the gaseous products showed that this entails vigorous formation of CO and the consequent establishment of a rapid sequence of the following reactions[173]:

$$(CH_3)_2CH\dot{C}O \overset{h\nu}{\rightleftarrows} (CH_3)_2\dot{C}H + CO \ ,$$

$$(CH_3)_2\dot{C}H + (CH_3)_2CHCHO \rightarrow \begin{cases} (CH_3)_2CH\dot{C}O \\ (CH_3)_2\dot{C}CHO \end{cases} + (CH_3)_2CH_2 \ .$$

Thus data [176–178] obtained solely on the basis of the analysis of poorly resolved ESR spectra are open to objection and at the present time it can be regarded as established that the principal photochemical process involving acyl radicals is their dissociation.

The formation of acyl radicals in the course of photolysis and radiolysis greatly increases the region of the spectral sensitivity of the materials and promotes their effective decomposition under the influence of light. For example, a study of the mechanism of the photolysis of acetaldehyde at 77 K showed that the rate of accumulation of CO and methane exceeds almost by an order of magnitude the rate of accumulation of the radicals[200]. Since, according to the results of Pariiskii et al.[201], the contribution of the molecular decomposition of acetaldehyde in photolysis by the total radiation of a high-pressure mercury lamp at 77 K is 30%, the high rate of accumulation of gaseous products is associated with the effective dissociation of the acetyl radical:

$$CH_3\dot{C}O \overset{h\nu}{\rightleftarrows} \dot{C}H_3 + CO \ .$$

V. PHOTOCHEMICAL REACTIONS OF RADICALS DERIVED FROM ALCOHOLS AND ETHERS

The radiolysis of alcohols and ethers and their photolysis sensitised or initiated by various additives in the solid phase involve the preferential formation of the radicals $R_1R_2\dot{C}OR_3$ most stable under these conditions, where R_1, R_2, and R_3 are hydrogen atoms or alkyl groups.

The conjugation of the unpaired electron with the electrons of the lone pair of the oxygen atom leads to a bathochromic shift in the absorption spectra of the radicals relative to the spectra of the initial compounds. Table 6 presents the available literature data for the absorption spectra of radicals derived from alcohols and ethers. The excited state of alcohol and ether radicals arises when a π-electron of the carbon atom is transferred to the σ^*-orbital (the transition is forbidden by symmetry rules)[6]. The action of radiation at the wavelengths corresponding to the absorption bands of the alcohol and ether radicals induces photochemical reactions, which have been investigated in a large number of studies[113, 114,160–164,167,168,180,192,193,210–212,218,229,230,233–262].

The photochemical reactions of alcohol and ether radicals were first observed in a study[211] where the changes occurring under the influence of radiation on a series of alcohols and ethers subjected to preliminary γ-irradiation at 77 K were recorded by ESR. For methanol and CH_3OD, a doublet ESR spectrum was observed under these conditions with a splitting of 129 G, but for deuteromethanol (CD_3OD) a doublet spectrum was not noted. The lack of a correct interpretation of the ESR spectra precluded the explanation of the experimental results.

When dilute frozen solutions of acetaldehyde in ethanol were photolysed at 77 K directly in the resonator of the ESR spectrometer, it was observed[233,234] that the alcohol radicals $CH_3\dot{C}HOH$ formed in this system in the course of the photolysis are effectively decomposed by ultraviolet radiation with formation of methyl radicals.

A sharp increase of the yield of gaseous and liquid products was observed[235,236] after the ultraviolet irradiation of alcohols subjected to preliminary γ-radiolysis at 77 K. The increase of the amounts of hydrogen and CO was attributed in the case of methanol to the photolysis of the radicals $\dot{C}H_2OH$:

$$\dot{C}H_2OH \overset{h\nu}{\rightarrow} H\dot{C}O + H_2 \ ,$$

$$H\dot{C}O \overset{h\nu}{\rightarrow} H + CO \ .$$

However, the proposed mechanism did not explain the increase of the yield of the remaining gaseous and liquid products. The authors[235,236] suggested that complexes of the radicals with alcohol molecules are formed, in which the alcohol molecule can be decomposed as a result of the absorption of radiation by the radical.

Table 6. Absorption spectra of radicals derived from alcohols and ethers.

*The notation is the same as in Table 1.

The greatest number of studies have been devoted to the photochemical reactions of radicals in methanol, ethanol, and diethyl ether. The benzene-sensitised and hydrogen peroxide-initiated photolysis of methanol and ethanol at 77 K has been investigated[162,237,238] and, on the basis of the study of the kinetics of the accumulation and interconversion of the radicals, a mechanism has been proposed for the photochemical reactions of the alcohol radicals. Under the influence of the ultraviolet radiation of a high-pressure mercury lamp on the $CH_3OH + H_2O_2$ system, the formation of the radicals $\dot{C}H_3$ and $H\dot{C}O$ was recorded by EPR, their concentration rising to a limit. The amount of gaseous photolysis products increased continuously and their composition was independent of the duration of photolysis (57% H_2, 26% CO, and 17% CH_4). At the same time the increase of the concentration of free radicals was accompanied by a decrease of the rate of consumption of hydrogen peroxide, indicating the occurrence of hydrogen peroxide-initiated reactions, which continued for some time even without the participation of the initiator. Two possible mechanisms of the photolysis of alcohol radicals, taking into account the experimental results obtained, have been examined[237]. The first presupposes the formation of the radicals $\dot{C}H_3$ and $H\dot{C}O$ in parallel reactions:

$$\dot{C}H_2OH \xrightarrow{h\nu} \begin{cases} \ddot{C}H_2 + \dot{O}H \xrightarrow{2CH_3OH} \dot{C}H_3 + 2\dot{C}H_2OH + H_2O \\ H\dot{C}O + H_2 \end{cases} \quad (1)$$

The second involves the photolysis of the radicals $\dot{C}H_2OH$ linked by hydrogen bonds to the surrounding alcohol molecules:

(2)

The necessity for hydrogen bonds to permit the formation of the radicals $\dot{C}H_3$ in the photolysis of methanol radicals was confirmed by a study[239] where the authors failed to observe the formation of methyl radicals when methanol radicals were photolysed in a sulphuric acid matrix. Data[162,240], according to which an increase of the concentration of free radicals (to 30%) was observed when the radicals $\dot{C}H_2OH$, obtained by the benzene-sensitised photolysis of methanol at 77 K, were irradiated at wavelengths in the range $290 \leq \lambda \leq 320$ nm and γ-irradiated methanol was exposed to light at wavelengths in the range $240 \leq \lambda \leq 400$ nm, can serve as evidence in support of the possibility of reactions (1) and (2). However, in the majority of studies, for example those[161,180,192,210] where the alcohol radicals were obtained by γ-radiolysis, an increase of the radical concentration was not observed when the radicals $\dot{C}H_2OH$ were exposed to ultraviolet radiation.

An ESR study of the radicals obtained as a result of the irradiation at $\lambda = 253.7$ nm at 77 K of ethanol deuterated in various positions resulted in the measurement of the spectra of the radicals $\dot{C}_2H_5(C_2H_5OH)$, $\dot{C}_2H_5(C_2H_5OD)$, $CD_3\dot{C}H_2(CD_3.CH_2OH)$, and $CH_3\dot{C}D_2(CH_3CD_2OH)$.[241] Evidently, when a quantum of radiation is absorbed by an alcohol radical, ethyl radicals are formed from alcohol molecules linked to the radicals by hydrogen bonds.

The photochemical reactions of radicals in ethanol and diethyl ether in the hydrogen peroxide-initiated and naphthalene-sensitised photolysis have been investigated in detail[171] When light was allowed to act on ethanol and diethyl ether containing added hydrogen peroxide at 77 K, the radicals $\dot{C}H_3$ and $\dot{C}_2H_5$ were detected in the ESR spectra. In the dark, the alkyl radicals were converted into the radicals $CH_3\dot{C}HOR$ ($R = H$ or C_2H_5) and in addition a radical giving rise to a

singlet ESR spectrum appeared. In the naphthalene-sensitised photolysis the ESR spectra revealed the presence of the radicals $\dot{C}H_3$, $\dot{C}_2H_5$, $CH_3\dot{C}HOR$, and, after prolonged photolysis, $CH_3\dot{C}O$, to which a singlet ESR spectrum was assigned. Analysis of the gaseous products, carried out simultaneously with the ESR study of the radicals, showed that in diethyl ether the ratio of the amount of hydrogen to that of ethane diminished with increasing duration of the exposure to radiation, while in ethanol it increased. On this basis, it was concluded that the photolysis of the radicals $CH_3\dot{C}HOH$ results in the formation of hydrogen, while the photolysis of the radicals $C_2H_5O\dot{C}HCH_3$ leads to ethane. The following mechanism has been proposed to account for the results[171]:

$$CH_3\dot{C}HOR \xrightarrow{h\nu} CH_3CHO + \dot{R} \ , \qquad (3)$$

$$CH_3\dot{C}H(H)-O-OCH_2CH_3 \xrightarrow{h\nu} CH_3CHO + H_2O + \dot{C}_2H_5 \ , \qquad (4)$$

$$CH_3\dot{C}HOR \xrightarrow{h\nu} \dot{C}H_3 + \ddot{C}HOR \ , \qquad (5)$$

$$\ddot{C}HOR \xrightarrow{h\nu} CO + RH \ ,$$

$$\ddot{C}HOR \rightarrow RCHO \ ,$$

$$\dot{C}H_3\ (\dot{C}_2H_5) + CH_3CH_2OR \rightarrow CH_4\ (C_2H_6) + CH_3\dot{C}HOR \ ,$$

$$\dot{R} + CH_3CHO \rightarrow RH + CH_3\dot{C}O \ ,$$

$$CH_3\dot{C}O \xrightarrow{h\nu} \dot{C}H_3 + CO \ . \qquad (6)$$

This mechanism explained many experimental results; however, the preferential occurrence of reaction (5) compared with reaction (6), which the authors[171] postulated, conflicted with the detection[164] of $\dot{C}_2H_5$ and species giving rise to a singlet ESR spectrum rather than methyl radicals when ethanol radicals $CH_3\dot{C}HOH$ were irradiated at a wavelength in the range $300 \leq \lambda \leq 400$ nm.

The mechanism of the photolysis of alcohol and ether radicals has been studied in greatest detail by Chervonenko and coworkers[180,192]. According to these investigators, the principal reaction of alcohol radicals is their dissociation reaction (3). This mechanism is supported by a number of factors.

1. The main product when alcohol radicals are irradiated is hydrogen.

2. The formation of ethyl radicals is observed in the photolysis of the radicals $\dot{C}H_2OH$ in methanol in the presence of ethylene, which is an effective acceptor of hydrogen atoms, while the rate of consumption of $\dot{C}H_2OH$ radicals increases markedly as a result of the suppression of the process

$$CH_3OH + H \rightarrow \dot{C}H_2OH + H_2 \ .$$

3. Calculation on the $\dot{C}H_2OH$ radical by the CNDO method showed[192] that, after the excitation of the π-electron to the lowest vacant σ-orbital, the O–H bond order diminishes, i.e. the bond is weakened. The dissociation of ether radicals takes place similarly. The quantum yields of reaction (3), determined from the initial linear sections of the kinetic curves for the accumulation of hydrogen in ethanol and of ethane in diethyl ether under the influence of light at a wavelength $\lambda = 310$ nm at 77 K on the corresponding radicals proved to be 0.3 ± 0.2.

The formation of the radicals $R_1R_2\dot{C}H$ in the photolysis of the alcohol radicals $R_1R_2\dot{C}OH$ has been explained[180,192] by reaction (4). The quantum yield of this process, measured in ethanol under the influence of light at a wavelength $\lambda = 310$ nm is 0.03 ± 0.02. Hydrogen bonds play an important role in reaction (4), but one should note that the mechanism proposed requires the transfer of excitation energy over a considerable distance, which imposes severe limitations on the probability of its occurrence. At the same time CNDO calculations for the $\dot{C}H_2OH$ radical showed that the C–O bond is strengthened in the excited state, so that the occurrence of reactions (1) and (2) is unlikely.

Studies have been published recently[114,218,242-244] in which a fundamentally different mechanism is proposed for the formation of the radicals $R_1R_2\dot{C}H$ in the photolysis of alcohol radicals, involving their photoionisation. According to theoretical estimates[245], the ionisation potential of the alcohol radicals $CH_3\dot{C}HOH$ in a solid acetaldehyde matrix can be reduced to 2.5 eV, which corresponds to the energy of a light quantum with a wavelength $\lambda = 495$ nm.

A study of the influence of radiation at a wavelength $\lambda = 253.7$ nm on ethanol radicals, obtained in the photolysis of hydrogen peroxide solutions in ethanol at 77 K in the presence of N_2O, established[218] that the gaseous reaction products contain nitrogen, the formation of which is associated with photoionisation of the alcohol radical:

$$CH_3\dot{C}HOH \xrightarrow{h\nu} CH_3CHOH^+ + e^- \ ,$$

$$e^- + N_2O \rightarrow N_2 + O^- \ .$$

The accumulation of ethyl radicals formed in the photolysis by light at wavelengths in the range $250 \leq \lambda \leq 350$ nm of the alcohol radicals $CH_3\dot{C}HOH$ in γ-irradiated neutral, acid, and alkaline ethanol solutions at 77 K, has been investigated. It has been observed that the initial rate of accumulation of $\dot{C}_2H_5$ is almost independent of the concentration of added acid (H_2SO_4), but decreases sharply with increase of the amount of added alkali (NaOH), At the same time the limiting yield of $\dot{C}_2H_5$ is a maximum in neutral solutions and decreases both with increase of the concentration of alkali and with increase of the concentration of the acid. In order to explain the experimental data obtained, the following reactions have been postulated[242]:

$$CH_3\dot{C}HOH \rightarrow CH_3CHOH^+ + e^- \ ,$$

$$C_2H_5OH + CH_3CHOH^+ \rightarrow CH_3CHO + C_2H_5OH_2^+ \ ,$$

$$e^- + C_2H_5OH_2^+ \rightarrow \dot{C}_2H_5 + H_2O \ .$$

Furthermore, in alkaline media, the reactions

$$C_2H_5O^- + C_2H_5OH_2^+ \rightarrow 2C_2H_5OH \ ,$$

$$OH^- + C_2H_5OH_2^+ \rightarrow C_2H_5OH + H_2O \ ,$$

can occur, while in acid matrices there is a possibility of the reactions

$$e^- + HSO_4^- \rightarrow SO_4^{2-} + H \ ,$$

$$H + C_2H_5OH \rightarrow CH_3\dot{C}HOH + H_2 \ .$$

The possibility of the photoionisation of alcohol radicals has been considered in a number of studies[114,243,244] to explain the results obtained when radicals were u.v. irradiated in water–methanol mixtures, ethylene glycol–water mixtures[243], and ethanol[244] irradiated at 77 K. However, according to the authors[244], it remains obscure why the radicals $R_1R_2\dot{C}H$ are not formed on annealing stabilised electrons in irradiated specimens.

Thus the main process associated with the action of radiation on alcohol and ether radicals is their dissociation. On the other hand, the problem of the mechanism of the formation of the radicals $R_1R_2\dot{C}H$ in the photolysis of alcohol radicals requires additional study.

The occurrence of the photochemical reactions of radicals in poly(vinyl alcohol)[229,230] and poly(ethylene oxide)[246] at 77 K and higher temperatures lead to an effective degradation of the polymers.

VI. PHOTOCHEMICAL REACTIONS OF RADICALS DERIVED FROM ESTERS, ALDEHYDES, KETONES, ACIDS, AND ACID ANHYDRIDES

Data for the absorption spectra of ester, aldehyde, ketone, acid, and acid anhydride radicals are presented in Table 7. The photochemical reactions of ester radicals were first

reported in a study[211] where the appearance of a doublet signal with a splitting of 129 G was observed in the ESR spectra of methyl acetate (γ-irradiated at 77 K) after its exposure to ultraviolet radiation.

Table 7. Absorption spectra of radicals derived from esters, aldehydes, ketones, acids, and acid anhydrides.

Radical	λ_{max}	$10^{-3}\varepsilon_{\lambda max}$, litre mol^{-1} cm^{-1}	Conditions of generation*	Refs.

*The notation is the same as in Table 1.

The photochemical reactions of the radicals in methyl formate and methyl acetate in the toluene-sensitised or hydrogen peroxide-initiated photolysis at 77 K have been investigated[275]. When the radicals $RCOO\dot{C}H_2$ were irradiated at a wavelength in the range $290 \leq \lambda \leq 380$ nm, the formation of methyl and formyl radicals as well as radicals giving rise to a singlet ESR line was observed. The total number of free valences then increases, which was attributed to the following reactions:

$$RCOO\dot{C}H_2 \xrightarrow{h\nu} \begin{cases} \rightarrow H\dot{C}O + RCHO \\ \rightarrow \ddot{C}H_2 + RCOO\dot{} \end{cases},$$

$$\ddot{C}H_2 + RCOOCH_3 \rightarrow \dot{C}H_2 + RCOO\dot{C}H_2 .$$

The singlet line in the ESR spectra was assigned to radicals of the type RCOO (resistant to the action of light according to the authors), RO, and ROCO (which enter into photochemical reactions). This interpretation of the spectra is open to serious objections, because it is known[276] that radicals of type RCOO are unstable and decompose spontaneously, while radicals of the type RO cannot be stabilised in ester matrices. Analogous changes in the ESR spectra were observed in the photolysis of methyl acetate, sensitised by aromatic compounds, at 77 K.[277]

The photochemical reactions of the free radicals formed in the photolysis sensitised by aromatic compounds and γ-radiolysis of alkyl acetates at 77 K have been studied in detail[182, 278-280]. It was established that the radicals formed as a result of the abstraction of a hydrogen atom from the alcohol moiety of the molecule are effectively photolysed by light at a wavelength $\lambda = 365$ nm, giving rise to acetyl radicals and the molecules of the corresponding aldehydes and ketones;

$$CH_3COO\dot{C}R_1R_2 \xrightarrow{h\nu} CH_3\dot{C}O + O{=}CR_1R_2 .$$

The action of light at a wavelength $\lambda \geq 300$ nm on the radicals arising following the abstraction of a hydrogen atom from the acid moiety of the molecules obtained on γ-irradiation (at 77 K) of α-halogenoacid esters did not lead to an appreciable change of the ESR spectra[280]. Possibly in this case the reaction proceeds via the following mechanism:

$$R_1R_2\dot{C}COOR \rightarrow R_1R_2C{=}C{=}O + \dot{O}R .$$

However the lack of data for the photolysis products precludes a final determination of its mechanism at the present time.

The study of the photochemical reactions of ester radicals in polymeric matrices [poly(vinyl acetate) (PVA), poly(methyl methacrylate) (PMMA), and others] is of considerable interest. It has been established[76,155,281-283] that the action of light at a wavelength $\lambda \leq 380$ nm on the radicals $\sim CH_2\dot{C}(OCOCH_3)CH_2\sim$, which are formed in PVA γ-irradiated at 77 K, leads to the formation of radicals giving rise to a 4-line ESR spectrum with a splitting of 23 G and intensity ratios of 1 : 3 : 3 : 1. When PVA specimens are kept at 77 K, the initial ESR spectrum is restored. The observed reactions of the radicals of PVA were explained by the isomerisation of the macroradicals[76,155,282]:

$$\sim CH_2\dot{C}(OCOCH_3)CH_2\sim \underset{}{\overset{h\nu}{\rightleftarrows}} \sim CH(OCOCH_3)\dot{C}HCH(OCOCH_3)\sim .$$

However, the study of the gaseous products formed in the photolysis of the radicals $\sim CH_2\dot{C}(OCOCH_3)CH_2\sim$ by light at a wavelength $\lambda \geq 360$ nm showed[283] that this involves the accumulation of considerable amounts of methane and carbon monoxide. Consequently macroradicals undergo photodissociation in this instance too:

$$\sim CH_2\dot{C}(OCOCH_3)CH_2\sim \xrightarrow{h\nu} \sim CH_2\underset{\underset{O}{\|}}{C}CH_2\sim + CH_3\dot{C}O ,$$

with subsequent photolysis of the acetyl radicals. Thus the 4-line ESR spectrum observed in a number of studies[76,155,281,282] refers to the methyl radical and not to $\sim CH(OCOCH_3)\dot{C}HCH.(OCOCH_3)\sim$.

When PMMA,[282,284] poly(methyl acrylate), and poly(n-hexyl methacrylate)[284] specimens γ-irradiated at 77 K were exposed to radiation, changes were observed in the ESR spectra, which were explained by the occurrence of a number of photochemical reactions of free radicals. However, the mechanism proposed by the authors[284] for these processes is inaccurate owing to the erroneous interpretation of certain signals in the ESR spectra.

When poly(ethyl acrylate) γ-irradiated at 77 K is exposed to light[285], the radical species giving rise to a singlet ESR spectrum vanishes and ethyl radicals are formed:

$$\sim CH_2-\underset{\dot{O}-\underset{\dot{O}-C_2H_5}{\overset{|}{C}}-C_2H_5}{\overset{|}{CH}}\sim \xrightarrow{h\nu} \dot{C}_2H_5 + \sim CH_2-\underset{\underset{\dot{O}-C_2H_5}{\overset{|}{C}}=O}{\overset{|}{CH}}\sim .$$

However, the observed changes in the ESR spectra are most probably associated either with the photochemical reactions of the acyl radicals or with the photolysis of the corresponding radical-anion, which can be stabilised in the ester matrix on γ-radiolysis[286,287].

The mechanism of the photochemical reactions of radicals in PMMA has been studied in greatest detail by Toptygin and coworkers[198,199,288]. Analysis of the ESR spectra established

that the radicals in PMMA enter into the following photochemical reactions:

$$\sim (CH_3)\,C\,(COOCH_3)\,\dot{C}H\,(CH_3)\,C\,(COOCH_3) \sim \xrightarrow{h\nu} \rightarrow \sim (CH_3)\,C\,(COOCH_3)\,CH{=}C\,(CH_3) + O\dot{C}OCH_3 \ .$$

The radicals $O\dot{C}OOCH_3$ dissociate under the influence of light at a wavelength $\lambda \leq 380$ nm with formation of $\dot{C}H_3$ and CO_2 (it has been established[289] that the radicals $O\dot{C}OR$ have an absorption maximum at $\lambda = 330$–335 nm; $\varepsilon \cong 10^3$ litre mol^{-1} cm^{-1}; the quantum yield of photolysis by light at a wavelength $\lambda = 313$ nm at 77 K is 0.24).

The radicals formed as a result of the abstraction of a hydrogen atom from the alcohol moiety in PMMA dissociate under the influence of radiation to form the radicals $H\dot{C}O$:

$$\sim CH_2\,(CH_3)\,C\,(COO\dot{C}H_2)\,CH_2 \sim \xrightarrow{h\nu} [\sim CH_2\,(CH_3)\,C\,(\dot{C}{=}O)\,CH_2 \sim + H_2CO] \rightarrow \rightarrow \sim CH_2\,(CH_3)\,C\,(CHO)\,CH_2 \sim + H\dot{C}O \ .$$

Furthermore, it might have been expected that photochemical reactions of central macroradicals can occur in PMMA with dissociation of the main polymer chain, for example:

$$\sim (CH_3)C(COOCH_3)\,\dot{C}H\,(CH_3)C(COOCH_3) \sim \xrightarrow{h\nu} \dot{C}H_2 \sim (CH_3)C(COOCH_3) \sim + + \sim (CH_3)C(COOCH_3)\,CH{=}(CH_3)C(COOCH_3) \ .$$

The study of the degradation of PMMA in its photolysis initiated by iron(III) chloride and potassium hexacyanoferrate(II) [290,291] and in the direct photolysis and photolysis sensitised by aromatic compounds[287,292,293] showed that the decomposition of the main polymer chain occurs mainly in thermal and not photochemical reactions of radicals.

An ESR study of the photolysis of liquid acetone in the presence of various additives established that, together with the spectrum due to the radical $\dot{C}H_2COCH_3$, there are lines associated with the methyl radical[294]. On this basis, the authors suggested that the following reaction occurs on irradiation:

$$\dot{C}H_2COCH_3 \xrightarrow{h\nu} \dot{C}H_3 + CH_2{=}C{=}O \ . \qquad (7)$$

The action of light at a wavelength $\lambda \leq 340$ nm on the radicals $\dot{C}H_2COCH_3$, stabilised in acetone γ-irradiated at 77 K, led to a decrease of their concentration and to a simultaneous increase of the concentration of methyl radicals $\dot{C}H_3$ and acetyl radicals, giving rise to a singlet ESR spectrum[264]. The rate constants for the destruction of acetonyl radicals and the accumulation of $\dot{C}H_3$ radicals, obtained from the linear sections of the kinetic curves, proved to be approximately equal. These data confirm that the acetonyl radical decomposes via reaction (7). The appearance of the radicals $CH_3\dot{C}O$ may be caused by the photolysis of keten and by the subsequent dark reactions involving CO. Analogous results were obtaineed in a study of the photolysis of acetone in the presence of hydrogen peroxide[295].

The mechanisms of the photolysis of aliphatic aldehydes and ketones at 77 K (acetaldehyde, propionaldehyde, and isobutyraldehyde; ethyl methyl ketone, isopropyl methyl ketone, and diethyl ketone) have been investigated. It has been observed[173,265,296] that, when radicals are irradiated at a wavelength $\lambda \leq 340$ nm in aldehydes and ketones, changes occur in the ESR spectra, associated, according to the authors, with the following reactions:

$$R_1R_2\dot{C}CHO \xrightarrow{h\nu} R_1R_2\dot{C}H + CO \ ,$$
$$R_1R_2\dot{C}COR \xrightarrow{h\nu} R_1R_2\dot{C}H + R'{=}C{=}O \ .$$

It is important to note that the reaction mechanism has been proposed solely on the basis of the analysis of complex ESR spectra and apparently consists of many stages. When solutions of hydrogen peroxide in acetic acid were acted upon by the total radiation of the high-pressure mercury lamp at 77 K, the formation of methyl and formyl radicals as well as species giving rise to a singlet ESR spectrum was observed by ESR. The authors[275] believe that, under the influence of light at a wavelength $\lambda \leq 400$ nm, the $\dot{C}H_2COOH$ radicals undergo a branched-chain photolysis with formation of the radicals $\dot{C}H_3$, $H\dot{C}O$, and $\dot{C}OOH$:

$$\dot{C}H_2COOH \xrightarrow{h\nu} \begin{cases} \rightarrow H\dot{C}O + CH_2O \\ \rightarrow \dot{C}H_2 + \dot{C}OOH \end{cases} \ , \qquad (8)$$
$$\dot{C}H_2 + CH_3COOH \rightarrow \dot{C}H_3 + CH_2COOH \ .$$

The formation of methyl radicals in the photolysis by radiation at a wavelength $\lambda \geq 270$ nm of the radicals $\dot{C}H_2COOH$, obtained by the γ-radiolysis of aqueous acetic acid solutions at 77 K, has been observed[297]. Calculation of the electronic structure of the $\dot{C}H_2COOH$ radicals by the CNDO method showed[192] that, on σ–π^* excitation, the dissociation of the C–OH bond is most probable (bond energy approximately 2.5 eV). The probability of dissociation at the C–C bond diminishes, which throws doubt on the possibility of reaction (8).

The photochemical reactions of monocarboxylic acid radicals have been studied in greatest detail by Chervonenko and Roginskii[192,298], who established that irradiation at a wavelength in the range $300 \leq \lambda \leq 400$ nm of the $R\dot{C}HCOOH$ radicals, formed in γ-irradiated acetic, propionic, butyric, and isovaleric acids, leads to the formation (among other reaction products) of CO_2 and the hydrocarbons RCH_3 in approximately equal yields. The fact that methyl radicals are formed in the CH_3COOD matrix on photolysis of the radicals $\dot{C}H_2COOD$ at 77 K shows that the radicals $R\dot{C}HCOOH$ in the excited state react with the surrounding molecules:

$$R\dot{C}HCOOH + RCH_2COOH \xrightarrow{h\nu} RCH{=}C\,(OH)_2 + RCH_2C\dot{O}O \ , \qquad (9)$$
$$RCH{=}C\,(OH)_2 \rightarrow RCH{=}C{=}O + H_2O \ ,$$
$$RCH_2C\dot{O}O \rightarrow R\dot{C}H_2 + CO_2 \ . \qquad (10)$$

The quantum yield of reaction (9), determined from the initial linear section of the curve for the accumulation of methyl radicals in 10 and 25% acetic acid solutions in 10 M H_2SO_4 on irradiation at a wavelength $\lambda = 310$ nm, proved to be $(4 \pm 2) \times 10^{-3}$.

Apart from reaction (9), the photolysis of the radicals $R\dot{C}HCOOH$ may be expected to involve processes which are difficult to detect by ESR and by analysing stable reaction products, particularly the reaction

$$R\dot{C}HCOOH \xrightarrow{h\nu} RCH{=}C{=}O + \dot{O}H \ . \qquad (11)$$

The study of the photolysis by light at a wavelength $\lambda \geq 360$ nm of the radicals $\dot{C}H_2COOH$, obtained by the γ-irradiation of a 10% monochloroacetic acid solution in 1-propanol at 77 K, showed that 1-propanol radicals then accumulate. The quantum yield of the reaction for light at a wavelength $\lambda = 310$ nm is 0.3 ± 0.2.

When the radicals stabilised on γ-irradiation in acetic, propionic, and butyric anhydrides at 77 K are acted upon by light, the main process is their dissociation[299]:

$$R\dot{C}HCOOCOCH_2R \xrightarrow{h\nu} RCH{=}C{=}O + RCH_2C\dot{O}O \ . \qquad (12)$$

The dissociation is followed by the spontaneous decomposition of $RCH_2C\dot{O}O$ via reaction (10). The quantum yield of reaction (12), determined from the linear section of the kinetic curve for the accumulation of the radicals $\dot{C}H_3$ in acetic anhydride on irradiation at a wavelength $\lambda = 313$ nm at 77 K, is 0.9 ± 0.1.

Thus the main process when ester, aldehyde, ketone, acid, and acid anhydride radicals are acted upon by light at the wavelengths corresponding to their absorption bands is their dissociation.

VII. CONCLUSION

Despite the apparent wide variety of the photochemical reactions of radicals in different systems, there are certain characteristics which make it possible to predict with a particular degree of probability the type of reaction as a function of the type of excitation[5]. Table 8 shows that radicals subjected to $\pi-\sigma^*$ and $\sigma-\pi^*$ excitation undergo virtually only the photodissociation reaction and the quantum yields of these processes are high. Less definite conclusions can be reached concerning the mode of the photochemical reactions with $n-\pi^*$ excitation; here it is necessary to obtain additional experimental and calculated data.

Table 8. Photochemical reactions of free radicals of different types.

Radicals	Excitation	Type of reaction	Quantum yield	Refs.
Alkyl	$\pi \rightarrow \sigma^*$	dissociation	0.01	30
Alkyl	$\pi \rightarrow \sigma^*$	substitution	0.5 ± 0.15	30
Peroxy	$n \rightarrow \pi^*$	dissociation, substitution	$(0.04\pm0.01)\times(0.7\pm0.3)$	150, 151
Acyl	$\sigma \rightarrow \pi^*$	dissociation	—	—
From alcohols	$\pi \rightarrow \sigma^*$	dissociation, ionisation (?)	0.3 ± 0.2	180, 192
From ethers	$\pi \rightarrow \sigma^*$	dissociation	0.3 ± 0.2	180, 192
From esters	$\pi \rightarrow \sigma^*$	dissociation	—	—
From aldehydes	$\pi \rightarrow \sigma^*$	dissociation	—	—
From ketones	$\pi \rightarrow \sigma^*$	dissociation	—	—
From acids	$\pi \rightarrow \sigma^*$	dissociation	0.3 ± 0.2	192, 298
From acid anhydrides	$\pi \rightarrow \sigma^*$	dissociation	0.9 ± 0.1	192, 299

Cobalt Complexes of Carbaboranes

E.V.Leonova

The results of studies on the chemical behaviour and methods of synthesis of cobalt complexes of carbaboranes are surveyed and described systematically. The methods of synthesis are classified and the applications of each method are considered. A systematic account is given of methods for the identification of cobalt complexes of carbaboranes. The chemical properties of such complexes are determined by the structure and properties of the carbaborane ligand. The electronic configuration of the cobalt atom in different cobalt complexes of carbaboranes varies within wide limits (d^8–d^5). The review deals with studies in the period 1965-1978 and partially in 1979.

I. INTRODUCTION

Polyhedral π-complexes of metals belonging to the Cu, Cr, Mn, Fe, Co, and Ni subgroups, based on the highest and lowest carbaboranes, are now known. Preparative methods have been developed for their synthesis and their properties are being vigorously investigated. The principal achievements in this field have been described in a number of reviews[1-11]. Exhaustive information about the period from 1965 to 1972 is presented in the review of Zakharkin and Kalinin[12]. The aim of the present publication is to isolate cobalt complexes from the overall wide variety of polyhedral and transition metal π-complexes as the most typical representatives of compounds of this class which have attracted the attention of investigators.

II. GENERAL CHARACTERISTICS OF THE COMPLEXES

Carborane π-complexes of iron and cobalt having the general formula $[(B_9C_2H_{11})_2M]^{z-}$ (M = Fe or Co, $z = 2$ or 1), the formal analogues of compounds of the type of ferrocene and the cobaltocenium cation, were synthesised for the first time in 1965. In these complexes the iron and cobalt atoms are coordinated to the dicarbollide dianion[13,14]. The results of X-ray diffraction studies on metal complexes of carbaboranes[15,16], ^{11}B and ^1H NMR and NQR data[17] for these compounds, as well as their magnetic, electronic[18] and electrochemical properties agree with the hypothesis of the sandwich nature of the metal–ligand bond in these π-complexes. The possibility of the existence of metal complexes of carbaboranes follows from the quantum-mechanical description of the dicarbollide ion[19,20]. The calculation is based on the hypothesis of the formation by the five atomic orbitals of the open pentagonal B_3C_2 surface of three bonding and two antibonding molecular orbitals[19,20]. The filling of the bonding molecular orbitals with six electrons makes the dicarbollide ion an isoelectronic and isostructural analogue of the Cp anion (Cp = C_5H_5) (see also Zakharkin and Kalinin[12]).

Apart from compounds of the type $[(B_nC_2H_{n+2})_2Co]^-$, Cp-containing complexes having the general formula $(\eta^5\text{-CpCo})_mB_nC_2H_{n+2}$ ($m = 1$–4; $n = 3$–10) are also known at the present time.

One of the qualitative features of the stability of metal complexes of carbaboranes is the validity of the empirical rule concerning the number of electrons required for the formation of the π-complex with participation of bonds in the ligand. It has been shown[21] that this number is given by the formula $2k + 14$, where k is the number of vertices in the polyhedron of the metal carbaborane complex. For example, in $CpCo.B_3C_2H_{11}$ ($m = 1$, $n = 9$; 12 vertices) there are altogether 60 electrons, which include five electrons from the Cp ligand, 9 electrons from the cobalt atom, 11 electrons from the 11 hydrogen atoms, 27 electrons from the 9 boron atoms, and 8 electrons from the 2 carbon atoms. The formation of all the CH and BH bonds requires 22 electrons, while the remaining 38 electrons are involved in the formation of bonds in the π-complex and their number can be calculated from the empirical formula $2k + 14$ ($k = 12$).[21] For bimetallic carbaborane complexes $(\eta^5\text{-CpCo})_2B_nC_2H_{n+2}$, the formula $2k + 26$ is used[21].

The stability of the complexes and their chemical properties depend on the formal degree of oxidation (f.d.o.) of the metal and the overall charge of the π-complex. Complexes whose overall charge is smaller and whose metal atom has the usual f.d.o. are more stable. On the other hand, a high molecular charge of the π-complex and an uncharacteristic f.d.o. of the metal reduce the stability of the compound[21] (see also Section IV). The molecular geometry of the cobalt complex of a carbaborane also influences its stability. The most stable compounds are those whose polyhedron is an icosahedron[22]. In dicobalt complexes of carbaboranes the direct Co–Co interaction stabilises the system[23], but, at an elevated temperature, compounds in the polyhedron of which cobalt atoms do not occupy neighbouring vertices are more stable. Such a disposition of cobalt atoms does not interfere with the more vigorous vibration of the Cp rings[23].

There exists the view[21] that a complex of the type $CpCo.B_nC_2H_{n+2}$ can be regarded as a heterocarbaborane in which the BH fragment has been replaced by the isoelectronic CpCo fragment. It is suggested that, like the BH fragment, the CpCo group supplies three orbitals and two electrons of the binding process[21,24]. To a first approximation, this concept explains satisfactorily and predicts certain chemical and physicochemical properties of cobalt complexes of carbaboranes, particularly the existence of a number of analogies in the chemistry of cobalt complexes of carbaboranes and of

carbaboranes themselves[25]. An example may be provided by the polyhedral expansion and contraction, polyhedral rearrangement, and electrophilic bromination reactions. However, bearing in mind the specific formalism underlying this concept, one must use it with caution in discussing the chemical and physicochemical properties of cobalt complexes of carbaboranes. In the first place we may note that symmetrical complexes of the type $[(B_mC_2N_{n+2})_2Co]^-$, which do not contain the CpCo fragment, also have a number of properties resembling those of carbaboranes and asymmetric cobalt complexes of carbaboranes of the type $CpCoB_nC_2H_{n+2}$. These concern the involvement of the above compounds in the same polyhedral contraction (see Section III), polyhedral rearrangement, and electrophilic bromination (see Section IV) reactions.

Furthermore, the study of the ^{11}B and ^{13}C NMR of halogen-substituted cobalt complexes of carbaboranes $\{[(1,2\text{-}B_9C_2H_{11})_2.Co]^-$, $[(9\text{-}Br\text{-}1,2\text{-}B_9C_2H_{10})_2Co]^-$, and $[(9,12\text{-}Br_2\text{-}1,2\text{-}B_9C_2H_9)_2Co]^-\}$ established that the nature of the change in electron density following the introduction of the halogen is the same for the cobalt complexes of carbaboranes and icosahedral boranes and carbaboranes[26]. The most intense deshielding is observed at boron or carbon atoms occupying the opposite vertices relative to the halogen-substituted boron atoms. The carbon atoms in the complex $[(9,12\text{-}Br_2\text{-}1,2\text{-}B_9C_2H_9)_2Co]^-$ are deshielded to the greatest extent, while the $B_{(5)}$ and $B_{(11)}$ atoms, closest to the substituted $B_{(9)}$ and $B_{(12)}$ atoms, are deshielded to a smaller extent[26]. Furthermore, it has been shown for $3,1,2\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$ by infrared spectroscopy that the coordination of the dicarbollyl ligand to the cobalt atom does not abolish the capacity of the CH group for the formation of a hydrogen bond[27]. Next, a study of the photoelectron spectra of bis(dicarbollyl)cobalt derivatives containing a bridging ligand in the 8- and 8′-positions [−S−S, −S−, −S−$\overset{+}{S}$(Me)−, −S−$\overset{+}{C}$H−S−, −$\overset{+}{S}$(Me)−, and −$\overset{+}{O}$(Me)−] showed that, firstly, within the carbaborane ligand in each derivative there is a uniform distribution of charge density over the boron atoms and, secondly, the presence of a bridging atom more electronegative than boron (S, $\overset{+}{S}$, $\overset{+}{O}$) causes a shift of electron density both from the two carbaborane ligands and from the central cobalt(III) atom[28]. All these findings show that the nature of the bond within the polyhedral ligand apparently does not undergo profound and fundamental changes as a result of coordination; this entails the retention of the properties of carbaboranes in their cobalt complexes. Furthermore, whereas the presence of the negative charge in $[(B_nC_2H_{n+2})_2.Co]^-$ gives rise to certain anomalies, neutral complexes of the type $CpCoB_nC_2H_{n+2}$ are even closer in their properties to the corresponding carbaboranes. The chemical and physicochemical properties of cobalt complexes of carbaboranes therefore in general still depend largely on the structure and properties of the carbaborane fragments involved in the complex.

However, this does not imply that the role of the metal in the carbaborane complexes is insignificant. The possibility, in principle, of the existence of a metal complex of a carbaborane and its stability depend on the nature of the metal atom. In the Fe, Co, Ni series the cobalt atom, which has the stable d^6 electronic state, forms diamagnetic complexes which either have a low molecular charge $\{[(B_nC_2H_{n+2})_2Co]^-\}$ or are altogether uncharged $(CpCoB_nC_2H_{n+2})$. At the same time, as a result of its high molecular charge, the complex $[(1,2\text{-}B_9C_2H_{11})_2Fe^{II}]^{2-}$ is readily oxidised [Fe(II) → Fe(III)] and is converted into the paramagnetic complex $[(1,2\text{-}B_9C_2H_{11})_2Fe^{III}]^-$. Iron ($d^5$ electronic configuration) is an effective oxidant, which to a large extent determines the properties of the paramagnetic complex. (For nickel complexes, see Zakharkin and Kalinin[12].) One may also not that, as a result of coordination, there is a partial redistribution of electron density within the carbaborane ligand in the metal complexes.

The electron-donating influence of the *C*-substituted dianion $(B_9C_2H_{11})^{2-}$ is a combination of the inductive effect (+*I*) and the conjugation effect (+*R*).[29] The direction of the inductive effect in the coordinated dicarbollyl ligand changes (−*I*), while the nature of the conjugation effect remains the same (+*R*).[29,30] The replacement of the dicarbollyl ligand in the complex $[Co(B_9C_2H_{11})_2]^-$ by the cyclopentadienyl ligand enhances the electron-accepting properties of the residual *C*-substituted dicarbollyl group[29]. Comparison of the constants σ_i and σ_R^0, calculated by Taft's method, shows that the $B_9C_2H_{11}CoC_5H_4$ group is a stronger accepter than the $C_5H_5CoB_9C_2H_{10}$ group.

The study of the ^{11}B and ^{13}C NMR of the paramagnetic complexes $CpMB_nC_2H_{n+2}$ [$n = 6$–9, M = Cr(III), Fe(III), Ni(III), or Co(II)] showed that, firstly, there is a redistribution of the unpaired electron density from the non-bonding orbitals of the central metal atom to the molecular orbitals of the carbaborane ligand and, secondly, the unpaired electrons interact not only with atoms linked to the central metal atom, but also with the more remote boron atoms[31]. In cobalt complexes of carbaboranes containing two cobalt atoms one may expect even more profound changes in electron density distribution, particularly in those cases where a Co−Co bond is present in the complex. An increase in the number of cobalt atoms in polyhedral π-complexes should therefore apparently entail changes in properties such that the new compounds will resemble to a decreasing extent their parent compounds (carbaboranes) and the properties will probably approach those of the usual cluster compounds of cobalt. During this transition, one may expect the appearance of compounds of a new type, with unique properties different from those of carbaboranes and clusters.

Theoretically[32,33] it is possible to predict the molecular geometries on the basis of the overall number of valence electrons in the polyhedron. At the same time the structure can be established and the cobalt complexes of carbaboranes identified by comparing the ultraviolet, infrared, NMR and mass spectra as well as the oxidation-reduction potentials. The ultraviolet spectra of cobalt complexes of *closo*-carbaboranes† are known to contain a band in the range 600–650 nm (green and blue complexes), while complexes with a *nido*-structure do not absorb in this region and they are red or brown[35]. Furthermore, the isomers of cobalt complexes of carbaboranes differing in the number of carbon atoms in the open pentagonal surface coordinated to the cobalt atom also exhibit differences in their ultraviolet spectra. In the isomer sequence *a* → *b* → *c* → *d* (Fig. 1 for R = H), the number of carbon atoms diminishes from two to zero and at the same time λ_{max} for the band referred to the *d*–*d* transition undergoes a hypsochromic shift in the ultraviolet spectra of the complexes[6]. Analogous behaviour has been observed in the ultraviolet spectra of the isomers 1,2,4-, 1,2,3-, and $10,2,3\text{-}(\eta^5\text{-Cp})Co(Me_2B_8C_2H_8)$.[36] We may also note that complexes of the type $(CpCo)_2B_nC_2H_{n+2}$ ($n = 6$–8), which differ in the presence or absence of the Co−Co bond, also have characteristic absorption bands in the ultraviolet spectra[37].

The infrared spectra of cobalt complexes of carbaboranes having the general formula $(LCoB_nC_2H_{n+2})^z$ (L = Cp, $z = 0$; L = $B_nC_2H_{n+2}$, $z = -1$) retain all the principal characteristic

† For the nomenclature of the complexes, see Ref. 34 and the reviews by Zakharkin and Kalinin[12] and Grimes[193].

frequencies of the carbaboranes[35,38] and cyclopentadienyl ligands[39] and, on substitution in these ligands, the infrared spectra of the complexes exhibit the same changes as those of the substituted carbaboranes[38] and cyclopentadienylcobalt complexes[39]. The formation of the metal–dicarbollyl bond in $[Co(B_9C_2H_{11})_2]^-$ is characterised by a very intense polarised line in the Raman spectrum at 180–300 cm^{-1}, which has been assigned to the metal–dicarbollyl stretch[40].

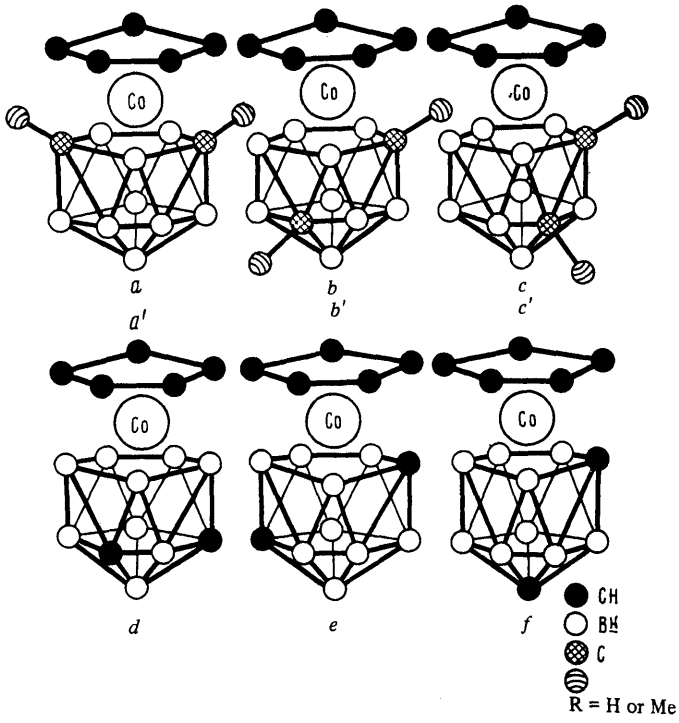

Figure 1. Postulated structures of the isomers (*a*–*f*) formed in the thermal gas-phase rearrangement of 3,1,2-(η^5-Cp)Co.$(1,2\text{-}R_2B_9C_2H_9)$: R = H (*a*–*c*) or CH_3 (*a'*–*c'*).

The use of triple resonance to observe the proton spectra with simultaneous suppression of signals due to ^{11}B and ^1H nuclei permits unambiguous assignments of the resonance lines[41]. Thus parameters of the ^1H [41] and ^{11}B [42–44] NMR spectra such as the chemical shift, the integral intensity, and the spin–spin splitting constant as well as the spin–lattice relaxation times T_1 of the ^{11}B and ^1H nuclei[45] are used successfully for the standard identification of metal complexes of carbaboranes.

Furthermore, substitution in the carbaborane ligand in $CpCo(HCB_9H_9Cr)$ leads to an alteration of the chemical shift of the protons in the Cp ring[46]. With increase of the number of bromine atoms in $CpCoB_9C_2H_{11-n}Br_n$ ($n = 1$–3), the signal of the protons of the Cp ring shifts downfield[47]. (For a description of the influence of the structure of cobalt complexes of carbaboranes on the reduction potential, see Section IV.) However, the most reliable results in the determination of the polyhedral structures were obtained by diffraction methods. X-Ray diffraction analysis of Cs[Co.$(B_9C_2H_{11})_2$] [15] yields the general type of structure of bisdicarbollylcobalt complexes. Figs.2 [48] and 3 [49] illustrate derivatives of the bisdicarbollylcobaltate anion. In both cases substitution takes place at the boron atoms. The cobalt atom in the structure of the anion $[Co(B_7C_2H_9)_2]^-$ (**Fig.4**) is located between the pentagonal B_3C_2 surfaces where the position (6 or 9) of one of the carbon atoms has not been rigorously established[16].

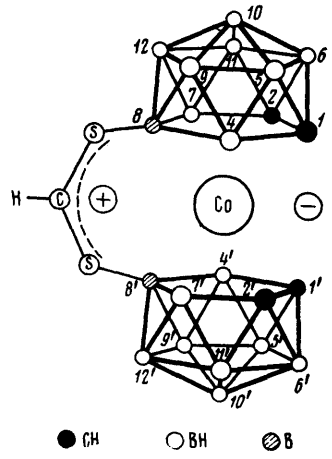

Figure 2. The structure of $[3,3'\text{-}Co(1,2\text{-}B_9C_2H_{10})_2]S_2C^+H$.[48]

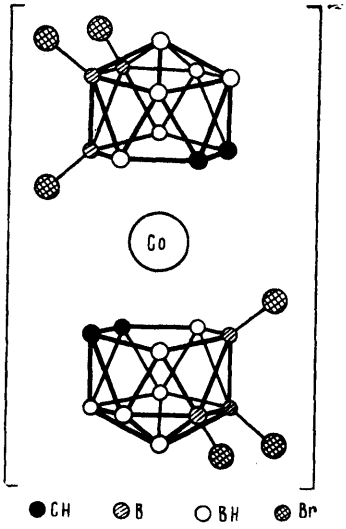

Figure 3. The structure of the $[Co(B_9C_2H_8Br_3)_2]^-$ ion[49].

The carbon atom in the $[3,4\text{-}(\eta^5\text{-}Cp)CoB_7CH_8]^-$ polyhedron (Fig.5) has a low coordination number (5),[50] which agrees with the general postulate, according to which the carbon atom in the polyhedron of the carbaborane in its metal occupies mainly a vertex with a low coordination number[51,52]. The cobalt atom in $(CpCoB_7CH_8)^-$ is coordinated to five boron atoms, where three Co–B distances are 2.15–2.18 Å while two are 1.97 and 1.98 Å.[50]

Figs. 6 and 7 present the structures of two *nido*-complexes 8,6,7-(η^5-Cp)$CoB_7C_2H_{11}$ [53] and (1,2-$B_9C_2H_{11}$-3,11'-Co-9'-C_5H_5N-7',8'-$B_8C_2H_{10}$)$^-$.[54,55] The $CpCoB_7C_2H_{11}$ molecule has a geometry similar to that of decaborane with three heteroatoms (C,C,Co) in the open first surface. Two hydrogen atoms [$H_{(1)}$ and $H_{(2)}$] occupy bridging positions[53]. The carbaborane ligand $B_8C_2H_{10}$ in $(B_9C_2H_{11}CoB_8C_2H_{10}Py)^-$ has an open six-atom surface $C_{(7')}B_{(2')}B_{(6')}B_{(10')}B_{(9')}C_{(8')}$, four atoms of the surface being involved in coordination to the cobalt atom[54,55]. The pyridine fragment is linked to the boron atom. The position of the extra hydrogen has not been established.

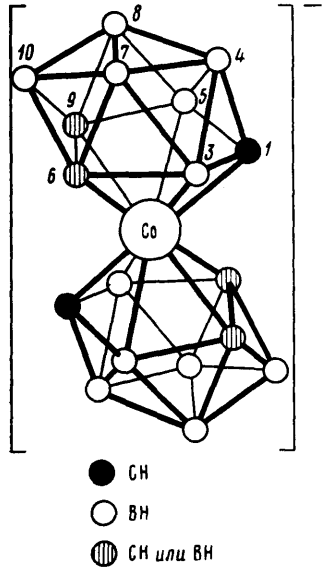

Figure 4. The structure of the $[Co(B_7C_2H_9)_2]^-$ ion[16].

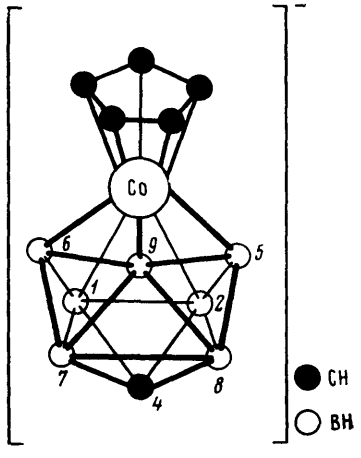

Figure 5. The structure of the $[CpCoB_7CH_8]^-$ ion[50].

The structure of 2,9,1,10-(η^5-CpCo)$_2B_6C_2H_8$ is a distorted square antiprism (Fig. 8), while the 2,3,1,7-(η^5-CpCo)$_2B_8C_2H_{10}$ molecule is a distorted icosahedron (Fig. 9). In both polyhedra the cobalt atoms occupy neighbouring vertices and the Co–Co bond length is 2.489 Å [24,52] and 2.389 Å [56] respectively.

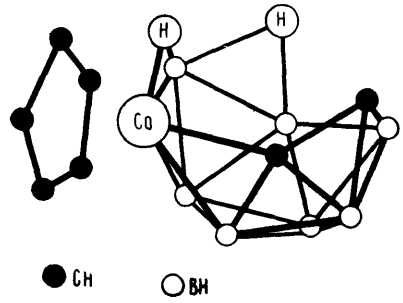

Figure 6. The structure of $CpCoB_7C_2H_{11}$.[53]

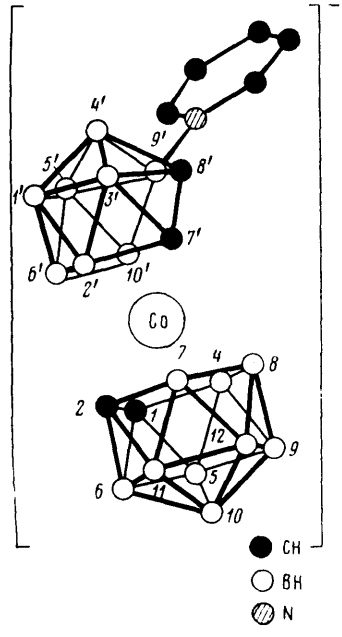

Figure 7. The structure of $[B_9C_2H_{11}Co(B_8C_2H_{10}C_5H_5N)]^-$.[54,55] (The bridging hydrogen atom is not represented.)

The carbaborane ligands in the complex [(η^5-Cp)Co_2.$(B_8C_2H_{10})_2$]$^-$ are non-equivalent and there is no Co–Co bond (Fig. 10). One of the carbaborane ligands is bidentate[44].

Figs. 11 [57,58] and 12 [58,59] illustrate di- and tri-cobalt complexes of carbaboranes, which are derived from the bidentate dicarbacanastide anion $(B_8C_2H_{10})^{4-}$. The Fe–Co bond is present in the (η^5-Cp)CoFe($Me_4B_8C_4H_8$) complex. The molecule has the form of two pentagonal bipyramids joined by the common vertex, which is occupied by the iron atom. The B–H fragment is the vertex of two trigonal pyramids, whose bases consit of the trigonal planes of the two pentagonal

bipyramids. The system is interesting because it contains two electrons less than would be expected according to the number of vertices in the polyhedron[60,63].

III. SYNTHESIS OF COBALT COMPLEXES OF CARBABORANES

The existing methods for the synthesis of cobalt complexes of carbaboranes can be largely divided into three groups. These include in the first place a series of methods based on the combination of the products of the partial degradation of carbaboranes and (or) their cobalt complexes. The "direct" synthesis, where the starting materials are *nido*- and *arachno*-carbaboranes and cobalt complexes of carbaboranes[20,61,62,64], as well as the polyhedral contraction method, based on the use of cobalt complexes of carbaboranes, should be assigned to this series. Next we may note the polyhedral expansion reaction which includes the reduction of polyhedral *closo*-carbaboranes and (or) cobalt complexes of carbaboranes by sodionaphthalene with subsequent reduction of the resulting anions by $CoCl_2$ and CpNa. These reactions lead to the formation of cobalt complexes of carbaboranes[4,52,65,66] and (or) di- and tri-cobalt carbaborane complexes[67–70] respectively, the new polyhedron containing one vertex more than the initial polyhedron. The third method involves the "direct" synthesis of cobalt complexes of carbaboranes from carbaboranes in the gas phase. We shall examine each method in detail.

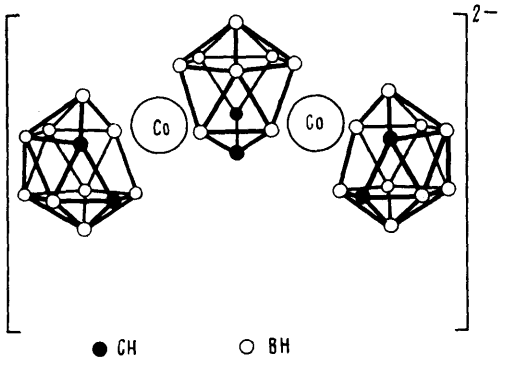

Figure 11. The structure of the $(B_9C_2H_{11}CoB_8C_2H_{10}CoB_9C_2H_{11})^{2-}$ ion[57].

1. The "Direct" Synthesis of Polyhedral Cobalt Complexes of *closo*-Carbaboranes from *nido*- and *arachno*-Carbaboranes

The method can be represented by the following general sequence of reactions:

$$B_{10}C_2H_{12-n}R_n \xrightarrow{Nu} (B_9C_2H_{12-n}R_n)^- \quad , \qquad (1)$$

$$(B_9C_2H_{12-n}R_n)^- \underset{H^+}{\overset{Nu'}{\rightleftarrows}} (B_9C_2H_{11-n}R_n)^{3-} \quad , \qquad (2)$$

$$(B_9C_2H_{11-n}R_n)^{3-} + Co^{2+} \rightarrow [(B_9C_2H_{11-n}R_n)_2Co]^- \quad . \qquad (3)$$

Attack by strong nucleophiles (Nu are alkali metal alkoxides[71,72], ammonia[73], dialkylamines[73], trialkylamines[74], piperidines[75–78], and hydrazines[79–83]) on the electropositive boron atom[38,84,85] leads to the formation of an anion with an open pentagonal surface over which the hydrogen atom is located. Studies of ^{11}B and ^{13}C NMR spectra of the isomers of the dicarba-*nido*-dodecahydroundecaborate(1-) anion showed that the bond between the "extra" hydrogen atom and

the boron atoms is of the bridge type. In the case of $(1,2\text{-}B_9C_2H_{12})^-$ it can be regarded as a three-centre bridge bond or as the product of the dynamic process $B_{(8)}\text{–}H\text{–}B_{(4)} \rightleftharpoons B_{(8)}\text{–}H\text{–}B_{(7)}$. The existence of the $B_{(8)}\text{–}H\text{–}B_{(4)}$ bridge has been postulated in the isomer $(1,7\text{-}B_9C_2H_{12})$.[86] Being an acid ($pK_a = 21.3$,[87,88] R = H), the anion $(B_9C_2H_{12-n}R_n)^-$ readily reacts with nucleophiles (Nu′ = Na,[13] NaH,[13,89] or n-BuLi [90]) with formation of the dianion $(B_9C_2H_{11-n}R_n)^{2-}$. In an aqueous medium NaOH is used as the nucleophile[20,91]. The coordination of the dicarbollide dianions to cobalt ions leads to the formation of the symmetrical polyhedron $[(B_9C_2H_{11-n}R_n)_2Co]^-$, which is an isoelectronic analogue of the cobaltocenium cation. In the presence of the Cp anion, the neutral complex $CpCo.B_9C_2H_{11-n}R_n$ is formed. $[3,1,2\text{-}B_9C_2H_{11}Co(CO)_2]^-$, an analogue of the corresponding Cp derivative of cobalt, has been obtained by treating $Co_2(CO)_8$ with the dicarbollide dianion $(B_9C_2H_{11})^{2-}$.[92]

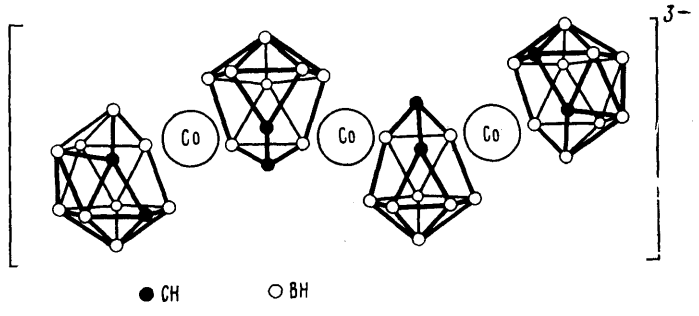

Figure 12. The structure of the $[(B_9C_2H_{11}CoB_8C_2H_{10})_2Co]^{3-}$ ion[59].

Table 1 presents the carbollyl and dicarbollyl sandwich π-complexes of cobalt obtained by the "direct" method. Columns 4 and 5 list respectively the initial carbaborane and the nucleophile (Nu) acting on the former. Next, Table 1 lists the anion formed or its salt (column 6), the reagent reacting with it (column 7), and the polyanion or its salt (column 8) produced by this interaction. Column 9 lists the cobalt compounds reacting with an anion or polyanion to form a π-complex.

The choice of the nucleophile for the first two stages depends on the nature of the carbaborane and the strength of the R–carbaborane bond[38]. The synthesis is carried out in aqueous and alcoholic media or in an absolute complex-forming solvent [tetrahydrofuran (THF), ether, and dimethoxyethane (DME)][20].

The "direct" synthesis under consideration has acquired particular importance when its single-stage version was developed: the anion $(B_9C_2H_{12})^-$ (obtained *in situ* by the alkaline methanolysis of the *o*-carbaborane $B_{10}C_2H_{12}$) $CoCl_2.6H_2O$, and C_5H_6 were added in the presence of an excess of KOH.[64] The yield of $(\eta^5\text{-Cp})CoB_9C_2H_{11}$ was 72%. The authors note[64] that the optimum yield of the asymmetric complex is attained when methanol is used as the solvent. $(\eta^5\text{-Cp})Co.(2,3\text{-}B_8C_2H_{10})$ was obtained similarly[64].

The method of synthesis of the bis(dicarbazapyl)cobaltate ion $[(B_7C_2H_9)_2Co]^-$ [2,2′-*commo*-bisnonahydridodicarba-2-cobalta-*closo*-decaborate (Ed.of Translation)] differs somewhat from that described above[16,61,62]. The initial compound is also a *nido*-carbaborane (Fig.13), which is converted under the influence of sodium hydride into the dianion $(1,3\text{-}B_7C_2H_{11})^{2-}$ (Fig.14). Next, the anion $(1,3\text{-}B_7C_2H_{11})^{2-}$ is made to react with anhydrous $CoCl_2$, which immediately leads to the formation of the polyhedral *closo*-complex $[(B_7C_2H_9)_2Co]^-$. Two moles of hydrogen are evolved in the reaction. The hydrogen is probably formed as a result of the elimination of two bridging hydrogen atoms from the *nido*-carbaborane anion (Fig.14). The structure of the bis(dicarbazapyl)cobaltate anion[16] is illustrated in Fig.4.

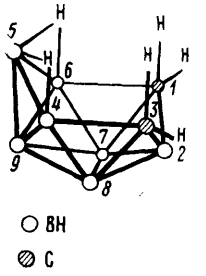

Figure 13. The structure of 1,3-dicarba-*nido*-nonaborane-(13).[38]

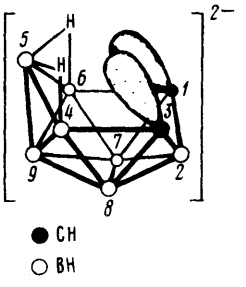

Figure 14. The postulated structure of the 1,3-dicarba-*nido*-undecahydroborate(2-) ion.

2. The "Direct" Synthesis of Polyhedral Dicobalt Complexes of Carbaboranes from Cobalt Complexes of Carbaboranes

It had been established previously that the "direct" synthesis of cobalt complexes of carbaboranes is accompanied in many instances by the formation of di- and tri-cobalt complexes of carbaboranes[58,64,109,110]. The alkaline degradation of $1,2\text{-}B_{10}C_2H_{12}$ led to the isolation of polyhedral cobalt complexes—derivatives of the bifunctional ligand $(B_8C_2H_{10})^{4-}$.[58,109]. The structures of the resulting bimetallic complex $(1,2\text{-}B_9C_2H_{11}\text{-}3,3'\text{-}Co\text{-}1',2'\text{-}B_8C_2H_{10}\text{-}6',3''\text{-}Co\text{-}1'',2''\text{-}B_9C_2H_{11})^{2-}$ (Fig.11) and the trimetallic complex $\{[(3,1,2\text{-}B_9C_2H_{11})Co.(3,6,1,2\text{-}B_8C_2H_{10})]_2Co\}^{3-}$ (Fig.12) were established by X-ray diffraction[57,59]. It has been suggested[58] that the formation

Table 1. Cobalt complexes of carbaboranes obtained by the "direct"method and the reagents used in the synthesis.

**Optically active compound.

of these polyhedral complexes is a result of the partial dehydration of $[(B_9C_2H_{11})_2Co]^-$, formed during the reaction, which gives rise to $[(B_9C_2H_{11})Co(B_8C_2H_{10})]^{3-}$. The interaction of the latter with Co^{2+} and $(B_9C_2H_{11})^{2-}$ results in the

formation of a bimetallic complex, while the reaction of these two anions with Co^{2+} leads to the formation of a trimetallic complex.

Probably the same principle underlies the formation of $3,6,1,2\text{-}(\eta^5\text{-CpCo})_2B_8C_2H_9CH_2OH$ in the alkaline cleavage and 1-hydroxymethyl-o-carbaborane $B_{10}C_2H_{11}CH_2OH$ by treatment with OH^- in absolute alcohol and after subsequent addition of C_5H_6 and $CoCl_2$ in the presence of an excess of KOH; the compound was obtained in 73% yield[111].

Alkaline alcoholysis of cobalt complexes of carbaboranes with subsequent interaction of the resulting anions with M^{2+} (M = Co or Fe) and C_5H_6 is used nowadays as a preparative method for the synthesis of di- and tri-cobalt complexes of carbaboranes[64,70,112].

The reaction of $4,1,8\text{-}(\eta^5\text{-Cp})CoB_{10}C_2H_{12}$ with KOH in EtOH and then with $CoCl_2$ and C_5H_6 yielded $4,5,1,8\text{-}(\eta^5\text{-CpCo})_2B_9C_2H_{11}$. The corresponding dimethyl derivative was obtained analogously from $4,1,8\text{-}(\eta^5\text{-Cp})Co(B_{10}C_2H_{10}\text{-}1,8\text{-}Me_2)$. The compounds were isolated in 43–58% yield[112]. The same method makes it possible to obtain bimetallic carbaborane heterocomplexes by carrying out the reaction in the presence of $FeCl_2$. Thus, $4,5,1,8\text{-}(\eta^5\text{-Cp})_2\text{-}4\text{-Co-}5\text{-Fe-}B_9C_2H_{11}$ and its dimethyl derivative were isolated and characterised[112]. Furthermore, $CpCo(B_9C_2H_{11})FeCp$ was obtained from CpCo.$(6,7\text{-}B_{10}C_2H_{12})$ in EtOH by treatment with KOH and then with an excess of $FeCl_2$ and C_5H_6.[113] The tricobalt carbaborane complex $\{[(\eta^5\text{-Cp})CoB_9C_2H_{11}]_2Co\}^-$ was isolated by treating $4,1,8\text{-}(\eta^5\text{-Cp})CoB_{10}C_2H_{12}$ in ethanol with KOH and by subsequent reaction with $CoCl_2$ in the absence of C_5H_6.[112] The cobalt carbaborane complex $CpCoB_9C_2H_{11}$ is the starting material for the synthesis of $3,6,1,2\text{-}(\eta^5\text{-CpCo})_2B_8C_2H_{10}$. The reaction is carried out in MeOH and the yield is 57%.[64] The synthesis of $[2,11,1\text{-}(\eta^5\text{-CpCo})_2B_9C_2H_{10}]$ by the reaction of Cp_2Co with $(1\text{-}B_9CH_{10})^-$ in the presence of sodium amalgam is of interest[114].

The presence of bridging hydrogen atoms with acid properties in the *nido*-complex $(\eta^5\text{-Cp})CoB_3C_2H_7$ is responsible for its reaction with NaH. Deprotonation gives rise to the anion $(CpCoB_3C_2H_6)^-$, which interacts with $CoCl_2$ and RC_5H_4Na (R = H,[62,102] Me, Et, or $SiMe_3$ [116]) in THF, which gives a moderate yield of the "three-layer" sandwich complex $1\text{-}(\eta^5\text{-Cp})\text{-}7\text{-}(\eta^5\text{-}C_5H_4R)\text{-}1\text{-Co-}7\text{-Co-}2,3\text{-}B_3C_2H_5$.[70,115,116] The *nido,closo*-complex $[(Me_2B_3C_2H_5)Co(Me_2B_4C_2H_4)]^-$ reacts with $CoCl_2$ and NaCp to give a low yield of the neutral complex $(\eta^5\text{-Cp})Co(Me_2B_3C_2H_5)CoH(Me_2B_3C_2H_5)$.[98]

In conclusion we may note that the above method is synthetically simple, can be used on a preparative scale, and as a rule does not give rise to a complex mixture of reaction products. Its disadvantage is a fairly limited set of initial carbaboranes employed.

3. The Polyhedral Contraction Method

The method includes a stage with partial degradation of the cobalt complex of the carbaborane (removal of the BH^{2+} species) and the subsequent oxidation stage. Cobalt complexes of carbaboranes whose molecules contain one vertex more than the initial cobalt carbaborane complex are obtained by this method[110,117,118]. In a general form the reaction is

$$(LCoB_nC_2H_{n+2})^z \xrightarrow[2)\ -2e]{1)\ -BH^{2+}} (LCoB_{n-1}C_2H_{n+1})^z,$$

$$L{=}Cp,\ z{=}0;\ L{=}B_nC_2H_{n+2},\ z = -1.$$

The nucleophiles employed are KOH and EtOH and the oxidants are H_2O_2 and $FeCl_3$. It has been suggested that the polyhedral contraction reaction proceeds via the intermediate formation of *nido*-complexes[35,53]. Indeed, when the *closo*-complex $[3,3\text{-}Co(1,2\text{-}B_9C_2H_{11})_2]^-$ is treated with KOH in an aqueous medium, the product is the *nido*-complex $(1,2\text{-}B_9C_2H_{11}\text{-}3,9'\text{-Co-}7',8'\text{-}B_8C_2H_{11})^-$ in 63% yield. The oxidation of the latter with H_2O_2 in an alkaline medium gives the *closo*-complex $(1,2\text{-}B_9C_2H_{11}\text{-}3,1'\text{-Co-}2',4'\text{-}B_8C_2H_{10})^-$.[35] Furthermore, $CpCoB_8C_2H_{10}$ is converted in the presence of EtOH and $FeCl_3$ into the *nido*-complex $CpCoB_7C_2H_{11}$, which can be dehydrogenated to the *closo*-complex $CpCoB_7C_2H_9$.[53] The study of the intermediates in the polyhedral contraction reaction of $3,1,2\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$ is also consistent with the above hypothesis[35].

The polyhedral contraction of $3,1,2\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$ leads to the formation of the normal reaction product $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ (63%) and the cobalt carbaborane complex $2,6,7\text{-}(\eta^5\text{-Cp})CoB_7C_2H_9$.[117,118] The initial compound reacts with KOH in an ethylene glycol–ethanol–water mixture and the resulting red solution is then treated with H_2O_2. The hypothesis of the $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ structure is based on ^1H and ^{11}B NMR data[118] and certain structural analogies[54]. The compound retains the *closo*-geometry of the initial metal carbaborane complex and is its lowest homologue. Under the conditions of the polyhedral contraction reaction, the symmetrical complex $[3,3\text{-}(1,2\text{-}B_9C_2H_{11})_2Co]^-$ forms only the lowest homologues $(1,2\text{-}B_9C_2H_{11}\text{-}3,1'\text{-Co-}2',4'\text{-}B_8C_2H_{10})^-$.[118]

The conversion into the next metal carbaborane complex homologue (B_7) is achieved by refluxing $(1,2\text{-}B_9C_2H_{11}\text{-}3,1'\text{-Co-}2',4'\text{-}B_8C_2H_{10})^-$ in ethanol in the presence of $FeCl_2$.[118] The compound obtained (11% yield) has the structure $(1,2\text{-}B_9C_2H_{11}\text{-}3,2'\text{-Co-}1',6'\text{-}B_7C_2H_9)^-$. If the polyhedral complex $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ undergoes the polyhedral contraction reaction, the resulting cobalt carbaborane complex CpCo.$.B_7C_2H_{11}$ does not retain the *closo*-geometry of the initial polyhedron[118]. The ^1H NMR spectrum of this compound contains two broad signals to a high field of the tetramethylsilane signal, indicating the presence of non-terminal hydrogen atoms[54,119]. It has therefore been suggested that the resulting complex has the *nido*-structure. The reaction led to the isolation also of a small amount (2%) of $6,7\text{-}(\eta^5\text{-Cp})$.$.CoB_7C_2H_9$—the usual product of the polyhedral contraction reaction. On treatment of $3,1,7\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$ and $1,2,3\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ with bases, only cobalt hydroxide is formed[118]. The complex is probably decomposed in this case more rapidly than boron is eliminated from the polyhedron of the cobalt complex of the carbaborane. On treatment of $(\eta^5\text{-Cp})CoB_{10}C_2H_{12}$ with an ethanol solution of KOH, the product is (in 60% yield) the polyhedral complex $(\eta^5\text{-Cp})Co.$.$(2\text{-}B_7CH_8)$.[120] If $(\eta^5\text{-Cp})CoB_{10}C_2H_{11}Me$ is used as the starting material, then $(\eta^5\text{-Cp})Co(2\text{-}B_7CH_8)$ and the corresponding *C*-methyl derivative are isolated[120,121].

4. The Polyhedral Expansion Method

(*a*) *The polyhedral expansion of carbaboranes.* In contrast to the first method ("direct" synthesis), which is based on the use of the initial *nido*- and *arachno*-carbaboranes, the polyhedral expansion reaction is based on the comparatively readily available *closo*-carbaboranes $B_nC_2H_{n+2}$ ($n = 4\text{–}10$). Like aromatic benzenoid systems, *closo*-carbaboranes readily combine with two electrons, using for this purpose the nonbonding and the lowest-lying antibonding molecular orbitals. This was demonstrated first for $1,2\text{-}B_{10}C_2H_{12}$:[122]

$$1,2\text{-}B_{10}C_2H_{12} + 2e \rightarrow (1,2\text{-}B_{10}C_2H_{12})^{2-}.$$

As a result of the Jahn–Teller effect or other distortions, the *closo*-carbaborane struture is opened. The dianion

formed exhibits the properties of a complex-forming ligand capable of reacting with the transition metal[3].

The reduction of the carbaborane 1,7-$B_9C_2H_8$#[38] with sodionaphthalene constituted experimental confirmation of the concept of polyhedral expansion[52,123]:

$$1,7\text{-}B_6C_2H_8 + Na \xrightarrow[THF]{C_{10}H_8} Na_2B_6C_2H_8 \quad .$$

When the reduction product is treated with an excess of sodium cyclopentadienide in the presence of an excess of $CoCl_2$, 1,4,5-(η^5-Cp)$CoB_6C_2H_8$ is formed[52,123]. The compound contains one vertex more than the initial $B_6C_2H_8$ and is a typical product of the polyhedral expansion reaction. Another compound obtained in this reaction was the bimetallic complex 2,9,1,10-(η^5-CpCo)$_2B_6C_2H_8$,[52,123] whose structure was established by X-ray diffraction[52] (see Fig.8). This complex is obtained as a result of the polyhedral expansion reaction of a cobalt carbaborane complex—in the present instance of the 1,4,5-(η^5-Cp)$CoB_6C_2H_8$ formed (for further details, see below). We may add that the polyhedral expansion reaction of 1,7-$B_6C_2H_8$, carried out in the absence of CpNa, gives rise to the symmetrical complex $(Ph_4As)^+$(4,5-$B_6C_2H_8$-1,1'-Co-4',5'-$B_6C_2H_8$)$^-$.[52] The carbaborane 4,5-$B_7C_2H_9$ enters into the polyhedral expansion reaction[52]:

$$4,5\text{-}B_7C_2H_9 + 2e \rightarrow (B_7C_2H_9)^{2-}$$
$$(B_7C_2H_9)^{2-} \xrightarrow{Co^{2+};\ Cp^-} 2,3,10\text{-}(\eta^5\text{-Cp})CoB_7C_2H_9 + 4,6\text{-}(\eta^5\text{-Cp})CoB_6C_2H_8 \quad .$$

Under the conditions of the polyhedral expansion reaction, both isomers (1,6- and 1,10-) of the carbaborane $B_8C_2H_{10}$ [38] give rise to symmetrical and asymmetric polyhedral π-complexes of cobalt[52,65]:

$$1,6\text{-}B_8C_2H_{10} \xrightarrow{2e} (B_8C_2H_{10})^{2-} \xrightarrow{Co^{2+};\ Cp^-} 1,2,3\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10} +$$
$$+ (CpCo)_2B_8C_2H_{10} + [(B_8C_2H_{10})_2Co]^- + 1,6\text{-}(\eta^5\text{-Cp})CoB_7C_2H_9 +$$
$$+ [\eta\text{-}(\sigma\text{-}B_8C_2H_9)B_8C_2H_9]Co(\eta^5\text{-Cp}) \quad .$$

At room temperature the main reaction product (44%) is 1,2,3-(η^5-Cp)$CoB_8C_2H_{10}$. The reaction of the isomer 1,10-$B_8C_2H_{10}$ is also not unambiguous. Together with 1,2,3-(η^5-Cp)$CoB_8C_2H_{10}$ (44%), a large number of side products were isolated: $CpCoB_7C_2H_9$ (4%), $CpCoB_9C_2H_{11}$ (2%), $(CpCo)_2$.$B_8C_2H_{10}$ (two isomers—1 and 0.2%), and $CpCo(B_8C_2H_9$-$B_8C_2H_9)$ (4%). When the polyhedral expansion reaction of the carbaborane 1,6-$B_8C_2H_{10}$ is carried out at −80 °C, mainly three bimetallic complexes are formed, two of which are isomers of $(CpCo)_2B_8C_2H_{10}$ and the third is $[(\eta^5\text{-Cp})Co_2$.$(B_8C_2H_{10})_2]^-$.[44] The amount of the normal polyhedral expansion reaction product, which is 1,2,3-(η^5-Cp)$CoB_8C_2H_{10}$ is greatly reduced compared with the conditions[52] examined above.

Under the conditions of the polyhedral expansion reaction, the carbaborane 2,3-$B_9C_2H_{11}$ gives rise to the two isomers 2,4- and 2,9-(η^5-Cp)$CoB_9C_2H_{11}$.[52] The reaction products were also found to contain the polyhedral π-complexes 2,3-(η^5-Cp)$CoB_8C_2H_{10}$, 1,6- and 3,10-(η^5-Cp)$CoB_7C_2H_9$, and $(CpCo)_2B_8C_2H_{10}$. It has been suggested[74] that the above compounds are formed as a result of the decomposition of the initial carbaborane 2,3-$B_9C_2H_{11}$. The 13-vertex polyhedra (7,9-$B_{10}C_2H_{12}$-13,13'-Co-7',9'-$B_{10}C_2H_{12}$)$^-$ and 13,7,9-(η^5-Cp).$CoB_{10}C_2H_{12}$ (Fig.15c) have been obtained by the reduction of the carbaborane 1,2-$B_{10}C_2H_{12}$ with sodionaphthalene in THF [122,124] followed by the interaction of the resulting dianion with an excess of CpNa and $CoCl_2$;[125,126] the structure of the second compound was determined by X-ray diffraction[127,128].

The side products of the polyhedral expansion reaction of 1,2-$B_{10}C_2H_{12}$ are[125,126] 7,8-(η^5-Cp)$CoB_9C_2H_{11}$ (1%) and the zwitter-ion (η^5-C_2H_5)Co(η^5-$C_5H_4B_9C_2H_{11}$). The latter compound is a cobaltocenium derivative in which the C-substituted anion $(B_9C_2H_{11})^-$ plays the role of a substituent and an anion simultaneously (Fig.16).[129] The "extra" hydrogen atom in the anion (1,2-$B_9C_2H_{11}$)$^-$ is located over the pentagonal surface, is linked to all the atoms of the latter, and is displaced closer to the $B_{(8)}$ atom (Fig.16). The distances of the hydrogen atom from each atom in the surface are smaller than the coresponding van der Waals B–H and C–H radii[129].

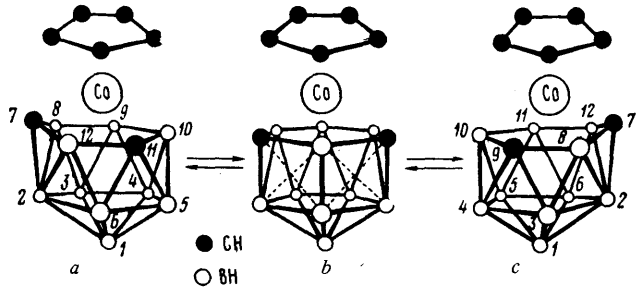

Figure 15. The postulated mechanism of the interaction of the 7,9- and 7,11-enantiomers of (η^5-Cp)$CoB_{10}C_2H_{12}$.

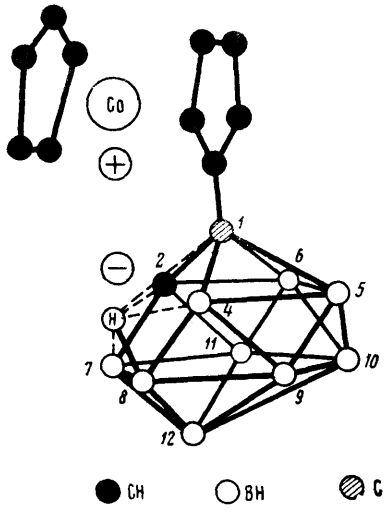

Figure 16. The structure of the zwitter-ion (η^5-Cp)Co(η^5-$C_5H_4B_9C_2H_{11}$) (H is a bridging atom)[129].

The formation of $[(B_{10}H_{10}C_2RR')_2Co]^-$ (R = R' = H or Me; R = H, R' = Me or Ph) from the corresponding dianions $(B_{10}H_{10}C_2RR')^{2-}$ is accompanied by the partial oxidation of the initial dianions to the carbaboranes and of the resulting complexes $[(B_{10}H_{10}C_2RR')_2Co]^-$ to the isomeric B_{10} carbaboranes. The ease of oxidation of the dianions depends on the reduction potential of the carbaborane $B_{10}H_{10}C_2RR'$. The

In previous reviews[3,4] this carbaborane is represented as the 1,6-isomer, which conflicts with the X-ray diffraction study of the *C,C'*-dimethyl analogue[58].

easier the reduction of the carbaborane, the easier the oxidation of its dianion[130]. Thus the dianion $[B_{10}H_{10}C_2HPh]^{2-}$ has been converted under the conditions into the corresponding monoanion $[(B_{10}H_{10}C_2HPh)_2Co]^-$, whereas in the case of $(B_{10}H_{10}C_2Ph_2)^{2-}$ it was possible to isolate only $B_{10}H_{10}C_2Ph_2$.[130] $E_{1/2}$ is known to be −1.95 and −1.14 V respectively for $B_{10}H_{10}C_2HPh$ and $B_{10}H_{10}C_2Ph_2$.

The use of the lowest carbaboranes, particularly $B_5C_2H_7$, under the conditions of the polyhedral expansion reaction, has led to somewhat unexpected results[66]. The formation of twenty compounds, among which $(\eta^5\text{-Cp})CoB_4C_2H_6$ is present in the greatest amount (20–25%), has been observed. Monocobalt carbaborane complexes $(\eta^5\text{-Cp})CoB_nC_2H_{n+2}$ ($n = 5$, 6) and dicobalt carbaborane complexes $(\eta^5\text{-CpCo})_2B_nC_2H_{n+2}$ ($n = 4$, 5, 6), as well as the substituted compounds (η^5-Cp).Co[η^5-(σ-$B_5C_2H_6$)$B_4C_2H_5$] and (η^5-Cp)Co[η^5-(σ-$C_{10}H_7$)$B_4C_2H_5$] have been isolated. The remaining compounds have not been characterised. The product of the polyhedral expansion reaction of 2,4-$B_5C_2H_7$, carried out in the absence of CpNa, is $[Co(2,4\text{-}B_4C_2H_6)_2]^-$ in a very low yield[70].

Under the conditions of the polyhedral expansion reaction, the *nido*-carbaborane 2,3-$B_4C_2H_8$ is largely converted into $(\eta^5\text{-CpCo})_2B_3C_2H_5$ and $(\eta^5\text{-Cp}_6)CoB_3C_2H_5$.[70] The carbaborane 1,6-$B_4C_2H_6$ also does not give rise to the normal polyhedral expansion reaction product and yields 2,4-CpCo.$B_3C_2H_5$CpCoB$_4C_2H_5$-$C_{10}H_7$ and 1,7,2,4-$(CpCo)_2B_3C_2H_5$.[70,115] The latter compound belongs to the new class of "three-layer" sandwich complexes. Under the conditions of the polyhedral expansion reaction, cobalt complexes of carbaboranes have not been obtained at all from the carbaborane 1,5-$B_3C_2H_5$.[70] These findings show that the polyhedral expansion reaction is less typical for the lowest carbaboranes. However, one should note that the change in reaction conditions (time, temperature, etc.) can apparently lead to other results.

(*b*) *The polyhedral expansion reaction of cobalt complexes of carbaboranes.* Like *closo*-carbaboranes, cobalt complexes of carbaboranes are involved in the polyhedral expansion reaction[4]. In a general form, the reaction is as follows:

$$CpCoB_nC_2H_{n+2} \xrightarrow[3)\ [O]]{1)\ 3e;\ 2)\ M'Cl_2;\ CpNa} (Cp)_2CoM'B_nC_2H_{n+2}$$
$$M' = Co \text{ or } Fe.$$

The reduction proceeds formally in two stages: (1) reduction of the metal: Co(III) → Co(II); (2) two-electron reduction of the carbaborane fragment with formation of the anion of the cobalt complex of the *nido*-carbaborane. The subsequent reaction of CpNa with $M'Cl_2$ ($M' = Co$ or Fe) gives a mixture of the di- and tri-cobalt complexes of carbaboranes, which is then oxidised in air. The new compound has one or two vertices more than the initial cobalt carbaborane complex. The reaction time and temperature depend on the initial cobalt carbaborane complex[69].

The first examples of the polyhedral expansion reaction of cobalt carbaborane complexes were examined for the complexes $CpCoB_6C_2H_{10}$ [67] and 2,1,6-$CpCoB_7C_2H_9$.[68] The principal advances in this field have been described by Evans and Hawthorne[69]. Under the conditions of the polyhedral expansion reaction, the complex 2,1,6-$CpCoB_7C_2H_9$ gives rise to a mixture of $(CpCo)_2B_7C_2H_9$ isomers and the trimetallic complex $(CpCo)_3B_7C_2H_9$. The isomers 1,10,2,3-$(CpCo)_2B_7C_2H_9$, 1,8,2,3-$(CpCo)_2B_7C_2H_9$§, and 1,4,2,3-$(CpCo)_2B_7C_2H_9$ were identified by ^1H and ^{11}B NMR. This reaction is accompanied by the polyhedral rearrangement of the initial 2,1,6-$CpCoB_7C_2H_9$, which leads to 3,2,10-CpCo.$B_7C_2H_9$. In addition, 1,9,4,5-$(CpCo)_2B_5C_2H_7$ was detected in the reaction products[69].

The products of the polyhedral expansion reaction of 1,2,3-$CpCoB_6C_2H_{10}$ are 2,3,1,7-$(CpCo)_2B_6C_2H_{10}$ (Fig. 9), whose structure has been established by X-ray diffraction[56], and $[(2,3\text{-}B_6C_2H_{10})_2Co]^-$. Under these conditions, the isomer 1,2,4-$CpCoB_6C_2H_{10}$ gives rise to three compounds, one of which is 3,4,1,2-$(CpCo)_2B_6C_2H_{10}$.[69]

Together with the normal products of the polyhedral expansion reaction of the complex 3,1,2-$CpCoB_9C_2H_{11}$, which consist of the isomers $(CpCo)_2B_9C_2H_{11}$ and [3,3-Co(1,2-$B_9C_2H_{11})_2]^-$, 2,1,7-$CpCoB_9C_2H_{11}$ was also isolated[69].

The isomers 1,14,2,10- and 1,14,2,9-$(CpCo)_2B_{10}C_2H_{12}$ with a 14-vertex polyhedron were obtained under the conditions of the polyhedral expansion reaction of two $CpCoB_{10}C_2H_{12}$ isomers[43]. The reduction of 2,1,6-$CpCoB_7C_2H_9$ and subsequent treatment with an excess of CpNa and $FeCl_2$ lead to a paramagnetic compound, whose reduction with $NaBH_4$ yielded the diamagnetic complex $[CpCo^{III}(B_7C_2H_9)Fe^{III}Cp]$.[113]

The polyhedral expansion reaction of $[CpCoB_7CH_8]^-$ in the presence of $NiBr_2.2C_2H_4(OMe)_2$ leads to the formation of four $[CpCo^{III}(B_7CH_8)Ni^{IV}Cp]$ isomers[131]. However, the only product of the analogous reaction of 2,1-$CpCoB_{10}CH_{11}$ was the naphthalene complex 2,1-$(\eta^6\text{-}C_{10}H_8)CoB_{10}CH_{11}$.[132]

Thus the polyhedral expansion reaction is applicable mainly to the intermediate and higher homologues of carbaboranes and their cobalt complexes. The method makes it possible to obtain a large series of mono-, di-, and tri-cobalt carbaborane complexes as well as dimetallic heterocomplexes of carbaboranes. The possibility of synthesising polymetallic carbaborane complexes by this method is probably problematical. The method is synthetically simple and the initial compounds are readily available, but it often gives rise to a complex mixture of products.

5. The Gas-Phase Synthesis of Cobalt Complexes of Carbaboranes

The direct synthesis of metal complexes of carbaboranes in the gas phase is carried out in a special reactor at an elevated temperature. The initial compounds are the lower carbaborane homologues $B_nC_2H_{n+2}$ ($n = 3$–5) and $CpCo(CO)_2$.[133]

In the presence of $CpCo(CO)_2$ at 230 °C, the carbaborane 1,5-$B_3C_2H_5$ yields $(\eta^5\text{-Cp})CoB_3C_2H_5$ (10%) and two isomers of the dicobalt carbaborane complex: 1,7,2,4- and 1,2,3,5-$(\eta^5\text{-CpCo})_2B_3C_2H_5$. 1,2,4-$(\eta^5\text{-Cp})CoB_4C_2H_6$ (70%) and a small amount (5%) of the eight-vertex polyhedron 3,5,1,7-$(\eta^5\text{-CpCo})_2B_4C_2H_6$ were obtained from the carbaborane 1,6-$B_4C_2H_6$ at 270–280 °C. In the presence of $CpCo(CO)_2$ at 260 °C, a mixture of products, consisting of the cobalt carbaborane complexes $(\eta^5\text{-Cp})CoB_5C_2H_7$ and $(\eta^5\text{-Cp})CoB_4C_2H_6$, two isomers of the dicobalt carbaborane complex $(\eta^5\text{-CpCo})_2B_5C_2H_7$, and two isomers of the tricobalt carbaborane complex $(\eta^5\text{-CpCo})_3B_5C_2H_7$, was obtained from the carbaborane 2,4-$B_5C_2H_7$. The trimetallic carbaborane complex {(η^5-Cp)Co.(2,3-$Me_2B_4C_2H_4$)[$Fe(CO)_3]_2$} is formed when 1,2,3-(η^5-Cp)Co.(2,3-$Me_2B_4C_2H_4$) (structure established by Weiss and Bryan[134]) interacts with an excess of $Fe(CO)_5$ at 125 °C.[135]

Thus the method examined is at present the only preparative procedure for the synthesis of the lowest homologues of cobalt carbaborane complexes. However, under the reaction conditions, the initial carbaborane and its newly formed cobalt complex undergo a polyhedral rearrangement, which leads to a complex mixture of products and hinders their isolation.

§ This is possibly the 1,2,3,8-isomer.

The thermolysis of cobalt complexes of carbaboranes can also be regarded as one of the methods for the synthesis of such complexes. The method is used to synthesise various isomers of cobalt complexes of carbaboranes which cannot be obtained by other methods or for the synthesis of di- and tri-cobalt complexes of carbaboranes from the corresponding monocobalt complexes. The first type of synthesis has already been examined in Section IV. We shall consider separately only the elegant solution of the problem of the synthesis of 1-(η^5-Cp)-7-(η^5-C_5H_4R)-1-Co-7-Co-2,4-$B_3C_2H_5$ from 1-(η^5-Cp)-7-(η^5-C_5H_4R)-1-Co-7-Co-2,3-$B_3C_2H_5$.[116] Whereas the direct reaction of $[(\eta^5\text{-Cp})CoB_3C_2H_6]^-$ with $CoCl_2$ and NaC_5H_4R can be used to synthesise the 1,7,2,3-isomer, in the case of the 1,7,2,4-isomer the polyhedral rearrangement method is the only possible procedure.

Six isomers of the dimetallic carbaborane complex (η^5-$CpCo)_2B_8C_2H_{10}$ were obtained on heating $(\eta^5\text{-Cp})CoB_8C_2H_{10}$ at 235 °C in hexadecane for 7 h; 2,9,1,12-(η^5-$CpCo)_2B_8C_2H_{10}$, in which the cobalt atoms are located in the *para*-positions of the $Co_2B_8C_2H_{10}$ icosahedron, was isolated from the mixture of isomers[136]. The gas-phase thermolysis of the cobalticenium salt $[(\eta^5\text{-Cp})_2Co]^+[Co(B_8C_2H_{10})_2]^-$ at 525 °C and in hexadecane at 270 °C gives rise to five (η^5-$CpCo)_2B_8C_2H_{10}$ isomers[136].

In conclusion one should note that the anionic complexes of carbaboranes are usually isolated as ammonium or alkali metal salts. The synthesis of $[(B_{10}H_{10}S)_2Co]^-[(\eta^5\text{-Cp})_2Co]^+$. where the cobalticenium ion plays the role of the cation, has also been described[107].

IV. THE PROPERTIES OF POLYHEDRAL π-COMPLEXES OF COBALT

1. Intramolecular Rearrangements in the π-Complexes

The absence of symmetry elements from the carbaborane ligand leads to the optical isomerism of the polyhedral π-complexes of cobalt. In particular, the complexes $[(B_9H_9CHP.CH_3)_2Co]^-$,[104] 1,2,4-(η^5-Cp)$CoB_8C_2H_{10}$,[118] and 7,9-(η^5-Cp)$CoB_{10}C_2H_{12}$ (Fig.15*c*)[127] are optically active. The pure enantiomers have not been isolated[104,118,127], but the form of the ^{11}B NMR spectrum of $CpCoB_{10}C_2H_{12}$ at −90 °C indicates unambiguously the presence of two asymmetric 7,9- and 7,11-isomers (Figs.15*a* and 15*c*).[127,128] Below −30 °C, their interconversions can be observed.

The proposed mechanism of the optical rotation of the enantiomers[126] is illustrated in Fig.15. The phenomenon of the polyhedral rearrangement is well known in the carbaborane chemistry[38]. Cobalt complexes of carbaboranes, whose properties are largely determined by the presence of the carbaborane fragment in the molecule, also undergo a polyhedral rearrangement. However, with increase of the number of CoCp fragments in the molecule of the cobalt carbaborane complex, the properties of the latter begin to differ appreciably from those of the carbaborane analogues (see Section I). Indeed, although the occurrence of the isomerisation reaction 2,3,8,1,6-(η^5-$CpCo)_3B_5C_2H_7$ → 2,3,4,1,10-($\eta^5$$CpCo)_3B_5C_2H_7$ has been established in principle (Fig.17), on heating 2,3,8,1,6-(η^5-$CpCo)_3B_5C_2H_7$ mainly decomposes and gives rise to equimolar amounts of 1,8,5,6- and 1,7,5,6-(η^5-$CpCo)_2B_5C_2H_7$.[23] The polyhedral rearrangement of cobalt complexes of carbaboranes was first observed for $Cs[(B_7C_2H_9)_2Co]$ and its asymmetric derivative $CpCoB_7C_2H_9$.[137] The isomers formed are a result of the migration of the carbon atom via the carbaborane fragment. Subsequently it was shown[25,37] that the migration of both the carbon and the cobalt atoms is possible in the isomerisation of cobalt complexes of carbaboranes.

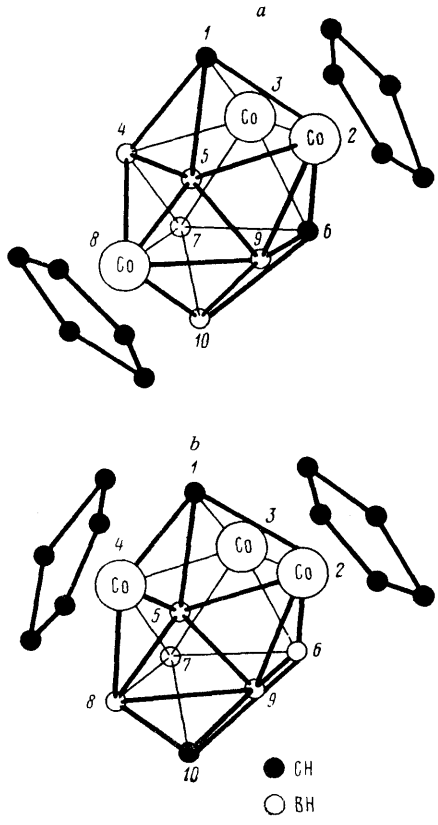

Figure 17. The postulated structures of 2,3,8,1,6-(η^5-$CpCo)_3B_5C_2H_7$ (*a*) and 2,3,4,1,10-(η^5-$CpCo)_3B_5C_2H_7$ (*b*) (one of the Cp ligands is not represented).

(*a*) *Polyhedral rearrangement of cobalt complexes of carbaboranes.* The presence of the cobalt atom in the polyhedron of a cobalt carbaborane complex facilitates the polyhedral rearrangement of the latter compared with the carbaborane itself[22]. Among polyhedral π-complexes the crystal of the 12-atom (η^5-Cp)$CoB_3C_2H_{11}$ polyhedron has the highest energy barrier to the polyhedral rearrangement, which is believed[22] to indicate a high resonance stabilisation of the icosahedron. Non-icosahedral cobalt complexes of carbaboranes of the type (η^5-Cp)$CoB_nC_2H_{n+2}$ ($n = 6$, 7, 8, and 10) have similar activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$, so that it is believed[22] that the polyhedral rearrangements of these complexes have similar mechanisms.

According to an empirical rule governing the polyhedral rearrangement of non-icosahedral systems of the type (η^5-Cp)$CoB_nC_2H_{n+2}$ ($n = 6$, 7, 8, and 10),[22] (1) the coordination number of the cobalt atom, which is high in the polyhedron of the cobalt complex of the carbaborane, does not change in the rearrangement, (2) as a result of the rearrangement there is no mutual approach of the carbon atoms

of the polyhedron, (3) the coordination number of the carbon atom decreases in the course of the rearrangement, and (4) the distance between the carbon and cobalt atom increases. In the latter case the postulates indicated in (2) and (3) must hold. With certain limitations, this rule is applicable also to the lowest homologues of cobalt complexes of carbaboranes ($n = 3$, 4, 5) where partes (2) and (3) mainly hold, while part (4) frequently simply cannot be fulfilled[23].

We shall consider specific examples of the isomerisation of cobalt complexes of carbaboranes. The polyhedral rearrangement of the 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ icosahedron[138] and its *C*-alkyl derivatives[139] proceeds in accordance with the empirical rule[22]. In the gas phase (at 400–700 °C) 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ gives rise to six new isomers in 87–93% yields (Figs.1*a*–1*f* for R = H). If 3,1,2-(η^5-Cp)Co(1,2-$Me_2B_9C_2H_9$) is sublimed in a hot tube at 400–500 °C, three isomers are formed (Figs.1*a'*–1*c'* for R = Me).[139] At the same time, the rearrangement of 3,1,2-(η^5-Cp)Co[1,2-$(CH_2)_3B_9C_2H_9$] (Fig.18*a*) at 500 °C led to the isolation of only one isomer (Fig.18*b*) in which both carbon atoms are in the *ortho*-positions[139]. The presence of the trimethylene bridge precludes the second part of the empirical rule.

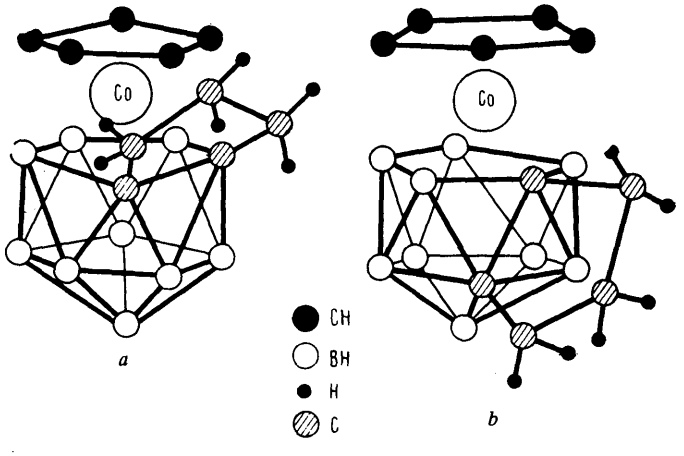

Figure 18. The postulated stuctures of the isomers 3,1,2-(η^5-Cp)Co[1,2-$(CH_2)_3B_9C_2H_9$] (*a*) and 3,1,6-(η^5-Cp)Co[1,6-$(CH_2)_3B_9C_2H_9$] (*b*).

In order to explain the mechanism of the polyhedral rearrangements under consideration, one must assume that the rearrangement follows the *dsd* (*diamond–square–diamond*) scheme proposed by Lipscomb[140] with the simultaneous rotation of the triangular B_2C plane [12,141]. The 4,1,7-(η^5-Cp)$CoB_{10}C_2H_{12}$ non-icosahedral system readily isomerises in solution. On heating at 40 °C, the 4,1,8-isomer is formed, while at 70 °C, the 4,1,13-isomer has been isolated[22]. The identification of the 1,8- and 1,13-isomers has not been confirmed by X-ray diffraction.

Heating of 1,2,4-(η^5-Cp)$CoB_8C_2H_{10}$ [Fig.19 (I, R = H)][32] and its *C*-substituted derivative 1,2,4-(η^5-Cp)Co(2,4-$Me_2B_8C_2H_8$) [Fig.19, (I, R = Me)][36] in solution is also accompanied by a polyhedral rearrangement. In the first case the 1,2,3-isomer [Fig.19, (III, R = H)] was isolated in 94% yield[22]. On heating (2,4-$B_8C_2H_{10}$-1,3'-Co-1',2'-$B_9C_2H_{11}$)$^-$ the only product is also (2,3-$B_8C_2H_{10}$-1,3'-Co-1',2'-$B_9C_2H_{11}$)$^-$.[22] In the case of 1,2,4-(η^5-Cp)Co(2,4-$Me_2B_8C_2H_8$) [Fig.19, (I, R = Me)] a mixture of two isomers is formed[36]. It is believed that in this instance the isomerisation proceeds in steps (1,2,4 → 10,2,3 → 1,2,3) via the intermediate formation of the least stable isomers 10,2,3-(η^5-Cp)Co.(2,3,-$Me_2B_8C_2H_8$)[Fig.19,(II, R = Me)]. The transition 1,2,4-(η^5-Cp)Co(2,4-$Me_2B_8C_2H_8$) → 10,2,3-(η^5-Cp).Co(2,3-$Me_2B_8C_2H_8$)[Fig.19, (I) → (II), R = Me] is accompanied by a decrease of the coordination number of cobalt and an increase of the distance between the carbon atoms in the open B_4C_2 hexagonal surface of the CoB_8C_2 polyhedron. The latter factor promotes the stabilisation of the high positive charge on the cobalt atom by the carbaborane ligand (see Section II). In the course of the further isomerisation (10,2,3 → 1,2,3) [Fig.19, (II) → (III), R = Me] the coordination number of the cobalt atom increases, which agrees with the first part of the empirical rule. However, the fourth part breaks down, since the open hexagonal surface of the 1,2,3-(η^5-Cp)Co(2,3-$Me_2B_8C_2H_8$) isomer now contains two carbon atoms[36]. We may note that mass-spectrometric, ultraviolet spectroscopic, NMR, and oxidation-reduction potential data have been used for the identification of the isomers.

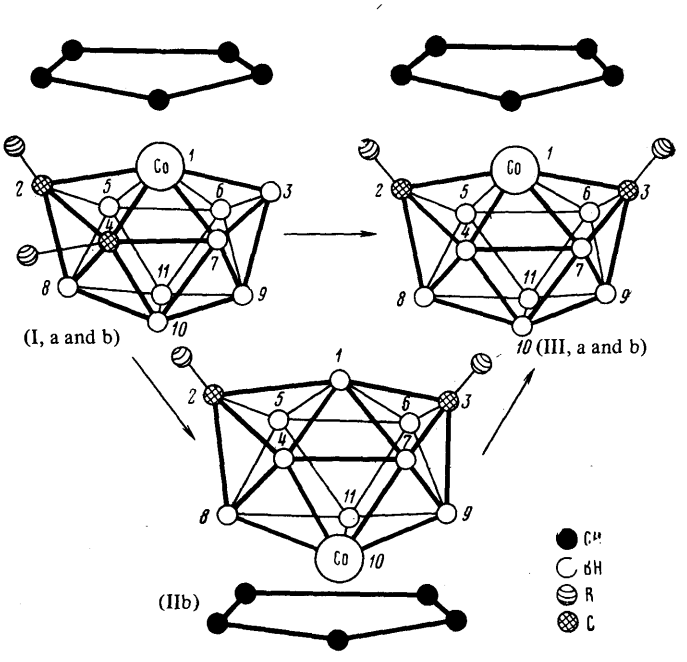

Figure 19. The polyhedral rearrangement of 1,2,4-(η^5-Cp)Co(2,4-$R_2B_8C_2H_8$) (R = H or CH_3).

Five isomers (2,6,9- 2,1,6-, 2,1,7-, 2,1,10-, and 2,3,10-) of the cobalt carbaborane complex (η^5-Cp)$CoB_7C_2H_9$ are known, the complex 2,1,10-(η^5-Cp)$CoB_7C_2H_9$ having the highest thermal stability[22,62]. On heating in solution[22,118] or in the gas phase[62,137], each isomer is converted into the 2,1,10-isomer (Fig.20). The gas-phase rearrangement of the symmetrical complex [(2,1,6-$B_7C_2H_9$)$_2$Co]$^-$$Cs^+$ proceeds analogously[62,137]. The isomerisation of 2,4,5-(η^5-Cp)$CoB_6C_2H_8$ also takes place in conformity with the empirical rule. When the complex is heated in cyclooctane at 150 °C, 2,4,6-(η^5-Cp)$CoB_6C_2H_8$ is

formed[22]. Theoretically[22] the complex 3,1,7-(η^5-Cp)$CoB_5C_2H_7$ (assumed structure) can be converted into the 3,1,8-isomer, since in this case the carbon atom migrates from the open surface of the polyhedron, which decreases the number of Co–C interactions. However, the complex 3,1,7-(η^5-Cp).$CoB_5C_2H_7$, which is stable up to 250 °C, does not isomerise at 340 °C, disproportionating with formation of 2,4-$B_5C_2H_7$, (η^5-CpCo)$_3B_5C_2H_7$, and (η^5-CpCo)$_3B_5C_2H_7$ (traces)[23].

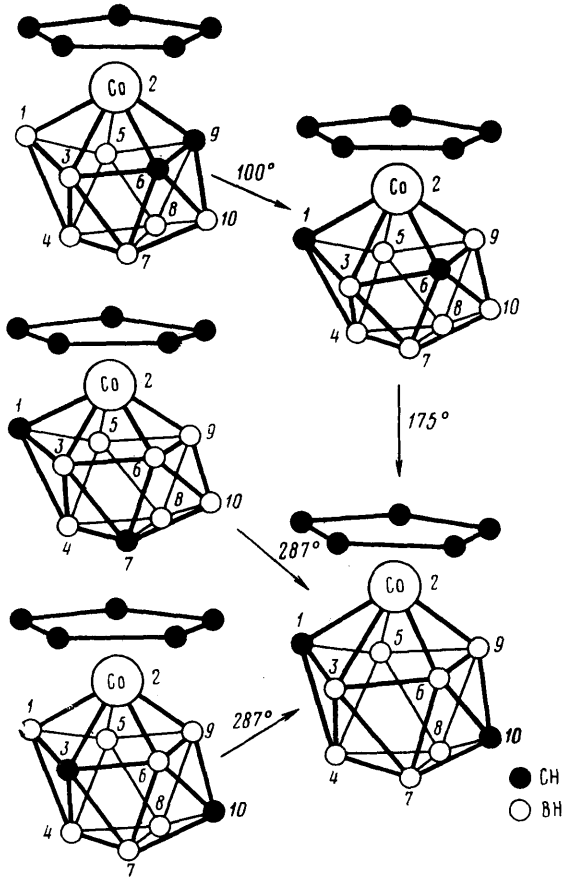

Figure 20. The poyhedral rearrangement of (η^5-Cp)Co.$B_7C_2H_9$.

The polyhedral rearrangement of 1,2,3-(η^5-Cp)$CoB_4C_2H_6$ and its methyl derivative 1,2,3-(η^5-Cp)Co(2-Me$B_4C_2H_5$) (whose structure has been established) takes place in accordance with the empirical rule (the distance between the carbon atoms increases) and leads to the formation of the corresponding 1,2,4-isomers and a small amount of 1,7,2,4-(η^5-CpCo)$_2B_3C_2H_5$.[23]

Among the three possible isomers of the CoB_3C_2 system, only 1,2,4-(η^5-Cp)$CoB_3C_2H_5$ is known, its carbon atoms being located at non-neighbouring vertices[23]. Such carbaboranes and their metal complexes have the highest thermal stabilities. In conformity with these findings, heat treatment of 1,2,4-(η^5-Cp)$CoB_3C_2H_5$ in the gas phase is accompanied solely by the decomposition of the initial compound and the formation of the CoB_4C_2, $Co_2B_3C_2$, and $Co_2B_4C_2$ systems[23].

(b) Polyhedral rearrangement of dicobalt complexes of carbaboranes. The prsence of a second CpCo group in the polyhedron greatly facilitates the isomerisation of the complex. In the course of the rearrangement complexes containing the Co–Co bond are formed as a rule. In these compounds the cobalt and carbon atoms have smaller coordination numbers than in the initial complexes. Furthermore, the initial distances between the carbon atoms can also be retained. Polyhedra with the Co–Co bond are formed at a lower temperature than the final product of the polyhedral rearrangement.

On heating 4,5,1,8-(η^5-CpCo)$_2B_9C_2H_{11}$ at 150 °C in cyclooctane, the isomer 4,5,1,13-(η^5-CpCo)$_2B_9C_2H_{11}$ is formed. In contrast to the initial isomer, in the new isomer both Cp ligands are equivalent. The polyhedral rearrangement of 4,5,1,8-(η^5-CpCo)$_2$(1,8-$Me_2B_9C_2H_9$) proceeds analogously. After the isomerisation, the two Me groups are also equivalent[112]. The hypothesis concerning the structure of the isomer was based on infrared and ultraviolet spectroscopic and NMR data.

The isomers 2,3,1,7-(η^5-CpCo)$_2B_8C_2H_{10}$ [50] and 3,6,1,2-(η^5-CpCo)$_2B_8C_2H_{10}$ [59] (whose structures have been established) isomerise at 250° and 330 °C respectively to 2,4,1,8-(η^5-CpCo)$_2B_8C_2H_{10}$.[25,37] The CpCo fragment and the carbon atom migrate in the former and latter case respectively. The coordination number remains unchanged in the course of the isomerisation.

The 1,4,2,3-(η^5-CpCo)$_2B_7C_2H_9$ polydehdron, containing the Co–Co bond, is formed on isomerisation of 1,6,2,4-(η^5-CpCo)$_2B_7C_2H_9$ and 1,8,2,3-(η^5-CpCo)$_2B_7C_2H_9$. In the course of the 1,6,2,4 → 1,4,2,3 rearrangement the Co–Co bond is retained and the coordination number of the carbon atom decreases. The Co–Co bond appears as a result of the process 1,8,2,3 → 1,4,2,3, Further isomerisation of the 1,4,2,3-isomer gives rise to the 1,10,2,3-(η^5-CpCo)$_2B_7C_2H_9$ polyhedron from which the Co–Co bond disappears. The reaction is accompanied by the formation of (η^5-CpCo)$_3B_7C_2H_9$.[25,37]

The polyhedral rearrangement of 2,6,1,10-(η^5-CpCo)$_2B_6C_2H_8$ (whose structure has been established[24]) gives rise to 2,7,1,10-(η^5-CpCo)$_2B_6C_2H_8$. The compound was identified on the basis of NMR and ultraviolet spectroscopic data. The Co–Co bond disappears as a result of the migration of the CpCo group. The coordination number of cobalt does not change under these conditions[25,37].

The isomerisation 1,8,5,6-(η^5-CpCo)$_2B_5C_2H_7$ → 1,7,5,6-(η^5-CpCo)$_2B_5C_2H_7$ is an exothermic process, i.e. the conversion of the red 1,8,5,6-isomer, in which the cobalt atoms occupy non-neighbouring vertices, into the green 1,7,5,6-isomer, containing the Co–Co bond, is accompanied by the evolution of heat. In addition, it has been shown that at 340 °C equilibrium is established between these isomers[23]. The structure of the isomers has been determined on the basis of a set of spectroscopic data[23] and has been confirmed by X-ray diffraction[142].

Only the single isomer 3,5,1,7-(η^5-CpCo)$_2B_4C_2H_6$ is known for the $Co_2B_4C_2$ system; its structure has been determined by ^1H and ^{11}B NMR. Its conversion into 3,5,2,8-(η^5-CpCo)$_2$.$B_4C_2H_6$ is theoretically possible, since this would entail a decrease of the number of direct Co–C interactions from four to two. However, the isomerisation products were not detected below the decomposition temperature (340 °C).[23]

At 300 °C 1,7,2,3-(η^5-CpCo)$_2B_3C_2H_5$ is converted into 1,7,2,4-(η^5-CpCo)$_2B_3C_2H_5$. There is no Co–Co bond in either compound[102,129]. The structure of the complexes has been established[115,143]. The latter compound does not isomerise up to its decomposition temperature (~400 °C). The rearrangement of the methyl-substituted 1,7,2,3-isomer proceeds similarly. When the isomerisation of 1,7,2,3-(η^5-CpCo)$_2B_3C_2H_5$ was carried out at a lower temperature, the 1,2,4,5- and

1,2,3,5-isomers were also isolated; they both contain the Co–Co bond (the structure was postulated on the basis of ^{11}B NMR data). It has been suggested that the isomerisation of the 1,7,2,3-isomer proceeds in accordance with the scheme 1,7,2,3→1,2,4,5→1,2,3,5→1,7,2,4 (Fig.21). In the first stage the *ortho*-positions of the carbon atoms are retained, but the coordination number of the cobalt atom decreases. The formation of the 1,2,3,5-polyhedron is accompanied by an increase of the distance between the carbon atoms and the migration of the CpCo fragment gives rise to the 1,7,2,4-isomer in which there is no Co–Co interaction and the cobalt atoms have the initial coordination numbers[23].

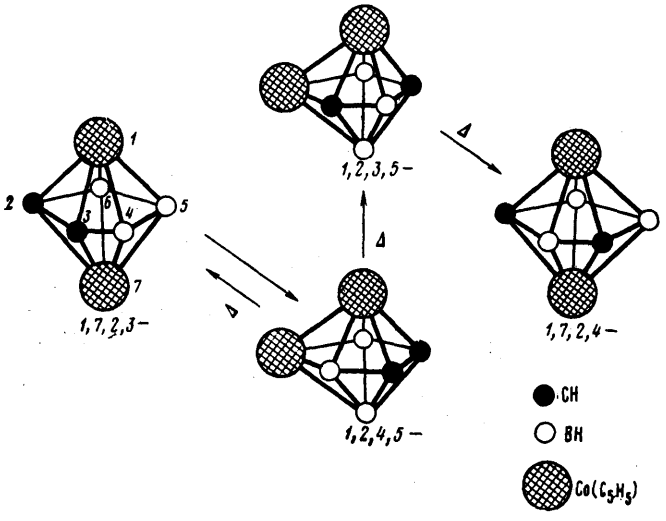

Figure 21. The polyhedral rearrangement of 1,7,2,3-$(\eta^5$-$CpCo)_2B_3C_2H_5$.

corresponding derivatives (V) (Fig.22). Their structure was established by infrared spectroscopy, NMR, and mass spectrometry.

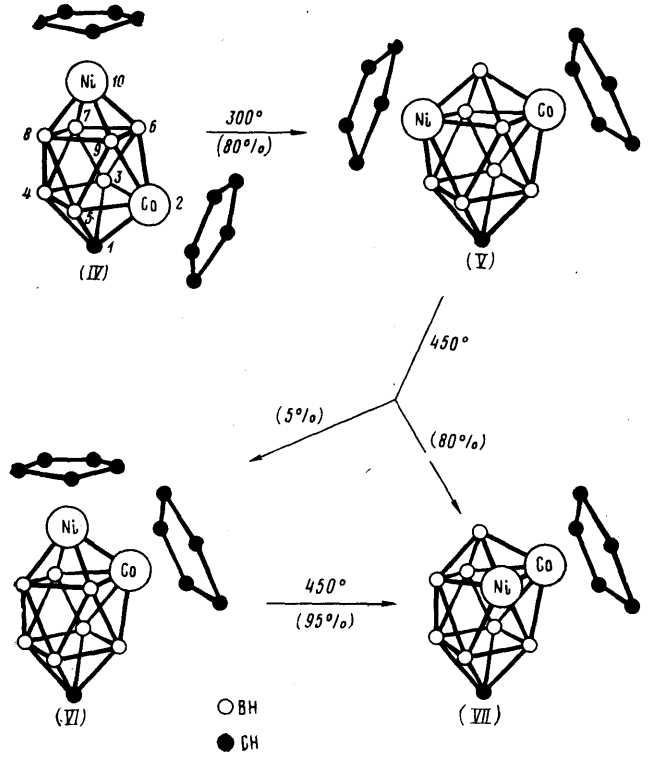

Figure 22. The polyhedral rearrangement of $(\eta^5$-$Cp)^2Co.NiB_7CH_8$ [in (VII) the Cp ligand at the nickel atom is not represented].

Thus the presence of two cobalt atoms in the polyhedron does not by itself introduce fundamental changes into the properties of the complexes, but a new tendency is clearly shown. Firstly, the ability of the polyhedron to undergo a rearrangement depends on the possibility of the formation of complexes with a Co–Co bond in the course of the isomerisation. Secondly, complexes with a Co–Co bond always isomerise. In those cases where compounds with a Co–Co bond were not detected in the course of the polyhedral rearrangement, the reaction was carried out at a high temperature. Possibly the use of milder conditions will permit the isolation of these intermediate complexes.

(c) *Polyhedral rearrangement of bimetallic heterocomplexes of carbaboranes.* It has been suggested that the Co(III)–Fe(III) derivatives, which are electron-deficient systems, decompose under the conditions of the polyhedral rearrangement[21]. Indeed, 4,5,1,8-$(\eta^5$-$Cp)_2CoFeB_9C_2H_{11}$ decomposes on heating and does not give rise to isomerisational products[112]. The bimetallic carbaborane complexes $(\eta^5$-$Cp)_2CoNiB_7CH_8$ readily undergo the polyhedral rearrangement. The isomerisation gives rise to polyhedra with a Co–Ni bond [Fig.22, (IV)–(VII)][132]. The bromo-derivatives (IV) (Fig.22) $(\eta^5$-$Cp)_2CoNiB_7CH_{8-n}Br_n$ ($n=1$, 2) gives rise only to the

The ability of cobalt π-complexes of carbaboranes to isomerise in boiling solvents complicates their analysis and purification.

2. The Oxidation-Reduction Properties of Cobalt Complexes of Carbaboranes

(a) *Electrochemical properties.* The electronic configuration of the cobalt atom in monocobalt complexes of carbaboranes can vary within wide limits ($d^8 \rightarrow d^5$) (Table 2).[91,144] However, complexes containing cobalt in the formal +3 oxidation state (d^6) have been isolated mainly in a chemically pure form. At the same time, oxidation of the yellow-orange diamagnetic compound $[(B_{10}H_{10}CH)_2Co]^{3-}$ gives rise to the black paramagnetic complex $[(B_{10}H_{10}CH)_2Co]^{2-}$, containing cobalt in the d^5 state[99,101].

The cobalt atom has the d^7 electronic configuration in the complex $(B_9C_9CHPCH_3)_2Co$.[104] The existence of the complex $[(B_9C_9CHPCH_3)_2Co]^+$ (d^8) has been demonstrated electrochemically, but it has not been isolated[104]. It followed from the foregoing that, although polyhedral ligands are capable of stabilising the highest and lowest oxidation states of the

cobalt atom, a particular oxidation state of cobalt is preferred for each. The nature of the change in the electrochemical behaviour of cobalt complexes of carbaboranes within a single homologous series is still unknown. However, a clear relation has been established between the reduction potential of the cobalt carbaborane complex and the structure of its isomers. The closer the carbon atom in the polyhedron to the cobalt atom, the easier the reduction of the complex. The isomer containing two carbon atoms in the cobalt coordination plane has the lowest reduction potential compared with other isomers of the given cobalt carbaborane complex (see Nos. 15—17, 21, 22, 23, and 24 in Table 2). This is because the carbon in the polyhedron of the cobalt carbaborane complex is an electron deficient centre and reduces the electron density on the cobalt atom, which facilitates its reduction[99,139]. This property has been used to determine the structures of the isomers of cobalt complexes of carbaboranes[22,36,139].

There exists an analogy between the nature of the influence of substituents on the electrochemical properties of cobalt complexes of carbaboranes and their carbaborane parent compounds[145]. Methyl and phenyl groups at the carbon atom of the dicarbollyl ligand lower the reduction potential of the complex (see Nos. 9, 10, and 11 in Table 2). The presence of three bromine atoms in the polyhedron greatly facilitates the reduction of the complex (No. 12 in Table 2). It is believed that the formal high negative charge of the complex (−3), formed in the $d^6 \rightarrow d^7 \rightarrow d^8$ reduction process, is stabilised as a result of the electron-accepting properties of the bromine atoms[20].

Table 2. The potentials of oxidation-reduction processes (relative to the saturated calomel electrode).

*P = polarographic method; CVA = cyclic voltamperometric method. The measurements were performed under the following conditions: *a*) in 0.10 M $LiClO_4$ in 50% aqueous acetone as the supporting electrolyte; *b*) in 0.10 M Et_4NClO_4 in acetonitrile as the supporting electrolyte; *c*) in 0.10 M n-Bu_4PF_6 in acetonitrile as the supporting electrolyte; *d*) in 0.15 M n-Bu_4NPF_6 in dimethoxyethane as the supporting electrolyte.

Unsuccessful attempts have been made to carry out the reversible reduction of the complexes $[(B_{10}H_{10}S)_2Co]^-$ [107] and $[(B_9H_9CHP)_2Co]^-$.[104] However, it is not clear whether this is a property of the above π-complexes or is a consequence of the chosen experimental conditions. The reduction of the isomers of $(\eta^5\text{-Cp})Co^{III}(Me_2B_6C_2H_8)$ is a two-stage two-electron process. The first wave corresponds to the Co(III) → Co(II) transition and the second corresponds to the addition of a second electron and the formation of the anion $[CpCo^{II}.(Me_2B_6C_2H_8)]^{2-}$. For the 1,2,4- and 10,2,3-isomers, both stages are reversible: $E_{1/2} = -0.83$ and −1.64 V in the former case and $E_{1/2} = -1.23$ and −1.57 V in the latter. The second stage in the reduction of $1,2,3\text{-}(\eta^5\text{-Cp})Co(2,3\text{-}M_3B_6C_2H_8)$ takes place irreversibly ($E_{1/2} = -0.75$ and −1.66 V).[36]

The complex $2,1\text{-}(\eta^6\text{-}C_{10}H_8)CoB_{10}CH_{11}$, containing the coordinated neutral arene ligand $C_{10}H_8$, is also reduced in two stages. The reversible reduction observed at −0.62 V is attributed to the Co(III) → Co(II) transition. As −1.31 V a quasi-reversible process is observed and is regarded as the reduction of the naphthalene ligand $C_{10}H_8$.[132]

The reduction and oxidation of cobalt complexes of carbaboranes containing two or three metal atoms as a rule proceeds in a reversible one-electron stage (Table 3). The reduction of cluster compounds of transition metals takes place similarly[146]. Probably[112] in this case the high degree of electron delocalisation determines the behaviour of the group of metal atoms within the polyhedron as a single metallic centre.

The reduction potentials of di- and tri-cobalt complexes of carbaboranes also depend on the isomeric structure of the complex. The same relations as those mentioned above for monocobalt complexes of carbaboranes have been observed[112] (see Nos. 2—4, 5, and 6, in Table 3).

Table 3. The reduction and oxidation potentials of di- and tri-metal complexes of carbaboranes.

It is known[112] that the oxidation and reduction of bimetallic heterocomplexes of carbaboranes containing iron and cobalt atoms proceed in a single reversible one-electron stage (Nos. 9 and 10 in Table 3). In this case there is an analogy with the electrochemical behaviour of $(\eta^5\text{-CpCo})_2B_nC_2H_{n+2}$ ($n = 5$ to 10).[43,112] On the other hand, according to cyclic voltamperometric data, the $(\eta^5\text{-Cp})_2CoNiB_7CH_8$ isomers are reduced in a single reversible one-electron stage, while their oxidation is irreversible. The reduction of $(\eta^5\text{-Cp})_2Co^{III}Ni^{IV}.B_7CH_8$ gives rise to a complex containing Co^{III} and Ni^{III}, but it has not been isolated.

(*b*) *The effect of reducing and oxidising agents.* When $[(B_9C_2H_{11})_2Co]^-$ is acted upon by n-BuLi, the product is an analogue of cobaltocene—the complexes $[(B_9C_2H_{11})_2Co]^{2-}$,

which is unstable in air[14]. Paramagnetic complexes of the type $CpCo^{III}(B_nC_2H_{n+2})Fe^{III}Cp$ ($n=7$, 9) are reduced by $NaBH_4$, which yields diamagnetic compounds of the type $[CpCo(B_nC_2H_{n+2})FeCp]^-$.[113]

It has been established that $CpCoB_9C_2H_{11}$ is stable in oxidising media such as in solution of CrO_3 in CH_3COOH, or acetone in the presence of H_2SO_4, or an alkaline solution of $KMnO_4$.[46] At the same time, on treatment with $CuCl_2$ and other oxidants the complexes $[(B_{10}H_{10}C_2RR')_2Co]^-$ are converted quantitatively into *o*-carbaboranes of the type o-$B_{10}H_{10}C_2RR'$ ($R=R'=H$ or Me; $R=H$, $R'=Me$ or Ph).[130]

3. Chemical Properties of Cobalt Complexes of Carbaboranes

There is an analogy between the chemical behaviour of cobalt complexes of carbaboranes and carbaboranes themselves, although under the reaction conditions the cobalt atom or the Cp ligand are not reaction centres (polyhedral expansion reaction, polyhedral rearrangement, bromination, etc.). Reactions of cobalt complexes of carbaboranes are known in which the nature of the products is determined by the presence of the CoCp fragment in the polyhedral molecule. These are metallation, acetylation, and nitration reactions. As far as is allowed by the available structural data, we shall endeavour to compare the chemical properties of cobalt complexes of carbaboranes, carbaboranes, and Cp sandwich complexes of cobalt. Aqueous alkaline solutions of cobaltocenium salts are known to be stable under radiolysis conditions[147]. The complex $[(1,2\text{-}B_9C_2H_{11})_2Co]^-$ is also stable in the water–nitrobenzene system under irradiation from a ^{60}Co γ-source[148]. At the same time the radiolysis of $[(1,2\text{-}B_9C_2H_{11})_2Co]Cs$ in methanol[149] or the nitrobenzene–bromoform mixture[150] leads to the formation of the corresponding bis-(dicarbollyl)cobalt(III) derivative in which the substituent

(>CHOH or –CBr=CBr–) occupies a bridging position

between the two dicarbollyl ligands.

The reaction of $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ with (*trans*-PhCH=CHPh)$Pt(PEt_3)_2$ in toluene at 20 °C leads to $1\text{-}(\eta^5\text{-Cp})Co\text{-}8\text{-}(PEt_3)_2Pt\text{-}2,7\text{-}B_8C_2H_{10}$ (Fig.23), which is regarded as a compound resulting from the inclusion of the $(Et_3P)_2Pt$ fragment in the carbaborane ring[151]. Another bimetallic carbaborane heterocomplex $(C_8H_{12})NiC_2B_8H_{10}CoCp$ is formed when $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ is treated with $(1,5\text{-}C_8H_{12})_2Ni$.[151] We may note that the carbaborane $2,3\text{-}Me_2\text{-}2,3\text{-}B_9C_2H_9$ also reacts with the analogous zerovalent nickel and platinum complexes to form *closo*-carbaborane complexes of nickel and platinum[151].

In aqueous THF solution in the presence of acid the complex $(C,C'\text{-}Me_2B_4C_2H_2)_2CoH$ is almost quantitatively converted into $(Me_2B_3C_2H_5)CoH(Me_2B_4C_2H_4)$.[98] The latter compound contains two B–H–B fragments and a Co–H fragment. NMR studies failed to demonstrate the occurrence of exchange between B–H–B and Co–H, although the authors[98] do not rule out the possibility of such an exchange at a very low rate. It is of interest that, under the influence of NaH or KOH, $[(Me_2B_3C_2H_5).Co(Me_2B_4C_2H_4)]^-$ is obtained from $(Me_2B_3C_2H_5)CoH(Me_2B_4C_2H_4)$, the proton being split off from the cobalt atom, while the B–H–B fragments are retained. We may note that this process is reversible[98].

The symmetric and asymmetric *closo*-complexes having the general formula $[(2,4\text{-}B_8C_2H_{10})CoL]^{z-}$ ($L=1,2\text{-}B_9C_2H_{11}$, $z=-1$; $L=Cp$, $z=0$) are converted into complexes with the *nido*-structure of the type $[(B_8C_2H_{10}.Nu)CoL]^z$ ($Nu=$pyridine, piperidine, or ethanol) on interaction with Lewis bases[35, 53,117,118] The structure of $(1,2\text{-}B_9C_2H_{11}\text{-}3,11'\text{-}Co\text{-}9'\text{-}C_5H_5N\text{-}7',8'\text{-}B_8C_2H_{10})^-$ has been established by NMR [35,117] and X-ray diffraction[54,55] (Fig. 7).

It is believed[35] that the structure of the $CoB_8C_2H_{10}.Nu$ fragment in the *nido*-complexes $(\eta^5\text{-Cp})CoB_8C_2H_{10}.Nu$ ($Nu=C_5H_5N$ or $C_5H_{10}NH$), obtained by treating $1,2,4\text{-}(\eta^5\text{-Cp}).CoB_8C_2H_{10}$ with pyridine or piperidine, is analogous to that discussed above. However, there is no unanimous view concerning the structure of $(\eta^5\text{-Cp})CoB_8C_2H_{10}.EtOH$.[53,118]

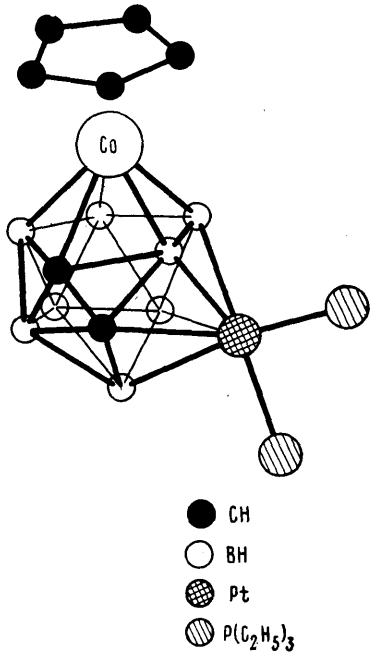

Figure 23. The structure of $1\text{-}(\eta^5\text{-Cp})Co\text{-}8\text{-}(PEt_3)_2Pt\text{-}2,7\text{-}B_8C_2H_{10}$.[151]

The hydrogen atoms attached to the boron atoms in $3,1,2\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$ and $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ are exchanged for deuterium in the presence of $(PPh_3)_3RuHCl$. The exchange apparently proceeds via a stage involving the oxidative addition of the terminal BH bond of the complex to the catalyst[152].

The moderate acidity of the hydrogen atom in the C–H bond of the carbaborane $B_{10}C_2H_{12}$ is responsible for the ready formation of the *C*-lithio-derivative in the reaction of the carbaborane with n-BuLi. The reaction of the carbaborane with RMgBr proceeds similarly[38]. The reaction of organometallic compounds (RLi, RMgBr) with an isoelectronic analogue of the complex $CpCoB_9C_2H_{11}$—the cobalticenium cation—gives rise to the products of addition to the Cp ring, i.e. $CpCoC_5H_5R$. There has been only one mention of the formation of the substituted cobalticenium $[RC_5H_4CoCp]^+$ in this reaction, but hitherto this finding has not been confirmed experimentally[153]. We shall now turn to cobalt complexes of carbaboranes. The reaction n-BuLi with $1,2,4\text{-}(\eta^5\text{-Cp})CoB_8C_2H_{10}$ in ether leads to the alkylation of the complex in the Cp ligand and the formation of $1,2,4\text{-}(\eta^5\text{-}C_5H_4Bu).CoB_8C_2H_{10}$.[35] RLi ($R=$n-Bu or C≡CPh) [154] and ArMgBr ($Ar=Ph$, *m*-FC_6H_4, or *p*-FC_6H_4) [155] in THF also react with $3,1,2\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11}$. The reaction of $3,6,1,2\text{-}(\eta^5\text{-CpCo})_2$.

$.B_8C_2H_{10}$ with RLi (R = Bu or Ph) in THF leads to the substitution of the hydrogen atom in one of the Cp ligands by an R-group with formation of 3-(η^5-CpCo)-6-(η^5-C_5H_4RCo)-1,2-$B_8C_2H_{10}$ (R = Bu or Ph).[156]

It is believed[35,154-156] that the reduction process Co(III) → Co(II) takes place in the course of the reaction and the radical $C_4H_9^{\cdot}$ is formed, which leads to the alkylation of the Cp ring. On the other hand, on treatment of 3,1,2-(η^5-Cp).$CoB_9C_2H_{11}$ with BuLi (molar ratio 1:1) in ether, the main product is the *C*-lithio-derivative 3,1,2-(η^5-Cp)Co(1-$LiB_9C_2H_{10}$). For a reactant ratio of 2:1, the product is 3,1,2-(η^5-Cp)Co(1,2-$Li_2B_9C_2H_9$). The compounds have been isolated in the form of carboxylic acids. 3,1,2-(η^5-C_5H_4Bu)$CoB_9C_2H_{11}$ is formed in a small amount as a side product[154].

Instances of the electrophilic substitution of hydrogen atoms in the polyhedral ligand of a cobalt carbaborane complex are known. Substitution takes place at the boron atoms most remote from the carbon atoms, which results in an enhancement of their electron density[157,158]. When $[(1,2\text{-}B_9C_2H_{11})_2Co]^-$ is treated with an excess of bromine in glacial acetic acid, the bromo-derivative $[(8,9,12\text{-}Br_3\text{-}1,2\text{-}B_9C_2H_8)_2.Co]^-$, illustrated in Fig.3, is formed[20]. Its structure was established by X-ray diffraction[49]. The asymmetric complex 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ is also brominated under analogous conditions[47]. It has been established that the bromination of 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ with bromine in CH_2Cl_2 in the presence of $AlCl_3$ takes place in steps. Depending on the amount of bromine, mono-, di-, or tri-bromo-derivatives of 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ are formed. The authors suggest[47] that initially substitution takes place at the boron atom in the 8-position and then successively in the 9- and 12-positions. 3,1,2-(η^5-Cp)Co(1-$MeB_9C_2H_{10-n}Br_n$) (n = 1, 2) has been obtained similarly[47]. On bromination of the complex CpCo(1,6-$B_7C_2H_9$),[62] substitution takes place also at the boron atom[159]. On treatment with an excess of bromine in CCl_4, CpCo.$(B_7C_2H_7Br_2)$ is formed.

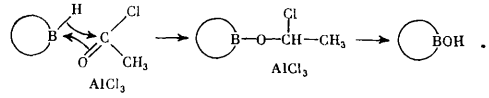
Bimetallic carbaborane heterocomplexes, particularly isomers IV and V of the complex $(\eta^5\text{-Cp})_2CoNiB_7CH_8$, are also brominated successfully (Fig.22). Bromination is achieved with one or two moles of bromine in CCl_4, which yields respectively mono- and di-bromo-derivatives[132]. In all the instances examined, there is no substitution in the Cp ligand. We may note that cobaltocene is oxidised by bromine to the cobalticenium ion[160].

Thus cobalt complexes of carbaboranes behave analogously to carbaboranes under the conditions of electrophilic bromination[38]. In addition, bromination of the π-complexes takes place also in glacial acetic acid, while carbaboranes are inert under these conditions.

Another electrophilic substitution reaction, the Friedel–Crafts acetylation, also leads to the formation of B-substituted complexes only.

Acetylation of (η^5-Cp)Co(1,6-$B_7C_2H_9$) gives a 72% yield of (η^5-Cp)Co(8-$CH_3CO\text{-}B_7C_2H_8$). The acetyl derivative readily gives rise to the corresponding 2,4-dinitrophenylhydrazone, but is not converted into the corresponding carbinol in the presence of $LiAlH_4$.[159] The complex (η^5-Cp)Co(1,10-$B_7C_2H_9$) is inert under the conditions corresponding to the acylation of the 1,6-isomer. This is apparently a consequence of a more symmetrical distribution of electron density in the ligand of the 1,10-isomer.

The acetylation of 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ does not proceed as smoothly as in the case of (η^5-Cp)Co(1,6-$B_7C_2H_9$).[161] The reaction is carried out in an atmosphere of nitrogen by treatment with CH_3COCl and $AlCl_3$. As in bromination, substitution takes place at the $B_{(8)}$ atom, which is most remote from the electron-deficient carbon atoms and therefore has the highest electron density. The structure of 3,1,2-(η^5-Cp)Co(8-$CH_3COB_9C_2H_{10}$) has been established by X-ray diffraction[161]. However, 3,1,2-(η^5-Cp)Co(8-$CH_3COB_9C_2H_{10}$) is formed in a small amount and is not the only reaction product. At the same time, 3,1,2-(η^5-Cp)Co(8-$RB_9C_2H_{10}$), where R = Cl, OH, or $OCOCH_3$, have been isolated[161]. Acetylation of 3,1,2-(η^5-Cp)Co(1-$PhB_9C_2H_{10}$) with a mixture of CH_3COCl and $AlCl_3$ in dichloroethane at 45–55 °C leads only to the oxidation of the B–H bond and the formation of the B-hydroxy-derivative[162]. We may note that, among the known cyclopentadienyl π-complexes of cobalt, acetylation is undergone only by (η^5-Cp)Co(η^4-C_4H_4), with substitution at a carbon atom of the C_4H_4 ligand (yield approximately 10%).[163]



When 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ is refluxed in benzene with an excess of $AlCl_3$, the B-substituted derivative 3,1,2-(η^5-Cp)Co(8-$ClB_9C_2H_{10}$) is formed[161].

The B–H bond in 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ is oxidised more readily than in the *o*-carbaborane. The oxidation takes place under the influence of CrO_3 in $(CH_3CO)_2O$ or CH_3COOH in the presence of H_2SO_4 [162] and of the nitrating mixture ($HNO_3:H_2SO_4 = 1:3$) [162] and also in Friedel–Crafts acetylation[161,162]. In the first case the *B*-acetoxy and *B*,*B*-diacetoxy-derivatives are formed together with 3,2,1-(η^5-Cp)Co(8-$HOB_9C_2H_{10}$).[162] The reaction with the nitrating mixture gives the nitrate 3,2,1-(η^5-Cp)Co(8-$O_2NOB_9C_2H_{10}$).[162]

The nitration of 3,2,1-(η^5-C_5H_4Ph)$CoB_9C_2H_{11}$ and 3,2,1-(η^5-Cp)Co(1-$PhB_9C_2H_{10}$) gives two series of compounds. On the one hand, the *para*-nitro-derivatives 3,2,1-(η^5-$C_5H_4C_6H_4NO_2$-*p*)$CoB_9C_2H_{11}$ and 3,2,1-(η^5-Cp)Co(1-*p*-$NO_2C_6H_4B_9C_2H_{10}$) are formed, and, on the other, the products are the corresponding $B_{(8)}$ derivatives 3,2,1-(η^5-$C_5H_4C_6H_4NO_2$-*p*)Co(8-$O_2NOB_9C_2H_{10}$) and 3,2,1-(η^5-Cp)Co(1-*p*-$NO_2C_6H_4$-8-$O_2NOB_9C_2H_9$).[162] It is believed that the *B*-hydroxy-derivative is formed initially and is then converted into the nitrate.

The formation of the *B*-hydroxy- and *B*-acetoxy-derivatives 3,2,1-(η^5-Cp)Co(8-$RB_9C_2H_{10}$) (R = OH or $OCOCH_3$ from 3,2,1-(η^5-Cp)$CoB_9C_2H_{11}$ under the conditions of the acetylation reaction (treatment with $CH_3COCl + AlCl_3$) is fairly unexpected[161,162], since the $CH_3COCl + AlCl_3$ mixture does not have very pronounced oxidising properties. Furthermore, the reaction of CH_3COCl and $AlCl_3$ with 3,2,1-(η^5-Cp)Co(1-$PhB_9C_2H_{10}$) in dichloroethane also led to the formation of the *B*-hydroxy-derivative 3,2,1-(η^5-Cp)Co(1-Ph-8-$HOB_9C_2H_9$) instead of the expected acetylation in the benzene ring[162]. 3,2,1-(η^5-Cp)Co(1-Me-8-$HOB_9C_2H_9$) has been obtained similarly[162].

It is believed that the formation of the *B*-hydroxy-derivatives must be regarded as a hydride shift reaction:

This hypothesis agrees well with the idea that there is enhanced electron density at the $B_{(8)}$ atom and with known experimental facts (the formation of $B_{(8)}$ derivatives alone).

The enhanced hydride mobility of the hydrogen atoms linked to boron atoms facilitates the hydrogen–halogen exchange in reactions of alkyl halides with 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ compared with the carbaboranes $B_{10}C_2H_{12}$. On treatment of 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ with RX (R = Me, Et, or iso-Br; X = I or Br), both alkylation and exchange halogenation in the carbaborane ring takes place. The reaction leads to the formation of the *B*-alkyl-*B*-halogeno-derivatives $CpCoB_9C_2H_{11}$:[164]

$$3,1,2\text{-}(\eta^5\text{-Cp})\,CoB_9C_2H_{11} + RX \xrightarrow[20^\circ]{AlCl_3} (\eta^5\text{-Cp})\,CoB_9C_2H_{11-n-m}R_nX_m \quad n = 3, 4;\ m = 1, 2.$$

There exists another series of reactions of dicarbollylcobalt complexes in which substitution takes place only at the $B_{(8)}$ atom. All these reactions are carried out in the presence of acids. On treatment of $[3,3\text{-}Co(1,2\text{-}B_9C_2H_{11})_2]^-$ with diethyl sulphide in a strongly acid medium, a neutral compound is formed[165]:

$$[3,3\text{-Co}(1,2\text{-}B_9C_2H_{11})_2]^- + HCl + Et_2S \rightarrow 1,2\text{-}B_9C_2H_{11}\text{-}3,3'\text{-Co-}8'\text{-}SEt_2\text{-}1',2'\text{-}B_9C_2H_{10} + H_2.$$

Treatment of $[3,3\text{-Co-}(1,2\text{-}B_9C_2H_{11})_2]^-$ with carbon disulphide in the presence of $AlCl_3$ and HCl yields the compounds $\{[3,3\text{-Co-}(1,2\text{-}B_9C_2H_{10})_2]^-S_2C^+H\}$, in which two dicarbollyl groups are linked by the $[SC^+(H)S]$ bridge[166]. The 1,7-isomer reacts similarly[166]; the structure of the resulting compound is illustrated in Fig. 2.[48,167]

The electron-deficient carbon atom in the complexes formed is stabilised by the free electron pair of the sulphur atom. The compound in which the $[OC^+(CH_3)O]$ fragment is a bridge between dicarbollyl groups has been isolated by treating $[3,3\text{-Co}(1,2\text{-}B_9C_2H_{11})_2]^-$ with the CH_3COOH–$(CH_3CO)_2O$ mixture in the presence of catalytic amounts of $HClO_4$.[147] It has been suggested[165] that a protonated complex is formed in the course of the reaction and is then subjected to nucleophilic attack by a neutral molecule (Et_2S or CS_2), which results in the formation of the corresponding $B_{(8)}$ derivative and evolution of molecular hydrogen[165,166]. The protonated complex hypothesis agrees satisfactorily with the hypothesis of the hydride properties of the hydrogen at the boron atom in the 8-position[162].

The carbonium centres in the complexes $\{[(1,2\text{-}B_9C_2H_{10})_2Co]^-.O_2C\overset{+}{C}H_3\}$ and $\{[(1,2\text{-}B_9C_2H_{10})_2Co]^-S_2\overset{+}{C}H\}$ are inert towards protic solvents. This is probably a consequence of the partial delocalisation of the positive charges of the neighbouring heteroatoms and the proximity of the negative charge. The interaction with $NaBH_4$ is rapid and gives a good yield[166]:

$$\{[(1,2\text{-}B_9C_2H_{10})_2Co]^-S_2C^+H\} + NaBH_4 \rightarrow [(1,2\text{-}B_9C_2H_{10})_2CoS_2CH_2]^-.$$

The hydrolysis of $\{[(1,2\text{-}B_9C_2H_{10})_2Co]^-O_2C^+CH_3\}$ and the analogous sulphur-containing derivatives leads to the formation of a diol and a dithiol respectively[166]. Furthermore, the corresponding thiolothioformyl derivative was isolated in the hydrolysis of $\{[(1,2\text{-}B_9C_2H_{10})_2Co]^-S_2C^+H\}$.[166]

The reaction of $[3,3\text{-Co}(1,2\text{-}B_9C_2H_{11})_2]^-$ with S_2Cl_2 in CH_2Cl_2 leads to $[8,8\text{-}S(B_9C_2H_{10})_2Co]^-$ after alkaline methanolysis[168]. This reaction has no analogies in the chemistry of carbaboranes. The sulphur atom in the complex is highly reactive and is readily alkylated with formation of 8,8-RS.$.(B_9C_2H_{10})_2Co$, R = alkyl[168].

In the presence of diazonium salts $[(7,8\text{-}B_9C_2H_{11})_2Co]^-$ gives rise to the complex $RC_6H_4N_2.[(7,8\text{-}B_9C_2H_{11})Co]$. On heating, this compound is converted into the *B*-substituted derivative in which the phenylene unit occupies a bridging position between the two dicarbollyl groups[169].

The reaction of the dicarbollyl complex 3,2,1-(η^5-Cp).$.CoB_9C_2H_{11}$ with $PhBCl_2$ is interesting[170]: there is a complete analogy with the chemical behaviour of cobaltocene. In both cases the addition of the Ph(Cl)B fragment to the Cp ligand is accompanied by the heterolysis of the B–Cl bond and a ring expansion reaction, which leads to the formation of a six-electron borinate ion involved in a π-type coordination[153]:

$$3,2,1\text{-}(\eta^5\text{-Cp})CoB_9C_2H_{11} + PhBCl_2 \rightarrow 3,2,1\text{-}(\eta^6\text{-}C_6H_5B\text{—Ph})CoB_9C_2H_{11}.$$

3,2,1-(η^5-Cp)$CoB_9C_2H_{11}$ is initially reduced with sodionaphthalene in THF, whereupon, after the addition of an excess of $PhBCl_2$ and exposure of the reaction product to air, a derivative of the borinate ion is obtained in 17% yield[170]. When $CpCoB_9H_9CHCCH(OH)R$ is treated with $LiAlH_4$ and H_2AlCl, the CHOH group is reduced and $CpCoB_9H_9CHCCH_2R$ is formed[171].

The oxidation of 3,1,2-(η^5-Cp)$CoB_9H_9CHCCH_2OH$ with chromium trioxide in acetone in the presence of H_2SO_4 yields 3,1,2-(η^5-Cp)$CoB_9H_9CHCCHO$. The oxidation of the CH_2OH group to CHO then takes place more readily than the oxidation of the aldehyde group to the carboxy-group[46]. Under the influence of CrO_3 in an acid medium, the complex $(\eta^5\text{-CpCo})_2.$ $.B_8H_8CHCCH_2OH$ yields the corresponding aldehyde. Further oxidation of $(\eta^5\text{-CpCo})_2B_8H_8CH_8CCHO$ is difficult apparently owing to pronounced steric hindrance[111].

The aldehyde and ketone groups in 3,1,2-(η^5-Cp)Co.$.B_9H_9CHCR$ (R = CHO [46] or $COCH_3$ [161]) form the corresponding hydrazones on reaction with 2,4-dinitrophenylhydrazine. On treatment of 3,1,2-(η^5-Cp)$CoB_9H_9CHCCHO$ with C_2H_5ONa or t-C_4H_9ONa, the CHO group is split off with formation of $CpCoB_9H_9C_2H_2$, while the reactions with Grignard reagents take place stereoselectively and leads to diastereoisomeric secondary alcohols[171]. The Clemmensen reduction of 3,1,2-(η^5-Cp)$CoB_9H_9CHCCOCH_3$ gives rise to an ethyl-substituted complex[161]. The carboxylic acid 3,1,2-(η^5-Cp)$CoB_9H_9CHC.$ $.COOH$ ($pK_a = 3.54$) is converted into the methyl ester by treatment with diazomethane or into the acid chloride by reaction with PCl_5.[46] The acid chloride 3,1,2-(η^5-Cp)Co.$.B_9C_9CHCCOCl$ does not hydrolyse and undergoes very slowly the Friedel–Crafts reaction with benzene. The passivity of the COCl group is also regarded as a consequence of steric factors[46]. Treatment of the *B*-hydroxy-derivative 3,1,2-(η^5-Cp)Co(8-$HOB_9C_2H_{10}$) with acetic anhydride or CH_3COCl leads to the corresponding *B*-acetoxy-derivative 3,1,2-(η^5-Cp)Co(8-$CH_3OCOB_9C_2H_{10}$).[161,162] The amino- (pK_a = 6.04) and vinyl groups in 3,1,2-(η^5-Cp)Co(6-$RB_9C_2H_{10}$), where $R = NH_2$ or $CH=CH_2$, exhibit a reduced reactivity compared with the corresponding carbaborane derivatives[96]. The nitro-derivatives 3,1,2-(η^5-Cp)$CoB_9H_9CHCC_6H_4NO_2$ and 3,1,2-(η^5-$C_5H_4C_6H_4NO_2)CoB_9C_2H_{11}$ are reduced to the corresponding substituted anilines on treatment with tin and HCl in an alcoholic solution[162].

Thus it follows from the examples presented that the chemical behaviour of the functional groups in the polyhedral ligand in a cobalt carbaborane complex differs little from the usual chemical reactions of these groups.

In conclusion of the discussion of the chemical properties of cobalt complexes of carbaboranes, we may mention that the properties of the complex [(η^5-Cp)Co(7-$B_{10}CH_{11}$)]$^-$ differ significantly from those of the compounds considered here. The complex is chemically inert and is stable for 90 h at 100 °C in KOH and EtOH solutions. It does not undergo polyhedral expansion and contraction reactions. The anion [(η^5-Cp)Co(7-$B_{10}CH_{11}$)]$^-$ is not converted into a neutral complex containing Co(IV) on treatment with oxidants ($KMnO_4$, $FeCl_3$, or the Ce^{4+} ion).[102]

V. POLYHEDRAL COBALT COMPLEXES OF *NIDO*-CARBABORANES

The *nido*-complexes of cobalt are obtained by the polyhedral contraction reaction[35,118] (see Section III) or by treating with nucleophiles (pyridine, piperidine, and ethanol) *closo*-complexes of the type $[(B_8C_2H_{10}CoL)]^z$, where L = 1,2-$B_9C_2H_{11}$ with $z = -1$ or L = Cp with $z = 0$ [35,53,117,118] (for further details, see Section IV).

When polyhedral cobalt *nido*-carbaborane complexes $[(B_8C_2H_{10}NC_5H_5)CoL]^z$ [35,117] or $CpCoB_7C_2H_{11}$ (Fig. 6) are oxidised[118] with iron(III) chloride, a non-terminal hydrogen atom is split off and the closed system of the cobalt *closo*-carbaborane complex is formed:

$$[(7,8\text{-}B_8C_2H_{10}\cdot NC_5H_5)CoL]^z \xrightarrow{FeCl_3} [(2,4\text{-}B_8C_2H_9NC_5H_5)CoL]^{z+1}$$
$$L = C_5H_5,\ z = 0;\ L = 1,2\text{-}B_9C_2H_{11},\ z = -1$$
$$CpCoB_7C_2H_{11} \xrightarrow{FeCl_3} CpCo(6,7\text{-}B_7C_2H_9).$$

The $[1,2,4\text{-}(\eta^5\text{-Cp})Co(7\text{-}C_6H_5NB_8C_2H_9)]^+$ formed is precipitated by PF_6 anions. The compound is decomposed in polar solvents[35]. A more stable neutral *closo*-complex $(\eta^5\text{-Cp}).CoB_8C_2H_9C_5H_{10}$ is obtained in 34% yield by oxidising $(\eta^5\text{-Cp}).CoB_8C_2H_{10}.NHC_5H_{10}$ and iron(III) chloride and by subsequent treatment with K_2CO_3.[35]

Like the anion $(B_9C_2H_{12})^-$, the cobalt *nido*-carbaborane complex $(1,2\text{-}B_9C_2H_{11}\text{-}3,9'\text{-}Co\text{-}7',8'\text{-}B_8C_2H_{11})^-$ is protonated in the presence of HCl and converted into the complex $(1,2\text{-}B_9C_2H_{11}\text{-}3,9'\text{-}Co\text{-}7',8'\text{-}B_8C_2H_{12})^-$ having the *nido*-structure[35]. The oxidation of the latter with hydrogen peroxide in an alkaline medium gives rise to $(1,2\text{-}B_9C_2H_{11}\text{-}3,1'\text{-}Co\text{-}2',4'\text{-}B_8C_2H_{11})^-$ (yield 75%).[35]

The main product of the reaction between $(\eta^5\text{-Cp})CoB_8C_2H_{10}$ (VIII) and EtOH in the presence of $FeCl_3$ is $2,1,10\text{-}(\eta^5\text{-Cp})Co.B_7C_2H_9$ (IX). It has been suggested[53] that the reaction proceeds via the intermediate formation of the *nido*-complex $8,6,7\text{-}(\eta^5\text{-Cp})CoB_7C_2H_{11}$ (X), which is converted into $3,2,1\text{-}(\eta^5\text{-Cp})CoB_7C_2H_9$ (XI) after dehydrogenation. The thermal rearrangement of the latter gives the final *closo*-complex (XI).[53]

On refluxing in cyclooctane (at approximately 150 °C) complexes with the *nido*-structure can also be converted into cobalt complexes of *closo*-carbaboranes[53,118]:

$$CpCoB_7C_2H_{11} \xrightarrow{\Delta} CpCo(1,10\text{-}B_7C_2H_9)$$

$$(1,2\text{-}B_9C_2H_{11}\text{-}3,9'\text{-}Co\text{-}7',8'\text{-}B_8C_2H_{12})^- \xrightarrow{\Delta} (1,2\text{-}B_9C_2H_{11}\text{-}3,1'\text{-}Co\text{-}2',3'\text{-}B_8C_2H_{10})^-.$$

Thus cobalt complexes of *nido*-carbaboranes usually have the properties of carbaboranes with the *nido*-structure[38].

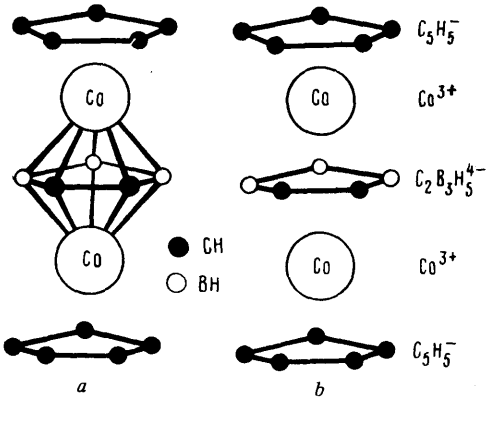


Figure 24. Schematic illustration of two different descriptions of the type of bond in the "three-layer" sandwich compound $(\eta^5\text{-CpCo})_2B_3C_2H_5$.

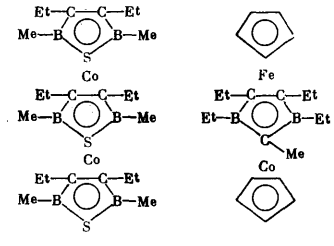
VI. CARBABORANE-CONTAINING THREE-LAYER SANDWICH STRUCTURES



The complex $(\eta^5\text{-CpCo})_2B_3C_2H_5$ is the lowest homologue among the known polyhedral dicobalt complexes of carbaboranes having the general formula $(\eta^5\text{-CpCo})_2B_nC_2H_{n+2}$ ($n = 3$–10). The compound exists in the form of four isomers, two of which [1,7,2,3- and 1,7,2,4-$(\eta^5\text{-CpCo})_2B_3C_2H_5$] contain cobalt atoms in the *para*-position with respect to the carbaborane fragment (Fig.24). In the non-Soviet literature compounds of this type are referred to as "triple-decker sandwich structures"; we shall refer to them as three-layer sandwich structures. There exist two equivalent but different qualitative descriptions of the type of binding in these compounds[116,143]. They can be regarded as dicobalt complexes of carbaboranes existing as a result of strong and highly localised covalent interactions (Fig.24*a*). Here the central $Co_2B_3C_2$ fragment contains 16 valence electrons, in agreement with the empirical rule[21,172]. The other alternative description of the binding is based on the formal subdivision of the molecule into three planar ring systems ($C_5H_5^-$, $B_3C_2H_5^{4-}$, and $C_5H_5^-$) and two Co^{3+} ions (Fig.24*b*).

The structures of $1,7,2,3\text{-}(\eta^5\text{-CpCo})_2(3\text{-}MeB_3C_2H_4)$ [115] and $1,7,2,4\text{-}(\eta^5\text{-CpCo})_2(2\text{-}MeB_3C_2H_4)$ have been determined[143]. All the three rings in the complexes are planar but not parallel. The C–C distances in the carbaborane ligand in the 1,7,2,3- and 1,7,2,4-isomers are 1.44 and 1.52 Å respectively.

The results of the study of the ^1H and ^{11}N NMR of the two isomers show that the electron density in the $B_3C_2H_5$ ligand of the 1,7,2,4-isomer is delocalised over the ring, while in the 1,7,2,3-isomer it is localised mainly at the C–C bond[116]. The presence of substituents in the $B_3C_2H_5$ ligand alters the positions of the chemical shifts for all three rings. Substitution of the Cp ring influences mainly the electron density in the central $B_3C_2H_5$ ligand[116]. The red complex $1,7,2,3\text{-}(CpCo)_2B_3C_2H_5$ absorbs in the ultraviolet at 776 nm, while the green complex $1,7,2,4\text{-}(CpCo)_2B_3C_2H_5$ absorbs in the region of 555 μm.[116] The thermal stability of the 1,7,2,3-isomer is lowest. At 200 °C it is converted into the 1,2,3,5-, 1,2,4,5-, and 1,7,2,4-isomers[23]. The isomers of $(CpCo)_2B_3C_2H_5$ are diamagnetic, resistant to oxidation in the solid state, and do not react with water[115,143].

The isomer $1,7,2,4\text{-}(CpCo)_2B_3C_2H_5$ has been obtained by oxidising the products of the reaction of CpNa and an excess of $CoCl_2$ with the carbaborane $1,6\text{-}B_4C_2H_6$ subjected to preliminary treatment with sodionaphthalene[70,115]. Another isomer and its C-substituted derivatives have been obtained by the reaction of $(RB_4C_2H_6)^-$ with CpNa and $CoCl_2$ followed by oxidation (R = H, Me,[70,115] Ph, or $SiMe_3$ [116]). The 1,7,2,3-isomer or its Cp-substituted derivative $CpCoB_3C_2H_5Co(C_5H_4R)$ (R = H, Me, Et, or $SiMe_3$) has been obtained by the reaction of $[(\eta^5\text{-Cp})CoB_3C_2H_6]^-$ with an excess of $CoCl_2$ and RC_5H_4Na in THF.[70,115,116] The three-layer sandwich structure $1,7,2,3\text{-}(\eta^5\text{-CpCo})_2(\mu\text{-}2,3\text{-}1,3\text{-}C_3H_4B_3C_2H_3)$ is also known[173]. The reaction of $CpCo(CO)_2$ with $(C,C'\text{-}Me_2B_4C_2H_4)_2CoH$ in THF on irradiation or on refluxing in the absence of irradiation yields $1,2,4,5\text{-}(\eta^5\text{-CpCo})_2(Me_2B_3C_2H_3)$ and $(\eta^5\text{-Cp})Co.(Me_2B_3C_2H_3)CoH(Me_2B_3C_2H_5)Co(\eta^5\text{-Cp})$,[98] while the reaction of $CpCo(CO)_2$ with $(Me_2B_4C_2H_4)_2FeH_2$ results in the formation of $1,7,2,3\text{-}(\eta^5\text{-Cp})Co(Me_2B_3C_2H_3)Fe(CO)_3$.[63] In the reactions considered three-layer sandwich structures are formed in low yields (≤5%) and are mixed with other cobalt complexes of carbaboranes[70,98,115,173]. The compounds are isolated by chromatographic methods on silicone gel. The interaction of $Co_2(CO)_8$ with thiaborolene gives rise to the formation of a three-layer sandwich structure (XII) in which the thiadiborolene ligand plays the role of both a μ-ligand and an η-ligand[174]. The Lewis acid 1,3-diborolene reacts with $Co_2(CO)_8$ to form $[\eta\text{-}R_4(Me)B_2C_3]Co(CO)_2$.[175] The interaction of 1,3-diborolene with $CpCo(CO)_2$ in the presence of $[CpFe(CO)_2]_2$ gives rise to the formation of compound (XIII).[175] Compounds (XII) and (XIII) have high thermal stability and are resistent

to oxidation:

(XII) (XIII)

VII. COBALT σ-COMPLEXES OF CARBABORANES

As a result of the marked electron-deficient properties $B_{10}C_2H_{12}$, the σ-complex $\{[(B_{10}C_2H_{10})_2]_2Co\}^{2-}$ does not contain the usual stabilising ligands (CO or PR_3). A cobalt complex is formed when 2,2′-ligand dilithiobiscarbaborane is treated with anhydrous $CoCl_2$.[176,177]

The coordination sphere of the cobalt atom consists of four Co–Co σ-bonds and the Co–H–B bridge bond. In the carbaborane icosahedra there is a tetrahedral arrangement around the cobalt atom[178]. Under the influence of oxidants and reductants, the cobalt in $\{[(B_{10}C_2H_{10})_2]_2Co\}^-$ readily undergoes a change in its formal oxidation state from +3 to +1.[176,177] The complex $(HC_2B_{10}C_2H_{11})Co_2(CO)_6$, obtained from $Co_2(CO)_8$ and $HC{\equiv}CB_{10}C_2H_{11}$, is also known[179]. It does not contain a direct cobalt-carbaborane σ-bond, but is an interesting example of carbaborane-containing acetylenic cobalt complexes[180].

VIII. COBALT-CONTAINING BORANES

Like the cobalt complexes of carbaboranes, the known cobalt complexes of boranes can be regarded as borane derivatives in the polyhedra of which the BH vertex has been replaced by the CpCo group. Fig.25 illustrates the molecular structure of 2-(η^5-cyclopentadienyl)-2-cobalt-*nido*-η^3-pentaborane(9).[181] The cobalt atom is located between the Cp and B_4H_8 fragments, the latter behaving as a three-electron-donating ligand in relation to cobalt[181]. The complex (η^5-Cp).Co(5-B_9H_{13}), the dicobalt borane complex 1,2-(η^5-CpCo)$_2B_4H_6$, and its substituted derivatives 1,2-(η^5-CpCo)$_2$-(3-cyclo-$C_5H_9B_4H_{15}$), 1,2-(η^5-CpCo)$_2$(4-cyclo-$C_5H_9B_4H_5$), and (η^5-Cp.Co)$_2$(σ-4-$C_5H_9B_4H_5$) are also known[173].

The crystal and molecular structures of (η^5-Cp)Co(5-B_9H_{13}) have been determined by X-ray diffraction[182]. The complex has the *nido*-structure and contains four bridge bonds, among which three are of the B–H type and one is of the B–H–Co type. The B_4 surface of the borane ligand is almost parallel to the plane of the Cp-ring.

The above compounds are resistant to the action of air and water. The complex 2-(η^5-Cp)CoB_4H_8 undergoes a polyhedral rearrangement at 200 °C, the cobalt atom migrating to the 1-position[173]. A mixture of complexes has been obtained by adding an excess of $CoCl_2$ and CpNa in THF to a solution of $Na^+[B_5H_8]^-$ at −196 °C; it was then separated by thin-layer chromatography and silica gel. (CpCo)$_2$(3-cyclo-$C_5H_9B_4H_5$) and (CpCo)$_2$(4-cyclo-$C_5H_9B_4H_5$) are apparently formed when the Cp anion is hydrogenated by the hydroborate anion $(B_5H_8)^-$.[173,183] Apart from the compounds enumerated above, (η^5-CpCo)$_3B_3H_5$, (η^5-CpCo)$_3B_4H_4$, and (η^5-CpCo)$_4B_4H_4$ were later isolated in lower yields from the products of the reaction of $Na^+[B_5H_8]^-$ with $CoCl_2$ and CpNa.[173,184] The crystal and molecular structures of 1,2,3-(η^5-CpCo)$_3B_3H_5$ and 1,2,3-(η^5-CpCo)$_3B_4H_4$ gave been determined by X-ray diffraction[185]. Under the conditions of the gas-phase method, not only the complexes described above[183,184] but also clusters containing five boron atoms, (η^5-CpCo)$_3B_5H_5$ and (η^5-CpCo)$_3B_5H_4C_5H_5$,[186] have been obtained from pentaborane(9), cyclopentadiene, and cobalt.

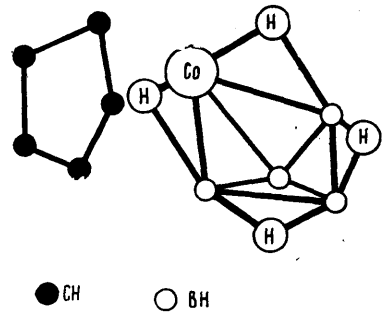


Figure 25. The structure of 2-(η^5-cyclopentadienyl)-2-cobalta-*nido*-pentaborane(9).[181]

The symmetrical cobalt borane complex $[(B_{10}H_{12})_2Co]^{2-}$ is formed when the labile $Zn(B_{10}H_{12}).(C_4H_8O)_2$ [187] is acted upon by anhydrous $CoCl_2$ in acetone[188]. The salt $[N(CH_3)_4]_2.[(B_{10}H_{12})_2Co]$ is sparingly soluble in water, is more soluble in alcohol, and is very readily soluble in acetonitrile, acetone, and DMF.

The interaction of $Co_2(CO)_8$ with $NaB_{10}H_{13}$ [188] or $Na_2(B_{18}H_{20})$ [189,190] in THF yielded carbonyl derivatives of cobalt borane complexes $[N(CH_3)_4][(B_{10}H_{12})Co(CO)_3]$ (yield 55%) and $[N(CH_3)_4][(B_{18}H_{20})Co(CO)_3]$ (yield 20%) respectively. The complex $[N(CH_3)_4]_2[Co(B_{10}H_{12})_2]$ catalyses the condensation of nitriles with acetylenes, which leads to the formation of alkylpyridines[191]. The cobalt-containing derivatives of phosphadecaborane (η^5-Cp)Co(7-$B_{10}H_{10}$PR) and [(η^5-Cp)Co(7-$B_{10}H_{10}$P)]$^-$ (R = Me, Et, n-Pr, or Ph) have been obtained in 15–35% yield by the reaction of 7-$B_{10}H_{12}$PR with $CoCl_2$ and C_5H_6 in the presence of an excess of KOH in anhydrous EtOH. The alkylation of [(η^5-Cp)Co(7-$B_{10}H_{10}$P)]$^-$ with RI (R = Me, Et, or n-Pr) gives a high yield of (η^5-Cp)Co(7-$B_{10}H_{10}$PR). A hypothesis concerning their structure was put forward on the basis of ^{11}B and ^1H NMR and ultraviolet spectroscopic data[192].

During the preparation of this review for the press, a while series of communications devoted to the development of theoretical ideas about the structure and nature of the bonds in metal carbaborane complexes as well as new methods of synthesis and new compounds were published. A review[193] discusses the nature of the bonds in metal complexes of carbaboranes, their structure, and nomenclature, as well as general problems of the synthesis of such complexes. It includes tabes with data on known complexes; the methods of synthesis of principal metal carbaborane complexes are described. Another review[194] discusses advances in the chemistry of metal carbaborane complexes during the last ten years. These reviews[193,194] include exhaustive information about studies on the chemistry of metal complexes of carbaboranes published up to 1974 inclusive. The bibliography for 1950–1976, reflecting the results of electrochemical research into transition metal complexes, including cobalt complexes of carbaboranes, is presented in another review[195].

The topology of the bonds in polyhedral boranes, carbaboranes, and metal complexes of carbaboranes is discussed from the standpoint of graph theory in a paper by King and Rouvray[196]. Wade's empirical rule[196,197] is used widely in the study of the principal characteristics of various types of rearrangements in carbaboranes and their metal complexes[198] and in the discussion of the structures of cobalt complexes of carbaboranes[199–203]. The *closo*-complexes 1,8,2,3-(η^5-Cp)$_2$-1-Fe-8-Co-$B_7C_2H_9$ [199] and (η^5-CpCo)$_4B_4H_4$,[200] whose structures have been determined by X-ray diffraction, contain fewer electrons than would be expected from Wade's rule. It is believed[204] that such electron deficiency leads either to partial filling of the *d* orbitals of the transition metal or to the formation of the so-called M–M "extra bond" and the consequent distortion of the geometry of the polyhedron (see, for example, Stanko et al.[199]). The presence of five 12-vertex clusters, containing twenty eight electrons and having both *nido*- and *closo*-structures, also constitutes a deviation from Wade's rule[201,202,205]. The causes of these deviations are also discussed by Nishimura[206].

The structures of the zwitter-ions 5-[(η^5-Cp)Co(η^5-C_5H_4)-2,3-$Me_2B_4C_2H_3$]Co(2,3-$Me_2B_3C_2H_5$) [209] and (η^5-Cp)Co(η^5-C_5H_4)-$Me_4B_8C_4H_8$,[210] the mixed cluster 2,3,10-(η^5-Cp)$_2$-2-Ni-3-Co-B_7CH_8,[211] the cluster (η^5-CpCo)$_2$($Me_4B_6C_4H_6$),[203] the isostructural analogue of one of the isomers of the corresponding unsubstituted complex[205], the pentasubstituted compound 8,1,2,3,7-(η^5-Cp)Co(12-C_2H_5O-1,2,3,7-$Me_4B_7C_4H_6$),[201] the polyhedron (NMe_4)[(η^5-CpCo)$_2B_9CH_{10}$],[209] the three-layer sandwich compound 1,7,2,3-(η^5-CpCo)$_2$[(μ-2,3)-1,3-$C_3H_4B_3C_2H_3$], whose planar bicyclic ligand $(B_3C_5H_7)^{4-}$ is isoelectronic with the pentalenide anion $(C_8H_7)^-$,[210] and the metal *closo*-carbaborane complex 1,2-(η^5-CpCo)$_2B_4H_6$, in which the Co–Co distance amounts to 2.577 Å and is a maximum for compounds of this kind[211], have been determined by X-ray diffraction.

The gas-phase reaction is used widely for the direct synthesis of cobalt complexes of boranes and carbaboranes. 1-(η^5-Cp)CoB_5H_9 and 2-(η^5-Cp)CoB_9H_{13},[212] (η^5-Cp)Co(Me_2-$SnB_4C_2H_4$),[213] 1,7,2,5-(η^5-CpCo)$_2$(2,5-Me_2-$B_5C_2H_5$), and others[214] have been obtained. In the last instance[214] the synthesis was carried out without the preliminary formation of the carbaborane ligand, metallic cobalt or $CpCo(CO)_2$, pentaborane(9), and but-2-yne may be used as the starting materials. $CpCo(CO)_2$ is being used with increasing fequency as the starting material. The reaction is carried out under ultraviolet irradiation[205] or with heating[218]. The isomeric compounds (η^5-Cp)Co($Me_4B_6C_4H_6$) and (η^5-Cp)Co($Me_4B_7C_4H_7$) [205] as well as the isomeric compounds 2-[1,3,5-(2',4'-$B_5C_2H_6$)-1,8,5,6-(η^5-CpCo)$_2B_5C_2H_6$] [218] have been obtained in this way.

The method based on the use of the products of the partial degradation of polyhedral carbaboranes and boranes under the influence of nucleophiles continues to be developed[219]. The π-complex [1,2-(η^5-Cp)CoB_9CH_{10}]$^-$ [220] and new cobalt heteroborane complexes containing arsenic[221,222], antimony[222], selenium, and tellurium[223] have also been obtained by this method. ($Me_2B_4C_2H_4$)$_2FeH_2$ [204] and 2-(η^5-Cp)CoB_4H_8 [224] have been used as starting materials.

The range of applications of the polyhedral expansion reaction has been increased. The reaction has been carried out for $Me_4B_8C_4H_8$ [205] and the nickel borane complex [*nido*-(η^5-Cp)$NiB_{10}H_{12}$]$^-$.[225]

The oxidative coupling reaction, examined previously[98], has been studied in relation to new examples. The synthesis of (η^5-Cp)Co[(R)(Me_4)$B_7C_4H_6$] (R = H [205] or C_2H_5O [204]) has been achieved by the interaction of [($Me_2B_4C_2H_4$)CoH.($Me_2B_3C_2H_3$)]$^-$ [205] or ($Me_2B_4C_2H_4$)$_2FeH_2$ [204] with $CoCl_2$ in the presence of a cyclopentadienylating agent. The complex (η^5-Cp)$CoB_7C_4H_{11}$ and three isomers of the complex (η^5-CpCo)$_2B_6C_4H_{10}$ are formed on treating *closo*-1,2,3-(η^5-Cp)$CoB_4C_2H_6$ or *nido*-1,2,3-(η^5-CpCo)$B_3C_2H_7$ with a KOH solution in ethanol.

The tetramethyl derivative (η^5-CpCo)$_2$($Me_4B_6C_4H_6$), which is a structural analogue of one of the isomers of the complex (η^5-CpCo)$_2B_6C_4H_{10}$, was obtained as the only reaction product under analogous conditions from the corresponding C,C'-dimethyl-substituted cobalt complexes of carbaboranes[205]. The mechanism of the reaction and the causes responsible for it have been discussed[202,205].

The chemistry of the dicarbollylcobalt complex has been enriched by new reactions. When 3,1,2-(η^5-Cp)$CoB_9C_2H_{11}$ reacts with sulphur in benzene in the presence of $AlCl_3$, a mixture of mercapto-isomers 3,1,2-(η^5-Cp)Co(n-HS-$B_9C_2H_{10}$), where n = 8 or 9, is formed. The symmetrical complex gives rise to the S-bridged compound Cs[Co(3,1,2-$B_9C_2H_{10}$)$_2$-8,8'-S] under these conditions. In the absence of sulphur the final reaction product is the complex Cs[Co(3,1,2-$B_9C_2H_{10}$)$_2$-8,8'-(1,2-C_6H_4)] with the phenylene unit in the bridge position[221]. The substitution of the hydrogen at the boron atom in the 8-position, which has enhanced electron density, and the formation of complexes with substituents in the bridge position have been observed also in the reaction of [Co.($B_9C_2H_{11}$)$_2$]$^-$ with $NaNO_2$, RCHO (R = H or Me), SeO_2, or Te in H_2SO_4. Nitrogen-, selenium-, and tellurium-containing complexes are readily alkylated by treatment with Me_2SO_4, forming [Co($B_9C_2H_{10}$)$_2$-8,8'-X], where X = NHMe, NMe_2, Se^+Me, or Te^+Me.[222] The oxidation-reduction properties of "thre-layer" sandwich compounds of the type ($CpCo)_2B_3C_2H_5$ have been investigated by electrochemical methods[228].

Like boranes, cobalt complexes 2-(η^5-Cp)CoB_4H_8 are deprotonated by sodium hydride and interact with acetylene. In the latter case the product is a carbaborane system, in particular 1,2,3-(η^5-Cp)$CoB_5C_2H_7$. The reaction with higher alkynes RC≡CR' gives rise to "addition products" of the type $CpCoB_4H_8.RC_2R'$, which are regarded as intermediates[219]. Ultraviolet irradiation of 2-(η^5-Cp)CoB_4H_8 in the presence of $Fe(CO)_5$ gives rise to the mixed cluster 1,2,3-(η^5-Cp)$_2Co_2$.$(CO)_4FeB_3H_3$.[219]

Liquid chromatography has been used successfully for the separation and identification of cobalt π-complexes of carbaboranes[223].

Theoretical Foundations of the Classification of Molecules by Luminescence Spectra

V.G.Plotnikov

The relationship between the luminescence spectra and the structure of aromatic molecules is discussed theoretically. Various semi-empirical methods of calculating the electronic states of polyatomic molecules are briefly described. The orbitals involved in the electronic transitions and states and the effect of molecular structure and other factors on the energy of the states are considered. The spin-orbit interaction of molecular states is discussed, and radiative transitions in molecules are examined in relation to the nature of the molecule. Modern views on the nature of the conversion processes are outlined, and the variation of their rate with the type of transition and with the energy spectrum and structure of the molecule is analysed. Molecules are classified into five types according to their luminescence spectra, and a justification of this classification is given.
The bibliography includes 154 references.

I. INTRODUCTION

Many problems in photochemistry, radiation chemistry, the chemistry of organic phosphors and scintillators, chemiluminescence, and photobiology are difficult (or impossible) to solve without a knowledge of the relationship between the luminescence-spectral properties of molecular systems and their structure. This is because of the widespread use of luminescence as a method of investigation in those fields of science, and also because the light emission process (luminescence) is one of the most important paths for the dissociation of electronically excited molecules, and must be included in the overall scheme of possible reaction mechanisms.

The study of the luminescence spectra of molecules as a function of molecular structure is a fundamental aspect of molecular spectroscopy: it is one part of the more general problem of the relationship between properties and structure in molecules, first formulated and investigated by Butlerov. The practical importance of this problem was suddenly magnified by the increasing use of organic molecules (especially aromatic molecules, including dyes) in laser technology[1]. A rational search for compounds offering good generation properties (i.e. efficient phosphors and scintillators) presupposes an understanding of the dependence of the luminescence properties on the structural parameters of the molecules.

In the last 5–10 years important advances have been made towards the solution of this problem as a result of the widespread application of theoretical ideas on the structure of molecules and on the nature of their electronic states to the large number of experimental results stimulated by the discovery of the Shpol'skii effect. The experimental aspects of this work have been discussed[2,3] and reviewed[4], but the theoretical side has not yet been reviewed in detail. This article aims to fill this gap. The discussion will be limited mainly to aromatic and hetero-aromatic molecules (all of which will be termed aromatic in the interest of brevity) in the condensed phase. These are the systems of greatest practical interest, both because of their widespread application in different fields of technology and because of the multiplicity of their luminescence properties. The vast majority of the published work, both experimental and theoretical, relates to molecules of this type.

Our decision to confine the discussion to the condensed phase stems not only from the overwhelmingly greater practical importance of condensed systems. No less relevant is the fact that the fast ($\lesssim 10^{-11}$ s) vibrational relaxation processes which are possible in the condensed phase introduce a considerable simplification of the theoretical treatment, since both radiative and non-radiative processes normally take place from an electronically excited state in vibrational equilibrium. This is not always true in the case of luminescence from vapours at low pressures[5,6], and the theoretical treatment of this case is less well developed than its experimental study[7]. Discussions of molecules in the condensed phase are usually confined to the low-temperature region, where the vibrational energy of the molecules (active vibrations, see Section VII) would be greater than the thermal energy. Under these conditions the problem is simplified still further, because the initial state of the radiative and conversion processes is the zeroth vibrational state of the excited energy level.

Throughout most of the discussion we shall assume that the molecules are photochemically stable, as is the case in practice for most aromatic compounds in rigid solvents[8]. Only in the concluding section will the effect of possible photochemical reactions be considered (briefly). Most of the formulae use a system of atomic units in which the charge and mass of the electron and Planck's constant $\hbar$ are taken to be unity.

II. THE ADIABATIC APPROXIMATION

The Hamiltonian of a molecular system can be expressed as the sum of the electronic kinetic energy operator T_r, the nuclear kinetic energy operator T_R, terms describing the interactions of electrons ($U(r, r')$), nuclei ($U(R, R')$), and electrons and nuclei ($U(r, R)$), and the spin–orbit interaction operator H_{so}:

$$H = T_r + U(r, r') + U(r, R) + T_R + U(R, R') + H_{so}, \quad (1)$$

where r denotes the set of electron coordinates $\{r_i\}$ and R the set of nuclear coordinates $\{R_q\}$. The eigenfunctions of the Hamiltonian (1) cannot be found in the general case, and we must resort to approximate methods.

In molecules which contain no heavy atoms the effect of spin–orbit interaction on the position of the electronic states is not very important. Therefore in the first stage of our discussion we can ignore the operator H_{so}, but we shall allow for it (by using perturbation theory) in the subsequent treatment (see Sections VI and VII). The eigenfunction ($H - H_{so}$) of the Hamiltonian can be chosen to be also the eigenfunction of the operator of the square of the total electronic spin moment of the molecule ($\hat{S}^2$) and of the operator of one of its projections ($\hat{S}_z$). The states described by these wave functions are called pure spin states and can be classified in terms of the quantum numbers S and S_z. In most molecules the ground state is a singlet ($S = 0$, $S_z = 0$). Excited states can be either singlet or triplet ($S = 1$, $S_z = 0, \pm 1$). Under the influence of spin–orbit and spin–spin interaction and of an external magnetic field the triplet state splits into three sublevels corresponding to the three possible values of S_z.

The second approximation, known as the adiabatic or Born–Oppenheimer approximation[9–14], relies on the fact that the mass of the nuclei is several orders of magnitude greater than the mass of the electrons, and therefore the velocity of the electrons is much greater than that of the nuclei. The full wave function of the system in the adiabatic approximation is expressed as the product $\Phi_j(r, R)\Omega_j^n(R)$. The electronic part of the wave function $\Phi_j(r, R)$, which is parametrically dependent on the coordinates of the nuclei, is determined by a wave equation with fixed values of R:

$$[T_r + U(r, r') + U(r, R) + U(R, R') - E_j(R)]\,\Phi_j(r, R) = 0, \quad (2)$$

where $E_j(R)$ is the electronic energy of the system for fixed values of the nuclear coordinates. The subscript j denotes the set of electronic quantum numbers; $E_j(R)$ defines the potential energy surface of the electronic state of the system (energy level). The wave function describing the motion of the nuclei, $\Omega_j^n(R)$, is found from the equation

$$[T_R + E_j(R) + \langle \Phi_j(r, R) | T_R | \Phi_j(r, R) \rangle - W_{jn}]\,\Omega_j^n(R) = 0, \quad (3)$$

where the index n denotes the set of vibrational quantum numbers and W_{jn} is the vibronic energy of the system. The term $\langle \Phi_j(r, R) | T_R | \Phi_j(r, R) \rangle$, in which the angle brackets indicate integration with respect to the coordinates of the electrons, is usually small.

The states described by the wave function $\Phi_j(r, R)\Omega_j^n(R)$ are called adiabatic pure spin states. We shall also use the symbol $|j\{n\}\rangle$ for these states. The methods of evaluating the wave functions $\Phi_j(r, R)$ are described in Section III. The problem of evaluating the wave functions $\Omega_j^n(R)$ reduces to solving the classical problem of small vibrations in a system of particles[11]. The potential surface is determined from the condition of correspondence between calculated and experimental vibration frequencies. The Morse potential is commonly used[12] when allowance for the anharmonicity of the vibrations is needed.

Let us briefly examine the conditions under which the adiabatic approximation is valid†. We shall define the non-adiabaticity operator $\hat{V}$ through its effect on the adiabatic wave functions:

$$\hat{V}(\Phi_j\Omega_j^n) = \Omega_j^n T_R \Phi_j - \sum_q M_q^{-1} \frac{\partial \Phi_j}{\partial R_q} \cdot \frac{\partial \Omega_j^n}{\partial R_q}, \quad (4)$$

where M_q is the mass of the nucleus q, and the operator T_R takes the form

$$T_R = \frac{1}{2} \sum_q M_q^{-1} \frac{\partial^2}{\partial R_q^2}. \quad (5)$$

A detailed analysis[9,10,13] has shown that the adiabatic approximation is valid when the $\langle j\{n\}|\hat{V}|j'\{n'\}\rangle$ matrix elements with $j \neq j'$ are small compared to the difference in energy between the corresponding states. A sufficient condition is low molecular vibration frequencies (as compared to the electronic transition energies[10,13]). Similarly, the approximation in which the operator H_{so} is ignored is valid if the $\langle j\{n\}|H_{so}|j'\{n'\}\rangle$ matrix elements are small in comparison to the energy of the transitions. In molecules which do not contain heavy atoms these matric elements are usually smaller than ~100 cm^{-1} (see Section V). Both conditions are easily met by the lower vibrational levels of the ground state of most molecules. On the other hand in electronically excited states neither of these criteria applies, and as a result we have long-lived after-effects. Nevertheless, for the non-trivial reasons discussed in Section VII, we are forced to use adiabatic pure spin functions in any discussion of the luminescence, photochemical, and other spectral properties of molecules.

The most widely used (and often quite satisfactory) model is the "coarse" adiabatic approximation, which ignores the dependence of Φ_j on the coordinates of the nuclei and assumes equilibrium values of R_0 (for a given electronic state) in the expression for Φ_j.[14] The expressions for the H_{so} and $\hat{V}$ matrix operators become

$$\langle j\{n\}|\hat{V}|j'\{n'\}\rangle = \langle \Omega_j^n | \Omega_{j'}^{n'} \rangle \langle \Phi_j^0 | T_R | \Phi_{j'}^0 \rangle - \sum_q M_q^{-1} \left\langle \Omega_j^n \left| \frac{\partial}{\partial R_q} \right| \Omega_{j'}^{n'} \right\rangle \left\langle \Phi_j^0 \left| \frac{\partial}{\partial R_q} \right| \Phi_{j'}^0 \right\rangle, \quad (6)$$

$$\langle j\{n\}|H_{so}|j'\{n'\}\rangle = \langle \Phi_j^0 | H_{so} | \Phi_{j'}^0 | \rangle \langle \Omega_j^n | \Omega_{j'}^{n'} \rangle; \quad (7)$$

where the differentials with respect to nuclear coordinates, the Φ_j^0 and $\Phi_{j'}^0$ wave functions, and the H_{so} operator are taken for equilibrium geometry. This approximation is also known as the Condon approximation. The Franck–Condon factors $\langle \Omega_j^n | \Omega_{j'}^{n'} \rangle$ do not vanish, in general, for $n \neq n'$. The following formula is also useful for calculating (from Eqn.(2)) the matrix elements of the operator $\hat{V}$:

$$\left\langle \Phi_j \left| \frac{\partial}{\partial R_q} \right| \Phi_{j'} \right\rangle = \left\langle \Phi_j \left| \frac{\partial U(r, R)}{\partial R_q} \right| \Phi_{j'} \right\rangle [E_{j'}(R) - E_j(R)]^{-1}. \quad (8)$$

When allowance for the variation of Φ_j with R is unavoidable (for example, when the matric elements vanish in the Condon approximation) we use the Herzberg–Teller expansion[15] in which the dependence of the electronic wave functions on the nuclear coordinates is allowed for by an expansion with respect to electronic wave functions of the different electronic states (with an equilibrium configuration), using coefficients depending on the deviation (δR_q) of the coordinate R_q from its equilibrium value:

$$\Phi_j(r, R) = \Phi_j^0 + \sum_q \sum_{j' \neq j} a_{j'j}^q \delta R_q \Phi_{j'}^0. \quad (9)$$

†The terminology used in recent publications often fails to distinguish between the adiabatic approximation and the approximation in which the H_{so} operator also is ignored.

Under conditions for which the first-order perturbation theory is applicable the quantity $a^q_{j'j}$ is given by

$$a^q_{j'j} = \left\langle \Phi^0_{j'} \left| \left(\frac{\partial U(r, R)}{\partial R_q} \right)_{R=R_0} \right| \Phi^0_j \right\rangle [E_j(R_0) - E_{j'}(R_0)]. \quad (10)$$

III. TYPES OF MOLECULAR ORBITAL, ELECTRONIC TRANSITION, AND ELECTRONIC STATE

The molecular orbital (MO) method is the most widely used and effective approach to the study of the electronic structure of molecules, but the localised orbital (LO) method is also commonly used to describe the spectroscopic characteristics of molecules. The former method can be used to describe directly the one-electron properties of molecules (e.g. in photo-electron spectroscopy). The latter method often offers a fairly clear interpretation of the nature and properties of electronically excited states of molecules. In their most developed form (allowing for configurational interaction) the two methods give the same results for identical sets of basic functions.

The MO method is discussed extensively in the literature[16-20], and therefore we shall limit our own discussion to a few general remarks. In the simplest case the electronic wave function of the system (Φ_j) is expressed as a Slater determinant, assembled from one-electron spin orbitals in which the spatial part is an expansion with respect to fixed basic functions

$$\psi_i = \sum_\nu \chi_\nu c_{\nu i}. \quad (11)$$

In the case of a singlet ground state the equations for the coefficients $c_{\nu i}$ and for the orbital energies ε_i have the form[16]

$$\sum_{\nu'} (F_{\nu\nu'} - \varepsilon_i S_{\nu\nu'}) c_{\nu' i} = 0, \quad (12)$$

where $F_{\nu\nu'}$ are the matrix elements of the Hartree–Fock operator F, and $S_{\nu\nu'} = \langle \chi_\nu | \chi_{\nu'} \rangle$ are the overlap integrals of the basic function. The system (12) is solved by an iterative method.

In calculations for complex polyatomic systems the functions χ_ν are usually represented by Slater atomic orbitals, which for the atoms of the first two periods can be written

$$\begin{gathered} 1s = (\xi^3/\pi)^{1/2} e^{-\xi r}, \quad 2s = (\xi^5/3\pi)^{1/2} r e^{-\xi r}, \\ 2p_x = (\xi^5/\pi)^{1/2} e^{-\xi r} x, \quad 2p_y = (\xi^5/\pi)^{1/2} e^{-\xi r} y, \\ 2p_z = (\xi^5/\pi)^{1/2} e^{-\xi r} z, \end{gathered} \quad (13)$$

where ξ are the Slater parameters[9]. The functions (13) are defined in a system of Cartesian coordinates with its origin at the nucleus of the appropriate atom.

In planar molecules (which include most aromatic and hetero-aromatic molecules) we can distinguish two types of molecular orbital: π and σ. If the z axis of the coordinate system is chosen at right angles to the plane of the molecule the π orbitals will contain only p_z functions in their expansion, whereas the σ orbitals will contain (in general) p_x, p_y, and s atomic functions.

Semi-empirical methods of studying π-electron systems rely on the principle of zero differential overlap[17-20]. The expressions for the $F_{\nu\nu'}$ matrix elements in this approximation (the Pariser–Parr–Pople or PPP approximation) are

$$\begin{gathered} F_{\nu\nu} = H_{\nu\nu} + N_\nu \gamma_{\nu\nu} - \frac{1}{2} p_{\nu\nu} \gamma_{\nu\nu} + \sum_{\nu'} (p_{\nu'\nu'} - N_{\nu'}) \gamma_{\nu\nu'}, \\ F_{\nu\nu'} = H_{\nu\nu'} - \frac{1}{2} p_{\nu\nu'} \gamma_{\nu\nu'}. \end{gathered} \quad (14)$$

In these expressions $H_{\nu\nu} = -I_\nu$ if the ν atom contributes one electron to the π system ($N_\nu = 1$), and $H_{\nu\nu} = -I_\nu - \gamma_{\nu\nu}$ if $N_\nu = 2$; I_ν is the ionisation potential of the p electrons of the ν atom; $\gamma_{\nu\nu}$ and $\gamma_{\nu\nu'}$ are the one-centre and the two-centre Coulomb integrals of the electronic interaction respectively; $p_{\nu\nu}$ is the electron density on the ν atom; $p_{\nu\nu'}$ is the bond order of the ν and ν' atoms; $H_{\nu\nu'} = \beta_{\nu\nu'}$ is the resonance integral. The integrals $\gamma_{\nu\nu}$, $\gamma_{\nu\nu'}$, and $\beta_{\nu\nu'}$ are determined empirically[17-20]. In spite of the large number of different ways of defining the quantities $\gamma_{\nu\nu}$, $\gamma_{\nu\nu'}$, and $\beta_{\nu\nu'}$ most of the results discussed below are independent of the method of parametrisation. Of course, in studies of specific classes of molecules the integrals must be defined uniquely#.

Various semi-empirical methods of calculating the electronic structure of molecules in the valence approximation have been proposed. In molecules containing hetero-atoms whose valence is lower than the number of electrons in the valence shell we can distinguish some σ orbitals for which the coefficients of the expansion are large only on the hetero-atom or on several equivalent hetero-atoms in the molecule. These orbitals (whose energy is greater than ~−10 eV) are doubly occupied in the electronic ground state and correspond to the antibonding orbitals of the LO method (n orbitals). Assuming full localisation of the n orbitals on the hetero-atom (as in the LO method, see below), the energy ε_n for these orbitals is determined only by the diagonal matrix element $\langle n|F|n\rangle$, where $|n\rangle$ denotes the atomic wave functions of the n electrons. If the number of π electrons of a hetero-atom with n electrons is one, the energy ε_n is given by the expression[21-23]

$$\varepsilon_n = -I_n - \sum_\nu (p_{\nu\nu} - N_\nu) \gamma_{\nu n} - \frac{1}{2} p^\pi_n \varkappa, \quad (15)$$

where I_n is the ionisation potential of the unshared pair of the hetero-atom in the valence state, $\gamma_{\nu n}$ are the integrals of the Coulomb interaction of the n electrons with the $p\pi$ electrons of the ν atom, p^π_n is the density of π electrons on the hetero-atom with n electrons, and $\varkappa$ is the one-centre exchange interaction integral of the n and $p\pi$ electrons.

The parameters which appear in Eqn.(15) can be evaluated semi-empirically[20-24]. In carbonyl, nitro, and thiocarbonyl compounds the n electrons of the O (or S) atoms are described by a p atomic orbital whose axis of symmetry is perpendicular to the bond between the carbon atom and the hetero-atom. In aza-heterocyclic compounds the wave function of the n orbitals takes the form of an sp^2 hybrid orbital. In compounds containing several equivalent pairs of n electrons (for example, in nitro compounds) the wave function of the n electrons should be expressed, strictly speaking, as a linear combination of the orbitals of the individual atoms even in the localised model: this leads to some change in the energy values and to splitting of the energy levels of the excited states[24]. This splitting is usually small, but it can be important in the interpretation of the luminescence spectra of molecules[4].

Another method frequently used for qualitative conclusions at present is the Hückel method, in which the parameters are the matrix elements of the Hartree–Fock operator $F_{\nu\nu} = \alpha_\nu$ and $F_{\nu\nu'} = \beta_{\nu\nu'}$.[18,20]

The π and σ orbitals can be bonding or antibonding: in the latter case they are denoted as π^* and σ^*. In the electronic ground state the bonding orbitals and the n orbitals are doubly occupied by electrons (see Fig.1). Knowing ε_i and $c_{\nu i}$ we can calculate the energy of the ground state

---

#Typical values are $\gamma_{\nu\nu} \cong 10$ eV, $\gamma_{\nu\nu'} \leqslant 5$–$7$ eV, $\beta_{\nu\nu} \leqslant 2$ eV, and $\varkappa \cong 1$ eV (see also formula (15)).[17-20,23,24]

(Φ_0) by the formula

$$E_0 = 2\sum_i \varepsilon_i - \sum_{i,i'} (2J_{ii'} - A_{ii'}), \qquad (16)$$

where the summation extends only over the occupied orbitals, $J_{ii'}$ is the Coulomb interaction integral, and $A_{ii'}$ is the exchange interaction integral of the electrons on the i and i' MO.

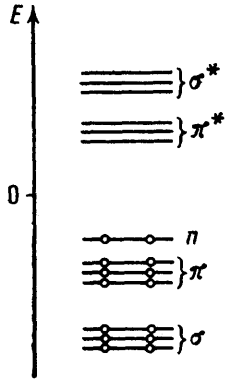

Figure 1. Relative position of one-electron levels in molecules.

In complex molecules the wave functions of the excited states and their energies are usually defined as follows. Using π^* and σ^* virtual orbitals we construct the $|i \to k>$ excited configurations, corresponding to the transition of an electron from the i orbital (filled in the ground state) to the vacant k orbital. These configurations can be singlet (S) or triplet (T), and their energies are given by the formulae

$$^S E_{ik} = \varepsilon_k - \varepsilon_i - J_{ik} + 2A_{ik}, \qquad (17)$$

$$^T E_{ik} = \varepsilon_k - \varepsilon_i - J_{ik}, \qquad (18)$$

where the integrals J_{ik} and A_{ik} have the same significance as in Eqn.(16). The wave function of the excited state is assembled as a superposition of excited configurations with coefficients given by the variational principle. We note that since $A_{ik} > 0$ the energies of the triplet configurations (and of the triplet states) are lower than the energies of the corresponding singlets. The parameters used in the calculation of $F_{\nu\nu'}$ are also used to evaluate the integrals J_{ik} and A_{ik}. In the Hückel method the energy of a transition is equal to the difference between the corresponding orbital energies§.

Thus, the following types of electronic transition are possible in aromatic molecules: $\pi \to \pi^*$, $n \to \pi^*$, $\sigma \to \sigma^*$, $n \to \sigma^*$, $\pi \to \sigma^*$, and $\sigma \to \pi^*$, as well as the following electronic states: $S_{\pi\pi^*}$, $T_{\pi\pi^*}$, $S_{n\pi^*}$, $T_{n\pi^*}$, $S_{\pi\sigma^*}$, $T_{\pi\sigma^*}$, $S_{\sigma\sigma^*}$, $T_{\sigma\sigma^*}$, etc. We should remember that these designations apply only in the absence of quasi-degeneracy of the states.

The designations of the $\pi\pi^*$ states are unnecessarily general, because they contain no detailed information on the nature of the electronic transition. Yet it is experimentally well established[4,25-27] that the luminescence spectra of π-electron molecules are strongly influenced by the presence of electron-donor (OH, NH_2, OCH_3, Hal, etc.) or electron-acceptor (BH_2) substituents. Hence we must distinguish different types of $\pi\pi^*$ state while retaining as far as possible the generality of the designation. This is most conveniently (and most clearly) done in the language of the LO method[28].

Let us examine the most characteristic features of the LO method by considering aromatic molecules containing electron-donor substituents. In addition to the σ (and n) electrons the hetero-atoms of the donor substituents (O, N, Hal) have an unshared pair of electrons which can take part in π-conjugation (unlike the n-electrons). The orbitals of these electrons are conventionally designated by the index l.[25]

In the zeroth approximation we can ignore the interaction of the electrons in the aromatic part of the molecule with the l-electrons of the substituent. The configuration which contributes most to the ground state is obtained from the doubly occupied π orbitals and the atomic l orbital. In addition to this configuration we can construct other configurations corresponding to the excitation of π electrons and configurations with an electronic transition from an l orbital to a π^* orbital. The latter configurations (involving charge transfer) can be designated $l\pi^*$ (or la_π configurations in Kasha's nomenclature[25]). These make some contribution to the wave function of the ground state. The wave functions of the excited states are constructed by superimposing $\pi\pi^*$ and $l\pi^*$ configurations. In molecules containing relatively few π-electrons these configurations have comparable weight[29]. Electronically excited states in molecules with l-electrons have therefore been designated[29] as $\pi l, \pi^*$. The only difference between the $\pi l, \pi^*$ states of planar molecules and $\pi\pi^*$ states is a substantial redistribution of the electron density during the transition from the S_0 to the $\pi l, \pi^*$ state. Nevertheless the difference in the corresponding luminescence spectra is very marked (see below). The designation is widely used at present, though it is somewhat artificial, since as the number of π-electrons increases the contribution of $l\pi^*$ configurations to the excited states decreases and the $\pi l, \pi^*$ states are continuously transformed into $\pi\pi^*$ states[29].

The situation is very similar in the case of molecules containing atoms (or electron-acceptor groups) with low-lying empty atomic orbitals (ν orbitals). The charge-transfer configurations are now those in which an electron has been transferred from a π orbital to a ν orbital: $\pi\nu$ configurations, which can interact with the $\pi\pi^*$ configurations of the aromatic part of the molecule. Therefore we have suggested[30] the designation $\pi,\nu\pi^*$ for the $\pi\pi^*$ excited states in the special case of boron-aromatic molecules. This designation has not yet been extended to include compounds with electron-acceptor groups (H–C=O, NO_2, etc.), in which the vacant π^* orbitals of the groups act as ν orbitals. We therefore retain the conventional designation $\pi\pi^*$ of these states. In molecules containing l and ν orbitals the excited states can, of course, be termed $\pi l, \nu\pi^*$. In the case of molecules with n-electrons and ν-orbitals we can use the designation $n,\nu\pi^*$ for the $n\pi^*$ states. We should stress that the LO method is often applied to aromatic molecules which do not contain l and ν orbitals, but consist of weakly bound fragments. In this case the π and π^* orbitals of the fragments play the role of localised orbitals.

As stated above, the concept of n-electrons localised on a hetero-atom is more characteristic of the LO than of the MO method. Indeed, calculations by the MO method show some delocalisation (often substantial) of the n-electrons on the σ-orbitals[31-34]. Experimental data[35], mainly on vibronic spectra (see Section VI), indicate a large degree of localisa-

§ The exchange interaction A_{ik} of the electrons should not be confused with the exchange interaction of the Heitler–London theory, which in most cases (in the S-state) leads to bonding and therefore has a negative sign.

tion of n-electrons and $n \rightarrow \pi^*$ transitions. The slight inconsistency between MO results and experiment can be avoided by allowing for the interaction of the $\sigma\pi^*$ configurations, which leads to marked localisation of the excitation. It follows that in order to calculate the energy of $n\pi^*$ states allowing for the interaction of the $n\pi^*$ configurations but not of the $\sigma\pi^*$ configurations we must use a localised model of the n-electrons with partial allowance for electron correlations.

Only very brief mention of non-planar molecules can be made here. If the deviation from planarity is small, and the energies of the π orbitals are significantly different from those of the σ orbitals, the unavoidable mixing of the π and σ orbitals is also not very great[36]. This mixing has little effect on the position of the lower electronically excited states of the molecules, and therefore on the probability of singlet–singlet optical transitions. However one of the parameters of the electronic structure of molecules is very sensitive to deviations from planarity: the spin–orbital interaction (see Section V). We must therefore allow for this effect when considering $S-T$ conversion and the properties of triplet states. Throughout this paper the lower excited states of this type of molecule will be interpreted as $\pi\pi^*$, πl, π^*, etc.

IV. EFFECT OF STRUCTURE ON THE POSITION OF THE LOWER ELECTRONICALLY EXCITED STATES IN MOLECULES

Calculations of the energies of $\pi\pi^*$ states are described in many recent publications[17,18,20–24,37–41]. In spite of the variety of the methods used, two important conclusions can be drawn from these measurements. 1) The energy of the $\pi\pi^*$ states decreases as the length of the chain of conjugated bonds in the molecule increases, the magnitude of this effect increasing with the conjugation energy. 2) The difference in energy between the lower $S_{\pi\pi^*}$ and the lower $T_{\pi\pi^*}$ states is relatively high ($\geq$1 eV or 10^4 cm^{-1}, see below)[21–24,29,37–41]. The first of these conclusions can be obtained by the simple Hückel method. Thus, for a polyene chain containing $N\pi$-electrons (where N is even) the energy of the long-wave transition (between the $(N/2)$ and $(N/2)+1$ orbitals) is given by the expression[28]

$$E_{\pi\pi^*} = 4|\beta| \sin \frac{\pi}{2(N+1)}, \qquad (19)$$

where β is the resonance integral. We can see from this equation that the energy of the transition decreases as N increases, and vanishes in the limit of $N \rightarrow \infty$. However formula (19) is not applicable at high values of N, since experimental values of $E_{\pi\pi^*}$ tend towards a finite limit. It has been shown[42] that allowance for electron correlation makes the asymptotic value of $E_{\pi\pi^*}$ finite at high values of N. The energies of $\pi\pi^*$ states in aromatic molecules span the range 5–1 eV. The general rules describing the change in the energy of $\pi\pi^*$ states with the size and the topology of the conjugated bond system in aromatic hydrocarbons are discussed in Refs.4 and 41.

The second conclusion, which is fully consistent with experiment, stems from the presence of large (~10 eV) $\gamma_{\nu\nu}$ one-centre Coulomb integrals in the expression for the exchange integral A_{ik} of Eqn.(17): the coefficients in front of $\gamma_{\nu\nu}$ are not small, since the π and π^* orbitals are not spatially separated.

The energy of the $n\pi^*$ states depends on several characteristics of the molecules, the most important of which are the nature of the atom with n-electrons, the length and topology of the chain of conjugated bonds, and the presence of electron-donor substituents (l-orbitals) in the system.

According to formula (15) the energy of the $n\pi^*$ states decreases as the ionisation potential of the atom with n-electrons decreases. It follows, for example, that the energy of the $n\pi^*$ states should decrease on going from the carbonyl to the analogous thiocarbonyl compounds. This conclusion is confirmed by the experimental $S_{\pi\pi^*}$ energies[4] of the $S_{\pi\pi^*}$ states for benzophenone (~3.3 eV) and thiobenzophenone (1.8 eV) molecules.

Let us discuss the dependence of the energy of the $n\pi^*$ states on the length of the conjugated chain. The simplest treatment, based on the Hückel method, leads to the conclusion that the energy of the $n\pi^*$ states should decrease with increase in the length of the chain of conjugated bonds. Thus, if we assume that the energy of the n-orbital ε_n is independent of the length of the conjugated chain (a valid assumption, since the ionisation potential for the n-electrons is only weakly affected by the number of π-electrons[43]) we can express the energy of the $n \rightarrow \pi^*$ transition as $E_{n\pi^*} = \varepsilon_{\pi^*} - \varepsilon_n$, where ε_{π^*} is the energy of the lower vacant π-orbital. For a polyene molecule with a substituent containing n-electrons (e.g. O=CH–(CH=CH)$_{(N/2)-1}$–H) we have $\varepsilon_{\pi^*} = \alpha + 2\beta \cos[j\pi/(N+1)]$ with $j = (N/2)+1$ if we ignore the effect of the hetero-atom on the π-system[28]. Therefore[44]

$$E_{n\pi^*} = 2\beta \cos \frac{(N+2)\pi}{2(N+1)} + \alpha - \varepsilon_n = \Delta I_n + 2|\beta| \sin \frac{\pi}{2(N+1)}, \qquad (20)$$

where ΔI_n is a parameter of the same order of magnitude as the difference in ionisation potential between the p-electrons of the C atom and the n-electrons. It follows from (19) and (20) that the energy of the $n\pi^*$ states increases more slowly than the energy of the $\pi\pi^*$ states (by a factor of two, on average) when N increases. Since for small N the energy of the $n\pi^*$ states is lower than that of the $\pi\pi^*$ states[4,41] the levels should become inverted as N increases. This result[44] was one of the basic propositions used to construct a systematic classification of the molecules.

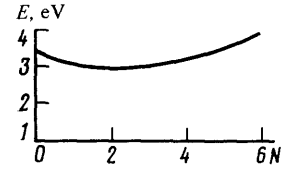

Figure 2. Energy of the $S_{n\pi^*}$ states of H–(CH=CH)$_N$–HC=O molecules as a function of N.

A stricter analysis[23], allowing for electron interaction and configurational interaction, confirmed this conclusion but revealed additional complications. It is clear from formulae (17) and (18) that the energy of the transition is determined by two terms, since the quantity A_{ik} is small for $n\pi^*$ states (see below). The first term, $\varepsilon_{\pi^*} - \varepsilon_n$, varies with N as described by formula (20). The Coulomb interaction integral $J_{n\pi^*}$ also decreases as N increases, since the π-electrons are becoming more delocalised. These two terms appear in the expressions with different signs, and therefore different variants of the change in the $n \rightarrow \pi^*$ transition energy with N are possible: the energy can decrease, remain unchanged, or increase as N increases. All these possibilities are realised in the polyene ketone molecules (Fig.2) with different values of N. The conclusion that the $n\pi^*$ and $\pi\pi^*$ states can become inverted as N increases remains valid, but the value of N for which inversion takes place is defined more exactly.

The singlet–triplet splitting of the $n\pi^*$ states is much smaller than the splitting of the $\pi\pi^*$ states. This is because the expression for the $A_{n\pi^*}$ exchange integral contains only the κ exchange integrals, the largest of which (one-centre integral) is ~1 eV. Furthermore the spatial separation of the n- and π-electrons makes $A_{n\pi^*}$ smaller than $A_{\pi\pi^*}$. Calculations[22–24,45–52], supported by experiment[4,41], give values between 0.2 and 0.5 eV for the $S-T$ splitting of the $n\pi^*$ states.

Calculated values of the energies of the $S_{\pi\pi^*}$, $T_{\pi\pi^*}$, $S_{n\pi^*}$, and $T_{n\pi^*}$ states for $H-(CH=CH)_N-CH=O$ molecules[23] are shown in Fig.3. We can distinguish five different variants (or types) of relative position of the electronic states. Similar results have been obtained for aromatic ketones (Fig.4), and also (both theoretically[23,24,52] and experimentally[2–4]) for aza-aromatic and nitro compounds, quinones, and thioketones. All these results indicate the existence of five different types of relative position of $n\pi^*$ and $\pi\pi^*$ S and T state. Classification of molecules into five types according to the relative position of these energy states was suggested for the first time[53] in 1966.

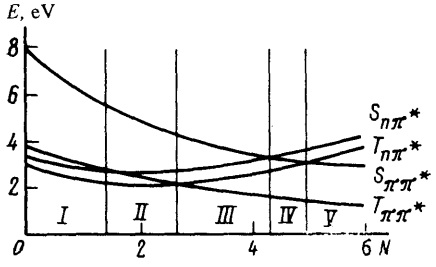

Figure 3. Five types of relative position of the electronic states of $H-(CH=CH)_N-HC=O$ molecules.

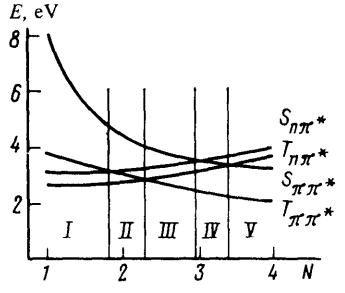

Figure 4. Relative position of the electronic states of $Ph-(CH=CH)_N-HCO$ molecules.

The change in relative position of the $n\pi^*$ and $\pi\pi^*$ states caused by electron-donor substituents is due to the change in energy of both the $n\pi^*$ and $\pi\pi^*$ states attending the transformation of the latter into $\pi l, \pi^*$ states. Many theoretical studies of the position of the $\pi l, \pi^*$ states with respect to the $\pi\pi^*$ states of the unsubstituted hydrocarbons have been published[24,28,29,52,54]: the conclusion in every case is that the introduction of l-orbitals into a system of π-conjugated bonds decreases the energy of the lower $\pi\pi^*$ (or, more accurately, $\pi l, \pi^*$) states. This effect is most marked when the ionisation potential of the l-electrons is low and the chain of conjugated bonds is short[29,52]. The influence of the substituent decreases as the length of the conjugated chain of the hydrocarbon part of the molecule increases. This is a consequence of the lack of a sharp boundary between $\pi\pi^*$ and $\pi l, \pi^*$ states (in contrast to the $\pi\pi^*$ and $n\pi^*$ states).

An important spectroscopic property of the $\pi l, \pi^*$ states is their relatively low $S-T$ interval (0.7–0.8 eV [25–29]), which is lower than that of the $\pi\pi^*$ states of aromatic hydrocarbons though it is greater than that of $n\pi^*$ states. This lowering is due to the contribution of $l\pi^*$ configurations to the wave functions of the excited states and to the spatial separation of the l and π orbitals, which lowers the value of A_{ik} in Eqn.(17).[29,54,55] All these statements apply also to the $\pi, \nu\pi^*$ states[30].

The introduction of electron-donor groups into the molecule increases the energy of the $n\pi^*$ states. The simplest explanation of this effect[46,56] postulates an increase in the energy level of the π^* orbital on introducing l-orbitals into a π-conjugation system. Calculations by the PPP method[24] indicate a substantial contribution to the increase in energy of the $n\pi^*$ states from the change in Coulomb interaction of the electrons. The electronic states of the nitrobenzene molecule and its amino derivatives, calculated[24] by that method, are shown in Fig.5: it is clear that the introduction of l-electrons does indeed raise the energy of the $n\pi^*$ states, the magnitude of the effect depending on the position of the substituent. Many examples of the effect of electron-donor substituents on the relative position of the $n\pi^*$ and $\pi\pi^*$ (or $\pi l, \pi^*$) states are given in Ref.4. Substituents with ν-orbitals should lower the energy of the $n\pi^*$ states[52], but this effect has not been adequately studied.

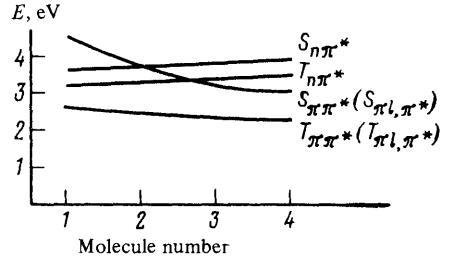

Figure 5. Electronic states of the following molecules: 1) nitrobenzene, 2) *p*-nitroaniline, 3) *m*-nitroaniline, 4) *o*-nitroaniline.

Another factor which influences the relative position of the $n\pi^*$ and $\pi\pi^*$ states is the hydrogen bond, or the formation of complexes with protonic solvents (in the limit, the protonation of the molecule). Hydrogen bond formation (or protonation) leads to bonding of the n-electrons, increases I_n in Eqn.(15), and hence causes a sharp increase in the energy of the $n\pi^*$ states, which can invert the relative position of the levels corresponding to $\pi\pi^*$ and $n\pi^*$ states[57,58].

In conclusion we shall summarise the properties of $n\pi^*$ and $\pi\pi^*$ states which can be used to distinguish these states experimentally. The energy of the $\pi\pi^*$ states decreases steeply as the length of the conjugation chain increases. At the same time the energy of the $n\pi^*$ states can decrease (though less markedly), it can remain unchanged, or it can even increase. The $S-T$ splitting of the $\pi\pi^*$ states is $\geq$1 eV, and substantially greater than the $S-T$ splitting of the $n\pi^*$ states (~0.2–0.5 eV). The $S-T$ splitting of the $\pi l, \pi^*$ (or $\pi\nu, \pi^*$) states lies between these two extremes. The introduction of l-electrons into the molecule produces a large increase in the energy of the $n\pi^*$ states and a decrease

in the energy of the $\pi\pi^*$ states (accompanied by their transformation into $\pi l, \pi^*$ states). Hydrogen bond formation (or protonation) produces a large increase in the energy of the $n\pi^*$ states and can lead to inversion of the levels. The most fundamental of these results is the conclusion that five types of relative position of the S, T, $n\pi^*$, and $\pi\pi^*$ states are possible. The factors listed above determine which of these five types is realised in practice.

V. SPIN–ORBIT INTERACTION IN ELECTRONIC STATES OF MOLECULES

The spin–orbit interaction (spin–orbit bond) of electronic states is characterised by the matrix element $\langle i|H_{so}|f\rangle$, where $|i\rangle$ and $|f\rangle$ are electronic wave functions of states of different multiplicity. The spin–orbit interaction operator is written[59]

$$H_{so}=\frac{1}{2c^2}\sum_q\sum_i\frac{Z_q}{r_{qi}^3}(\hat{l}_{iq}\cdot\hat{S}_i), \tag{21}$$

where c is the velocity of light, Z_q is the effective charge of the nucleus q, r_q is the distance between this nucleus and the electron i, and $\hat{l}_{iq}$ and $\hat{S}_i$ are the operators of the orbital and spin moment of the electrons. The brackets in Eqn.(21) contain the scalar product of the vector operators $\hat{l}_{iq}$ and $\hat{S}_i$. According to this approximation (whose justification is discussed in Ref.60) the H_{so} operator is a one-electron operator. Hence the matrix elements of the configurations included in $|i\rangle$ and $|f\rangle$, which differ only by one spin orbital, are non-zero[61]. This is one of the selection rules which the matrix elements of the H_{so} operator must satisfy: it implies, for example, that the $\pi\pi^*$ states are not bound to $\sigma\sigma^*$ states by spin–orbit interaction, though $\pi\pi^*$ states may be bound to $n\pi^*$ states.

Allowing for the effect of the spin moment projection operators on the spin functions[62] and considering the interaction of a singlet S_{ik} excited configuration (transition of an electron from the i-th orbital of the ground state configuration to the k-th vacant orbital) and of the three triplet configurations $T_{ik'}^0$, $T_{ik'}^{+1}$, and $T_{ik'}^{-1}$ (with projections of the spin moment on the z axis of 0 and ±1 respectively) we can write, after integration of the spin variables[63,64],

$$\begin{aligned}
\langle S_{ik}|H_{so}|T_{ik'}^0\rangle &= -\langle k|H_{so}^z|k'\rangle,\\
\langle S_{ik}|H_{so}|T_{ik'}^{+1}\rangle &= \frac{1}{\sqrt{2}}\langle k|H_{so}^x|k'\rangle+\frac{i}{\sqrt{2}}\langle k|H_{so}^y|k'\rangle,\\
\langle S_{ik}|H_{so}|T_{ik'}^{-1}\rangle &= -\frac{1}{\sqrt{2}}\langle k|H_{so}^x|k'\rangle+\frac{i}{\sqrt{2}}\langle k|H_{so}^y|k'\rangle,
\end{aligned} \tag{22}$$

where, for example,

$$H_{so}^z=\frac{1}{4c^2}\sum_q\frac{Z_q}{r_{iq}^3}\hat{l}_{iqz},$$

and $\hat{l}_{iqz}$ is the operator of the projection of the orbital moment on the z axis. Integration of Eqn.(22) is carried out with respect to the coordinates of one electron.

Similar formulae can be written for the matrix elements in the case of the integration of S_{ik} configurations with T_{jk} configurations, or of the interaction of ground state configurations with triplet configurations. If the multi-configuration approximation is used for the wave functions the expression for $\langle i|H_{so}|f\rangle$ contains a sum of matrix elements in the form of (22) with coefficients which define the contribution of each configuration to $|i\rangle$ and $|f\rangle$.

If the $|k\rangle$ and $|k'\rangle$ molecular orbitals are in LCAO form the matrix elements of (22) are evaluated by finding the effect of the $\hat{l}_x$, $\hat{l}_y$, and $\hat{l}_z$ operators on the atomic orbitals and calculating the one-, two-, and three-centre integrals for electron–nucleus interaction. We note that the one-centre integrals (when not identically equal to zero) are usually greater in absolute value than the two-centre integrals, and the latter are usually greater than the three-centre integrals.

In many important cases the coordinate system can be defined so that one of the matrix elements in (22) is non-zero: for example, the matrix element of the H_{so}^z operator. The effect of the $\hat{l}_x$, $\hat{l}_y$, and $\hat{l}_z$ operators on the p-functions is easily found from the explicit form of these operators[13] and of the atomic orbitals (Eqn.(13)):

$$\hat{l}_z p_z=0,\ \hat{l}_z p_x=ip_y,\ \hat{l}_z p_y=-ip_x. \tag{23}$$

In these expressions the $\hat{l}_z$ operator and the p-functions are given for the same centre. The action of the $\hat{l}_x$, $\hat{l}_y$, and $\hat{l}_z$ operators on the s-functions is to make these functions vanish, since they are eigenfunctions of the $\hat{l}_x$, $\hat{l}_y$, $\hat{l}_z$ operators with eigenvalues of zero. If the operators and the functions are given for different centres appropriate formulae can be obtained[64].

We shall now turn to specific cases. For the interaction of the $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ states of planar molecules the $\langle\pi_k^*|H_{so}^z|\pi_k^*\rangle$ matrix element (the only non-zero one if the z axis is perpendicular to the plane of the molecule) is expressed in terms of one-, two-, and three-centre integrals containing only p_z atomic functions (or $2p_z$ in the case of aromatic hydrocarbons). One-centre integrals are identically equal to zero as a consequence of the first of formulae (23). The two-centre integrals are also zero[59,64]. In this case only the three-centre integrals are finite[59], and even these are small in absolute value because the overlap of the $2p_z$-functions of the different atoms is not very marked and the interaction energy falls off very rapidly ($\propto r^{-3}$) with increasing interatomic distance. Calculations allowing for the terms of the spin–orbit interaction operator not included in (21) give ~0.3 cm^{-1} for the spin–orbit bond energy of the $\pi\pi^*$ states[65]. The matrix elements of the spin–orbit interaction of the $n\pi^*$ states also have approximately this value, since π^* orbitals appear as the k and k' orbitals in this case. A spin–orbit interaction of ~0.3 cm^{-1} should be interpreted as small.

However even this level of spin–orbit interaction is not always realised in the $\pi\pi^*$ states. The matrix elements of the H_{so} operator for molecules possessing symmetry elements must obey the selection rules (which are fully discussed in Ref.41). For the present discussion it is important to note that as a consequence of the symmetry properties the lower triplet state of many aromatic hydrocarbons is not connected by spin–orbit interaction to the electronic ground state[41]. This conclusion is highly relevant to the mechanism of $T-S$ conversion in aromatic hydrocarbons.

In the case of $n\pi^*$ and $\pi\pi^*$ states of different multiplicity the $\langle k|H_{so}^z|k'\rangle$ matrix element will include (for $|k\rangle$) the wave function of the n-electron orbital, and for $|k'\rangle$ the wave function of the π-electron orbital. We choose a coordinate system such that the x axis is perpendicular to the plane of the molecule and the axis of symmetry of the wave function of the n-orbital (in the one-centre approximation) coincides with the y axis. From the second formula (23) we can easily obtain

$$\langle S_{n\pi^*}|\hat{H}_{so}|T_{\pi\pi^*}\rangle\cong -ic_{k'n}b\,\frac{1}{4c^2}\left[np_y np_y\left|\frac{Z_n}{r^3}\right|\right], \tag{24}$$

where $c_{k'n}$ is the expansion coefficient of the k' π-orbital for an atom containing n-electrons. The one-centre integral $\left[np_y np_y\left|\frac{Z}{r^3}\right|\right]$ describes the interaction of the electron density $|np_y(r)|^2$ with the nucleus of the atom containing n-electrons, which has an effective charge Z. The other integrals in (24) are ignored (see below). An identical expression (but with

the opposite sign) can be obtained for the $\langle S_{\pi\pi^*}|H_{SO}|T_{n\pi^*}\rangle$ matrix element.

The integral in formula (24) can be evaluated analytically: the result is $1/3Z^4n^{-3}$, where n is the principal quantum number of the p-orbital. Equating Z to the Slater charges on the nuclei, and taking the $c_{k'n}$ values obtained in any of the π-MO approximations, we can find the value of (24). Calculations of this type[24,60,63,66-70] show that the spin–orbit interaction energy of the $n\pi^*$ and $\pi\pi^*$ states of different multiplicity is greater than ~10 cm^{-1} in the case of molecules containing N, O, and S atoms, and greater than ~100 cm^{-1} in molecules with heavy atoms (Br, I).

The one-centre integral $\left[np_y np_y \left|\frac{Z}{r^3}\right.\right]$ is used in the theory of atomic spectra to express the multiplet splitting constant ζ (given[71] as $1/6c^{-2}Z^4n^{-3}$). Hence the matrix element (24) can be written

$$\langle S_{n\pi^*}|H_{so}|T_{\pi\pi^*}\rangle = -ic_{k'n}b\frac{\xi}{2}. \qquad (25)$$

Calculations by formula (25) with experimental values of ζ give values of the spin–orbit bond of $n\pi^*$ and $\pi\pi^*$ states in good agreement with those given by formula (24). Allowance for the delocalisation of n-electrons and for the two-centre integrals in the expression for the matrix elements, and the use of multi-configuration wave functions[24], have very little effect on the result of the calculation.

The order of magnitude of the matrix element in formula (24) can be determined (with low precision, and with some *ad-hoc* assumptions) from data on the life time of the $T_{n\pi^*}$ states[72]. These "experimental" values of the spin–orbit coupling of $T_{n\pi^*}$ and $S_{\pi\pi^*}$ states are consistent with calculated values[73].

Formula (24) was obtained by assuming that the molecule contains only one pair of n-electrons. In more complicated cases the expression for the $\langle S_{n\pi^*}|H_{SO}|T_{\pi\pi^*}\rangle$ matrix element contains a summation over the different (equivalent) atoms with n-electrons. In these circumstances the one-centre integrals could mutually cancel out, making the matrix element small. In practice this does not happen. Because of the small splitting of the $n\pi^*$ states (in this case, $S_{n\pi^*}$) the vibronic interaction with non-fully-symmetrical vibrations leads to almost complete mixing[33]. The order of magnitude of the matrix element is found to be independent of the symmetry of the wave functions of the n-electrons.

These considerations lead to the very important conclusion that the spin–orbit interaction of states of different orbital type ($n\pi^*$ and $\pi\pi^*$) exceeds more than 30-fold the spin–orbit interaction of states of the same orbital type. The ratio of the square of their moduli, which appears in all calculations, is 10^3–10^4 for molecules containing N, O, and S atoms and over 10^4 for molecules containing halogen and other heavy atoms. This conclusion was reached[72] for molecules of aromatic azines from measurements of the life-time of $T_{n\pi^*}$ and $T_{\pi\pi^*}$ states, and from a theoretical study[63] of azines and of the carbonyl derivatives of thiocarbonyl compounds and nitro compounds. This large difference between the spin–orbit coupling between the different states is not surprising, since in the case of $n\pi^*$ and $\pi\pi^*$ interactions the matrix element contains one-centre integrals, whereas in the interaction of states of the same orbital type the matrix element contains only three-centre integrals.

The following general statement appears to be valid: if the $|k\rangle$ and $|k'\rangle$ orbitals (or one of them) contain different p-functions in their expansion with respect to atomic orbitals we can expect to find non-zero one-centre integrals in the expression (22) for one of the matrix elements. In general this matrix element is quite large, and increases rapidly with the charge on the nucleus of the atoms present in the molecule.

Other electronic states may be mentioned briefly. The matrix elements of the spin–orbit interaction operator for $\pi\pi^*$ and $\sigma\pi^*$ (or $\pi\sigma^*$) states of aromatic molecules contain non-zero one-centre integrals, leading to large interaction energies. The spin–orbit interaction amounts to 2–5 cm^{-1} for molecules of aromatic hydrocarbons[64,65,74], and exceeds 10 cm^{-1} for their derivatives containing atoms with a nuclear charge greater than that of carbon atoms. The spin–orbit interaction of $\sigma\sigma^*$ states is also large, which explains the low quantum yield of fluorescence in aliphatic molecules[64].

Non-planar molecules containing π-electrons are especially interesting. Typical of these are many aromatic and unsaturated amines in which the nitrogen atom is in an sp^3 hybrid state. As was pointed out in Section III, in these molecules the orbitals corresponding to the π-orbitals of the planar configuration include a small contribution from σ-orbitals, and their expansion in general contains not only p_z functions but also other p-functions (with a small statistical weight). Accordingly, the matrix elements of the spin–orbit interaction operator for the S_0, $S_{\pi l,\pi^*}$, and $T_{\pi l,\pi^*}$ states contain one-centre integrals, and their value is estimated[36] to be of the order of 1 cm^{-1}, i.e. intermediate between the corresponding quantities for the $\pi\pi^*$ states and the $n\pi^*$ and $\pi\pi^*$ states. When the amines form complexes with electron-acceptor systems (protons) the contribution of $l\pi^*$ configurations to the excited states decreases, and the spin–orbit interaction decreases at the same time[75]. These effects are manifest in the luminescent properties of the amines[76].

All the above statements apply equally to non-planar molecules with ν-orbitals, but so far no calculations of spin–orbit interactions have been reported for these molecules.

The spin–orbit interaction of $\pi l,\pi^*$ and $n\pi^*$ states is slightly smaller than that of $\pi\pi^*$ and $n\pi^*$ states in molecules which do not contain l-electrons. This is due to the spatial separation of the n- and l-orbitals[24].

The fundamental conclusion from this discussion is the statement[63,72] that the spin–orbit interaction of S and T states of different orbital type in planar molecules is over 30 times greater than the spin–orbit interaction of states of the same orbital type. This conclusion is crucially important to an understanding of the luminescence-spectral properties of molecules.

VI. RADIATIVE TRANSITIONS IN AROMATIC MOLECULES

The term radiative transition denotes transitions between vibronic states of molecules accompanied by the absorption or emission of photons. The photon emission process (luminescence) may or may not involve a change in the multiplicity of the states. In the latter case it is termed fluorescence, in the former case phosphorescence.

The probability of a transition from the state $|i\{n\}\rangle$ to the state $|f\{n'\}\rangle$ is proportional to the square of the matrix element $\langle i\{n\}|\mathbf{r}|f\{n'\}\rangle$, where integration is carried out over the variables r and R, and $\mathbf{r} = \sum_i \mathbf{r}_i$ is the sum of the radius vectors which define the position of the electrons in the molecule[13].

The probability of transitions which are allowed by symmetry and multiplicity can usually be calculated quite satisfactorily by the Condon approximation

$$\langle i\{n\}|\mathbf{r}|f\{n'\}\rangle = d_{if}\langle\{n\}|\{n'\}\rangle, \qquad (26)$$

where $\mathbf{d}_{if} = \langle i|\mathbf{r}|f\rangle$. The second multiplier in Eqn.(26) is the Franck–Condon factor, which defines the intensity of the individual spectral lines of the vibronic band. In the case of transitions allowed by multiplicity but forbidden by

symmetry the Condon approximation becomes invalid because the quantity d_{if} vanishes. If the transition is from the ground state to an electronically excited state we only need to allow for the dependence on R of the electronic wave function of the excited state. If the Herzberg–Teller expansion (9) is applicable we can write the following expression for the matrix element (26):

$$\langle i\{n\}|\mathbf{r}|f\{n'\}\rangle = \sum_{f'\neq f,q} \mathbf{d}_{if'} a^q_{f'f} \langle\{n\}|\delta R_q|\{n'\}\rangle = \\ = \sum_q \mathbf{d}^q_{if} \langle\{n\}|\delta R_q|\{n'\}\rangle, \quad (27)$$

where the subscript f' denotes the number of the electronically excited state, $a^q_{f'f}$ is defined by Eqn.(10), and δR_q is the deviation of the coordinate of the oscillator (q) from the equilibrium position. The matrix elements $\langle i\{n\}|\mathbf{r}|f\{n'\}\rangle$ for pure spin functions of different multiplicity are zero because of the orthogonality of the spin functions. The probability of transitions between states of different multiplicity can be made finite only by allowing for spin–orbit interaction. In this case, by analogy with (27) we obtain

$$\langle i\{n\}|\mathbf{r}|f\{n'\}\rangle = \sum_{f'\neq f} \mathbf{d}_{if'} b_{f'f} \langle\{n\}|\{n'\}\rangle = \tilde{\mathbf{d}}_{if}\langle\{n\}|\{n'\}\rangle, \quad (28)$$

where $b_{f'f} = \langle f'|H_{SO}|f\rangle (E_f - E_{f'})^{-1}$ and the multiplicity of the state $|f'\rangle$ is different from that of the state $|f\rangle$ but equal to that of the state $|i\rangle$. If necessary we can allow for the mixing of the wave function of the ground state $|i\rangle$ with the wave functions of the excited states in the derivation of formulae (27) and (28). By comparing the expressions (26), (27), and (28) we can understand the origin of the matrix element of a transition forbidden by multiplicity and symmetry[77] but which is allowed in the second-order perturbation theory for the vibronic interaction operators (10) and H_{SO}.

Transitions involving the absorption of a photon are usually characterised by their oscillator strength f, and the reverse transitions with emission of a photon by the rate constant for the radiative dissociation of the state (k_r) or by the radiative life time $\tau = 1/k_r$. In most cases the quantities f and k_r denote summations over all values of $\{n'\}$ in the last term with averaging (using the Boltzmann factor) over the vibrational states of the first term. Allowing for normalisation and for the full set of vibrational wave functions in the Condon approximation we have[13]

$$f = \frac{2\omega}{3}|\mathbf{d}_{if}|^2 = \frac{2\omega}{3}(x^2_{if} + y^2_{if} + z^2_{if}), \quad (29)$$

$$k_r = \frac{4\omega^3}{3c^3}|\mathbf{d}_{if}|^2 = \frac{4\omega^3}{3c^3}(x^2_{if} + y^2_{if} + z^2_{if}), \quad (30)$$

where ω is the frequency corresponding to the maximum of the vibronic band, c is the velocity of light, $x_{if} = \langle i|x|f\rangle$, etc. Eqns.(29) and (30) apply to non-degenerate states. In the case of a multiplicity-forbidden transition the value of $\mathbf{d}_{if}$ given by formula (28) must be used in formulae (29) and (30). From (29) and (30) we obtain the useful relationship $k_r = (\omega^2/1.5)f$ s^{-1} (if ω is expressed in cm^{-1}). In the case of symmetry-forbidden transitions, and assuming that the equilibrium position of the oscillators (q) involved in the transition is the same in states $|i\rangle$ and $|f\rangle$, we obtain (for low temperatures)

$$f = \frac{2\omega}{3}\sum_q |\mathbf{d}^q_{if}|^2 (2\mu_q\omega_q)^{-1}, \quad (31)$$

$$k_r = \frac{4\omega^3}{3c^3}\sum_q |\mathbf{d}^q_{if}|^2 (2\mu_q\omega_q)^{-1}, \quad (32)$$

where μ_q and ω_q are the reduced mass and frequency of the oscillator q. We note that the f and k_r values for symmetry-forbidden transitions are a function of temperature.

Let us examine the characteristic quantities f and k_r. We shall begin with the symmetry-allowed singlet–singlet transitions. In the case of $\pi \to \pi^*$ transitions the matrix element $\mathbf{d}_{ij}$ equals $\sqrt{2}\langle\pi_i|\mathbf{r}|\pi^*_f\rangle$, where π_i and π^*_f are the molecular orbitals between which the electronic transition takes place. From symmetry considerations the matrix components of the vector $\mathbf{r}$ lying in the plane of the molecule are non-zero. It follows that the $\pi \to \pi^*$ transitions are polarised in the plane of the molecule. The matrix elements $|\langle\pi_i|\mathbf{r}|\pi^*_f\rangle|$ are relatively large (~2 a.u.). According to formula (29) the value of f is approximately 0.1.[37–39,78–80]. For large conjugated molecules (e.g. dyes) f could approach or even exceed unity. From formula (30) we find that k_r for $S_{\pi\pi^*}$ states is ~10^8–10^7 s^{-1}, and the radiative life time is ~10^{-8}–10^{-7} s. In dye molecules the k_r value can be as high as 10^9 s^{-1}.[41] Singlet–singlet $n \to \pi^*$ transitions are allowed in many aza-aromatic molecules, in which the n-orbital includes a contribution from the 2s atomic function. The matrix element of the transition contains the non-zero one-centre integrals $[2s2p_z|z]$, which can be evaluated[9] and found to be ~1 a.u. Calculations of f in azines[80–82] give ~5×10^{-3}–10^{-2}, and ~10^6 s^{-1} for k_r in $S_{n\pi^*}$ states. These values agree with experiment[41]. The allowed $n \to \pi^*$ transitions are polarised perpendicular to the plane of the molecule. The mechanism of $\sigma \to \pi^*$ and $\pi \to \sigma^*$ transitions in aromatic hydrocarbons is entirely analogous: these transitions have f values of the same order and they are polarised perpendicular to the plane of the molecule[78].

In the molecules of carbonyl, thiocarbonyl, and nitro compounds, in which the n-orbitals have some p-character, and also in some azines, singlet–singlet $n \to \pi^*$ transitions are symmetry-forbidden in the Condon approximation. In order to calculate their probability we must allow for the vibronic interaction. Since we can put $(2\mu_q\omega_q)^{-1} \cong 10^{-1}$ in Eqn.(28), and $a_{f'f}$ has a similar value[70], we obtain ~5×10^{-4} and ~10^5 s^{-1} for f and k_r respectively in the case of symmetry-forbidden $n \to \pi^*$ transitions[81,83,84]. The polarisation of these transitions is determined by the polarisation of the transitions which limit the intensity, and it can therefore vary[83,85]. The probability of the symmetry-forbidden $\pi \to \pi^*$ transitions is similar to that of allowed $n \to \pi^*$ transitions in azines[41,86,87].

Singlet–triplet $\pi \to \pi^*$ transitions are allowed because of the spin–orbit interaction of the $T_{\pi\pi^*}$ states with $S_{\pi\pi^*}$, $S_{\sigma\pi^*}$, $S_{\pi\sigma^*}$, and $S_{n\pi^*}$ states (if n-electrons are present in the molecule), and of the interaction of the S_0 state with the $T_{\pi\pi^*}$, $T_{\sigma\pi^*}$, $T_{\pi\sigma^*}$, and $T_{n\pi^*}$ states. The spin–orbit coupling between the $T_{\pi\pi^*}$ state and the $S_{\sigma\pi^*}$, $S_{\pi\sigma^*}$, and $S_{n\pi^*}$ states is fairly strong (see Section V), but the oscillator strengths of the $S_0 \to S_{\sigma\pi^*}$, $S_0 \to S_{\pi\sigma^*}$, and $S_0 \to S_{n\pi^*}$ transitions are small. The oscillator strengths of the $S_0 \to S_{\pi\pi^*}$ transitions are large, but the spin–orbit coupling between $T_{\pi\pi^*}$ and $S_{\pi\pi^*}$ states is weak. It follows that the terms of the summation in Eqn.(28) contain a small multiplier for these transitions, and $\tilde{\mathbf{d}}_{if}$ is small. The situation is unchanged if allowance is made for the interaction of the S_0 state with the T states. The values of f and k_r for S–T transitions are calculated[88,89] to be ~10^{-7}–10^{-8} and ~10–1 s^{-1} respectively. Hence the radiative life time of the $T_{\pi\pi^*}$ states is ~0.1–1 s, i.e. these states are relatively long-lived (see below). In the case of symmetry-forbidden S–T transitions the life time of the $T_{\pi\pi^*}$ states is an order of magnitude greater[41,77]. It was shown experimentally[90,91,96] that $T_{\pi\pi^*} \to S_0$ transitions in aromatic hydrocarbons are polarised almost perpendicular to the plane of the molecule, and therefore k_r is determined by the spin–orbit interaction of $\pi\pi^*$ states with $\sigma\pi^*$ and $\pi\sigma^*$ states.

Singlet–triplet $n \to \pi^*$ transitions are allowed because of the spin–orbit interaction of the $T_{n\pi^*}$ states with the $S_{\pi\pi^*}$ and S_0 states: their energy is greater than ~10 cm^{-1}. Since the

f value for $\pi \rightarrow \pi^*$ singlet–singlet transitions is also large, the life time of the $T_{n\pi^*}$ states should be small. Calculation[66-68,89] gives $f \cong 10^{-5}$ for the $S_0 \rightarrow T_{n\pi^*}$ transitions, and $k_r \cong 10^3-10^2$ s^{-1} for the $T_{n\pi^*}$ states. Thus the $T_{n\pi^*}$ states are relatively short-lived. Since the $S_0 \rightarrow T_{n\pi^*}$ transitions determine the intensity of the $S_0 \rightarrow S_{\pi\pi^*}$ transitions they are polarised in the plane of the molecule. These results are consistent with experiment[41,72].

The probability of $S_0 \rightarrow S_{\pi l, \pi^*}$ and $S_0 \rightarrow T_{\pi l, \pi^*}$ transitions in substituted hydrocarbons is usually greater than the probability of long-wave $\pi \rightarrow \pi^*$ transitions in unsubstituted aromatic hydrocarbons. In the case of $S_0 \rightarrow S$ transitions this is because the presence of the substituent often leads to removal of the symmetry prohibition[29]. In the case of $S-T$ transitions the increase in probability arises from the decrease in the energy of the $\sigma\pi^*$ and $\pi\sigma^*$ states (decrease in the quantity $E_j - E_{j'}$ in Eqn.(28)), from the increase in the energy of the spin–orbit bond between the states (since the charge of the nuclei in the substituent is greater than the charge of the carbon nucleus, see Section V), and also from the non-planar structure of the molecule (for example, in the case of many amine molecules)[36]. The increase in probability is specially marked in the case of $S-T$ transitions in halogen-substituted molecules, for which the k_r value of the $T_{\pi l, \pi^*}$ states is ~$10-10^2$ s^{-1}. All these statements apply also to molecules with ν-orbitals, but this case has not been discussed theoretically (with one exception[30]), though it has been studied experimentally[92].

Let us examine briefly the problem of the vibrational structure of the absorption and luminescence bands, which has attracted much experimental[93-105] and theoretical[106-108] work. In the harmonic and in the Condon approximation the probability of a transition from the zero vibrational state $|0\rangle$ with excitation of the n-vibrational state of a normal oscillator in the molecule is proportional to the square of the Franck–Condon factor

$$|\langle 0|n\rangle|^2 = e^{-\gamma}\gamma^n (n!)^{-1}, \qquad (33)$$

where $\gamma = 0.5\Delta^2\mu\omega$, Δ is the change in the equilibrium position of the normal coordinate of this oscillator, and ω and μ are the frequency and mass of the oscillator. Formula (33) often describes the distribution of line intensities in vibrational progressions quite satisfactorily[98,106,108]. However in many cases we must go beyond the Condon approximation[99,100].

The following two observations are specially relevant to this discussion. Firstly, the vibrational structures of fluorescence and phosphorescence bands due to transitions of the same orbital type are approximately the same[41,95,106]. This means that the geometric characteristics of a molecule in the $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ (or $S_{n\pi^*}$ and $T_{n\pi^*}$) states are not very different. The γ parameter has been shown[95] to differ by less than 30% between the fluorescence and the phosphorescence spectra of aromatic molecules. Secondly, the vibrational structure of bands arising from $\pi \rightarrow \pi^*$ transitions is very different from that of bands arising from $n \rightarrow \pi^*$ transitions. This means that molecules in the $\pi\pi^*$ and $n\pi^*$ states have very different geometrical structures. Thus the most active vibrations (with $\gamma \cong 1$) in the bands of $\pi \rightarrow \pi^*$ transitions in carbonyl compounds are those of the aromatic rings, whereas in the bands of $n \rightarrow \pi^*$ transitions the stretching vibrations of the C=O group are the most active, with $\gamma \geq 1$.[93,94,99-101]. In thiocarbonyl compounds the vibrations of the C=O group are replaced by those of the C=S group[102], and in nitro compounds by the symmetrical stretching vibrations of the NO_2 group[105]. In aza-aromatic compounds the vibrations of the aromatic ring are active in the $\pi \rightarrow \pi^*$ bands, and those of the  corner are active in the $n \rightarrow \pi^*$ bands[96,97,103,104]. This difference in the vibrational structure of the bands is due to the nature of the transitions and is consistent, in particular, with localisation of the $n \rightarrow \pi^*$ transitions.

The vibrational structure of the absorption and luminescence bands associated with $\pi l, \pi^*$ and $\pi, \nu\pi^*$ states is usually much more diffuse than the vibrational structure of $\pi \rightarrow \pi^*$ bands[26,27]. This is due to the contribution of the $l\pi^*$ (or $\pi\nu$) configurations to the wave functions of the excited states, and to the consequent change in bond length and in bond angle in the group with l- or ν-orbitals[29,30]. The contribution from these configurations decreases as the length of the chain of conjugated bonds increases, and also on going from singlet to triplet states. Therefore the vibrational structure is less diffuse in the phosphorescence spectra, and in molecules with a large number of π-electrons[26].

We note that even in very complex molecules the parameter γ is significantly different from zero for a small number (1–3) of oscillators[93-108]. In most aromatic molecules the highest-frequency vibrations of the C–H bonds are inactive, and therefore the γ value for these vibrations is close to zero. All these results are highly relevant to the mechanism of non-radiative conversion processes (see Section VII).

Thus the radiative life time of $S_{\pi\pi^*}$ states is typically ~$10^{-7}-10^{-8}$ s, i.e. one or two orders of magnitude smaller than the radiative life time of $S_{n\pi^*}$ states. The radiative life times of triplet states show the opposite relationship: the life time of $T_{n\pi^*}$ states is ~$10^{-2}-10^{-3}$ s, and is two or three orders of magnitude shorter than the life time of $T_{\pi\pi^*}$ states. The radiative life time of the $T_{\pi l, \pi^*}$ states is intermediate between the life time of the $T_{\pi\pi^*}$ states in aromatic hydrocarbons and that of the $T_{n\pi^*}$ states. The vibrational structures of the bands due to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions differ very substantially as a result of the difference in geometric structure of the molecule in the $\pi\pi^*$ and $n\pi^*$ states, and of the localised nature of the $n \rightarrow \pi^*$ transitions. The bands associated with transitions into (or from) the $\pi l, \pi^*$ (or $\pi, \nu\pi^*$) states are usually more diffuse than bands due to $\pi \rightarrow \pi^*$ transitions.

Early measurements of luminescence quantum yields have shown[109] that the yield is almost invariably less than unity, even in the absence of photochemical reactions. This effect is due to the non-radiative conversion processes discussed in the next Section.

VII. NON-RADIATIVE CONVERSION PROCESSES

The term non-radiative conversion denotes transitions between electronic states in molecules for which the electronic excitation energy is fully or partly converted into vibrational energy of the system as a whole. Conversion processes are a special case of intramolecular non-radiative transitions, which include various photochemical molecular transformation or pre-ionisation processes. Non-radiative transitions have been discussed in detail[110-114]: for our present purpose we only need to consider the dependence of the rate constant of the conversion upon the type of transition, the energy spectrum of the molecule, and the structure of the molecule.

One of the basic problems in the theory of non-radiative transitions concerns the nature of the interaction giving rise to the transition. This problem is directly associated with the problem of defining the state into which a molecule is converted upon electronic excitation. The problem was solved relatively recently[115-117] when it was shown that excitation by a broad-band source of light brings the molecule to a state whose wave function is not an eigenfunction of the full Hamiltonian of the system. (The case of monochromatic or quasi-monochromatic excitation is discussed in Refs.118 and

119.) This result, assumed without proof¶ until recently[115-117], is valid provided that (as is usually the case) the excitation region includes one pure spin adiabatic state into which an optical transition from the ground state is allowed. The pure spin adiabatic state is not a stationary state because its wave function is not an eigenfunction of the full Hamiltonian of the system, and such a state can dissociate non-radiatively under the influence of the operators V and H_{SO}. The dissociation is irreversible only if the system in its final state has a continuous (or quasi-continuous) spectrum of energy levels[13,115-117]. In the case of molecules in a condensed phase this condition is invariably satisfied.

Since only some of the intramolecular oscillators undergo a marked change in equilibrium position (and in frequency) during electronic transitions in substituted hydrocarbon molecules (see Section VI), sometimes accompanied by similar changes in some of the local vibrations of the solvent, the matrix elements of the non-adiabaticity and of the spin–orbit interaction operators will differ from zero, with a small number of oscillators excited in the final electronic state (see Section II). These oscillators (active in non-radiative conversion) are directly involved in the conversion process, accepting electronic energy and subsequently transferring it to other (inactive) vibrational modes of the molecule and of the solvent. In addition to the oscillators whose characteristics are different in the combined electronic states, the most anharmonic (and high-frequency) oscillators in the immediate vicinity of the part of the molecule where the electronic transition is localised are also active. All these conditions limit the number of modes which can be active in non-radiative transitions, and make it possible to calculate the rate constants of the conversion processes even in complex molecules.

At low temperatures ($kT < \omega$, where ω is the frequency of the active oscillators, $\omega \geq 500$ cm^{-1}), and if the vibrational relaxation rate constant (Γ) is greater than the conversion rate constant, we can write the following expression for the rate constant of the conversion between the levels i and f:[121,122]

$$k_{nr} = \sum_{\{n\}} \Gamma \left| \langle i\{0\}| \hat{R} | f\{n\} \right\rangle|^2 \cdot \left(\Delta^2_{\{n\}} + \frac{\Gamma^2}{4}\right)^{-1}, \qquad (34)$$

where the summation is taken over the vibrational states of the level f, for which $\Delta_{\{n\}} = E_{i(0)} - E_{f\{n\}} \leq 100$ cm^{-1}, and $\hat{R}$ is the level shift operator, defined by the expression

$$\hat{R} = V + H_{so} + (V + H_{so}) g_1 \hat{R} + V + H_{so} + (V + H_{so}) g_1 (V + H_{so}) + \ldots, \qquad (35)$$

and g_1 is given by

$$g_1 = \sum_{f'\{n'\}} \frac{|f'\{n'\}\rangle \langle f'\{n'\}|}{E_i - E_{f'\{n'\}}}.$$

The summation in this expression is taken over the states not included in Eqn.(34). If the value of k_{nr} given by (34) is greater than Γ the conversion rate constant is $\Gamma/2$.[118]

We can define different types of non-radiative conversion. If the multiplicity of the state is unaffected by the transition the process is termed internal conversion. If there is a change in the multiplicity of the state the process is called intercombinations ($S-T$ or $T-S$) conversion. For a transition of the system to the ground state the term "conversion" is sometimes replaced by "degradation" (internal, $S_1 \rightsquigarrow S_0$, or intercombinational, $T \rightsquigarrow S_0$).

Two rules on the rate of internal conversion processes have been formulated empirically: Kasha's rule[25] and Ermolaev and Sveshnikova's rule[123-125]. The first states that in most molecules internal conversion processes between electronically excited states (of the same resultant spin) take place in times shorter than ~10^{-11} s, and a significant quantum yield ($\geq 10^{-3}$) can be expected only for transitions from the lower excited state of the given multiplicity. The Ermolaev–Sveshnikova rule states that in many light-stable molecules in a condensed phase the conversion between S_1 and S_0 states can be ignored in comparison to fluorescence processes.

The theory of internal conversion processes in aromatic molecules containing additives has been developed in the writer's laboratory[126]. The expression for the internal conversion rate constant is

$$k_{IC} = \sum_{\{n\}} |V^{if}_{\{n\}}|^2 \Gamma (\Delta^2_{\{n\}} + \Gamma^2/4)^{-1}, \qquad (36)$$

where $V^{if}_{\{n\}}$ is a matrix element of the non-adiabaticity operator, calculated from the vibronic functions $|i\{0\}\rangle$ and $|f\{n\}\rangle$.

The main contribution to k_{IC} in the case of transitions between $\pi\pi^*$ (or $\sigma\sigma^*$) states, or between an $S_{\pi\pi^*}$ state and the ground state, comes from the matrix elements containing differentials with respect to the coordinates of the stretching vibrations of the C–H bonds (promoting modes[113]). This is because these vibrations have the greatest anharmonicity and the highest frequency of all the vibrations in the molecule. Ignoring the dispersion of the C–H stretching vibration frequencies, which is small even for small n [11] and decreases rapidly as n increases[127], we can re-write the expression for k_{IC} as[126]

$$k_{IC} \cong 10^{15} E^2_{if} \sum_{\nu,\{n\}} |c_{\nu i} c_{\nu f}|^2 \left| \left\langle 0 \left| \frac{\partial}{\partial x_\nu} \right| n \right\rangle \right|^2 \prod_{\nu' \neq \nu} |\langle 0 | n_{\nu'} \rangle|^2 \ (s^{-1}), \qquad (37)$$

where E_{if} is the difference in electronic energy of the i and f levels (in eV), the summation over ν includes all the C–H bonds in the molecule, $c_{\nu i}$ and $c_{\nu f}$ are the coefficients of the expansion of the π-orbitals, whose population is different in the $|i\rangle$ and $|f\rangle$ states, and x_ν is the coordinate of the C–H stretching vibrations. The ν' product in Eqn.(37) is taken for all the vibrations of the molecule whose characteristics are different in the $|i\rangle$ and $|f\rangle$ states (acceptor modes).

Using the Morse potential to describe the vibrations of the C–H bonds we can convert the formula for $|\langle 0|\frac{\partial}{\partial x}|\rangle|^2$ into

$$\left| \left\langle 0 \left| \frac{\partial}{\partial x} \right| n \right\rangle \right|^2 = \frac{\alpha^2 \Gamma^2 (2s - n + 1)}{n! \, \Gamma(2s - 2n) \, \Gamma(2s - 2n + 1) \, \Gamma(2s)} \cdot \eta^{2s} \rho^{-4s+2n} \times$$
$$\times \left[\frac{\eta}{2\rho} F\left(-n, 2s - n + 1; 2s - 2n + 1; \frac{1}{\rho}\right) - \right. \qquad (38)$$
$$\left. - \frac{s}{2s - n} F\left(-n, 2s - n; 2s - 2n + 1; \frac{1}{\rho}\right) \right]^2,$$

where α is the parameter of the Morse potential (~1 a.u.), $\eta = e^{\alpha\Delta}$, $\rho = \frac{1}{2} + \eta/2$, $\Gamma(x)$ is the gamma-function, $F(\alpha, \beta; \gamma; x)$ is a hypergeometric function, $s = 2D/\omega - \frac{1}{2}$, D is the dissociation energy of the C–H bond, ω is its vibration frequency, and Δ is the difference in length of the C–H bond between states $|i\rangle$ and $|f\rangle$. The Franck–Condon factors $\langle 0|n_{\nu'}\rangle$ are easily calculated because the $n_{\nu'}$ values are small and we can use the harmonic approximation in which $|\langle 0|n_{\nu'}\rangle|^2$ is given by Eqn.(33).

As was pointed out in Section VI electronic transitions in polyatomic molecules do not give rise to significant changes in the length of the C–H bonds. The γ parameter (formula (33)) for the stretching vibrations of the C–H bonds of the benzene molecule is ~10^{-2} ($\Delta = -0.014$ Å [128]). As the number of aromatic rings in the molecule increases the value of γ falls off rapidly to ~10^{-3} or less for a molecule containing two or more rings[99]. It follows that the most characteristic case is when $\Delta = 0$.

¶ The need for a proof was first stated in Ref. 120.

In Fig.6 the logarithm of the function $\theta = k_{IC} E_{if}^2 [\Sigma_\nu |c_{\nu i} c_{\nu f}|^2]^{-1}$ is plotted against the energy of the electronic transition for different values of Δ for C–H bonds, assuming typical values of $\gamma = 1$ for stretching vibrations of the aromatic nuclei at a frequency of ~1400 cm^{-1} and $\gamma = 0.5$ for bending vibrations at a frequency of ~400 cm^{-1}. The summation with respect to ν is easily evaluated because the $c_{\nu i}$ and $c_{\nu f}$ values are known for many molecules[37-40]. It is of the same order of magnitude as N_{C-H}/N^2, where N_{C-H} is the number of C–H bonds and N is the number of π-electrons in the molecule.

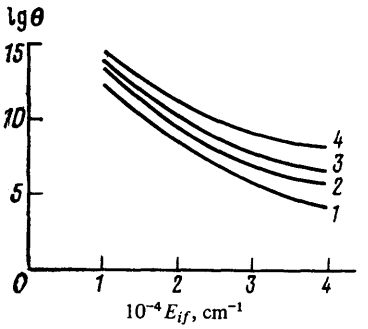

Figure 6. Variation of the factor θ with the energy of the transition: *1*) $\Delta = 0$, *2*) $\Delta = -0.01$ a.u., *3*) $\Delta = -0.02$ a.u., *4*) $\Delta = -0.03$ a.u.

These calculations lead to a number of conclusions. The internal conversion rate constant for $E_{if} \lesssim 10^4$ cm^{-1} is $\gtrsim 10^{11}$ s^{-1}, irrespectively of the value of Δ, and this is the main dissociation process available to the state $|i\rangle$. A similar (or smaller) value of E_{if} is characteristic of transitions between electronically excited states, and this calculation of k_{IC} is a theoretical justification of Kasha's rule. For E_{if} values lying between 10^4 and 2×10^4 cm^{-1} the internal conversion rate constant is of the same order as the rate constants for allowed radiative transitions. This is observed, for example, for the $S_2 \rightsquigarrow S_1$ transition in the azulene molecule, with an E_{if} value of 1.4×10^4 cm^{-1}. Formula (37) gives $\leq 10^9$ s^{-1} for the k_{IC} value of this transition, confirming that the luminescence properties of this molecule infringe Kasha's rule[129].

For $E_{if} \geq 2 \times 10^4$ cm^{-1} (as found in the transitions between S_1 and S_0 states in many aromatic molecules) the parameter k_{IC} depends not only on E_{if} but also on the Δ value of the C–H bonds. For many molecules we can write $\Delta = 0$: in this case (see Fig.6) k_{IC} is smaller than the radiative dissociation constant (k_r) of the S_1 states. It is also smaller than the rate constants for the $S-T$ conversion (see below). This result is a theoretical verification of the Ermolaev–Sveshnikova rule. It can also apply, with acceptable precision, for slightly smaller values of E_{if} if one of the following conditions obtains: 1) fast (~10^{-11} s) $S-T$ conversion processes between $n\pi^*$ and $\pi\pi^*$ states are possible; 2) the molecules have narrow luminescence bands and the γ parameter for their skeletal vibrations is $\gamma \leq 0.5$; 3) the radiative life time of the S_1 states is small (~10^{-9} s). The last two conditions are obeyed by many dye molecules, which can show strong fluorescence corresponding to transitions between S_1 and S_0 states even for $E_{if} < 2 \times 10^4$ cm^{-1} (but nevertheless $E_{if} > 10^4$ cm^{-1}).

In small aromatic molecules the Δ value of the C–H bonds can be relatively large in absolute value, so that $\pi \rightarrow \pi^*$ excitation may produce a decrease in length of the C–H bonds: for example, in benzene[128] and phenol[130] $\Delta \cong -0.03$ a.u. As a result the k_{IC} values can be close to the k_r values for the S_1 states even for $E_{if} \cong 4 \times 10^4$ cm^{-1}. This is an example of deviation from the Ermolaev–Sveshnikova rule. A similar behaviour may be discovered in other small molecules (for example, azabenzene), for which we can expect $|\Delta| \cong 0.03$ a.u. However in most aromatic molecules $|\Delta| < 10^{-2}$ a.u.[99], and the Ermolaev–Sveshnikova rule is accurately obeyed.

Internal conversion processes between $n\pi^*$ and $\pi\pi^*$ states have also been studied[126], as well as conversion between $S_{n\pi^*}$ and S_0 states. For $E_{if} > 5000$ cm^{-1} these processes are found to be slower than the conversion between $\pi\pi^*$ states, because the stretching vibrations of the C–H bonds in planar molecules do not act as promoting vibrations in this case. This result has been confirmed experimentally for the thioxanthone and thioxanthione molecules[102].

The probability of singlet–triplet conversion is very sensitive to the spin–orbit interaction of the states involved in the conversion. Using the calculations of spin–orbit interaction given in Section V we obtain the following expression[89,131] for the rate constant of the $S-T$ conversion between $\pi\pi^*$ (or $n\pi^*$) states in planar molecules in the Condon approximation and in first-order perturbation theory for the H_{SO} operator:

$$k_{ST} \cong 10^9 \sum_{\{n\}} \prod_q |\langle 0 | n_q \rangle|^2 \ (s^{-1}), \qquad (39)$$

and the following expression for the rate constant of the $S-T$ conversion between $S_{n\pi^*}$ and $T_{n\pi^*}$ (or between $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$) states:

$$k_{ST} \cong 10^{12} \sum_{\{n\}} \prod_q |\langle 0 | n_q \rangle|^2 \ (s^{-1}). \qquad (40)$$

In Eqns.(39) and (40) the summation extends over the vibrational quantum numbers of the high-frequency ($\omega > 500$ cm^{-1}) oscillators whose characteristics differ in the S and T states and for which the squares of the Franck–Condon factor are a maximum. The n_q values must satisfy the condition of minimum $|E_{if} - \sum_q n_q \omega_q|$. Thus the calculation of k_{ST} reduces to a calculation of the Franck–Condon factors.

An estimate of $|\langle 0|n_q\rangle|^2$ can easily be obtained by using the Robinson–Frosch semi-empirical formula[132]. This approach gave the following results[89]. The rate constants for the $S-T$ conversion between states of the same orbital type lie between 10^6 and 10^8 s^{-1}, which is of the same order as the rate constants for the radiative dissociation of singlet states. The characteristic rate constants for $S-T$ conversion between states of different orbital type are ~10^{10}–10^{11} s^{-1}, i.e. more than two or three orders of magnitude greater than the rate constants for the radiative dissociation of singlet states. These calculations have led to the classification of molecules into five types according to their luminescence spectra[53,89].

In recent years a great deal of experimental information has been obtained on the spatial structure of aromatic molecules in different electronic states (see Section VI). Therefore we can now evaluate k_{ST} more reliably by using expressions of the type of (33). This was done in Ref.131 for molecules of carbonyl, thiocarbonyl, aza-heterocyclic, and nitro compounds, and the results were consistent with the estimates of k_{ST} given in Ref.89. It was shown that the spin–orbit coupling of combining states is not the only reason for the large difference (three orders of magnitude) between the k_{ST} values for transitions between states of different orbital type and states of the same orbital type, or the k_r values for singlet states. As pointed out in Section VI, the spatial structure of the molecules is different in the $n\pi^*$ and $\pi\pi^*$ states. As a result, the Franck–Condon factor for the

$S \rightsquigarrow T$ transition between $n\pi^*$ and $\pi\pi^*$ states is significantly higher than the factor for transitions between states of the same orbital nature.

These considerations lead to the important conclusion that if $S-T$ conversion can occur between states of different orbital nature it has a rate constant of $10^{10}-10^{11}$ s^{-1}, and it gives rise to fluorescence quenching. Recent experimental measurements[133-135] on transitions between $n\pi^*$ and $\pi\pi^*$ states have given $k_{ST} \cong 10^{11}$ s^{-1}.

By using data on the spatial structure of molecules in electronically excited states and on the structure of their energy spectrum we can calculate not only the most probable range of k_{ST} values but also the dependence of k_{ST} on the structure of the molecule. Thus it has been shown[131,136] that the probability of $S-T$ conversion between $\pi\pi^*$ states increases sharply in the presence of a $T_{\pi\pi^*}$ state. But even in this case the k_{ST} value does not exceed ~10^9 s^{-1}. Other conditions being equal the k_{ST} value for a transition between $\pi\pi^*$ states is lower, the lower the value of γ in formula (33). However γ decreases as the length of the chain of conjugated bonds increases[98], and this is why many dye molecules have a high fluorescence quantum yield.

The effect of highly excited $n\pi^*$ states on the probability of $S-T$ conversion between $\pi\pi^*$ states has been studied[70]. In molecules containing N, O, and S atoms and having spin–orbit coupling between $n\pi^*$ and $\pi\pi^*$ states of intermediate magnitude the vibronic mixing effects do not substantially increase k_{ST} for transitions between $\pi\pi^*$ states. As before, k_{ST} is of the same order of magnitude as k_r for $S_{\pi\pi^*}$ states. However this parameter decreases quite markedly as the energy difference between the $\pi\pi^*$ and $n\pi^*$ states increases (for example, as the length of the conjugation chain increases, in the presence of electron-donor substituents, or when proton-donor substituents are used, see Section IV). All these factors tend to increase the fluorescence yield of the molecules in which the lower S and T states are of the $\pi\pi^*$ type ($\pi l, \pi^*$ and $\pi, \nu\pi^*$).

In molecules containing atoms with a large nuclear charge (Br, I, Cl) the vibronic mixing effects affecting $n\pi^*$ and $\pi\pi^*$ states can make k_{ST} take a value of ~10^{10} s^{-1} for conversion between $\pi\pi^*$ states in molecules with a small ($\leq$10) number of electrons; as the number of electrons increases this value rapidly decreases[70]. Thus in molecules containing heavy atoms fluorescence is possible if the number of π-electrons is large. Deviations of k_{ST} from the usual behaviour can occur in small molecules, and are related to the weakening of the LS coupling in heavy atoms.

In molecules with $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ states lying above the lower $S_{n\pi^*}$ state (see Figs.3 and 4) the vibronic interaction effects can cause quenching of the fluorescence from $S_{n\pi^*}$ states. This is due to the smallness of k_r for $S_{n\pi^*}$ states and also to the fact that the difference in energy between $T_{n\pi^*}$ and $T_{\pi\pi^*}$ states can be small (2000–3000 cm^{-1}). This explains the absence of fluorescence in many aromatic carbonyl compounds such as benzophenone and anthrone[137]. However the situation is made more complicated by the lack of planarity of these molecules.

Deviation from planarity in molecules leads to mixing of the π and σ orbitals, to an increase in the spin–orbit interaction of states of the same orbital type (Section V), and to an increase in k_{ST}. The $\pi l, \pi^*$ states of non-planar aromatic molecules can be taken as an example[96]. Another example is provided by aliphatic hydrocarbon molecules[64], and by the non-planar aromatic carbonyl molecules mentioned above.

We can now turn to a discussion of the role of internal conversion processes in the dissociation of excited states. The variation of the internal conversion constant k_{IC} with E_{if} is shown diagrammatically in Fig.7 for $\Delta_{C-H} = 0$. The cross-hatched region shows the most characteristic values of the rate constant for the dissociation of an S state by the radiative mechanism and by the $S-T$ conversion mechanism (k) on the assumption that $\pi\pi^*-n\pi^*$ conversion is not involved. Three energy regions can be defined: the Kasha region, in which $k_{IC} > k$, an intermediate region ($k_{IC} \cong k$), and the Ermolaev–Sveshnikova region ($k_{IC} < k$). When $S-T$ conversion processes between $\pi\pi^*$ and $n\pi^*$ states are possible the k value increases sharply and the Ermolaev–Sveshnikova region expands. We shall examine the case of molecules which obey the Ermolaev–Sveshnikova rule, even if only approximately, i.e. molecules in which the first singlet excited state has an energy in excess of ~1.5 eV.

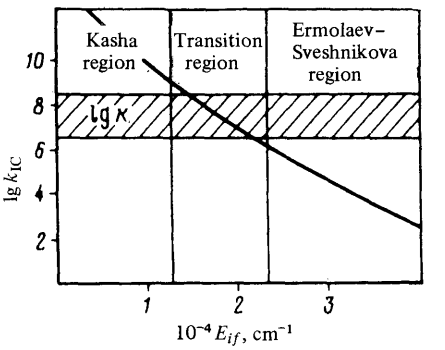

Figure 7. Relative values of k_{IC} and k as a function of the energy of the transition.

We have to consider processes of intercombination conversion from the lower triplet state to the ground state, which compete with the phosphorescence process. These processes have been studied in depth, both experimentally and theoretically, and they are discussed in the monograph literature[8,41] and in reviews[111,112]. In spite of their different approaches, all the theoretical studies conclude that the rate constant for conversion between S_0 states (k_{TS}) increases rapidly as the difference in energy between the states decreases[132,138,139]. This result, which follows directly from the simple formula (33) for the Franck–Condon factor, is consistent with experiment. However order-of-magnitude quantitative agreement between experimental and theoretical values of the constant has not yet been obtained, or has been obtained by postulating unrealistic potential energy surfaces for the molecules in excited states[111].

The difficulty of calculating the constant k_{TS} arises from the fact that, since E_{if} is large ($\geq$1 eV), the Franck–Condon factors for the $T \rightsquigarrow S_0$ transitions are small, and therefore the second- and higher-order terms in formula (35) cannot be ignored. (This is the difference between $T-S_0$ conversion and $S-T$ conversion.) The situation is made even more complex by the fact that in many aromatic molecules the matrix element of the operators of the spin–orbit interaction between the lower T state and the S_0 state is identically equal to zero in the Condon approximation (see Section V). In this case the transition is forbidden in the first-order (and in the Condon approximation) for the operator H_{SO}, and agreement between calculated values of k_{TS} and experiment cannot be obtained simply by improving the precision of the calculated Franck–Condon factor.

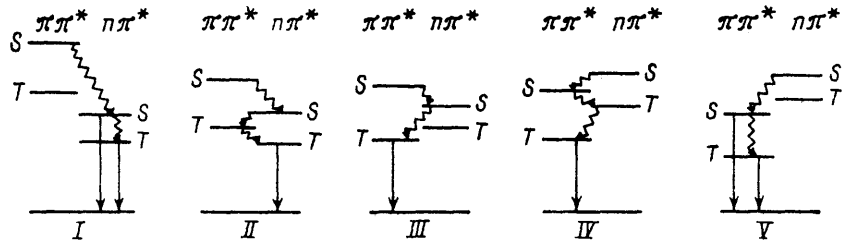

Figure 8. Most probable conversion processes between excited states, and radiative processes, involving molecules of the five luminescence-spectral types.

An important contribution[140] to our understanding of the mechanism of $T-S$ conversion in aromatic molecules points out that the constant k_{TS} is proportional to the constant k_r of the triplet state and to the overlap integral of the phosphorescence spectrum and of the infrared absorption spectrum of the molecule corresponding to the upper vibrational states of the C–H bonds, into which transitions are allowed as a result of the anharmonicity of the vibrations. This means[141,142] that k_{TS} is determined by a non-adiabatic interaction, and it should be calculated with allowance for second- and higher-order terms in the operators V and H_{SO}. It follows that k_{TS} should be proportional to the spin–orbit coupling of the T states with the S states, and to the constant k_{IC} for the conversion between these S states and the S_0 state (calculated for an E_{if} value equal to the energy of the T state[136]). Since the vibrational factor in the calculation of k_{IC} contains differentials with respect to the coordinates of the C–H bonds, and allowance for the anharmonicity of the vibrations is essential, the vibrational factor cannot be reduced to a Franck–Condon factor. In particular, the quantity $\langle 0|n\rangle$ for $n \neq 0$ and $\Delta = 0$ vanishes, and the quantity $\langle 0|\frac{\partial}{\partial x}|n\rangle$ for the anharmonic oscillator under these conditions cannot vanish for any value of n.

Conversion between $T_{\pi\pi^*}$ and the S_0 state can be achieved by mixing $S_{\pi\pi^*}$, $S_{n\pi^*}$, $S_{\sigma\pi^*}$, and $S_{\pi\sigma^*}$ states with the $T_{\pi\pi^*}$ state, and by mixing the appropriate triplet states with the S_0 state. In this case both the spin–orbit interaction and k_{IC} are small, since internal conversion between an $n\pi^*$ (or $\sigma\pi^*$, or $\pi\sigma^*$) state and the S_0 state cannot be promoted by stretching vibrations of the C–H bonds (see above, and Ref. 126). Therefore the conversion rate constants (k_{TS}) in the solid phase and at low temperatures are relatively small: in most molecules these constants differ by less than an order of magnitude from the k_r value for the $T_{\pi\pi^*}$ states[41,143]†. Under these conditions the dependence of the rate constant for the $T-S$ conversion on E_{if} is determined by the dependence of the matrix elements of (38) upon n, and is not very different from the dependence of k_{IC} on E_{if}. Theoretical calculations of k_{TS} as a function of E_{if} agree satisfactorily with experiment[140,136]. For $E_{if} \lesssim 1.5$ eV the constant k_{TS} becomes greater than k_r: in these molecules phosphorescence is impossible. At these energies the predominant contribution to k_{TS} can be obtained by the first-order perturbation theory if $\langle T_S|H_{SO}|S_0\rangle \neq 0$.[136]

The $T_{n\pi^*} \rightsquigarrow S_0$ intercombination conversion is much faster than conversion from a $T_{\pi\pi^*}$ state. This is because the spin–orbit interaction of $T_{n\pi^*}$ states with both S_0 and $S_{\pi\pi^*}$ states is large. In the condensed phase at low temperatures the constant k_{TS} for conversion from $T_{n\pi^*}$ states is similar in value to k_r for $T_{n\pi^*}$ states in many molecules[41,143]. The theory of $T-S_0$ conversion processes is still far from being fully developed.

To conclude this Section we shall list the main features of the conversion processes. Internal conversion between electronically excited states occur in ~10^{-11} s. In photochemically-stable molecules in a condensed phase we can usually ignore the $S_1 \rightsquigarrow S_0$ internal conversion (degradation) process. The rate constant for $S-T$ conversion between $n\pi^*$ and $\pi\pi^*$ states is ~10^{10}–10^{11} s^{-1}. The rate constant for $S-T$ conversion between states of the same orbital type in planar molecules is ~10^6–10^8 s^{-1}. The only exception are molecules containing heavy atoms (e.g. halogen) and having a small number ($\lesssim 10$) of π-electrons, for which the constant k_{ST} can be as high as 10^{10} s^{-1}. In the case of transitions between $\pi\pi^*$ states k_{ST} decreases as the energy difference between the $\pi\pi^*$ and $n\pi^*$ states increases and as the length of the conjugated bond chain increases. In non-planar molecules k_{ST} is higher than in planar molecules. The rate constants for $T \rightsquigarrow S_0$ conversion in the solid phase are similar in magnitude to the k_r values for triplet states. As the energy of the T state decreases the constant k_{TS} increases, lowering the phosphorescence yield.

VIII. CLASSIFICATION OF MOLECULES BY LUMINESCENCE SPECTRA

Let us now consider the luminescence-spectral properties of molecules in relation to the relative position of their electronically excited states#. We shall show that each of the five types of relative position of the $\pi\pi^*$ and $n\pi^*$ states (see Section IV) has its own set of luminescence-spectral characteristics, i.e. it corresponds to a type of molecule[53,89]. We shall assume that the molecules obey the Kasha and the Ermolaev–Sveshnikova rules, that they do not contain heavy atoms, and that their structure is planar.

Type I. The sequence of states is: S_0, $T_{n\pi^*}$, $S_{n\pi^*}$, $T_{\pi\pi^*}$, $S_{\pi\pi^*}$. Since the rate constants k_r (for $S_{n\pi^*}$ states) and k_{ST} (for the $S_{n\pi^*} \rightsquigarrow T_{n\pi^*}$ conversion) are similar in value (see Sections VI and VII), both fluorescence and (in the solid

†With rare exceptions, phosphorescence is not observed in the liquid phase because of the possibility of quenching of the T states by bimolecular processes.

#In this discussion the electronically excited states are arranged in order of increasing energy.

phase) phosphorescence are possible in these molecules. The fluorescence yield cannot be large because the constant k_r is relatively small. These molecules have a long-lived fluorescence and a short-lived phosphorescence. In the absorption spectra of molecules of the first luminescence-spectral type the bands corresponding to $n \to \pi^*$ and $\pi \to \pi^*$ transitions are separated by a relatively large ($\geq$1 eV) energy difference. Examples of this type of molecule are acetone, diacetyl, thiobenzophenone, and other molecules[4,53].

Type II. The sequence of states is: S_0, $T_{n\pi^*}$, $T_{\pi\pi^*}$, $S_{n\pi^*}$, $S_{\pi\pi^*}$. Because of the possibility of fast (~10^{-11} s) $S_{n\pi^*} \rightsquigarrow T_{\pi\pi^*}$ interconversion this type of molecule has a short-lived phosphorescence from the $T_{n\pi^*}$ state, and the fluorescence yield cannot exceed 10^{-3}. The $n \to \pi^*$ and $\pi \to \pi^*$ absorption bands are also well resolved in molecules of type II. Typical type II molecules are acetophenone, naphthoquinone, anthraquinone, and others[2-4].

Type III. The sequence of states is: S_0, $T_{\pi\pi^*}$, $T_{n\pi^*}$, $S_{n\pi^*}$, $S_{\pi\pi^*}$, Fast $S_{n\pi\pi^*} \rightsquigarrow T_{\pi\pi^*}$ interconversion is possible also in molecules of this type. Therefore these molecules can have only long-lived phosphorescence from the $T_{n\pi^*}$ states; the fluorescence yield cannot be greater than 10^{-3}. In the absorption spectra the $n \to \pi^*$ band is close to the $\pi \to \pi^*$ band, with the possibility of partial overlap. Examples of this type of molecule are benzoic acid, phthalic anhydride, etc.[4].

Type IV. The sequence of states is: S_0, $T_{\pi\pi^*}$, $T_{n\pi^*}$, $S_{\pi\pi^*}$, $S_{n\pi^*}$. Because of the possibility of $S_{\pi\pi^*} \rightsquigarrow T_{\pi\pi^*}$ interconversion processes in times of the order of 10^{-11} s the long-lived phosphorescence from $T_{\pi\pi^*}$ states is predominant in the radiation from these molecules. The fluorescence yield is small, but it can exceed the fluorescence yield of type-III molecules because the k_r values for $S_{\pi\pi^*}$ states are substantially higher than those for $S_{n\pi^*}$ states. An important difference between the luminescence properties of type IV and type III molecules is the ability of the former to be converted into type-V molecules (see below) under the influence of solvents giving rise to hydrogen bonds, since the energy difference between the $S_{\pi\pi^*}$ and $T_{n\pi^*}$ states is ~1000 cm^{-1}. Activation of the fluorescence of type II and type III molecules requires a much greater increase in the energy of the $n\pi^*$ states, which can be realised by dissolving the molecules in acids[144]. The bands corresponding to $n \to \pi^*$ transitions in the absorption spectra of type-IV molecules show complete overlap with the much stronger $\pi \to \pi^*$ bands, and they are not observed in poorly resolved spectra. Typical molecules of this type are acridine and quinoline in non-polar solvents.

Type V. The sequence of states is: S_0, $T_{\pi\pi^*}$, $S_{\pi\pi^*}$, $T_{n\pi^*}$, $S_{n\pi^*}$. Since the relatively slow ($\geq 10^{-9}$ s) $S_{\pi\pi^*} \rightsquigarrow T_{\pi\pi^*}$ processes are the only interconversion processes possible in this type of molecule we can expect both fluorescence and phosphorescence, with comparable yields. The ratio of the yields is determined by the relative values of k_r for the $S_{\pi\pi^*}$ states and k_{TS} for the $S_{\pi\pi^*} \to T_{\pi\pi^*}$ conversion, and of k_r for the $T_{\pi\pi^*}$ states and k_{TS} for the $T_{\pi\pi^*} \rightsquigarrow S_0$ conversion, which were discussed in the last two Sections. The $n \to \pi^*$ bands in the absorption spectra of type-V molecules are usually overlapped by the stronger bands due to $\pi \to \pi^*$ transitions, and they can be observed only when they lie between two of these bands. Dye molecules are typical of the luminescence-spectral type V.

The most probable conversion processes between electronically excited states and radiation processes involving molecules of the five luminescence-spectral types are illustrated in Fig.8. The diagram corresponds to k_{ST} values obtained in the Condon approximation. By going beyond this approximation[70] we can, on the one hand, describe differences between molecules in the same spectral type, and on the other hand we can demonstrate the absence of sharp boundaries between the five spectral types. We shall justify the latter statement by considering the transition from type I to type II. As the $T_{\pi\pi^*}$ state approaches the $T_{n\pi^*}$ state the extent of mixing of these states due to vibronic interaction increases, and the constant k_{ST} for the $S_{n\pi^*} \rightsquigarrow T_{n\pi^*}$ transition also increases very markedly. The energy of the $T_{\pi\pi^*}$ state can be higher than that of the $S_{n\pi^*}$ state, but since the $S-T$ splitting of the $n\pi^*$ states and the constant k_r for the $S_{n\pi^*}$ state are both small the fluorescence may be suppressed. Similar arguments can be applied in the other cases.

In other words, great care is needed to describe the luminescence-spectral properties of molecules whose electronic states lie in the transition region between two of the types defined above. This conclusion is entirely consistent with the well known increase in complexity of the spectral properties of systems with degenerate or quasi-degenerate states (the Jahn–Teller effect or pseudo-effect)[145]. The criterion for the validity of the scheme shown in Fig.8 is that the vibronic interaction of $n\pi^*$ and $\pi\pi^*$ states must be small compared with the energy difference between these states. In most cases this criterion is obeyed and the scheme of Fig.8 is applicable[79].

In the light of these considerations, the differences in properties between $\pi\pi^*$ (or $n\pi^*$) states arising from differences in orbital nature, from the presence or absence of quasi-degeneracy of the lower $S_{\pi\pi^*}$ state with the upper $T_{\pi\pi^*}$ state, from the differences in the vibronic bond with the upper states, etc. are only second-order differences and can be allowed for in the scheme proposed here. This is because none of the rate constants for $S-T$ conversion suffers a catastrophic change (by several orders of magnitude) as a result of these effects. The scheme outlined in Fig.8 remains valid, though there may be a change in the designation of the states and (or) a limited change in the rate constants for the dissociation of the states leading to luminescence.

Possible luminescence-spectral types of molecules of different orbital classes*.

Class	Type					Class	Type				
	I	II	III	IV	V		I	II	III	IV	V
(σn)	–	–	–	–	+	($\sigma\pi n$)	+	+	+	+	+
($\sigma\pi l$)	–	–	–	–	+	($\sigma\pi ln$)	+	+	+	+	+
($\sigma n v$)	–	–	–	–	+	($\sigma n v n$)	+	+	+	+	+
($\sigma n l v$)	–	–	–	–	+	($\sigma n l v n$)	+	+	+	+	+

*The plus sign denotes that this type of molecule can exist, the minus sign that it cannot.

The luminescence-spectral type to be expected in molecules of various types can therefore be stated without difficulty. Aromatic (unsaturated) molecules can be divided into the following classes[146], depending on the set of orbitals which characterise their electronic structure: ($\sigma\pi$), ($\sigma\pi l$), ($\sigma\pi v$), ($\sigma\pi lv$), ($\sigma\pi n$), ($\sigma\pi ln$), ($\sigma\pi vn$), and ($\sigma\pi lvn$). These designations hardly need to be explained: for example, the ($\sigma\pi$) class includes the aromatic hydrocarbon molecules, the ($\sigma\pi l$) class the aromatic hydrocarbon molecules with donor substituents, etc. The possibilities of observing the various luminescence-spectral types are summarised in the Table[146].

A set of molecules of different classes but of the same luminescence-spectral type is termed a luminescence-spectral series. Molecules of one series have similar (but numerically different) properties owing to the differences in orbital nature of their states and to the other factors discussed above. Transitions between molecules of different types or classes can be brought about by changes in chemical structure and by external factors (see Section IV).

All the above statements apply to molecules which do not contain heavy atoms, i.e. atoms with a multiplet splitting constant ξ greater than ~500 cm^{-1}.[70] Infringement of this condition causes k_{ST} for transitions between $\pi\pi^*$ states in molecules formally classified as type V to reach values of the order of 10^{11} s^{-1}: these molecules will have a low ($\leqslant 10^{-3}$) fluorescence quantum yield. The effect is clearly shown by molecules with a small ($\leqslant 10$) number of π-electrons.

The agreement between the luminescence-spectral classification of molecules and experimental data has been demonstrated by many workers[2-4,53,58,92,99,100,147-150].

This method of classification offers a unified description of the properties of a large number of molecular systems. It has been applied in the chemistry of phosphors and scintillators[147], in biophysics[148], and in photochemistry[114], and it has helped in the selection of materials with good light-emitting properties (for the active regions of lasers operating in the visible and the u.v. region)[144,149,150]. It has also been valuable in molecular spectroscopy[4].

The validity of our classification is limited by the possibility of photochemical processes. The problem is by no means trivial, because conversion processes can be initiated by photochemical processes whose yield is immeasurably low. A special case is met in systems with two or more minima in the potential surface of one electronic state[151].

Since this paper was submitted for publication the following relevant papers have appeared: a discussion[152] of the general problems in systematising the luminescence-spectral properties of molecules, a study[153] of the initiation mechanisms of conversion by photochemical reactions, and an analysis[154] of the mechanism of triplet–singlet conversion processes.

Chemical Chain Reactions in the Devitrification of the Matrix

I.M.Barkalov

The results of studies of the mechanisms of chain reactions occurring in the devitrification of vitreous matrices are surveyed and the characteristics of the kinetics and the mechanisms of the chain reactions accompanying the devitrification process are examined: chlorination of hydrocarbons, polymerisation, copolymerisation, and graft polymerisation. The possible applied aspects of chain reactions in the devitrification of the matrix are also considered.
The bibliography includes 64 references.

I. INTRODUCTION

With decrease of temperature, the short-range order structure in a low-molecular-weight liquid or in a polymer varies continuously at a rate which depends on the relaxation time of the system. The rate of this rearrangement decreases as the temperature is reduced and at a certain temperature, called the glass point (T_g), the structure of the liquid or polymer is fixed and the substances passes to the vitreous state.

We may isolate two main factors which determine the probability of the conversion of a liquid into a glass rather than a crystal: a sufficiently high rate of cooling of the melt and a high viscosity in the range of crystallisation temperatures. A high viscosity of the melt retards the migration of the structural units and the relaxation time increases. Therefore at sufficiently high rates of cooling the equilibrium structure of the liquid corresponding to temperatures $T \geq T_g$ is "frozen". However, if the rate of cooling is reduced, the same liquid can be crystallised. On the other hand, typically crystallisable substances can be obtained, in principle, in a vitreous state at very high rates of cooling.

The ability of organic low- and high-molecular-weight compounds, to the reactions of which this review is devoted, to pass to the vitreous state is associated as a rule with a fairly intense intermolecular interaction in the liquid. The vitreous state is formed readily by alcohols (particularly dihydric and trihydric), amines, branched paraffins, and high-molecular-weight compounds.

The vitreous state is thermodynamically unstable but is in practice extremely stable owing to kinetic obstacles to the migration of structural units. When a vitreous substance is heated slowly in the devitrification region, there is a transition to a supercooled liquid thermodynamically unstable at the given temperature. This transition is accompanied by a fairly sharp increase in heat capacity. On the other hand, the viscosity of the system falls under these conditions. For a vitreous substance at $T \leq T_g$, the viscosity exceeds 10^{14} P, while transition to a supercooled liquid entails a fall of the viscosity to 10^7 P for silica and 10^2 P for alcohol. Naturally the sharp change in molecular mobility in the medium over a narrow temperature change should lead to extremely specific features of the mechanism of a chain reaction occurring under these conditions.

Among the chain reactions developing against the background of such a rearrangement of the matrix, polymerisation has aroused most interest among investigators. As early as 1962, it was shown[1] that vinyl acetate can be obtained in both vitreous and crystalline states. On the other hand, the rates of polymerisation under identical conditions proved to be higher by an order of magnitude for vitreous vinyl acetate than for the crystalline substance. High rates of polymerisation of vinyl monomers have been noted for the postradiation polymerisation in vitreous solutions in liquid paraffin and other solvents capable of forming a glass. The results of this series of investigations have been described in reviews[2,3]. Extremely high rates of polymerisation on devitrification of the matrix have been demonstrated for a large number of vitreous solutions of various vinyl monomers. Chapiro[2] suggested that such high rates of polymerisation at comparatively low temperatures ($T_g \cong -100°$ to -150 °C) are associated with the fact that in a vitreous matrix the monomer exists in the form of liquid microdrops incapable of forming crystals. Therefore, in spite of the very low temperatures, polymerisation takes place in a liquid monomer. However, if this hypothesis were valid, then the temperature dependence of the rate of polymerisation would undergo no sharp changes on passing through the matrix vitrification region. Nevertheless, it was shown in Chapiro's later study[3] that in all the instances investigated there is a sharp maximum in the rate in the region of the devitrification of the matrix.

In general a significant deficiency of all the early studies was the use of the traditional gravimetric method for the determination of the yield of the polymer and of the corresponding rate of polymerisation. As a result of the application of this method, the yield of the polymer, for example, at temperatures in the devitrification region, was inferred from measurements carried out at room temperature after the disintegration of the matrix. On the other hand, quantitative kinetic studies, necessary to understand the mechanisms of the chain reactions on devitrification, required primarily the development of methods whereby one could follow the process directly at the instant of its occurrence and not after its completion and disintegration of the surrounding matrix. In the first place, direct measurements of the rates of reaction, the rate constants for the elementary steps, and their temperature variations were necessary. Phase analysis of the two-component "monomer–vitrifying matrix" system, the

determination of the limits of miscibility at the glass temperatures of the system, and finally the determination of the vitrification region itself were needed in each specific instance.

Further advances in the study of the mechanisms of chain reactions on devitrification are associated mainly with the employment of the calorimetric technique in which the above methodological problems have been solved successfully. The application of the EPR method, which made it possible to follow the conversion of the active centres in radical processes directly at the instant of their occurrence, both qualitatively and quantitatively, also proved to be very fruitful. The latest advances in research into the characteristics of chain reactions on devitrification, associated mainly with the application of calorimetry and EPR, will be examined in this review.

II. DESTRUCTION OF RADICALS

Stabilised active centres accumulate in vitreous substances during their low-temperature radiolysis ($T < T_g$). Translational migrations (leading, for example, to the encounter and recombination of radicals) are greatly hindered in both crystalline and vitreous solids. This factor is in fact responsible for the comparatively high limiting concentrations of radicals which can be attained in the low-temperature radiolysis. On the other hand, the transition of the matrix to the liquid state on fusion of the crystals or to a supercooled liquid on devitrification leads to a sharp decrease of the viscosity of the system and an increase of the rate of translational movements and consequently of the rate of recombination of the radicals accumulated.

We shall consider this process in greater detail in relation to the destruction of stabilised radicals in radiolysed methanol[4]. On freezing, pure methanol crystallises and the vitreous state is not observed. However, the addition of small amounts of salts soluble in methanol such as $CoCl_2$, leads to the transition of these solutions to the vitreous state when the rate of cooling is sufficiently high. The use of differential scanning calorimetry[5] makes it possible to follow the phase transformations of the given system. When a solution of $CoCl_2$ in methanol is heated in the calorimeter in the region of the devitrification of the system (110–115 K), a sharp change in the heat capacity of the system is observed—there is a "step" (Fig.1, curve *a*). The solution then passes from the vitreous to the supercooled liquid state. On further increase of temperature, the thermodynamically unstable supercooled liquid crystallises. The crystallisation is accompanied by the evolution of heat (exothermic peak on curve *a* in Fig.1). Further heating leads to the fusion of methanol (endothermic peak). With increase of the $CoCl_2$ concentration in methanol, the viscosity of the solution apparently increases and the crystallisation of the supercooled liquid becomes increasingly more difficult. Thus, whereas approximately half of the methanol crystallises for a 2% concentration of $CoCl_2$, in 10% solution appreciable crystallisation and hence also fusion are no longer observed (Fig.1, curve *b*).

The radiolysis of such a vitreous $CoCl_2$ solution in methanol at 77 K leads to the accumulation of stabilised radicals. Measurement of the concentration of radicals by EPR shows that the stabilised radicals recombine effectively when the matrix passes from the vitreous to the liquid state. This recombination process can be followed also calorimetrically on the basis of the heat evolution accompanying it. Indeed heat evolution in irradiated specimens is observed precisely in the temperature range of the devitrification process (Fig.1, shaded exothermic peak) and the amount of evolved heat increases with increase of the dose until the attainment of a limiting concentration of radicals. The observed heat evolution is related precisely to the recombination of radicals. For a dose of approximately 100 Mrad, when the limiting concentration of radicals is attained, the contribution of charge recombination to the heat evolution can be neglected, because the concentration of charges is small compared with that of the radicals[6].

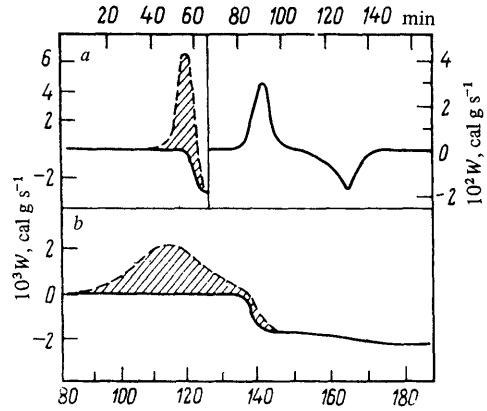

Figure 1. Calorimetric heating curves before (continuous lines) and after (dashed lines) irradiation of 2% (*a*) and 10% (*b*) solutions of $CoCl_2$ and CH_3OH with a dose of 100 Mrad at 77 K. Shaded regions—heat evolution associated with the recombination of radicals.

The radicals $^{\cdot}CH_2OH$, which are stabilised and accumulate in the low-temperature radiolysis, recombine with formation of ethylene glycol. On recombination, 70 ± 8 kcal mol^{-1} is evolved. The concentration of stabilised $^{\cdot}CH_2OH$ radicals can be calculated from the measured heat evolution. It was found that the EPR method and calorimetry yield virtually concordant results.

Thus, following the sharp change in the translational mobility of molecules, which occurs on transition from the vitreous to the supercooled liquid state, relatively small radicals recombine effectively. This takes place in systems where there exists virtually only one possible interaction channel—the recombination of radicals. In systems where the radicals liberated on devitrification are capable of initiating a chain reaction a different behaviour is observed, as will be shown below.

III. POLYMERISATION

As mentioned in the introduction, it has been shown in relation to a large number of examples that the polymerisation of vinyl monomers is sharply accelerated on devitrification of the matrix. The calorimetric method, which makes it possible to measure the rate of polymerisation directly at the instant of its occurrence, has been used successfully in an attempt to elucidate the causes of such acceleration of the polymerisation process. It has been shown by the calorimetric method[7] that the polymerisation of vitreous vinyl acetate and butylene dimethacrylate does not occur in the low-temperature radiolysis ($T < T_g$) and takes place only when the irradiated specimen

is heated in its devitrification region. It has also been established by the calorimetric technique[8] that the polymerisation of monomers in a vitrifying polymeric matrix proceeds vigorously immediately after the devitrification of the system.

Butyl methacrylate forms a complex with anhydrous zinc chloride, which passes to the vitreous state on freezing. The application of the calorimetric method in combination with EPR in the study of the postpolymerisation in the devitrification of this complex demonstrated the growth of radical chains after devitrification without termination[9]. The sharp inhibition of the termination of polymer chains in the supercooled liquid in the vicinity of the devitrification region itself provides a qualitative explanation of the high rates of polymerisation under these conditions. However, the problem of the rate of chain growth under such conditions remained open. In order to understand the mechanism of the polymerisation process on devitrification it was necessary to compare the propagation rate constants in the supercooled liquid, in the intrinsic crystal lattice of the monomer, and in the thermodynamically stable liquid.

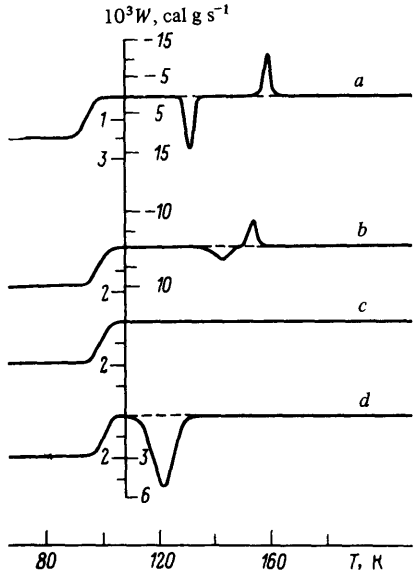

Figure 2. Calorimetric heating curves for pure ethanol (*a*), 10% (*b*) and 17% (*c*) acrylic acid solutions in ethanol, and a 17% acrylic acid solution in ethanol irradiated with ^{60}Co γ-rays for a dose of 2 Mrad at 77 K (*d*).

A system comprising a solution of acrylic acid in ethanol was studied[10] in order to solve these problems. Fig.2 shows that, when rapidly frozen (~100 K min^{-1}) solutions of acrylic acid in ethanol are warmed, the calorimeter reveals a characteristic change in heat capacity, a "step" associated with the transition of the system from the vitreous to the supercooled liquid state. On further increase of temperature in pure ethanol and dilute solutions (≤10 wt.%) of acrylic acid, the supercooled liquid crystallises and the calorimetric curve shows the corresponding heat evolution (Figs.2*a* and 2*b*). At higher temperatures the crystallised system melts (endothermic peak). With increase of acrylic acid concentration, the crystallisation of the supercooled solution after its devitrification becomes increasingly difficult and, in the presence of 17 wt.% of acrylic acid in alcohol, the solution does not crystallise at all (Fig.2*c*). All further studies were carried out[10] precisely for this simpler system—a non-crystallising 17% vitreous solution of acrylic acid in alcohol. Direct calorimetric measurements in the field of ^{60}Co γ-radiation showed that there is virtually no polymerisation in the vitreous solution of acrylic acid in alcohol at $T < T_g$. The calorimetric curve, obtained on heating the vitreous solution irradiated by ^{60}Co γ-rays at 77 K, shows an intense heat evolution, associated with polymerisation of acrylic acid, immediately after the devitrification step (i.e. after the transition to the supercooled liquid state) (Fig.2*d*). The overall yield of the polymer then reaches 80%.

At approximately 108 K the EPR spectra indicate the conversion of the monomeric radicals and the radicals of the alcohol matrix R_M, formed on radiolysis, into the radicals of the growing polymer chain R–C$_\beta$H$_2$–$^{\cdot}$C$_\alpha$H–COOH (R_p) (Fig.3).[10] In the supercooled liquid this radical assumes a non-equilibrium conformation with an angle $\phi \cong 75°$ between the axis of the unpaired electron orbital and the projection of the R–C$_\beta$ bond on to a plane perpendicular to the C$_\beta$–C$_\alpha$ bond; the EPR spectrum then consists of a doublet of triplets (Fig.3*b*). On raising the temperature to 120 K, the destruction of R_p begins, because the growing macroradicals now acquired sufficient translational mobility. Under these conditions they apparently "roll up", become surrounded by the polymer units, acquire a conformation normal for the polymer matrix with $\phi = 15°$, and give rise to a triplet EPR spectrum (Fig.3*c*).[11] The conformational transformations at the end of the growing radical in such systems has been examined in greater detail by Bol'shakov et al.[12]

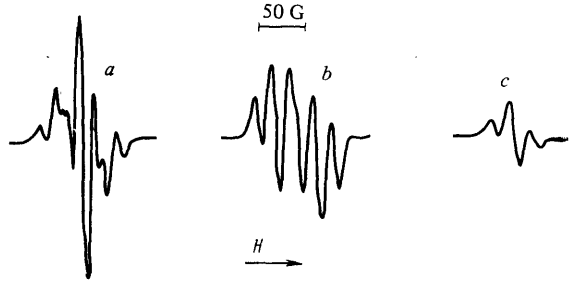

Figure 3. EPR spectra of a 17% acrylic acid solution in ethanol γ-irradiated with a dose of 2 Mrad at 77 K: *a*) at 77 K (R_M); *b*) specimen heated to 110 K (R_p); *c*) at 121 K.

Chain initiation is accompanied by the recombination of some of the monomeric radicals and only approximately half of them are converted into growing polymer radicals. On further increase of temperature, in the temperature range where acrylic acid is vigorously polymerised, the concentration of growing polymer radicals remains unchanged. Thus, over a comparatively narrow temperature range in the region of the devitrification of the matrix, the polymerisation process proceeds virtually without chain termination. This extremely important conclusion was convincingly confirmed experimentally for a whole series of systems[9,10,13,14].

Rates of polymerisation of the kind observed in a supercooled alcoholic solution of acrylic acid are reached in solid acrylic acid only at temperatures higher by 70–80 °C [15] and there is no termination of macroradicals in either case. This comparison clearly demonstrates the decisive role of the intermolecular interactions of the matrix. The translational mobility of the monomeric radicals, which is close to the mobility of the monomeric molecules, was estimated from the initial sections of the curves for the destruction of the radicals[15]. It proved to be $\nu_t \cong 2 \times 10^{-2}$ s^{-1}, while the frequency of the addition of monomeric molecules to the active centre is $\nu_p \cong 1.3 \times 10^{-3}$ s^{-1}. The frequencies of the reorientational mobility in this system are $\nu_r \cong 10^8$ s^{-1}. Thus $\nu_r \gg \nu_t > \nu_p$, i.e. the types of molecular mobility examined do not limit the polymer chain growth step.

However, the Arrhenius parameters of the propagation rate constant are very high[10]. The chain propagation rate constant in the temperature range 110–120 K has been estimated for the postpolymerisation of acrylic acid in the devitrification of the alcohol matrix[16]:

$$k_p \simeq 5 \cdot 10^{-3} \exp(-10700/RT), \text{ cm}^3 \text{ s}^{-1}.$$

The high Arrhenius parameters and their variation with increasing preliminary irradiation dose[10] indicate a cooperative nature of the process manifested by the compensation effect[17]. Consequently the monomer addition step continues to be limited by some third type of molecular movement.

After the mutual approach of the monomeric molecule and the active centre as a result of the translational and reorientational migrations, the rate-limiting stage is apparently the steric deformation of the molecules in the addition step[1c,12], for which mainly barriers to intermolecular interactions are overcome.

The monomeric radicals formed in the low-temperature radiolysis of glasses, should be destroyed when the matrix passes to the supercooled liquid state, unless they have attained during the growth process a critical length, which, when exceeded, precludes bimolecular recombination. Naturally, the rate of heating of the system by radiolysis will have a significant influence on the process mechanism: depending on the rate of heating, there either is or is not sufficient time for the monomeric radicals to be stabilised by conversion into growing polymer radicals[13]. Indeed constant heating of the system prevents the "setting" of the polymer chains and a fairly low rate of heating ensures the stabilisation of growing macroradicals[14].

On comparatively rapid (~2 K min^{-1}) heating of radiolysed vitreous butyl methacrylate, a polymer is hardly formed, while on slow heating (~0.05 K min^{-1}), virtually complete conversion is observed[13]. The postpolymerisation of pure butyl methacrylate during its devitrification is a radical process occurring in the absence of the destruction of radicals and chain transfer, i.e. proceeding via the mechanism of "living chains"[13].

A characteristic feature of the polymerisation of allylamine on devitrification of the matrix is the suppression of the "allylic termination" typical for the polymerisation of this monomer in the liquid state, this leads to the formation of a product with a very high molecular weight in such systems[18].

The nature of the chain process occurring on devitrification of the matrix depends significantly on the rigidity of the latter, the width of the devitrification temperature range, and the differences between the viscosities of the medium in the vitreous and supercooled liquid states. Thus it has been shown[19] that the radiation-induced polymerisation of vinyl chloride takes place solely in long-chain paraffin matrices, whereas in glasses consisting of low-molecular-weight paraffins a polymer is not formed. It has been suggested[20] that the supermolecular structure of the glass has a decisive influence on the development of polymerisation in the glass; in glasses comprising long-chain molecules the supermolecular formations consist of "packets" in which particularly favourable conditions may arise for the growth of polymer chains.

The polymerisation of vinyl chloride, vitrified in liquid paraffin, has been investigated on the basis of the changes in the energy losses by the ultrasonic emitter in the course of the radiolysis of the system at 77 K.[20] A change in the resistance to waves was observed in the course of the radiolysis, which the authors attributed to the formation of a polymer in the vitreous matrix at 77 K ($T_g \cong 183$ K for this system). Unfortunately the technique employed in the above study[20] did not permit the estimation of the amount of polymer formed at such low temperatures. Nevertheless, the

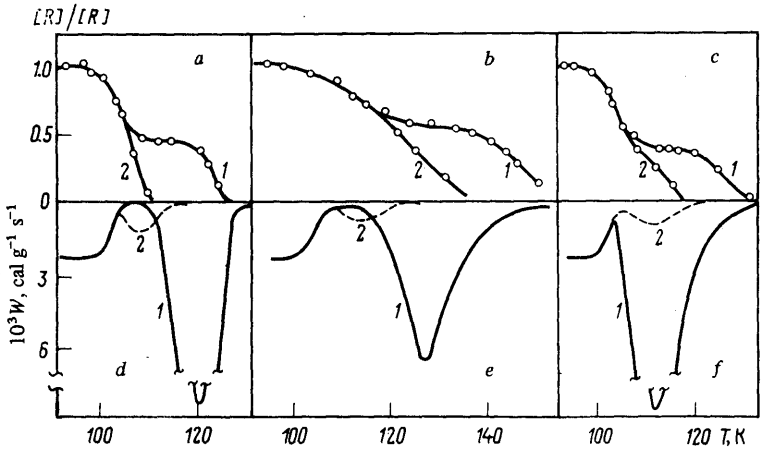

Figure 4. Temperature dependence of the stationary concentration of radicals [R_{st}] (*a*–*c*) and of the rate of polymerisation (*d*–*f*)(calorimetric heating curves) in γ-irradiated solutions (17 wt.%): *1a*) and *1d*) acrylic acid; *1b*) and *1e*) acrylamide; *1c*) and *1f*) methyl acrylate; *2a*) and *2d*) methacrylic acid; *2b*) and *2e*) methacrylamide; *2c*) and *2f*) methyl methacrylate.

main bulk of the polymer in these systems is formed on devitrification of the matrix[2]. The growth of polymer chains in the vitreous matrix at temperatures much smaller than T_g is believed[20] to take place in the region of extended defects in the glass, at the boundary between the ordered elements of the type of packets and the disordered medium.

Infrared spectroscopy has been used to investigate the characteristics of the chain propagation and termination reactions in the polymerisation of vinyl chloride vitrified in liquid paraffin[21]. It was established that, under isothermal conditions, the polymerisation is retarded in the system investigated, a further increase of temperature resulting in its acceleration. The phenomenon is extremely similar to the problem of the "setting" and "reviving" of polymer chains, first established[22] for solid-phase polymerisation.

It has been shown that, in postpolymerisation in supercooled alcoholic solutions, the reactivities of acrylic and methacrylic derivatives differ sharply[23]. Whereas on raising the temperature of vitrified alcoholic solutions of acrylic acid, acrylamide, and methyl acrylate, the yield of the polymer is 80%, the corresponding yield for their methacrylic analogues—methacrylic acid, methacrylamide, and methyl methacrylate—does not exceed 3–5% under identical conditions (Figs.4*d*–4*f*, cf. curves *1* and *2*).[23]

When solutions irradiated at 77 K are heated above T_g, the chain initiation and propagation are accompanied by the partial recombination of the radicals. The first monomer addition step, leading to the formation of an oligomeric radical, can be detected from the EPR spectra. For acrylic and methacrylic derivatives, the relative concentrations of the oligomeric radicals proved to be similar (Figs.4*a*–4*c*). Consequently the sharp difference between the rates of polymerisation of acrylic and methacrylic derivatives is not associated with the difference between the efficiencies of the initiation processes. With increase of the length of the growing polymer chain, its translational mobility falls and hence there is also a decrease of the probability of the destruction of the chain by recombination. For acrylic derivatives the concentration of the growing polymer radicals remains constant over a temperature range (Figs.4*a*–4*c*) and the polymer chain grows virtually without termination (Figs.4*d*–4*f*). On the other hand, a completely different picture is observed for methacrylic derivatives, The oligomeric radicals R_{ol} possess a fairly high translational mobility, are not stabilised, and recombine rapidly (Figs.4*a*–4*c*, curve *2*).

In order to elucidate the causes of such a sharp difference, the EPR spectra were analysed and the conformations of the terminal macroradicals in acrylic and methacrylic derivatives were determined from the hyperfine splitting by β-protons[23]. As a result of the interaction with the alcohol matrix, the terminal macroradicals of acrylic monomers exist in a specific conformation (Fig.5*a*, spectrum *2*), which differs from the conformation characteristic of the polymerisation of monomers in the crystalline state[10]. Methacrylic monomers do not give rise to a specific conformation and the terminal macroradicals have the same conformation as in their polymerisation in the crystal lattice of the monomer. The EPR spectra of the growing macroradicals are virtually identical in the polymerisation of methacrylic acid in a supercooled alcohol matrix (Fig.5*b*) and in its own crystal matrix (Fig.5*c*). Hence it follows that the presence of the CH_3 group near the reaction centre prevents the interaction of the growing macroradicals with the alcohol matrix, which leads to an increase of the probability of chain termination and to a decrease of the yield of the polymer. On the other hand, for acrylic monomers, the growing macroradical is associated with the alcohol molecules surrounding it, which leads to the formation of a specific conformation and the "coat" formed prevents its destruction. This is apparently the main cause of the sharp difference between the characteristics of the polymerisation of acrylic and methacrylic monomers[24]. On the other hand, the difference between the propagation rate constants is small and cannot account for the large difference in behaviour. Thus in a liquid medium $k_p = 1.45 \times 10^6 \exp(-4700/RT)$ for methyl acrylate and $k_p = 5.35 \times 10^5 \exp(-4700/RT)$ litre mol^{-1} s^{-1} for methyl methacrylate[25].

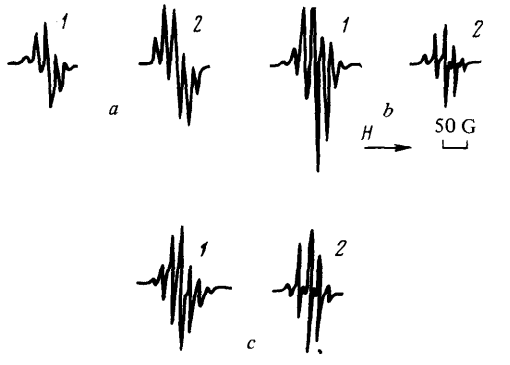

Figure 5. EPR spectra of 17% solutions γ-irradiated with a dose of 2 Mrad at 77 K: *a*) acrylic acid in ethanol at 77 K (curve *1*) and 120 K (curve *2*); *b*) methacrylic acid in ethanol at 77 K (curve *1*) and 112 K (curve *2*); *c*) spectrum of a polycrystalline methacrylic acid specimen at 77 K (curve *1*) and of the growing radical at 300 K (curve *2*).

Thus, in contrast to the usual liquid-phase polymerisation, a sharp difference is observed in the capacities of acrylic and methacrylic monomers for polymerisation on devitrification, which is associated with the more intense interaction with the growing acrylic macroradicals with the medium.

On heating irradiated vitreous monomers or their solutions, the following picture is thus observed: in the vicinity of the devitrification region the matrix is softened to such an extent that the conversion of monomeric radicals into the oligomeric radicals of the growing chain becomes possible. However, the characteristic times for the elementary chain propagation step are in this region extremely long and the chain growth is limited by the supply of the monomer to the growing active centre. With increase of temperature, the viscosity of the system is significantly reduced on passing to the supercooled liquid state, which facilitates the supply of the comparatively small monomer molecules to the growing polymer radical. At the same time, the viscosity of the supercooled liquid is still sufficiently high to prevent the bimolecular destruction of the macroradicals of the growing polymer chains. In this temperature range the polymerisation develops in accordance with the "living chain" mechanism. At high temperatures the matrix softens to such an extent that the bimolecular destruction of the growing macroradicals becomes possible and leads to the cessation of polymerisation. Such ideas concerning the mechanism of the polymerisation process on transition of radiolysed vitreous solutions of monomers to the supercooled liquid state proved to be applicable to a wide range of systems.

The polymerisation processes occurring on devitrification of the matrix by an ionic mechanism have also been investigated in fair detail. Not only radicals but also trapped electrons are known to be stabilised in glasses on low-temperature radiolysis. It has been found that there exist conditions under which ionic active centres stabilised in glasses can initiate ionic polymerisation. The anionic postpolymerisation of acrylonitrile has been observed on heating its vitrified solutions in methyltetrahydrofuran[26], dimethylformamide, and triethylamine[3] after the latter have been subjected to low-temperature radiolysis. The polymerisation process in these systems reached a maximum immediately after the transition of the system from the vitreous to the supercooled liquid state.

The polymerisation of the above systems at temperatures exceeding T_g was not observed, but it was possible to observe postpolymerisation via an ionic mechanism. It was found that the addition of acetone during the heating of vitreous acrylonitrile solutions fully suppresses its anionic polymerisation. It is noteworthy that, in a study of this system, the authors[26] noted for the first time the decisive role of the rate of heating of the radiolysed glass, showing that, when the system is heated slowly, a much greater amount of polymer is produced.

The anionic mechanism of postpolymerisation on devitrification has been demonstrated most clearly in the study of the polymerisation of nitroethylene vitrified in a methyltetrahydrofuran glass[27]. Electrons stabilised in the low-temperature radiolysis of glasses can be ejected from traps by visible and ultraviolet light, whereupon they recombine with holes. This optical "bleaching" method was first used to suppress ionic polymerisation[28] in order to demonstrate the ionic mechanism of the polymerisation of solid acrylonitrile. By subjecting nitroethylene glasses in methyltetrahydrofuran radiolysed at 77 K to optical bleaching before heating, the authors[27] showed that the postpolymerisation of this monomer is fully suppressed on devitrification of the matrix.

A cationic mechanism of the polymer chain propagation has been observed in the postpolymerisation of styrene vitrified in hexachlorobutadiene and methylene chloride[26]. Under comparable conditions, the amount of polymer formed in the above systems is smaller by an order of magnitude than in the anionic polymerisation of acrylonitrile on devitrification. However, here too a sharp maximum of the rate of polymerisation is observed in the region of the devitrification of the system. A qualitatively identical picture has been found for the polymerisation of a whole series of other systems on devitrification[29]. Cationic polymerisation on devitrification has also been observed for the postpolymerisation of isobutene vitrified in a poly(vinyl chloride) matrix[26].

Thus one must conclude that the characteristics of the polymerisation process on devitrification of the matrix, namely (1) the formation, before the transition of the system from the vitreous to the supercooled liquid state, of growing active centres sufficiently long to prevent their destruction and (2) the occurrence of the polymerisation reaction over a narrow temperature range above T_g without the termination of the growing active centres, are associated mainly with the specific physical nature of the rearrangement of the matrix on devitrification and are qualitatively the same for the radical and ionic mechanisms of chain propagation.

IV. GRAFT POLYMERISATION

Not only low-molecular-weight compounds but also polymers can be used as vitrifying matrices. As will be shown below, the same qualitative behaviour has been observed for vitreous solutions of a monomer in a polymer matrix as in the post-polymerisation of acrylic acid in an alcohol matrix. However, whereas the formation of macroradicals before the transition to the supercooled liquid state was necessary for polymerisation on devitrification of alcoholic solutions of the monomer in order to reduce the probability of the termination of the growing chains, when polymers are used as matrices, this condition is fulfilled automatically.

On cooling to 77 K, polyisobutylene passes to the vitreous state (Fig. 6*a*).[8] At low concentrations the monomers dissolved in it, for example acrylonitrile (the monomers were introduced into polyisobutylene by swelling it in the monomer vapour at room temperature), pass to the vitreous state without phase separation. The calorimetric heating curve for such solutions does not show peaks corresponding to the fusion of the individual monomers, although the sensitivity of the calorimeter was quite sufficient. Consequently, at these monomer concentrations the system consists of a solution over the entire temperature range. At higher temperatures part of the monomer becomes segregated as a separate phase on cooling and the calorimetric curve shows a monomer fusion peak (Fig. 6*b*). We may note that the calorimetric method is in this case convenient for the determination of the limiting solubility of the monomer in the polymer at the low temperatures employed.

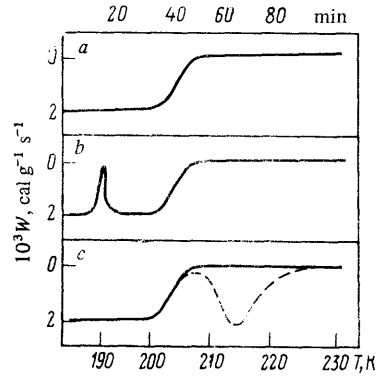

Figure 6. Calorimetric heating curves: *a*) polyisobutylene; *b*) 2% acrylonitrile solution in polyisobutylene; *c*) 1% acrylonitrile solution in polyisobutylene irradiated with 5 Mrad dose at 77 K.

As for monomers vitrified in an alcohol matrix, intense polymerisation is observed in radiolysed vitreous solutions of a monomer in a polymer on their devitrification (Fig. 6*c*). It can be easily shown that, in the low-temperature radiolysis of such vitreous solutions (monomer concentration 1–2%), mainly macroradicals of the polymer matrix are formed and stabilised. On devitrification, they acquire a sufficient mobility for the initiation of the polymerisation of the monomer introduced. Thus the polymerisation of the polymer matrix is initiated by macroradicals under the given conditions, i.e. graft polymerisation takes place. Since the monomer was first dissolved in the polymer matrix, polymers grafted in the bulk phase are formed.

In contrast to the usual methods of radiation-induced graft polymerisation—joint radiolysis of the polymer and the monomer (as a rule at temperatures higher than T_g for the polymer) and postpolymerisation of monomers on a radiolysed polymer matrix (*in vacuo* or in the presence of oxygen)[30,31]—graft polymerisation on devitrification makes it possible to employ most efficiently the macroradicals formed on radiolysis for the initiation of the grafted chains. The above factor is associated with the fact that, near T_g for the polymer matrix, conditions are created under which the destruction of the macroradicals formed is still difficult, while the supply of small monomer molecules to the growing active centres proceeds readily. This explains the high rates of graft copolymerisation observed under these conditions.

Intense graft polymerisation on devitrification of monomer solutions in polyisobutylene has been observed for a whole series of vinyl monomers: styrene, methyl acrylate, methyl methacrylate, etc.[8] Intense grafting of acrylonitrile, dissolved in poly(vinyl chloride), has been observed in the devitrification of the polymer matrix[32]. In the grafting of acrylonitrile, effective cross-linking of the macromolecules of the polymer matrix was also observed on devitrification of polyisobutylene as a result of the involvement of the C≡N group in the reaction[8]. Subsequently the grafting of acrylonitrile was used to cross-link polyethylene, and the cross-linking of macromolecules as a result of the dissociation of the C≡N groups of the grafted chains was demonstrated experimentally[33].

Radiation-induced graft polymerisation of readily polymerisable monomers such as tetrafluoroethylene by the method involving the joint irradiation of the monomer and polymer is extremely difficult. The point is that under these conditions the homopolymerisation of the monomer becomes the dominant process. Grafting on to polymers subjected to preliminary irradiation is also ineffective (for example, only 2–3% of tetrafluoroethylene can be grafted onto polyethylene[34]). The yield of the graft polymer can be increased only by employing polyethylene with an extremely high surface area and by carrying out the reaction at reduced temperatures[35]. However, under these conditions too the rate of reaction is low. The method of postradiation grafting on devitrification proved to be the most satisfactory in this instance[36].

To achieve partial dissolution of tetrafluoroethylene in powdered polyethylene (grain size 10–20 μm) and to fill the micropores in the polymer grains by the monomer, the polymer was first kept in liquid tetrafluoroethylene under a small pressure. The system was then cooled to 77 K and radiolysed. The calorimetric heating curve for this system (Fig.7) shows that the heat evolution associated with the graft polymerisation of tetrafluoroethylene is recorded starting from approximately 225 K. The grafting process takes place most effectively in the range 230–250 K, i.e. in the region of the devitrification of the amorphous portions of the polyethylene matrix. The yield of the graft polymer then reaches 200–300% (relative to the weight of the initial polyethylene). The graft polymer is soluble in boiling xylene and its infrared spectra clearly reveal absorption bands at 1160–1200 cm^{-1}, which are absent from the spectrum of polyethylene and are characteristic of polytetrafluoroethylene[36].

This method of grafting tetrafluoroethylene on devitrification of the matrix could be extended also to other polymeric supports. Treatment of polypropylene and ethylenepropylene rubber in liquid tetrafluoroethylene leads to the partial dissolution of the monomer in the polymer. When such a solution is cooled, it passes to the vitreous state without phase separation. When specimens of this kind, subjected to low-temperature radiolysis, are heated, vigorous polymerisation takes place on devitrification of the matrix[37].

Thus, when polymers are used as vitrifying matrices, the same qualitative picture is observed as for low-molecular-weight matrices with the sole difference that graft copolymers are formed. The advantages of the method of postradiation grafting on devitrification of the polymer matrix are as follows: (1) decrease of the irradiation dose required to obtain a specific yield of the graft polymer relative to the usual methods; (2) the formation of polymers grafted in the bulk phase—in the usual methods grafting takes place as a rule in the surface layer; (3) the possibility of grafting readily polymerisable monomers such as tetrafluoroethylene.

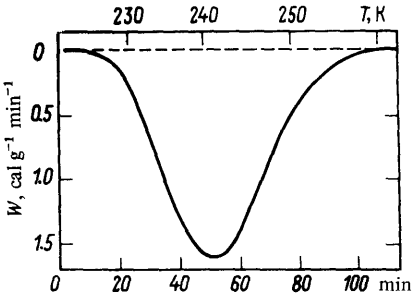

Figure 7. Postradiation grafting of tetrafluoroethylene in the devitrification of a polyethylene matrix. Irradiation dose 5 Mrad at 77 K.

V. COPOLYMERISATION

When the copolymerisation reaction is carried out in liquid and gas phases, the composition of the copolymer is determined by the relative reactivities of the comonomers and a homogeneous copolymer is obtained only in the initial stage of the copolymerisation. As one of the monomers is consumed, the resulting copolymer is as a rule enriched in the less reactive monomer and the polymer chains have an inhomogeneous composition.

As already mentioned above, a characteristic feature of the supercooled liquid state obtained on devitrification is a comparatively high viscosity. This feature must be manifested in some way in altering, compared with the usual liquids, the capacity of monomers for polymerisation. The preceding section presented examples of the sharp differences between the polymerisation capacities of acrylic and methacrylic derivatives on devitrification, while on polymerisation in the liquid state the propagation rate constants for these monomers were comparable as regards order of magnitude. Hence it was natural to expect that copolymerisation on devitrification can lead to a composition of the copolymer different than in the liquid phase copolymerisation.

The copolymerisation of methyl methacrylate with styrene on devitrification of an aniline matrix has been investigated[38]. A 30% solution of the monomer in aniline was devitrified at approximately 170 K. The copolymerisation was carried out by irradiating the system at 178 K, i.e. already in the supercooled liquid state. The authors claim that the composition

of the copolymer formed under these conditions is identical to that obtained on radical polymerisation, but they do not quote experimental data confirming this[38]. Subsequently these results were not confirmed either.

A series of studies on the mechanism of alternating copolymerisation in a vitreous system were carried out at Moscow State University[39-43]. Copolymerisation on devitrification in systems such as methyl methacrylate and methyl acrylate in the presence of $ZnCl_2$ and other complex-forming agents[39], butyl acrylate and 2,3-dimethylbutadiene, also in the presence of a complex forming agent[40], maleic anhydride and dimethylbutadiene[41], and sulphur dioxide together with a series of electron-donating monomers[43] takes place with formation of alternating copolymers. The introduction of a complex-forming agent into these systems entails a sharp increase of the cross chain propagation rate constant. Thus the copolymerisation proceeds via a mechanism involving the consecutive addition of monomers to the end of the growing chain. The cause of this mechanism is the possibility of donor–acceptor interactions between the chain growth radical and the monomer[41].

Another cause of the formation of an alternating copolymer is the formation of a charge-transfer complex between two monomeric species. Its reactivity is higher than that of each monomeric species and the alternation is thus explained by the homopolymerisation of this complex[43]. Sulphur dioxide probably forms a charge-transfer complex with dimethylbutadiene; on cooling, the system passes to the vitreous state. When a radiolysed glass of this kind is heated in the range $T_g \cong 113-133$ K, vigorous copolymerisation is observed. A 1:1 alternating copolymer is formed and its composition is almost independent of that of the initial mixture. The mechanism of the alternation consists in the addition of the complex formed by the monomers to the end of the growing chain[43].

The copolymerisation on devitrification of radiolysed alcoholic solutions of monomers in the absence of complex formation has been studied by Bol'shakov et al.[44] It was investigated for two pairs of comonomers: acrylic acid with acrylamide and acrylamide with methyl acrylate. For an overall concentration of comonomers in ethanol of 17 wt.%, the solution passes fully to the vitreous state on cooling. On subsequent heating, the solution devitrifies at $T_g \cong 102$ K and the supercooled liquid does not crystallise. When the monomer ratio is altered (but the overall concentration of the monomers in ethanol remains at 77 wt.%) over a wide range, the form of the calorimetric curve remains unaltered; consequently, over the entire temperature range from 77 to 300 K, when the monomer ratio is altered from 1:8 to 8:1, the monomers remain uniformly distributed throughout the bulk of the specimen, as in a liquid solution.

On devitrification of radiolysed solutions of this kind, vigorous heat evolution, associated with the copolymerisation, is observed. The yield of the copolymer increases monotonically with increasing preliminary irradiation dose and reaches approximately 95%. The copolymerisation could be interrupted, after the attainment of any required extent, by heating the specimen rapidly (at approximately 250 K min^{-1}) to room temperature. When the yield of the copolymer was altered from 1 to 90%, its composition hardly changed (Fig.8). Nevertheless, the composition of the copolymer in the systems investigated by Bol'shakov et al.[44] could be varied by altering the initial ratio of the monomers in solution. This means that the composition of the copolymer depends solely on that of the initial solution. For a solution of acrylic acid and acrylamide in ethanol, the composition of the resulting copolymer fully corresponds to that of the initial solution, while the composition of the copolymer obtained on radiation-induced copolymerisation of these monomers in the liquid phase at room temperature is determined by their relative reactivities, the copolymerisation constants being $r_1 = 0.25$ and $r_2 = 0.77$ respectively[45].

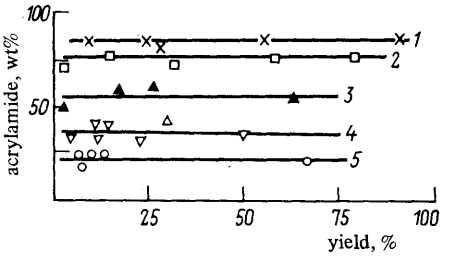

Figure 8. Dependence of the content of acrylamide in the copolymer on the degree of conversion for a 17% solution in ethanol; acrylamide : acrylic acid ratio (by weight): 1) 9:1; 2) 4:1; 3) 1:1; 4) 1:2; 5) 1:5.

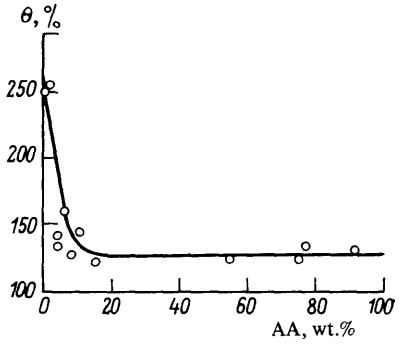
The composition of the copolymer has also been found to be independent of the degree of conversion in the copolymerisation on devitrification of an alcoholic solution of acrylamide and methyl acrylate. However, up to an 80% content of acrylamide in the initial solution of this system, its content in the copolymer remains smaller throughout than in the initial mixture although it does continue to increase[44].

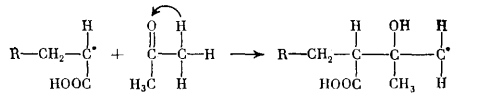
In the viscous supercooled liquid formed on devitrification of the solutions, the time of the mutual contact between the reacting species is much longer than in gas and liquid phases and the frequencies of the addition of the monomer to the active centre of the growing polymer chain are comparable in order of magnitude to the frequencies of the translational migrations of the monomers in the system[10]. Thus the increased viscosity of the supercooled liquid leads to a sharp increase of the time of mutual contact between the comonomers. On the other hand, the rate of growth of the polymer chain is not limited by diffusion under these conditions, because the frequency of the addition of the monomer to the growing macroradical is not limited by the rate of the translational migrations[10]. Presumably the increase of the time of mutual contact between the growing macroradical and the monomer in the systems indicated actually leads to the addition of the monomer in virtually every collision, in contrast to the behaviour observed in the usual liquids; this is in fact responsible for the identity of the compositions of the initial solution and the copolymer.

Such increase of the time of mutual contact between the reactants and the supercooled liquid gives rise to the hope that compounds which are not usually regarded as monomers can be involved in copolymerisation on devitrification. An interesting example of such copolymerisation and devitrification is provided by the acetone–acrylic acid system[46]. The polymerisation of acetone via the carbonyl group was first reported by Kargin et al.[47] Polyacetone was later obtained also by solid-phase radiation-induced polymerisation[48]. This polymer proved to be very unstable and decomposed rapidly to the monomer even at room temperature. Thermostable acetone–acrylic acid copolymers have been obtained by copolymerisation on devitrification[49]. When solutions of acrylic acid in acetone are cooled rapidly, partly or fully

vitreous specimens are formed. The amount of the vitreous phase then depends on the rate of cooling and on the concentration of the monomer in the solution. A fully vitrified specimen can be obtained by cooling a 10% solution of acrylic acid in acetone at a rate of 150 K min^{-1}. The calorimetric heating curve for such a specimen reveals devitrification at approximately 110 K; next, at approximately 133 K, a eutectic mixture crystallises from the supercooled liquid and then melts at 165 K.

When a vitreous solution of acrylic acid in acetone irradiated at 77 K is heated slowly in the calorimeter, heat evolution associated with polymerisation is observed immediately after the system passes to the supercooled liquid state. The conditions governing the formation of the polymer fully ruled out the possibility of the physical retention of acetone by the polymer matrix. The amount of unreacted acrylic acid was determined by titration and the yield of the polymer was calculated in relation to the amount of acrylic acid in the polymer. Fig. 9 illustrates the dependence of the yield of the polymer on the concentration of acrylic acid in the initial solution. In dilute solutions the yield of the polymer reaches 250%, which corresponds to the composition of the polymer: two acetone molecules per acrylic acid unit. With increase of the concentration of acrylic acid, the yield of the polymer falls rapidly to 130–140% and is then almost independent of the composition of the initial solution.





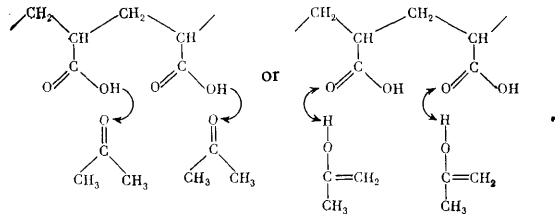


Figure 9. Dependence of the yield of the acrylic acid–acetone copolymer (θ) on the initial acrylic acid (AA) concentration in acetone. The yield of the polymer is referred to the acrylic acid which has reacted.

The incorporation of acetone into the composition of the polymer is observed also when the system is irradiated in the liquid state at 195 K.[50] 100% conversion is rapidly attained in the first stage of the polymerisation. This rapid stage is followed by a fairly slow stage, in which the conversion reaches 140–150% with respect to the acrylic acid which has reacted. It is extremely interesting that the incorporation of acetone into the copolymer is fully suppressed by traces of water. At the same time, traces of water do not have this kind of inhibiting influence on the homopolymerisation of acrylic acid. Two mechanisms, explaining the incorporation of acetone into the polymer formed have been proposed: (1) copolymerisation of acrylic acid and the enolic form of acetone:

[this mechanism is similar to that proposed previously for the polymerisation of acetaldehyde with formation of poly(vinyl alcohol)[51,52]]; (2) the formation of associated species comprising one or other tautomeric form of acetone and polyacrylic acid:

VI. CHLORINATION OF HYDROCARBONS

The chlorination of paraffinic hydrocarbons and their chloro-derivatives in the gas and liquid phases on radiation initiation and photoinitiation has been investigated in fair detail[53]. However, the characteristic features of the mechanism of these processes in solid and viscous media have been hardly studied. Investigations carried out recently have shown that the characteristics of the chain process occurring on devitrification of the matrix, demonstrated in relation to the polymerisation reaction, are maintained qualitatively also in reactions such as the chlorination of paraffins.

The characteristic features of low-temperature radiation-induced chlorination in vitrifying matrices have been studied for the butyl chloride–molecular chlorine system[54]. Solid chlorine undergoes no phase transformations and melts at 172 K (Fig. 10*a*). Butyl chloride passes to the vitreous state on fairly rapid cooling and, when such a specimen is heated, devitrification is observed at 96 K (Fig. 10*b*). On further increase of temperature, butyl chloride crystallises and then melts at a temperature as low as 150 K. A solution of chlorine in butyl chloride was prepared in the dark and no chemical reaction was observed. On cooling, this solution also passes to the vitreous state. The simplest phase transformations are observed on dissolution of one mole of Cl_2 in three moles of C_4H_5Cl—after devitrification the solution does not crystallise and does not melt (Fig. 10c). Consequently, for these proportions of the reactants, phase separation does not occur in the vitrifying solution. This finding is extremely important, because the interpretation of kinetic data for homogeneous one-component systems is significantly simplified.

The heat of the radiation-induced chlorination in the system investigated is 33 kcal per mole of chlorine. The relations presented in Fig. 11 shows that the radiation-induced chlorination takes place with acceleration at 114 K. The retardation of the process and the subsequent fall of the rate are associated with the consumption of the initial chlorine.

The radiation-induced chlorination of butyl chloride takes place in the solid phase, i.e. at temperatures below the devitrification region. When the system passes from the vitreous to the supercooled liquid state, the rate of reaction rises (Fig. 11). A characteristic feature of the process in this temperature range is a virtually linear increase of the rate of chlorination as a function of time. When the initiating γ-radiation is switched off, the rate of the process gradually falls. The characteristic time of the decrease of the rate of

chlorination after switching off γ-irradiation has been determined as $\tau_0 \cong 1500$ s. Such a slow decrease of the rate indicates a long lifetime of the active centres in the supercooled liquid at the temperatures indicated. This finding is in fact responsible for the non-stationary process kinetics—the accumulation of active centres in the course of the radiolysis entails an increase of the rate of the process with time in the initial stage.

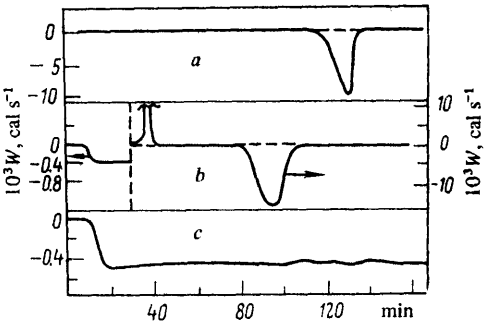

Figure 10. Calorimetric heating curves: *a*) chlorine (3.7×10^{-3} M); *b*) butyl chloride (5.26×10^{-3} M); *c*) chlorine solution (8.7×10^{-4} M) in butyl chloride (2.4×10^{-3} M).

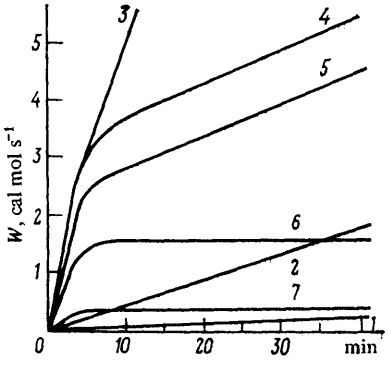

Figure 11. Time variation of the rate of radiation-induced chlorination of butyl chloride at different temperatures (K): 1) 98; 2) 107; 3) 113; 4) 118; 5) 122; 6) 127; 7) 150. Dose rate 30 rad s^{-1}.

The kinetics of the process change significantly with increase of temperature (Fig.11). The process takes place most vigorously at 114 K. On further increase of temperature, the matrix softens, which leads to a sharp decrease of the lifetime of the active centres. At 127 K a constant rate of the process is established immediately (more precisely after the characteristic time of the calorimetric apparatus has elapsed) when the ionising radiation is switched off. The increase probability of chain termination lowers the overall rate of the process over the increase of temperature.

The radiation-induced chlorination of butyl chloride on devitrification of the matrix can be described by the following simple scheme:

$$ClRH \overset{\gamma}{\rightsquigarrow} ClR^{\cdot} + H^{\cdot}, \quad (1)$$

$$ClR^{\cdot} + Cl_2 \rightarrow ClRCl + Cl^{\cdot}, \quad (2)$$

$$Cl^{\cdot} + ClRH \rightarrow ClR^{\cdot} + HCl, \quad (3)$$

$$\left.\begin{matrix} Cl^{\cdot} \\ ClR^{\cdot} \end{matrix}\right\} \rightarrow \text{termination}. \quad \begin{matrix} (4) \\ (5) \end{matrix}$$

In the temperature range 98–114 K the termination of the kinetic chains is extremely slow ($1/\tau_0 \cong 6.6 \times 10^{-4}$ s^{-1}). Judging from the data of Eckling and Goldfinger[55], the rate constant for reaction (2) in the photochemical chlorination of C_2H_5Cl in the temperature range in which we are interested can exceed by several orders of magnitude the rate constant for reaction (3). Consequently, reaction (3) will limit the rate of the given process. For the initial rate of the process (when chain termination can be neglected), we obtain the following expression[54]:

$$w_0 = -d[ClRH]/dt \simeq k_3 g I t [ClRH], \quad (6)$$

where g is the radiation yield of the centres initiating the chlorination and I the intensity of the γ-radiation.

Using this expression, the temperature variation of k_3 was determined from the initial sections of curves *1–3* in Fig.11. This relation is illustrated in Fig.12 (curve *1*). Assuming that $g \cong 1$ in Eqn.(6), we can estimate the constant k_3, which has the following value in the range 98–114 K:

$$k_3 \simeq 10^{11} \cdot \exp(-5600/RT) \text{ litre mol}^{-1} \text{ s}^{-1}. \quad (7)$$

As already mentioned, at higher temperatures the rate of termination increases sharply and a stationary rate of the chlorination process is established. Assuming that the kinetic chains are terminated mainly by reaction (5), the following expression is obtained for the stationary rate of chlorination:

$$w_{st} = -d[ClRH]/dt = k_3/k_4 g I [ClRH]. \quad (8)$$

An analogous expression for the stationary rate has been used[56] after the same assumptions to describe the radiation-induced liquid-phase chlorination of tetradecane. Indeed, in conformity with Eqn.(8), the rate in this temperature range rapidly attains a stationary value and ceases to depend on time (Fig.11, curves *6* and *7*). On substituting Eqn.(8) the values of k_3 calculated by Eqn.(7) and the value of w_{st} (Fig.11, curves *6* and *7*), we obtain $k_4 = 7$ s^{-1} (for 150 K) and $k_4 = 0.05$ s^{-1} (for 127 K). Taking into account the experimental value $k_0 = k_4 = 6.6 \times 10^{-4}$ s^{-1} for 107 K, we obtain the temperature variation of k_4 in the range 150–107 K (Fig.12, curve *2*) and the following expression for the termination rate constant:

$$k \simeq 10^{12} \cdot \exp(-7400/RT), \text{ s}^{-1}.$$

It follows from Eqn.(8) that the activation energy for the overall process $E_{OV} = E_3 - E_4 - 5.6 - 7.4 = -1.8$ kcal mol^{-1}. A similar activation energy in fact characterises the rate of the overall process in this temperature range (Fig.12, curve *3*).

Thus, as in polymerisation, the chain chlorination of chloroalkanes in the supercooled liquid state is characterised by a long lifetime of the active centres. With increase of temperature in the supercooled liquid, the rate of chain propagation reaches a maximum and, when the liquid passes to the thermodynamically stable state and the viscosity of the medium falls sharply, the probability of termination increases. Consequently the suppression of the chain termination process combined with the attainment of conditions ensuring

effective chain growth—conditions which are automatically obtained in the vicinity of the region of devitrification of the system—make it possible to increase significantly the overall rate of reaction.

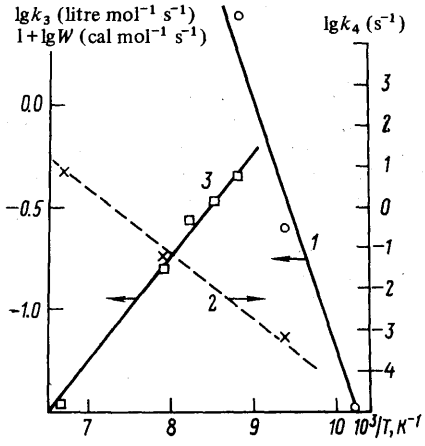

Figure 12. Temperature variation of the rate constants k_3 (line *1*) and k_4 (line *2*) and of the rate of radiation-induced chlorination of butyl chloride for a 4% degree of conversion of chlorine (curve *3*).

Possibly other low-temperature chain processes, such as, for example, hydrohalogenation and halogenation of olefins, the interaction of N_2O_4 with unsaturated compounds, etc.[57,58] under conditions corresponding to the devitrification of the matrix will be characterised by the suppression of chain termination with simultaneous attainment of conditions ensuring vigorous chain propagation.

VII. APPLIED ASPECTS

Graft polymerisation on devitrification of the matrix permits an effective use of the active centres and hence of the expensive ionising radiation energy which generates them. The employment of this process for the grafting of tetrafluoroethylene appears to be most promising. The prospect of the modification of polymeric materials and articles by grafting to impart to them properties close to the unique properties of polytetrafluoroethylene is extremely attractive. The grafted layer of polytetrafluoroethylene can significantly lower the coefficient of friction of the polymer surface and increase its thermal and chemical stabilities. The use of tetrafluoroethylene grafts in order to regenerate PTFE waste is also promising[59,60]. In all these processes the method of graft polymerisation on devitrification of matrices can be used successfully.

A new class of polymerisable oligomers—oligocarbonate-acrylates—is characterised by high rates of radiation-induced hardening[61,64]. All the oligocarbonate-acrylates investigated pass to the vitreous state on rapid cooling. When the oligomers irradiated in the vitreous state are heated, intense postpolymerisation is observed after the system passes to the supercooled liquid state (Fig. 13). The efficiency of the method is so high that a dose of only 100 krad is sufficient for the required degree of hardening[61,63].

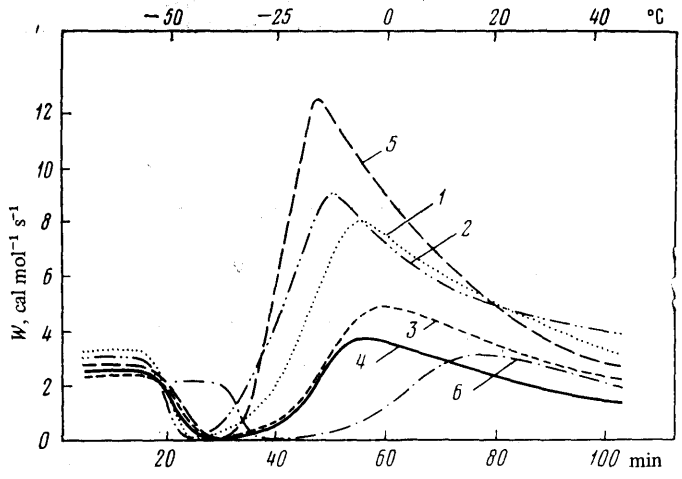

Figure 13. Calorimetric heating curves for oligocarbonate-acrylates irradiated with an 8 krad dose of ^{60}Co γ-rays at 77 K: 1) OKM-3; 2) OKM-4; 3) OKA-2; 4) OKM-1; 5) OKM-2; 6) OKM-7.

For low doses of the preliminary irradiation (1–5 krad), the presence of atmospheric oxygen dissolved in the oligomer causes sharp inhibition of the process and the appearance of an induction period. However, when the preliminary irradiation dose is increased to 50–100 krad, the inhibiting effect of oxygen ceases to influence the kinetics of the hardening process. This effect is probably associated with the increase of the rate of initiation of the process. The absence of an inhibiting influence of oxygen in a closed system even for a dose of 50–100 krad is of interest. Indeed, the elimination of the stickiness of the surface layers (insufficient hardening due to inhibition by oxygen) constitutes a serious problem in the radiation-induced hardening of coatings based on polymerisable oligomers.

The selection of the appropriate vitrifying matrix makes it possible to carry out the chain reaction at extremely low temperatures—as a rule significantly below the melting points of the reactants. On the other hand, the occurrence of a chain reaction in the crystal lattice is hindered by the low translational mobility of the reactants. Furthermore a chain reaction at the lowest possible temperature is of interest because a decrease of temperature entails a kind of selection of the possible reaction channels. Indeed, the channel with the lowest activation energy "survives" at low temperatures. Thus a decrease of the reaction temperature should lead to a high process selectivity. Furthermore, with decrease of temperature, the entropy factors, which are so important in the thermodynamics of chemical reactions, play a continuously decreasing role and the equilibrium in all the reactions is therefore displaced towards exothermic reactions, even those in which highly ordered systems are produced. On the other hand, the employment of vitrifying matrices permits chain reactions at temperatures close to 77–100 K.

Thermodynamics of Isotope Exchange Reactions

N.M.Zhavoronkov, D.A.Knyazev, A.A.Ivlev, and G.D.Klinskii

The present state of the theory of the equilibrium chemical isotope effect is examined and the methods for the approximate and exact calculation of the partition functions of the isotopic forms of polyatomic molecules are analysed. Also analysed is the possibility of employing the chemical isotope effect for the interpretation of the force fields of molecules of transition complexes; relations between the isotope effects associated with the stepwise substitution of isotopes, coupled isotope effects, etc, are considered.
The relations between the isotope effects and the structural and general chemical phenomenological characteristics of compounds are discussed and a systematic treatment of chemical isotope effects together with the methods for the statistical prediction of the magnitude of these effects are considered.
The bibliography includes 117 references.

I. INTRODUCTION

For a long time the interest in chemical isotope effects was concentrated on the possibility of using them for the separation of the isotopes of light elements. During the last 10–12 years, much more attention has been devoted to them but largely for other reasons. It was found that the measurement of isotope effects is useful for research in many fields of chemistry, biochemistry, and geochemistry. For example, the kinetic hydrogen and carbon isotope effects have been used successfully to study the mechanisms and activated complexes of organic reactions; the hydrogen, carbon, and sulphur effects have been employed to predict the presence of petroleum and natural gas in geometrical regions, the oxygen and hydrogen effects have been used in paleogeothermometry, and the effects of biogenic elements have found applications in the study of the mechanisms of cell metabolism.

The value of isotope effects as sources of information in research is due to one specific feature of their theory. Statistical thermodynamics reveals a relation, of rare simplicity, between the isotope effects and the characteristics of intramolecular force fields. This feature makes it possible to infer intramolecular characteristics directly from changes in macroscopic quantities—the isotope concentrations, but not conversely, which is in general characteristic of the applications of the molecular-statistical theory. Hence follows the possibility of securing information about the force fields not only of simple stable molecules, which can be studied by other

methods, but also of investigating short-lived compounds and fragments of large molecules, which play an important role in chemical, biochemical, and geochemical systems and mechanisms.

The general, extensive literature on chemical isotope effects has been reflected systematically in frequently published reviews, specialised compilations, and monographs. Being unable to analyse the state of the problem in fields adjoining chemistry, we shall indicate the reviews and monographs dealing with various aspects of the applications of isotope effects in biochemistry[1-5] and geochemistry[6-13]. Compilations and review articles have been devoted to chemical isotope exchange reactions used for the separation of stable isotopes of light, medium, and heavy elements (ranging from hydrogen to uranium inclusive)[14-20]. The results of the study of isotope effects[18-22] and their applications to the study of molecular structures[14-24], reaction kinetics and mechanisms[21,24-29], phase exchange[14,24,30], solutions, and the behaviour of solvents[14,24,30] are reflected in the reviews and monographs quoted above.

However despite their relatively large number, the aim of the review articles published in the last decade was to inform the reader about fairly narrow questions and they consisted too often of handbooks and bibliographic compilations. Owing to their specialist characteristics, both the reviews and monographs are concerned either only with the main features or only with special features of the general theory, so that a general picture of the scope of the theory is not built up.

Nevertheless, in many of the fields indicated, the interpretation of chemical isotope effects is invariably based on the thermodynamics of isotope exchange reactions. This is because the methods for the analysis of kinetic and equilibrium isotope effects are fundamentally the same and are based on the general theoretical apparatus of statistical thermodynamics and the theory of the vibrations of polyatomic molecules. Significant new theoretical results, which make it an effective weapon in the hands of research chemists, biochemists, and geochemists, have not as yet been described in one publication. Nor has any attempt been made to carry out a combined analysis of isotope effects which would reflect their relation to the chemical nature and specific features of the elements. The aim of the present review is to fill these gaps to some extent.

II. THERMODYNAMICS OF ISOTOPE EXCHANGE REACTIONS

1. General Theory

In the general case a chemical compound can contain an element undergoing isotope substitution in several different non-equivalent positions. Non-equivalent atoms are characterised by different equilibrium and kinetic isotope effects, while equivalent atoms have identical effects.

Following the procedure of Varshavskii and Vaisberg[31], we shall consider the equilibrium in the isotope exchange of an element X between two compounds AX_n and BX_m. The first contains n atoms X capable of isotope substitution in the given equivalent positions. The remainder of the molecule of A may contain exchangeable atoms of the element X, but in other equivalent positions, which are not taken into account in the present treatment. Similarly in the molecule BX_m account is taken only of the exchange of m equivalent atoms of the element X. If the numbers n and m are not unity, the exchange of isotopes X and X′ will proceed through a series of stages. Each stage can be formulated as:

$$AX_{n-i+1}X'_{i-1} + BX_{m-j}X'_j \rightleftarrows AX_{n-i} + X'_i + BX_{m-j+1}X'_{j-1}, \quad (1)$$

where $i = 1,2,\ldots,n$ and $j = 1,2,\ldots,m$.

The equilibrium constant K_{ij} for this stage can be expressed in terms of the concentrations of the isotopic forms:

$$K_{ij} = \frac{[AX_{n-i}X_i]\ [BX_{m-j+1}X'_{j-1}]}{[AX_{n-i+j}X'_{i-1}]\ [BX_{m-j}X_j]}. \quad (2)$$

In all there are nm independent stages in the reaction under consideration with equilibrium constants of the type defined by Eqn.(2). Their sequence, from the first to the last, corresponds to the overall exchange reaction between the fully substituted isotopic forms:

$$mAX_n + nBX_m' \rightleftarrows mAX'_n + nBX_m \quad (3)$$

whose equilibrium constant K_Σ is equal to the product of the constants K_{ij}:

$$K_\Sigma = \prod_{i=1}^{n}\prod_{j=1}^{m} K_{ij}. \quad (4)$$

The real equilibrium includes all nm stages and is characterised by the isotope separation factor α measured experimentally:

$$\alpha = \frac{[X'_{AX_n}]/[X_{AX_n}]}{[X'_{BX_m}]/[X_{BX_m}]}, \quad (5)$$

where [X] and [X′] are the overall mole fractions of the isotopes X and X′ in the compounds AX_n and BX_m.

The quantities K_{ij}, K_Σ, and α are related to one another and to the symmetry numbers of the isotopic forms of the molecules AX_n and BX_m by the following expressions:

$$K_{ij} = \alpha \frac{\sigma(AX_{n-i+1}X'_{i-1})\,\sigma(BX_{m-j}X'_j)}{\sigma(AX_{n-i}X'_i)\,\sigma(BX_{m-j+1}X'_{j-1})}, \quad (6)$$

$$K_\Sigma = \alpha^{nm}. \quad (7)$$

Statistical thermodynamics expresses the equilibrium constant K_{ij} in terms of the partition functions Q of the isotopic forms of the compounds AX_n and BX_m:

$$K_{ij} = \frac{Q'_{AX_n}/Q_{AX_n}}{Q'_{BX_m}/Q_{BX_m}}, \quad (8)$$

where the prime refers to forms AX_n and BX_m containing the larger number of atoms of the X′ isotope.

In the ideal gas approximation, usually employed for chemical equilibrium, one neglects the dependence of the partition functions on the phase state of the given substance, which makes it possible to calculate these quantities from molecular spectra and molecular constants without taking into account the interactions of the molecules. A further simplification is achieved by employing the Born–Oppenheimer approximation concerning the subdivision of the internal energy of molecules into the electronic, spin-nuclear, vibrational, rotational, and translational components[32]. For the majority of isotope equilibria, this approximation is also the only one possible, since more accurate calculations require much more detailed information about the molecular force field.

In the calculation of thermodynamic isotope effects there is no necessity to calculate the electronic and spin-nuclear components of the partition function. The electronic component does not differ from the statistical weight of the electronic ground state for the vast majority of molecules in the range 0–2000 K, since the excited electronic levels are usually much higher than the ground levels. For the rare molecules where there is a possibility of thermal excitation of even one electronic level, the total partition functions must be calculated for each level separately because excitation is accompanied by a sharp change in the vibrational characteristics and a very significant change in the rotational characteristics of the molecules[33,34]. An analogous situation obtains also for the spin-nuclear component, which plays a significant role only for molecular hydrogen, where it must be taken into account by

calculating separately the partition functions for the *ortho*- and *para*-forms[35].

The exclusion of the electronic and spin-nuclear components reduces the task of finding the thermodynamic isotope effects to the calculation of the vibrational, rotational, and translational partition functions or, in the refined version, to the calculation of the vibrational-rotational and translational partition functions.

In the most accurate studies the vibrational-rotational component is calculated taking into account the anharmonicity of the vibrations, the centrifugal stretching effect, and the effects associated with vibration-rotation interactions[36,37]. However, the information required for this purpose is available for very few molecules and in the calculation of the isotope effects of all elements except hydrogen one therefore employs simplified models of the vibrational and rotational motions, which are assumed to be independent. The simplest and most widely used harmonic oscillator–rigid rotator model neglects the three corrections enumerated above, and makes it possible to resolve completely the rotational and vibrational partition functions[38,39].

The calculation of the thermodynamic isotope effects does not require the separate determination of the partition functions for each isotopic form of the compound. It is more rational to calculate the ratio of the partition functions of the isotopic forms (RPFIF) of the given molecule.

In terms of the "rigid rotator–harmonic oscillator" approximation, the RPFIF, also denoted by f, can be formulated as follows[27,40]:

$$f = \frac{\sigma}{\sigma'}\left(\frac{M'}{M}\right)^{3/2}\left(\frac{I'_A I'_B I'_C}{I_A I_B I_C}\right)^{1/2}\exp\left[\frac{hc}{2kT}\left(\sum_i d_i\omega_i - \sum_i d'_i\omega'_i\right)\right]\frac{\prod_i [1-\exp(\omega_i hc/kT)]^{d_i}}{\prod_i [1-\exp(\omega'_i hc/kT)]^{d'_i}}, \quad (9)$$

where M is the molecular weight, $I_A I_B I_C$ the product of the moments of inertia of the molecule relative to the three (principal) Cartesian axes, ω_i the ith harmonic vibration frequency, and d_i the multiplicity of its degeneracy; the primes refer, as in Eqn.(8), to isotopic forms containing a greater number of atoms of the isotope X′. If the prime is attributed to isotopic forms of molecules containing a greater number of heavy isotope atoms involved in exchange while the symbols without prime are assigned to forms with a greater number of light isotope atoms, then Eqn.(9) leads to a convenient specific relation: $f\sigma'/\sigma \geq 1$.

Eqn.(9) can be significantly simplified by the application of the Teller–Redlich theorem[41,42], which relates the moments of inertia, the vibration frequencies, the molecular weights M and M', and the masses of the isotopes m and m' in the isotopic forms, which differ in the isotopes of a single element:

$$\frac{I'_A I'_B I'_C}{I_A I_B I_C}\left(\frac{M'}{M}\right)\left(\frac{m}{m'}\right)^{3n}\prod_i\left(\frac{\omega}{\omega'}\right)^2 = 1. \quad (10)$$

Substitution of Eqn.(10) in Eqn.(9) leads to the following relation:

$$f = \frac{\sigma}{\sigma'}\left(\frac{m'}{m}\right)^{3n/2}\frac{\prod_i \{\omega'_i \exp(-\omega'_i hc/2kT)[1-\exp(-\omega_i hc/2kT]^{-1}\}^{d'_i}}{\prod_i \{\omega_i \exp(-\omega_i hc/2kT)[1-\exp(-\omega_i hc/2kT]^{-1}\}^{d_i}}. \quad (11)$$

The multiplier $(m'/m)^{3n/2}$, determined by the masses of the pair of isotopes under consideration, enters into all the RPFIF referring to this pair of isotopes; in the calculation of isotope effects it always cancels out and is therefore omitted. In most studies the ratio σ/σ', which is equal to RPFIF when all isotope distributions are equally probable, is transferred to the left-hand side of Eqn.(11). The so-called reduced frequencies $\omega_i hc/kT$ are in general designated by u_i. When account is taken of these conventional procedures and notations, Eqn.(11) can be put in the form

$$\left(\frac{\sigma'}{\sigma}\right)f = \frac{\prod_i \{u'_i \exp(-u'_i/2)[1-\exp(-u'_i)]^{-1}\}^{d'_i}}{\prod_i \{u_i \exp(-u_i/2)[1-\exp(-u_i)]^{-1}\}^{d_i}} = \frac{\prod_i [\mathrm{sh}(u_i/2)/u_i]^{d_i}}{\prod_i [\mathrm{sh}(u'_i/2)/u'_i]^{d'_i}}. \quad (12)$$

The difficulty of the determination of the quantities $(\sigma'/\sigma)f$ by Eqn.(12) depends on the number of atoms in the molecule and on the symmetry of the isotopic forms under consideration. The symmetry numbers σ and the degree of degeneracy of the vibration classes d_i and d'_i depend on the latter. With decrease of the symmetry of the given form, the degrees of degeneracy diminish and the orders of the submatrices of the secular equations of vibrational motion increase. The latter implies an increase of the number of non-identical cofactors in the products in the numerator and denominator of Eqn.(12). In the limit one of the products can have $3N-6$ cofactors, but the main difficulties in the application of Eqn.(12) do not depend on the fact that the number of cofactors can be large. A large number of non-identical frequencies implies a sharp increase of the difficulty of their calculation, because the frequencies of isotopic forms are usually unknown and are found by solving the secular equations using particular models of the potential energy of the molecules.

Evidently the number of different isotopic forms $AX_{n-i}X'_i$ of the compound AX_n is $n+1$; in order to characterise fully the thermodynamic non-equivalence of these forms, it is necessary and sufficient to calculate n independent values of the RPFIF.

For equilibrium between the molecules of AX_n and BX_m, the calculation of the isotope effects requires the determination of $n+m$ values of the RPFIF, and, as just shown, each of these determinations can be very complicated. A successive radical simplification of the calculation of isotope effects is achieved by replacing the RPFIF for all possible pair combinations of the isotopic forms for any molecule by the simplest functions of a single RPFIF referring to the fully substituted forms AX_n and AX'_n. This replacement not only greatly reduces the number of RPFIF required for the consideration of the equilibrium (two instead of $n+m$), but also simplifies to the maximum extent the very calculation of these two necessary values of the RPFIF, since the high and identical symmetries of the fully substituted forms reduce to a minimum the number of different vibration frequencies.

The "rules of the sums of isotopic frequencies", first obtained by Sverdlov[45,46] and Decius and Wilson[47] and subsequently modified by Broderson[48], follow from the theory of the vibrations of polyatomic molecules[42–44]. These rules can be represented by the formula

$$\sum_i^{3N-6}\omega_i^{2p}(AX_{n-j}X'_j) - \sum_i^{3N-6}\omega_i^{2p}(AX_{j-k}X'_{n-(j+k)}) = \sum_i^{3N-6}\omega_i^{2p}(AX_{n-l}X'_l) - \sum_i^{3N-6}\omega_i^{2p}(AX_{n-(l+k)}X'_{l+k}), \quad (13)$$

where the symbols X and X′ refer to the light and heavy isotopes of the element X respectively and p is any integer.

Using Eqn.(13) with $p = 1,2$, Bigeleisen[17,49] showed that, for the values of $\ln(f\sigma'/\sigma)$ referring to different members of the isotope-homologous series $AX_{n-j}X_j$, the "geometrical mean rule", which assumes the general form

$$\frac{1}{j-k}\ln\left[\frac{\sigma'}{\sigma}f(AX_{n-j}X'_j/AX_{n-k}X'_k)\right] = \text{const}. \quad (14)$$

holds with an adequate degree of approximation. This rule, first discovered empirically in an early study by Urey[40], has been frequently subjected to numerical tests[15,17,49,50], which invariably confirmed its adequate accuracy [the deviation from the rule does not exceed 1.0% of $\ln(f\sigma'/\sigma)$].

When the isotopic equilibrium of a specific pair of isotopes is considered, the geometrical mean rule makes it possible to characterise the entire set of isotopic homologues by a single value of the RPFIF, which establishes an unambiguous (isomorphous) correspondence between the chemical compound (molecule, ion) and the characteristics of its possibilities as regards isotope separation. Varshavskii and Vaisberg[31] suggested that the concept of the β-factor, which is related to f, be used for this purpose. If the RPFIF refers to the fully substituted forms AX_n and AX'_n containing n equivalent atoms of X capable of isotope substitution, then, regardless of the complexity of the compounds and the value of n, the following very simple relation holds:

$$\ln\beta = \frac{1}{n}\ln f\,(AX_n/AX'_n). \tag{15}$$

The advantage of the concept of the β-factor over the RPFIF thus consists in the fact that it defines unambiguously the degree of thermodynamic non-equivalence of two isotopes in the given molecule, while the RPFIF includes in addition the equally probable distribution factor, which is equal to the ratio of the symmetry numbers. The expression for the β-factor can be written in the form

$$\ln\beta = \frac{1}{n}\sum_i d_i \ln\left\{\frac{u'_i \exp(-u'_i/2)\,[1-\exp(-u'_i/2)]^{-1}}{u_i \exp(-u_i/2)\,[1-\exp(-u_i/2)]^{-1}}\right\} \tag{16}$$

or

$$\ln\beta = \frac{1}{n}\sum d_i \ln\left[\frac{\mathrm{sh}\,(u_i/2)}{\mathrm{sh}\,(u'_i/2)}\Big/\frac{u_i}{u'_i}\right] \tag{17}$$

Eqn.(16) has become the main working relation in most studies devoted to the thermodynamics of isotope exchange and kinetic isotope effects, although the necessary stipulations concerning the conditions governing its application are not made in many investigations.

Brodskii[51] and Varshavskii and Vaisberg showed in the general case[31] that, when account is taken of the equal probabilities of the distributions of isotopes between all the isotopic forms of substances AX_n and BX_m, the isotope separation factor α, corresponding to the equilibrium in the entire set of type (2) reactions, is given by the very simple equation

$$\alpha = \beta_{AX_n}/\beta_{BX_m}. \tag{18}$$

The simplicity of Eqn.(18) constitutes yet another piece of evidence demonstrating the superiority of the concept of the β-factor compared with that of RPFIF.

In view of the difference in the significance of these concepts, we thought it essential to confine ourselves to only one of them in the present review, namely the β-factor. Nevertheless, in order to simplify and facilitate the exposition, both terms are used in the text below. Unless otherwise stated, here the significance of the term "RPFIF" is always identical to that of the term "β-factor".

2. Refined Quantum-Statistical Relations

The "harmonic oscillator–rigid rotator" approximation, to which Eqns.(12), (16), and (17) correspond, ensures an accuracy of the calculation of the RPFIF sufficient for the majority of practical problems in the thermodynamics of isotope exchange. Here we shall consider the refinements and corrections which follow from improved models and which are necessary in certain special situations. At the same time, such treatment should indicate the limits of the accuracy of Eqn.(12), (16), and (17).

Real molecules are anharmonic oscillators and non-rigid rotators. Different vibrations of polyatomic molecules are not independent. The same applies to the vibrational and rotational motions of the molecule as a whole. Furthermore, the energies of states with zero vibrational quantum numbers differ from the quantity $hc\omega_i/2$. Finally, account must be taken of the effects of the internal rotation of groups in the molecule and (at low temperatures) of the difference between the rotational partition functions and their classical values (quantisation effects). The influence of these factors on the RPFIF decreases approximately in the following sequence: (1) anharmonicity and interaction between the vibrations; (2) quantum effects of the rotation; (3) hindered internal rotation; (4) non-rigidity of the rotators (centrifugal stretching); (5) interaction between rotation and vibrations.

All these corrections are introduced in the form of the corresponding multipliers of the quantity β_{harm} found by Eqns.(12), (16), or (17) in terms of the "harmonic oscillator–rigid rotator" approximation:

$$\beta_{exact} = \beta_{harm}\, C_1 C_2 C_3 C_4 C_5. \tag{19}$$

The correction for anharmonicity C_1 includes simultaneously the effect of the deviation of the shape of the potential energy surfaces of the molecules from the parabolic form and the interaction of different normal vibrations[36,52,53]. The vibrational energy levels of polyatomic molecules are usually specified by the expression[39]

$$E_{vibr} = \sum_i hc\omega_i\left(v_i+\frac{1}{2}\right) + \sum_i hcx_{ii}\left(v_i+\frac{1}{2}\right)^2 + \sum_{i<j} hcx_{ij}\left(v_i+\frac{1}{2}\right)\left(v_j+\frac{1}{2}\right) + \ldots, \tag{20}$$

in which v_i and v_j are the vibrational quantum numbers of the vibrations i and j and x_{ii} and x_{ij} are anharmonicity constants. Since the forms of the potential energy surfaces have been little studied, we shall confine ourselves to the first terms of the expansion of E_{vibr} in Eqn.(20). In terms of this approximation, the correction for anharmonicity is[52,53]

$$C_1 = \exp\left[\frac{hc}{4kT}\sum (x'_{ij}-x_{ij})\,d_i d_j\right]\cdot\left\{1+\frac{hc}{kT}\sum d_i(d_i+1)\times\right. \tag{21}$$
$$\left.\times\left[\frac{x'_{ii}\cdot e^{u'_i}}{(e^{u'_i}-1)^2}-\frac{x_{ii}e^{u_i}}{(e^{u_i}-1)^2}\right]+\frac{hc}{kT}\sum d_i d_j\left[\frac{x'_{ij}(e^{u_i}+e^{u_j})}{(e^{u'_i}-1)(e^{u'_j}-1)}-\frac{x_{ij}(e^{u_i}+e^{u_j})}{(e^{u_i}-1)(e^{u_j}-1)}\right]\right\}$$

The first term in this expression, which reflects the influence of anharmonicity on the zero-point energy, makes the main contribution. The expression in braces corresponds to the thermal excitation of the vibrational levels and at the usual temperatures hardly differs from unity. Taking this factor into account, the correction for anharmonicity in relation to Eqns.(16) and (17) is expressed thus:

$$C_1 = \exp\left[\frac{hc}{4kT}\sum d_i d_j\,(x_{ij}-x_{ij})\right]. \tag{22}$$

According to the Darling–Dennison rule[54], we have for fully substituted isotopic forms

$$x_{ij}'/x_{ij} = \omega_i'\omega_j'/\omega_i\omega_j. \tag{23}$$

Eqn.(22) transforms into[53]

$$C_1 = \exp\left[\frac{hc}{4kT}\sum_{i<j} d_i d_j\left(\frac{\Delta\omega_i}{\omega_i}+\frac{\Delta\omega_j}{\omega_j}\right)\right];\quad \Delta\omega_i = \omega_i'-\omega_i. \tag{24}$$

Wolfsberg[24,55,56] showed that the correction to zero-point energy for anharmonicity, expressed by equations of type (20), suffers from a significant inaccuracy, because it does not take into account the component of the zero-point energy which is independent of the vibrational quantum numbers. A more accurate expression for the vibrational levels should include

the constant terms G_0, which converts Eqn.(22) into the following expression:

$$C_1 = \exp\frac{hc}{kT}\left[(G_0' - G_0) + \sum_{i<l}\frac{d_i d_l}{4}(x_{il}' - x_{il})\right]. \qquad (24')$$

Allowance for the constant terms G_0 introduces a contribution to the correction for anharmonicity which is comparable to the correction itself[56,57]. Using the Morse potential function, Ishida[58] expanded the analysis of the correction for anharmonicity and tabulated the increments in partition functions corresponding to it as functions of u and x.

The presence of a single hindered rotation in a molecule implies a decrease of the number of vibrational degrees of freedom by unity, a decrease of the number of cofactors in the expression for the partition function ratio, and hence an appreciable decrease of the ratio. The vanishing cofactor is replaced by the ratio of the internal rotation partition functions, which in the general case differs very little from unity[59]. This correction (C_2) amounts to several tenths per cent of $\ln\beta$ at the usual temperatures for the protium–deuterium substitution and falls to hundredths per cent for heavier elements.

The correction C_3 due to the quantisation of the rotational motion[36,37,60] is significant in the protium–deuterium substitution at low temperatures, while in other cases it is insignificant. The corrections for the centrifugal stretching of the bonds in the molecules[36,37,61] (C_4) and for the interaction of the vibrational and rotational motions[36,62,63] (C_5) are always negligible at temperatures above 100 K.

In a series of recent studies[64,65] the accuracy of the initial Born–Oppenheimer approximation itself was analysed in relation to diatomic molecules. A correction for its inaccuracy can be introduced into Eqn.(19) by means of a correction coefficient C_6. In the examples examined[65] the contribution of this correction to $\ln\beta$ does not exceed 0.1%.

3. Approximate Relations

The quite satisfactory accuracy of the "rigid rotator–harmonic oscillator" approximation, the low availability of more detailed information about the energy states of the molecules, and the applicability of the geometrical mean rule make Eqn.(16) the main mathematical relation of the thermodynamics of isotope effects. Despite its simplicity, its practical application is quite laborious. In order to develop computer programs for its calculation, a number of attempts have been made to reduce it to forms more suitable for calculations.

The method of Bigeleisen and Mayer[66] is widely used. They expressed RPFIF as the following function of reduced frequencies and their isotopic shifts:

$$\beta = 1 + \Sigma G(u_i)\Delta u_i; \quad \Delta u_i = u_i - u_i'; \qquad G(u_i) = 1/2 - 1/u_i + 1/(e^{u_i} - 1). \qquad (25)$$

Eqn.(25) significantly reduces the values of $\ln\beta$—the relative error of the calculation reaches 15–17%. Despite this, Eqn.(25) is frequently employed as a simple means of estimating the contributions of different vibrational frequencies to RPFIF and as a means of interpreting the different overall variations of RPFIF due to the absolute values of u_i and Δu_i.

Another expansion of β, in terms of functions of u_i and Δu_i, is sufficiently accurate for computational purposes[61]:

$$\ln\beta = \Sigma G(u_i)\left[1 + \frac{S(u_i)}{2G(u_i)}\cdot\left(\frac{\Delta u_i}{u_i}\right) + \frac{C(u_i) - 2S(u_i)}{6G(u_i)}\left(\frac{\Delta u_i}{u_i}\right)^2\right]\Delta u_i,$$
$$G(u_i) = 1/2 - 1/u_i + 1/(e^{u_i} - 1); \quad S(u_i) = 1/u_i - u_i e^{u_i}/(e^{u_i} - 1)^2; \quad C(u_i) = \qquad (26)$$
$$= 2u_i^2 e^{2u_i}/(e^{u_i} - 1)^3 - u_i(u_i + 2)e^{u_i}/(e^{u_i} - 1)^2.$$

The functions $G(u_i)$, $S(u_i)$, and $C(u_i)$ as well as their derivatives with respect to u have been tabulated using small steps in u[66,67].

III. METHODS FOR THE INTERPRETATION OF CHEMICAL ISOTOPE EFFECTS

As mentioned in the introduction, the theory of chemical isotope effects has two complementary aspects—the use of isotope effects as a research technique and the consequent problem of the analysis and interpretation of the measured effects, and the prediction of effects in order to select chemical systems for the separation of isotopes or in order to devise a research technique. Both problems involve the same mathematical procedures and differ solely in their formulation and the preference given to different methods of solution.

Depending on the means used for the analysis and prediction, it is possible to distinguish three levels in these problems: the level of the rigorous theory of the vibrations of polyatomic molecules; the level of semiempirical relations using the correlations between the isotope effects with separate exact or approximate characteristics of the molecular force field; the phenomenological level, operating with concepts such as the degree of oxidation of the element, the type of geometrical configuration of the compound or its fragment, and the type of donor atom or ligand attached to the element.

The first level is naturally of key importance, since a rigorous treatment of the values of α and β in terms of the theory of vibrations makes it possible to isolate the most important determining groups of molecular characteristics, which can then be expressed approximately in terms of the other two levels. Nevertheless the first level is used nowadays solely for the interpretation of isotope effects (in consequence of the complexity of the mathematical relations for this level and the existence of simpler but accurate procedures which make it possible to calculate the isotope effect directly); it is therefore the level of the rigorous interpretation of isotope effects.

1. Approximate Relations

The relative simplicity of the theoretical relations between chemical isotope effects and the intramolecular characteristics has already been mentioned. The simplest relation, whereby one can obtain a general estimate of the influence of various factors on $\ln\beta$, is the linear Bigeleisen–Mayer approximation, which is valid at high temperatures[66]:

$$\ln\beta = \frac{1}{24n}\sum_i [u_i^2 - (u_i')^2] = \frac{1}{24n}\left(\frac{h}{kT}\right)^2 \Delta\,\mathrm{Sp}\,(GF), \qquad (27)$$

where $\Delta\mathrm{Sp}(GF)$ is the isotopic increment in the trace of the product of the kinematic coefficients matrix G and the force constants matrix F.

Bearing in mind that the stretching vibration frequencies make the main contribution to $\ln\beta$, Bigeleisen proposed a modification of Eqn.(27) which is suitable in the region of all of the usual temperatures. This is achieved by introducing a correction coefficient $\gamma_S(u_S)$ determined by the reduced frequency u_S of the symmetrical stretching vibration[68,69]:

$$\ln\beta = \frac{\gamma_s}{24n}\left(\frac{h}{kT}\right)^2 \Delta\,\mathrm{Sp}\,(GF); \quad \gamma_s = 12G(u_s)/u_s. \qquad (28)$$

Subsequently he described[23] a method whereby one can fit to γ a finite Chebyshev polynomial as a function of u_{max}—the maximum stretching vibration frequency of the molecule. It has been shown[70] that, instead of u_S and u_{max}, it is more desirable to employ the weighted-mean frequency using the isotopic increments in the squares of the frequencies themselves as the weighting factors.

A simpler method has been proposed[71] for the determination of γ from the u_{as} (asymmetric stretching vibration frequencies) and $\Delta Sp(GF)$ whereby an expression can be fitted to $\ln\beta$ with a relative error of ±2% and the necessity to take into account the isotopic shifts of all the frequencies of the molecule is eliminated. The values of γ_{as} have been tabulated[71] as functions of u_{as} and the ratio of the isotope shift Δu to u.

The analytical value of Eqns.(27) and (28) consists in the fact that they reveal the principal intramolecular parameters which determine the values of $\ln\beta$. These are the force constants, geometrical characteristics, and atomic masses in the molecule. Analysis of $\Delta Sp(GF)$ makes it possible to estimate the relative role of each of the three groups of factors and the relative contributions of different components within these groups. In terms of their influence on $\ln\beta$, the above groups can be arranged in the following sequence. The influence of the masses of the atoms capable of undergoing isotope substitution is strongest, that of the force constants is weaker, and that of molecular geometry is weaker still. However, one should bear in mind that this subdivision of molecular parameters into groups is conventional, since the atomic weight of the element and the characteristics of the force fields of the molecules in which it is included depend on one another, and the force constants and molecular geometry are interrelated to an even greater extent.

Analysis of $\Delta Sp(GF)$ revealed a virtually rigorous proportionality of the quantity $\ln\beta$ and hence also $\ln\alpha$ to the square of μ, the reciprocal of the atomic weight of the element involved in isotope substitution, and explained the very rapid decrease of the chemical isotope effects with increasing atomic weight[66]:

$$\Delta Sp\,(GF) = \Delta\mu \sum_{ij} a_{ij} f_{ij} = \frac{\Delta m}{m\,(m+\Delta m)} \sum_{ij} a_{ij} f_{ij} \qquad (29)$$

where $\Delta m = m' - m$, m and m' are the atomic weights of the isotopes of the given element, μ and μ' are the reciprocals of the atomic weights of the isotopes, a_{ij} are coefficients in the elements g_{ij} of the matrix G which depend solely on the molecular geometry, and f_{ij} are the elements of the force constants matrix F.

Eqn.(29) permits a rough estimate of the degree of diminution of the chemical isotope effects on passing from the first element in the Periodic System (hydrogen) to the last—for example, uranium. The quantities $\ln\beta$ and $\ln\alpha$, recalculated in terms of a single increment in the mass difference Δm, should then diminish by a factor of $(2-3)\times 10^4$. Although in reality the scale of the decrease of the effects is somewhat smaller[72] owing to the influence of the second cofactor on the right-hand side of Eqn.(29), this equation imposes very stringent limitations on the overall scope of both chemical isotope separation methods and the applications of isotope effects as the basis of a research technique. The first factor on the right-hand side of Eqn.(29) is in fact the main factor, which determines the limits of the development of these fields at the present time and shows that they are applicable to the set of relatively light polyisotopic elements.

Another corollary of Eqn.(29) is the proportionality of the isotope effects to the difference between the isotopic masses Δm or, more precisely, the direct proportionality of $\ln\beta$ and $\ln\alpha$ to the increment in the reciprocal of the mass of the isotope Δu. This relation is responsible for the large magnitude of the isotope effects and the ease of their measurement and application in those cases where $\Delta m > 1$. At the same time it can be used to test the accuracy of the experimental determination of the effects, when the latter have been measured in relation to three or more isotopes of the given element.

The masses of other elements (incapable of isotopic substitution) do not enter into the expression for $\Delta Sp(GF)$, so that the values of RPFIF and $\ln\alpha$ depend only slightly on them[73]. The influences of the masses of other elements linked to those involved in isotope substitution are appreciable only in hydrides, where protium can be substituted by deuterium and tritium which are twice and three times as heavy.

Table 1. Algebraic expressions for $\Delta Sp(GF)/\Delta\mu$ for certain types of molecules XY_n and $X(YZ)_n$ with linear ligands (YZ) (r and R = XY and YZ distances; α = YXY angle; β = XYZ angle in the YXY plane; θ = XYZ angle in the plane orthogonal to the YXY plane; γ = angle defining the displacement of the XY bond from the plane; f_r = XY bond force constant; f_{rr} and f'_{rr} = force constants for the interaction of the adjacent and opposite XY bonds; f_α = YXY valence angle force constant; $f_{\alpha\alpha}$ and $f'_{\alpha\alpha}$ = force constants for the interaction of adjacent and opposite angles; f_β, $f_{\beta\beta}$, $f'_{\beta\beta}$, etc. are defined analogously).

Type of molecule and its symmetry	$\sum_{ij} a_{ij} f_{ij} = \Delta Sp\,(GF)/\Delta\mu$
$XY_2\,(D_{\infty h})$	$2\,(f_r - f_{rr}) + 8\,f_\alpha$

$X\,(YZ)_4\,(D_{4h})$	$4\,(f_r - f'_{rr}) - 16\,(f_{r\alpha} - f'_{r\alpha}) + 8\,(f_\alpha - f'_{\alpha\alpha}) + 8\,(f_\gamma - f_{\gamma\gamma}) -$ $- 16\sqrt{\frac{R}{r}}\,(f_{\alpha\beta} + f_{\alpha\theta}) + 4\left(\frac{R}{r}\right)(f_\beta + f_\theta - 2\,f_{\beta\theta} - f_{\theta\theta})$
$XY_4\,(T_d)$	$4\,(f_r - f_{rr}) - 16\sqrt{2}\,(f_{r\alpha} - f'_{r\alpha}) + 16\,(f_\alpha - f'_{\alpha\alpha})$
$X\,(YZ)_4\,(T_d)$	$4\,(f_r - f_{rr}) - 16\sqrt{2}\,(f_{r\alpha} - f'_{r\alpha}) + 16\,(f_\alpha - f'_{\alpha\alpha}) - 16\sqrt{\frac{R}{r}}\times$ $\times (f_{\alpha\beta} + f'_{\alpha\beta}) + 24\sqrt{\frac{R}{r}}\,(f''_{\alpha\beta} + f'''_{\alpha\beta}) + 8\left(\sqrt{\frac{R}{r}}\right)(f_\beta + f_{\beta\beta} -$ $- 3\,f'_{\beta\beta})$
$XY_6\,(O_h)$	$6\,(f_r - f'_{rr}) - 48\,f_{r\alpha} + 24\,(f_\alpha + 2\,f_{\alpha\alpha} - f'_{\alpha\alpha})$
$X\,(YZ)_6\,(O_h)$	$6\,(f_r - f'_{rr}) - 48\,f_{r\alpha} + 24\,(f_\alpha + 2\,f_{\alpha\alpha} - f'_{\alpha\alpha}) - 48\sqrt{\frac{R}{r}}\,(f_{\alpha\beta} + f'_{\alpha\beta} +$ $+ 2\,f''_{\alpha\beta}) + 12\left(\sqrt{\frac{R}{r}}\right)(f_\beta + f_{\beta\beta} - f'_{\beta\beta})$

In terms of the range of its accuracy, Eqn.(29) makes it possible to separate the influence of the isotopic masses from the influence of the force constants and molecular geometry within $\ln\beta$. The role of the last two factors can be seen from Table 1, which presents the algebraic expressions for the sums $\sum_{ij} a_{ij} f_{ij}$ for isotope substitutions of the central atoms X in compounds of the type XY_n and $X(YZ)_n$.[74] Both the force constants f_{ij} and the coefficients a_{ij}, which are determined by the molecular geometry, are derivatives of the

characteristics of the potential energy surface of the molecules and their effects can be separated only by convention. Nevertheless, inspection of the expressions in Table 1 shows that formally such subdivision can be readily achieved and this makes it possible to separate the influence of bond strength from the influence of molecular geometry. We shall take into account the fact that the force constants for the deformation of bonds f_r, the deformation of valence angles f_α, the interaction of bonds f_{rr}, the interaction of bonds and angles $f_{r\alpha}$, and the interaction of angles with one another $f_{\alpha\alpha}$ decrease in a specific sequence[75,76]:

$$f_r \gg f_\alpha \gg f_{rr} \geqslant f_{\alpha\alpha} \geqslant f_{r\alpha}. \qquad (30)$$

This means that the main contribution to $\Delta Sp(GF)$ comes invariably from $(f_r - f_{rr})$ combinations multiplied by the coefficients a_{ii}, equal to the number n of attached atoms Y or atomic groups YZ. Despite the much greater numerical values of the coefficients a_{ij} of other combinations of constants, the fraction of this contribution does not fall below 60% of $\Delta Sp(GF)$ and is in the range 80–90% for the vast majority of molecules. Thus the force constants f_r for the deformation of bonds and their number n make the main contribution to $\Delta Sp(GF)$.[66,76] If one is dealing with a molecule of the type $XY_1Y_2...Y_i...Y_n$ in which the atom X involved in isotope substitution is linked to different atoms or groups Y_i, then the dominant component of the sum $\sum_{ij} a_{ij} f_{ij}$ is $\sum_i f_{ri}$.

According to the concept of the transferability of force constants[75,76], the bond deformation force constants for series of related molecules have the same numerical value or change comparatively slightly. Together with the considerations described above, this justifies the treatment of the quantities $\ln\beta$ as sums of certain constant increments corresponding to each bond. It has been shown[74,77] that in isostructural series of the type CH_4, CH_3F, CH_2F_2, CHF_3, CF_4 or BF_3, BF_2Cl, $BFCl_2$, BCl_3 the additivity of the values of $\ln\beta$ for the central carbon and boron atoms holds with a high degree of accuracy. However, even for an approximate maintenance of the additivity of $\Delta Sp(GF)$, numerous conditions must hold, which are partly outside the scope of the concept of transferability of the force constants[78]. The next section of this review will show that the rigorous additivity of $\ln\beta$ is incompatible with the rigorous additivity of the higher terms of the expansion of $\ln\beta$ in series in terms of the quantities $\Delta Sp(GF)^j$ even for series of geometrically similar molecules. The assumption of the additivity of the thermodynamic isotope effects of carbon for arbitrary sets of organic compounds[7,79] is therefore erroneous.

2. Exact Relations

Eqns.(28)–(29) make it possible to interpret the values of $\ln\beta$ only to within a correction factor γ. Although in most cases the latter lies within a narrow range of values, the corrections which it introduces can reach 30% of the true value of $\ln\beta$. This is a result of the failure to take into account the non-linear terms of the expansion of $\ln\beta$ in terms of the characteristics of the force field.

An accurate expansion in a variable-sign power series with Bernoulli coefficients B_{2j-1} was obtained by Bigeleisen[68] for the range $u_{max} < 2\pi$:

$$\ln\beta = \sum_{j=1}^{\infty} \frac{(-1)^{j+1} B_{2j-1}}{2j\,(2j)!} \sum_{i=1}^{3N-6} \delta\,(u_i^{2j}) = \\ = \sum_{j=1}^{\infty} \frac{(-1)^{j+1} B_{2j-1}}{2j\,(2j)!} \left(\frac{hc}{kT}\right)^{2j} \Delta\,\mathrm{Sp}\,(GF)^j. \qquad (31)$$

The condition for the convergence of this series ($u_{max} < 2\pi$) holds only for molecules with comparatively weak bonds or at relatively high temperatures.

This limitation as well as the low rate of convergence of series (31) stimulated the derivation of approximate expressions for $\ln\beta$ over an arbitrary range of values of u. Considerable efforts were wasted in the search for ways of achieving a sufficiently accurate mathematical description of $\ln\beta$ with the aid of finite orthogonal Jacobi polynomials[14,23,80]. Analysis of different versions of this description by Bigeleison and Ishida[23] led to the conclusion that the following approximate expression, in which the terms of series (31) are modulated by finite first-order Chebyshev polynomials, is best:

$$\ln\beta = \sum_{j=1}^{n} T\,(n, j, u_{|max}) \frac{(-1)^{j+1} B_{2j-1}}{2j\,(2j)!} \left(\frac{hc}{kT}\right) \Delta\,\mathrm{Sp}\,(GF). \qquad (32)$$

The accuracy ensured by the Bigeleisen–Ishida expansion (32) is determined by the order n of the modulating Chebyshev function $T(n,j,u_{max})$ and the required range of values $u \in [0, u_{max}]$. The accuracy of Eqn.(32) is higher the higher the order n and the narrower the required range of values of u. The marked increase of the error of the approximate expression (32) with increase of u necessitates the application of a (third–fourth)-order function $T(n,j,u_{max})$ and the introduction into $T(n,j,u_{max})$ of exact values of u_{max} corresponding to the maximum frequency of the vibrations of the molecule in the "light isotope" form.

Nemeth et al.[81] used the minimax method in order to expand the components of $\ln\beta$ into a finite polynomial; the resulting approximate expression is

$$\ln\beta \simeq \sum_{j=1}^{n} a\,(n, j, u_{max}) \cdot \sum_{i}^{3N-6} \delta\,(u_i/u_{max})^{2j} = \\ = \sum_{j=1}^{n} a\,(n, j, u_{max}) \cdot \left(\frac{hc}{kT}\right)^{2j} \Delta\,\mathrm{Sp}\,(GF)^j \quad , \qquad (33)$$

where $a(n,j,u_{max})$ are modulating polynomials analogous to $T(n,j,u_{max})$, and their numerical values have been tabulated[81].

The difference between Eqn.(33) and (32) is that the $\ln\beta$ polynomials $a(n,j,u_{max})$ fit much better the components of $\ln\beta$ and over a wide range values of u. Although the accuracy of Eqn.(33) is ultimately comparable to that of Eqn.(32), the weak dependence of the error of the former equation on u makes it possible to employ the same numerical values with $a(n,j,u_{max})$ for large sets of molecules over a wide temperature range. This converts Eqn.(33) into an algebraically simple expression and greatly facilitates the mathematical analysis of the relations between the RPFIF and all its intramolecular characteristics.

Having used the perturbation technique, Singh and Wolfsberg[82] obtained a new relation expressing the RPFIF directly in terms of the force constants, masses, and geometrical parameters of the molecule. To a second approximation, this method ensures an error in the fitting of an expression to $\ln\beta$ at the level of several per cent. The resulting expression is not algebraically simple[83] and has not as yet been subjected to a general analysis from the standpoint of the possibility of using it for the investigation of the structural characteristics of the thermodynamics of isotope exchange.

Eqn.(32) has been used in a series of studies[50,83–88] in order to investigate in detail the relations between the RPFIF and the force constants. The following example provides an idea about the complexity of the resulting specific relations[85]: the overall form of the expression for $\Delta Sp(GF)^3$ for a non-linear triatomic molecule has 113 terms. If it is necessary to estimate the scale of the significance of various constants, this makes numerical analysis of specific molecules preferable and lowers the generality of the conclusions.

The estimation of the contributions of various force constants to $\ln\beta$ with the aid of equations of type (32) involves a significant difficulty: the replacement of the real (numerical) value of the force constant by zero has the physical

significance of either bond rupture (if one is dealing with the valence constant), or the complete elasticity of the valence angle (zero deformation constant for the angle), or the cessation of the interaction between unlike coordinates. Such substitution can influence the coefficients of the characteristic polynomial to such an extent that certain vibration frequencies of the molecule "modified" in this way can prove to be imaginary. A special method has therefore been proposed[87] for the extrapolation of $\ln\beta$, in terms of the force constants, from the region where all the frequencies of the "modified" molecule retains positive values to zero values of the force constant. This method must be used in estimating the contributions of the valence and deformation constants, which are largest. On the other hand, the constants for the interaction between unlike coordinates can be estimated directly with the aid of Eqn.(32).

This exact analysis confirmed the dominant role of the valence force constants f_r (which follows from the analysis of the approximate relations and empirical correlations), the secondary role of the deformation constants f_α, and the much smaller influence of constants of the type f_{rr}, $f_{\alpha\alpha}$, and $f_{r\alpha}$, which reflect the interaction of unlike internal coordinates of the molecule. It has been shown[87] that the contributions of the valence constants to $\ln\beta_H$, characterising polyatomic deuterium-substituted hydrides, are almost additive at normal temperatures (300 K) and are rigorously additive at higher temperatures. The isotope effects of oxygen and in general of any element whose atoms play the role of terminal atoms are similarly almost additive and cumulative with respect to the force constants[83,88]. On the other hand, additivity breaks down significantly for elements of the type of carbon, which form numerous bonds and play the role of central atoms[83].

Expansion (32) has been used[50] to test the accuracy of Eqn.(14), which postulates the thermodynamic equivalence of all the stages of the isotope substitution of equivalent atoms. In contrast to earlier studies, it was found that the corrections to the geometrical mean rule are appreciable and can amount to 0.1–1% of $\ln\beta$.

Table 2. The functions b_j in Eqn.(35) [$B_j = (3.55559\times 10^{-6}/T^2u_{max})^{2j}$, $a_ja_j = a(n,j,u_{max})$ according to Nemeth et al.[81] and n = degree of polynomial].

n	Function b_j
1	$b_1 = b_1$
2	$b_1 = B_1 + 2B_2\sigma_1$ $b_2 = -2B_2$
3	$b_1 = B_1 + 2B_2\sigma_1 + 3B_3\sigma_1^2 - 3B_3\sigma_2$ $b_2 = -2B_2 - 3B_3\sigma_1$ $b_3 = 3B_3$
4	$b_1 = B_1 + 2B_2\sigma_1 + 3B_3\sigma_1^2 - 3B_3\sigma_2 + 4B_4\sigma_1^3 - 8B_4\sigma_1\sigma_2 + 4B_4\sigma_3$ $b_2 = -2B_2 - 3B_3\sigma_1 - 4B_4\sigma_1^2 - 4B_4\sigma_2$ $b_3 = 3B_3 + 4B_4\sigma_1$ $b_4 = -4B_4$

A deficiency of Eqns.(32), (33), and other polynomial expansions of $\ln\beta$ in terms of the parameters $\Delta Sp(GF)^j$ is the algebraic complexity, already mentioned, of the increments in the traces of the degrees of the matrix (GF), which constitutes a significant obstacle in the mathematical analysis of the relations between the RPFIF and the characteristics of the molecules. A definite advance in this respect was made by the simplification achieved using Waring's formulae[89,90]. Their application replaces the parameters $\Delta Sp(GF)^j$ by $\Delta\sigma_j$ (isotopic increments in the coefficients σ_j of the characteristic polynomial for molecular vibrations):

$$\sigma_1 = 4\pi^2c^2\sum_i \omega_i^2,$$
$$\sigma_2 = (4\pi^2c^2)^2\sum_{i\neq k}\omega_i^2\omega_k^2, \qquad (34)$$
$$\sigma_3 = (4\pi^2c^2)^3\sum_{i\neq k\neq l}\omega_i^2\omega_k^2\omega_l^2.$$

This replacement of the parameters of the expansion reduces Eqns.(32) and (33) to the form

$$\ln\beta = \sum_j b_j\Delta\sigma_j + \sum_{j,k} b_{jk}\Delta\sigma_j\Delta\sigma_k + \sum_{j,k,l} b_{jkl}\Delta\sigma_j\Delta\sigma_k\Delta\sigma_l + \ldots, \qquad (35)$$

where b_j, $b_{j,k}$, and $b_{j,k,l}$ are functions of σ_j of different orders, which depend on the choice of modulating polynomials. If the functions b_j, $b_{j,k}$, ... are found by the method of Nemeth et al.[81] from the polynomials $a(n,j,u_{max})$, then their form is significantly simpler than in the case where $T(n,j,u_{max})$ is used for the same purpose (Table 2).

The advantages of Eqn.(35) compared with Eqns.(32) and (33) are as follows. Despite its apparent greater complexity, Eqn.(35) has a simpler structure and converges more rapidly, but Table 3 shows that the contribution of even the second sum on the right-hand side of Eqn.(35) is comparable to the error of the approximation and can therefore be neglected together with higher terms. The first sum $\sum_j b_j\Delta\sigma_j$ has a convenient structure. In contrast to the variable-sign sums on the right-hand sides of Eqns.(32) and (33), it includes only positive terms whose absolute magnitude decreases rapidly. Table 3 shows that the first term with $\Delta\sigma_1$ amounts to 70–90% of $\ln\beta$, the contribution of the second term with $\Delta\sigma_2$ is 10–30%, and that of the term with $\Delta\sigma_3$ is about 1% of $\ln\beta$, i.e. is comparable to the error of the approximation. This enables us to speak of the relative contribution of each term to $\ln\beta$, while a similar statement does not have such a clear-cut significance in relation to the terms of the variable-sign sums (32) and (33).

Table 3. The structure of the contributions of the terms of expansion (35) to $\ln\beta$ at 300 K (degree of polynomial fitted $n = 3$, n' = degree of secular equation).

Molecule	$\ln\beta_{harm}$ [Eqn.(16)]	n'	$\sum b_j\Delta\sigma_j$	$b_1\Delta\sigma_1$	$b_2\Delta\sigma_2$	$b_3\Delta\sigma_3$

Furthermore, the first sum $\sum_j b_j\Delta\sigma$ consists of simple functions. Table 2 shows that the values of b_j are power functions of the coefficients σ_j of the characteristic polynomial. These coefficients refer to an isotopically unperturbed molecule and can be readily expressed not only in terms of the frequencies [Eqn.(34)] but also in terms of the matrices G and F. The values of σ_j are equal to the sums of products of the principal minors of order j of the matrices G and F.[91] The isotopic increments $\Delta\sigma_j$ can be expressed quite similarly.

Overall, the properties of σ_j and $\Delta\sigma_j$ make it possible to separate relatively simply the influence on $\ln\beta$ of force characteristics, on the one hand, and of the geometry and mass of the molecules, on the other. This makes Eqn.(35) convenient for the interpretation of isotope effects and for the search for relations.

An example of useful applications of Eqn.(35) is the derivation of the quantitative coupling relations between the isotope effects of different elements and the frequency characteristics of the molecules[92]. For the reaction

$$HCO_3^- \rightleftarrows CO_2 + OH^- \qquad (36)$$

four isotope exchange processes are possible between all three substances and there can be four equilibrium isotope effects with respect to three elements:

$$\begin{aligned}
&H\overset{*}{C}O_3^- + CO_2 \rightleftarrows HCO_3^- + \overset{*}{C}O_2; \quad \alpha_C = \beta_{CO_2}/\beta_{HCO_3^-},\\
&\overset{*}{H}CO_3^- + OH^- \rightleftarrows HCO_3^- + \overset{*}{O}H^-; \quad \alpha_H = \beta_{OH^-}/\beta_{HCO_3^-},\\
&HCO\overset{*}{O}_2^- + CO_2 \rightleftarrows HCO_3^- + C\overset{*}{O}_2; \quad \alpha_O^{(1)} = \beta_{CO_2}/\beta_{HCO_3^-},\\
&HC\overset{*}{O}O_2^- + OH^- \rightleftarrows HCO_3^- + \overset{*}{O}H^-; \quad \alpha_O^{(2)} = \beta_{OH^-}/\beta_{HCO_3^-}.
\end{aligned} \qquad (37)$$

The coupling relation for Eqns.(37) or, what amounts to the same thing, for reaction (36), is as follows:

$$\begin{aligned}
&\frac{\mu_C}{\Delta\mu_C}\ln\alpha_C + \frac{\mu_H}{\Delta\mu_H}\ln\alpha_H + 2\frac{\mu_O}{\Delta\mu_O}(\ln\alpha_O^{(1)} + \ln\alpha_O^{(2)}) =\\
&= \sum_i jb_i(CO_2)\,\sigma_i(CO_2) + \sum_i jb_i(OH^-)\,\sigma_i(OH^-) - \sum_i jb_i(HCO_3^-)\,\sigma_i(HCO_3^-).
\end{aligned} \qquad (38)$$

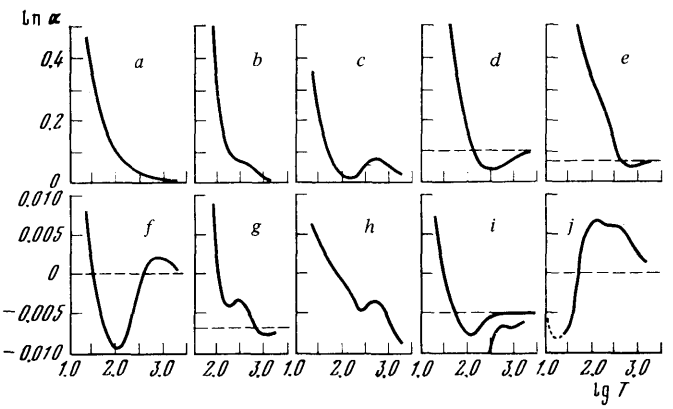

Figure 1. Types of temperature variations of theoretically calculated isotope separation factors for oxygen, carbon, and hydrogen in terms of the variables $\ln\alpha$ and $\lg T$ in the following systems: *a*) $^{18}OCS/CH_3CH^{18}O$; *b*) $Br_2C^{18}O/H^{18}OCO_2$; *c*) $CH_3{}^{13}CHO/H^{13}COO^-$; *d*) $CH_3CHDCH_3/DCOOH$; *e*) $CH^{18}OCH_3/Cl_2C^{18}O$; *f*) $CH_2{}^{13}CO/H^{13}COO^-$; *g*) $DONO_2$/*trans*-DONO; *h*) $^{13}CO_2/CH_3COCH_3$; *i*) $DONO_2/HCOOD$; *j*) $CH_2DCOCH_3/CH_2DCH_2CH_3$.

With the aid of coupling relations of type (38), it is possible to estimate isotope effects which have not been investigated experimentally, to test the reliability of the results, and to determine the characteristics of the transition complexes.

3. Temperature Variation of Isotope Effects

The most complete theoretical treatment of the nature of the temperature variation of $\ln\beta$ and $\ln\alpha$ has been achieved by Denisov et al.[71] and by Stern and coworkers[93,94]. The analysis was based on the study of the $\ln\beta_i$ components of the RPFIF corresponding to different vibration frequencies ω_i [see Eqn.(17)]. Each component $\ln\beta_i$ can be effectively fitted at low temperatures by a linear relation in terms of the reciprocal of the absolute temperature and at high temperatures by a quadratic relation. The transition from the first type of relation to the second occurs at higher temperatures for each frequency the higher the frequency. In the general case the resultant value of $\ln\beta$ in the region of moderate temperatures therefore depends on temperature in a complex way and, while obeying the linear and quadratic relations at low and high temperatures, always exhibits a monotonic decrease with increase of temperature. In contrast to $\ln\beta$, the values of $\ln\alpha$, which are equal to differences between the $\ln\beta$, can vary non-monotonically with increase of temperature. It has been shown[71,93,94] that there are several types of temperature variation of $\ln\alpha$, which include relations with inversion of the sign of $\ln\alpha$, with a maximum, with a minimum, and with points of inflection (Fig.1).

IV. CHARACTERISTICS OF THE VARIABILITY OF ISOTOPE EFFECTS

1. Semiempirical Structural Relations

The study of the correlations between the RPFIF and the exact or approximate characteristics of molecular force fields leads to the possibility of estimating the RPFIF with the aid of extremely limited spectroscopic or non-spectroscopic information. Conversely, measurement of isotope effects makes it possible to find the approximate values of the force constants, the stretching vibration frequencies, and other molecular parameters.

As shown above, the valence force constants f_r, corresponding to the longitudinal deformation of the valence bonds involving the atom undergoing isotope substitution, make the dominant contribution to the values of $\ln\beta$. In series of related compounds there are definite relations between the quantities f_r and other force constants of the molecules (f_α, f_{rr}, $f_{r\alpha}$, $f_{\alpha\alpha}$) or their simple combinations (elements of the *F*-matrix)[74,75,95,96], which permits a definite selection of the valence force constants f_r as the main argument in the study of RPFIF correlations. Since the valence force constants f_r are characteristics of the bond strength and there are many other bond properties correlated with them, the quantities $\ln\beta$ should exhibit fairly close correlations with many parameters of both the bonds themselves in the molecules and of the atoms involved in the bonds.

The density of such correlations and hence their reliability and usefulness are determined both by the selected method of expressing the bond strength and by the nature of the set of compounds for which such correlations are constructed For example, for simple sets such as those of diatomic molecules[97-99], the observed relations are so close and simple that the RPFIF can be expressed analytically as a function of the properties of the atoms forming the molecule. On the other hand, for the set of hydrides of different elements, it has been possible merely to conclude that the variation of the RPFIF is periodic[31]. In the general case of polyatomic molecules dense linear $\ln\beta - \Sigma f_r$ and $\ln\beta - \Sigma(f_r \pm f_{rr})$ correlations

are observed for sets formed by geometrically similar compounds. A variable phenomenological feature of the compounds in such sets is usually the nature of the donor atom attached to the atom undergoing isotope substitution. Examples of such correlations are presented in Figs. 2 and 3.[100-103] In series of the type XY_n and $XY_iY'_{n-i}$, where Y and Y' are different halogens, hydrogen, oxygen, and chalcogens, etc, these correlations are so close that methods of comparative calculation of the RPFIF become justified, for example, those based on the linear relations of the $\ln\beta_X - \ln\beta_{X'}$ type (Fig. 4).[103]

In compounds $XY_iY'_{n-i}$, where the geometry of the coordination sphere of the atom involved in isotope substitution is retained, $\ln\beta_X$ is nearly additive: the values of $\ln\beta_X$ can be obtained as the sums of certain increments for the X–Y and X–Y' bonds. As shown above, this is a consequence of the transferability of the force constants in such series of molecules.

The correlations between $\ln\beta$ and $\Sigma(f_r \pm f_{rr})$ for a set of compounds with different geometries have a much smaller density. For such sets (Fig. 5), the correlation coefficients are approximately 0.8. This is a natural consequence of the influence of the component of $\Delta Sp(GF)$, which is not proportional to Σf_r and reflects the differences associated with the geometrical variety of molecules.

Frequently only the stretching vibration (symmetric or anti-symmetric) frequencies are known for the compounds of interest. The knowledge of these frequencies is virtually equivalent to the knowledge of one of the combinations $(f_r \pm f_{rr})$ and the squares of the stretching vibration frequencies ν can therefore be used as bond characteristics for compounds where the central atom is linked to monatomic ligands. Such correlations are equally well applicable to sets containing the elements of a single Group or a single Period. It is also necessary to exclude the influence of masses by introducing the corresponding multiplier (Figs. 6 and 7).

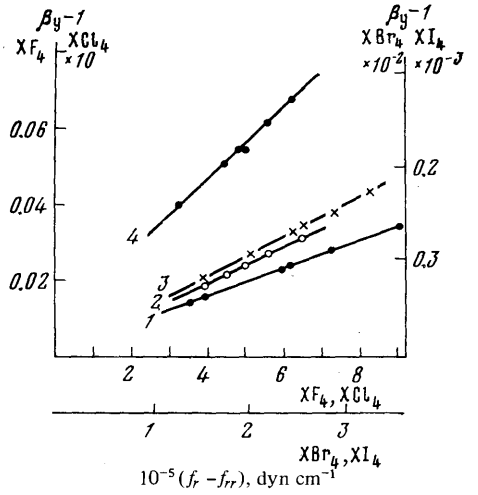

Figure 3. Dependence of $\beta_Y - 1$ for the terminal atoms Y in the tetrahalides XY_4 of the elements in the carbon subgroup on the combination of force constants $f_r + f_{rr}$ at 300 K; 1) XF_4; 2) XCl_4; 3) XBr_4; 4) XI_4.

The force constants are second derivatives of the bond energies E with respect to internuclear distances corresponding to equilibrium distances r_e. It is therefore natural to expect that relations of the type $\ln\beta - E$ or $\ln\beta - \sum_i E_i$ should be fairly simple. However, even for sets of related diatomic compounds such expectations are not borne out in practice[97-99]. For polyatomic molecules, the above relations are

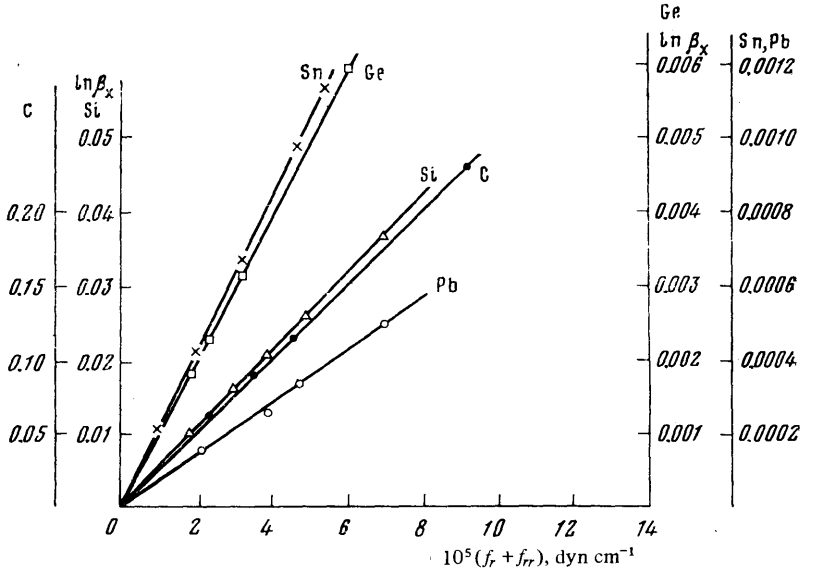

Figure 2. Dependence of $\ln\beta_X$ for the tetrahalides XY_4 of the elements in the carbon subgroup on the combination of constants $fr + f_{rr}$ at 300 K.

also not simple[103]. A much better correspondence is observed between $\ln\beta$ and the argument $\eta_0(y_X y_Y / y_X^0 y_Y^0)^{1/2} E/r_e$, where η_0 is a constant, y_X and y_Y are the first ionisation potentials of the atoms X and Y forming the molecule, and y_X^0 and y_Y^0 are the first ionisation potentials of the alkali metals belonging to the same Periods as X and Y. The use of this argument (Fig.7) is based on the familiar empirical relation $f_r = cE/r_e$, which Lippincott generalised[104]. The above relation has been confirmed for a fairly large set of compounds[105].

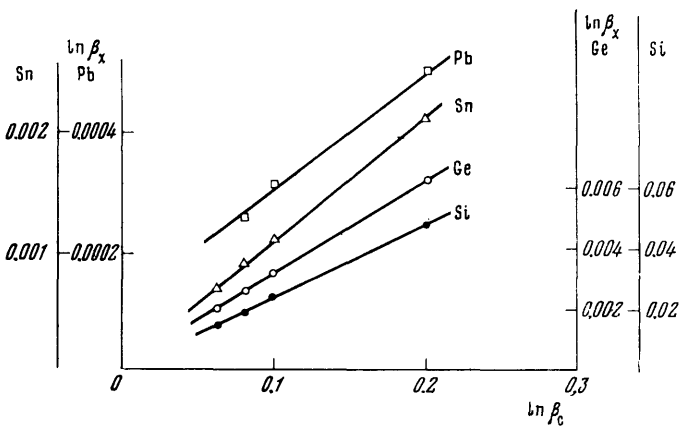

Figure 4. Correlation between the $\ln\beta_X$ for silicon, germanium, tin, and lead tetrahalides and $\ln\beta_C$.

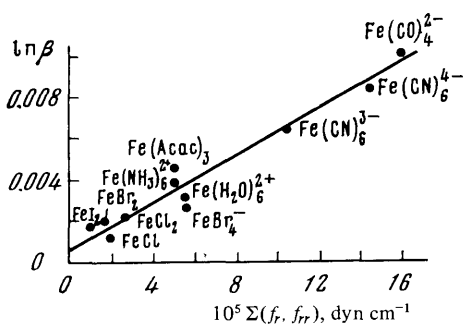

Figure 5. Correlation between $\ln\beta_{Fe}$ and $\Sigma(f_r, f_{rr})$.

Among the numerous other methods for fitting approximate expressions to the sum of valence force constants, we may note the empirical relations of Gordy[106], Guggenheimer[107], Ferreira[108], Varshni[109], and Somayajulu[110], which made it possible to obtain linear correlations between $\ln\beta$ and the internuclear distances, electronegativities, the numbers of valence electrons in the atoms, and other characteristics[97-103] (Figs.8 and 9).

For hydrogen isotope effects, the influences exerted on the H–X bond by other atoms linked to the hydride-forming element are significant. Characteristics such as the electronic charge of the bond, the electron density at the bond, the electronegativity of the substituting group, and the Taft and Hammett constants are fairly closely correlated with $\ln\beta_H$ for the corresponding sets of hydrides[101,102] (Figs.10–12).

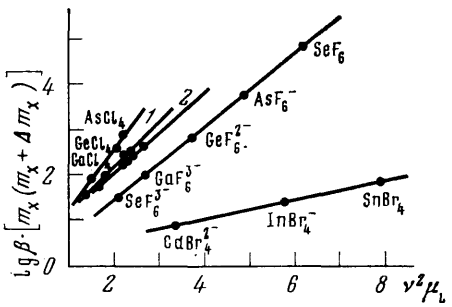

Figure 6. Dependence of $\lg\beta[m_X(m_X + \Delta m_X)]$ on $\nu^2\mu_L$, where ν is the stretching frequency and μ_L the reduced mass $[\mu_L = m_L m_X/(m_L + m_X)]$: 1) cyanides; 2) acetylacetonates.

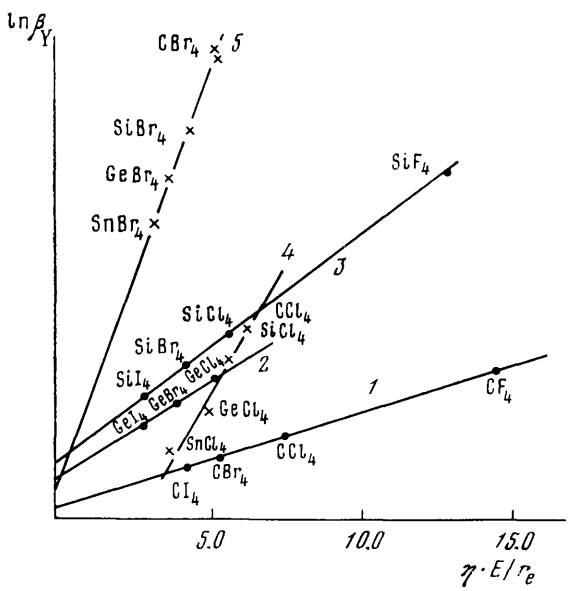

Figure 7. Dependence of $\ln\beta$ on $\eta E/r_e$: 1)–3) for C, Ge, and Si; 4) and 5) for Cl and Br.

2. Phenomenological Relations

This concept includes correlations which can be observed by comparing the isotope effects of one or several elements with generally accepted chemical concepts such as the degree of oxidation of the element, the type of donor atom or ligand,

and the configuration of the coordination sphere of the element involved in isotope substitution. The choice of these features of the chemical compound as the phenomenological equivalent of the intramolecular force field is justified by the possibility of a direct comparison of the isotope effects with a wide variety of chemical data[76,100,111].

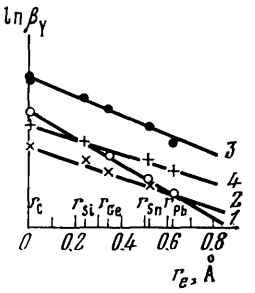

Figure 8. Correlation between $\ln\beta_Y$ and r_e for the tetrahalides XY_4 of Group IV elements: 1) fluorides; 2) chlorides; 3) bromides; 4) iodides.

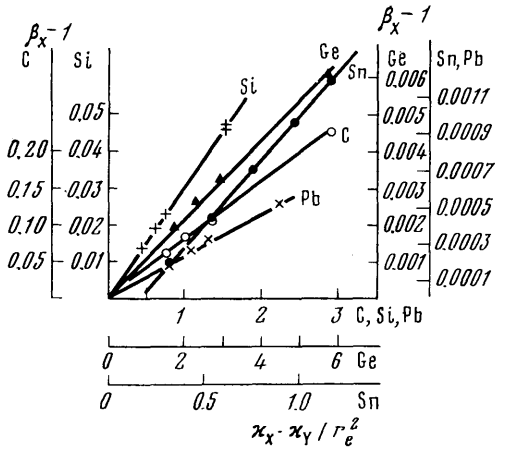

Figure 9. Correlation between $\beta_X - 1$ and the Gordy–Ferreira factor $\kappa_X\kappa_Y/r_e^2$ for the tetrahalides XY_4 of Group IV elements; κ_X and κ_Y = atomic electronegativities; r_e = internuclear distance.

The oxidation state of the element, the type of ligand, and the type of configuration sphere are interrelated discrete parameters. While the others are kept constant, each can vary only within narrow limits. In order to extend the range of values of the given parameter, it is necessary to adjust the isotope effects of different elements to a single scale and to include them in an overall analysis. This is achieved in two ways. Firstly, if one needs to compare the isotope effects of different elements, then one should use effects corresponding to a unit increment in isotopic masses. All the numerical values of $\ln\beta$ and $\ln\alpha$ quoted in this review satisfy this condition. Secondly, if one needs to exclude the influence not only of Δm but also of the atomic mass m of the element involved in isotope substitution, then the quantities $\ln\beta/\Delta\mu$ should be analysed. In conformity with the significance of Eqns. (28) and (29), these quantities can be referred to as the effective force fields in which the atoms in the molecule involved in isotope substitution are located.

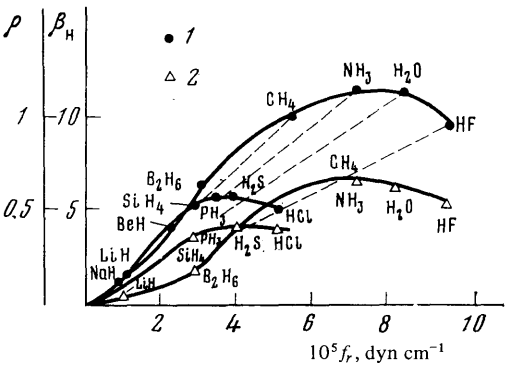

Figure 10. Dependence of β_H (*1*) and electron density ρ (*2*) of the H–X bond on the force constant f_r.

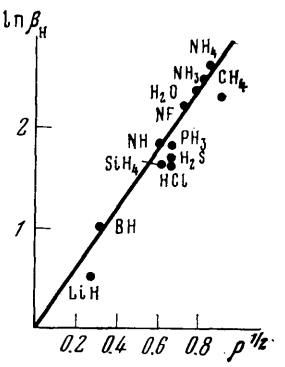

Figure 11. Correlation between $\ln\beta_H$ and the bond electron density ρ.

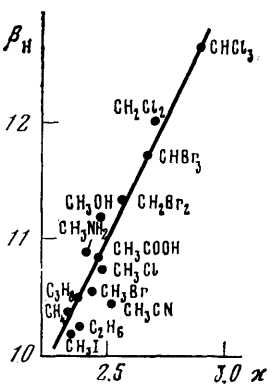

Figure 12. Correlation between β_H and the electronegativity κ of the hydrogen-substituting groups.

The influence of the degree of oxidation of the central atom on its $\ln\beta$ can be most readily followed for the sequence of compounds formed by elements with the same donor atom or ligand. The variation of the effective field $\ln\beta/\Delta\mu$ is simplest for the sequence of isoelectronic-isostructural compounds. Fig. 13 shows that the values of $\ln\beta/\Delta\mu$ are linear functions of the formal oxidation state in the series of tetraoxo-anions and tetra- and hexa-halogeno-complexes of both *p* and *d* elements in the highest oxidation states. For transition metals in isostructural series of compounds the variation of $\ln\beta/\Delta\mu$ with increasing degree of oxidation remains monotonic (Table 4). For σ-donor and (σ−π)-donor ligands, $\ln\beta/\Delta\mu$ increases, while for σ-donor and π-acceptor ligands it diminishes with increasing degree of oxidation.

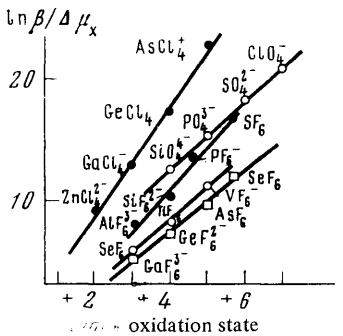

Figure 13. Relation between $\ln\beta_X/\Delta\mu_X$ and the formal oxidation state of the central atom in series of isoelectronic molecules.

The increase of the degree of oxidation of *p* elements is coupled with a change in the number of attached ligands, the type of hybridisation of the valence orbitals, and the configurations of the compounds. The monotonic increase of the effective force fields observed in such sequences (Table 5) must be attributed to the increase of the degree of oxidation, since the configuration can be regarded as derived from the oxidation state and the type of ligand. The monotonic variation of $\ln\beta/\Delta\mu$ for sequences of this type does not imply their simplicity. In these sequences there is a change of both the type of hybridisation and of the number of non-bonding electron pairs. A more flexible and exact equivalent of the concept of the degree of oxidation proves to be the sum of bond orders, which exhibits a closer correlation with $\ln\beta$ (Fig. 14).

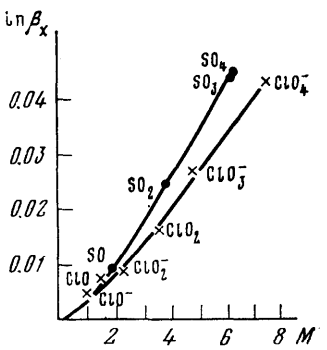

Figure 14. Correlation between $\ln\beta$ of sulphur and chlorine oxides and the sum of bond orders *M*.

The study of the relations between the RPFIF and the nature of the ligands and donor atoms is complicated by the fact that at the present time the values of $\ln\beta$ are known mainly only for compounds with the simplest monatomic ligands. Table 6 shows that, in series of isostructural compounds formed by donor atoms of the elements of a single Group of the Periodic Table, there is a marked decrease of $\ln\beta_X$ with increase of the atomic number of the donor element in the Group. Fairly rigorous relations of the type

$$\ln\beta(XY_n)/\ln\beta(XY_n') = t \simeq \text{const.} \qquad (39)$$

are observed between the values of $\ln\beta_X$ for halides, oxides, and chalcogenides. The values of *t* are then close to the ratios of the electronegativities of the donor elements Y and X. Compounds with different oxidation states of the central atom and ligands belonging to the same Period (F^- and O^{2-}, Cl^- and S^{2-}, Br^- and Se^{2-}) have approximately the same values of the RPFIF of the central atoms.

For octahedral complexes of doubly- and triply-charged metal ions belonging to the first transition Period, the following sequence, corresponding to the variation of $\ln\beta_X$ with the nature of the ligand, apparently holds:

$$CN^->Acac>F^->H_2O\simeq NH_3\geqslant O^{2-}{}_x. \qquad (40)$$

Se	0.0938	0.0865	—	—	—	0.00159	0.00047

Overall, there are three factors which determine the dependence of the RPFIF on the nature of the ligand: the occurrence of the donor atom of the ligand in a definite Period, the chemical individuality of the donor atom, and the influence on the donor atom by the remaining atoms of the ligands. The available data for different complex-forming ligands permits the conclusion that the first factor is of greatest importance, while the individuality of the donor atom has less influence and the latter is comparable to the influence of the remaining part of the ligand. There is a satisfactory correspondence between the sequence based on the variation of $\ln\beta$ and the familiar simple sequence of donor elements:

$$C\geqslant N\geqslant O\geqslant F>S\geqslant Cl>Br>I. \qquad (41)$$

The variation of $\ln\beta$ with the degree of oxidation of the element and with the nature of the donor atom or ligand added to it follows the analogous variation of the valence force constants f_r. This correspondence is confirmed by numerous empirical relations between f_r and both phenomenological features of the compound specified above and is caused by the relation between $\ln\beta$ and f_r already discussed.

The relation between the RPFIF and the configurations of the coordination spheres of the element in the compound can be traced only for a few types of configurational transitions. Examples of such transitions are provided by transitions of the following types:

$$CO_2\,(D_{\infty h}) \rightarrow CO_3^{2-}\,(D_{3h});$$
$$BF_3\,(D_{3h}) \rightarrow BF_4^-\,(T_d),$$
$$SiF_4\,(T_d) \rightarrow SiF_6^{2-}\,(O_h).$$

Table 7 shows that in the majority of instances such transtions, associated with an increase in the number of added donor atoms and a change in the type of hybridisation of the electronic orbitals of the atom involved in isotope substitution, are accompanied by a decrease of $\ln\beta$. This can be explained by the marked decrease of f_r in such transitions. However, the configurational transitions caused by the addition of electron-deficient species and by the delocalisation of the nonbonding electron pair of the atom can be accompanied by an appreciable increase of $\ln\beta$. An example of such transitions is $NH_3(C_{3v}) \rightarrow NH_4(T_d)$.[101]

V. SYSTEMATIC TREATMENT OF CHEMICAL ISOTOPE EFFECTS AND THEIR PREDICTION

In both applications of isotope effects—in the separation of stable isotopes and in the employment of such effects as the basis of a research technique—it is necessary to solve the following problems: the determination of the limits of applicability of the corresponding methods and prediction of the systems and situations in which these methods are most effective. In other words, the problems can be formulated in the following way: (a) statistical estimation of the isotope effects for various elements of the Periodic System; (b) the search for a method of rational classification of isotope exchange reactions as the basis for a systematic treatment of isotope effects; (c) the determination of the principles governing the prediction of systems with large isotope effects on the basis of general chemical information. The above problems have been solved[111–117] and the results will be considered briefly in this section.

1. Statistical Estimation of the Isotope Effects of Different Elements

The sets of possible chemical exchange systems of different elements are quantitatively non-equivalent but their number is always at least several thousands. On the other hand, the number of compounds of each element for which the values of the RPFIF are known is almost always small. The sets of systems with calculated isotope separation factors α susceptible to a statistical treatment are also small and for the majority of elements the sets of possible systems are insufficiently representative. The deficiency of information can be compensated by extending the framework of the treatment by combining the systems of different elements in a single set. However, the values of $\ln\beta$ and $\ln\alpha$ depend to the greatest extent on the atomic weight of the element and such combination requires the normalisation of the $\ln\alpha$, i.e. they must be adjusted to a single scale.

For this purpose, the concept of the γ-factor has been introduced; it is defined as the ratio of the absolute value of $\ln\alpha$ for a specific chemical exchange system of a given element to the maximum possible value $\ln\alpha_{max}$ for the same element. α_{max} is numerically equal to the separation factor for a hypothetical system in which the exchange takes place between the compound with the maximum possible value β_{max} and the non-bonded atomic form for which $\beta = 1$:

$$\gamma = |\ln\alpha|/\ln\beta_{max}. \qquad (42)$$

For any element, γ varies in the same range $0 \leq \gamma \leq 1$. The available information about the characteristic features and limits of variation of β is sufficient to create a reference system of maximum values β_{max} for the majority of elements of the Periodic Table. Compounds in which the element exhibits the highest oxidation state, coordinates ligands with donor atoms of elements in the Second Period (C,N,O, and F), and has a nearly saturated coordination sphere have the highest values of β. For a large number of elements, it is possible to indicate directly compounds whose β-factors should be extremely close to the upper limit; for others, the β_{max} were estimated by correlation methods[112]. Comparison of the β_{max} for different elements reveals a periodicity in their variation with increase of the atomic number of the element in the Periodic Table.

Table 8. The γ distribution functions (the probabilities of finding systems in different ranges of γ values).

Type	Characteristic of set	No. of systems	Ranges of γ values						
			0—0.1	0.1—0.2	0.2—0.3	0.3—0.4	0.4—0.5	0.5—0.6	$\gamma_{cp.}$
I	Set taking into account the abundances of different classes	1081	0.573	0.238	0.094	0.063	0.025	0.007	0.126
II	Set not taking into account the abundances of different classes	—	0.381	0.281	0.172	0.091	0.061	0.014	0.171
III	Set of experimentally investigated systems	161	0.410	0.349	0.138	0.058	0.025	0.010	0.150

The separation factors for each element can assume different values within the range $[1; \beta_{max}]$. The frequency of the appearance of larger and smaller values of α can be different. The concept of attainable values of α has the significance of maximum values, the probability of the appearance of which remains acceptably large from the practical point of view. A direct empirical estimate of the probability of the existence of different α is mathematically equivalent to the construction of statistical distribution functions for α.

The conversion of statistical distribution functions for α into statistical distribution functions for γ makes it possible to compare directly the functions for different elements, to estimate the degree of their similarity, and to solve the problem of the possibility of employing average (generalised) distribution functions for γ in order to estimate the attainable values of α for those elements for which direct analysis of the problem is impossible or difficult.

The γ distribution function is determined by the nature of the set of systems for which it is constructed. It is possible to distinguish hypothetical random sets formed by pair combinations of all the compounds with known β-factors; the sets of thermodynamically compatible systems; the sets of systems with a high rate of isotope exchange or a rate satisfactory for practical purposes. The γ distribution functions of the three types have been investigated in the case of eleven elements (H,B,C,N,O,F,Fe,Co,Ni,Zn). It has been established that overall the γ-functions of each type differ little despite the marked chemical individuality of each of the elements enumerated. Hence it follows that the estimation of the attainable values of α for different elements can be achieved with the aid of averaged γ-functions.

However, the set of systems satisfactory in both thermodynamic and kinetic respects can be constructed in different ways. It is possible to investigate the set of all the systems with known values of α in which account is taken of the different abundances of different classes of systems (set I, Table 8). The γ distribution function for such a set will reflect the probability of a random selection or discovery of systems with particular values of γ. One can investigate the γ-functions for each class of systems (see below). The averaging of such functions without taking into account the abundances of the classes leads to γ-functions taking into account the element of specificity in the search for systems (Set II). Finally, one can investigate the γ-function for the set of experimentally investigated systems (set III). Evidently all three types of functions are suitable for the estimation of the attainable values of α.

Table 8 presents the γ distribution functions corresponding to the three specified methods of construction of the initial sets. The probability of obtaining high values of γ is highest for the function which does not take into account the abundance of systems of different classes and is lowest for the function which does take this factor into account. The

function of experimentally investigated systems occupies an intermediate position, which is evidently a consequence of the low specificity of the empirical search for systems to be used in isotope separation. At the same time all three functions are on the whole similar. This shows that their use for the estimation of the attainable values of α is fairly reliable.

Table 9 presents the estimates of the attainable values of α at 300 K, obtained for all the elements in the Periodic Table, with the exception of the lanthanides, actinides, and the noble gases.

2. Classification of Isotope Exchange Reactions

In order to serve as an effective instrument for interpretation and prediction, the classification of chemical exchange systems must cover fairly completely the entire region of equilibrium chemical isotope effects and must constitute a flexible means of combining specific information with general chemical information. The set of features defining the systematic classification must meet these requirements. The choice of the state of oxidation of the element, the type of coordinated ligand, and the configuration of the coordination sphere of the compound as features of this kind is satisfactory in this respect.

Allowance for the three features of each compound implies that each chemical exchange system is described by six features and that in each pair of like features the two can be either identical or different. Hence follows the subdivision of the entire set of isotope exchange reactions into eight classes. Table 10 defines the different classes and presents examples of the corresponding reactions. All the classes can be subdivided into four groups: class I—the class of homomolecular exchange reactions for which the isotope separation factors are mathematically rigorously equal to unity; three "simple" classes (II, III, and IV) in which the number of differing features of the compounds is unity; three classes (V, VI, and VII) with two differing features of the compounds; class VIII, in which the number of differing features of the compounds is a maximum and equal to three. Each class can be subdivided in its turn into subclasses corresponding to a specific combination of both variable and invariant features. However, the available data are insufficient for a detailed investigation of the subclasses and in the main only the classes as a whole are so far susceptible to analysis. Analysis of the experimentally investigated systems does not allow a comparison of the possibilities of different classes, because the vast majority of systems investigated refer to class VII, isolated systems in classes III, IV, VI, VIII have been studied, while classes II and V have not been studied at all.

Table 11. The γ distribution functions for different classes (probabilities of finding systems in different ranges of γ values).

Class	γ_{av}	Ranges of γ values					
		0—0.1	0.1—0.2	0.2—0.3	0.3—0.4	0.4—0.5	0.5—0.6
II	0.174	0.30	0.35	0.22	0.11	0.02	0.00
III	0.079	0.85	0.14	0.00	0.00	0.01	0.00
IV	0.105	0.48	0.30	0.16	0.04	0.05	0.00
V	0.198	0.28	0.38	0.24	0.03	0.07	0.00
VI	0.282	0.08	0.34	0.22	0.12	0.18	0.02
VII	0.124	0.55	0.31	0.09	0.05	0.00	0.00
VIII	0.310	0.16	0.16	0.29	0.24	0.16	0.08

Table 11 illustrates the γ distribution functions for seven classes with $\gamma \neq 0$ obtained as a result of the interpretation of calculated theoretical data[113]. Table 11 shows that the average value γ_{av} for a given class increases with increasing

Table 10. Classification of isotope exchange reactions. Examples of kinetically satisfactory isotope exchange reactions belonging to different classes (290–300 K)[115,116].

Class	System	Kinetic characteristic	α_{theor} ($\Delta m = 1$)	α_{exp} ($\Delta m = 1$)	γ for reaction
Class II Configuration and ligand identical, oxidation states different	$Fe(CN)_6^{3-} + Fe(CN)_6^{4-}$	$k = 3.5 \times 10^2$ litre mol^{-1} s^{-1}	1.00216	—	0.24
	$Mo(CN)_8^{-3} + Mo(CN)_8^{4-}$	$k = 355$ litre mol^{-1} s^{-1}	1.00075	—	0.19
Class III Oxidation state and configuration identical, ligands different	$HDS + H_2O$	HETS = 10 cm	2.20	2.38	0.27
	$Mn(CN)_6^{4-} + Mn(H_2O)_6^{+}$	rapid exchange	1.0032	—	0.21
	$ZnI_4^{2-} + ZnI_3F^{2-}$	very rapid exchange	1.00052	—	0.16
Class IV Oxidation state and ligand identical, configurations different	$NH_3 + NH_4^{+}$	$k = 24.6$ mol s	1.034	1.035	0.25
	$SiF_6^{2-} + SiF_4$	rapid exchange	1.0150	—	0.32
	$HgCl_2 + HgCl_4^{2-}$	rapid exchange	1.00005	—	0.20
Class V Configurations identical, oxidation states and ligands different	$V(H_2O)_6^{2} + V(CN)_6^{3-}$	rapid exchange	1.0012	—	0.08
	$Mn(H_2O)_6^{3+} + Mn(CN)_6^{4-}$	rapid exchange	1.0008	—	0.07
Class VI Ligands identical, configurations and oxidation states different	$NO + NO_3^{-}$	rapid exchange	1.079	—	0.54
	$NO + NO_2$	rapid exchange	1.035	1.028	0.24
Class VII Oxidation states identical, configurations and ligands different	$CO_2 + H_2O$	HETS = 13 cm	1.021	1.021	0.18
	$SO_2 + HSO_3$	rapid exchange		1.010	0.22
	$Zn(H_2O)_6^{2+} + ZnI_4^{2-}$	rapid exchange	1.0007	—	0.30
Class VIII Configurations, oxidation states, and ligands different	Li(amalgam) + $Li(H_2O)_6^{+}$	HETS = 10 cm	1.050	1.055	0.72
	$NO + HNO_3$	HETS = 2–3 cm		1.065	0.43
	Mg (amalgam) + $Mg(H_2O)_6^{2+}$	rapid exchange	1.0105	1.0105	0.43

*HETS = height equivalent to the theoretical stage.

number of differing features. The difference between the influences of individual variable features on γ_{av} can also be clearly traced. The classes of systems with a variable valence state have higher values of γ_{av} than the classes with variable configurations of the coordination spheres, while the classes with different types of ligands have the lowest values of γ_{av} (this is associated with the stepwise nature of the substitution of the ligands and the predominance of the O- and N-donor ligands among those investigated). The most complex class VIII, in which all three features of the contrasted compounds, forming the systems, are different, has the highest value of γ_{av}.

3. Principles of the Prediction of Systems with High Isotope Effects

Both as a means for isotope separation and as the basis for a research technique, chemical isotope effects are more suitable the higher their absolute value. The problem of the prediction therefore usually involves the search for systems with large effects. On the other hand, the principles of the prediction must be formulated as the most rational method for finding such systems on the basis of the entire available information about chemical systems. Direct theoretical calculation and correlation estimates of the values of α are the most reliable means used in such search. However, the computational method of prediction is limited by the small availability of the required initial data. The knowledge of the thermodynamic characteristics of isotope exchange can to some extent compensate for this deficiency and can play the role of the main guiding principle.

However, the broadest base for a rational search and for a comprehensive analysis of systems is provided by the above classification of chemical exchange systems, since it is derived not only from the common causes of the occurrence of isotope effects but also ensures the possibility of employing the most readily available general chemical information.

Isotope effects should be predicted taking into account the specific purpose of the systems sought. In relation to the specific search for chemical exchange systems suitable for isotope separation on the basis of the classification described above, the principle of the selection of systems with high isotope separation factors can be formulated as follows. One of the two compounds of the system should be formed by an element in its highest oxidation state and the ligands coordinated by the element must contain donor atoms belonging to the Second Period (the σ-donor or $\sigma\pi$-donor atoms F, O, and N) and must form an unsaturated coordination sphere. The other compound must contain the given element in the smallest possible oxidation state; the ligands coordinated by this element must contain the elements of higher Periods as donor atoms ($\sigma\pi$-donor ligands with weak π-acceptor properties) and the coordination sphere must be saturated.

This principle conflicts with other requirements. Apart from a high separation factor, the "promising" chemical system must have specific qualities, namely thermodynamic stability, satisfactory kinetics of isotopic exchange, ready separability of the juxtaposed chemical forms between the juxtaposed phases, and simplicity of the interconversion of the juxtaposed chemical forms. Since the thermodynamic classification of chemical exchange systems takes into account the general chemical unity of different classes, it can serve as a basis for a general analysis of the possibilities of different classes, including also the series of specific requirements enumerated.

The prediction of isotope effects in systems which can be fruitful objects of study using the isotope effects themselves constitutes a more difficult problem which awaits solution.

Saccharinic Acids

R.A.Gakhokidze

Data on the chemistry of saccharinic acids are examined and described systematically. The alkaline degradation of mono-, oligo- and poly-saccharides is discussed, much attention being devoted to the conditions which influence the course of the reaction. It is shown that the nature of the alkali metal cation, the pH of the medium, temperature, and the structure of the carbohydrate play an important role. Data concerning the stabilisation of polysaccharides in alkali are described in detail. The problem of the applications of saccharinic acids is examined.
The bibliography includes 254 references.

I. INTRODUCTION

The complex and varied reactions of carbohydrates in alkali have long attracted the attention of investigators. However, despite vigorous research, the interconversions and degradation reactions of carbohydrates in alkaline solutions have still been inadequately studied. The conversion of reducing sugars under the influence of aqueous bases includes the following processes[1-3]: mutarotation (anomerisation); epimerisation (the Lobry de Bruyn–van Ekenstein transformation); retroaldol cleavage, the products of which are capable of new reactions; saccharinic rearrangement. The formation of carbocyclic compounds[4-8], the Cannizzaro reaction[9], and intramolecular oxidation–reduction[10] are also possible. The formation of polymeric compounds[11] (probably via aldoxyloses at elevated temperatures[12]) has also been noted. In addition, sugars form complexes (saccharinates) with metal hydroxides[13-19]. Under the influence of alkalies, glycosylamines undergo the Amadori rearrangement[20]. Alkaline agents cause numerous carbohydrate derivatives to undergo intramolecular substitutions, for example the elimination of groups such as alkyl and arenesulphonyloxy-groups, halide ions, or nitrate and sulphate ions with the formation of an epoxy-ring (an intramolecular ether)[21,22] and migration of acyl groups[21], involving isomerisation via intramolecular transesterification. However, sugars are fairly resistant to the action of a base at 5°. Thus 85–90% of a sugar (*D*-glucose, *D*-mannose, and *D*-fructose) remains unchanged after prolonged contact (9 months) with dilute sodium hydroxide[23].

The present review is an attempt to describe the present state of the chemistry of saccharinic acids†. Saccharinic acids, which are formed from reducing carbohydrates under the influence of various alkalies, include all the monobasic hydroxy-acids (deoxyaldonic acids) with the empirical formula $C_nH_{2n}O_n$, which have the same compositions as the corresponding carbohydrates. The first mention of substances of this type dates back to 1838.[28,29] The first such substance investigated was erroneously assumed to be an isomer of saccharose (sucrose)—hence the name saccharinic acids.

† For review of earlier studies, see Refs.24–27.

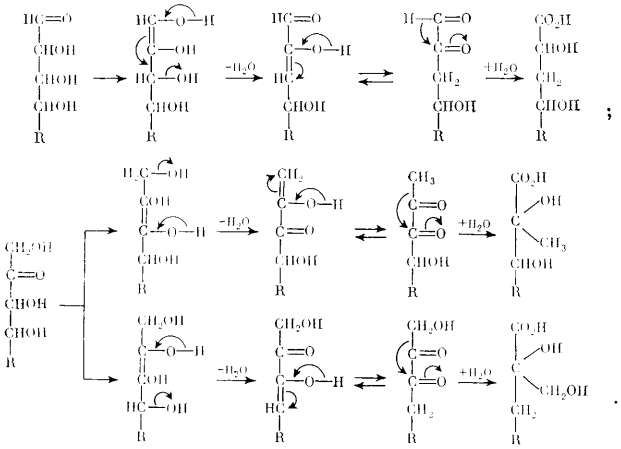
Saccharinic acids can be synthesised from non-sugar-like compounds[30] and by the oxidation of the corresponding deoxysugars. The Grignard[31] and Fischer–Kiliani (the cyanohydrin method) reactions[32,33] have also been used to synthesise saccharinic acids and their derivatives. However, the present review deals with the problems of the formation of saccharinic acids from reducing carbohydrates in an alkaline medium in the absence of oxygen. In an alkaline medium in the presence of oxygen carbohydrates undergo both oxidation and alkaline degradation with formation of a complex mixture of products#. According to their carbon skeleton, saccharinic acids belong to three types: 3-deoxyaldonic (metasaccharinic) acids (I), 2-*C*-methylaldonic (saccharinic) acids (II), and 2-*C*-(hydroxymethyl)-3-deoxyaldonic (isosaccharinic) acids (III):

The structure of saccharinic acids has been reviewed[26]. Later the configuration of α-*D*-glucoisosaccharinic acid[36-38] and its lactone[39] was established by X-ray diffraction; both proved to be *erythro*-compounds. It has been shown by chemical methods[40] that α-*D*-glucosaccharinic acid has the *ribo*-configuration. The γ-lactone of α-*D*-glucosaccharinic acid (2-*C*-methyl-*D*-ribonic acid) and hamamelose (2-*C*-hydroxymethyl-*D*-ribose), whose structure has been established by an independent method, have the same absolute configurations, which has been confirmed by the transformation of each compound into 5-deoxy-2-*C*-methyl-*D*-ribitol[41]. Branched saccharinic acids[42] and di- and tri-deoxysaccharinic acids[43,44] have been detected in the conversion products of polymeric carbohydrates in alkali. Despite the fact that saccharinic

After the oxidation of *D*-glucose and cellobiose with oxygen in a highly alkaline medium, 13 and 19 monobasic acids were isolated respectively[34]. The isolation of 21 organic acids from the products of the oxidation of cellobiose by molecular oxygen in an alkaline medium has been reported[35].

acids are known to form in highly alkaline solutions, metasaccharinic acids and their sulphur-containing derivatives have been obtained by treating carbohydrates with neutral[45-48] or acid sulphite solutions (pH 4.4–6.0; 135 °C).[49-51]

The saccharinic rearrangement of a carbohydrate is undoubtedly of wider importance in nature than has been thought hitherto. Saccharinic acids have been found in plants[52,53]; they are apparently formed from monosaccharides in weakly alkaline media and probably give rise to deoxysugars with straight and branched carbon skeletons as a result of the reduction of the carboxy-group. However, deoxidation of sugars can also take place via reductive reactions of the alcoholic groups.

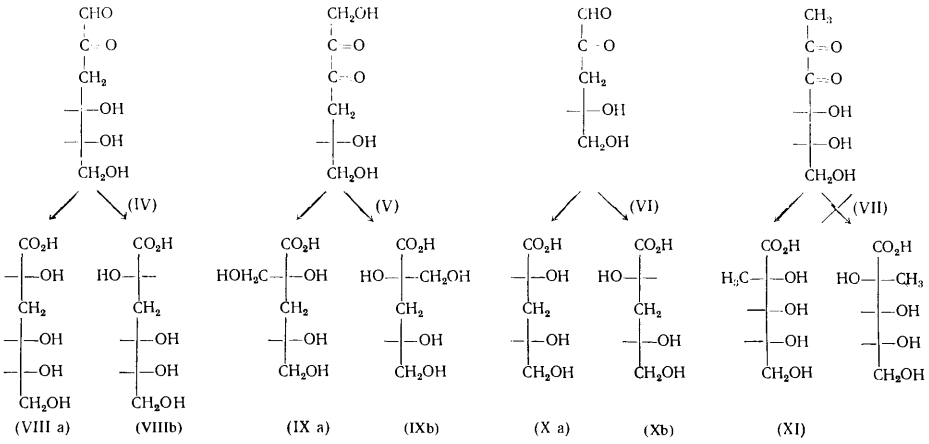


The application of gas chromatography[54-63], mass spectrometry[64-67], and spectrophotometry[68,69], as well as ion-exchange[70,71] and thin-layer[72] chromatography make it possible to determine saccharinic acids rapidly in the complex mixture obtained on alkaline degradation of carbohydrates.

II. THE MECHANISM OF THE FORMATION OF SACCHARINIC ACIDS

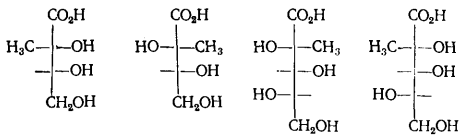
Numerous mechanisms have been proposed for the formation of saccharinic acids from reducing sugars. In order to account for the formation of saccharinic acids, Nef[11,73] proposed schemes according to which monoses are converted initially into biradicals in consequence of the elimination of water from an alcoholic group; the migration of hydrogen atoms from another, adjacent alcoholic group to a carbon atom involved in a saturated bond leads to the formation of an aldehydo-ketonic or diketonic form, which undergoes the benzilic acid rearrangement to saccharinic acids. However, this mechanism is complex and the formation of biradicals at a particular site in the chain is doubtful.

Other workers[74,75] modified Nef's scheme, postulating the formation of enediol oxides as intermediates in the isomerisation of carbohydrates. These substances are converted into diketones, which undergo the benzilic acid rearrangement. However, the formation of unsaturated epoxide structures is regarded as unlikely at the present time. It has been suggested[76] that saccharinic acids are formed via a mechanism involving the pinacol rearrangement via alcoholic epoxide forms. The formation of saccharinic acids via the recombination of carbohydrate fragments has been discussed[77,78].



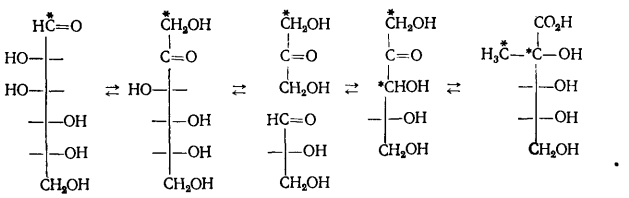
The ionic mechanism put forward by Isbell[79], who treats Nef's hypothesis from the standpoint of electronic ideas, has gained the widest currency at the present time. According to Isbell, the mechanism of the formation of saccharinic acid involves the following stages: (a) the formation and ionisation of the enediol; (b) β-elimination of a hydroxy- or alkoxy-group; (c) rearrangement to an α-dicarbonyl intermediate; (d) benzilic acid rearrangement with formation of saccharinic acid. Accordingly, the formation of saccharinic acids can be represented by the following reactions:

The postulated intermediate dicarbonyl compounds, involved in the formation of saccharinic acids, have been synthesised or isolated after the alkaline treatment of appropriately substituted sugars§. Their rapid conversion into saccharinic acids under the influence of lime water supports the Nef—Isbell mechanism. The proposed mechanism has been partly confirmed in experiments using labelled compounds[67,70,82,83].



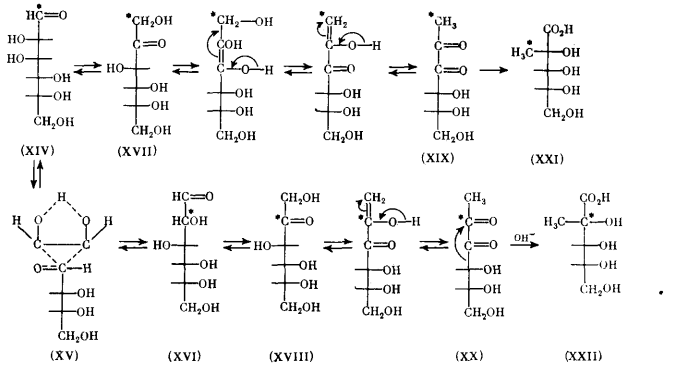
Two possible saccharinic acids are obtained from the intermediates (IV) and (V)—α- and β-*D*-glucosaccharinic acids (VIIIa, VIIIb) and α- and β-*D*-glucoisosaccharinic acids (IXa, IXb) respectively. Similarly in an alkaline medium compound (VI) gives rise to metasaccharinic acids with five carbon atoms (Xa, Xb).[84] However, treatment of compound (VII) with alkali yields only α-*D*-glucosaccharinic acid (XI)[54] (see Scheme 1).

Scheme 1



§ For details of the dicarbonyl derivatives of carbohydrates, see Theander[80] and Anet[81].

Since only compound (VII) has an asymmetric carbon atom adjoining the carbonyl group, it has been suggested[54] that the stereospecificity depends on the asymmetry of compound (VII), while compounds (IV) and (V) should give rise to two isomeric acids. Indeed treatment with alkali converts *D-arabino*-2-hexosulose (*D*-glucosone) preferentially into *D*-mannonic acid[85]. However, treatment of *D*-xylose[57] and *L*-sorbose[33] with calcium hydroxide yields respectively α- and β-*D*-xylosaccharinic acids (XIIa, XIIb) and α- and β-*L*-galactosaccharinic acids (XIIIa, XIIIb):



(XIIa) (XIIb) (XIIIa) (XIIIb)

It has been shown with the aid of labelled hexoses[82,83] that different acids arise via different mechanisms. Treatment of *D*-[1-^{14}C] galactose with $Ca(OH)_2$ yielded α-*D*-galactometasaccharinic acid. It was found that 95% of the initial activity was located in the carboxy-group, which is fully consistent with the Nef–Isbell mechanism. Under the same conditions, α-*D*-glucoisosaccharinic acid, in which 94% of the initial activity was contained in $C_{(2)}$, was obtained from [1-^{14}C] lactose; this is also fully consistent with the Nef–Isbell mechanism. However, treatment of *D*-[1-^{14}C] mannose with calcium hydroxide led to the formation of α-*D*-glucosaccharinic acid containing 39% of the initial activity in the CH_3 group and 57% is $C_{(2)}$. In contrast to these observations, the Nef–Isbell mechanism predicts that the radioactivity should appear wholly in the CH_3 group. To account for this phenomenon, it has been suggested[86] that *D*-mannose undergoes rapid retroaldol decomposition under the reaction conditions and that labelled [1,3-^{14}C] hexose is reformed from the resulting dihydroxyacetone and *D*-glyceraldehyde and undergoes a further rearrangement with formation of [2,2'-^{14}C] saccharinic acid.

However, this hypothesis was rejected by Sowden and coworkers[26,82]. They believe that the recombination of trioses should lead to a uniform distribution of the radioactivity in the ketohexose between $C_{(1)}$ abd $C_{(2)}$. According to Isbell's scheme, this would lead to α-*D*-glucosaccharinic acid in which the $C_{(2)}$ atom and the carbon atom in CH_3 would be equally radioactive. The isomerisation of *D*-[1,^{14}C] mannose (XIV) to *D*-[2-^{14}C] glucose (XVI) as a result of the intramolecular rupture of the bond between $C_{(2)}$ and $C_{(3)}$ in the intermediate (XV) has been suggested[87]. *D*-[1-^{14}C] fructose (XVII) and *D*-[2-^{14}C] fructose (XVIII) can give rise, via the Isbell and intramolecular mechanisms respectively, to α-*D*-glucosaccharinic acid with the radioactivity in the methyl group [compound (XXI)] and at $C_{(2)}$ [compound (XXII)]:

(XIV) (XVII) (XIX) (XXI)

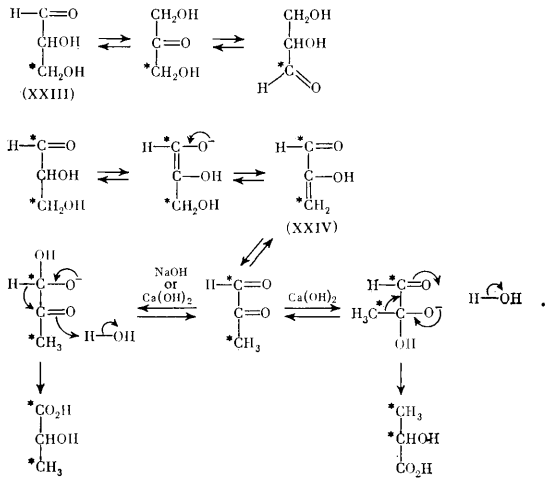
(XV) (XVI) (XVIII) (XX) (XXII)

However, the hypothesis of the migration of the methyl and [CH_2OH–CHOH–CHOH] groups respectively in the dicarbonyl intermediates (XIX) and (XX) does not take into account the experimental results, and the formation of α-*D*-glucosaccharinic acid with a reduced radioactivity (2%) in the carboxy-group when the methyl group migrates in compound (XX) weakens this hypothesis. Furthermore, *D*-fructose, prepared from *D*-[1-^{14}C] mannose under conditions analogous to those used to obtain α-*D*-glucosaccharinic acid, contained 98% of the radioactivity in $C_{(1)}$.[23]

According to another mechanism[23], α-*D*-glucosaccharinic acid can be formed from a hexose via a 3-deoxydicarbonyl intermediate. In fact this product gives rise to metasaccharinic acids only[81,88,89]. Thus the problem of the mechanism of the formation of *D*-glucosaccharinic acid remains virtually open.

The formation of saccharinic acids with four, five, and six carbon atoms from *D*-xylose and *D*-fructose[56], as well as the detection of α-*D*-glucosaccharinic acid in the products of the interaction of $Ca(OH)_2$ with glycerose[90] show that the reaction proceeds via a mechanism involving fragmentation and recombination together with direct isomerisation.

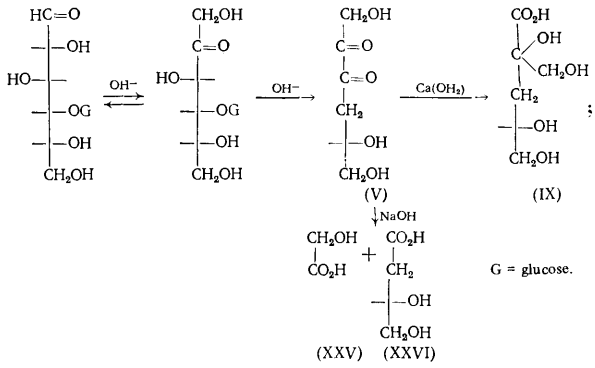
III. THE INFLUENCE OF THE NATURE OF THE ALKALI METAL CATION, pH, AND TEMPERATURE ON THE FORMATION OF SACCHARINIC ACIDS



Early studies by Kiliani and Nef[26] showed that glucose is converted into glucosaccharinic acids under the influence of calcium hydroxide, while treatment of the sugar with sodium hydroxide leads mainly to metasaccharinic acid and insignificant amounts of isosaccharinic acid¶. An analogous result was obtained when *D*-fructose was treated with a concentrated solution of sodium hydroxide; *D*-glucosaccharinic acid was not detected, but it was the main product on treatment of *D*-fructose with $Ca(OH)_2$.[56] After treating *D*-xylose with $Ca(OH)_2$, α- and β-*D*-xylosaccharinic acids together with other acids were isolated[56]. Consequently the influence of

¶ *D*-[1-^{14}C]galactose and *D*-[1-^{14}C] mannose isomerise on treatment with $Ca(OH)_2$ to α-*D*-galactometasaccharinic acid and α-*D*-glucosaccharinic acid respectively[82]. It has been shown[91] that the yields of *D*-glucometasaccharinic and α-*D*-glucosaccharinic acids become comparable at high calcium ion concentrations.

the nature of the cation on the mechanism of the formation of saccharinic acid is evident and can be attributed to the kinetic effect[92]†.



It has been shown[90] that *D*-[3-^{14}C]glycerose (XXIII) isomerises in 1.68 *N* NaOH at 25 °C to lactic acid, where the radioactivity is distributed only between the $C_{(1)}$ and $C_{(3)}$ atoms. An analogous result was obtained on treating *D*-[1-^{14}C]glucose with 3 *N* NaOH at 25 °C.[97] In contrast to this, *D*-[2-^{14}C]glycerose isomerises in saturated lime water at 25 °C to lactic acid with 37, 13 and 50% of the initial radioactivity in the $C_{(1)}$, $C_{(2)}$, and $C_{(3)}$ atoms respectively[90].

Evidently the epimerisation glycerose ⇆ 1,3-dihydroxypropanone is faster in an alkaline medium than the saccharinic rearrangement. In an alkaline medium a hydoxide ion adds to the aldehyde carbonyl of the α-dicarbonyl intermediate [methylglyoxal (XXIV)]. In the presence of $Ca(OH)_2$ the hydroxide ion attacks the ketone carbonyl group in (XXIV), which can probably be accounted for by the stabilisation of the transition state as a result of interaction with the divalent calcium ion and subsequent migration of the methyl group. *D,L*-Lactic acid is the main product of the alkaline degradation of 1-O-substituted fructose[86] and 6-O-substituted sugars—6-O-methyl-*D*-glucose[98] and melibiose)6-O-α-*D*-galactopyranosyl-*D*-glucose).[99,100]

The intermediate in the formation of isosaccharinic acids postulated by the Nef–Isbell theory, namely 4-deoxy-*D*-glycerohexose-2,3-diulose (V), was isolated[110] on treating maltose with sodium hydroxide; treatment with calcium hydroxide yielded only traces of compound (V). Compound (V), isolated on treatment with an aqueous solution of calcium hydroxide, was converted almost quantitatively into *D*-glucoisosaccharinic acid. The α-diketo-group in the sugar molecule is also subjected to extremely vigorous attack by alkalies, which leads to the dissociation of the carbon–carbon bond. Calcium ions catalyse the benzilic acid rearrangement of diulose to saccharinic acids, i.e. (V) → (IX), while sodium ions promote cleavage into fragments (Scheme 2).

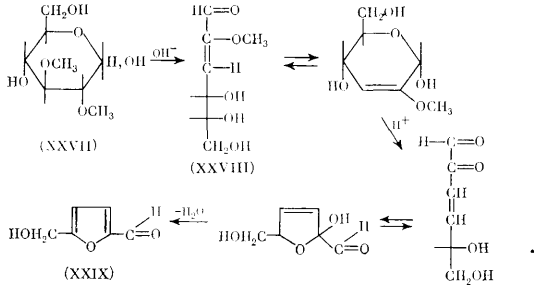
Scheme 2

It has been shown[102] that treatment of 4-O-substituted *D*-glucose with sodium hydroxide results in the formation of large amounts of fragmentation products—glycolic acid (XXV) and *D*-3,4-dihydroxybutyric acid (XXVI). The formation of formic and lactic acids in concentrated sodium hydroxide solution is accelerated on raising the temperature. The temperature dependence of the relative amounts of acids obtained when hydrocellulose is acted upon by NaOH has been demonstrated[58].

A change in the pH of the reaction medium has a considerable influence on the formation of saccharinic acids as a function of the concentration of the alkali and sugar. For example, *D*-glucose gives rise to a greater amount of acid at low hydroxide concentrations than at high concentrations[91]. The main products of the alkaline degradation of cellobiose with sodium hydroxide are isosaccharinic acids together with small amounts of 2-deoxytetronic, 3-deoxypentonic, and 3,4-dideoxypentonic acids[43,103,104], while on treatment of cellobiose with bicarbonate the latter predominate[43].

IV. THE INFLUENCE OF SUBSTITUENTS ON THE FORMATION OF SACCHARINIC ACIDS

1. The Influence of the 1-O-Substituent



Acetal-O-substituted carbohydrates (alkyl glycosides[105–108], sucrose[109], and trehalose[109]) are usually stable in alkaline solutions free from oxygen and undergo alkaline hydrolysis only under severe conditions, for example, on treatment with a 10% NaOH solution for several hours at 170 °C. However, the glycosides derived from phenols, enols, and alcohols substituted by an electronegative group in the β-position are sensitive to the action of alkalies[110].

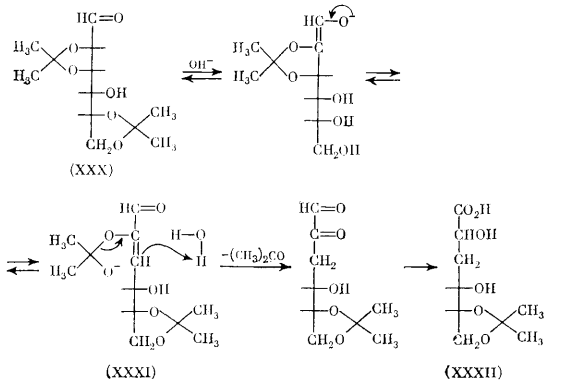
1-O-Substituted ketoses are converted into the usual saccharinic acids. For example, treatment of 1-O-methyl-*D*-fructose with lime water gives rise to the formation of α-*D*-glucosaccharinic acid with a higher yield (together with *D,L*-lactic acid) than that obtained from *D*-fructose[86]. When *D*-fructose 1,6-diphosphate is acted upon by alkali (0.46 *N* NaOH at 100 °C, 15 min), α-*D*-glucosaccharinic acid 6-phosphate is formed[111], while alkaline degradation of *D*-glucose 6-phosphate leads to the formation of the 6-phosphate of *D*-glucometasaccharinic acid[112].

† Many reactions of sugars depend on the nature of the cation of the alkali. For example, in the Lobry de Bruyn–van Ekenstein reaction divalent metal hydroxides are somewhat more effective (at comparable concentrations) than sodium or potassium hydroxide. The calcium ion has a stronger influence than the barium ion[93,94]. In methylation with dimethyl sulphate sodium hydroxide is more effective than potassium hydroxide[93]. The tendency towards the formation of an alkoxide in the reaction of cellulose with alkali increases in the sequence LiOH < NaOH < KOH < RbOH < CsOH < organic quaternary bases[96].

2. The Influence of the 2-O-Substituent

2-O-Substituted aldoses are relatively stable in alkaline solutions and do not give rise to saccharinic acids[113-115]. The absorption spectrum of 2,3-di-O-methyl-*D*-glucose (XXVII) in an alkaline solution corresponds to the 1,2-unsaturated carbonyl derivative (XXVIII), which is readily converted into 5-hydroxymethylfurfural (XXIX) under acid conditions[115].

(XXVII) (XXVIII) (XXIX)



Substitution at $C_{(2)}$ prevents the formation of saccharinic acid as a result of the inability of the carbohydrate residue at CO_2 to ionise. However, it has been shown for xylans isolated from wood and containing 4-O-methyl-α-*D*-glucopyranosyluronic acid residues at $C_{(2)}$,[116] 2-O-*D*-xylopyranosyl-*L*-arabinose[113], 2-O-(4-O-methyl-α-*D*-glucuronopyranosyl)-*D*-xylose[117], and 4-O-β-*D*-glucopyranosyl)-2-O-methyl-β-*D*-glucose (2-O-methylcellobiose)[118] that the 2-O-substituent does not inhibit the degradation process at high temperatures. In 1 *M* NaOH (in the absence of oxygen) 2,3,4-tri-O-methyl-*D*-glucose decomposes fully after 5 h at 100 °C. Formic, acetic, lactic, glycolic, and glyceric acids were isolated from the reaction mixture. Under analogous conditions, 2-O-methylcellobiose is fully converted after 4 h. Apart from the products obtained from 2,3,4-tri-O-methyl-*D*-glucose, *D*-glucose and saccharinic acids were detected in the reaction products[118]. In both cases the 4-O-substituted compound (XXVIII) was identified. The main product of the conversion of 2-deoxy-*D*-*arabino*-hexose under the influence of alkali is 3,6-anhydro-2-deoxy-*D*-*arabino*-hexose[119].

3. The Influence of the 3-O-Substituent

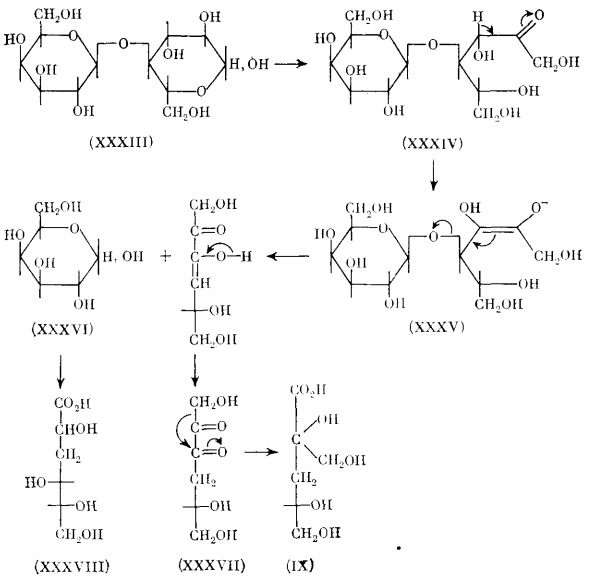
Alkaline degradation of 3-O-substituted sugars, namely 3-O-methyl-*D*-glucose[120], 3-O-methyl-*D*-fructose[120], 3-O-ethyl-*D*-glucose[121], 3-O-n-propyl-*D*-glucose[121], 3-O-n-butyl-*D*-glucose[121], 3-O-benzyl-*D*-glucose[121], 3-O-methane-sulphonyl-*D*-glucose[121], and 3-O-toluene-*p*-sulphonyl-*D*-glucose[121], leads to the preferential formation of α- and β-*D*-glucometasaccharinic acids: the degradation proceeds more readily in lime water than in a solution of sodium hydroxide of the same normaility[120]. The conversion of 3,6-anhydro-*D*-glucose in lime water[122] leads to the formation of mainly *D*-glucometasaccharinic acid (apart from traces of lactic, glyceric, and 2-deoxypentonic acids, which are obtained in sodium hydroxide solutions). The main product of the alkaline degradation of 3-O-methyl-*D*-xylose with calcium hydroxide[123] is 3-deoxy-*threo*-pentonic acid, but a small amount of 3-deoxy-*erythro*-pentonic acid was also detected. Glycosyl phosphates and other non-reducing phosphates are resistant to the action of alkalies. However, compounds such as glycerose 3-phosphate, *D*-ribose 3-phosphate, and *D*-glucose 3-phosphate readily undergo β-elimination with formation of *D,L*-lactic, *D*-glucometasaccharinic, and 3-deoxypentonic acids[124].

3, 6-Di-O-methyl-*D*-glucose[98] and 6-O-β-*D*-glucopyranosyl-3-O-methyl-*D*-glucose[125] are converted into 6-O-methyl-*D*-glucometasaccharinic and 6-O-β-*D*-glucopyranosyl-*D*-glucometasaccharinic acids under the influence of $Ca(OH)_2$ at room temperature. Alkaline degradation of 3-O-methyl-*D*-glucose 6-(dihydrogen phosphate) leads to the formation of the 6-(dihydrogen phosphates) of *D*-glucometasaccharinic acids[126], while the conversion of *D*-arabinose 3,5-(hydrogen phosphate) or *D*-xylose 3,5-(hydrogen phosphate) results in the formation of a mixture of 3-deoxy-5-phospho-*D*-*erythro*-pentonic and 3-deoxy-5-phospho-*D*-*threo*-pentonic acids[127].

2-O-Substituted aldoses are stable in relation to the action of alkali, but 2,3; 5,6-di-O-isopropylidene-*D*-mannose (XXX) is converted under the influence of calcium hydroxide[128] into 5,6-O-isopropylidene-*D*-glucometasaccharinic acids (XXXII), since β-elimination leads to the removal of the 2,3-O-isopropylidene group#.

(XXX) (XXXI) (XXXII)

4. The Influence of the 4-O-Substituent



The alkaline degradation of 4-O-substituted sugars leads to the formation of isosaccharinic acids. For example, the main products of the degradation of 4-O-methyl-*D*-glucose[54,102,129,130], 4-O-methyl-*D*-fructose[129], and 4,6-O-benzylidene-*D*-glucose[128] are *D*-glucoisosaccharinic acids. Treatment of 4,6-di-O-methyl-*D*-glucose with alkali[98] results in the formation of 5-O-methyl-α-*D*-glucoisosaccharinic acid. Treatment of *D*-glucose 4,6-(hydrogen phosphate) with alkali leads to the formation of a mixture of 2-*C*-(hydroxymethyl)-3-deoxy-5-phospho-*D*-*erythro*-pentonic and the corresponding *threo*-pentonic acids (5-phospho-*D*-glucoisosaccharinic acids).[127] 4-O-Methyl-*D*-xylose is converted into *D*-xyloisosaccharinic acids in alkali.[131]

The formation of saccharinic acids from 4-O-substituted sugars takes place more slowly than from 3-O-substituted sugars. 4-O-Substituted ketoses decompose at a higher rate than the related aldoses, which is consistent with the Nef–Isbell mechanism. However, lactose and lactulose are converted more slowly than maltose or maltulose. Cellobiose decomposes at approximately the same rate as lactose.

Compound (XXX) remains unchanged at 25 °C in saturated lime water free from oxygen as a result of the inability of the initial anion (XXXI) to be converted into an α-diketone and subsequently into compound (XXXII). However, at 100 °C dissociation takes place with formation of compound (XXXII).

5. The Influence of the 6-O-Substituent

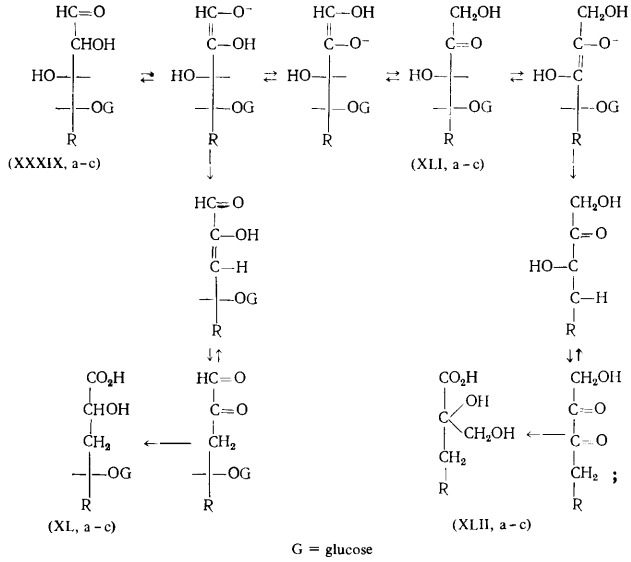
Substitution at $C_{(6)}$ activates attack by alkali on the hydroxy-groups at $C_{(3)}$ or $C_{(4)}$. For example, 3,6- and 4,6-di-O-methyl-*D*-glucoses decompose faster in lime water than the corresponding 3- and 4-O-methyl-*D*-glucoses. When *D*-glucose is treated with calcium hydroxide, the product is mainly α-*D*-glucosaccharinic acid (together with a small amount of *D*-glucoisosaccharinic acids), while analogous treatment of 6-O-substituted *D*-glucose leads to the formation of α- and β-*D*-glucometasaccharinic acids. It has been shown[98,99] that the main products of the conversion of 6-O-substituted sugars are *D*,*L*-lactic acid and 6-O-substituted metasaccharinic acid.

V. THE FORMATION OF SACCHARINIC ACIDS BY THE CLEAVAGE OF OLIGO- AND POLY-SACCHARIDES WITH ALKALI

Treatment of polysaccharides with alkalies has been described in detail in a number of reviews[110,132-137]. This section deals with the formation of saccharinic acids in the absence of oxygen. Alkaline degradation of polysaccharides proceeds under these conditions with formation of definite types of saccharinic acids characteristic of the bonds present in the polysaccharide, and chain branching has a specific influence on the cleavage process.

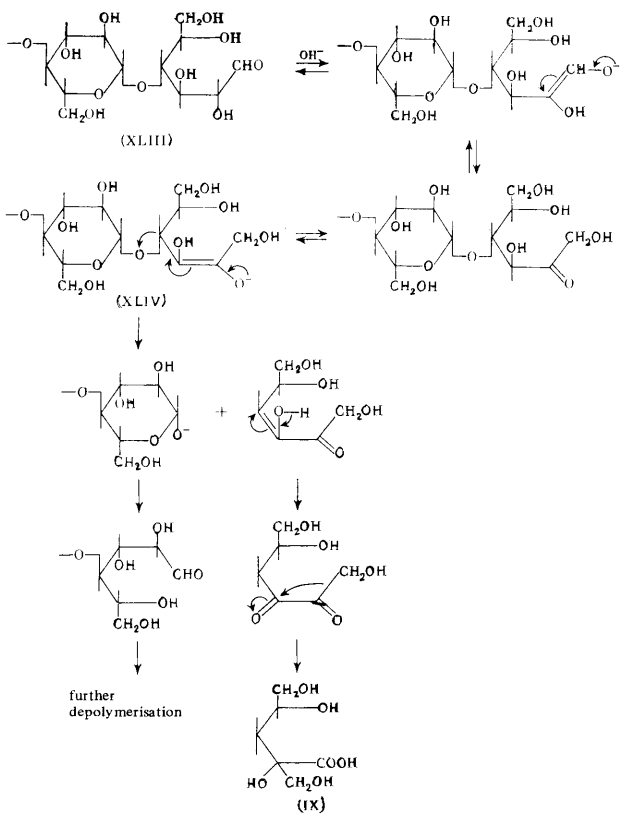
1. Glycans with (1→4)-Linkages

(*a*) *Lactose and Lactulose.* It has been known for a long time that reducing disaccharides with (1 → 4)-bonds are cleaved by lime water with formation of α-*D*-isosaccharinic acid. Thus early investigations[138] showed that alkaline degradation of lactose leads to the formation of succinic acid, formic acid, and a crystalline lactone, which has been identified[139] as α-*D*-glucosaccharinolactone. Approximately 20% of this lactone is formed from lactose on treatment with $Ca(OH)_2$. Apart from this, *D*-galactose[140,141], formaldehyde[142], and other saccharinic acids were detected in the reaction products. The presence of a small amount of β-*D*-glucoisosaccharinic acid has also been demonstrated[11,54,129,143-146]. α-*D*-Galactometasaccharinic acid was first detected as a product of prolonged treatment of lactose with lime water at room temperature[147]. It was later shown that it can be obtained by treating *D*-galactose[26] or melibiose[99] with solutions of sodium and calcium hydroxides. Crystalline lactulose (4-O-β-*D*-galactopyranosyl-*D*-fructose) was isolated from the products obtained on treating lactose with alkali[138]. At the very beginning of the process lactose (XXXIII) is slowly converted into the corresponding lactulose (XXXIV). Lactulose is then converted at a higher rate, via postulated intermediates, (XXXV) → (XXXVII), into a mixture of α- and β-*D*-glucoisosaccharinic acids (IX) and *D*-galactose (XXXVI), which is converted in its turn into α- and β-*D*-galactometasaccharinic acids (XXXVII).[144]



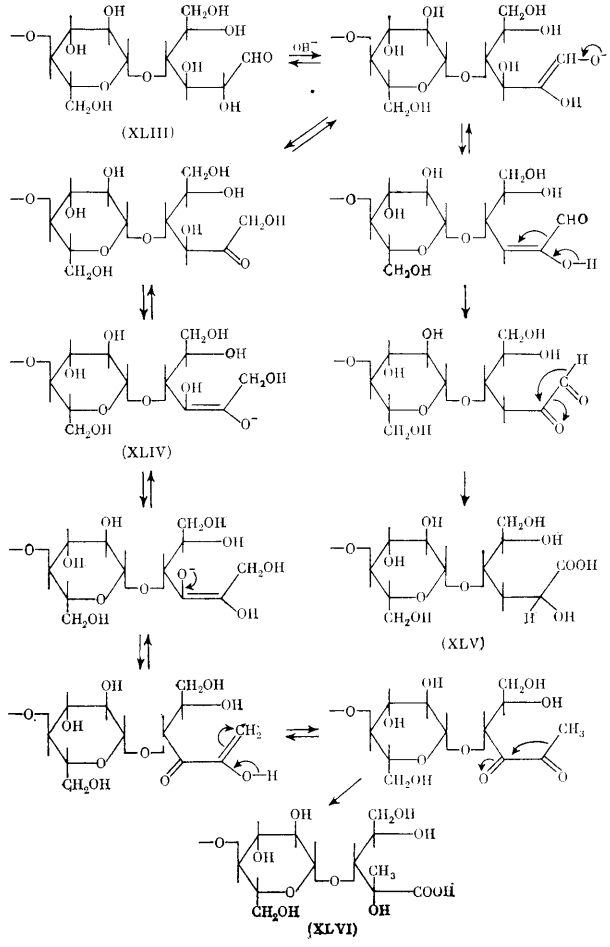
(*b*) *Maltose and Maltulose.* When maltose[54,144] or maltulose[144] are treated with $Ca(OH)_2$ at 25 °C a mixture of α- and β-*D*-glucoisosaccharinic acids is formed. Alkaline degradation of maltose should proceed via maltulose, like the degradation of lactose. However, maltulose decomposes so fast in an alkaline medium, compared with lactulose, that its detection is virtually impossible.

(*c*) *Cello-, manno-, and xylo-oligosaccharides.* It has been established[148] that α-*D*-glucoisosaccharinic acid is the main product of the degradation of cellobiose by $Ca(OH)_2$. Apart from isosaccharinic acid, cellobiulose, *D*-glucose, and *D*-fructose are formed. In NaOH solution other acid products are detected together with isosaccharinic acid. It has been shown[149] that, under the influence of 1 *M* NaOH, cellobiose gives rise to the epimeric 4-O-β-*D*-glucopyranosyl-*D*-mannose (glucosylmannose), cellobiulose, *D*-glucose, *D*-fructose, and *D*-mannose. When cellobiose was treated with 0.04 *N* $Ba(OH)_2$ at 25° and 50 °C, a considerable amount of *D*-glucosaccharinic acid and *D*-glucose was detected[150,151], apart from small amounts of glyceric, 3,4-dihydroxybutyric, and *D*-arabinonic acid. In the presence of oxygen the oxidation reaction involving the formation of aidonic acids predominates[150,152,153]. Cellobiulose[148] reacts with $Ca(OH)_2$ to form cellobiose, *D*-fructose, *D*-glucose, and α-*D*-glucoisosaccharinic acid. Alkaline degradation of cellotetraose[148] and partly hydrolysed cellulose[132] leads to the formation of the same *D*-glucoisosaccharinic acid.



Xylobiose (4-O-β-*D*-xylopyranosyl-*D*-xylose)[154,155] (XXXIXc) undergoes an analogous degradation under the influence of alkali, probably via xylobiulose (4-O-β-*D*-xylopyranosyl-*D*-xylose) (XLIc) and intermediates with formation of 2-*C*-(hydroxy methyl)-2,4-dihydroxybutyric acid (XLIIc). Compound (XLIIc) is formed similarly from xylotriose[156]. By investigating the kinetics of the degradation of the xylotetraose molecule from the reducing end, it has been established[157] that the overall rate of degradation is largely determined by the rate of conversion of the anion derived from the reducing end of the xylose unit into a xylulose unit. In the second stage of the degradation reaction, which determines the overall rate, the terminal group of xylulose rearranges with dissociation of the glycosidic linkage. This reaction stage is slower for cellotetraose than for xylotetraose and the rate is

independent of the number of xylose units in the oligomer. On treatment with bases, isosaccharinic acids (XLII, a-c) and O-glycosylsaccharinic acids (XL,a-c) respectively are formed from cellobiose (XXXIXa), 4-O-β-*D*-mannopyranosyl-*D*-mannose (XXXIXb), and 4-O-β-*D*-xylopyranosyl-*D*-xylose (XXXIXc). O-Glycosylsaccharinic acids hydrolyse to form metasaccharinic acids[158] (Scheme 3):



Scheme 3

(*d*) *Cellulose.* Isosaccharinic acid (IX) is the main product of the degradation of cellulose (XLIII) by alkalies[102,159-161] (the "peeling" process).

Alkaline degradation of cellulose and other polysaccharides usually does not go to completion. The termination of the "peeling" process is due to the conversion of the reducing monosaccharide terminal units into non-reducing saccharinic acids[159,162]. Machell and coworkers[163,164] subjected alkali-stabilised hydrocellulose to acid hydrolysis and isolated *D*-glucometasaccharinic acids, whose formation on treatment with alkali may be a consequence of the β-elimination of the hydroxygroup at the $C_{(3)}$ atom in terminal *D*-glucose and subsequent rearrangement of the resulting enol. *D*-Glucometasaccharinic acids have also been isolated from the hydrolysate of sulphate cellulose from pine, demonstrating the occurrence of the stabilisation reaction during sulphate digestion[165]. Small amounts of α-*D*-glucosaccharinic acid have also been detected[163]. However, the formation of the usual stable saccharinic end units (XLV) is difficult, since the intermediate enol (XLIV), produced in the course of the formation of the metasaccharinic terminal units, (XLIII) → (XLVI), can readily undergo transformations via the alternative mechanism (XLIII) → (IX):

Hydrocellulose derived from cotton cellulose subjected to alkaline treatment at 170 °C included α- and β-*D*-glucometasaccharinic and 2-*C*-methylglyceric acids and a smaller amount of α-*D*-glucosaccharinic acid[166]. 2-*C*-Methylglyceric acid has also been detected in the products of the hydrolysis of unbleached eucalyptus and pine celluloses[167].

The stabilisation reaction ("inhibition" process) is usually slower than the degradation reaction ("peeling" process) from the reducing end owing to the influence of the 4-O-substituent. It has been shown[168] that the activation energy

for the degradation of cellulose under the influence of a 5% NaOH solution is 24 kcal mol^{-1}, while the activation energy for the stabilisation reaction is 34 kcal mol^{-1}, the rate of stabilisation increasing with increase of temperature. Above 150 °C glucosidic linkages are hydrolysed with formation of new reducing end groups, which promote further degradation via the "peeling" mechanism[169]. It has been shown[170] that the rate of hydrolysis of the glucosidic linkages in cotton cellulose is directly proportional to the concentration of hydroxide ions and the activation energy is 35.9 kcal $mole^{-1}$. Hydrocellulose undergoes degradation faster and the sensitivity of the pre-hydrolysed wood celluloses to alkali increases during alkaline digestion[171]. With decrease of the degree of polymerisation, the rate of degradation of hydrocellulose increases[162,172].

Much attention has been devoted in recent years to the problem of the formation of saccharinic acids from wood polysaccharides during sulphate digestion. As was to be expected, the main products (50%) of the sulphate digestion of pine cellulose are *D*-glucoisosaccharinic acids[104]. Lactic acid (20%) and insignificant amounts of glycolic, 2-hydroxybutyric, 3-hydroxypropionic, 2,5-dihydroxyvaleric, *D*-xyloisosaccharinic, and 3-deoxypentonic acids were also detected. *D*-Xyloisosaccharinic and *D*-glucoisosaccharinic acids predominate in the sulphate digestion of birchwood[104].

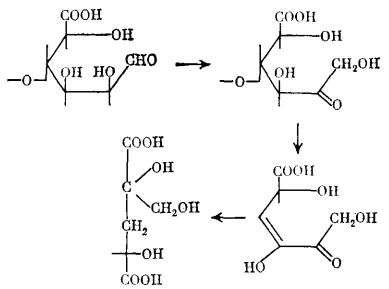
The main products of the conversion of hydrocellulose[175], cotton cellulose[177], and cellobiose[150,186] under the influence of alkalies in the absence of oxygen are isosaccharinic acids, while treatment with atmospheric oxygen in an alkaline medium leads to the oxidation of the terminal aldehyde group to aldonic (mainly arabinonic, mannonic, and erythronic) acids. The oxidative stabilisation of cellulose, glucomannan, and xylan takes place with the intermediate formation of glucosone (*D-arabino*-hexosulose) and xylosone (*D-threo*-pentosulose) structures and their conversion into aldonic acid residues[85,181,182,187].

Alkaline degradation of cellulose is of enormous theoretical and practical importance. In the first place it must be taken into account in the isolation of cellulose from plant materials (alkaline digestion, refining) and chemical processing of cellulose (manufacture of viscose fibre, ethers, xanthates, and certain partly substituted cellulose derivatives for technical purposes, mercerisation of textile materials) in an alkaline medium. Since the degradation of cellulose from the reducing end, which occurs inevitably to some extent under these conditions, leads to a considerable loss of cellulose in the form of low-molecular-weight substances (for example, in the manufacture of cellulose its yield reaches only 20–45% depending on the manufacturing method used), the reduction of losses of this kind to a minimum is an important task for the paper and textile industries. A decrease of these losses can be achieved, in principle, in different ways: by modifying the reducing end groups of cellulose with formation of structural end units resistant to the action of alkalies (by glucosidation and reduction or oxidation of hemiacetal groups) or by decreasing the degree of degradation of cellulose from the reducing end as a result of the acceleration of the stabilisation reaction[136].

The resistance of polysaccharides to the action of alkalies can be increased by the catalytic hydrogenation[188] and reduction with sodium tetrahydroborate[131,159,162,180,188–197] of the terminal aldehyde groups to primary alcoholic groups, by the oxidation of the reducing groups to aldonic acids with chlorite (sodium chlorite or chlorous acid)[198–201], polysulphide (usually sodium polysulphide)[165,176,188,201–207], bisulphite (sodium bisulphite or a mixture of sodium bisulphite and sulphite)[208], and a copper ammine solution[209], by glycosidation (treatment of the polysaccharide with an alcoholic solution of hydrogen chloride[210] or methylation with the aid of dimethyl sulphate and alkali and subsequent treatment with metnyl iodide and silver oxide[131]), by thermal dehydration in an inert medium at 175–220 °C (this probably leads to the formation of an intramolecular anhydride incorporating a glycosidic hydroxyl)[211], and by the conversion of the reducing end groups into mercapto-groups under the influence of hydrogen sulphide in the presence of aqueous sodium carbonate[212].

At the same time there are indications that the degradation of cellulose[158,172] and model compounds[213] can be limited by accelerating the stabilisation reaction with the aid of alkaline earth metal ions (Ca^{2+}, Sr^{2+}, Ba^{2+}). Magnesium[175,187,214–217] and lanthanum[184,218] compounds proved to be the most effective. The role of inhibitors has not been established accurately. It has not yet been fully demonstrated that bivalent cations stabilise the intermediate enol as a result of complex formation[121,219,220] or influence the benzilic rearrangement[102]. Iron, cobalt, copper, and manganese salts have an appreciable catalytic effect on the rate of degradation[35,184,217], while the introduction of lignin, xylan, and glucose intensifies the catalysis by heavy metals[217]. The influence of a multiplicity of reagents has been investigated in order to increase the resistance of polysaccharides to the action of alkalies[221–223].

(*e*) *Amylose.* Amylose is an alkali-sensitive component of starch. In dilute alkaline solutions in the absence of oxygen amylose is poorly cleaved and degradation of potato amylose (degree of polymerisation 415) ceases after the elimination of 230 glucose units from each chain[224]. On treatment of amylose with oxygen-free 1 *N* and 0.5 *N* NaOH at 100 °C, stepwise depolymerisation takes place vigorously. The degradation proceeds with formation of *D*-glucoisosaccharinic, formic, and lactic acids, while the stabilisation reaction leads to the formation of alkali-resistant amylose with a *D*-glucometasaccharinic end-group[225,226].

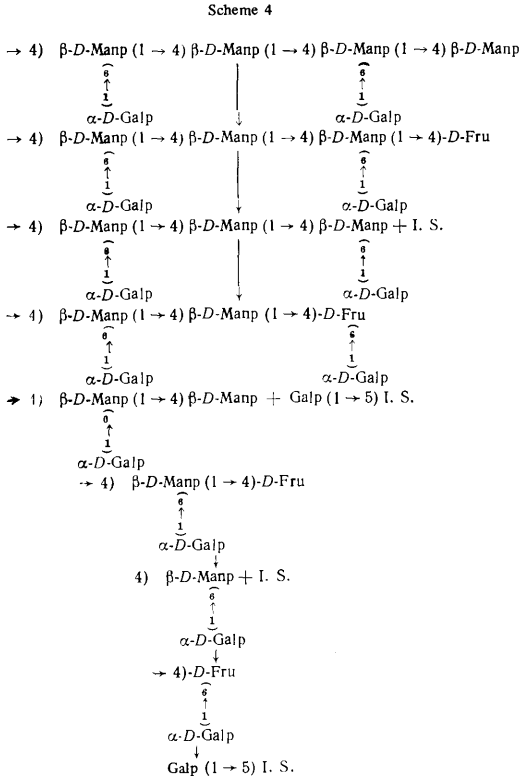


In contrast to amylose, the second fraction of starch (amylopectin) is relatively resistant to the action of alkalies and undergoes only insignificant degradation on treatment with 1 *N* NaOH in the absence of oxygen at room temperature[227], which is apparently due to its highly branched structure. A kinetic study of the degradation of amylose has been made[228]. At 100 °C an increase of the concentration of alkali to 0.1 *N* entails an increase of the rate of degradation. Higher concentrations of alkali do not affect the rate of degradation, while the rate of the stabilisation reaction increases on raising the concentration of alkali to 1.5 *N*. The activation energies for the degradation and stabilisation reactions in 1.25 *N* NaOH are 21.1 and 19.3 kcal mol^{-1} respectively[228].

(*f*) *Xylan.* The xylan from corn cobs is fairly resistant to the action of 1 *N* NaOH at 100 °C [156]§, while its oxidative alkaline degradation leads to large amounts of 3-deoxy-2-*C*-hydroxymethyltetronic acid (xyloisosaccharinic acids)[178]. However, when arabinoxylan from rye flour is treated with an oxygen-free dilute aqueous solution of sodium hydroxide, 3-deoxy-2-*C*-hydroxymethyltetronic and other acids are formed at room temperature[131]. Alkaline degradation of birch xylan in the absence and presence of oxygen leads to the formation of approximately equal amounts of xyloisosaccharinic

§ It has been shown[178] that the molecule of the xylan from corn cobs contains *L*-arabinoduranose residues as well as glucuronic acid and its 4-O-methyl derivative and that the latter add to the main chain via (1 → 2)-linkages. The branching of the $C_{(2)}$ atom in the main chain, joined by (1 → 4)-linkages, should arrest the degradation process.

acid[183]. It has been shown[131] that the inhibition of the degradation is caused by the conversion of the reducing end groups into non-reducing xylometasaccharinic units. After preliminary reduction with tetrahydroborate[131,188], xylans become resistant to the action of alkali and the formation of acids or a decrease of the molecular weight is not observed.



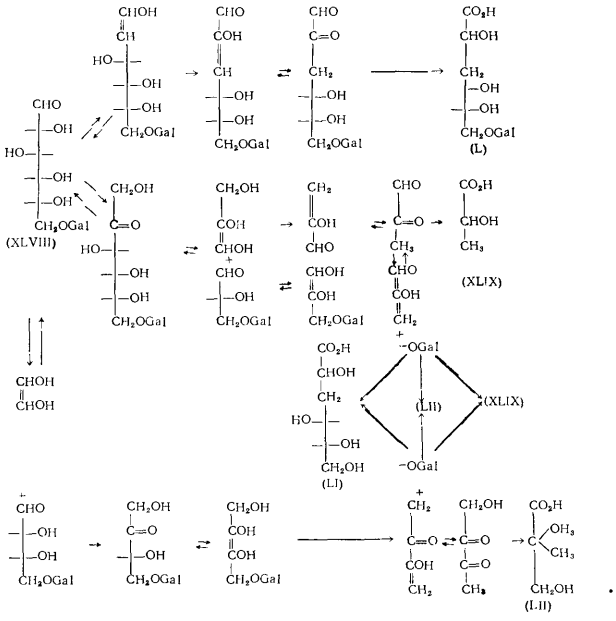
(*g*) *Alginic acid.* The main products of the degradation of alginic acid (heteroglucuronoglycan consisting of *D*-mannuronic and *D*-guluronic acid residues) salts and esters under the influence of alkalies are 3-deoxy-2-*C*-hydroxymethyl-*D*-*erythro*(*threo*)-pentaric acids (dibasic isosaccharinic acids with six carbon atoms) (XLVII) [229]:

3-Deoxy-2-*C*-hydroxymethylpentaric acids (with the *threo*-isomer predominating) are formed also when 4-O-methyl-*D*-glucuronic acid is treated with alkali[230]. The ready isomerisation of 4-O-methyl-*D*-glucuronic acid to the corresponding hexulose in an alkaline medium[231] supports the proposed mechanism.

(*h*) *Guaran.* The alkaline degradation of guaran [a polysaccharide with a main chain consisting of β-(1 → 4)-*D*-mannopyranose residues, to the alternate members of which α-*D*-galactopyranose residues are added via the $C_{(6)}$ atoms] leads to the formation of *D*-glucoisosaccharinic[54,145] and 5-O-α-*D*-galactopyranosyl-*D*-glucoisosaccharinic acids[145]. It has been suggested that the degradation reaction proceeds via the β-alkoxycarbonyl mechanism. The initially reducing terminal mannose residue is converted under the influence of alkali into a fructose residue, which is eliminated in the form of the enol of a dicarbonyl compound; under the reaction conditions, the enol immediately undergoes a subsequent rearrangement to isosaccharinic acid. The formation of *D*-glucoisosaccharinic acid and 5-O-α-*D*-galacto-pyranosyl-*D*-glucoisosaccharinic acid is determined by the structure of guaran. The detection of *D*-galactose and equal amounts of *D*-glucoisosaccharinic and 5-O-α-*D*-galactopyranosyl-*D*-glucoisosaccharinic acids in the reaction products is consistent with the proposed mechanism (see Scheme 4).

Scheme 4

2. Glycans with (1 → 3)-Linkages

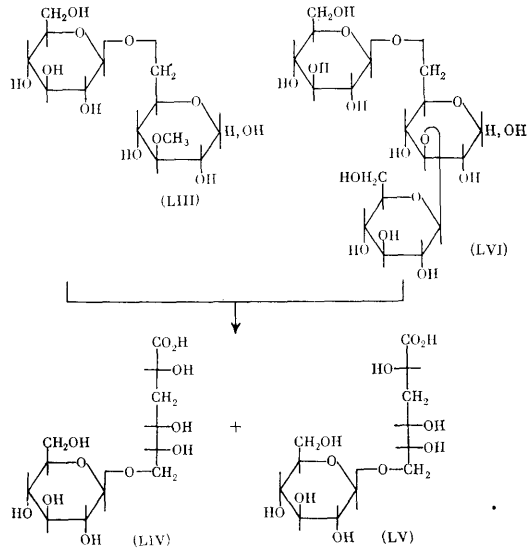


Laminaribiose (3-O-β-*D*-glucopyranosyl-*D*-glucose)[232], turanose (3-O-α-*D*-glucopyranosyl-*D*-fructose)[232], and laminarin[148,233] are degraded by alkalies with the formation of *D*-glucometasaccharinic acids. When 48% of the initial laminarin has been degraded, the process ceases and then restarts after partial hydrolysis of the residue. The termination of the degradation process may be due to a structural feature of the chain. In fact, it has been shown recently[234] that laminarin contains chains with terminal non-reducing mannitol units. The decomposition of laricinan and pachyman[233] takes place in exactly the same way under these conditions with formation of metasaccharinic acids. It may be that the presence of branches is also the cause of the incomplete degradation of these polysaccharides. The results of kinetic studies on the alkaline degradation of (1 → 3)-glucans have been published[233].

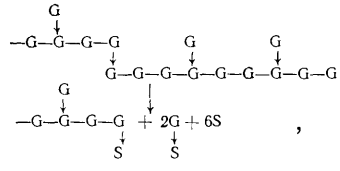
3. Glycans with (1 → 6)-Linkages

When melibiose (6-O-α-*D*-galactopyranosyl-*D*-glucose) (XLVIII) is treated with calcium hydroxide, the products are[99] *D*,*L*-lactic acid (XLIX), *D*-galactose, 6-O-α-*D*-galactopyranosyl-*D*-glucometasaccharinic acid (L) and the corresponding isosaccharinic acid. Treatment of melibiose with barium hydroxide[235] led to the formation, apart from the above compounds, of considerable amounts of 3-deoxy-*D*-xylohexonic and 3-deoxy-*D*-lyxohexonic acids (α- and β-*D*-galactometasaccharinic acids) (LI) and 2-*C*-methylglyceric acid (LII). 6-O-α-*D*-Galactopyranosyl-*D*-glucosaccharinic acids are formed via the Isbell mechanism and the glycosidic linkage remains unaffected; the rupture of the glycosidic linkage in melibiose is accompanied by the formation of compounds (XLIX), (LI), and (LII). The cleavage of the $C_{(3)}$–$C_{(4)}$ linkage in the

reducing *D*-glucose unit of the disaccharide leads to the formation of a triose, which rearranges to *D,L*-lactic acid after the elimination of *D*-galactose. The rupture of the $C_{(2)}-C_{(3)}$ bond should lead to the formation of a 4-O-substituted tetrose, which can be cleaved with formation of 2-*C*-methylglyceric acid (LII). The *D*-galactose eliminated in this process can undergo subsequent rearrangement with formation of *D*-galactometasaccharinic acids (LI) (Scheme 5).



Scheme 5



According to this scheme, compound (LII) and pyruvic acid (precursor of lactic acid), labelled at $C_{(4)}$ and $C_{(3)}$ respectively , should be formed from *D*-glucose-6-*t*. In fact, the radioactivities of *D*-glucose-6-*t* (LII) and pyruvic acid were almost identical (to within 5%)[235].

2-*C*-Methylglyceric acid is a product of the successive chain degradation of isomaltose oligosaccharides (isomaltose, isomaltotriose, and isomaltotetraose) under the influence of $Ba(OH)_2$. Apart from 2-*C*-methylglyceric acid, considerable amounts of stabilisation products, in particular 6-O-substituted 3-deoxy-*D*-hexonic acids, are formed[235].

As shown above, substitution at $C_{(6)}$ tends to increase the rates of degradation of 3-O- and 4-O-substituted sugars with retention of the 6-O-substituent. When 6-O-β-*D*-glucopyranosyl-3-O-glucose (LIII) is acted upon by lime water at room temperature, O-glycosylmetasaccharinic acids are formed; 6-O-β-*D*-glucopyranosyl-α-*D*-glucometasaccharinic acid (3-deoxy-6-O-β-*D*-glucopyranosyl-*D-ribo*-hexonic acid) (LIV) and 6-O-β-*D*-glucopyranosyl-β-*D*-glucometasaccharinic acid (3-deoxy-6-β-*D*-glucopyranosyl-*D-arabino*-hexonic acid) (LV) [125]. The acids were characterised by reduction to substituted 3-deoxyhexoses. The same 6-O-glucosylmetasaccharinic acids are formed[236] on treatment of the trisaccharide 3-O-β-6-β-di-*D*-glucopyranosyl-*D*-glucose (LVI) with 0.05 *N* $Ba(OH)_2$:

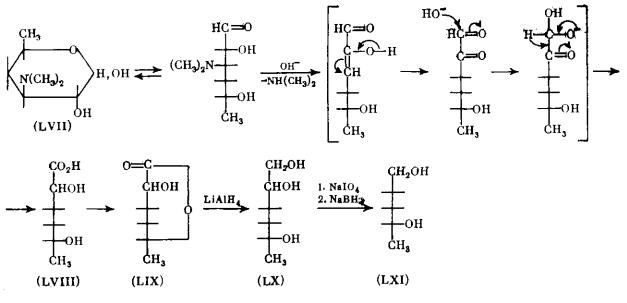
Compounds (LIII) and (LVI) are models of the (1 → 3)-linked β-*D*-glucan from *Sclerotium rolfsii* containing β-*D*-glucopyranosyl substituents at each third glucose residue of the main (1 → 6)-linked chain[237]. The degradation of this polysaccharide by NaOH in the absence of oxygen at 56 °C leads to compounds (LIV) and (LV)[125]:

where G = β-*D*-glucopyranose, S = *D*-glucometasaccharinic acid residue, a line indicates a (1 → 3)-linkage, and an arrow indicates a (1 → 6)-linkage.

It has been shown[238] that dextran is cleaved on treatment by 1 *N* NaOH at 60 °C with formation of a stable acid dextran containing 1 unit of *D*-glucometasaccharinic acid for each dextran chain. Hydrolysis of the acid dextran leads to α- and β-*D*-glucometasaccharinic acids.

Alkaline degradation of oxidised celluloses and the influence of the supermolecular structure of cellulose on its alkaline degradation are discussed in a review[137].

VI. THE PROPERTIES AND APPLICATIONS OF SACCHARINIC ACIDS



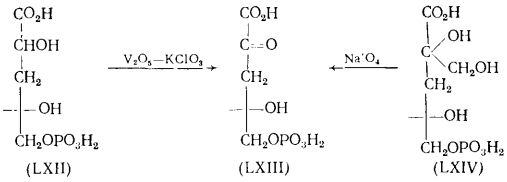
1. The Formation of Saccharinic Acids as an Analytical Method for the Investigation of the Structures of Polysaccharides and Certain Carbohydrate Derivatives

The study of the influence of alkalies on model, partly substituted, monosaccharides, oligosaccharides, and polysaccharides with known structures has shown that in broad outline it is possible to predict which reaction products should be formed when the main polysaccharide chains are acted upon by alkali. Thus polysaccharides with (1 → 2)-linkages are resistant to dilute alkali at 25 °C. Polysaccharides with (1 → 3)-linkages are cleaved by alkali in the absence of oxygen with formation of metasaccharinates and those with (1 → 4)-linkages

are cleaved with formation of isosaccharinates. Polysaccharides with (1 → 5)-linkages are stable, while those with (1 → 6)-linkages exhibit a relative resistance to dilute alkali at 25 °C; they give rise to 6-O-glycosylmetasaccharinate, 2-*C*-methylglycerate, and lactate at a higher temperature and an increased concentration of alkali. Polysaccharides with (2 → 1)-linkages, containing ketose units (for example, inulin), are cleaved by dilute alkali with formation of the usual saccharinates.

In the presence of chain branching the alkaline degradation and the nature of the substances formed can frequently yield information concerning the types of bonds in the initial monosaccharide. Thus the branch at the $C_{(6)}$ atom will be split off and, depending on the type of bonds in the main chain, the product will have stable iso- or meta-saccharinate end groups. The branches at $C_{(4)}$ in main chains joined by (1 → 5)- or (1 → 6)-linkages are not cleaved owing to the resistance of the main chains to the action of alkali. When the branches at $C_{(4)}$ in chains joined by (1 → 3)-linkages as well as branches at $C_{(3)}$ are split off, a stable metasaccharinate terminal unit is formed from the residue in the main chain to which the branch had been attached. This unit will be located at the branch ($C_{(4)}$) in the former case and in the main chain in the latter ($C_{(3)}$). The main chain does not undergo further degradation, but the eliminated branches decompose via a pathway which depends on the type of bonds in the branch. The branches at the $C_{(2)}$ atom in the main chain joined by (1 → 3)-linkages should be split off and should terminate in a 2,3-unsaturated monosaccharide unit, resistant to alkali, formed from the monosaccharide residue of the main chain to which the branch was attached. The branches at the $C_{(2)}$ atom in the main chain, joined by (1 → 4)-linkages, should arrest the degradation process. Thus the use of the saccharinic rearrangement as an analytical method in combination with other procedures makes it possible to obtain extremely valuable information about the structure of polysaccharides.

The saccharinic acid method is particularly useful for the establishment of the structures of mono-O-substituted reducing sugars. This method has been used successfully[239] to determine the absolute configuration in the 5-position of desosamine—an important carbohydrate component of the macrolide antibiotics erythromycin, methymycin, narbomycin, oleandomycin, and picromycin. Alkaline degradation of desosamine (3,4,6-trideoxy-3-dimethylaminohexose) (LVII) led to *erythro* + *threo*-2,5-dihydroxyhexonic acid (LVIII). The δ-lactone of this acid (LIX) gave rise to the hexanetriol (LX) after reduction with lithium tetrahydroaluminate. Oxidation of the hexanetriol with sodium periodate followed by reduction with sodium tetrahydroborate led to pentane-1,4-diol (LXI) whose molecule retains only one asymmetric centre, corresponding to the fifth carbon atom of desosamine. Since the absolute configuration of the pentanediol (LXI) corresponds to that of *D*-glyceraldehyde, it follows that desosamine belongs to the *D*-series.



2. Syntheses of Deoxysugars via Saccharinic Acids

Saccharinic acids are particularly useful for the synthesis of deoxysugars and branched sugar derivatives. When γ-lactones of α- and β-*D*-glucometasaccharinic acids are reduced. 3-deoxy-*D*-*ribo*-hexose and 3-deoxy-*D*-*arabino*-hexose are formed respectively[32]. The reduction of the γ-lactones of α- and β-*D*-glucoisosaccharinic acids leads to 3-deoxy-2-*C*-hydroxymethyl-*D*-*erythro*-aldopentose and 3-deoxy-2-*C*-hydroxymethyl-*D*-*threo*-aldopentose respectively. It has been shown[56] that the reduction of both γ-lactones with sodium tetrahydroborate proceeds more effectively than with sodium amalgam. The reduction of the lactone of α-*D*-glucoisosaccharinic acid had been investigated previously[240]. 2-*C*-Methyl-*D*-ribose has been obtained by the reduction of the lactone of α-*D*-glucosaccharinic acid with sodium amalgam[56]¶.

2-Deoxy-*D*-xylose has been obtained by the Ruff cleavage from *D*-galactometasaccharinic acids[241]. Numerous studies[242,244] have been devoted to the conversion of *D*-glucometasaccharinic acid salts into 2-deoxy-*D*-*erythro*-pentose (2-deoxy-*D*-ribose) by the same method. Synthesis via metasaccharinic acids has also been used to obtain 2-deoxy-*D*-*erythro*-tetroses and 2-deoxy-*D*-*threo*-tetroses from *D*-arabinose and *D*-xylose respectively[245].

3-Deoxy-2-oxo-*D*-*threo*-hexonic acid has been obtained from α-*D*-galactometasaccharinic acid[246]. Selective oxidation of a mixture of the 5-phosphates of 3-deoxy-*D*-*erythro*-pentonic and 3-deoxy-*D*-*threo*-pentonic acids (LXII) at the $C_{(2)}$ atom with potassium chlorate and vanadium pentoxide yielded the 5-phosphates of 3-deoxy-2-oxo-*D*-glyceropentonic acid (LXIII). The latter has been obtained also by the periodate oxidation of a mixture of the 5-phosphates of 3-deoxy-2-*C*-hydroxymethyl-*D*-*erythro*- and -*D*-*threo*-pentonic acids (LXIV)[247]:

The 6-phosphates of 3-deoxy-2-oxo-*D*-*erythro*- and *D*-*threo*-hexonic acids have been obtained from the 6-phosphates of *D*-glucometasaccharinic and *D*-galactometasaccharinic acids respectively[248]. The formation of a cyclic enol by oxidising the 6-phosphates of *D*-glucometasaccharinic acid with potassium chlorate in the presence of vanadium pentoxide has been studied[249]. The γ-lactone of α-*D*-glucosaccharinic acid has been used as the initial compound in the synthesis of nucleosides containing branched sugars[250-252].

Certain properties of saccharinic acids have been described in a review[26]. It was shown subsequently[56,145] that α- and β-*D*-glucoisosaccharinic acids are resistant to alkaline solutions up to 125 °C and are not interconverted under these conditions. α-*D*-Glucosaccharinic acid is also not isomerised on treatment with alkali or on heating[56], while the lactones of α- and β-*D*-glucometasaccharinic acids are interconverted via epimerisation[49,120,166,253]. A similar transformation has been observed by Nef[11] for the lactones of *D*-galactometasaccharinic acids. Acids which do not contain hydrogen atoms at $C_{(2)}$ do not undergo this transformation.

¶ The corresponding polyrols can also be obtained by the reduction of saccharinic acids with tetrahydroborate[56].

The γ-lactones of saccharinic acids are more stable in aqueous solutions than the lactones of aldonic acids and remain unchanged for several days. Like normal aliphatic esters and lactones, the lactones of deoxy- and 2-*C*-methylaldonic acids are extremely resistant to non-catalysed hydrolysis[254].

The Formation of the Azoxy-group in Reactions Involving Anions with Nitrogen - Nitrogen Bonds

V.N.Yandovskii, B.V.Gidaspov, and I.V.Tselinskii

The methods for the formation of azoxy-compounds by substitution reactions with participation of anions having nitrogen - nitrogen bonds are examined. Attention is concentrated on the alkylation reactions of alkanediazotates, nitrosohydroxylamines, and nitroamines as well as substitution reactions involving the distal nitrogen atom in azoxy-compounds. The literature up to 1976 inclusive is covered.
The bibliography includes 194 references.

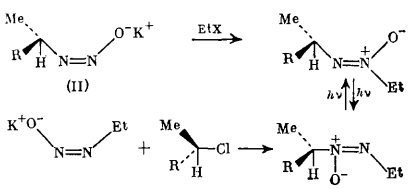
V. Nucleophilic substitution reactions involving *N*-nitroamines and *N*-nitroamides 242
VI. Conclusion 244

I. INTRODUCTION

The chemistry of azoxy-compounds is now attracting considerable interest as shown by the publication of several monographs and reviews in the last ten years[1-9]. The vigorous growth of research in this field has led to the discovery of new methods for the introduction of the azoxy-group into organic compounds and has imparted a new significance to the studies by Bamberger, Hantzsch, Angeli, and others carried out at the beginning of the XXth century. In a previous review[10] we examined the methods for the formation of the azoxy-group by the oxidation of compounds with nitrogen–nitrogen bonds[10]. This review deals with the formation of the azoxy-group in substitution reactions with participation of ambident anions having nitrogen–nigrogen bonds.



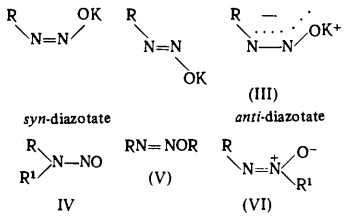
II. ALKYLATION OF ALKANEDIAZOTATES

A convenient method for the synthesis of azoxyalkanes, consisting in the alkylation of alkanediazotates, has been developed by Moss and coworkers[11-16]:

(I)

Azoxyalkanes, particularly those containing asymmetric substituents (I, $R \neq R^1$) were previously described in isolated instances only, but have now become more available. The method of synthesis described is unsuitable for compounds (I) where R and (or) R^1 = aryl or t-alkyl, but it does have many advantages, as noted by Moss et al. [12], and makes it possible to vary the groups R and R^1, which can be primary and (or) secondary alkyl or arylalkyl groups. The synthesis by this method is specific, and it leads to a single structural iosmer. The method makes it possible to obtain optically active azoxyalkanes, since the alkylation stage is not accompanied by the loss of chirality in the R and R^1 groups[12,13,15,16] (see also McGahren and Kunstmann[17]):

(II)



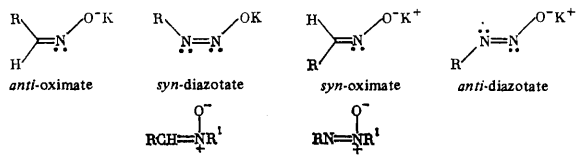
Evidently the configuration of the centre in the distal position remains unchanged, but there is a complete inversion at the carbon atom of the reagent[13,15,16].

The retention of the chiral centre in the diazotate (II) in the alkylation reaction has been used in a 12-stage synthesis of the dihydro-derivative of elaiomycin—an antiobiotic and carcinogen, which is encountered in nature and which contains the azoxy-group[15]. The photochemical interconversions of the distal and proximal isomers into their equilibrium mixture without loss of asymmetry at C* constitute an additional confirmation of the possibilities of the new method of synthesis of azoxyalkanes, which makes it possible to obtain a chiral centre in R and (or) R^1.[13]

The possibility of using allyl halides for the alkylation of diazotates indicates yet another interesting aspect of their practical application, since "functional" alkylating agents can be introduced into the reaction[14].

Alkanediazotates, which are the key compounds in the new synthesis, usually occur merely as intermediates in the nitrosative deamination of alkylamines and alkylhydrazines[16,18,19], in the alkaline cleavage of *N*-alkyl-*N*-nitroso-urethanes[20-30], etc. but can also be isolated in a pure state[20-27]. Moss[31] modified somewhat the procedure for the decomposition of urethanes, usually employed for the synthesis of diazoalkanes, and carried out the reaction with potassium t-butoxide in an inert solvent. Diazotates are then obtained in the form of solid salts and are believed to have the *syn*-configuration[16]. Other methods, for example, the alkaline nitrosation of hydrazines, give rise to the more stable *anti*-diazotates, but the *syn* → *anti* conversion is greatly hindered[16,27]. The N–N (1.32 Å) and N–O (1.29 Å) bond lengths in *syn*-methanediazotate are intermediate between the values for single and double bonds, so that the compound is best represented by

the mesomeric anion (III).[16,32] The presence of *p* electrons at $N_{(2)}$ is responsible for the formation of nitrosoamines (IV), diazoethers (V), or ethoxy-compounds (VI) in the alkylation of the anion:



syn-diazotate (III) *anti*-diazotate

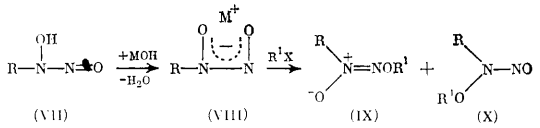
IV (V) (VI)

The yield of azoxyalkanes varies from 30 to 60% and is little affected by the solvent. In alkylation in hexamethylphosphoramide, a polar aprotic solvent which causes the dissociation of the salt, an appreciable proportion of the alkanediazotate remains in the form of the anion. The high electron density at the oxygen atom and its appreciable steric accessibility compared with the $N_{(1)}$ atom cause the yield of the nitrosoamine to be small and make the yield of the *O*-alkylation product up to 50%. In a less polar solvent (95 : 5 ether–hexamethylphosphoramide mixture) a considerable proportion of the alkanediazotate is present in the form of ion pairs, the $O_{(3)}$ atom is blocked by the counter-ion, and the nitrosoamine (IV) predominates over the diazoether (V) among the side products[16]. Arylation of the alkanediazotate (III, $R = CH_3$) gives rise exclusively to compound (IV), i.e. takes place at the $N_{(1)}$ atom[21].

It is of interest to compare all these data with the alkylation of arenediazotates. The latter are known to exist in the more stable form of isodiazotates[33–39] (equivalent to the *anti*-configuration of alkanediazotates) and calculation of the electron density in the anion shows that the site of attack is the key nitrogen atom and the oxygen atom[39]. Experimental data[39,40], indicating the predominant formation of *O*-alkylation products in dimethylformamide (DMF) and dimethyl sulphoxide (DMSO), are fully consistent with the calculations. Thus the ambident anion reacts in the usual way, at the first and third atoms[39,40], and azoxy-compounds are not formed in this case.

The unusual behaviour of alkanediazotates, manifested by the possibility of alkylation in the 2-position of the ambident anion, is associated with the presence of the electron pair at $N_{(2)}$. This situation is not unique in the series of nitrogen-containing functional groups and has a direct analogy in the alkylation of the oximate anion. In both cases the 2- and 3-positions in the ambident anion are alkylated preferentially. Whereas alkylation at $C_{(1)}$ is not observed in the oximate anion[41–43], $N_{(1)}$-alkylation does occur to a slight extent in the *syn*-alkanediazotate owing to the presence of an electron pair at the key nitrogen atom[12,16]:

anti-oximate *syn*-diazotate *syn*-oximate *anti*-diazotate

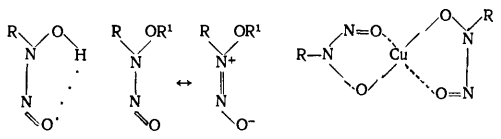


The *anti*-oximate anion, which is sterically equivalent to *syn*-diazotate†, is alkylated preferentially at the nitrogen atom[41–43,45–51], giving rise to a nitrone, i.e. the ambident anion is alkylated in both cases in the 2-position (but with different selectivities). The *syn*-oximate anion, which is sterically equivalent to the *anti*-diazotate and to the anion derived from ketoximes, gives preferentially $O_{(3)}$-alkylation products[41–43], i.e. in both cases the ambident anion is alkylated preferentially at the oxygen atom and nitrones or, correspondingly, azoxy-compounds[52] are not formed. The influence of the geometry of the diazo-bond on the regio- and stereo-specificity of the alkylation of alkanediazotates has been recently discussed[52].

The intramolecular interaction of propargyl[30,53,54], allene[55], and epoxy-groups[56,57] with the *syn*-diazotate ion, obtained by the decomposition of "functional" urethanes, proceeds in the same way as *O*-alkylation.

The formation of an azoxy-compound in the decomposition of cyclopropane-bisdiazotate, which constitutes an intramolecular *N*-cyclopropylation reaction, has been reported[58]. However, the multiplicity of pathways leading to the decomposition of the initial product hinders interpretation.

III. ALKYLATION (ACYLATION) OF *N*-NITROSOHYDROXYLAMINES

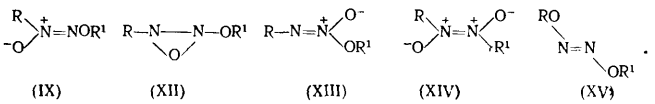


The alkylation of *N*-nitrosohydroxylamines (VII) and their salts (VIII) constitutes yet another group of reactions leading to the formation of azoxy-compounds (IX).[59–78]. The side products in this process are apparently alkoxynitrosoamines (X):

(VII) (VIII) (IX) (X)

The key compounds for this reaction—the acids (VII) and the salts (VIII)—constitute an interesting class of compounds; the problem of their structure has been discussed in earlier studies by Bamberger[62,63,79], Hantzsch[67,80,81], Traube[65,81–83], Gomberg[84], Angeli[85–87]#, and Thiele[88]. A recent review[78] is a first attempt at a systematic account of the relevant data (see also Bamberger and Baudisch[79], and Marvel, where methods for the preparation of cupferrons are summarised[89]). The acids (VII) are unstable in a free state, while their salts are more stable; for example, the ammonium salt of phenylnitrosohydroxylamine (cupferron) is a familiar analytical reagent[90,91].

O,*N*-Disubstituted nitrosohydroxylamines (X) exist preferentially and the free acids (VII) exclusively in the *trans*-configuration[92], whose additional stabilisation in the case of the acids (VII) is caused by the intramolecular hydrogen bond[92]. The salts of nitrosohydroxylamines, which are represented as the chelates (VIII) and (XI), have an analogous configuration[78,90,93]:



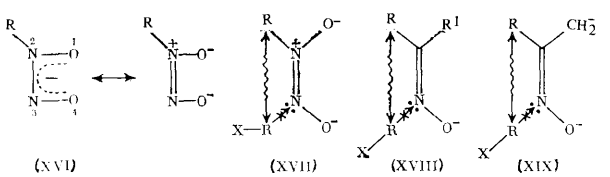
(VII) (X) (XI)

† The effective size of the free electron pair in space is even smaller than the size of bound hydrogen[44].

Angeli represented arylnitrosohydroxylamines by the formula $ArN(O) = NOH$ and regarded them as the oximes of nitro-compounds or as the oxides of diazohydrates[79,85–87].

The geometry of the salts and their stability are apparently associated with the formation of a 6-electron system, the principle of the structure of which has already been used to account for the geometry, thermal stability, and reactivity of the ketoxime dianions[94] and has been extrapolated to other "*U*-type" molecules–tosylhydrazone dianions[94,95] and *cis*-difluoro-olefins[94,96].

The salts of *N*-nitrosohydroxylamines are readily alkylated and, as shown for the first time[60,61] in relation to the benzylation of *N*-benzyl-*N*-nitrosohydroxylamines, can give rise to two reaction products—(IX) and (X) (R = R^1 = CH_2Ph). The structure of the latter compound was adopted immediately and was not questioned subsequently, since in the general case it can be obtained by specific synthesis—the nitrosation of alkoxyamines[61–63,77,78,97]. The structure of the first product (which is more stable), represented by formulae (IX),[63] (XII),[62] (XIII),[67] and (XIV),[70] has been the subject of a prolonged controversy. Wright and coworkers[70] seemingly demonstrated by all the available evidence that the first alkylation products exist in form (IX), but the fact that these compounds (R = alkyl or aryl; R^1 = alkyl) evolve methane on treatment with methylmagnesium chloride led them into a blind alley§. Wright and coworkers[70] then attributed formula (XIV) to the alkylation products and at the same time threw doubt on the structure of the dimers of nitroso-compounds:

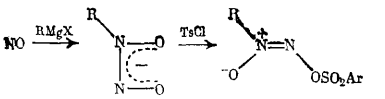


(IX) (XII) (XIII) (XIV) (XV)

Freeman[73] and Stevens[74] corrected this error and later Smith[59] and Woodward and Wintner[75,76] confirmed that the product has structure (IX). Bearing in mind that the structure of the dimers of nitroso-compounds was not immediately adopted and that the hyponitrites (XV) are isomeric with compounds (IX) and that the spectroscopic characteristics of their salts (XV, R = R^1 = Na) are close to those of nitrosohydroxylamines salts[98,99], the difficulties in the determination of the structure become understandable.

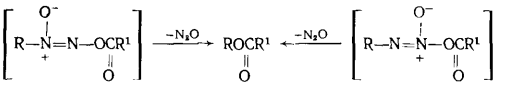
The alkoxydiazene oxides (IX) are isolated by the usual preparative methods—distillation, crystallisation, and chromatography. The products of the methylation of the Traube salt (VIII, R = $CH_2N_2O_2Na$, M = Na) as well as other alkoxydiazene oxides constitute surprising examples of stability[65,76–78]. Their high stability can be used for their purification by heating with sulphuric acid or alkali[77].

The geometry of compound (IX) has not been established, but Lamberton and Yusuf[77] clearly noted the formation of a single stereoisomer in the ethylation of *N*-nitrosomethylhydroxylamine.



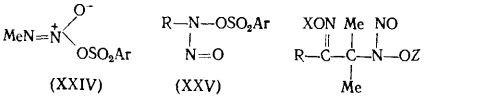
The anion (XVI) has three potential nucleophilic centres susceptible to attack—both oxygen atoms and the $N_{(3)}$ atom. In reality only the first possibility is realised:

(XVI) (XVII) (XVIII) (XIX)



§ Subsequently Stevens[74] explained this finding.

We believe that the general considerations concerning the alkylation of the oximate and diazotate anions, described above, are applicable in this case too. As the reagent approaches the nitrogen atom of nitrosohydroxylamine, a structure, analogous to the two non-realisable structures conceivable in the alkylation of the ketoximate anion (XVIII) and the dianion (XIX), is produced. In all three cases the nitrogen atom is sterically blocked, so that the oxygen atom (see Section II above) and the carbon atom are attacked in the alkylation of compounds (XVIII) and (XIX) respectively[94]; in compound (XVI) alkylation proceeds via both oxygen atoms. It is of interest that the electron pair of the nitrogen atom of the anion (XVI) is blocked also for other electrophilic reactions. Thus its tosylation takes place at the $O_{(4)}$ atom with formation of compound (XX)[74] in which the *cis*-orientations of the oxygen atoms are retained[100]:

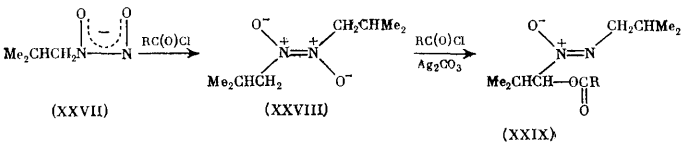


(XVI) (XX)

Compounds of type (XX) are of interest as starting materials for the synthesis of azoxy-compounds by substitution using various nucleophiles (carbanions and alkoxides) (see below) and are frequently obtained as a result of a single-stage reaction[74]. The tosyl derivatives (XX) are more stable than other acyl derivatives of *N*-nitrosohydroxylamines. For example, the alkali metal salts (VIII) evolve N_2O and give rise to the esters (XXI) on treatment with aroyl halides, since the intermediates (XXII) readily decompose[101]:

(XXII) (XXI) (XXIII)

It is of interest that both the diazene $N_{(2)}$-oxides (XXII) and the diazene $N_{(1)}$-oxides (XXIII)[101–104] behave similarly and that the position of the oxygen atom does not influence the formation of esters[101]. On the other hand, the tosyl derivatives (XX) and (XXIV) have sharply different stabilities; thus the attempt to tosylate the silver salt of methylnitroamine gives rise solely to methyl tosylate as a result of the decomposition of the intermediate (XXIV):[105]

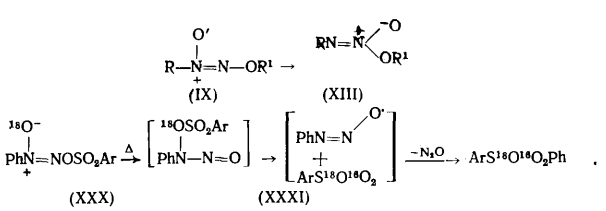


(XXIV) (XXV) (XXVI)

(a) R=Ph, X=MeCO, $Z=SO_2Ar$;
(b) R=Z=Me, X=H

Nor is it possible to obtain the tosyl derivative (XXV) by the nitrosation of the corresponding hydroxylamine[105], which confirms the validity of the choice, made for the first time by Stevens,[74], between the alternative structures (XX) and (XXV) in favour of (XX). In a recent study White et al.[100] explained some of the properties of compounds of type (XX). In contrast to these data, structure (XXVIa) has been attributed to the product of the tosylation of N-[1-acetoxymino-2-methyl-1-phenyl-(2-propyl)] hydroxylamine[106]. The anomalous course of the reaction may be due to the specific properties of the initial compound, so that the alkylation of its homologue (XXVI, R = Me, X = Z = H) with dimethyl

sulphate leads to the formation of compound (XXVIb),[106] which again conflicts with the analogous reaction of cupferron[70] or *N*-t-alkyl-*N*-nitrosohydroxylamines[105].

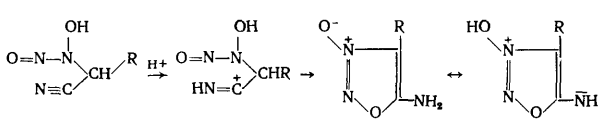


The prolonged controversies which have accompanied each new step in the development of the chemistry of nitrosohydroxylamines can be accounted for by the weak theoretical ideas concerning the state of the bonds in the initial anion (VIII) or structures of type (IX). Evidently its further development promises to have many unexpected features. For example, it has been observed quite recently that the 3,5-dinitrobenzoylation of salts of *N*-isobutyl-*N*-nitrosohydroxylamine (XXVII) gives rise to compound (XXIX),[107] whose formation is difficult to account for by the mechanism involving the acylation of the $O_{(1)}$ atom[108] or the $O_{(4)}$ atom[101] in the initial anion. It has been shown that in the general case compounds (XXIX, RCO = acetyl, 3,5-dinitrobenzoyl, or 3-nitro-1-naphthoyl) are products of the acylation of the nitroso-dimers (XXVIII), which is usually accompanied by reactions of *N*-nitrosohydroxylamines[107]:

(XXVII) (XXVIII) (XXIX)

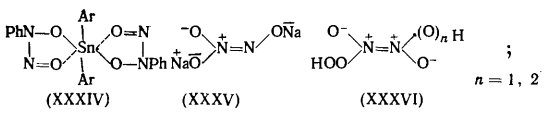
Acylating deoxygenation of compounds (XXVIII) constitutes a new type of rearrangements, related to the generalised Polonovskii reaction[109].

The alkylation of nitrosohydroxylamines gives rise to azoxy-compounds (IX), which are isomeric with the products of the alkylation of primary nitroamines (XIII). The possibility of the migration of oxygen from $N_{(1)}$ to $N_{(2)}$ has not been investigated by the intermediates in this migration [oxadiaziridines (XII)] have been erroneously regarded by Bamberger[62] as possible products of the alkylation of nitrosohydroxylamines. We may note, incidentally, that the double bond in diazoethers is not azoxidised under the influence of peracids[70]:



(IX) (XIII)

(XXX) (XXXI)

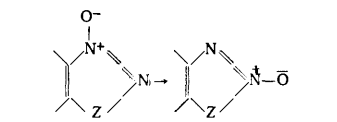


Another variety of isomeric transformations, namely in the pair of compounds (IX) and (X), has not been investigated, but it has been shown in relation to the thermal decomposition of the derivatives (XXX) labelled at the oxygen atom[110] that the tosyl group migrates to the *N*-oxide oxygen with formation of compound (XXXI). According to the mechanism presented above, its further decomposition gives rise to the phenyltosylate (Ar = *p*-tosyl) in which the label is uniformly distributed between the three oxygen atoms in the sulpho-group[110].

Nitrosohydroxylamines (XXXII) can also undergo intramolecular alkylation processes, giving rise to the sydnones (XXXIII):[141]

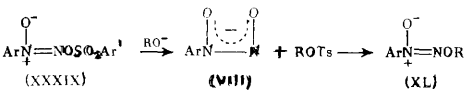
(XXXII) (XXXIII)

The interaction of diaryltin dichlorides with cupferron leads to chlorine-substitution products instead of the expected complexes suitable for the quantitative precipitation of the metal. According to a brief communication[112], the substance obtained has the structure (XXXIV), which has been demonstrated by infrared spectroscopy:



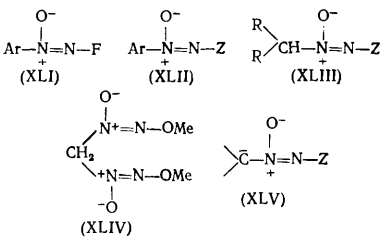
(XXXIV) (XXXV) (XXXVI) $n = 1, 2$

Organic derivatives of the Angeli salt (XXXV) and other oxyhyponitrites (XXXVI) have not been investigated at all[113]. When an attempt is made at a direct alkylation of (XXXV) by primary alkyl halides, the products are aldoximes and the reaction proceeds without the intermediate formation of the nitroxyl NOH.[114] It is also significant that in ethanol the nitrogen atom is alkylated and that the contribution of this process usually diminishes (relative to *O*-alkylation) on passing from alcohol to water[114].



IV. SUBSTITUTION REACTIONS INVOLVING THE DISTAL NITROGEN ATOM IN AZOXY-COMPOUNDS

Numerous substitution, addition, and degradation reactions of azoxy-compounds with retention of the azoxy-group are known. In the present section we shall confine ourselves to the consideration of processes involving direct substitution at the $-N=N(O)$ group. Reactions of this type include the photochemical reactions of aliphatic and aliphatic-aromatic azoxy-compounds as a result of the migration of the oxygen atom. They were considered in our previous review[10] and have been studied only in recent years. Analogous migration of oxygen from $N_{(1)}$ to $N_{(2)}$, induced photochemically, has been observed in heterocycles: triazole oxides (XXXVII)[115–117] and thiadiazole oxides (XXXVIII)[118–120]:

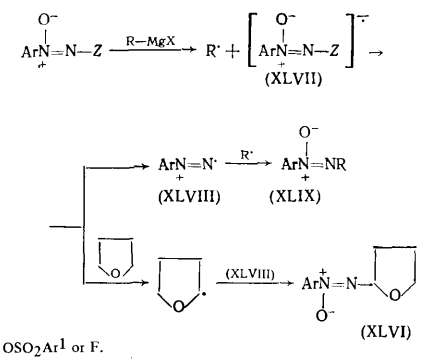


(XXXVII): Z = NR (XXXVIII): Z = S

Examples of migrations of this kind are few; reactions involving substitution at the distal nitrogen atom of the azoxy-group are more familiar. The formation of alkoxydiazene oxides (XL) in the reaction of alkoxides with tosyl derivatives (XXXIX) is fully consistent with this behaviour[74]. However, in reality the anion of nitrosohydroxylamine (VIII), liberated as a result of the substitution at the sulphur atom, is alkylated:

(XXXIX) (VIII) (XL)

The reaction of compounds (XXXIX)[74,121], (XL, R = Me),[70] and (XLI)[122] with organomagnesium reagents (Ar^1MgX, AlkMgX), which leads to the exchange of the OSO_2Ar^1, OMe, and F groups for a hydrocarbon group, giving rise to yet another possibility for the synthesis of the azoxy-compounds (XLII, Z = aryl or alkyl), takes place quite differently; however, the tosyl group in azoxysulphones (XLII, $Z = SO_2Ar^1$)[123] is not exchanged for the aryl group in Ar^1MgX:[124]

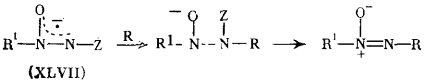


(XLI) (XLII) (XLIII) (XLIV) (XLV)

The attempt to substitute a group Z for a hydrocarbon group in aliphatic diazene oxides (XLIII, $Z = OSO_2Ar^1$ [74] or F[121,122]) was unsuccessful owing to the exchange of the proton in the α-position. For the same reason, the substitution of the alkoxy-group in bis(nitrosohydroxylamine)methane (XLIV) also fails, since the CH_2 group is metallated in the first place[70,76]. The stability of the anion having the general formula (XLV), where Z = Me, MeO, etc., has been used in a number of synthetic investigations[14,76].

Despite the fact that the distal group in the diazene oxides (XXXIX)–(XLI) can be exchanged for the alkyl (aryl) group in organomagnesium reagents, direct substitution at the nitrogen atom is not observed in reactions with other nucleophiles; for example, compounds (XLI) do not change under the influence of MeCOOH, MeONa, or Et_2NH.[121,122] Furthermore, in the reactions of compounds (XXXIX) and (XLI) with organomagnesium reagents in tetrahydrofuran (THF), compounds (XLVI) are formed as side products, evidently as a result of radical substitution[121]. (The α-position in THF is activated for radical substitutions of this kind; see, for example, Refs.125 and 126).

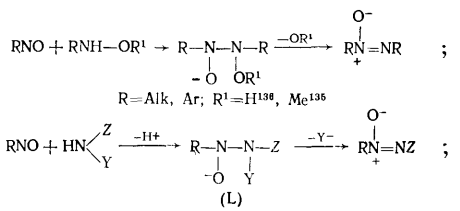
This finding and also the fact that, among the nucleophiles investigated, only Grignard reagents led to substitution at the nitrogen atom while other reagents proved to be inert or led to exchange at the sulphur atom or to metallation indicate the validity of the mechanism proposed by Stevens[121]:



(XLVII) (XLVIII) (XLIX) (XLVI)

Z = OSO_2Ar^1 or F.

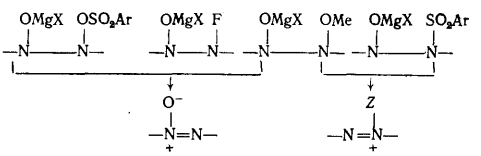
It is based on electron transfer to the azoxy-group with formation of the radical-anion (XLVII), which is converted into the azoxy-radical (XLVIII). The latter combines with the primary (R·) or secondary () radical, giving rise to compounds (XLIX) and (XLVI) respectively. Whereas the first stage, one-electron transfer from the organometallic compound to the azoxy-group, has aroused no doubts hitherto and has been adequately confirmed in the literature[127–129], the attempt to detect radical (XLVIII) by EPR has failed[121].



The azoxy-radical, with the unpaired electron at the nitrogen atom, is identical with the diazenyl radical, the possibility of the formation of which has been studied vigorously. Nevertheless many substitution reactions at the N–N bond can be accounted for on the basis of the addition–elimination mechanism[130–132] without resorting to ideas involving a discrete diazenyl radical.

Similar considerations are apparently applicable also to the substitution reactions with organomagnesium reagents involving the distal nitrogen atom of the azoxy-group, considered in this review. The final products of such reactions arise as a result of the pairing of the species (XLVII) with the primary or secondary radical present in the medium and subsequent elimination of the anionic fragment¶:

(XLVII)

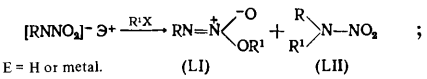


In this interpretation the substitution reaction is put in the same class with the already known processes involving the formation of the azoxy-group via the coupling of N-centred radicals†:

R = Alk or Ar; Z = Y = F[122] or Cl[137]; Y = Cl, Z = SO_2Ar[123]; Z = Y = Cl, H = Alk or Ar[138].

The formation of azoxysulphones[123] and not azoxychloro-derivatives by the condensation of nitroso-compounds with chloramine-T indicates the preferential rupture of the N–Cl bond compared with N–SO_2Ar in the intermediate (L, Y = Cl, Z = SO_2AR). It is also remarkable how much more difficult are the conditions for the elimination of the sulphinate group, for example in the Carpino reaction[139–141] compared with the analogous elimination of the sulphonate group, for example, in the amination of nitrogen-containing bases by hydroxylamine-*O*-

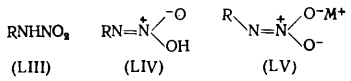
All the foregoing considerations illustrate the idea that the stabilisation of the intermediate (L) by the elimination of the anion (in the form of OMgX or Y) is apparently determined by the ease of dissociation of the N–O and N–Y bonds and the stability of the leaving anion:



¶ The coupling of R· with the O-centred radical-anion leads to deoxygenation to a first approximation. Such a process is well known for the reaction of azoxyarens with organomagnesium reagents[70,133,134].

† Another mechanism of these reactions involves nucleophilic addition to the N = O double bond (see, for example, Taylor et al.[135]).

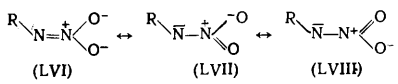
V. NUCLEOPHILIC SUBSTITUTION REACTIONS INVOLVING *N*-NITROAMINES AND *N*-NITROAMIDES



The alkylation of primary nitroamines, nitroamides, and their salts leads to the corresponding 1-alkoxydiazene 1-oxides (LI). The ratio of the *O*-alkylation [compound LI)] and *N*-alkylation [compound (LII)] products differs within very wide limits depending on the nature of the substituting group (R = alkyl, aryl, or SO_2AR), the alkylating agent, the metal cation (sodium, potassium, or silver), and the solvent:

E = H or metal. (LI) (LII)

Reactions in which primary nitroamines add to multiple bonds and many other nucleophilic substitution processes involving their anions also lead to a mixture of products (LI) and (LII). The chemistry of nitroamines has been considered in a number of reviews[144–150] and sections devoted to the alkylation of primary nitroamines are contained in a number of monographs[145,146,148,149]. However, since the publication of the last monograph, numerous experimental facts have accumulated, which have to be surveyed.



The structure of primary nitroamines and their salts has been the subject of theoretical disputes at the end of the XIXth and the beginning of the XXth century. The principal topic of these disputes has been the following question: do nitroamines exist in the form of true nitro-compounds (LIII) or do they have the structure of isonitroamines (LIV)# (for the history of the development of the relevant views, see Wright[147]):

(LIII) (LIV) (LV)

It has been shown recently that the N–N and N–O bond orders in methylnitroamine are to some extent equalised, which is accompanied by partial localisation of the negative charge at the oxygen atoms. However, primary nitroamines in the non-ionised state have the true nitroamine structure. It has been shown[152] that the ionisation of methylnitroamine entails an increase of the N–N bond force constant and a decrease of the N–O bond force constant, which corresponds to the isonitroamine structure being preferred for its salts, the metal cation being located in the *cis*-position relative to the alkyl group [structure (LV)].

Although the static distribution of charges in alkali metal salts of nitroamines is described by structure (LV), the reactivity of the corresponding anion is determined by the presence of three reaction centres—both oxygen atoms and the amino-nitrogen atom. The localisation of the electron pair at the central nitrogen atom is impossible in any of the main mesomeric structures (LVI)–(LVIII) and the central atom is consequently not susceptible to electrophilic attack:

(LVI) (LVII) (LVIII)

In a number of early studies, *N*-nitrosohydroxylamines were referred to as "isonitroamines", which introduced an additional confusion into this problem (See, for example, Traube[151]).

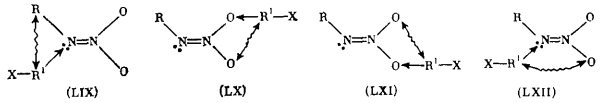
Nitroamines and their anions are typical examples of ambident (1,3) nucleophiles and many features of their individual behaviour can be accounted for on the basis of the general characteristics of the behaviour of such reagents. For example, it is well known that the reaction of silver salts of nitroamines gives rise to *O*-alkylation products, while alkali metal (potassium and sodium) salts give rise preferentially to *N*,*N*-dialkylnitroamines[145,146,148,149]. This conclusion is based both on studies carried out at the end of the XIXth and the beginning of the XXth century[153–159] and on more modern data[77,160–172]. Unfortunately in the majority of these investigations accurate ratios of the *O*- and *N*-alkylation products are not quoted. The available data are compiled in Table 1, which clearly illustrates the quantitative aspect of the relation.

Table 1. The ratios of the products of the *O*- and *N*-alkylation of $RNHNO_2$ and its salts.

No.	R/[$RNNO_2$]$^-$	Cation	Alkylating agent R^1/R^1X	Ratio* of products of *O*- and *N*-alkylation	Refs.
1	Isopropyl	K	MeI	0.15	162
2	Isopropyl	Ag	MeI	12.5	162
3	Neopentyl	Ag	MeI	12.5	162
4	Methyl	Na	$PhCH_2Cl$	0.25	167
5	Methyl	Na	*p*-$BrPhCH_2Cl$	0.14	167
6	Ethyl	Na	*p*-$BrPhCH_2Cl$	0.4	167
7	Methyl	Na	*p*-$CNPhCH_2Cl$	0.18	167
8	Ethyl	Na	*p*-$CNPhCH_2Cl$	0.4	167
9	Methyl	Li	$FcCH_2CH_2I$**	***	171
10	Methyl	Li	$FcCH_2X$**	***	170
11	n-Butyl	Na	n-BuI	0.75	160
12	Isopropyl	Na	iso-*o*-PrI	1.8	161
13	n-Octyl	Na	n-$C_8H_{17}I$	2.50****	161
14	Isopropyl	H	Me_2SO_4	1.2	162
15	Methyl	Na	$EtOCH_2Cl$	1.0	167

* The alkylation of alkali metal (Li, Na, K) salts was carried out in alcohol (MeOH, EtOH), that of silver salts was carried out in ether, and the alkylation with dimethylsulphate was carried out in water.

** Fc = ferrocenyl.



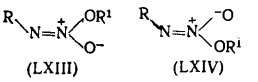
*** Only *N*-alkylation takes place.

**** The result is apparently distorted by partial decomposition on distillation.

The different modes of alkylation, depending on the metal cation, can be explained in terms of the general rule for the alkylation of ambifunctional nucleophiles; a polar electrophile combines primarily with the atom of the nucleophilic substrate having the highest electron density[173]. Such a centre in the nitroamine anion is the oxygen atom, which is attacked in the presence of a strong electrophilic catalyst (silver), which polarises the R^1–X bond[174]. Similarly other polar compounds [Me_2SO_4 and $EtOCH_2Cl$ (Nos. 14 and 15, Table 1)] give rise to a high percentage of the *O*-isomer.

Electrophiles with a small positive charge or electrically neutral electrophiles react preferentially with the atom of the ambifunctional system which is most readily polarised[173]. Such a centre in a nitroamine is the amino-nitrogen atom, which reacts preferentially, in relation to oxygen, with R^1–X (in the absence of silver ions) or adds to the multiple bond. Thus the condensation of alkylnitroamines with epoxyethane[175] and an activated double bond[146,148,168,176] as well as the aminomethylation of nitroamines[146,148,177] proceed exclusively at the nitrogen atom.

Another important feature is the increase of the amount of the *O*-isomer with increase of the bulk of the alkyl group. Comparison of Nos.1 and 12 in Table 1 shows that the methylation of isopropylnitroamine results in the formation of the *N*,*N*-isomer, while isopropylation gives preferentially the *O*,*N*-isomer. The progressive increase in the bulk of the group in both the alkylating agent and in the initial nitroamine (Nos.5–8 and 11–13) has a similar influence. Evidently the steric hindrance to the approach of the alkylating agent in structure (LIX) is manifested to a greater extent than in compounds (LX) or (LXI):



(LIX) (LX) (LXI) (LXII)

In conformity with the hypothesis put forward previously in the interpretation of the alkylation of diazotates (see Section II) (see also the earlier review[10]), the steric interactions with the vicinal group in structure (LXII) are less important than the steric interactions with the geminal group. It is also evident that, when R and R^1 are cumbersome groups, a situation may arise where the approach of the reagent to either the nitrogen atom [structure (LIX)] or to the oxygen atoms [structures (LX) and (LXI)] is impossible. Thus the failure of a reported attempt at the cyclohexylation of the sodium salt of cyclohexylnitroamines[161] was apparently caused by the high steric constant (−0.79)[178] for the cyclohexyl group.

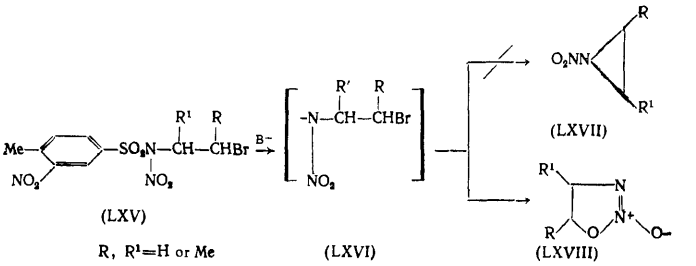
It follows from the inspection of formulae (LX) and (LXI) that they are non-equivalent. The steric hindrance of the approach of the reagent in compound (LXI) is smaller, since in the case of compound (LX) the interactions with group R are superimposed (see the footnote in Section II). This non-equivalence of the oxygen atoms in the limiting structure (LVI) has been confirmed in practice by the preferential formation of the *trans*-isomers in the alkylation of the silver salts of nitroamines.

The possibility of the existence of geometrical isomers of 1-alkoxydiazene 1-oxides (LI) was already suggested by Umbgrove and Franchimont[159] and was demonstrated experimentally in later studies[77,165]. Analysis of kinetic data for the alkaline hydrolysis of the products of the reaction of silver salts of alkylnitroamines led the authors[77,165] to the conclusion that compounds (LI), which had been believed for a long time to be chemical individuals, are in reality mixtures of the *cis*-isomer (LXIII) and the *trans*-isomer (LXIV). The latter are more resistant to the action of acids, alkalies, and light and can be obtained in a pure form.

(LXIII) (LXIV)

The content of the *cis*-isomer was estimated on the basis of the kinetics of the decomposition of "crude" reaction mixtures, (see Table 2).

Evidently the *trans*-isomers predominate quantitatively in the mixtures of products; a general tendency towards a decrease of the content of the *cis*-isomer with increase of the bulk of the groups R and R^1 is also evident. This tendency was confirmed in another investigation. For example, in the methylation of $RNHNO_2$ by diazomethane both the total amount of the *O*-isomer and its content of the *trans*-isomer increase in the sequence R = Me < Et < iso-Pr < t-Bu.[179]

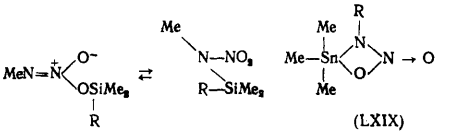


The estimate of the content of the *cis*-isomer in mixtures is not always objective, since its amount depends strongly on the action of light on the silver salt, the reaction time, the excess of the alkylating agent, etc.[77] It has been shown recently that the reaction of dicyclohexylcarbodiimide with ethyl nitroamine leads to the exclusive formation of the *trans*-isomer of the *O*,*N*-diethylnitroamine. This method has been proposed as a promising procedure for the synthesis of the pure product[166].

Table 2. The content of the *cis*-isomer (LXIII) in the reaction of silver salts of alkylnitroamines with alkyl iodides (according to the data of Lamberton and Newton[165]).

$R/RNHNO_2$	R^1/R^1I	Content of *cis*-isomer, %	$R/RNHNO_2$	R^1/R^1I	Content of *cis*-isomer, %
Methyl	Ethyl	15—20	Isopropyl	Methyl	20
Methyl	Isopropyl	15—20	Propyl	Methyl	10
Ethyl	Methyl	30	t-Butyl	Methyl	—

The silver salt of methylnitroamine reacts with methyl iodide, giving rise to a mixture of the *cis*- and *trans*-isomers of *O*,*N*-dimethylnitroamine[169], although it had been postulated earlier that the pure *trans*-isomer was produced in an analogous reaction[165].

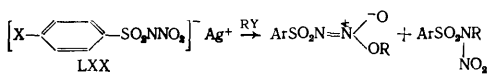


The intramolecular alkylation of nitroamine anions has also been investigated. When alkylnitrosulphonamides (LXV) are acted upon by alkali, the anion (LXVI) is displaced and, as a result of intramolecular alkylation, can give rise to both the *N*-alkyl derivative (LXVII) and the *O*,*N*-alkyl derivative (LXVIII):

(LXV) (LXVI) (LXVII) (LXVIII)

R, R^1=H or Me

In reality the second possibility is realised and it has been shown in relation to the isomeric compounds (LXV, R = H, R^1 = Me) and (LXV, R = Me, R^1 = H) that nitroaziridine (LXVII) is neither the final nor the intermediate product of this reaction[180]. Silylation of methylnitroamine or its silver salt leads to an equilibrium mixture of the *O*- and *N*-derivatives, the content of the *O*-isomer increasing with increasing temperature and in the sequence R = H < Me < iso-Pr ≪ t-Bu.[181,182]



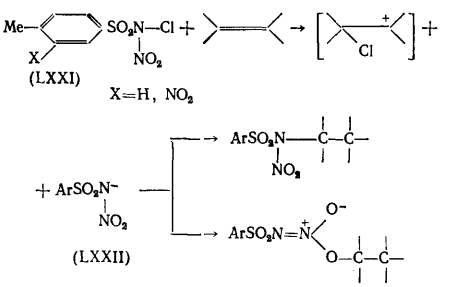
(LXIX)

In contrast to the unstable silyl derivatives, trialkylstannylation of nitroamines or their silver salt leads to stable *N*-derivatives (LXIX).[183] It has been suggested that tin is

coordinated to the oxygen atom of the nitro-group. This conclusion concerning the preferential *N*-stannylation conflicts with the results of the silylation of nitroamine salts[181,182]. Nevertheless, the possibility of *O*-stannylation has been rejected[183] on the basis of the analysis of the infrared spectra of the products.

We have already mentioned the alkylation of nitroamines by diazomethane. Degner and Pechmann[184] showed for the first time that the interaction of methylnitroamine with diazomethane leads to the exclusive formation of the *N*-methylation product, although it was found later that the mixture of products nevertheless contains also the *O*-methylation product[179]. The reaction with isopropylnitroamine gave a mixture of *N*- and *O*-methylation products in proportions of 7 : 3,[162] while other workers[185] ethylated triethylenetetranitroamine with diazoethane and obtained only the *N*-ethyl derivative. Despite certain discrepancies, one may conclude that the *N*-alkylation reaction predominates, but this requires certain comments. If it is assumed that the alkylating species is R^+ or the extremely unstable ion MeN_2^+, then preferential *O*-alkylation is to be expected. A mechanism involving the intermediate formation of a complex of MeN_2^+ with the nitroamine anion has been proposed[146]; this complex subsequently decomposes with evolution of nitrogen. The mechanism is apparently based on the familiar hypothesis by Smith[186] that the combination of diazomethane with a proton and the subsequent attack on methyldiazonium involve the same centre, since, in consequence of its rapid decomposition, the MeN_2^+ cation does not leave the sphere of action of the atom in the substrate. The prospect of testing for prototropic equilibria with the aid of diazomethane is attractive, but unfortunately this possibility is not confirmed in practice[186]. Phenylnitroamine, which has more pronounced acid properties than methylnitroamine, gives rise to the *O*-methylation product on interaction with diazomethane.

The anions of alkylnitroamides (LXX) also exhibit a dual reactivity. Like the anions of primary nitroamines, they can be attacked at the N or the O atom. The reactions of the silver salts of the nitroamides of arenesulphonic acids with alkyl halides give rise to *O*- and *N*-alkylation products[187,188]:



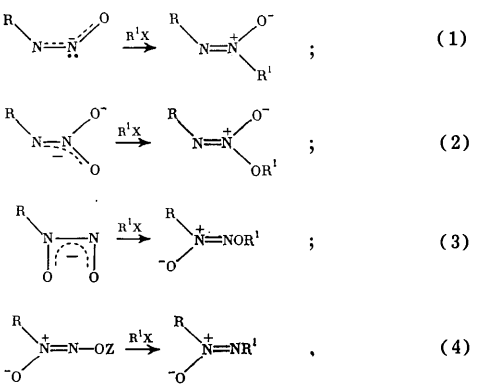
LXX

It has been shown[187] that the ratio of the *O*- and *N*-alkylation products for compound (LXX, X = Me, R = benzyl) is 3.5. Luk'yanov et al.[188] studied in detail the influence of various factors on the ratio of the products of the *O* and *N*-alkylation of compound (LXX). They found that the decrease of solvent polarity in the sequence DMF > acetonitrile > diglyme > ethyl acetate > ether > hexane and the increase of the effective volume of group R in the alkylating agent from the methyl group to the isopropyl group entail an increase of the fraction of the *O*-alkylated product. The latter also increases on passing from alkyl iodides to alkyl bromides.

The salts (LXX, X = Me) form trimethylsilyl and diethylboryl derivatives exclusively via the oxygen atom[189]. The trimethylsilyl group is rigidly bound to the oxygen atom and reversible migration to the nitrogen atom is not observed. Both trimethylsilyl and diethylboryl derivatives are readily hydrolysed and, on raising the temperature slightly, decompose with evolution of N_2O.[189]

Primary *N*-nitroamides have stronger acid properties than nitroamines, but, like the latter, they are alkylated by compounds with small rings (oxirans, aziridines) exclusively at the nitrogen atom[190].

N-Chloro-*N*-nitroamides of arenesulphonic acids (LXXI) add to olefins with formation of *O*- and *N*-alkulation products whose ratio (N/O) increases in the range from 2.0 (cyclohexene, X = H) to 1.4 (styrene, X = H).[191]



(LXXI)

(LXXII)

Luk'yanov et al.[191] proposed a mechanism involving the primary attack by the positively charged halogen on the double bond with subsequent alkylation of the anion (LXXII). If the intermediate existence of the cation is postulated, the *O*-alkylation product should be formed. In reality mainly the nitrogen atom is attacked. A situation analogous to that in the methylation of the *N*-nitroamines by diazomethane arises[146]. The formation of a cationic intermediate may be postulated, but alkylation proceeds contrary to the Kornblum rule. Additional studies will help to resolve these problems.

VI. CONCLUSION

Generalising the data described, one may note that the alkylation of ambident anions with nitrogen–nitrogen bonds can be divided into reactions of two types. Alkanediazotates of primary *N*-nitroamines give rise to azoxy-compounds with the proximal fixation of the *N*-oxide oxygen atom in relation to the incoming group; *N*-nitrosohydroxylamines and 1-alkoxy-(fluoro, toluenesulphonato)-diazene 2-oxides give rise to isomers with the distal fixation of the oxygen.

(1)

(2)

(3)

(4)

All these reactions represent new methods for the synthesis of azoxy-compounds. For example, reaction (1) was described for the first time in 1969[11] and reaction (4) was

described in 1964[74]§. Reactions involving the alklation of primary nitroamines or *N*-nitrosohydroxylamines were elucidated only after studies by Lamberton (1955–1961), Woodward, Freeman, and Stevens (1963–1969). Whereas the competitive alkylation of the O and C atoms has been investigated in comparative detail in relation to the enolate anions or nitroso-compounds[148,173,193,194] (at least in terms of the volume of factual data obtained), the analogous processes for the O–N or O–O atoms have been studied much less. The number of experimental studies whose main aim was preparative synthesis of the final products in the field indicated has been small; there are also difficulties in structural aspects (see, for example, Section III). Many characteristics of reactions (1)–(4) are therefore still obscure. There are no systematic data concerning the influence of the solvent, the metal cation, the salt concentration in solution, etc. on the alkylation processes. The significant role attributed to the study of the influence of these factors on the activity of ambident anions in recent years makes it probable that studies on these lines will be published in the immediate future.

§The exchange reaction (4) was investigated for the first time by Wright and coworkers[70] in relation to 1-alkoxy-2-phenyldiazene 2-oxides, but, since they attributed an incorrect formula to the initial reactant, the experimental results were also incorrectly interpreted. Furthermore, they introduced benzylmagnesium halide into the substitution reaction and obtained a compound whose structure, incidentally, served as a touchstone throughout half a century, but was not [properly] elucidated until the study by Woodward[192]. In view of the enormous factual data contained in the publications by Wright and coworkers, Wright can be regarded as the pioneer in this field.

Cathodic Coupling Reactions

A.V.Bukhtiarov and A.P.Tomilov

Cathodic coupling reactions, occurring in the electrolysis of mixtures of two activated olefins and of a carbonyl compound with olefins and alkyl halides, as well as reactions occurring in the electrolysis of onium salts in the presence of olefins and chemical reactions catalysed by electrochemically generated anions are examined.
The bibliography includes 55 references.

I. INTRODUCTION

Numerous studies dealing with the cathodic reduction of an organic compound to a carbanion or a radical in the presence of compounds capable of interacting with them have been published in recent years. It has been established that there is a possibility of the formation of "mixed hydrodimers", which can be the main reaction products under certain conditions. The number of examples of cathodic coupling reactions has become so great that they can be regarded as constituting a kind of electrochemical method of synthesis. It is quite timely to survey the accumulated data.

The study of the mechanism of the cathodic reduction of organic substances has shown that in many instances electron transfer to a molecule gives rise to highly reactive anions or radicals, which react exceptionally readily with certain organic compounds. The use of this phenomenon made it possible to achieve recently an enormous number of syntheses, some of which have no chemical analogs and are therefore of special interest for organic chemists.

The cathodic coupling reaction was achieved for the first time in 1955 by Wawzonek et al.[1], who obtained diphenylsuccinic acid by the electrochemical reduction of styrene dissolved in dimethylformamide in the presence of carbon dioxide. The authors explained the formation of diphenylsuccinic acid by the fact that the addition of two electrons to stilbene results in the formation of a dianion:

$$C_6H_5CH{=}CHC_6H_5 \xrightarrow{2e} C_6H_5\bar{C}H{-}\bar{C}HC_6H_5$$

The latter is stabilised by the addition of two molecules of carbon dioxide and two protons derived from the solvent:

$$C_6H_5\bar{C}H{-}\bar{C}HC_6H_5 \xrightarrow{2CO_2;\ 2H^+} C_6H_5CH(COOH)CHC_6H_5(COOH)$$

However, this study[1] did not arouse much response. At the beginning of the 1960s vigorous investigation of the electrochemical reduction of activated olefins, particularly acrylonitrile, began. This research demonstrated fairly convincingly that the addition of two electrons and one proton results in the formation under these conditions† of a relatively stable anion, which combines in a readily protonating medium with a second proton to form a product without a double bond. In a medium with a limited proton-donating activity, this anion behaves as a powerful nucleophile and can enter into various reactions. In the simplest case the nucleophile adds to the molecule of the initial substance and the addition product is stabilised as a result of protonation with formation of a hydrodimer. A number of reviews have been devoted to the cathodic hydrodimerisation reaction[2,3]; examination of this reaction is outside the scope of the present article, which deals only with the reactions of organic anions with other substances capable of nucleophilic addition.

† Although this view is not in fact generally accepted, it has been confirmed in many investigations.

II. COUPLING OF ACTIVATED OLEFINS

The cathodic hydrodimerisation of activated olefins achieved at the beginning of the 1960s made it possible to undertake the study of the coupling reaction of two different olefins in accordance with the equation

$$X{-}C{=}C{+}C{=}C{-}Y \xrightarrow{2e,\ 2H^+} X{-}\underset{H}{C}{-}\underset{}{C}{-}\underset{}{C}{-}\underset{H}{C}{-}Y \quad ;$$

X,Y=CN, COOR, $CONH_2$ etc.

The possibility, in principle, of achieving this reaction was first demonstrated in a study[4] where cathodic coupling reactions of acrylonitrile with benzylideneacetone and mesityl oxide, of diethyl fumarate with methyl vinyl ketone, and of methyl vinyl sulphone with cinnamic acid diethylamide were carried out; a high yield of products was noted. In the above study it was already suggested that only one reactant is reduced at the cathode with formation of organic anions, which interact with the second component.

The real possibility that the cathodic coupling reaction proceeds via this mechanism was demonstrated in relation to the cathodic coupling of acrylonitrile and methyl acrylate[5]. Methyl acrylate is the more readily reducible olefin. When present jointly, the two substances give rise to separate well defined polarographic waves. If methyl acrylate is added to a solution with a constant acrylonitrile concentration, then the acrylonitrile wave begins to decrease with increase of the methyl acrylate concentration. This phenomenon can be explained by the fact that the methyl acrylate anions generated in the first electrochemical stage interact with acrylonitrile, which reduces the concentration of the latter in the layer near the electrode. Thus the cathodic coupling of acrylonitrile with methyl acrylate can be represented by the

following scheme:

$$H_2C{=}CHCOOCH_3 \xrightarrow{2e,\ H^+} \bar{C}H_2CH_2COOCH_3 \ ,$$

$$\bar{C}H_2CH_2COOCH_3 \xrightarrow{H_2C=CHCN} CH_3OOCCH_2CH_2CH_2\bar{C}HCN \ ,$$

$$CH_3OOCCH_2CH_2CH_2\bar{C}HCN \xrightarrow{H^+} CH_3OOCCH_2CH_2CH_2CH_2CN \ .$$

Evidently it follows from this mechanism that the yield of the cathodic coupling reaction product depends to a large extent on the ratio of the reduction potentials of the coupled components and on the potential of the cathode at which the electrolysis is carried out.

A study of the effect of the cathodic potential ϕ on the yield of the cross-coupling product W was undertaken[6]. The following relation was obtained for the diethyl maleate–ethyl acrylate system [here (I) = diethyl maleate dimer and (II) = ethyl acrylate]:

φ, V(sat. cal. e-de)	1.314	1.425	1.500
W, mmole	1.18	5.95	12.10
Yield of (I), mmole	3.64	8.50	6.00
Yield of (II), mmole	-	-	8.66

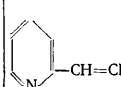
Evidently at cathodic potentials of 1.314 and 1.425 V only diethyl maleate is reduced and the cross-coupling product is formed exclusively as a result of the interaction of the diethyl maleate anions with ethyl acrylate molecules. A further increase of the cathodic potential favours the formation of the cross-coupling product, but, apart from the ethyl maleate dimer, the electrolysis products indicate the formation of the dimer of the component which is harder to reduce, namely ethyl acrylate. Analogous results were obtained in the electrochemical reduction of the diethyl maleate–acrylonitrile system. On the basis of these results, it was concluded[6] that, if the reduction potentials of two substances A and B differ by ~0.2 V (under effective potentiostatic conditions, the difference can be even smaller) and there is an excess of the harder substance to reduce (suppose that this is substance B), a high yield of the cross-coupling product is observed. The influence of the difference between the reduction potentials ($\Delta E_{1/2}$) of the coupled components on the yield of the cross-coupling product with respect to the current W can be demonstrated in relation to the reaction of acrylonitrile with α,β-unsaturated nitriles B:

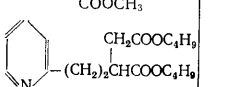
B	Methyleneglutaronitrile	1,4-Dicyanobut-1-ene	1-Cyanobuta-1,3-diene
$\Delta E_{1/2}$, V	0.02	0.10	0.17
W, %	35.4	54.3	81.0
References	7	8	9

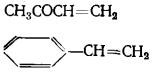
However, the yield of the coupling reaction product is not influenced solely by the cathodic potential and the reduction potentials of the coupled compounds. For example, in the electrolysis of a mixture of acrylonitrile and methyl acrylate the yield of the cross-coupling product depends significantly on the material of the cathode other conditions being equal[5]:

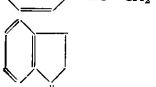
Material of cathode	Graphite	Sn	Pb	Cd	Hg	Al
Yield of ω-cyanovaleric acid ester	50.4	31.0	25.5	22.5	17.3	1.0

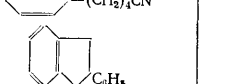
The highest yield of cathodic coupling products was obtained at a graphite cathode, which probably indicates a considerable influence of the surface concentration of the reactants. The component ratio also plays a significant role. As a rule, the component which is more difficult to reduce should be present in a greater excess. Thus, when methyl acrylate was coupled with acrylonitrile, the maximum yield of ω-cyanovaleric acid was obtained for a molar reactant ratio of 1 : 12.[5]

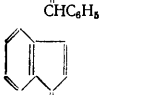


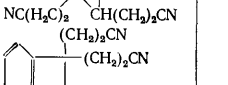












The cross-coupling reactions of the olefins investigated are presented in Table 1, which illustrates effectively the preparative scope of this method. Certain additional information about the olefin coupling reaction can be found in other reviews[2,13].

Subsequent studies showed that alkylidenemalononitriles having the general formula[14]

readily enter into the cathodic coupling reaction with acrylonitrile and methyl acrylate. The nature of the alkyl substituents R′ and R″ has a significant influence on the yield of the coupling products. Certain quantitative characteristics of this reaction are presented in Table 2. It is seen that an increase in the number of carbon atoms in the alkyl group and particularly the branching of the carbon chain lower the yield of the coupling product, evidently in consequence of steric hindrance.

Table 1. The coupling reactions of activated olefins.

Substance A	Substance B	Coupling product	Refs.
$CHCOOC_2H_5$ ‖ $CHCOOC_2H_5$	$H_2C{=}CHCOCH_3$	$CH_2COOC_2H_5$ | $CHCOOC_2H_5$ | $CH_2CH_2COCH_3$	4

$CHCOOC_4H_9$ ‖ $CHCOOC_4H_9$			10
$CH_3COCH{=}CH_2$		$CH_3CO(CH_2)_4$— 	10
	$H_2C{=}CHCN$		11
	$H_2C{=}CHCN$		12
	$H_2C{=}CHCN$		12

One should note that activated olefins are capable of undergoing the cathodic coupling reaction also with alkyl halides[15]. Unfortunately this interesting reaction has been studied only in relation to a few examples.

The electrochemical reduction of a mixture of acrylonitrile and carbon tetrachloride (in methylene chloride plus water as the solvent) in the presence of the Mackie salt (tetraethylammonium toluene-*p*-sulphonate) as the supporting electrolyte led to the formation of trichlorobutyronitrile (with a current yield up to 28%)[15]:

$$H_2C{=}CHCN + CCl_4 \xrightarrow[-Cl^-]{2e,H^+} CCl_3CH_2CH_2CN$$

Carbon tetrachloride is more readily reducible in this system. Evidently, the first stage of the reaction is transfer of the electrons to the carbon tetrachloride molecule and the formation of the ion $\bar{C}Cl_3$, which interacts with acrylonitrile and is then protonated.

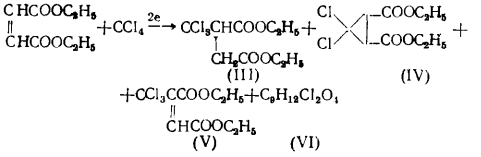

Table 2. The current yields of the products of the cathodic coupling of alkylidenemalononitriles.

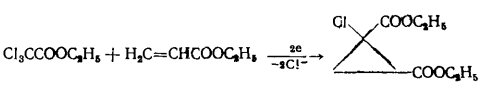
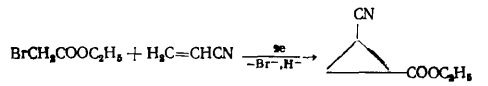
R′	R″	Acrylonitrile	Methyl acrylate	R′	R″	Acrylonitrile	Methyl acrylate
CH_3	CH_3	24.0	19.0	CH_3	t-C_4H_9	5.9	7.6
CH_3	C_2H_5	7.6	8.1	C_2H_5	C_2H_5	14.4	14.3
CH_3	iso-C_3H_7	12.5	7.9	$(CH_2)_4$	—	21.0	12.3

The analogous reaction with ethyl acrylate takes place less selectively[15]; a mixture of at least two products is formed:

$$H_2C{=}CHCOOC_2H_5 + CCl_4 \begin{cases} \xrightarrow{2e,H^+} CCl_3CH_2CH_2COOC_2H_5 \ (9\%) \\ \xrightarrow{2e} CCl_3CH_2CHClCOOC_2H_5 \ (24\%) \end{cases}$$



The reaction of carbon tetrachloride with diethyl fumarate is characterised by an even lower selectivity. An interesting feature of this reaction is that, together with products having a linear structure, cyclopropane derivatives are formed:



The yields of the individual coupling products (%) depend significantly on the cathodic potential ϕ:

Product	(III)	(IV)	(V)	(VI)
φ = -1.00 V	11.8	1.7	9.6	1.7
φ = -1.20 V	38	28	49.5	—

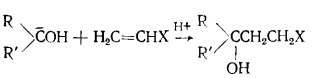
In the electrolysis of a mixture of ethyl acrylate and ethyl trichloroacetate [in an *N*,*N*′-dimethylformamide (DMF) + dichloroacetic acid mixture as the solvent] in the presence of tetraethylammonium chloride as the supporting electrolyte, the only reaction product is a cyclopropane derivative:

An analogous product is formed on coupling the bromoacetic ester with acrylonitrile (2.8%)[15]:

Allyl bromide reacts with acrylonitrile to form 1-cyanooct-4-ene in 12.6% yield[15]:

$$H_2C{=}CHCH_2Br + H_2C{=}CHCN \xrightarrow[-Br^-]{2e,H^+} H_2C{=}CH(CH_2)_3CN$$

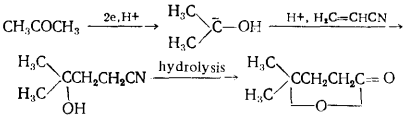
In conclusion of the discussion of the reactions of activated olefins, mention should be made of their interaction with carbon dioxide. For example, electrolysis of a solution of allyl chloride in DMF with a continuous supply of CO_2 leads to the formation of allyl crotonate in a low yield[15]:



$$H_2C{=}CHCH_2Cl + CO_2 \xrightarrow[-Cl^-]{2e,H^+} CH_3CH{=}CHCOOCH_2CH{=}CH_2 \ .$$

III. REACTIONS OF CARBONYL COMPOUNDS

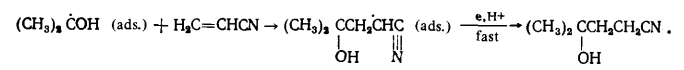
In the presence of quaternary ammonium salts as supporting electrolytes, aliphatic ketones undergo two-electron reduction. In acid solutions the reduction process is significantly facilitated apparently in consequence of protonation. It has been suggested[2] that in acid media the primary electrode process proceeds in accordance with the equation



The carbanion formed is capable of adding to Michael acceptors, forming a cross-coupling product:

The reaction has been studied in greatest detail in relation to the cathodic coupling of acetone and acrylonitrile.

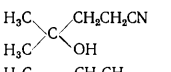
A brief communication[16], showing that the electrochemical reduction of a mixture of acetone and acrylonitrile in 20% sulphuric acid at a controlled potential of the mercury cathode of -1.2 V (sat.cal.e-de) leads to a mixture of γ-hydroxy-γ-methylvaleronitrile and its hydrolysis product γ,γ-dimethylbutyrolactone, was published in 1965; the overall yield of the cross-coupling product was ~70%. Since only acetone undergoes electrochemical reduction under the conditions described (the reduction potential of acrylonitrile in acid solutions is -1.5 V), the authors[16] proposed the following mechanism for the formation of the cross-coupling products:

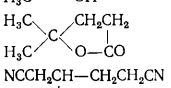


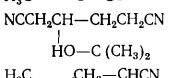
Subsequently this reaction was studied in greater detail[17]. Cyclic voltamperometric data showed that, in an acid solution at a mercury cathode, acetone forms unstable species at a potential of approximately -1.2 V, which undergo reversible oxidation. These species could be detected only at rate of application of potential of 960 V s^{-1}. It has been suggested[17] that these species are of a radical type, since the reduction of acetone is accompanied by the formation of organomercury compounds. The addition of acrylonitrile to the system decreases sharply the surface concentration of these reversibly oxidised species, which indicates their involvement in the interaction with the nitrile. The absence of polyacrylonitrile from the electrolyte solutions shows that the radical species are present on the surface of the electrode and do not diffuse into the bulk of the solution.

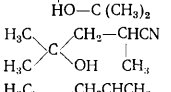
The presence of reactive species on the surface of the mercry cathode in the presence of acetone has also been confirmed by the method involving the application of a brief current

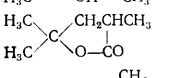
pulse against the background of triangular scanning. On the basis of the results, it was suggested[17] that the primary electrode step is the formation of adsorbed radical species:

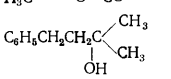


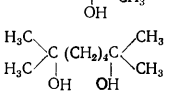












In this case the reaction is first order with respect to acetone; with increase in the acetone concentration to 1 M, the reaction order falls to zero, which shows that molecules of acetone (or of its protonated form) are adsorbed on the electrode before electron transfer. In the second stage of the reaction the adsorbed radicals react with acrylonitrile:

However, although this mechanism agrees with the observed change in the current on pulsation of the potential, it cannot be regarded as rigorously proved, since no direct measurements, indicating the transfer of a single electron to the acetone molecule in the primary electrochemical step, have been made.

Later it was shown[18] that the cathodic coupling of acetone with acrylonitrile can be achieved in a neutral medium at pH 7. The advantage of the neutral medium is that the cross-coupling product is stable under these conditions and the process can be used for the preparative synthesis of γ-hydroxyl-γ-methylvaleronitrile.

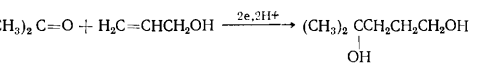


Table 3. The influence of the nature of the olefin on the yield of the product of the cathodic cross-coupling with acetone[18,19] (with respect to the given substance).

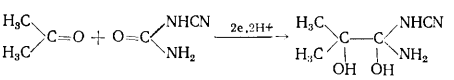
Olefin	Coupling product	Yield
Acrylonitrile		73
Methyl acrylate		70
Dicyanobut-1-ene		30
Methacrylonitrile		20
Methyl methacrylate		19
Styrene		8
Butadiene		6

When the reaction is carried out at a graphite cathode in 1 M aqueous solution of dipotassium hydrogen phosphate acidified with phosphoric acid to pH 7 at a temperature of 7–8 °C, a current density of 0.02–0.03 A cm^{-2}, and for a molar acetone : acrylonitrile ratio of 12 : 1, the yield of γ-hydroxy-γ-methylvaleronitrile is 52% with respect to the current and 85% with respect to the reacted acrylonitrile. By measuring the differential capacitance, it was shown that the maximum yield of the cross-coupling product at a mercury cathode is attained under the conditions of the preliminary adsorption of acrylonitrile on the surface of the electrode[18].



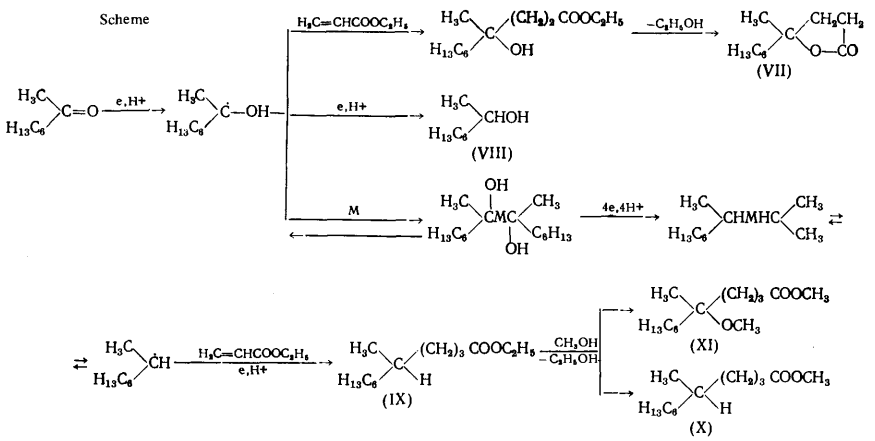
The development of the cathodic coupling of acetone with acrylonitrile on a preparative scale was followed by numerous studies of the applications of this reaction and of its extension to other carbonyl compounds and activated olefins. It was established that acetone enters into the cathodic coupling reaction with numerous activated olefins, forming tertiary alcohols[18,19]. Since the experiments were performed under comparable conditions (graphite cathode, 1 *N* solution of dipotassium hydrogen phosphate, molar ratio acetone : olefin = 10 : 1), it is possible to follow the influence of the nature of the olefin on the yield of the cross-coupling product (Table 3).

It follows from Table 3 that the highest yields of the cross-coupling products have been obtained from acrylonitrile and methyl acrylate, i.e. compounds with a strongly polarised bond. Unexpectedly, acetone undergoes the coupling reaction (albeit with a low yield) with olefins of low polarity such as styrene and butadiene. The yields of the coupling products can apparently be increased, since it has been reported that acetone has been coupled with styrene to give a yield of 42%, with butadiene to give a yield of 32%, and with stilbene to give a yield of 45%. The experimental conditions were not described in detail[20]. It has also been reported[21] that the coupling of acetone with allyl alcohol was achieved to give a high yield of product; electrolysis of a mixture of these substances in an aqueous solution of potassium phosphate at a graphite cathode yielded 2-methylpentane-2,5-diol:

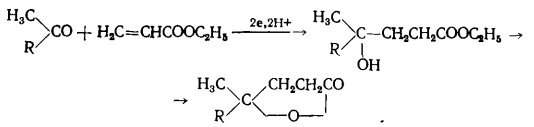
The yield of product was ~70% with respect to the current and 95–98% with respect to the reacted allyl alcohol.

The cross-coupling of acetone with cyanourea was described comparatively recently[22]:

At a mercury cathode in 40% sulphuric acid solution acetone couples with chlorotrifluoroethylene to give a current yield of ~43%.[23] The following reaction mechanism has been proposed:



This reaction resembles the radical addition of 2-propanol to chlorotrifluoroethylene.



Apart from acetone, many other aliphatic ketones undergo the coupling reaction. It was already mentioned in an early study[16] that ethyl methyl ketone and diethyl ketone undergo the coupling reaction with acrylonitrile, giving current yields of 60 and 30% respectively. Under the same conditions, i.e. in an acid medium, the coupling of acetone with methyl pentyl and hexyl methyl ketones was achieved[24], giving overall yields of coupling products of 70 and 72% respectively. Thus the coupling reaction in an acid medium is also entirely suitable for preparative purposes with high aliphatic ketones.

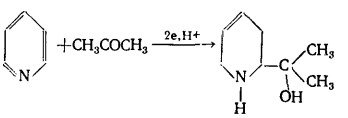
However, we may note that in an acid medium a considerable proportion of the hydroxynitrile formed (~30%) hydrolyses[24]. It is therefore more convenient to couple the ketone with an

Scheme

acrylate ester, for example ethyl acrylate:

In this case the reaction is no longer complicated by the hydrolysis and fairly high yields of lactones were obtained under the same conditions:

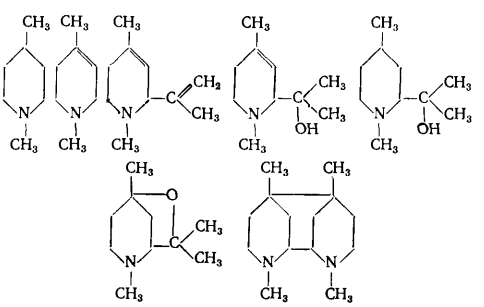
Ketone	$CH_3COC_2H_5$	$CH_3COC_3H_7$	$CH_3COC_5H_{11}$	$CH_3COC_6H_{13}$
Yield, %	80	70	74	42



When ketones are coupled with acid ester, side products are always formed[24]. The processes occurring in the electrolyis of a mixture of a ketone and an ester are presented in the Scheme below (M is the material of the cathode).

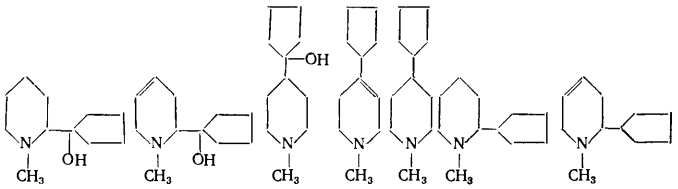
During the coupling of ethyl acrylate with hexyl methyl ketone in aqueous methanol, the formation of the main product, which is the γ-lactone (VII), is accompanied by that of 2-octanol (VIII), the amount of which increases as the potential is displaced to the cathodic region, ethyl 4-methyldecanoate (IX), considerable amounts of which have been noted only at a more cathodic potential, as well as small amounts of its methyl ester (X) together with traces of methyl 4-methoxy-4-methyldecanoate (XI).[24] Apart from the products indicated, also detected were insignificant amounts of hydrocarbons with molecular weights of 224 and 226, which were identified as 7,8-dimethyltetradecane and 7,8-dimethyltetradodecane respectively, and diisopropylmercury; pinacone was not detected as a side product.

In electrolysis in a neutral medium a smaller amount of side products is found[19]. Table 4 presents data for the cathodic coupling of various aliphatic ketones with acrylonitrile and methyl acrylate. A distinct decrease in the reactivity of the ketone with increasing complexity of its carbon skeleton is obseerved in both acid and neutral media.



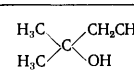
The coupling reaction of higher aliphatic ketones with unsaturated hydrocarbons has been studied in detail[25]. The electrolyte used in the experiments was tetraethylammonium toluene-*p*-sulphonate. The correct choice of solvent is very important in this instance. Preliminary experiments showed that cathodic coupling does not occur in *t*-butyl alcohol, *N*,*N*-dimethylformamide, the monomethyl ether of diethylene glycol, and s-butyl alcohol; in methanol reaction proceeds with an insignificant yield. Mixed solvents proved to be most effective: isopropyl alcohol (20%)–dioxan (80%) and isopropyl alcohol (25%)–dimethyl ether of triethylene glycol (75%). At a graphite electrode coupling proceeds with a higher yield than at a mercury electrode (Table 5).

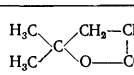
Interesting information concerning the cathodic coupling of acetone with pyridine has been published in a communication[26], whose authors showed that in an acid medium the reaction is directed preferentially to the α-position and proceeds with partial hydrogenation of the pyridine ring:

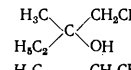


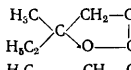
A more detailed investigation of this process showed[27] that the best electrode material in this instance is mercury. Under comparable conditions, the yields of the cross-coupling product at mercury, lead, and cadmium cathodes are 85, 59, and 39% respectively. Cathodic coupling requires the use of acid solutions, since cross-coupling products have not been detected in an alkaline solution. Both an increase in the length of the carbon chain of the aliphatic ketone and the introduction of substituents into the pyridine ring reduce the yield of the coupling product.

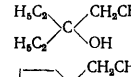
The coupling of 4-methylpyridine with acetone and of *N*-methylpyridinium with cyclopentanone has been studied in detail[28]. It was found that in both cases the coupling involves the 2-position of the pyridine ring. However, according to the authors[28], these reactions are of no preparative interest in view of their low selectivity. Thus the formation of the following products was observed in the electrolysis of a mixture of acetone and *N*,4-dimethylpyridinium:

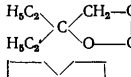


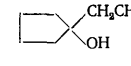


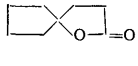












while the products

were isolated in the reduction of *N*-methylpyridinium with cyclopentanone. Further investigation of this reaction showed that the hydrocarbons are formed as a result of the reduction of the tertiary alcohols formed in the first stage of the cross-coupling reaction[29].

Table 4. The influence of the structure of the ketone on the yields of the products of the cathodic coupling of aliphatic ketones with acrylonitrile and methyl acrylate[19].

Ketone	Product of coupling with acrylonitrile*	Yield, %	Product of coupling with methyl acrylate**	Yield, %

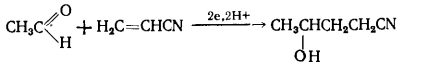
Diethyl ketone		28		21
Cyclopentanone		13		19

*Graphite cathode, 1 *N* solution of dipotassium hydrogen phosphate.



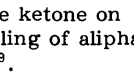
**Mercury cathode, 20% sulphuric acid.

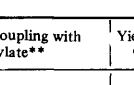
The cross-coupling processes involving aliphatic aldehydes have been studied in less detail. As in the reduction of aliphatic ketones, the reduction of aliphatic aldehydes gives rise to a single two-electron wave[30] and it has been established that the protonated form of the aldehyde is electrochemically active[31]. The first stage of the electrochemical reduction of aliphatic aldehydes involves the formation of an anion:

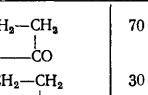
This anion readily reacts with Michael acceptors.

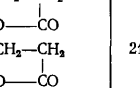
The first report of the possibility, in principle, of the cathodic coupling reaction with activated olefins appeared in a Japanese patent[32]. Later this reaction was investigated in greater detail. For example, it has been shown[33] that the electrochemical reduction of a mixture of acetaldehyde and acrylonitrile leads to the formation of a hydroxynitrile (1-cyano-3-hydroxybutane) in a high yield:

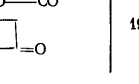
If acrylic acid or its esters are used instead of acrylonitrile, then in both instances the reduction leads to the formation of γ-lactones, since the γ-hydroxyacids and their esters, formed initially, are unstable under the electrolysis conditions and hydrolyse with formation of the corresponding lactones[34], for example:

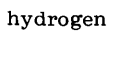


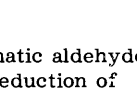


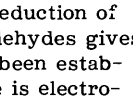












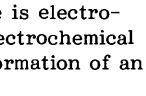


Table 5. Products of the coupling of aliphatic ketones RCOR′ with olefins (cathodic current density 0.014 A cm^{-2}).

*Hex-1-ene. ** Dec-1-ene. ***Penta-1,3-diene. In the remaining cases the olefin was oct-1-ene.

The available information about the cathodic coupling of aldehydes with activated olefins is presented in Table 6. [These data refer to the electrolysis of weakly acid solutions (pH4–6) using a graphite cathode[35]]. It has been shown that, under the conditions described by Tomilov and coworkers[34,35], there is a possibility of the cross-coupling of aldehydes also with alkyl halides. Thus the electrochemical reduction of acetaldehyde in the presence of carbon tetrachloride involves the following process:

An analogous reaction has been observed when other halogeno-compounds were used, such as methylene chloride, allyl chloride, chloroform, etc. The cross-coupling of aldehydes is carried out at the graphite cathode in potassium phosphate solutions in a weakly acid medium (pH 2.0–2.5). The required pH is maintained by the gradual addition of phosphoric acid to the cathodic compartment during electrolysis. Table 7 shows the products obtained in the interaction of aliphatic aldehydes with alkyl halides.

Table 6. Products of the cathodic coupling of aliphatic aldehydes with activated olefins[34,35].

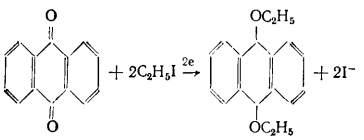
All the examples examined above refer to reactions of aliphatic carbonyl compounds. This type of reaction is not characteristic of aromatic carbonyl compounds. However, in a concentrated aqueous solution of the Mackie salt, it was possible to achieve the cathodic coupling of benzophenone with ethyl acrylate[20]. The yield of the cross-coupling product, γγ-diphenyl-γ-butyrolactone, is ~25%:

$$(H_5C_6)_2CO + H_2C=CHCOOCH_3 \xrightarrow{2e,2H^+} (H_5C_6)_2C(CH_2-CH_2)O-C=O$$

Acrylonitrile has been coupled with benzophenone and benzaldehyde under similar conditions[11]. In the latter case the reaction proceeds in accordance with the equation

$$C_6H_5C(=O)H + 2H_2C=CHCN \xrightarrow{3e,3H^+} C_6H_5CH(OCH_2CH_2CN)CH_2CH_2CN$$

An unusual type of cathodic coupling reaction has been observed[36] in the electrochemical reduction of an anhydrous mixture of benzaldehyde and ethyl iodide, which was saturated with tetraethylammonium iodide to make it electrically conducting. The following reaction takes place at a copper cathode with a low yield:



$$C_6H_5CH(=O) + 2C_2H_5I \xrightarrow{2e} C_6H_5CH(OC_2H_5)C_2H_5 + 2I^-$$

It leads to the formation of the ethyl ether of ethylphenylmethanol[36]; its mechanism has not been studied.

When a mixture of benzophenone and ethyl iodide was electrolysed in *N*,*N*-dimethylformamide, ethyldiphenylmethanol was obtained[37]:

$$C_6H_5C(=O)C_6H_5 + C_2H_5I \xrightarrow{2e,H^+} C_6H_5C(C_2H_5)(OH)C_6H_5 + I^-$$

The ethyl ether of 9,10-hydroanthroquinone is obtained from anthraquinone and ethyl iodide[38]:

IV. CATHODIC REDUCTION OF 'ONIUM SALTS

Conditions favourable for the reduction of 'onium cations are created in the electrolysis of solutions of 'onium salts in a medium with low conductivity or in aprotic solvents. The reduction of the cation is followed by its decomposition, leading to the generation of unstable reactive species. When the solution contains substances reacting with these species, a kind of cathodic coupling reaction takes place.

This type of reaction was achieved for the first time in relation to the generation of cyanomethylene anions[39]:

$$[(H_3C)_2SCH_2CN]^+ \xrightarrow{2e} (CH_3)_2S + \bar{C}H_2CN$$

The electrolysis of a solution of this salt in the presence of acrylonitrile yielded glutarodinitrile with a current yield of 83%. The reaction apparently proceeds as follows:

$$\bar{C}H_2CN + H_2C=CHCN \xrightarrow{H^+} CNCH_2CH_2CH_2CN$$

The electrolysis of a dimethylbenzylsulphonium salt in the presence of acrylonitrile under the same conditions gave a 68%

yield of 3-phenylbutyronitrile[39]:

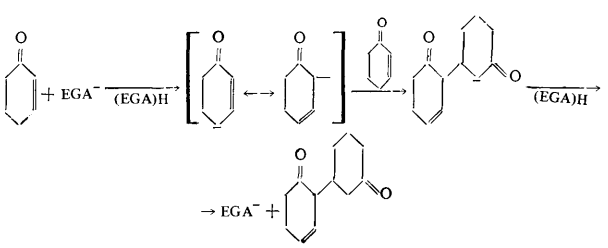
$$(CH_3)_2\overset{+}{S}CH_2C_6H_5 + H_2C{=}CHCN \xrightarrow{2e,H^+} C_6H_5CH_2CH_2CH_2CN + S(CH_3)_2$$

An analogous reaction takes place with phosphonium salts[40], but the yields of coupling products are appreciably lower (on average, they do not exceed 10–13%). It has been suggested[40] that the reaction proceeds via an intermediate stage involving the formation of an organomercury compound:

$$(C_6H_5)_3\overset{+}{P}(CH_2)_n CN \xrightarrow[Hg]{e} (C_6H_5)_3\dot{P}(CH_2)_n CN \,\|\, Hg \rightarrow$$
$$\rightarrow \begin{cases} \rightarrow (C_6H_5)_3P + [Hg(CH_2)_n CN]^{\cdot} \\ \rightarrow (C_6H_5)_3\dot{P}(CH_2)_n CN + Hg \rightarrow (C_6H_5)_3P + {}^{\cdot}(CH_2)_n CN \rightarrow \end{cases}$$
$$\xrightarrow{C_6H_5HC=CH_2} C_6H_5\dot{C}H(CH_2)_{n+1}CN \xrightarrow{e,H^+} C_6H_5(CH_2)_{n+2}CN$$

The nitriles of phenylvaleric ($n = 2$), phenylcaproic ($n = 3$), and phenyloenanthic ($n = 4$) acids have been synthesised in this way. Unfortunately, owing to the low yields, this reaction is hardly likely to find preparative applications. In the electrolysis of phosphonium salts with $n = 1$ neither dimerisation products nor organomercury compounds were detected.

V. OTHER REACTIONS INVOLVING ELECTROCHEMICALLY GENERATED ANIONS



Attempts have been made recently to carry out electrochemically certain classical reactions of organic synthesis, which proceed via a stage involving an organic anion, using the electric current to generate the latter. One of the most promising features of this field of research involves the Michael reaction.

The initiation of the Michael reaction by electrochemically generated anions (EGA^-), which behave as a strong base (for example, in the condensation of malonic ester with acrylonitrile), can be represented by the following equations:

$$EGA^- + CH_2(COOC_2H_5)_2 \rightleftarrows (EGA)H + \bar{C}H(COOC_2H_5)_2 \quad ,$$
$$\bar{C}H(COOC_2H_5)_2 + H_2C{=}CHCN \rightarrow (C_2H_5OOC)_2CHCH_2\bar{C}HCN \quad ,$$
$$(C_2H_5OOC)_2CHCH_2\bar{C}HCN + CH_2(COOC_2H_5)_2 \rightarrow$$
$$\rightarrow (C_2H_5OOC)_2CHCH_2CH_2CN + \bar{C}H(COOC_2H_5)_2 \quad .$$

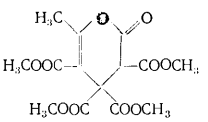
For the reaction to go virtually to completion, catalytic amounts of EGA^- are sufficient. The process described has been carreid out[41] using azobenzene, which on reduction in an aprotic medium gives rise to the fairly active dianions $C_6H_5\bar{N}-\bar{N}C_6H_5$, as the source of EGA^-.[42] The experiments carried out in the above study[41] showed that it is sufficient to add to the solution 0.0025 mole of azobenzene per mole of malonic ester for the above reaction to take place with a yield of 75%.

Furthermore, EGA^- can also be used to obtain dimerisation products when the same substance can behave as the donor and acceptor in the Michael reaction[41]. The reaction involving cyclohex-2-en-1-one can be formulated thus:

The dimer was obtained in 65 mole % yield with reduction of only 0.13 mole % of the monomer[41]. The reactions given in Table 8 were carried out similarly. However, in most cases there is no need to introduce a special substance generating anions. The acceptor itself can function as a substance of this kind. Thus in the above reaction of malonic ester with acrylonitrile, acrylonitrile can function as the source of EGA^- [41]:

$$H_2C{=}CHCN \xrightarrow{2e,H^+} \bar{C}H_2CH_2CN$$

Table 8. Examples of dimerisation reactions initiated by EGA^-.[41]



Monomer	Dimer	Amount of reduced monomer, %	Yield of dimer, %
$H_2C{=}CHCH_2CN$	$CNCH_2CH_2CH_2CHCH{=}CH_2$ (CN)	1.0	35
$CH_3OOCCH_2C{=}CHCOOCH_3$ (COOCH₃)	$CH_3OOCCH_2CHCH_2COOCH_3$ (COOCH₃)	1.5	88
	$CH_3OOCCH{=}CCHCOOCH_3$ (COOCH₃)		
$C_2H_5OOCCH_2CH{=}CHCOOC_2H_5$	$C_2H_5OOCCH_2CHCH_2COOC_2H_5$ (CHCOOC₂H₅)	2.0	50
	$C_2H_5OOCCH{=}CHCHCOOC_2H_5$ (CH₂COOC₂H₅)		

At a mercury cathode in solution in *N*,*N*-dimethylformamide in the presence of tetrabutylammonium fluoroborate as the supporting electrolyte the coupling reaction proceeds with a yield of 18.5% when 0.024 of a faraday of electricity per mole of acrylonitrile is passed through the system. Under these conditions, the coupling of ethyl acrylate with malonic ester was carried out to give a yield of 77% after passing 0.055 of a faraday of current[41].

$$CH_2(COOC_2H_5)_2 + H_2C{=}CHCOOC_2H_5 \xrightarrow{2e,H^+} (C_2H_5OOC)_2CH{-}CH_2CH_2COOC_2H_5$$

The coupling of methyl ethylenetetracarboxylate with methyl pyruvate proceeds to give a yield of 60% [41]:

$$(CH_3OOC)_2C{=}C(COOCH_3)_2 + CH_3COCH_2COOCH_3 \xrightarrow{2e}$$

The yield of the product of the coupling reaction between ethyl ethylenetetracarboxylate and malonic ester is 93%. All the reactions examined are undoubtedly of preparative value. Their characteristic feature is that the electric current is used solely to regenerate the catalyst of the chemical reaction.

The familiar Wittig reaction involves the conversion of carbonyl compounds under the influence of ylids, which are usually obtained by treating a quaternary phosphonium salt with phenyl-lithium:

$$((C_6H_5)_3\overset{+}{P}CH_3)Br + C_6H_5Li \rightarrow (C_6H_5)_3\overset{+}{P}\cdot\bar{C}H_2 + LiBr + C_6H_6$$

Ylids are also formed electrochemically in the electrolysis of phosphonium and sulphonium salts[43,44]. The electrochemical generation of ylids includes oxidation-reduction and acid–base reactions. This process can be achieved by electrolysing a mixture of a phosphonium salt and a substance which readily gives rise to organic anions, for example, azobenzene[45]. The electrolysis of such a mixture at the azobenzene reduction potential (-0.90 V) leads to the formation of the

anions of the latter, which split off protons from the phosphonium salt with formation of an ylid; next the yild interacts with a carbonyl compound, for example, benzaldehyde. The overall mechanism of the reactions can be expressed by the following equations:

$$C_6H_5N{=}NC_6H_5 \xrightarrow{2e} C_6H_5\bar{N}{-}\bar{N}C_6H_5 \text{ (reduction)},$$

$$(C_6H_5)_3\overset{+}{P}CH_2C_6H_5 \xrightarrow{1/2C_6H_5\bar{N}-\bar{N}C_6H_5} (C_6H_5)_3\overset{+}{P}{-}\bar{C}HC_6H_5 + 1/2C_6H_5NHNHC_6H_5 \text{ (abstraction of a proton)},$$

$$(C_6H_5)_3\overset{+}{P}{-}\bar{C}HC_6H_5 \xrightarrow{C_6H_5CHO} (C_6H_5)_3PO + C_6H_5CH{=}CHC_6H_5 \text{ (Wittig reaction)}.$$

It has been shown[45] that the Wittig reaction takes place with a high yield in the electrolysis of a mixture of azobenzene, benzyltriphenylphosphonium bromide, and benzaldehyde in anhydrous *N,N*-dimethylformamide containing lithium bromide. According to the authors[45], the electrochemical version of the Wittig reaction has definite advantages, since it becomes possible to establish readily the required concentration of the base by regulating the current and hence side reactions can be virtually eliminated.

Another example of this reaction is provided by the electrochemical version of the Stevens rearrangement, which involves the conversion of an ammonium salt into a tertiary amine under the influence of, for example, sodium amalgam {Na[Hg]}:

$$C_6H_5COCH_2\overset{+}{N}(CH_3)_2CH_2C_6H_5\ Br^- \xrightarrow{Na[Hg]} \left[C_6H_5CO\bar{C}H\overset{+}{N}(CH_3)_2CH_2C_6H_5\right] \rightarrow C_6H_5COCHN(CH_3)_2CH_2C_6H_5 .$$

In this case azobenzene cannot be used as a depolariser, because it is reduced at a more negative potential than benzyldimethylphenacylammonium bromide. However, the initial substance itself can be employed as the depolariser[46]. The overall chain of processes occurring can be represented by the equation

$$2C_6H_5COCH_2\overset{+}{N}(CH_3)_2CH_2C_6H_5 \xrightarrow[DMF/LiCl]{2e} C_6H_5COCH_3 + C_6H_5CH_2N(CH_3)_2 + C_6H_5CO\bar{C}H\overset{+}{N}(CH_3)_2CH_2C_6H_5 \rightarrow C_6H_5COCHN(CH_3)_2CH_2C_6H_5$$

The reductive acetylation reaction is an example of the use of electrochemically generated bases for organic synthesis. This process was initially investigated in relation to the acetylation of *N*-heterocyclic compounds[47]. The cathodic acetylation reaction consists of the electrolysis of a mixture of nitro- or nitroso-compounds with acetic anhydride in solution in anhydrous acetonitrile. A 0.8 M solution of sodium perchlorate is used as the supporting electrolyte:

$$RNO_2 \xrightarrow{e} [RNO_2]^{\cdot-} \xrightarrow[-AcO^-]{Ac_2O} \left[RN\begin{matrix}O\\OAc\end{matrix}\right]^{\cdot} \xrightarrow[-AcO^-]{e,Ac_2O} RN\begin{matrix}OAc\\OAc\end{matrix}$$

For a nitroso-compound, the process can be formulated as follows:

$$RNO \xrightarrow{e} [RNO]^{\cdot-} \xrightarrow[-AcO^-]{Ac_2O} [RNOAc]^{\cdot} \xrightarrow[-AcO^-]{e,Ac_2O} RN\begin{matrix}OAc\\Ac\end{matrix}$$

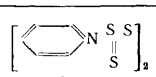
N-Substituted *N,O*-diacetylhydroxylamines have been obtained from various nitroso-compounds with the following yields[48]: CH_3NO_2—54%; $t\text{-}C_4H_9NO_2$—47%; $t\text{-}C_4H_9NO$—57%; $C_6H_5NO_2$—55%; C_6H_5NO—71%; $p\text{-}CH_3C_6H_4NO_2$—77%; $C_6H_4(NO_2)_2$—87%. This reaction is undoubtedly of preparative value.

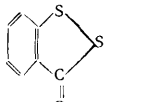
Data on the electrochemical acetylation and alkylation in the cathodic cleavage of disulphides are of interest[49,50]. The reaction is carried out in dimethyl sulphate or in *N,N*-dimethylformamide. A mixture of a disulphide with an alkyl halide or acetic anhydride is electrolysed. Alkylation and acetylation are observed in the former and latter case respectively:

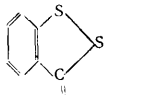
$$RSSR \xrightarrow{2e} 2RS^- \begin{cases} \xrightarrow{2R'X} 2RSR' + 2X^- \\ \xrightarrow[2Ac_2O]{} 2RSAc + 2AcO^- \end{cases}$$

The experiments showed that methylene chloride can be most conveniently used as the methylating agent[49]. The yields of methylation products obtained under these conditions in solution in *N,N*-dimethylformamide in the presence of lithium chloride as the supporting electrolyte are listed in Table 9.

Table 9. The yields of the products of the electrochemical methylation of disulphides[49].







Starting material	Yield, %	Starting material	Yield, %
$[C_6H_5CH_2S]_2$	82		78
$[C_6H_5S]_2$	83		
$[p\text{-}CH_3C_6H_4S]_2$	85		85
$[C_6H_5COS]_2$	70		
$[o\text{-}NO_2C_6H_4S]_2$	91		78

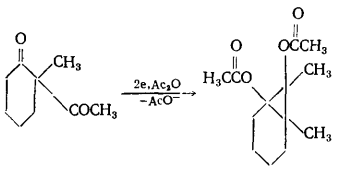
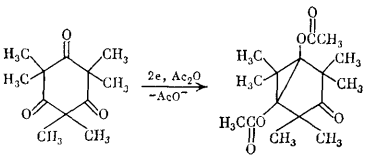
		$[(CH_3)_2NCS]_2$	81
			88

Table 10. Electrochemical alkylation and acylation of disulphides[49].



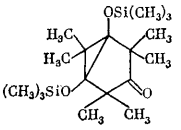
Initial disulphide	Electrode reagent	Yield of cathodic coupling product, %
CH_3SSCH_3	$C_6H_5CH_2Cl$	63
$CH_3COSSCOCH_3$	$C_6H_5CH_2Cl$	76
$C_6H_5SSC_6H_5$	$C_6H_5CH_2Cl$	92
$C_6H_5CH_2SSCH_2C_6H_5$	$CH_3CHClCH_3$	75
$C_6H_5CH_2SSCH_2C_6H_5$	$(CH_3CO)_2O$	83
$o\text{-}O_2NC_6H_4SSC_6H_4NO_2\text{-}o$	$(CH_3CO)_2O$	68
ditto	CH_3COCl	39
»	CH_3I	84
»	$(CH_3O)_2SO_2$	91
»	$(CH_3CH_2O)_2SO_2$	76
$(CH_3)_2NC(S)SSC(S)N(CH_3)_2$	$(CH_3)_2NCOCl$	37
$C_6H_5COSSCOC_6H_5$	CH_2Br_2	66

Somewhat lower yields have been obtained using other alkylating agents, but they nevertheless remain within limits adequate for a preparative process (Table 10).[49] The advantage of the electrochemical alkylation of disulphides over known chemical methods is that the electrochemical procedure makes it possible to obtain thioethers even when the corresponding thiols are unstable or do not exist at all[49].

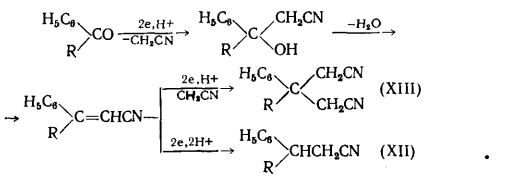


The study of the polarographic behaviour of benzophenone in solution in acetonitrile showed that the addition of acetic anhydride to the solution suppresses the second benzophenone reduction wave. Preparative electrolytic processes carried out at the potential of the first wave showed that benzophenone is acetylated under the conditions indicated[51]:

$$(C_6H_5)_2C{=}O \xrightarrow{+e} [(C_6H_5)_2C{-}O]^{\cdot-} \xrightarrow[-AcO^-]{Ac_2O} [(C_6H_5)_2COAc]^{\cdot} \xrightarrow{+e}$$
$$\rightarrow [(C_6H_5)_2COAc]^- \xrightarrow[-AcO^-]{Ac_2O} (C_6H_5)_2C(COCH_3)OAc \quad .$$



The electrochemical acetylation of diketones was achieved analogously[52]. An acetylated internal cyclisation product has been obtained by the reduction of 2-acetyl-2-methylcyclohexanone in solution in acetonitrile in the presence of tetraethylammonium bromide as the supporting electrolyte at a potential of -2.8 V (sat.cal.e-de) and with continuous supply of acetic anhydride:



The reduction of 2,2,4,4,6,6-hexamethylcyclohexane-1,3,5-trione takes place similarly, the yield of the acetylation product reaching 71%:

If chlorotrimethylsilane is added to the solution instead of acetic anhydride, an unstable trimethylsilyl derivative is formed[53]:

An unusual reaction has been observed in the reduction of aromatic ketones in anhydrous acetonitrile; 3-substituted propionitriles and glutaronitriles are formed under these conditions[54]. In order to explain this reaction, it has been assumed that the anion formed as a result of electron transfer to a molecule of the carbonyl compound exhibits such a high proton affinity that a proton is abstracted from a solvent molecule, generating the anion $\bar{C}H_2CN$:

For acetophenone, the yields of products (XII) and (XIII) are 35–50% and 35–45% respectively. Related carbonyl compounds—benzaldehyde and benzophenone—give rise to similar products. A more detailed study of the reaction mechanism[55] confirmed the involvement of the $\bar{C}H_2CN$ anions.

---oOo---

Thus cathodic coupling reactions are not only of theoretical but also of practical interest, since they extend significantly the applications of electrochemical methods in the synthesis of organic compounds. It is therefore of interest to carry out further studies in this field.

Biochemical Applications of Poly(Ethylene Glycol)

I.N.Topchieva

The literature data on the use of poly(ethylene glycol) (PEG) in biochemistry and molecular biology are analysed from the standpoint of the physical chemistry of polymers. The exclusion properties of PEG, used as a factor influencing the rate of enzymatic reactions, the intra- and intermolecular transitions in polymers, and biopolymer precipitation and crystallisation processes are examined. The suitability of three-component PEG-dextran-water mixtures for the purification and separation of mixtures of biopolymers and for analytical purposes as well as the possibility of using functional derivatives of PEG in immunological research and for the immobilisation of enzymes are discussed. A special section is devoted to the synthesis of PEG derivatives containing different functional groups at the ends of the polymer chain. The surface-active properties of PEG are examined.
The bibliography includes 78 references.

I. INTRODUCTION

The interest in poly(ethylene glycol) (PEG) has been recently stimulated by its successful application in biochemistry and molecular biology, where this polymer is widely used in different kinds of research. Analysis of literature data shows that the experience accumulated by biochemists in the use of PEG (mainly of its aqueous solutions) for the purification and separation of natural products and for analytical purposes can be extended and applied successfully in the solution of certain problems of the physical chemistry of high-molecular-weight compounds. On the other hand, these studies necessitate a more detailed investigation of the chemical and physicochemical properties of PEG and especially of reactions involving its end groups.

Furthermore, there have been a number of studies of the effect of PEG on certain processes in living systems. In its turn, this faces chemists with the problem of the study of the molecular mechanisms of such effects and leads to new prospects for the investigation of the physicochemical properties of PEG and its possible applications.

The aim of this review is to acquaint chemists, mainly specialists in the field of high-molecular-compounds, with experimental data on the applications of PEG in biochemical research and an attempt is made to interpret these results from the standpoint of the physical chemistry of polymers.

II. EXCLUSION PROPERTIES OF POLY(ETHYLENE GLYCOL)

The widest applications of PEG in biochemistry are associated with its use as an exclusion agent. The term "exclusion" was first introduced in biochemical literature and is in essence a synonym of the concept of the "incompatibility of polymers" familiar in the physical chemistry of polymer solutions.

The exclusion principle can be explained by considering the question of the influence of the presence of polymers on the properties of low- and high-molecular-weight substances in solution. In polymer solutions the mobility of small ions and molecules is determined by the "microscopic" viscosity of the system, which becomes appreciable in the range of polymer concentrations where the macromolecular coils appreciably interpenetrate one another (critical concentration). At lower concentrations the microscopic viscosity of the system is small and the diffusion coefficients of small molecules therefore change very little. On the other hand, if another high-molecular-weight compound is introduced into a solution containing a linear polymer, then an apparent increase of the true concentration of the components in relation to the case where the substances are present in solution in a pure state is observed. This effect is usually interpreted as the mutual exclusion of the macromolecules from part of the solution. The hypothesis of exclusion is based on the observation that the change in chemical potentials is a function of the size of the excluded molecules[1].

Studies on the influence of polymers on biochemical processes can be divided into three groups.

1. The study of enzymatic reactions in polymer solutions, i.e. in systems simulating the environment of intracellular enzymes.
2. The study of intra- and inter-molecular transitions in polymers in the presence of exclusion agents.
3. The use of polymers for the precipitation and crystallisation of biopolymers.

The point is that in vitro biochemical processes are in most cases investigated in aqueous buffer solutions. However, the same reactions in vivo take place in the presence of high concentrations of high-molecular-weight substances—proteins, nucleic acids, and carbohydrates, which influence various chemical equilibria.

The first step in the study of enzymatic reactions under conditions approaching those in nature involves enzymatic reactions in the presence of neutral linear polymers which do not interact specifically with the components of the enzymatic reaction. When a polymer is introduced into the system, the chemical activity of enzymes, substrates, and inhibitors increases. Consider a one-substrate reaction described by the equation

$$E+S \rightleftharpoons ES \rightarrow E+P \quad ,$$

where E is the enzyme, S the substrate, ES the enzyme–substrate complex, and P the reaction product. The dissociation constant of the enzyme–substrate complex can be formulated as follows:

$$K = \frac{\gamma_E \gamma_S}{\gamma_{ES}} \cdot \frac{c_E c_S}{c_{ES}}.$$

We shall consider how the size of the reaction components affects the ratio of the activity coefficients†. If the substrate has a low molecular weight, one can assume that the size of the enzyme molecule and of the enzyme–substrate complex and hence also their activity coefficients are similar. The activity coefficient ratio will therefore depend on γS; since the latter quantity apparently differs little from unity, the entire activity coefficient ratio will be close to unity. Thus, in the conversion of lactate into pyruvate catalysed by lactate dehydrogenase,

$$\text{lactate} + NAD^+ \rightleftharpoons \text{pyruvate} + NADH + H^+,$$

$\gamma_S = 0.76$ for pyruvate and lactate in 23% dextran gel, while its value for NAD^+ is 0.62.[1]

On the other hand, if the substrate is a high-molecular-weight compound, whose molecular size significantly exceeds the molecular size of the enzyme, the activity coefficient ratio will be determined by the activity coefficient of the enzyme γ_E, which is as a rule appreciably greater than unity; for example, $\gamma_E = 4$ for the hyaluronic acid–hyaluronate lyase–dextran system and the Michaelis constant K_M should increase approximately by a factor of four. The same order of magnitude of the changes in K_M is in fact observed for enzymatic systems under experimental conditions.

In addition to increasing the chemical potentials, the presence of polymers in solutions can cause a decrease of the diffusion coefficients of other system components, manifesting the so-called sieve effect[1]. This leads to a decrease of the frequency of collisions between the reactants and to a decrease of the maximum rate of reaction v_{max}. However, this effect should not influence the equilibrium constants for the reactions.

We may note that the view that the action of polymers on enzymatic reactions involves energy exchange between the polymeric medium and the enzyme–substrate complex has been expressed in a number of studies#.

The second group of studies is associated with the investigation of intra and inter-macromolecular processes in biopolymers. If the macromolecules can exist in solution in different conformational states characterised by different molecular volumes, then the presence of another polymer in the system should lead to different exclusions of different forms and in the presence of the added polymer the conformation having the smallest volume should be stabilised. The study of the conformational transitions of three polynucleotides from an ordered to a disordered conformation in the presence of dextran and PEG showed[2] that the increase of the stability of the ordered conformation depends on the concentration of the added polymers, PEG showing a higher efficiency in exclusion than dextran. The increase of the stability of the ordered conformation was inferred in the above study[2] from the change in the hypochromic effect as a function of temperature. Two families of melting curves for the poly(deoxyadenylic–thymidylic acid) helix, measured in the presence of PEG of different molecular weight and different dextran fractions, were obtained (Fig.1). The curves in Fig.1*a* show that the change in the melting temperature of the helix depends significantly on the molecular weight of the PEG for the low-molecular-weight fractions, while the dependence is slight for high-molecular-weight specimens (molecular weights of 4000 and 6000). In the case of dextran all the specimens had a high molecular weight, so that the melting temperature of the polynucleotide helix were the same in all cases.

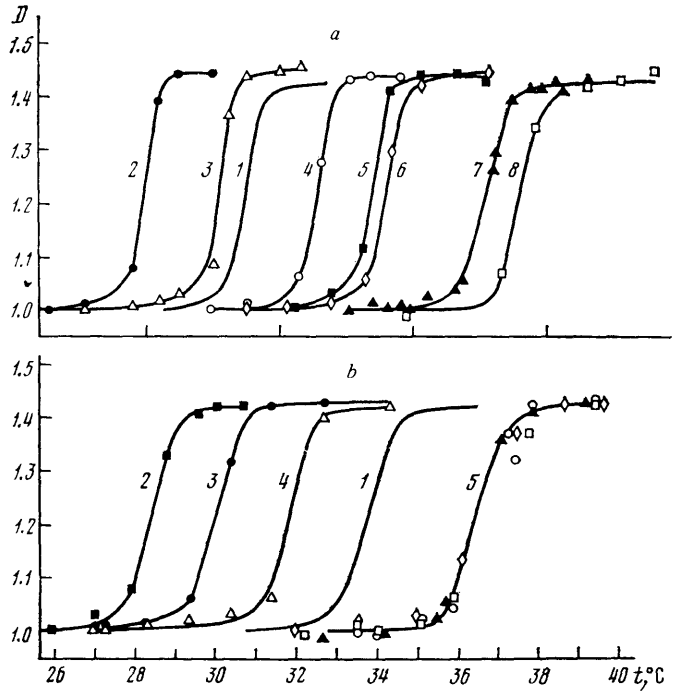

Figure 1. The influence of the molecular weights of PEG (*a*) and dextran (*b*) on the melting of the poly[d(A – T)·d(A – T)] helix in a saline tris buffer[2]; D = optical density at 260 nm: *a*) PEG concentration 20.6 g/100 ml of buffer [1) without addition of polymer; 2) monomer; 3) PEG-200; 4) PEG-400; 5) PEG-600; 6) PEG-1500; 7) PEG-4000; 8) PEG-6000]; *b*) dextran concentration 19.3–19.9 g/100 ml of buffer [1) without addition of polymers; 2) sucrose; 3) glucose; 4) raffinose; 5) dextran-10, dextran-40, dextran-80, dextran-500].

†The activity coefficients γ are found from the relation $K_{av} = 1/\gamma_E$, where K_{av} is the partition coefficient of the given substance between the polymer gel at a known concentration and a buffer.

#S.Damjanovich and B.Somogyi, "Symposia Biologica Hungarica. New Trends in the Description of the General Mechanism and Regulation of Enzymes", Academiai Kiado, Budapest, 1978, pp.159–184.

A good illustration of the exclusion effect is provided by the conversion of a two-stranded DNA molecule into a compact form in an aqueous salt solution after the addition of PEG.[3] This process can be regarded as a model of the structural transitions of DNA in the cell occurring under the influence of of polymers of biological origin.

The idea of using linear water-soluble polymers to act upon other important equilibrium processes in a living organism, such as, for example, the enzyme association–dissociation processes, proved to be very attractive in this connection. This possibility was first pointed out by Laurent[1]. It was realised experimentally in a study[4] where a system containing the enzyme phosphorylase B, which is capable of association, was treated with PEG having a molecular weight of 40000 at a concentration of 4 g/100 ml. The enzyme association process was followed by the sedimentation method in an ultracentrifuge. The enzyme concentration in the system without PEG is selected in such a way that the contents of the dimer and tetramer are 55 and 45%. In the presence of PEG the dimer ⇌ tetramer equilibrium is displaced towards the formation of the tetramer, whose fraction increases to 75%. One should note that in the above study[2] on the compaction of polynucleotides use was made of PEG solutions at concentrations higher by an order of magnitude than in the investigation of Kurganov et al.[4] In the latter case the method of observation precludes the use of such high polymer concentrations in view of the marked increase of the viscosity of the system; this can probably explain the relatively small influence of PEG on the association of the dimeric form of phosphorylase B. Furthermore, the use of higher PEG concentration becomes impossible because the enzyme precipitates at a PEG concentration exceeding 5 g/100 ml.

Yet another striking example of the important role of the polymeric medium in biochemical processes is provided by the observation of the interaction between unlike proteins in the presence of PEG. The following pair of enzymes were investigated: malate dehydrogenase–glutamate dehydrogenase§ and malate dehydrogenase–citrate synthase. It is important to note that the interaction of these enzymes, which are involved in the Krebs cycle, could not be detected in buffer systems in vitro.

Finally, the third region of application of the exclusion effect, which is most important in practice, is associated with the ability of linear polymers to induce the phase separation of the system, i.e. the precipitation of other macromolecular compounds. In this case an appreciable increase of the activity coefficient of the added polymer leads to attainment of the solubility limit by the latter. Together with dextran, PEG is widely used to precipitate proteins[5].

In comparing the abilities of PEG and dextran to induce the precipitation of proteins, one may note that PEG is three times more effective than dextran, in agreement with data obtained in the study of the influence of these polymers on the kinetics of enzymatic reactions[1].

A study has been published recently[6] illustrating the ability of PEG to induce the crystallisation of proteins from aqueous solutions. It has been shown for the crystallisation of 22 proteins that PEG is the most universal reagent compared with those employed previously. The study of the morphology of protein crystals isolated from PEG solutions showed that the structure of the crystals is the same as that of the preparations obtained by the usual methods.

Inspection of the literature data on the exclusion processes occurring in the presence of different water-soluble polymers shows that the most effective exclusion agents are PEG,[1,7–11] dextran[1], and hyaluronic acid[12–14]; polyvinylpyrrolidinone and poly(vinyl alcohol) are less effective[15].

The excluded volumes in systems containing different polymers with the same "partner" can serve as the most natural criterion for the comparison and estimation of the exclusion properties of polymers; however, such data are not available in the literature. Measurement of the excluded volumes is difficult[16]. Ogston¶ and Laurent[17] succeeded in greatly simplifying this problem by considering the simplest model of the interaction of a linear polymer, which can be represented by a long thin rod, with globular particles which are assumed to be spherical (Fig. 2). The greatest exclusion effect, expressed as the excluded volume for S, referred to unit mass of R, observed for asymmetric R. The centre of the spherical particle S cannot approach R to a distance less than r_S. The excluded volume for the centre of S is equal to the volume of the cylinder bounded by dashed lines whose radius is equal to the sum of the radii $r_S + r_r$ (r_r = the radius of the rod). If the end group effect can be neglected, then the volume excluded for the sphere is $\pi l_r (r_S + r_r)^2$, where l_r is the length of the rod. If d is the density of the rod, then its mass is $\pi l_r r_r^2 d$ and the excluded volume v_{excl}, referred to unit mass of R, is

$$v_{excl} = \frac{\pi l_r (r_S + r_r)^2}{\pi l_r r_r^2 d} = \frac{1}{d}\left(\frac{r_S}{r_r} + 1\right)^2.$$

The degree of exclusion increases with increasing radius of S and with decreasing radius of R or with increasing asymmetry of the polymer.

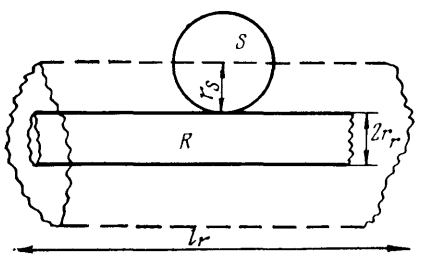

Figure 2. Scheme explaining the phenomenon of the exclusion of a spherical particle by a rodlike particle.

If a series of rods are distributed at random in space, the excluded volumes for individual rods should overlap. The expression for K_{av}, the overall volume accessible to spheres with radius r_S in the space containing randomly distributed long rods with radius r_r, is

$$K_{av} = \exp[-\pi L (r_S + r_r)^2],$$

where L is the sum of the lengths of all the rods per unit volume. We may note that the concentration of the rods (i.e. L) and the square of the radius of the sphere (r_S^2) are the only parameters which determine the accessible volume for $r_r \ll r_S$.

The fraction of the volume accessible for the given substance (K_{av}) is an extremely important parameter for the determination of the exclusion properties of the system. It is related to the excluded volume by the expression

$$v_{excl} = (1 - K_{av})/c_R,$$

where c_R is the concentration of the rods R expressed in terms of mass referred to the volume.

§L.A.Fahien, K.Kmiotek, and L.Smith, Arch.Biochem. Biophys., **192**, 33 (1979).

¶Quoted by Laurent[17].

Despite its simplicity, this theory proved to be entirely applicable to the description of the exclusion properties of certain polysaccharides, in particular dextran and hyaluronic acid[14]. It permits the calculation of K_{av} by Eqn.(5) from the values of r_S, r_r, and L. Comparison of these quantities with the experimental values obtained from gel-filtration data shows an excellent agreement. The linear hyaluronic acid is 4–5 times more effective than the branched dextran. Special experiments showed[8] that 5–10% solutions of dextran have the same exclusion properties as dextran gels at the same concentration. The values of K_{av} and hence the activity coefficients of the substances excluded by the polymer gel can therefore be used subsequently to calculate the activity coefficients of the substances present in solutions of the corresponding polymers.

The excluded volumes in three-component systems containing PEG, a globular polymer, and water, have been found by Edmond and Ogston[18] by measuring the thermodynamic parameters in systems with phase separation.

Adopting the Ogston–Laurent hypothesis as a basis for the description of exclusion effects, one should also bear in mind that polymers influence the structure of water[19–22]. It follows from NMR data for aqueous solutions of PEG that each oxygen atom in the polymer chain binds up to 16 water molecules[23]. Thus PEG has a structure-forming influence on several molecular layers of water. It may be that the structure-forming effect of PEG on water is in fact one of the causes of its appreciable exclusion properties.

One should note that the exclusion principle, which obtains in living organisms and is widely used in molecular biology, can be applied successfully also in the chemistry of high-molecular-weight compounds in order to carry out tasks such as the increase of the specificity of reactions between macromolecular components, the crystallisation of water-soluble polymers, etc.

III. THE USE OF THREE-COMPONENT POLY(ETHYLENE GLYCOL)–DEXTRAN–WATER SYSTEMS FOR PREPARATIVE AND ANALYTICAL PURPOSES

The same exclusion principle, namely the mutual displacement of polymers from part of the solution, is also responsible for phase separation in systems consisting of two polymers in a common solvent. When aqueous solutions of dextran and PEG at concentrations above the critical value are mixed, a two-phase system is formed in which PEG is contained in the upper phase and dextran in the lower phase. Such systems, which can be "buffered" and made isoosmotic, are widely used for the separation of biomacromolecules, cell particles, viruses, membranes, chloroplasts, etc. by partitioning the relative substances between different phases[24]. Together with the dextran–PEG pair, other pairs incorporating modified derivatives of these polymers are also used, for example, dextran–methylcellulose, dextran sulphate–dextran, dextran sulphate–carboxymethyldextran, etc.

The specific features of three-component systems containing two polymeric components are such that phase separation occurs even for polymers with very similar chemical structures, present in solution at low concentrations. The main application of two-phase systems consist in the separation of substances by partitioning between two polymeric phases. This method of separation is more effective than other procedures—electrophoresis and sedimentation[24].

The most remarkable property of the PEG–dextran system, containing non-ionogenic polymers, is the influence of electrolytes on the partition of substances between phases[25]. The fact that a given substance can be transferred from one phase to another simply by adding, for example, NaCl in excess relative to sodium phosphate or by substituting Li^+ ions by Na^+ ions is of interest from both theoretical and practical points of view. It has been noted[26] that negatively charged biomacromolecules have higher partition coefficients in two-phase systems containing sodium sulphate than in those containing sodium chloride; the opposite behaviour has been observed for positively charged compounds. Plots of the partition coefficients K of proteins in phases containing Na_2SO_4 and NaCl against pH consist of two curves intersecting close to the isoelectric point[24]. Such crossed curves are illustrated in Fig.3 for bovine serum albumin[27]. Using two-phase systems at different pH, Sasakawa and Walter[27] obtained the isoelectric points also for a number of other proteins and investigated the dependence of the isoelectric points of haemoproteins on the molecular weight. Blomquist[28] obtained the isoelectric points for the enolase isoenzymes. There is no doubt that this method can be used successfully also for the determination of the isoelectric points of synthetic polyelectrolytes.

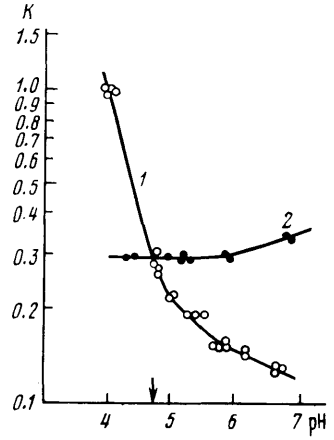

Figure 3. The cross-distribution curves for bovine serum albumin; pH dependence of the partition coefficient K in a two-phase system containing NaCl (curve *1*) and in a system containing Na_2SO_4 (curve *2*).

It is believed[24] that there is a non-uniform distribution of ions between the phases of the PEG–dextran–water system, which leads to a potential difference between the phases defined by the relation

$$U_2 - U_1 = \frac{RT}{(z^+ + z^-)F} \ln \frac{KB^{z^-}}{KA^{z^+}}, \qquad (1)$$

where z^+ and z^- are the numbers of positive and negative charges arising on partitioning the salt A_z-B_z+, F is the Faraday, and K_{Bz^-} and K_{Az^+} are the partition coefficients of the anion and cation respectively.

This potential difference influences in its turn the distribution of the polyelectrolyte or charged species, such as those of proteins and nucleic acids. As a result of the large number of charges on the biomacromolecules, the behaviour of such species in the partitioning process depends strongly on the interfacial potential even if the latter is relatively small.

The problem arises of the cause of the non-uniform distribution of different inorganic electrolytes between the phases. It is believed[25] that cations exhibit a greater affinity for PEG than for dextran, the affinity decreasing in the sequence $Li^+ > Na^+ > K^+$. At the same time, an increase of the affinity of the anions for PEG has been noted in the series of halides with decrease of their polarisability in the sequence $I^- > Br^- > Cl^-$. On the other hand, it has been found[25] that SO_4^{2-} and HPO_4^{2-} have a greater affinity for dextran. These phenomena are due to differences in the tendencies towards the formation of ion pairs in the two phases.

The introduction of charged groups at the ends of the PEG molecule has an even greater influence on the interfacial potential. Typical examples of charged PEG are bistrimethylamino-PEG and PEG-bissulphonate[29]:

$$(CH_3)_3\overset{+}{N}CH_2CH_2OCH_2CH_2O \ldots OCH_2CH_2\overset{+}{N}(CH_3)_3$$
$$^-O_3SCH_2CH_2OCH_2CH_2O \ldots OCH_2CH_2SO_3^- .$$

When these polymers are introduced into the PEG–dextran two-phase system, they move to the PEG-containing phase, as a result of which the system acquires the properties of a liquid ion exchanger.

The decisive factor in the distribution of proteins between the phases is their charge. On the other hand, the required distribution of substances could be attained either by introducing charged groups into the dextran molecule, using, for example, DEAE- or CM-dextrans, or by adding exogenous polyelectrolytes to the system. However, in this case the components of a polyelectrolyte two-phase system have such a high charge density in their molecules that, in conformity with Eqn.(7), the potential difference between the phases diminishes. Furthermore, dextran derivatives frequently migrate to the PEG-containing phase. Finally, the formation of polymeric complexes between polyelectrolyte molecules and cell particles, which are difficult to dissociate, has been noted[24]. Thus the main advantage of charged PEG is that the charges are located solely at the ends of the polymer and the macromolecules retain their affinity for the PEG-containing phase[24].

In his study of the distribution of proteins in two-phase systems, Albertson (quoted by Blomquist[28]) proposed a method which makes it possible to determine the surface charge of proteins. He derived the following equation which makes it possible to relate the partition coefficient of the protein K to the overall molecular charge z and the interfacial potential ψ:

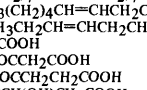
$$\ln K = \ln K^0 + zF\psi/RT,$$

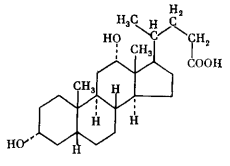
where K^0 is the partition coefficient of the protein having an overall charge of zero.

The use of two-phase systems also made it possible to discover a new method of estimating the hydrophobic properties of macromolecules and small molecules[30]. For this purpose, the end groups of PEG were modified with hydrophobic ligands, in particular, they were esterified by aliphatic acid residues. The PEG modified in this way moves to the same phase as the unsubstituted polymer and makes it less polar. By studying the distribution of a large number of compounds in the same system containing 80–95% of water, it is possible to compare their hydrophobic properties. Using this method, it is natural to adopt as a measure of the hydrophobic properties of the given substance the difference between the free energies of the transfer of 1 mole of the substance from the upper phase of the system containing unsubstituted PEG to the upper phase of another system containing the hydrophobic ligand bound to the polymer:

$$\Delta G'' - \Delta G' = -2.3\, RT\, \Delta \lg K, \qquad (2)$$

where $\Delta G''$ is the free energy of the transfer of 1 mole of the substance from one phase to another in a system containing a hydrophobic polymeric ligand and $\Delta G'$ is the corresponding quantity for a standard two-phase system containing unsubstituted PEG.[30] The quantity $\Delta \lg K$ in Eqn.(2) is defined as follows:





$$\Delta \lg K = \lg K_0'' - \lg K_0',$$

where K_0'' and K_0' are the distribution constants of the substance in the system containing the hydrophobic ligand and in the standard system.

This method for the determination of the hydrophobic properties of substances makes it possible to eliminate effects due to the electrostatic interactions between the molecules of the polymeric ligand and the protein. Another advantage of the method is that the hydrophobic interactions can be investigated in water, in the absence of organic solvents.

The use of hydrophobic ligands bound covalently to PEG constitutes one of the examples of the introduction of affinity ligands into PEG in order to enhance the specificity of the separation of natural products. The same principle has been used for the specific extraction of a number of proteins[31]. For example, a dinitrophenylated derivative of PEG has been used to isolate the S-23 myeloma protein from a mixture[32]. In order to purify steroid-binding proteins, such as plasma transport proteins, PEG containing oestradiol residues as end groups was synthesised as a ligand with a high affinity for the protein[33].

Table 1. Poly(ethylene glycol) esters of various acids.

Acid used to esterify PEG	No. of carbon atoms in acid residue	Degree of substitution, %
Acetic CH_3COOH	2	17
Butyric $CH_3(CH_2)_2COOH$	4	12
Caproic $CH_3(CH_2)_4COOH$	6	9
Caprylic $CH_3(CH_2)_6COOH$	8	12
Capric $CH_3(CH_2)_8COOH$	10	9
Lauric $CH_3(CH_2)_{10}COOH$	12	7
Myristic $CH_3(CH_2)_{12}COOH$	14	8
Palmitic $CH_3(CH_2)_{14}COOH$	16	9
Stearic $CH_3(CH_2)_{16}COOH$	18	11
Oleic $CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH$	18	11
Linoleic $CH_3(CH_2)_4CH{=}CHCH_2CH{=}CH(CH_2)_7COOH$	18	6
Linolenic $CH_3CH_2CH{=}CHCH_2CH{=}CHCH_2{=}CH{=}CH(CH_2)_7COOH$	18	6,5
Malonic $HOOCCH_2COOH$	3	15
Succinic $HOOCCH_2CH_2COOH$	4	16
Malic $HOOCCH(OH)CH_2COOH$	4	11
Tartaric $HOOCCH(OH)CH(OH)COOH$	4	6
Fumaric $HOOCCH{=}CHCOOH$	4	4
Benzoic 	7	4
Nicotinic 	6	4
Trichloroacetic CCl_3COOH	2	1
Bromoacetic $BrCH_2COOH$	2	36
Iodoacetic ICH_2COOH	2	5
Deoxycholic 	24	8

Affinity partition can also be used as an analytical method for the measurement of the binding constants and of the number of binding centres in proteins in relation to different ligands[34]. For this purpose, a number of PEG esters of carboxylic acids, both monobasic and dibasic with different numbers of carbon atoms as well as acids containing a double bond, hydroxy-groups, etc., have been synthesised (see Table 1).

Serum albumin (SA) is known to have a high affinity for aliphatic acids. This explains the significant influence of the addition of PEG esters of higher aliphatic acids to the two-phase system on the distribution of SA. In the standard system SA is displaced predominantly to the dextran-containing phase. In the presence of PEG esters, which migrate to the same phase as PEG, the aliphatic acid residues are absorbed on the SA surface.

SA is known to have seven centres which strongly adsorb long-chain aliphatic acids ($K_{ass} = 10^6-10^8$ litre mol^{-1}) and twenty centres with a much lower affinity ($K_{ass} = 10^2-10^3$ litre mol^{-1}).[34] If only strong binding is considered, it is seen that the protein can bind seven molecules of PEG esters. The resulting complex exhibits an affinity for the upper, PEG-containing phase.

An equation has been obtained[35] establishing a relation between the partition coefficient and the chemical structure of the partitioned substance; according to this equation, the introduction of a new chemical group of the given type into the molecule of the complex alters lg K by a constant amount[35]:

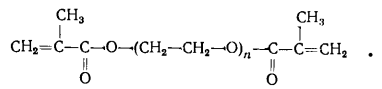
$$\lg K = \lg K^* + n\alpha,$$

where K is the distribution constant of the SA–PEG ester complex, K^* the distribution constant of free SA, n the number of PEG ester molecules in the complex, and α the increment in lg K following the introduction of each new ester molecule.

It has been shown[34] that the equation holds for SA–PEG ester complexes. Using different PEG esters, the increment α was determined and the values of n were calculated. In the calculations no account was taken of the decrease of the accessible surface of the protein with increasing number of bound ligand molecules. If this effect is not very great, the distribution in two-phase systems containing PEG esters can serve as a convenient method for the determination of the number of binding centres in the protein molecule. The binding curves (the dependence of lg K on the ester concentration) can be used to calculate the binding constants.

This method for the investigation of the binding of proteins to ligands is particularly convenient when it is necessary to work with small amounts of protein.

In such cases radioactive labels are used to detect proteins in solution. In this respect, the method for the investigation of binding using two-phase systems has advantages over the method of equilibrium dialysis. Another possibility of using "affinity partition" involves the determination of the type of binding centres present in biopolymers, membranes, and cells.



Thus the method based on the distribution of substances in two-phase systems permits not only the purification and separation of biomacromolecules but also yields much information about their various properties, about dimerisation and aggregation, about denaturation under certain conditions, and about the change in the charge of the proteins as a function of pH. The method can also be employed to determine the surface charge of the molecules, their isoelectric points, relative hydrophobic properties, the extent of binding to different ligands, etc.

IV. BIOCHEMICAL ASPECTS OF THE USE OF MONO- AND BI-FUNCTIONAL DERIVATIVES OF POLY(ETHYLENE GLYCOL)

In the description of the properties of two-phase systems the use of disubstituted PEG was already mentioned above[29, 32,33,67], although the need for specifically bifunctional derivatives was not considered.

One of the promising applications of disubstituted derivatives of PEG involves their use as cross-linking agents in the immobilisation of enzymes[36].

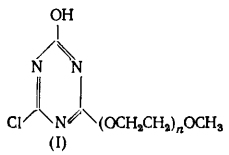
One study has already been made on the use of the bifunctionality of PEG in the immobilisation of enzymes[37]. In this study the PEG end groups were esterified by methacrylic acid, which yielded PEG dimethacrylate:

When PEG preparations with different molecular weights were used, polymers were obtained containing at the ends photosensitive functional groups located at the required distance from one another. Next, a mixture, containing the given polymer, enzyme, or microbial cells, was prepared and irradiated for several minutes with ultraviolet light. This yielded matrices cross-linked via their ends and containing the biological materials enclosed in them. The enzyme yeast invertase was immobilised in this way. The photosensitive polymers based on PEG have the following advantages: they form mechanically strong networks, are chemically inert, and are sufficiently permeable to the substrate and the products of the enzymatic reaction. This example by no means exhausts the possibilities of the use of PEG as a cross-linking agent.

In connection with the development of research into the synthesis of medicinal polymeric compounds (MPS), we think it would be extremely useful to synthesise and investigate the properties of such compounds based on PEG. The problem of the determination of the correlation between the structure of the MPS and its physiological activity, which is fundamental, can be solved most rigorously when only a controlled number of pharmacologically active fragments is introduced into the polymer chain. This approach can be used via the chemical modification of the end groups in macromolecules whose functionality is known beforehand.

PEG having hydroxy-groups at the ends of the chain meets these requirements fully.

On the other hand, a necessary requirement which must be met by polymeric carriers, is the immunostimulating activity of the polymer itself. This requirement is also satisfied by PEG, which exhibits the properties of an immunostimulant†.



The literature data available at present on the MPS based on PEG involve only one field of application—immunology. The possibility of employing mono- and bi-functional PEG derivatives as antigens for the study of the mechanism of the antigen–antibody interaction has been studied[38]. The interaction of antibodies isolated from immunised animals, with mono- and di-substituted derivatives of 2,4-dinitrophenyl-PEG has been investigated by methods involving the quenching of fluorescence[39] and light scattering[40]. The experimental data obtained in these investigations[38–40] made it possible

†I.N.Topchieva, N.Yu.Alekseeva, V.P.Evdakov, R.V.Petrov, I.V.Savinova, E.D.Filatova, L.I.Khaustova, R.M.Khaitov, and M.B.Temchenko, "Tezisy Doklada na IV Vsesoyuznom Nauchnom Simpoziume "Sinteticheskie Polimernye Materialy Meditsinskogo Naznacheniya"" (Abstracts of Reports at the IVth All-Union Scientific Symposium "Synthetic Polymeric Materials for Medical Purposes"), Dzerzhinsk, 1979, p.5.

to observe structural differences between the binding centres of immunoglobulins, to estimate the distances between the binding centres for two types [class IgG and IgG(T)] of antibodies, and to assess the differences between their conformations in solution.

An important stage in the study of PEG derivatives containing antigenic determinants is the investigation of their activity in vivo. The 2,4,6-trinitrophenylethyl ether of PEG with a molecular weight of 40000, which exhibited a high antigenic activity, was synthesised for this purpose†.

Studies on the chemical modification of proteins with PEG derivatives, which alters the immunological properties of the former, are of great interest[41–43]. The reagent was PEG with a molecular weight of 2000, in which one end group contained the 2-chloro-4-hydroxytriazine moiety, capable of interacting with the amino-groups of the protein, while the other was a hydroxy-group converted into the methoxy-derivative:

(I)

When catalase is treated with this reagent, it is possible to substitute up to 60% of the amino-groups while retaining the enzymatic activity of the protein[41]. A higher degree of substitution of the amino-groups by the reagent reduces the enzymatic activity of catalase. A catalase preparation with a 75% degree of substitution (PEG-catalase) proved to be inactive in relation to the antiserum for native catalase, which was established by gel diffusion and complement fixation methods. The introduction of PEG-catalase into the blood of mice did not lead to the production of antibodies against both PEG-catalase and native catalase. Thus chemical modification of catalase by the PEG reagent yielded a modified enzyme without immunogenic properties. These studies constitute the first step on the way to the solution of the problem of reducing the immunogenic properties of proteins, which will make it possible to extend significantly the therapeutic applications of exogenic enzymes.

A patented method involving the reductive alkylation of the NH_2 groups of enzymes using an aldehyde-derivative of methoxy-substituted PEG and sodium tetrahydroborate was devised in a continuation of the above investigation[42]. The method makes it possible to obtain enzyme preparations with a higher activity and stability compared with those obtained previously.

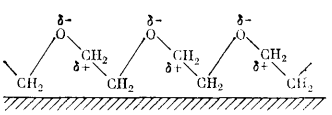
Reagent (I) has been used[43] for the chemical modification of antigen E, the principal protein allergen of ambrosia pollen. The aim of this modification was to obtain an antigen derivative with a reduced allergenic activity but retaining the immunogenic properties of the native molecule. According to the generally accepted concept, the allergenic activity consists in the liberation in the cell of chemical mediators of allergic symptoms in the interaction of polyvalent antigens with immunoglobulins of class IgE. Chemical modification of antigens, leading to a decrease of the number of accessible antigenic determinants or to a decrease of the affinity for specific antibodies, should reduce their allergenic activity. By controlling the degree and type of chemical modification, it is possible to obtain mixtures of derivatives partly (but not fully) retaining the immunogenic properties of the native protein.

In the interaction of the PEG-reagent with antigen E, containing 18 lysine amino-groups, on average 11 lysine residues reacted. The study of the immunological properties of the PEG derivative of antigen E showed[43] that the latter stimulates the production of specific antibodies, although it is a weaker immunogen than the native protein. At the same time, the PEG-antigen shows a markedly reduced allergenic activity compared with the native antigen. The properties of several derivatives of antigen E, modified via their amino-groups, namely PEG and dextran derivatives, as well as two other derivatives obtained as a result of the introduction of low-molecular-weight groups (*N*-carboxymethyl and butyrimidato-) into the molecule, have been compared[43] (Table 2). Evidently the PEG derivative undergoes a greater decrease of allergenic activity compared with the dextran derivatives, despite the fact that the molecular weight of dextran significantly exceeds that of the fragment of the polyoxyethylene chain. It is of interest to note that both these derivatives have the same molecular volumes, which follows[43] from the identity of their elution volumes in gel chromatography on Sepharose 6B.

Table 2. The properties of derivatives of antigen E modified at the lysine amino-group[43].

Derivative of antigen E	Molecular weight	No. of modified lysine residues	Molecular weight of introduced group	Overall charge of modified antigen	Relative allergenic activity
Native protein	38000	0	0	−9	1
PEG derivative	53000	7	2100	−16	0.024
N-Carboxymethyl derivative	39000	16	58	−31	0.56
Butyrimidato-derivative	39000	16	72	−9	1
Dextran derivative	140000	4	25000	−9	0.15

This finding can probably be explained on the basis of the difference between the degree of compactness of the PEG and dextran macromolecules in aqueous solutions. The more compact dextran molecules are less effective as regards the steric blocking of the antigenic determinants compared with the less compact PEG groups. We are probably dealing in this instance with exclusion effects generated by different polymers, which are now bound covalently to the molecules of the antigen protein, in relation to the antibody proteins. Examination of the mechanism of the action of PEG-containing proteins from this point of view makes it clear why the modification of the protein by the PEG reagent does not affect its interaction with low-molecular-weight substrates (catalase activity) but hinders significantly the protein–protein interactions (the immunogenic and allergenic activities).



V. THE SURFACE-ACTIVE PROPERTIES OF POLY(ETHYLENE GLYCOL)

The usefulness of PEG for the immobilisation of various physiologically active compounds is also associated with its ability to exert a specific influence on the lipid layer of membranes[44]. The idea of the influence of PEG on the structure of lipids arose as a result of observations that PEG induces the merging of plant protoplasts[45], chicken erythrocytes, chicken erythrocytes with yeast protoplasts[46], and mammalian cells[47].

In order to investigate the molecular mechanism of the action of PEG on cells, a study has been made[44] of the influence of PEG on phospholipid monolayers simulating cell membranes. The authors considered how relations of the surface pressure–area and surface potential–area type vary for phosphatidylcholine and phosphatidylethanolamine monolayers when various low-molecular-weight compounds (glycerol, sorbitol, and dimethyl sulphoxide) as well as PEG specimens with different molecular weights are introduced into the aqueous phase. It was found that all the compounds tested caused considerable changes in the surface potential of the phospholipid layer in the state of dense molecular packing. However, the orders of magnitude of the concentrations of the additive causing the maximum decrease of the surface potential are significantly different for the low-molecular-weight compounds and PEG. Thus the optimum concentrations of the additives in the case of monolayers of dipaltimoylglycerylphosphorylcholine are 3.8 M glycerol, 3 M dimethyl sulphoxide, 1.5 M sucrose, and 2 M sorbitol. On the other hand, the corresponding concentrations of different PEG fractions are 4.2×10^{3} M PEG-6000, 1.5×10^{-3} M PEG-15000, 2.5×10^{7} M PEG-300000, and 1×10^{9} M PEG-5000000. Thus, together with the much greater specificity of the action of PEG, one may note a significant dependence of its influence on its molecular weight.

The authors[44] do not reach a definite conclusion concerning the molecular mechanism of the action of PEG on membranes. In order to account for its role, one should probably turn to the properties of PEG at the interface, primarily at the water–air interface. A detailed study has been made of this problem[48] and it has been shown that PEG is able to form monomolecular films on the surface of water. Depending on the contraction pressure, the polymer can exist in two conformations—a looser conformation occupying an area of 28 Å^2 per monomer unit and a compact conformation occupying an area less than 16 Å^2 per unit.

The study of the behaviour of PEG under polarographic conditions[49] showed that it is adsorbed on negatively charged surfaces in such a way that the negatively charged polar atoms of the ether oxygen are directed towards water, while the non-polar $-CH_2-CH_2$ groups are directed to the negatively charged surface of mercury:

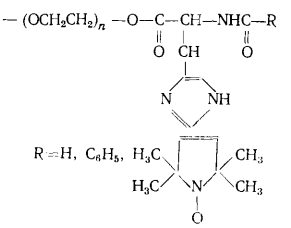
(3)

According to Hillson's calculations[49], the area occupied by the monomeric PEG unit, adsorbed on such a surface, is 13 Å^2.

These data suggest that, when PEG interacts with lipid monolayers, type (3) dipole interactions between the PEG units and the dipoles of the polar head of the lipid also take place. If this is the case, then the range of compounds interacting with PEG and capable of forming complexes of the type resembling the polymeric complexes of PEG with polymeric acids[50] can be greatly extended; numerous surface-active compounds, capable of forming monolayers on the surface of water, should be included among them.

On the other hand, the ability of PEG to act on membranes suggests that this property should be manifested not only in the phenomenon of cell fusion but also in other subcellular processes such as endocytosis, exocytosis, etc., which is extremely important for the functioning of physiologically active compounds incorporating PEG fragments.

Interactions of the dipole–dipole type probably constitute the basis of the molecular mechanism of the action of PEG as a stabiliser of hydrophobic sols[23]. It is striking that in this case one also notes a pronounced dependence of the stabilising activity of PEG on its molecular weight.



VI. THE SYNTHESIS OF DISUBSTITUTED DERIVATIVES OF POLY(ETHYLENE GLYCOL)

The great practical importance of PEG and the wide-scale employment of this substance and its derivatives in various fields of molecular biology have stimulated the development of research into the chemical modification of the hydroxy-groups at the ends of PEG. We may note that the thoroughly investigated hydroxyethylation reactions, used to synthesise non-ionic detergents[51], make it possible to obtain only monosubstituted PEG derivatives. The most rational method of synthesising bifunctional PEG derivatives consists in the chemical modification of the end groups of PEG.[51,52] Despite their apparent simplicity and triviality, these reactions have in fact many characteristic features and merit a more detailed examination.

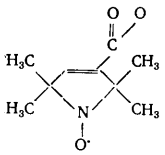
PEG specimens with molecular weights up to 20000 are obtained mainly by the hydroxyalkylation method; they contain hydroxy-groups at their ends. Polymers of expoxyethane having a high molecular weight are obtained by other methods; as a rule, they do not contain functional groups at their ends[52].

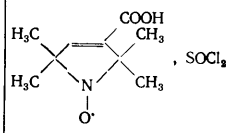
The hydroxy-groups of PEG undergo reactions of the type usual for alcohols. Numerous PEG derivatives of the type $R-O-(CH_2-CH_2-O)_n-R$, where R = Me, Ph, CH_3CO, or C_6H_5CO, and of the type $R-(CH_2-CH_2-O)_nR$, where R = C, Br, PhS, etc., are known. The reactions between PEG and the corresponding low-molecular-weight reagents are in many cases quantitative and can therefore be used to determine the number-average molecular weight and the molecular-weight distribution[53]. Table 3 presents a list of PEG derivatives substituted in their end groups.

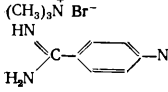
The specific features of the esterification of the hydroxy-groups of PEG were observed for the first time in the synthesis of polymeric derivatives of histidines having the general formula[71]

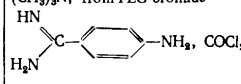
It was found that in all these cases it is impossible to achieve the complete substitution of the PEG end groups. Special experiments, whose aim was to increase the yield of the polyoxyethylene ethers by modifying the condensing agent and by altering the nature of the solvent and the order of mixing of the reactants, did not lead to a significant alteration of the degree of substitution. All these findings apparently reflect internal features, characteristic of the PEG chain, and definite structural changes occurring in the macromolecule on modification of the latter by the given substituents. The introduction of a polar group at the end of the polymer chain, for example, an imidazole or amide group, leads to structure formation, which hinders the complete modification of all the end groups.

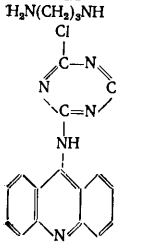
Table 3. Poly(ethylene glycol) derivatives.

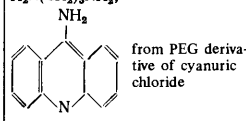


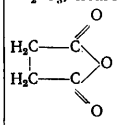


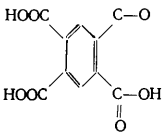


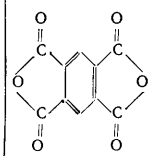


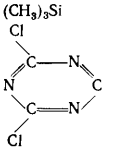


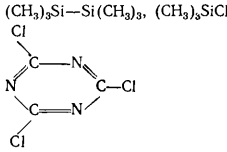


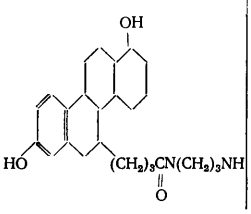


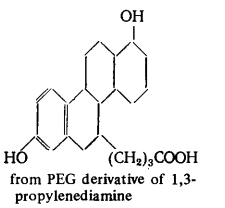


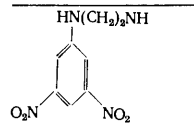


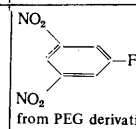


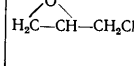


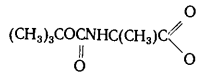


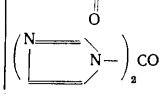


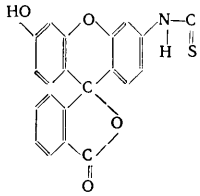


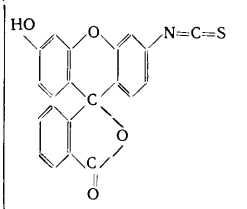


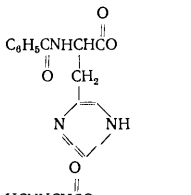


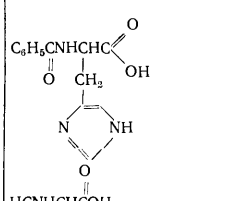


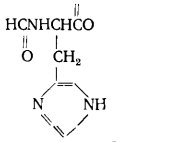


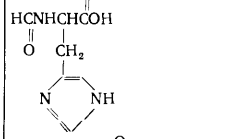


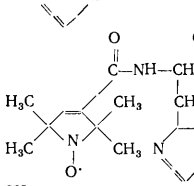


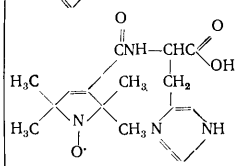


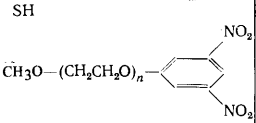


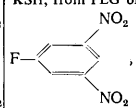


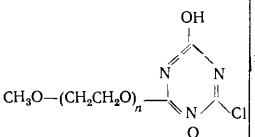


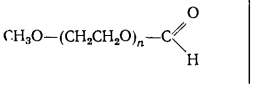












End of group of PEG derivative	Formula of reagent	Yield, %	Refs.
Br	PBr_3	quantitative	29

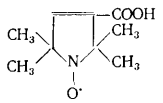
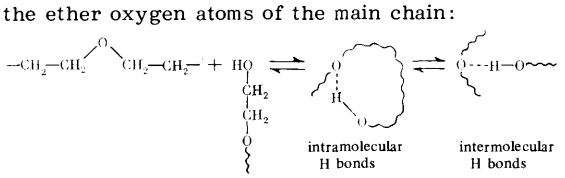
*Yield not indicated.



In order to analyse this problem, it is necessary to alter consecutively the nature of the substituent and to follow the changes in the yield and structural characteristics of the

resulting polymers. An attempt has been made[73] at a systematic investigation of the esterification reaction by employing a number of acids RCOOH, where R are aminoacid residues containing the iminoxy-substituent as the *N*-protecting group:

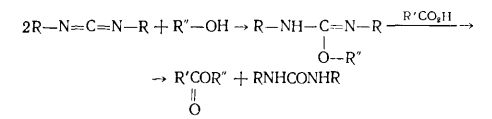


N-substituted glycine *N*-substituted phenylalanine

The simplest spin-labelled acid species, namely the 3-carboxy-2,2,5,5-tetramethylpyrrolin-1-yloxy-radical

was used as the first member of the series. It was shown[73] that the reaction involving the first member of the series goes almost to completion, in agreement with the literature[61]. On passing to the next member, a decrease of the degree of substitution to 35–40% was observed, while in the case of the PEG derivative of phenylalanine the degree of substitution fell to 8%. Thus one may conclude that the introduction of the amide group into the PEG molecule decreases significantly the reaction yield and to a greater extent the more bulky the substituent introduced into the composition of the acid residue.

In order to account for the characteristic features of the reactions described by Topchieva et al.[73], we should consider initially the modification of PEG by carboxylic acids without polar groups. As a rule, such reactions are carried out in non-polar media in which the hydroxy-end groups of the initial PEG form intra- or inter-molecular hydrogen bonds with the ether oxygen atoms of the main chain:



It was shown[60] that, depending on the PEG concentration, one or other type of hydrogen bonds predominate. It was natural to suppose that free hydroxy-groups are involved in the esterification reaction and, as the latter proceeds, the equilibrium shifts towards the non-associated hydroxy-groups.

On the other hand, if the polar group of the substituent is at the end of the macromolecule, then the latter, like the hydroxy-group will tend to form a hydrogen bond (intra- or inter-molecular) with the oxygen atoms of the main chain. The decrease of the degree of substitution on passing to a substituent incorporating polar groups indicates a decrease of the accessibility of the hydroxy-groups of the unreacted PEG. Presumably the hydroxy-groups of PEG, forming hydrogen bonds with the associated polymer molecules, become sterically relatively inaccessible for the reactants.

This hypothesis makes it possible to explain the experimentally observed[73] decrease of the degree of substitution following the introduction of substituents containing polar groups into the ends of the chain, on the one hand, and the dependence of the degree of substitution on the size of the terminal substituent, on the other. Indeed, the greater the bulk of the substituent the looser become the associated species and the greater the number of free hydroxy-groups which can be "entangled" within the associated macromolecules.

In this connection it is of interest to analyse data[34] on the synthesis of a number of polyoxyethylene ethers by the carbodiimide method. The authors[34] obtained an activated PEG derivative by treating it with dicyclohexylcarbodiimide and this derivative was then introduced into a reaction with a carboxylic acid:

The yields of the polymeric esters proved to be very low (Table 1). On the other hand, when palmitoyl chloride is used in the synthesis of the PEG ester of palmitic acid, then esters with a degree of substitution of approximately 80% are obtained. Preliminary activation of PEG by dicyclohexylcarbodiimide apparently leads to the formation of PEG derivatives containing the R–NH–C(=O–R′)= group, whose structure is very similar to that of the amide group, which can also form hydrogen bonds leading to the formation of associated macromolecular species. The correlation between the increase in the size of the substituents and the decrease of the degree of substitution of the esters is striking. Quantitative substitution could apparently be attained if dicyclohexylcarbodiimide was used to activate the carboxy-component with subsequent introduction of the glycol.

A considerable advance in the development of research into the chemical modification of PEG was made in studies[77,78] devoted to the synthesis of polyoxyethylene esters of aminoacids and peptides[75–78]. In the first place, using a large excess of low-molecular-weight reactants, the authors were able to obtain high yields (80–99%) of *N*-protected aminoacid esters by carrying out the reaction in an aqueous or organic solvent ("the liquid-phase method of synthesis")[77,78]. Next, as a result of the so-called crystallisation method which they developed[70], the authors were able to reduce greatly the duration of the synthesis by increasing the efficiency of the elimination of unreacted substances and impurities from the reaction products. Finally, another advantage of the use of PEG as the *C*-terminal protecting group consists in the fact that the latter facilitates the dissolution of sparingly soluble peptides in solvents of different chemical types, which makes it possible to investigate their conformational state in solutions by the method of circular dichroism[70]. We may note that the possibility of using this method in relation to PEG-peptides is due to the optical transparency of PEG in the visible and ultraviolet regions up to 190 nm.

The hydrophobic octapeptide of the myoglobin sequence 66–73 was investigated by this method[70] and the influence of the substituted or free *N*-terminal amino-group on the conformation of the peptide was observed. It was shown that the blocked octapeptide is more helical than the corresponding peptide with an unsubstituted amino-group. The conformational state of the PEG-esters of nona- and deca-alanines was studied in the same investigation in two solvents—trifluoroethanol and water—and it was shown that the peptide with the free amino-group has the β-conformation in both solvents. The corresponding peptide containing the *N*-protecting group has the helical conformation. Hence the authors[77] concluded that the terminal amino-group has a decisive influence on the formation of the β-structure of the peptide. It is striking that, following the introduction of terminal peptide fragments, capable of forming stable conformational isomers, the effects of the interaction of these groups with the main PEG chain in

organic solvents become minimal. However, in aqueous solutions of PEG-reagents containing hydrophobic end groups there is a possibility of hydrophobic interactions between the non-polar groups of the peptide fragment, leading to the formation of micellar structures in which the hydrophobic nucleus of the micelle consists of the non-polar end groups and the role of the hydrophilic surround is played by the polymeric PEG chains. Association of a similar type has been observed[71] for polyoxyethylene esters of *N*-substituted benzoylhistidines.

In conclusion we should like to emphasize that the study of the interaction of a polymer with biomacromolecules in vitro or with an organism in vivo should develop in parallel with the study of its physicochemical properties. One may hope that this approach will in fact lead to a mutual enrichment of these types of research.

The Structure of Organocyclosiloxanes

V.E.Shklover and Yu.T.Struchkov

X-Ray results form the basis of a discussion of the stereochemistry of monocyclic siloxanes—monomers yielding polyorganosiloxanes—as well as the structure of higher polycyclic siloxanes, simple oligomers. A list of 105 references is included.

I. INTRODUCTION

The practical usefulness of two classes of polymers having inorganic main chains—polycyclosiloxanes and polyphosphazens—is firmly established. Both hetero-organic and macromolecular aspects of the chemistry of organosiloxanes and organophosphazens have been studied in some detail.

Among the main lines of attack on which investigators attempting to produce novel polymers with inorganic main chains concentrate their efforts, three are directly related to the subject of the present Review—firstly the production of polymeric molecules having a non-traditional structure (cyclolinear, spirocyclic, etc.),[1,2] secondly a transition to polymers having main chains differing in composition (polysilazanes, polyheterosiloxanes, polyphosphoxans, polysilthians, polyborazens, etc.),[1-4] and thirdly study of the influence of the framework both on the character of the bond and the conformation of the inorganic unit and on the overall properties of the polymeric product[5].

There is no doubt about the importance of structural investigations for these three lines of research. The increasing number of studies, consequent mainly on the growth in instrumental physicochemical methods, have been made at different structural levels, from the simplest molecules containing only one silicon (phosphorus, etc.) atom in the organic framework to polymeric macromolecules of molecular mass $\sim 10^6$. The investigators usually attempt to relate their structural information to the observed (or supposed) properties of the compounds. The transferability of such conclusions to real compounds depends, of course, on the level at which the structural investigation has been made. Research on the structure of polymers is "closer to life" than that on simple molecules, but the information is considerably more complicated to interpret than in the latter case. Therefore the qualitative aspect predominates in the former, and the quantitative aspect in the latter studies.

The present Review summarises results of X-ray structural investigations on organocyclosiloxanes, which have been more thoroughly studied in relation to polymers than have other types of hetero-organic monomers (although numerically organophosphazens predominate), which helps to reveal several rules useful in analysing the structure of other classes of monomers.

In analysing and comparing structures it has been borne in mind that these compounds serve either as monomers or as oligomers of polymers containing common structural units. The following restrictions must, of course, be taken into account in elucidating correlations between the properties of the lower monomeric (and oligomeric) structures and those of the polymers. (i) The properties of polymers depend on their structure at all levels, i.e. on the primary, secondary, and tertiary structures (crystal-chemical analysis of the structure of the monomer will give information only on the primary and to some extent the secondary structures). (ii) Crystal-chemical analysis applies to molecules situated in a crystal field, which may change the equilibrium conformation of the free (reacting) molecule. (iii) It is improbable that the solid-phase polymerisation of siloxanes will have a purely topochemical mechanism: it will most likely occur in amorphous zones, while the elements of the crystalline order will be retained.

These and perhaps other limitations on crystal-chemical conclusions regarding the structure of polymeric products and reactivity in the solid phase must be borne in mind by the reader of the Review. However, it appears to the Reviewers that such restrictions do not so much diminish the practical value of the crystal-chemical approach as emphasise the complexity of the problems and thereby justify the idealised approach employed in the Review.

The chemistry of organosiloxanes is largely that of organosiloxane rings. Very great variation in size is characteristic of $(SiO)_n$ rings†, which may be either isolated (monocyclic siloxanes) or fused, with extremely diverse modes of fusion (spirocyclic, cyclolinear, and other polycyclosiloxanes).[1] The natural sequence in which cyclosiloxane structures are discussed in this Review (initially monocyclic, and then more complicated fused polycyclic systems) enables the structure of complex polycycles to be analysed in terms of results for their simpler constituents.

†The existence of disiloxane rings $(SiO)_2$[6,7] has not yet been confirmed by means of X-rays. Rings $(SiO)_n$ having $n = 10$–15 are probably of practical value, although there are indications of the existence of rings with n up to 400.[8]

II. MONOCYCLIC SILOXANES

Table 1 gives the most important structural constants for trisiloxane rings D_3# in monocyclic cyclotrisiloxane derivatives investigated by X-ray structural analysis. These rings have an approximately planar structure in which the maximum divergence of atoms from the planes of the rings is $\Delta = 0.01$ Å. Such a planar structure is evidence of some steric strain in these rings. Indeed the SiOSi bond angles in trisiloxane rings (131–134°) are among the smallest known. However, disruption of the planarity of the rings would have implied a still greater decrease in these bond angles, which, as will be shown below, would have weakened the silicon–oxygen bonds and diminished the stability of the rings. Even in complicated sterically strained fused polycyclic systems the departure of atoms from the planes of the trisiloxane rings does not exceed 0.4 Å (see below).

Table 1. Data on trisiloxane rings in monocyclotrisiloxanes.

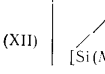
No.	Formula	l_{Si-O}, Å	α_{SiOSi}	Δ, Å	Ref.
(I)*	$(Me_2SiO)_3$	1.61	136°	0**	9
(II)	$(Ph_2SiO)_3$	—1.64	131.9°	0.07	10
(III)	*cis*-$(MePhSiO)_3$	1.65	132.3°	0.10	11
(IV)	*trans*-$(MePhSiO)_3$	1.65	132°	0.05	12
(V)	$Na_3[PhSi(O)O]_3$	1.647	133.5°	0.029	***

*Determination of this structure was inaccurate, and has been disregarded in the comparison with others.

**Molecule in a special position (see text).

***This compound crystallises as the octahydrate $Na_3(C_6H_5SiOO)_3.8H_2O$. Some of the results of this investigation have appeared in Ref. 13.

The molecule (I) has an ideally planar structure. Its great intrinsic symmetry (D_{3h}) is retained even in the crystal, where the molecules occupy unique positions (space group $R3m$, $Z = 1$). The impossibility of packing a large number of bulky phenyl substituents in a sufficiently highly symmetrical space group probably prevents realisation in the crystal of the potentially high intrinsic symmetry of molecule (II). An example of the geometrical isomerism of cyclosiloxanes is provided by molecules (III) and (IV). Organosiloxanes are often formed as mixtures of geometrical isomers. In some cases clear identification of isomers acquires practical importance, e.g. with isomers (III) and (IV), which differ sharply in their polymerisation properties[14]. Other examples of the use of X-ray structural analysis to solve problems of the identification of isomers will be found in the Review.



#The notation adopted for the configurations of organosiloxanes combines the symbols for the four structural units[8]

Functionality	Symbol	Unit
Mono	*M*	$R'R''R'''SiO_{1/2}$
Di	*D*	$R'R''SiO_{2/2}$
Tri	*T*	$RSiO_{3/2}$
Tetra	*Q*	$SiO_{4/2}$

The subscript following the oxygen atom denotes the number of oxygen atoms per silicon atom (e.g. $\frac{3}{2}$ indicates that the silicon atom is attached to three oxygen atoms, each of which is combined with another silicon atom).

Great interest attaches to the structure of the siloxane anion in sodium *cis*-1,3,5-triphenylcyclotrisiloxane-1,3,5-triolate (V). The distance Si–O^- to the ionised oxygen atom was first determined (on the average 1.586(2) Å). The T_3 ring in structure (V) is appreciably "flattened" in comparison with the D_3 rings in molecules (II)–(IV), and has well defined C_{3v} symmetry (crown conformation), with the plane of the three cyclic oxygen atoms located farther from the exocyclic oxygen atoms than is the parallel plane of the three silicon atoms. If the conformation of the ring can be explained by the *T* character of the cyclic silicon atoms (C_{nv} symmetry is characteristic even of larger T_n rings—see below), the great "flatness" is probably due to mutual electrostatic repulsion of Si–O^- groups. The cyclic silicon–oxygen bond lengths in (V) are the same as in other trisiloxane rings.

Table 2. Data on tetrasiloxane rings in monocyclotetrasiloxanes*.

No.	Formula	l_{Si-O}, Å	α_{SiOSi}	Symmetry of ring	Conformation of ring	Angles of fold	Ref.
(VI)	$(Me_2SiO)_4$ (β-form)	1.65	142.5	C_i	chair	31.3°	15
(VII)	$[(Me_2SiO)(Ph_2SiO)_2]_2$	1.62	148.5°	S_4	boat	27.5° и 31	16
(VIII)	*cis*-$[(MePhSiO)(Me_2SiO)]_2$	1.63	144.2°	C_2	boat	35.5°	17
(IX)	*trans*-$[(MePhSiO)(Me_2SiO)]_2$	1.622	145.2°	C_i	chair	31°	18
(X)	$(R_2SiO)_4$	1.62	149°	C_i	chair	34.2°	19, 20
(XI)	*cis*-$[(Me(OH)SiO(Ph_2SiO)]$	1.622	144°	S_4	boat	40.2°	см.*
(XII)		1.636	140°	C_i	chair	24°	см.*

*The angle of fold of the ring in (IX) is close to that found for structure (VI); the chair conformation in structure (X) differs (see text) from the chair conformation in (VI); for the structures (XI) and (XII) see Refs. 100 and 101 respectively; $R_2 = [CH_2]_4$; and $R' = CH_2.C(COOC_2H_5)_2.CH_2$.

The rings in organocyclosiloxanes $(RR'SiO)_n$ with $n > 3$ are non-planar, and hence may be expected to exist in different conformations. Table 2 gives data on structures having eight-membered tetrasiloxane rings. Comparison of Tables 1 and 2 shows§ that silicon–oxygen bonds are shorter in tetrasiloxane than in trisiloxane rings (on the average respectively 1.62 and 1.65 Å), and the SiOSi angles are larger (respectively 142–149° and 131–134°). Thus the silicon–oxygen bonds are more stable in D_4 than in D_3 rings.

Fig. 1 shows diagrammatically possible conformations of cyclic systems $(AB)_4$ comprising alternating atoms, which include tetrasiloxane rings. With the SiOSi bond angles observed in tetrasiloxanes (142–149°) all the conformations indicated in Fig. 1 (with the exception of D_{4h}) are possible, as well as conformational transitions between them.

X-Rays have been used to study the structure of the low-temperature β modification of octamethylcyclotetrasiloxane, which at −16.3 °C passes into the high-temperature α modification melting at 17.5 °C. In a crystal of the β modification

§It must be borne in mind when making the comparison that structures (I) and (VI) have not been determined with great accuracy.

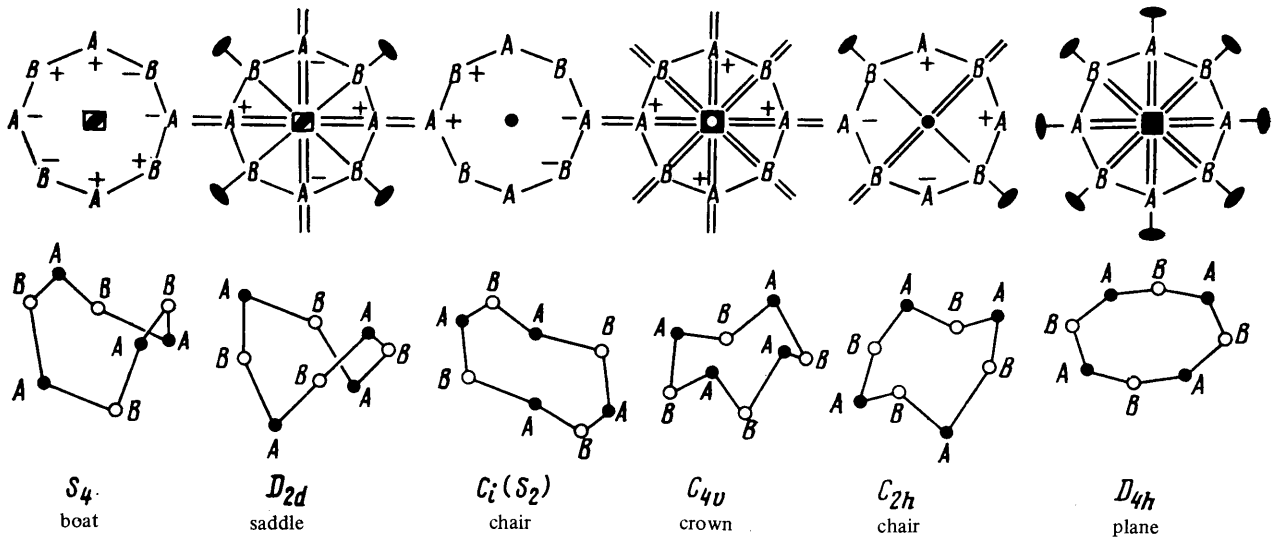


Figure 1. Possible ideal conformations of $(AB)_4$ rings comprising alternating atoms[16]. The plus and minus signs show the divergence of atoms above and below the mean plane of the ring.

the molecules are located at centres of symmetry, and the D_4 ring has a chair conformation (Fig. 1).[15] The molecule is located at a special position also in a crystal of the α modification, but now on a fourfold axis: i.e. it has a boat or saddle conformation[15]. It was supposed originally[15] that the phase transition involved the appearance of orientational disorder, since it was assumed by analogy with organic rings that the heat of transition would be too small to change the conformation of the molecule. A later spectroscopic investigation showed[21] that conversion into the high-temperature modification was a conformational transition with a change in the intrinsic symmetry of the molecule.

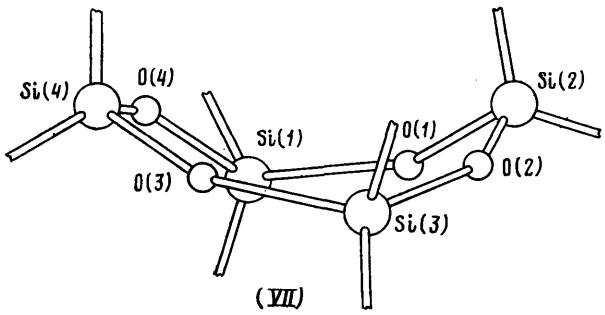

Figure 2. Conformation of D_4 ring in molecule (VII).[16]

The D_4 ring in molecule (VII) has non-crystallographic symmetry intermediate between S_4 and D_{2d} (closer to S_4), with a boat conformation (Fig. 2). The $Si_{(1)}O_{(1)}Si_{(3)}O_{(3)}$ plane, which constitutes the "bottom" of the boat, forms with the $Si_{(1)}O_{(4)}Si_{(4)}O_{(3)}$ and $O_{(1)}Si_{(2)}O_{(2)}Si_{(3)}$ planes dihedral angles of 27.5° and 31° respectively.

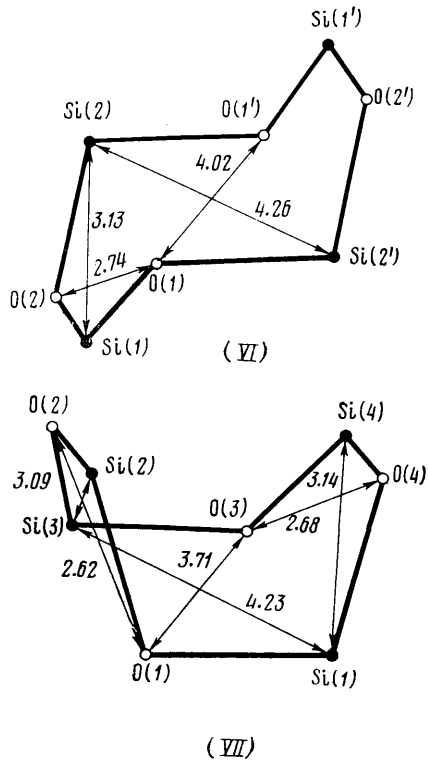

Figure 3. Non-bonded endocyclic distances in D_4 rings in molecules (VI) and (VII).[16]

Ideally chair–isomerism involves rotation of only one diatomic Si–O group relative to the remaining part of the ring. However, Fig. 3 shows that the real molecules (VI) and (VII) differ

also in the geometry of the central portion of the D_4 ring (the "bottom" of the boat). In particular, the difference between the diagonal Si...Si and O...O distances in the central portion is smaller in (VI) (4.26 and 4.02 Å) than in (VII) (4.23 and 3.71 Å). Furthermore, this portion is planar in (VI) (the molecule is situated at a centre of symmetry), whereas in (VII) the atoms forming the central four-membered portion depart by ±0.11 Å from its median plane[16].

Further discussion of the geometry of siloxane rings involves consideration of the nature of the silicon–oxygen bond in this group of compounds. These questions are not examined in detail in the present Review, since they have been covered exhaustively in several papers, cited e.g. in reviews[4,22]. Although the concept of silicon–oxygen p_π–d_π interaction has been increasingly criticised during recent years by several quantum chemists[23–25], this approach is nevertheless adopted in the present Review for the following two reasons.

(1) This approach provides a good explanation of the observed geometry even of extremely complicated organocyclosiloxane molecules. However, a serious problem for the concept of p_π–d_π interaction was presented by the $[(C_6H_5)_2Si]_2O$ molecule[28], in which the SiOSi angle had increased to 180° (the molecule was located at a centre of symmetry), while the silicon–oxygen bond had contracted only to 1.616(1) Å.¶

(2) An alternative approach, in which the silicon–oxygen bond length is assumed to be constant (the sum of the covalent radii corrected for the difference in electronegativity between silicon and oxygen atoms), and the SiOSi bond angle is explained by the separation of electron-pairs located in valency orbitals (the VSEPR method[27])†, is actually applicable only to a narrow range of compounds[27,28], in particular silicates having a Q unit as a structural element. There are other quantum-chemical treatments of the bonds formed by Group IVb elements (in particular silicon–oxygen bonds)[23,29,30], but as before the concept of p_π–d_π interaction remains the most popular for interpreting the geometry of organosiloxanes.

¶The fact that the MOM bond angles in $[(C_6H_5)_3C]_2O$ and $[(C_6H_5)_3Ge]_2O$ (128° and 135.2° respectively) are determined by non-bonded El...El interaction (where El = C, Ge) has led to surprise[26] that a linear geometry could occur in $[(C_6H_5)_3Si]_2O$. An "electronic" influence of the phenyl substituents should apparently be excluded in view of the quite long Si–C(C_6H_5) bonds (1.860–1.870 Å). Nevertheless, the Reviewers consider that steric factors are responsible for the geometry of this last molecule. Although intramolecular contacts between the phenyl groups are not critical here (the shortest C...H distance is 2.81 Å), the "pushing apart" of phenyl groups is fully able to affect the molecular geometry in such a fundamental fashion, as a consequence of the advantageous centrosymmetrical arrangement of the bulky phenyl groups and the relative ease of deformation of the SiOSi bond angles (in comparison with COC and GeOGe angles). The steric character of the factors governing the geometry of the $[(C_6H_5)_3Si]_2O$ molecule explains also the insufficient contraction (in a scheme with p_π–d_π interaction) of the silicon–oxygen bonds.

†Cases of linearity of oxy-bridges in $(R_3Si)_2O$ molecules are explained by the donor properties of the trialkylsilyl groups, which suppress the tendency of the oxygen bridge to assume a bent structure[102].

The rule of the interrelationship between the SiOSi angle and the length of the silicon–oxygen bonds forming it, which has been most sharply criticised by opponents of the hypothesis that p_π–d_π interaction is important, is well satisfied in organocyclosiloxanes, as shown below.

The set of almost isoenergetic chain conformations with bonds almost identical in character is considerably extended by the involvement in bonding of *d* orbitals of silicon atoms differently oriented relative to the axis of the siloxane chain[31], with a consequent diminished rigidity of the SiOSi bond angles and enhanced chain flexibility. This feature makes possible the appearance of geometrical isomers of siloxane chains, whose structures result from a compromise between the repulsion of non-bonded groups and the requirement of maximum p_π–d_π interaction[22,32].

The relation between the structure of the rings and the requirement of maximum p_π–d_π interaction was examined in detail by Craig and Paddock[31], who calculated the overlap integrals of *d* and *p* (or hybrid *sp*) orbitals for various conformations of the rings. They established the possibility of the existence of several energetically approximately equivalent conformations of rings formed by atoms possessing vacant *d* orbitals and atoms with lone pairs in *p* orbitals. Thus conformations of symmetry S_4, C_{2h}, C_{4v}, and D_{2d} are almost equally probable for eight-membered rings, e.g. D_4, with comparatively weak p_π–d_π interaction. The corresponding conformational transitions do not appreciably affect the degree of p_π–d_π interaction, since the silicon–oxygen bond lengths do not change with different conformations of the D_4 ring characterised by roughly the same SiOSi angles (142–149°).

This conclusion is supported also by numerous spectral investigations. Transition from the high-temperature crystalline modification of (VI) to the liquid phase is accompanied by a substantial change in spectra: the molecule acquires C_{4v} symmetry[21,32]. Electron diffraction by (VI) in the gas phase indicates S_4 molecular symmetry[33]. The conclusion that a conformation of C_{4v} symmetry is present in the liquid phase is consistent with the dipole moments of liquid cyclosiloxanes D_n with $n = 4–8$.[32] Among the types of symmetry possible for the tetramer only C_{4v} is consistent with the observed non-zero dipole moment.

Thus variation in the set of substituents, polymorphic transitions, and change in the state of aggregation may lead to a change in the conformation of the D_4 ring. Such rings in crystallographically independent molecules in the same crystal may also have different conformations, as has been observed e.g. with octamethylcyclotetrasilazane[34].

The molecule (XI) has non-crystallographic symmetry C_2 (approximately S_4 for the T_2D_2 ring—see Fig. 4). The planes of the phenyl rings $C_{(3)}...C_{(8)}$ and $C_{(21)}...C_{(26)}$ are almost parallel (dihedral angle 172.6°) and interact sterically, as is confirmed by the C...C distances between the ring atoms (3.17–3.50 Å). Such a molecular structure favours the development of activity by the *cis*-silanolic groups, since the approach of reagent molecules in solution is not subject to steric hindrance. Although the positions of the phenyl and methyl hydrogen atoms have been determined objectively, the hydrogen atoms of the silanolic groups could not be located. They probably undergo extremely vigorous thermal motion. It is interesting that the silanolic oxygen atoms have almost the same hybridisation as in the ring (mean Si–O(H) distance 1.643 Å).

Molecules (X) and (XII) are of interest in connection with the possible distorting influence on the structure of the D_4 ring of the "chelate" substituents, with ring closure at one or two silicon atoms (Figs. 5 and 6). The parameters of the D_4 ring in (X) have normal values (Si–O bond length 1.62 Å, SiOSi and OSiO bond angles 149° and 109°). The CSiC bond

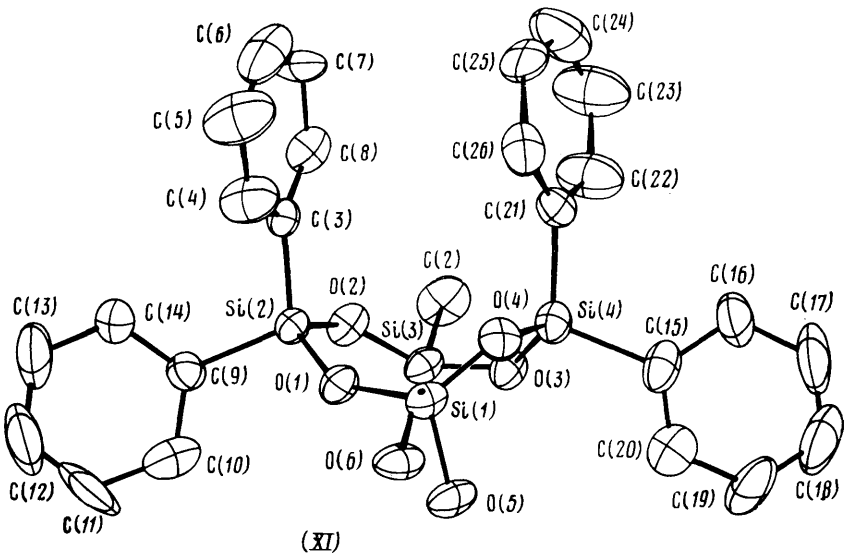

Figure 4. Structure of molecule (XI). The $Si_{(1)}$ ellipsoid shows the point of entry of the $Si_{(1)}-C_{(1)}$ bond with its methyl group.

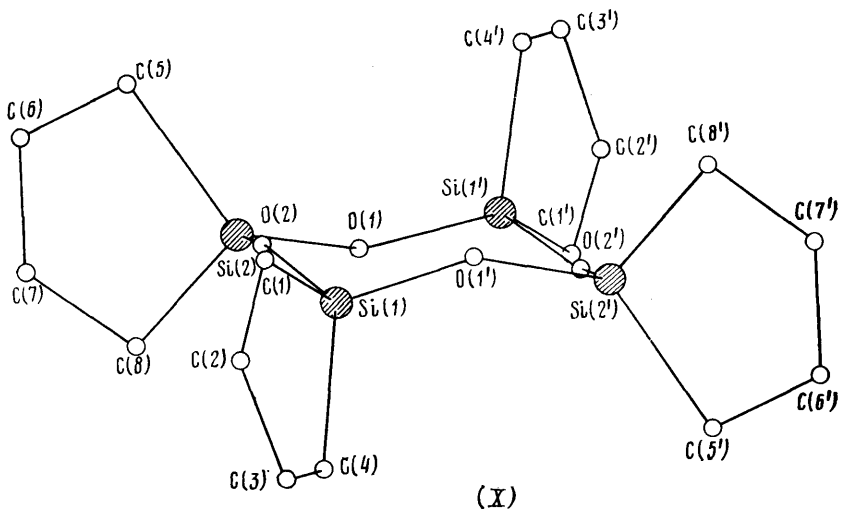

Figure 5. Structure of molecule (X) located at a centre of symmetry[20].

angles have decreased on the average to 97° owing to entry into five-membered heterocycles.

However, the D_4 conformation of the ring found in molecule (X) had not been observed for cyclotetrasiloxanes before the appearance of this recent work[19,20]. This is a particular case of the chair conformation (C_i symmetry), in which six ring atoms $[O_{(1)}Si_{(2)}O_{(2)}O_{(1')}Si_{(2')}O_{(2')}]$ are situated in the same plane (in (X) the emergence of atoms from this plane does not exceed 0.03 Å), from which the diametrically opposite silicon atoms (1) and (1') depart markedly on opposite sides (by ±0.53 Å—Fig. 5). Thus here the chair conformation is formed by the deflections of opposite triatomic groups from the remainder of the ring. The same conformation as in (X) and (XII) is exhibited by the mixed siloxazane ring of 1,3,5',7'-tetramethyl-1',3',5,7-tetraphenylcyclo-1,3,5,7-tetrasila-2,6-diaza-4,8-dioxane[35] and the silazane ring in 1,3,5',7'-tetramethyl-1',3',5,7-tetraphenylcyclotetrasilazane[36]. Both these rings have completely different sets of substituents from those in (X) and (XII).

The same conformation is found for the next D_4 derivative with "ring-closed" chelate substituents (XII), but here, instead of silicon atoms, oxygen atoms are deflected ($O_{(1)}$ and $O_{(1')}$ by ±0.69 Å) from the plane of the hexatomic fragment $Si_{(1)}Si_{(2)}O_{(2')}Si_{(1')}Si_{(2')}O_{(2)}$ (Fig. 6).

Before passing to cyclosiloxanes with >4 SiO units we note that derivatives of the D_4 ring have a special role in the

stereochemistry of organosiloxanes. These rings, which are the most frequently encountered among cyclosiloxane rings¶, form the most popular fragment in various organosiloxane polymers. Eight-membered rings based on SiO_4 tetrahedra are met quite often also among silicates (within infinite silicon–oxygen bridges, in which the silicon atoms usually have a *Q* configuration)[37].

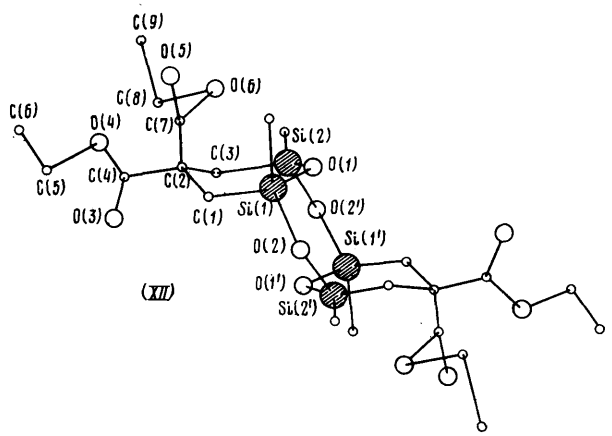

Figure 6. Structure of molecule (XII) located at a centre of symmetry.

Research on the biological activity of cyclic siloxanes of type $(C_6H_5CH_3SiO)_x[(CH_3)_2SiO]_y$ begun at the start of the 1970s has shown that several of them affect the reproductive function of mammals[38–40]. The D_4 derivatives (VIII) and $(C_6H_5CH_3SiO)_x[(CH_3)_2SiO]_3$ have proved the most active. The results of this work, which are significant from the point of view of a possible stereochemical analysis of the biological activity of organic derivatives of D_4 cyclosiloxanes, can be summarised: (1) the activity of organosiloxanes is due to the presence of arylsilicon groups; (2) the conformation and the configuration of D_4 derivatives are important (compound (VIII) has considerable oestrogenic activity, and (IX) is almost inactive); and (3) bioactivation in the animal organism does not involve conversion of chemically different organosiloxanes into chemically and (biologically) similar compounds.

Very little is known about the structure of D_n cyclosiloxanes having $n > 4$. The crystalline "octamer" $[(CH_3)_2SiO]_8$ has been examined by X-ray diffraction[32]. The molecules occupy positions having S_4 symmetry (space group $P\bar{4}2_1c$), while the conformation of the ring probably resembles that found for the D_4 ring in the α modification of (VI). Even these data indicate that the conformation of the D_8 ring may change on melting, since in the liquid phase these compounds have a non-zero dipole moment, which would be impossible with S_4 symmetry[32]. Spectral data[21] suggest that in the liquid phase the octamer molecule has C_8 symmetry.

X-Ray examination of decamethylcyclopentasiloxane $[(CH_3)_2SiO]_5$ in the liquid phase indicated[41] that the siloxane ring was buckled. However, the molecular parameters obtained (Si–O and Si–C 1.66 and 1.85 Å; SiOSi, OSiO, and CSiC respectively 145°, 115°, and 110°) suggest that this work was inaccurate (doubtful parameters are underlined).

Spectroscopic investigation shows[32] that the $[(CH_3)_2SiO]_6$ molecule can be assigned to the point groups D_{3d} and C_{6v} respectively in the crystal and in the liquid. In the crystal the dimethylsilylene groups face alternately above and below a plane perpendicular to the threefold (sixfold) axis, but in the liquid all these groups face the same direction. The diminution in symmetry from C_{6v} to D_{3d} is probably due to steric interaction of neighbouring dimethylsilylene groups. With the SiOSi angle remaining constant in C_{nv} conformations of $[(CH_3)_2SiO]_n$ molecules the distance between the methyl groups decreases with increase in *n*, and a decrease in symmetry to D_{3d} may prove energetically advantageous.

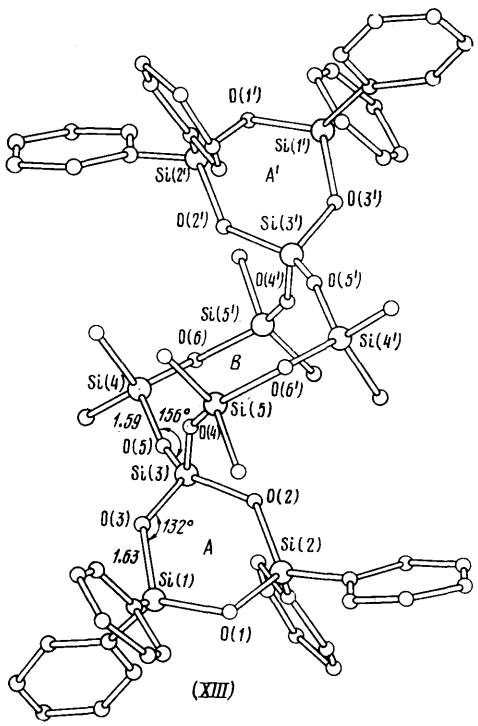

Figure 7. Structure of molecule (XIII) located at a centre of symmetry[43].

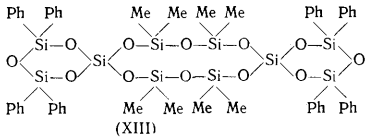


In contrast to rings in which *n* is even, the spectra of crystals with odd values of *n* differ little from those of the liquid phase: i.e. the conformation of the rings is the same in the liquid and in the crystal. Only groups D_n and C_n are consistent with the spectral data: the former can be rejected, since it has zero dipole moment, so that the molecules of pentamer and heptamer possess C_5 and C_7 symmetry, although certain features of the spectra indicate that the dimethylsilylene groups are arranged in conformity with a lower degree of symmetry.

Electron diffraction results for methyl derivatives of cyclopentasiloxane and cyclohexasiloxane in the gas phase[42] are not really consistent with any definite models. Better agreement is obtained with C_{5v} and D_{3d} symmetry respectively, with the oxygen atoms located in the same plane. Special

#See discussion at end of Section II.

attention was paid to C_5 and C_6 symmetry models, since they were based on spectral data[42]. We can pass from C_{nv} to C_n symmetry by rotating the dimethylsilylene plane relative to the corresponding OSiO fragment. However, this lower symmetry is less consistent than C_{nv} symmetry with the experimental results. It is supposed[42] that, owing to the large amplitudes of the low-frequency vibrations, molecules having large siloxane rings possess no definite conformation.

An X-ray structural investigation has been made[43] on 8,8,10,10,19,19,21,21-octamethyl-2,2,4,4,14,14,16,16-octaphenyldispiro[5,5,5,5] decasiloxane

(XIII)

whose molecule is located at a centre of symmetry and comprises three cyclosiloxane fragments (Fig.7), two six-membered (A and A') and one twelve-membered (B). The configurations of rings A and B are respectively D_2Q and D_4Q_2. The central twelve-membered siloxane ring B has the general chair conformation (symmetry C_i), with eight atoms $Si_{(4)}Si_{(5)}Si_{(4')}Si_{(5')}O_{(4)}O_{(6)}O_{(4')}O_{(6')}$ located approximately in the same plane (deviations do not exceed 0.3 Å). The deflection from it of the "chair-backs" (i.e. of the atomic planes $Si_{(3)}Si_{(4)}O_{(4)}O_{(5)}$ and $Si_{(3')}Si_{(4')}O_{(4')}O_{(5')}$) is 78°.

A most interesting feature of the structure of ring B is a sharp increase in the SiOSi angles (to an average of 156°) in comparison with e.g. eight-membered siloxane rings (Table 2). This value also exceeds the SiOSi angle of 149.6° in $[(CH_3)_2SiO]_6$ found by electron diffraction in the gas phase[42]. The increase in the angles leads to enhanced mobility of the oxygen atoms[43], which correlates with their larger temperature factors (7.6–9.6 Å^2) relative to the oxygen atoms in ring A (5.5–6.2 Å^2), in which the SiOSi angles are on the average 132°.

Structural comparison of the minerals bustamite $(Ca,Mn)SiO_3$ and wollastonite $CaSiO_3$ reveals a similar feature[32]. Both crystals are constructed of infinite chains $[SiO_3O_{9/2}]_\infty$ containing three silicon–oxygen tetrahedra in a repeating unit. The three non-equivalent SiOSi angles in the chain have the values

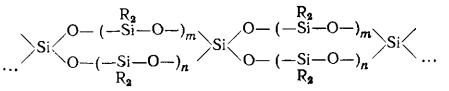
(Ca, Mn) SiO_3 : 161°, 135°, 137°;
$CaSiO_3$: 149°, 139°, 141°.

In the bustamite molecule the isotropic temperature factor of the oxygen atom in the grouping with the SiOSi angle straightened out to 161° was double that for the remaining oxygen atoms. In the wollastonite chain the temperature factor of the corresponding oxygen atom only slightly exceeded the mean value for all the remaining atoms[32].

In the structure of thortveitite $Sc_2Si_2O_7$ [44] the isotropic temperature factor of the bridging oxygen atom with the SiOSi bond angle 180° (the pyrosilicate group is located at a centre of symmetry) is almost double those for the terminal oxygen atoms (respectively 0.98, 0.55, and 0.65 Å^2), which are involved in the coordination of scandium atoms. The silicon–oxygen distance is shorter to the oxygen bridge than to the terminal atoms (respectively 1.605(1) and 1.629(1) Å).

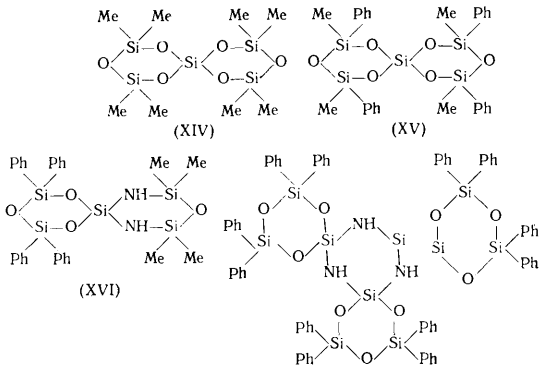
In structures with abnormally large oxygen bond angles (>150°) the retardation of internal rotation in ElOEl bridges is weakened[32]. This is favoured firstly by increase in the distance between substituents attached to the El atoms and secondly by decrease in the potential barrier to internal rotation due to increasing overlap of d orbitals of the element El with p orbitals of oxygen, whose nodal plane is perpendicular to the ElOEl plane. In the limiting case, with an ElOEl angle of 180°, rotation about the ElOEl bond is probably entirely free and will depend only on steric interaction of the framing groups.

Quantum-chemical examination of these problems showed[45] that the barriers to internal rotation are zero in the chains of organic cumulenes $H_2C{:}C{:}...{:}C{:}CH_2$, and only the relative rotations of the two terminal groups can be fixed: this distinguishes a system of cumulative bonds fundamentally from a system of conjugated bonds, where internal rotation is retarded. However, in such cumulative systems in which the chain has a framework (as in many polymers having an inorganic main chain) internal rotation may be hindered by the repulsion of atoms in the framing groups. Although it was considered[45] that such retardation could not be essential (since not every atom carries substituents), it may play a large part with bulky (e.g. phenyl) substituents. Furthermore, spectral data[32] indicate that, in structures with ElOEl angles close to 180°, slight retardation of internal rotation is accompanied by diminished rigidity of these angles, so that a considerable increase in mobility of the oxygen atoms can be expected both in the ElOEl plane (perpendicular to the El...El axis) and perpendicular to it.



The flexibility of the SiOSi fragments entails a general conformational non-rigidity of the ring B [(XIII)], which probably accounts for the higher temperature factors of the silicon atoms than in the ring A (respectively 5.1–6.7 and 5.0–5.1 Å^2).[43] Flexibility of the ring B is promoted also by the packing of the molecules in the crystal. Of a total of 29 independent intermolecular contacts < 4 Å some 25 are formed by phenyl groups, i.e. by substituents in rings A and A'. Four methyl groups are completely uninvolved in intermolecular contacts < 4 Å. Thus the conformation of ring B is almost completely determined by intramolecular interactions, with methyl groups situated in the "rarefied" (with respect to intermolecular contacts) zone along the periphery of the central ring.

The specific packing combined with the large free displacement of oxygen atoms in structures having "abnormally" large SiOSi angles leads to enhanced mobility of fragments of the molecule (including substituents attached to the silicon atoms) relative to the Si...Si axes. This may explain also the high temperature factors (11–17 Å^2) of the methyl carbon atoms in (XIII). In this compound, as in comparable silicate structures, enhanced mobility of the oxygen atoms characterises SiOSi bridges with the largest SiOSi angles together with the shortest silicon–oxygen interatomic distances, which indicate increased bond orders.



The conclusion that silicon–oxygen bonds are more stable in D_n rings with $n>4$ than in a D_4 ring is consistent with a study of the polymerisation⇌depolymerisation (cyclisation) equilibrium of dimethylsiloxanes, which indicated that the concentration of D_4 is higher than those of all other cyclic dimethylsiloxanes present in the mixture. Indeed, the lower content of more flexible and stable rings with higher values of n can be explained by the smaller probability of their closure than with the shorter D_4 chains. The greater abundance of D_4 than of D_3 rings is attributed to some strain in the latter[2,3], as well as to greater instability of their silicon–oxygen bonds (Tables 1 and 2). The advantage of eight-membered Q_4 rings in silicates has been mentioned by O'Keefe and Hyde[24], who have analysed a large number of structural investigations of silicates and concluded that the conformations of silicon–oxygen fragments in them are determined by non-bonded Si...Si interaction with almost constant silicon–oxygen bond lengths. The Si...Si distances have their most favourable values (3.08–3.10 Å) in Q_4 rings.

III. SPIROCYCLIC SILOXANES

Organospiropolycyclosiloxanes, a novel class of organopolysiloxanes[1,46], have the general formula

Structures have been determined for the five spirocyclosiloxanes (XIII)–(XVII)

whose geometrical parameters are given in Table 3. Like D_3 rings (Table 1) the D_2Q rings present in spirocyclosiloxanes have an approximately planar structure. According to Table 3 the silicon–oxygen bonds in the spiro-units of the D_2Q rings are somewhat shorter, which indicates that they are more stable than the usual siloxane bonds§. Such contraction is due to more complete involvement of the central silicon atom (than of the silicon atoms in ordinary siloxanes) in π coupling with the four surrounding oxygen atoms; the polarising effect of the latter leads to the appearance of a positive charge on the silicon atom, which diminishes the energy of its 3*d* orbitals. Such an explanation has been used, for example, in analysing the character of the bonds in siloxanes[22].

When the oxygen atoms forming the spiro-environment of silicon atoms are replaced by the less electronegative nitrogen atoms, of course, the positive charge on the silicon atoms diminishes, and the remaining silicon–oxygen bonds become weaker. As a result, for example, the D_2T spiro-ring in the molecule (XVI) has the same parameters as have D_3 rings. On passing to compound (XVII), however, the difference in the silicon–oxygen bond lengths again becomes appreciable. This indicates that in mixed siloxane–silazane polycycles the silicon–oxygen bonds in the spiro-units are stronger than the remaining silicon–oxygen bonds provided that the spiro-units involve silicon atoms of an inner silazane ring. The molecule (XVII) (Fig.8) exhibits a fairly sharp difference in planarity of the trisiloxane rings (Table 3): the $Si_{(9)}$ atom emerges markedly (by 0.43 Å) from the plane of the remaining five atoms of the ring $Si_{(3)}O_{(10)}Si_{(8)}O_{(11)}Si_{(9)}O_{(12)}$.

§The absence of this effect in the molecule (XIV) is probably due to inaccuracy in the investigation[47].

The presence of spiro-silicon atoms should enhance not only the three-dimensional rigidity¶ but also the thermal stability of the organopolycyclosiloxane chain. Two modes of construction of such chains are of interest in connection with the molecular mechanism of deformation. The first involves a chain of spiro-linked siloxane rings with a small number (3 or 4) of SiO units in each. Such chains should be characterised by strong intramolecular organisation and great rigidity. The second method incorporates into the general spirocyclolinear molecule siloxane rings with >4 SiO (or linear siloxane links with >4 SiO). The strengthening in such molecules of the silicon–oxygen bonds involving spiro-silicon atoms is combined with enhanced stability of the other silicon–oxygen bonds as a consequence of their entry into long siloxane chains, distinguished by stronger p_π–d_π interaction[32,45].

Table 3. Data on spirocyclic siloxanes (d_1 and d_2 are the mean Si–O bond lengths within and outside the spiro-group in the D_2Q ring, Δ_{max} is the maximum divergence of atoms from the D_2Q plane, and α is the mean SiOSi bond angle in the D_2Q ring).

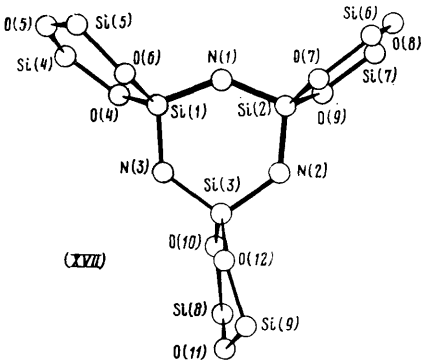

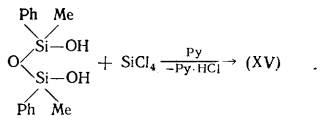

Figure 8. Tetracyclic fragment of molecule (XVII).

¶As already remarked, the rigid spiro-units in the molecule (XIII) stabilise the conformation of the inner twelve-membered siloxane ring, which enables single crystals of this compound to be obtained.

Organopolysiloxane chains of the second type, while retaining the rigidity inherent in organospirocyclosiloxanes, should possess better chemical and thermal stability. Phenyl substituents enhance the rigidity and the crystallisability of both types of organopolysiloxanes[51]. On the other hand, the presence of sterically rigid segments diminishes the thermal mobility of the molecular skeleton, with a consequent impairment of, for example, the resistance of the polymer to thermal oxidation. However, this adverse effect can be suppressed by incorporating into the general polyspirocyclosiloxane system extremely flexible extended polysiloxane segments (large rings).

The compound (XV) can exist as five stereoisomers depending on the orientation of the substituents relative to the planes of the siloxane rings (Fig. 9). Reaction with the *meso*-form of the diol accompanied by retention of configuration[52] gives the *cis,cis*-isomer of (XV) as a racemic mixture of the two enantiomers (XVa) and (XVb), for which the only element of molecular symmetry is a twofold axis:

The methyl groups in each of the siloxane rings of these enantiomers are diastereotopic, as is confirmed by the nuclear magnetic resonance spectra, in which two separate signals are observed from methyl protons. Reaction with silicon tetrachloride of the optically active forms *SS* and *RR* of the diol, and also of their racemic mixture†, should lead to formation of the *trans,trans*-isomer of (XV) as a mixture of the enantiomers (XVe) (conventionally the *d*-isomer) and (XVf) (conventionally the *l*-isomer) and the diastereomeric *meso*-form (XVg) (in the proportions 1 : 1 : 2). The molecules (XVe) and (XVf) have D_2 symmetry, i.e. three twofold axes, while the *meso*-form (XVg) has a fourfold inversion axis, and is thus optically inactive. When the reaction mixture contains both the *meso*-form and the *SS* and *RR* forms of the diol the isomers (XVc) and (XVd) may appear[48].

One of the *trans,trans*-forms of (XV) was isolated. The n.m.r. spectra did not distinguish whether this compound was a *trans-meso*-isomer (XVe) or (XVf), the racemate (XVe) + (XVf), or the *meso*-form (XVg). X-Ray structural analysis showed that the form of (XV) isolated was the *trans,trans-dl*-isomer (Fig. 10). Since the compound crystallised in the non-enantiomorphic space group $P2_1/a$, both optical antipodes (XVe) and (XVf) were present in the crystal[48].

IV. CYCLOLINEAR SILOXANES

The structure of cyclolinear organopolysiloxanes# (Fig. 11)[1] can be represented by various combinations of *cis*- and *trans*-linkings of tetrasiloxane rings. Structure (*b*), for example, has an alternation of *cis,trans,trans* linkages, whereas structure (*c*) has *trans,trans,trans*. From a study of the properties of solutions, X-ray powder data, and infrared spectra Brown[53] demonstrated the *cis*-syndiotactic structure of each $Si_{(1)}Si_{(2)}$... strand of the double chain of cyclolinear organopolysiloxanes corresponding to polymer (*c*), which is usually termed ladderlike. In such polymers, containing silsesquioxane fragments in a chain unit, every third silicon atom of each of the two chains repeats translationally the first (in structure (*b*) the first, fifth, ninth, etc. atoms are repeated).

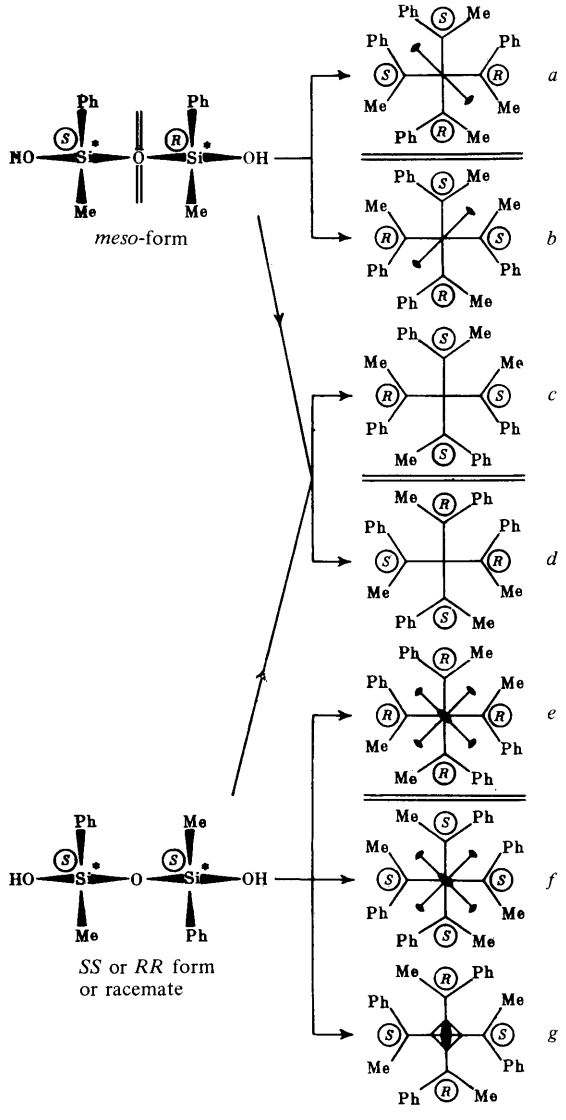

Figure 9. Possible stereoisomers of (XV). The molecules are shown diagrammatically (only substituents and their bonds with the ring, represented by a vertical or horizontal line) as a projection along the straight line passing through the spiro-atom and the two oxygen atoms most remote from it; *R* and *S* denote the configurations of the substituted silicon atoms. The symmetry elements of the molecules are indicated, as well as the mirror plane between the optical antipodes (by a pair of parallel lines).[48]

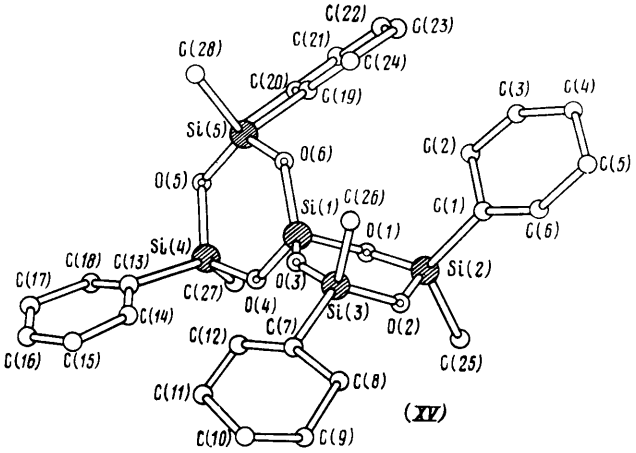
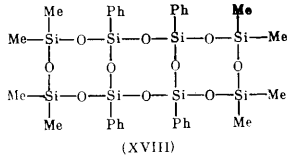
†Actually the reaction has been conducted only with the racemate of the diol.

#Such cyclolinear structures, in contrast to monocyclic structures, contain *T* units, and are usually termed silsesquioxanes.

Cyclolinear polyphenylsilsesquioxanes comprise semi-rigid macromolecules (persistent length§ 200–900 Å). The flexibility of such macromolecules is due to small fluctuations in torsional and bond angles, in contrast to flexible macromolecules (persistent length ~10–20 Å), e.g. polymethylphenylsiloxane, the mechanism of whose flexibility involves rotational isomerism[55].





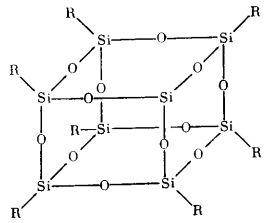


Figure 10. Structure of molecule (XV).[48]

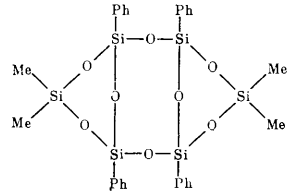
An important factor in the study of the preparation and properties of ladderlike organopolysiloxanes is their lowest oligomers, the octa(organosilsesquioxanes) $(RSiO_{1.5})_8$ (Fig.11*d*), which are formed as by-products[56] and can also serve as starting materials for the synthesis of macromolecular polyorganosilsesquioxanes[57,58]. Table 4 gives data on the T_4 rings in the series of cyclolinear organocyclosiloxanes (XVIII)–(XXIII)



(XVIII)

(XIX), R = H; (XX), R = Me; (XXI), R = Ph; (XXII), R = C_2H_3

§This quantity characterises the rigidity of a polymer chain. A strict definition will be found in Ref.54.

(XXIII)

The structure of (XVIII) is disordered[59,60]: silicon atoms 2, 3, 6, and 7, together with their methyl substituents, can each occupy two positions with approximately equal probability (Fig.12). Passage from one position to the other can be effected by rotation of the dimethylsilylene group through an angle Ω about an axis passing through the oxygen atoms, whose positions remain unchanged. For the four dimethylsilylene groups the angle Ω has a mean value of 60°, which corresponds to displacement of the silicon atoms along an arc ~1.0 Å in length, while the attached methyl carbon atoms move ~3.0 Å.

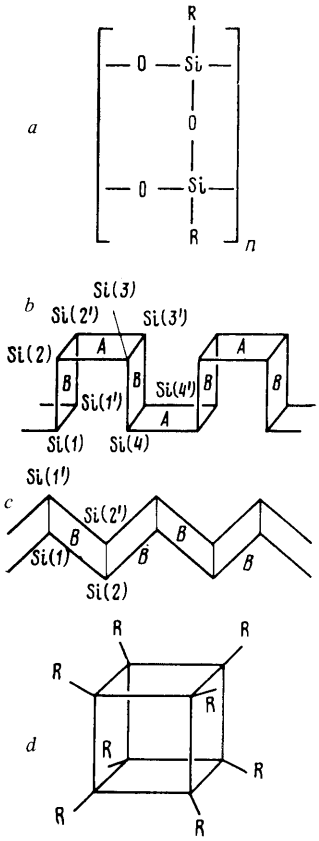


Figure 11. General formulae of: *a*) polyorganosilsesquioxane; *b*,*c*) two possible structures of a cyclolinear organopolysiloxane (a segment of a straight line corresponds to one tetrasiloxane ring; organic substituents are not shown); *d*) diagram of molecule of octa(silsesquioxane).[60]

Of the sixteen possible conformations (on the assumption that the four dimethylsilylene groups can each occupy two positions independently of the others) fourteen are forbidden because they would involve short intramolecular contacts (denoted in Fig.12 by the symbol ↓‾↓) between methyl groups attached to different silicon atoms. Thus the molecule has only two energetically equivalent conformations of its silicon atoms, i.e. 1–2–3–4–8–7–6–5 and 1–2′–3′–4–8–7′–6′–5¶.

Table 4. Data on T_4 rings in structurally studied simple cyclolinear polysiloxanes (α = mean SiOSi bond angle; d = mean Si–O bond length; and Δ_{max} = maximum emergence of O atoms from plane of four Si atoms).

*The four silicon atoms are almost coplanar.
**Relates to the SiOSi fragment common to the DT_2 and D_2T_2 rings.

In a free state (solution) the molecule (XVIII) may perform frequent transitions, under the influence of thermal vibrations, from one conformation to the other. This view is supported by the very prolate character and appropriate orientation of the ellipsoids representing the thermal vibrations of the atoms of disordered dimethylsilylene groups (Fig.12). Each conformational transition can be regarded as a simultaneous change in direction of twist of the two lateral D_2T_2 rings, which can be twisted only to one side in each of the permitted conformations.

The disorder of structure (XVIII) is interesting in connection with Brown's hypothesis on the condensation of cyclosiloxanes that identical functional groups attached to mobile portions of molecules, and therefore structurally non-equivalent, differ in reactivity[56]. The principle of equal reactivity of identical functional groups, on which the statistical theory of polycondensation is based, does not apply to such systems.

Fig.13 shows that, after initial formation of a dimer (*3*), condensation of the tetraol (*1*) can occur either intramolecularly to give (*4*) and (*5*) or intermolecularly in the sequence (*3*) → (*6*) → (*7*). The statistics of intermolecular vibrations, suggested as the decisive factor in intermolecular cyclisation[56], is probably less important in the present case owing to the relatively small number of degrees of freedom in each successive primary act of intermolecular condensation with formation of a polymeric cyclolinear structure, e.g. (*7*).

¶These conformations have intrinsic (non-crystallographic) symmetry C_2 and form a pair of optical antipodes.

If the compound differing from the tricyclic derivative (*3*) in the presence of methyl instead of phenyl groups in the lateral D_2T_2 rings is assumed to have the same type of disorder as the molecule (XVIII), the smaller steric interactions between substituents will result in preferential conversion of (*3*) into (*4*) instead of (*6*). This is explained by the shorter Si...Si distances, greater frequency of collisions (as shown by analysis of the thermal ellipsoids), and hence greater probability of chemical interaction along the lines $Si_{(2)}...Si_{(6)}$ (as well as $Si_{(2')}...Si_{(6')}$—Fig.12) and $Si_{(3)}...Si_{(7)}$ (and $Si_{(3')}...Si_{(7')}$) than along the lines $Si_{(2)}...Si_{(7)}$ (and $Si_{(2')}...Si_{(7')}$) and $Si_{(3)}...Si_{(6)}$ (and $Si_{(3')}...Si_{(6')}$), corresponding respectively to edges and two-dimensional diagonals of the silsesquioxane cube (Fig.13). The presence in compounds (*1*)–(*3*) of phenyl instead of methyl groups changes the mobility of the D_2T_2 rings and leads to greater probability of process (*3*) → (*6*) than of (*3*) → (*4*), i.e. to formation of a polymer of high molecular weight (the yields of the products are indicated in Fig.13).

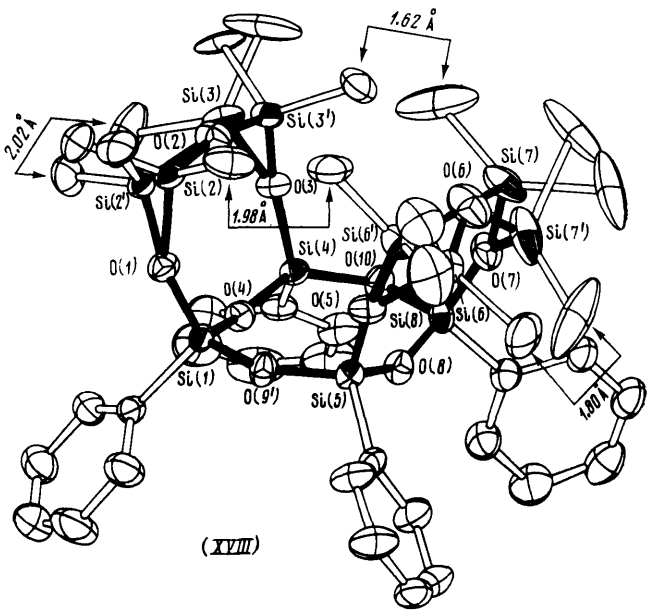

Figure 12. Structure of (XVIII) molecule[60] (explanation in text).

Neither of the "structurally" confirmed mechanisms of the deformation of tetrasiloxane rings [rotation of diatomic Si–O fragments or twisting of triatomic fragments in (XVIII)] explains the conformational transition (*a*) → (*b*) of T_4 rings (Fig.14 and Table 4). On the other hand, both mechanisms revealed for D_4 rings or the *D* portions of D_2T_2 rings, i.e. for siloxanes, involve the displacement of substituted silicon atoms, which is difficult to envisage in the more rigid silsesquioxanes. Conformational rearrangements probably have different mechanisms in D_4 and in T_4 rings. The conformational transitions of T_4 rings can be represented as the displacement of two *trans*-oxygen atoms. Such a mechanism of the conformational transition $S_4 \rightarrow C_{4v}$ had been suggested earlier (though in D_4 rings) in a spectroscopic paper[21].

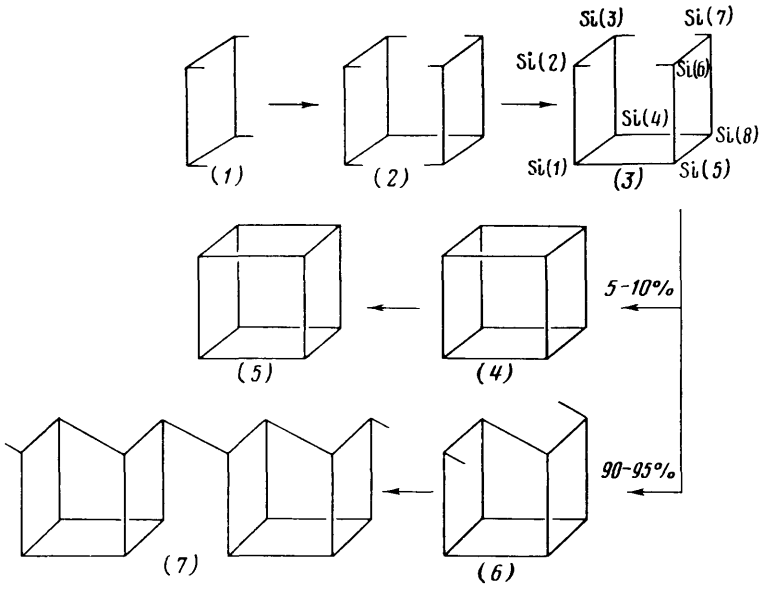

Figure 13. Scheme of condensation[56] of the tetraol (*1*) (tetraphenylcyclotetrasiloxanetetraol) via the tricyclic compound (*3*) into an octa(silsesquioxane) (*5*) and via the tetracyclic compound (*6*) into a poly(silsesquioxane) (*7*). The structures of (*3*) and (*5*) have been confirmed by X-ray examination[60,63]. Products (*4*) and (*6*) can exist as epimers with a different orientation of hydroxy-groups.

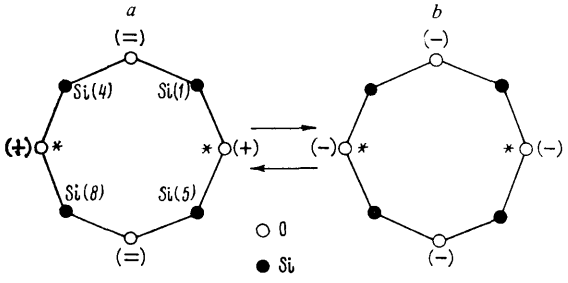

Figure 14. Scheme illustrating the differences and interrelationship between conformations of T_4 rings in the molecules: *a*) (XVIII), approximate symmetry S_4; *b*) (XXI), C_{4v}.[60] For simplicity the silicon atoms are shown in (XVIII) as lying in the same plane; the symbols (+), (−), and (=) indicate the positions of oxygen atoms above, and below, and in this plane. Asterisks denote oxygen atoms whose movements are perpendicular to the plane of the diagram and essentially determine the transitions (*a*) ⇌ (*b*). The silicon atoms are numbered in conformity with Fig. 12.

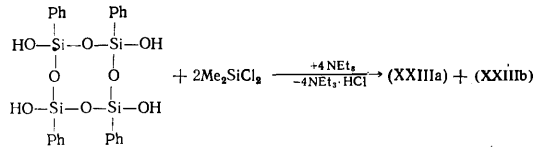
The two conformers of (XVIII) are characterised by closely similar dihedral angles of deflection of the planes of the lateral D_2T_2 eight-membered rings from that of the central T_4 ring (on the average 108°). As was to be expected, the silicon–oxygen bonds are shorter in silsesquioxane *T* units than in siloxane *D* units (on the average 1.606(3) and 1.621(6) Å respectively). Yet the difference in the mean silicon–oxygen bond lengths in T_4 and D_2T_2 rings is small (respectively 1.609(3) and 1.614(6) Å), just like the difference in mean SiOSi bond angles in these rings (151.7(2)° and 148.1(3)°).



Since the conformation of the siloxane ring (infrared spectra[66]) remains unchanged when the polymer chain is extended, the parameters (bond lengths and angles) of the T_4 ring are probably maintained even in the corresponding cyclolinear polymer.

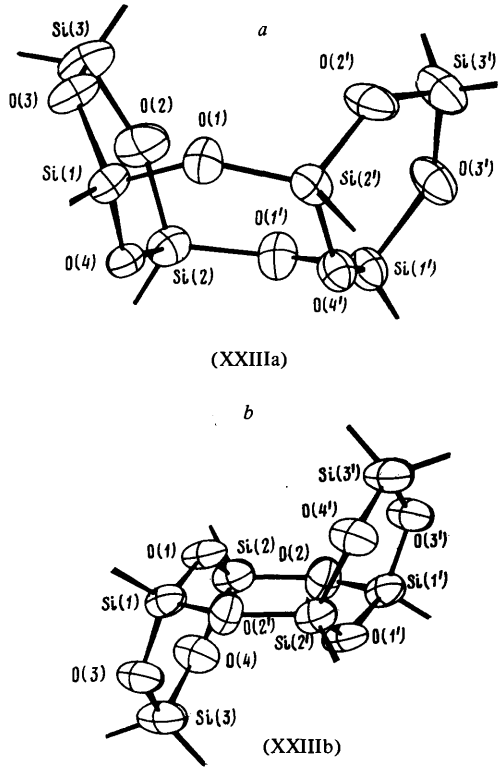
Conformational analysis has been used to determine the most probable angular parameters for *cis*-syndiotactic poly(phenylsilsesquioxane)[67]. The SiOSi angles in the "strand" (along an infinite polysiloxane chain) are 145–150°, rather smaller than the 155–170° in the "binder" (the cross-link between the polysiloxane chains). Experimental X-ray structural data[60] indicate that in the T_4 ring of (XVIII) the SiOSi angles are also somewhat smaller in the strand than in the binder (on the average 148.7° and 154.7° respectively).

As a consequence of the inductive effect the addition of aromatic substituents to the silsesquioxane cube [conversion of (XIX) and (XX) into (XXI)] strengthens appreciably the π interaction, which is apparent in an increase in the SiOSi angles in (XXI) and also in a "flattening" of the T_4 rings forming the cube (the mean emergence of the T_4 cyclic oxygen atoms from the plane through the four silicon atoms is respectively 0.34 and 0.30 Å in (XX) and in (XXI)—Table 4). This "flattening" should diminish the dipole moment of the T_4 ring and enhance d_π–p_π interaction in the silicon–oxygen bonds, but the lengths of the latter are closely similar in the T_4 rings in (XX) and in (XXI) (Table 4).

Passage from (XX) to (XXI) should be accompanied by a decrease in stability of the silsesquioxane skeleton towards radical reagents and an increase towards ionic reagents, as well as an enhancement of thermal stability. This is important in the choice of conditions for the polymerisation of octa(organosilsesquioxanes).

Compound (XXIII) is a cyclolinear oligosiloxane containing DT_2 as well as T_4 rings. Its preparation involves the isolation[65] of two products—(XXIIIa) and (XXIIIb)—differing in yield, melting point (respectively 162–163 and 222–223 °C), solubility, and physical properties:

Data have been published on (XXIIIa),[56,68,69] but (XXIIIb) has been isolated for the first time. A conformational difference is assumed between them. X-Ray examination indicates that (XXIIIa) is a *cis*-isomer of the D_2T_4 tricyclic system, and (XXIIIb) a *trans*-isomer (Fig.15).



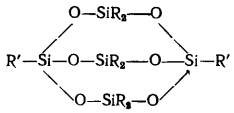


Figure 15. Structures of D_2T_4 tricyclic siloxane systems (Table 4) in the molecules: *a*) (XXIIIa)[65]; *b*) (XXIIIb).

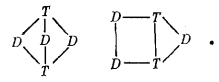
The structure of (XXIIIa)† is characterised by "anomalous" parameters of its tetrasiloxane and trisiloxane (T_4 and DT_2) rings (Fig.15): (i) the $Si_{(1)}O_{(4)}Si_{(2)}$ and $Si_{(1')}O_{(4')}Si_{(2')}$ bond angles are 127.5°, unusually small for tetrasiloxanes (cf. Tables 2 and 4), so that the T_4 ring in (XXIIIa) is considerably more strongly deformed than, for example, the T_4 ring in (XVIII), which has a similar chemical environment and the same symmetry S_4 (Table 4); and (ii) steric interaction of methyl groups attached to $Si_{(3)}$ and $Si_{(3')}$ (C...C distance 3.713 Å) leads to deformation of the DT_2 rings (departure of the cyclic atoms from their mean planes reaches 0.33 Å—cf. D_3 rings in Table 1). Furthermore, as a consequence of this steric interaction the angle of deflection of the lateral DT_2 rings in (XXIIIa) from the central ring (115°) exceeds that in (XVIII) (108°); the ideal symmetry C_{2v} of the tricyclic siloxane system in (XXIIIa) degenerates to C_2.[65]



In the *trans*-isomer (XXIIIb), the molecule is located at a centre of symmetry in the crystal, the lateral DT_2 rings have a more planar structure than in (XXIIIa) (departure of the atoms from the plane of these rings does not exceed 0.1 Å), and they conform approximately to C_{3v} symmetry. The eight-membered T_4 ring has a general chair conformation (symmetry C_i); the atoms $Si_{(1)}$ and $Si_{(1')}$ deviate by ±0.56 Å on opposite sides of the general plane of the ring. The SiOSi bond angles in the T_4 ring of (XXXIIIb) have a mean value of 132.5°, markedly smaller (by ~10°) than in other derivatives of eight-membered siloxane rings (Tables 2 and 4). The dihedral angle between the planes of DT_2 and T_4 rings is 82.4°.

V. OTHER POLYCYCLIC SILOXANES

Structures have been determined for two bicyclo[3,3,3]pentasiloxane D_3T_2 derivatives

(in (XXIV) $R = C_6H_5$ and $R' = CH_2.CH$ (Fig.16)[70]; in (XXV) $R = R' = CH_3$ (Fig.17)[71]) obtained in different ways. Whereas the structure (XXIV) alone is possible for the D_3T_2 product of the reaction between vinyltrichlorosilane and diphenylsilanediol[72], the D_3T_2 product of the thermal decomposition of branched polydimethylsiloxanes may have the two structures[71]

However, X-ray examination indicates that the two products have the same siloxane skeleton. These molecules are characterised by a non-crystallographic threefold axis passing through the silsesquioxane silicon atoms, but the silicon–oxygen skeleton has the overall non-crystallographic symmetry $\bar{6}2m$.

The three tetrasiloxane D_2T_2 rings in (XXIV) and (XXV) exhibit considerably greater "non-planarity" than do D_4 and T_4 rings. For example, in (XXIV) the mean dihedral angle between tetratomic fragments of D_2T_2 rings is 44° (in D_4 rings it is 27.5–40.2°, Table 2). As a consequence the mean SiOSi angle is 14°, smaller than in D_4 rings (142.5–149°). The considerable deformation of D_2T_2 rings in (XXIV) prevents development of their silsesquioxane nature, i.e. strengthening of silicon–oxygen bonds; the mean silicon–oxygen distance in (XXIV) is 1.63 Å, but no differences in length are observed between siloxane and silsesquioxane bonds[70].

Because of the smaller bulk of the substituents the D_2T_2 rings are less deformed in (XXV) than in (XXIV), but the mean SiOSi angle (145.6°) corresponds to this value in the D_4 rings, while being smaller than the SiOSi angles in T_4 rings. The silicon–oxygen distance (1.618 Å) is close to those found in T_4 rings (above). Yet the non-bonded diagonal Si...Si distances in (XXIV) and (XXV) are closely similar. Diagonals of type $Si_{(3)}...Si_{(5)}$ in (XXIV) (Fig.16) and of type $Si_{(2)}...Si_{(4)}$

†The molecule is located on a twofold axis.

in (XXV) (Fig.17) are respectively 4.21–4.26 and 4.236–4.256 Å, while the Si...Si distances along non-crystallographic threefold axes in (XXIV) and (XXV) ($Si_{(1)}...Si_{(2)}$ in Fig.16 and $Si_{(1)}...Si_{(3)}$ in Fig.17) are 3.71 and 3.76 Å. Thus a silicon–oxygen "skylight" of this type is "compressed" along an approximate threefold axis.

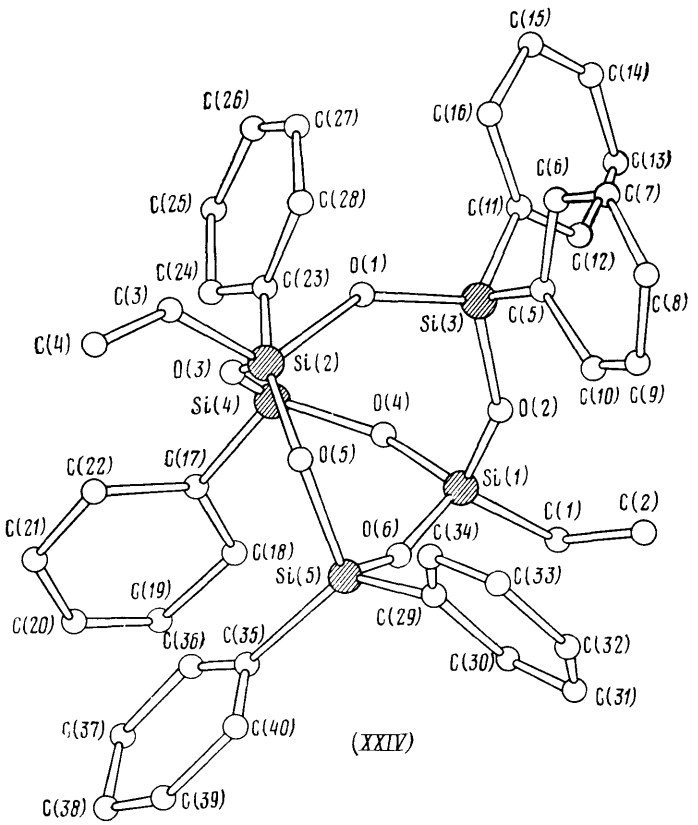


Figure 16. Structure of molecule (XXIV).[70]

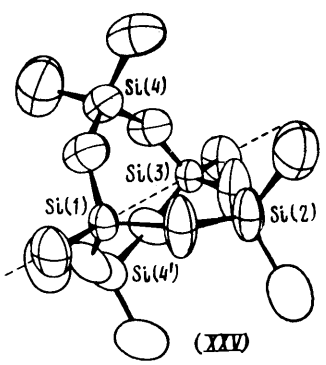

Figure 17. Structure of molecule (XXV).[71] The broken line shows the approximate threefold axis.

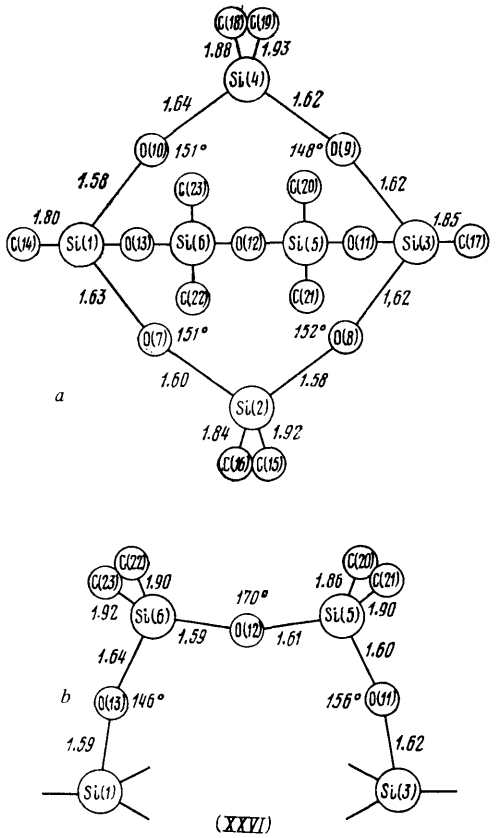

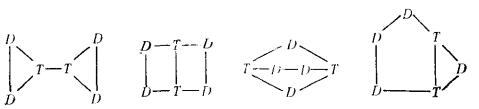

Figure 18. Structure of: *a*) molecule (XXVI); *b*) "semicircle".[73]

The thermal decomposition of branched polydimethylsiloxanes has led to the chromatographic isolation of three products (*a*)–(*c*) having the configuration D_4T_2, for which the structures

are possible[8]. X-Ray examination of one of the products has confirmed the suggested structure (*c*), i.e. (XXVI) in Fig.18.[73] In the molecule with approximate C_{2v} symmetry one D_2T_2 tetrasiloxane ring and two D_3T_2 pentasiloxane rings can be distinguished. The D_2T_2 ring has approximate D_{2d} symmetry (saddle conformation), with the atoms emerging rather less (up to 0.30 Å) from the plane of this eight-membered ring than in isolated D_4 rings, e.g. 0.49 Å in (XI). The atoms forming the "semicircle" $Si_{(1)}O_{(13)}Si_{(6)}O_{(12)}Si_{(5)}O_{(11)}Si_{(3)}$ lie to within 0.13 Å in the same plane, which is approximately perpendicular (dihedral angle 84.9°) to the mean plane of the D_2T_2 ring. The planarity of the "semicircle" $Si_{(1)}...Si_{(3)}$ and also the unexpectedly large SiOSi bond angle (170°) at the $O_{(12)}$ atom are the most interesting stereochemical features of the molecule (XXVI).[73]

The molecule (XXVII) (Fig.19) represents a completely different type of polycyclic organosiloxane[74]. It is located at a centre of symmetry and contains two D_2T rings joined by an extended siloxazane bridge. In a D_2T ring the mean

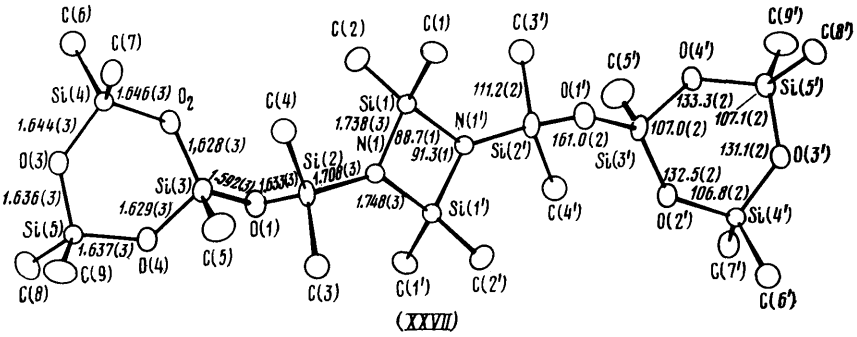

Figure 19. Structure of molecule (XXVII).[74]

silicon–oxygen distance in the *T* unit 1.628(3) Å is shorter than in the *D* units (on the average 1.641(3) Å) or in D_3 rings (Table 1). The maximum departure of atoms from the plane of the D_2T rings (0.08 Å) is of the same order as in D_3 rings. The bond lengths and angles (Fig.19) indicate an interesting strengthening of the linear bonding between siloxane and silazane rings due to intensified p_π–d_π interaction particularly in these parts of the molecule. Hence these siloxazane bridges should be not only the most stable energetically but also the most resistant to the action of ionic reagents. The silazane ring in (XXVII) has the usual geometry#.

VI. CRYSTALLINE STRUCTURE OF ORGANOCYCLOSILOXANES

Crystals of organosiloxanes usually have loose packing and weak intermolecular interaction[51]. Nevertheless, the some thirty crystalline structures known for organosiloxanes include several non-trivial examples related to the stereochemical peculiarities of such compounds and important from the point of view of their practical application.

In a crystal comprising conformationally disordered molecules of (XVIII) the methyl groups of identical§ conformers, the molecules of which are related by the translation *c* and also a centre of symmetry at ½,½,0, are separated by C...C distances of 3.58 (translation *c*), 3.52, 3.52, and 3.64 Å (centre at ½,½,0).[60]

The van der Waals radius of the methyl group is generally assumed to be ~2 Å.[9,75] However, in a crystal of *DL*-*N*-chloroacetalanine[76], for example, with a $C(CH_3)...C(CH_3)$ distance of 3.72 Å between molecules related by centres of symmetry, the H...H distances (the hydrogen atoms have been identified objectively) between these methyl groups are 2.88 Å, i.e. ~0.5 Å greater than double the van der Waals radius of the hydrogen atom[77]. If it is supposed that, with the shortened $C(CH_3)...C(CH_3)$ distances found in a crystal of (XVIII), orientations of the methyl groups are possible for which the H...H and C...H distances are not shortened, a random distribution of conformers of (XVIII) may occur in the crystal: i.e. both identical and different conformers may be neighbours. If, however, such orientations are impossible, some of the intermolecular contacts between identical conformers are forbidden. Unfortunately, X-ray structural analysis has not yet answered the question of the possible juxtaposition of conformers of the same or different types, or indicated the character of the disorder (statistical or dynamic) in a crystal of (XVIII). This requires investigations at low temperatures with location of the hydrogen atoms.

Two problems in organic crystal chemistry—the crystallisation of molecules with porous packing and the chemical interaction of molecules densely packed in a crystal—have special significance for crystals of organocyclosiloxanes. In a crystal of (XXI) cavities of volume ~150 Å³¶ have been observed around symmetry centres 0,½,0 (Fig.20). Clearly, the shape of molecules of (XXI) permits only two-dimensional dense packing: compact superposition of layers is impossible, and the above cavities, which may be filled with small solvent molecules, appear in the crystal. Indeed, differential synthesis of electron density has revealed in the cavities several peaks of electron density corresponding to disordered small molecules of solvents used in preparation and crystallisation[63].

The high temperature factors for atoms present in a solvent molecule are consistent with results obtained for clathrates. For example, the atoms of the dioxan molecules in the clathrate complex $Cd(NH_3)_2.Ni(CN)_4.2C_4H_8O_2$ have isotropic temperature factors of 23 and 14 Å².[78] The volume of a cavity considerably exceeds the molecular volume[80] of the solvents used in the preparation of (XXI) (pyridine 91 Å³, *o*-dichlorobenzene 100 Å³)†, so that the packing coefficient in the cavities is low ($k \approx 0.63$). Then, of course, the (XXI)...Solv intermolecular distances exceed the sum of the van der Waals radii. This explains the possible disorder in the arrangement of solvent molecules in the cavities[63]. When the occluded solvent molecules are taken into account, good agreement is obtained between calculated and measured densities of a crystal of (XXI). If, however, the occupation of the cavities is ignored, the calculated value is smaller than the measured density (1.29 and 1.34 g cm^{-3}), as for the second (not studied structurally) monoclinic modification[79].

#We intend to survey the structure of cyclosilazanes in a subsequent review.

§Corresponding distances between different conformers are considerably longer than 3.8 Å.

¶This quantity has been determined by means of a special programme of search for the positions and volumes of cavities in a crystal, established by L.M.Borisanova (Faculty of Chemistry, Moscow State University, 1976).

†Molecular volumes were calculated from the contributions by atomic groupings[80].

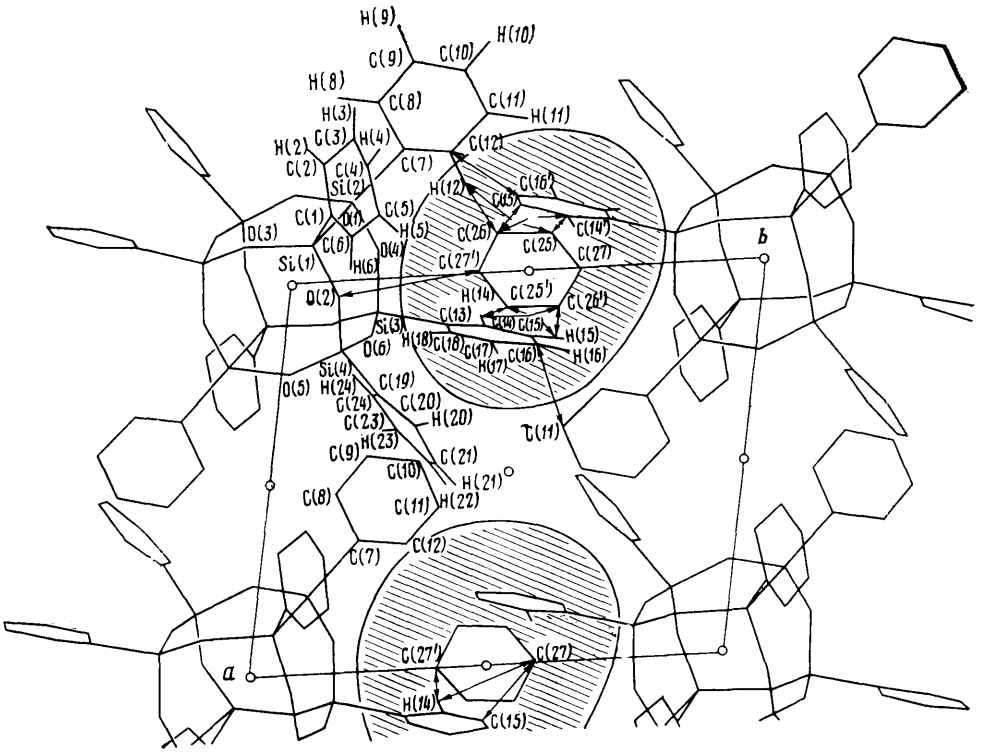

Figure 20. Projection [001] of structure (XXI). The arrows show distances between (XXI) and solvent molecules. Cross-sections of the cavities made by the plane of projection are shaded[63].

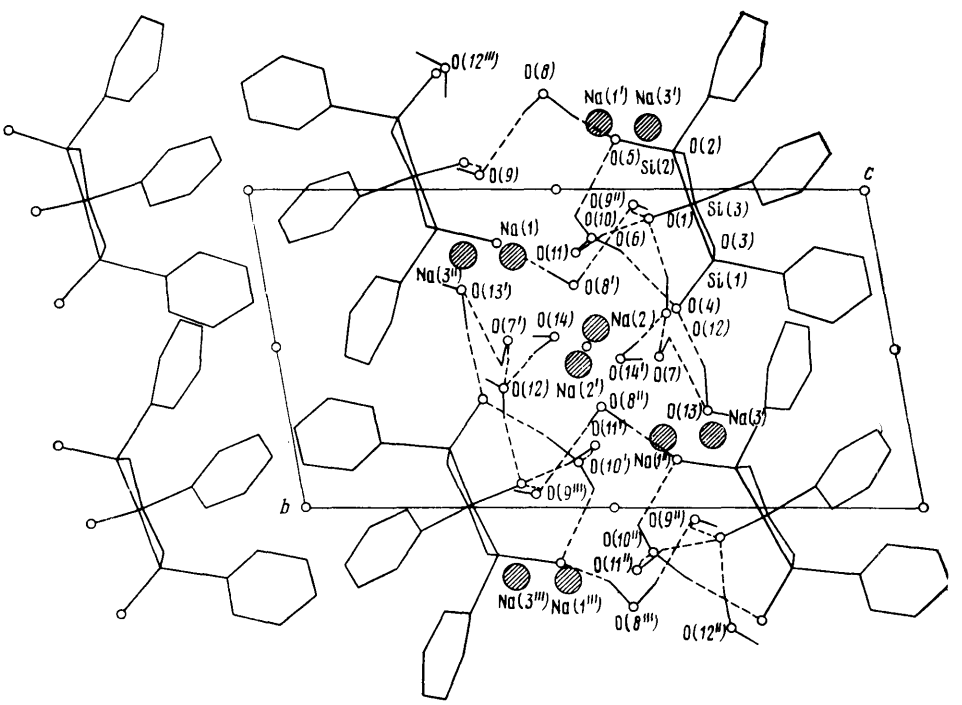

Figure 21. Projection on the face *bc* of the packing of molecules in a crystal of (V). Hydrogen bonds O–H...O are shown by broken lines[105].

Molecules of (XVII) also crystallise with porous packing. Centres of symmetry $0,\frac{1}{2},0$ (the crystals belong to space group $P\bar{1}$) are located in cavities filled with solvent (benzene) molecules. As with crystals of (XXI), the volume of a cavity exceeds that of a benzene molecule, so that the latter is slightly "disordered", which is evident in somewhat increased isotropic temperature factors (~50% larger than for phenyl substituents in the (XVII) molecule).[50]

Among all the crystalline structures of organosiloxanes investigated (around thirty have been determined) voids have been found only in crystals of (XVII) and XXI), which differ from other organocyclosiloxanes in a rigid silicon–oxygen skeleton and from siloxanes having such a skeleton [e.g. from the methyl derivative (XX)] in the presence of bulky phenyl substituents. These latter, by sharply increasing distances between siloxane skeletons, diminish the polar interaction inherent in, for example, crystals of octa(silsesquioxanes) with small substituents[61], as well as promoting the formation of cavities in the crystal.

The ability of several large skeletal siloxane molecules with bulky framing groups to pack with the formation of cavities acquires special interest in the light of the specific gas-permeability of certain cyclolinear organosiloxanes, which has found practical application[81–83]. Although the character of the system of cavities in crystals of (XXI) excludes the possibility of migration of even the simplest molecules from one cavity to another, it may be expected in principle that, by varying the substituents, we shall be able to obtain monolayers or double layers (and perhaps even three-dimensional structures) possessing the necessary permeability.

Many chemical reactions of siloxanes involve intermediate ionic structures. Interest therefore attaches to the results of the first X-ray structural investigation of the ionic sodium salt (V) of a siloxane[13]. The siloxane rings of the anions form layers parallel to the plane *ab*. The gaps between the layers are filled alternately with phenyl groups of the anions (van der Waals interaction between layers) and with sodium cations and water molecules (ionic interaction and hydrogen bonds) (Fig. 21). Interlayer spaces of the second type are characterised by strong electrostatic interaction, which is not found in ordinary molecular crystals of organosiloxanes. The coordination of the sodium ions and their distribution relative to charged fragments of the anion in a crystal of (V) are important for understanding the initial stages in the reactions of organosiloxanes in hydrophilic alkaline media.

Chemical reactions (including polymerisation) of molecules densely packed in a crystal have begun to be studied relatively recently. Several important papers on the crystal chemistry of these processes have been cited in a review[84]. A necessary condition for the occurrence of topochemical solid-phase reactions is that shifts in the equilibrium positions of atoms in the reactant molecules should be minimal with fairly intense vibrational thermal motion of the atoms. This is the fundamental principle of lattice-controlled reactions formulated

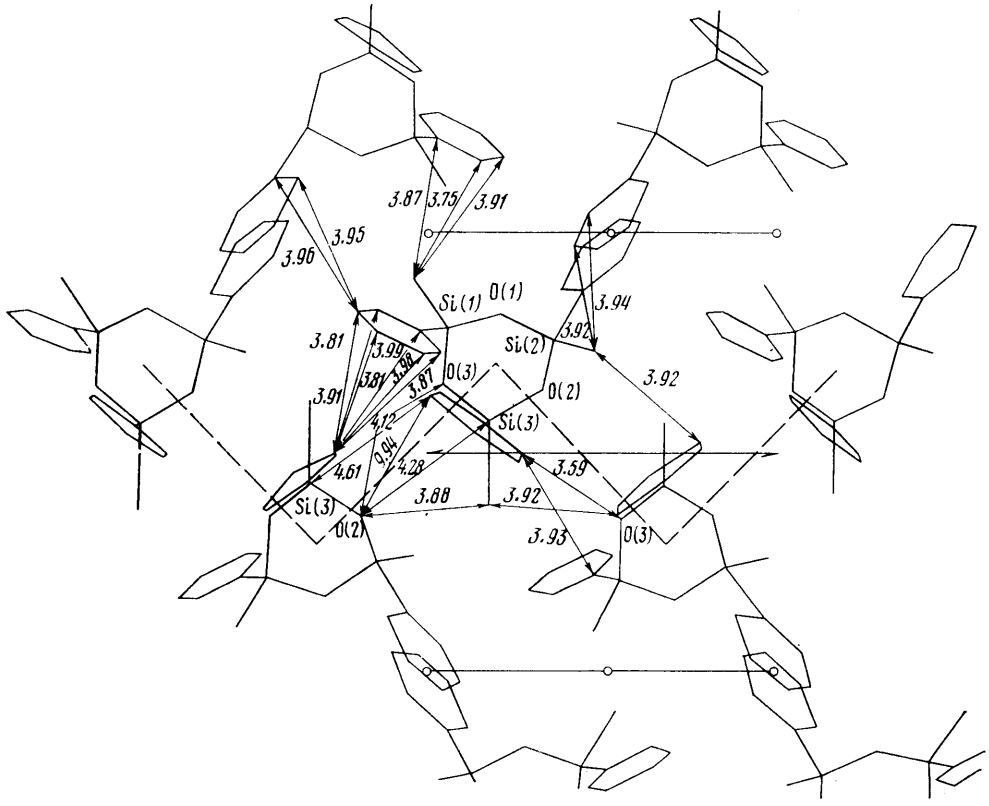

Figure 22. Arrangement of molecules in a layer in structure (IV). The broken lines join centres of D_3 rings in molecules forming chains. The numerals indicate intermolecular distances[12].

by Schmidt[85,86]. In application to solid-phase polymerisation this principle was formulated by Kargin and Kabanov[87].

Derivatives of D_3 rings—(I), (III), and (IV)— are capable of solid-phase polymerisation at room temperature or above in the presence of potassium trimethylsilanolate as initiator[88]. X-Ray examination of compounds (I)–(IV)[9–12] has led to several interesting conclusions on the possibility and the mechanism of the polymerisation of D_3 derivatives in the solid phase. Unfortunately, in contrast to, for instance, oligomers of formaldehyde, for which a molecular mechanism of polymerisation is based on numerous experimental confirmations of the formation of an oriented crystalline polyoxymethylene[89–91,84], results on the formation of ordered polysiloxanes by solid-phase polymerisation have not yet been obtained. Therefore discussion of the mechanism of the solid-phase polymerisation of siloxanes is tentative in character.

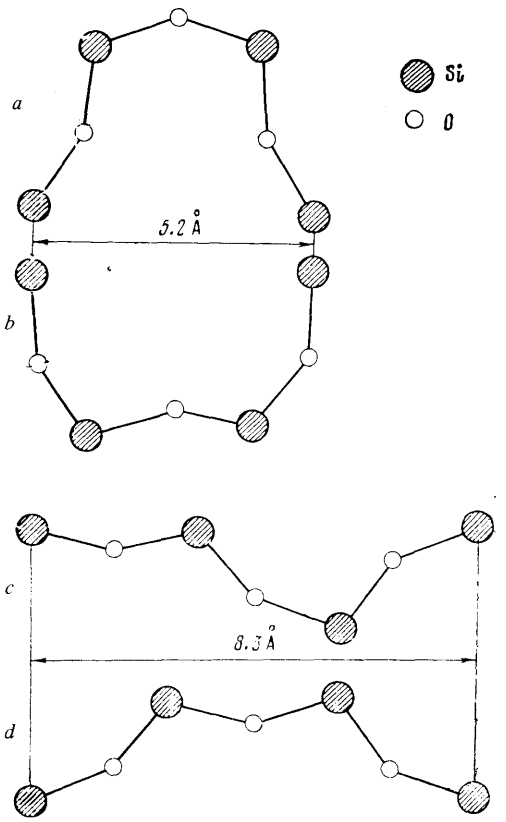

Figure 23. Some possible conformations of a planar monomeric unit in a polysiloxane chain: *a*) *trans,cis,cis,trans*; *b*) *cis,trans,trans,cis* ("shortest" units); *c*) *trans,trans,cis, trans*; *d*) *trans,trans,trans,trans* ("longest" units)[11,12].

In a crystal of (IV)[12] layers of molecules can be clearly distinguished, whose siloxane rings are very accurately coplanar. These layers have an interplanar spacing of 9.52 Å and are parallel to the $(1\bar{2}0)$ face. Fig.22 shows that a layer in turn contains distinct chains of molecules connected by a screw axis lying in the plane of the layer (e.g. 2_1 [$\frac{1}{2}$ $\frac{1}{4}$ z]). Within the layers the distances between silicon and oxygen atoms of neighbouring molecules in the same chain (4.28 and 4.61 Å) are appreciably shorter than the distances between chains (5.46 and 5.63 Å).

The structure of (III)[11] also contains distinct layers of molecules, parallel to the (100) face, but in contrast to (IV) the planes of the D_3 rings are non-coplanar, forming an angle of 27.5° with the plane of the layer. The Si...O distances between the rings of molecules in a layer are 5.46–7.54 Å (no well defined chains present), and those between rings in molecules of neighbouring layers ~9 Å.

In a crystal of (I) the molecules have a disordered distribution, which indicates that their number in a cell is anomalous (space group $R3m$, $z = 1$) with strong diffuse scattering on the X-ray photographs[9]. Layers having $z = 0$, $\frac{1}{3}$, and $\frac{2}{3}$ prove to be identical but displaced statistically one relative to the other along $\mathbf{a}\sqrt{3}/3$ vectors. In the layers the Si...O distances between the initial and each of the six neighbouring siloxane rings have been determined as 4.62 Å; the distance between layers is 6.4 Å.[9]

The packing of molecules of (II), which does not polymerise in the solid state[10], exhibits the following features: (i) all distances between atoms of siloxane rings in neighbouring molecules exceed 7 Å; (ii) although shorter intermolecular contacts are present in the structure of (II) than in that of (IV), they are all effected by atoms of the framing phenyl substituents (only one short C...O contact, of 3.38 Å, is present); (iii) the phenyl groups are so oriented that they shield siloxane rings in neighbouring molecules from each other; and (iv) the coplanar arrangement of D_3 rings in neighbouring molecules characteristic of the structure of (IV) is not observed in the crystal.

A layered distribution of D_3 rings, which in all cyclotrisiloxanes[9–12] have a somewhat strained planar configuration, is especially significant. Indeed, with such an arrangement the framing substituents are distributed between the layers and do not prevent interaction of siloxane rings within layers during polymerisation, which is especially important with such bulky substituents as phenyl. Thus a layered arrangement of D_3 rings favours the solid-phase polymerisation of an organocyclotrisiloxane monomer. Therefore compound (II), for example, whose crystals do not have a layer structure, does not polymerise in the solid phase. Consequently the scheme of polymerisation of cyclic monomers[92], suggested in particular for (I), according to which molecules are arranged in stacks in a crystal of the monomer, and polymerisation occurs with ring opening and formation of extended helices of a crystalline polymer, does not apply to D_3 rings.

The possibility of the polymerisation of a cyclic monomer in a given crystallographic direction can sometimes be assessed by comparing the distance between neighbouring rings in this direction with the length of a unit formed topochemically on opening of the rings. In view of the inevitable increase# in SiOSi angles from 132° to ~160° when a D_3 ring is opened, the resulting polysiloxane chain acquires a planar conformation, and the length of a unit in this chain, formed from a single ring, will vary from ~5.2 Å (*trans,cis, cis,trans*- or *cis,trans,trans,cis*-conformation) to ~8.3 Å (*trans,trans,cis,trans*- or *trans,trans,trans,trans*-conformation) (Fig.23). The distances between centres of siloxane rings corresponding to these limits are (*a*) in structure (IV)[12] respectively ~6.9 and ~8.1 Å between neighbouring molecules

#Since the SiOSi angles in D_3 rings are considerably smaller (~130°) than those in siloxanes with a large number of units, where these angles vary between 140° and 160°, polymerisation with ring opening should be accompanied by an increase in the angles.

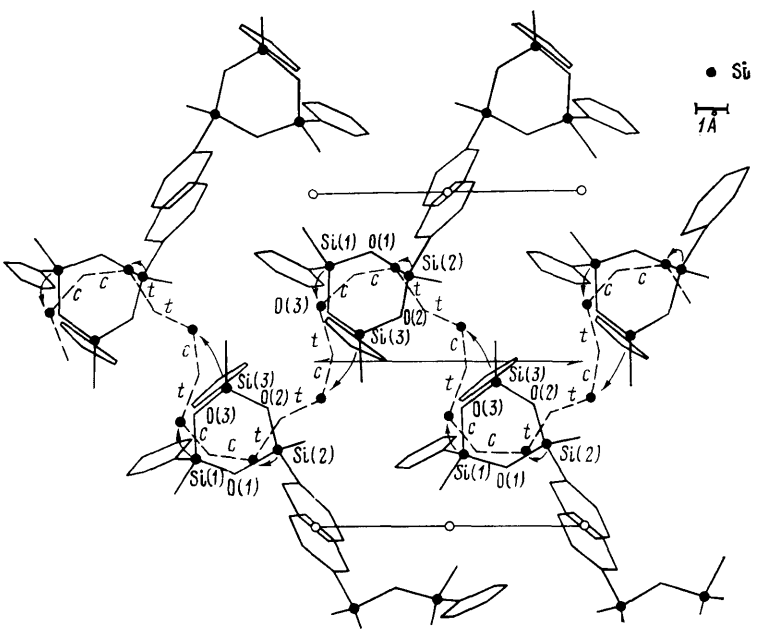

Figure 24. A layer in structure (IV). The broken line shows a planar polysiloxane chain which may be formed on the cleavage of rings at $Si_{(3)}-O_{(2)}$ bonds and the closure of $Si_{(3')}-O_{(2')}$ intermonomer bonds at the sites of the shortest intermolecular Si...O contacts (the arrows indicate the displacement of atoms on polymerisation). The letters *c* and *t* denote units in the polymer chain having *cis* and *trans* conformations respectively. The polymer chain formed has a *cis,cis,trans, trans,cis,trans* conformation of the monomeric unit[11,12].

in the chain and between molecules of neighbouring chains in the same layer related by centres of symmetry 0,0,0, (*b*) in structure (III)[11] ~8.6 and ~8.5 Å between molecules in the same layer related by translations *b* and *c*§, and (*c*) in structure (I) respectively ~7.6 and ~6.4 Å between neighbouring molecules in a layer and between molecules in neighbouring layers¶. The OSiO bond angles in mono- and poly-organosiloxanes are approximately constant and differ from the tetrahedral angle (109.5°) by at most 2–3°.

In relation to the solid-phase polymerisation of (IV) the main condition of topochemical polymerisation (retention by most atoms of their approximate positions during polymerisation[84]) leads to the requirement of maximum similarity of the configuration of the resulting polymer chain to that of the siloxane rings of the monomer. Fig. 24 shows that this requirement is met by a *cis,cis,trans,trans,cis,trans*-conformation of the monomeric unit in a polymeric chain constructed by changes in the SiOSi bond angles with the OSiO angles constant. It must be emphasised that this polymer chain is formed by opening the rings at the $Si_{(3)}-O_{(2)}$ bonds, which in a crystal of (IV) corresponds to the shortest intermolecular distance $Si_{(3)}...O_{(2')}$ (4.28 Å) of all the Si...O distances in the chain of molecules. Thus the suggested scheme of formation of the polymer chain satisfies both the condition of topochemical polymerisation and the condition of closest spatial proximity of chemically interacting atoms. It should lead to considerable compression of the crystal in the direction of the polymer chain. Actually the distance between the centres of siloxane rings in adjacent monomeric molecules in the chain is 6.9 Å, while the length of a unit in the resulting polymer chain (i.e. the distance between the centres of gravity of the trios of silicon atoms from one former ring) is ~5.9 Å.[11,12]

Thus analysis of the packing shows that the distances between the centres of neighbouring siloxane rings in structural layers of (I), (III), and (IV) probably permit chemical interaction of the rings with formation of polymer chains. The structure of (IV) is more favourable to the propagation of polymerisation in chains of molecules, which may lead (with a topochemical mechanism) to formation of an oriented polymer. In a crystal of (III) polymerisation in layers is most likely, while the direction of chain growth within a layer may vary, with formation of different macrocycles D_n. In contrast to a crystal of (IV), polymerisation in layers in (I) and (III) requires considerable three-dimensional rearrangement in the crystals of these monomers.

With regard to a possible mechanism for the initiation of polymerisation it is reasonable to assume[11,12] that deposition of the initiator on crystal faces parallel to the planes of layers of siloxane rings in crystals of (I), (III), and (IV), i.e. respectively on the faces (001), (100), and ($1\bar{2}0$), would lead to rapid two-dimensional polymerisation in these planes, leaving deep-seated portions of the crystal unaffected. Deposition of the initiator on faces perpendicular to the layer planes, however, will lead to development of polymerisation

§ A difference of ~0.3 Å from the upper limit is insignificant and "surmountable" by the thermal motion of the atoms at ordinary temperatures[80].

¶ The absence from a crystal of (I) of preferred directions (in the chain and in the layer) is consistent with the formation of an amorphous polymer by its solid-phase polymerisation[88].

in all densely packed layers of molecules, i.e. to the spread of polymerisation throughout the crystal†.

In a crystal of (XXVII) the D_2T rings in chains of molecules related by centres of symmetry $0,\frac{1}{2},\frac{1}{2}$ are significantly closer together (Fig.25). The $Si_{(4)}...O_{(3')}$ and $Si_{(4')}...O_{(3)}$ distances between these molecules are 4.12 Å, considerably less than any other Si...O intermolecular distance, the shortest of which is 5.46 Å. The layers are situated in $(01\bar{1})$ planes. The Si...O distances between D_2T rings in different layers exceed 7 Å.[74,94] The question arises whether the localisation of deformation of D_2T rings in the structure of (XXVII) and the relative weakening of $Si_{(4)}-O_{(3)}$ bonds are not caused by the observed closer approach of these particular parts of neighbouring molecules in the crystal. Such approach is probably due to electrostatic interaction of the antiparallel $Si_{(4)}-O_{(3)}$ and $Si_{(4')}-O_{(3')}$ dipoles.

It must then be ascertained whether such specific interaction of the molecules in the crystal does not affect the mechanism of polymerisation. If solid-phase polymerisation of (XXVII) is possible, this intermolecular interaction may lead to a polymer having a cyclolinear structure of alternating disilazane and D_4T_2 rings joined by trimeric siloxazane bridges with the polymer chain extended along the [011] direction of the monomer crystal (Fig.25).[94]

It follows from the crystal and molecular structure of (XXVII) that, if local attack by a nucleophilic species (with substantial initiation of solid-phase polymerisation) takes place at silicon–oxygen bonds in D units of the cyclic portion of a molecule located on the crystal surface, leading to cleavage of the siloxane ring and migration of the active centre to the oxygen atom, then rupture of a silicon–oxygen bond in an adjacent molecule (related to the initial centre of symmetry $0,\frac{1}{2},\frac{1}{2}$) should be facilitated. However, further transfer of the active centre to the other end of the molecule is impossible because of its great length, and all other distances between rings in the crystal are too large for topochemical interaction. "Chemical" intermolecular interactions other than the above interaction of D units are possible only in lattice defects.

In fact[74] solid-phase polymerisation in the presence of an ammonium catalyst involves 6–7% formation of an insoluble product, but >90% of the initial compound remains unchanged. In benzene solution at the same temperature (~50 °C) a polymer of predominantly network structure is formed together with a gel fraction (62%). Polymerisation goes similarly in the melt at higher temperatures#.

A crystal of (XXIV) contains infinite chains of molecules in contact at their vinyl side-chains with C...C distances of ~4 Å (Fig.26).[70] At such distances molecules are able to

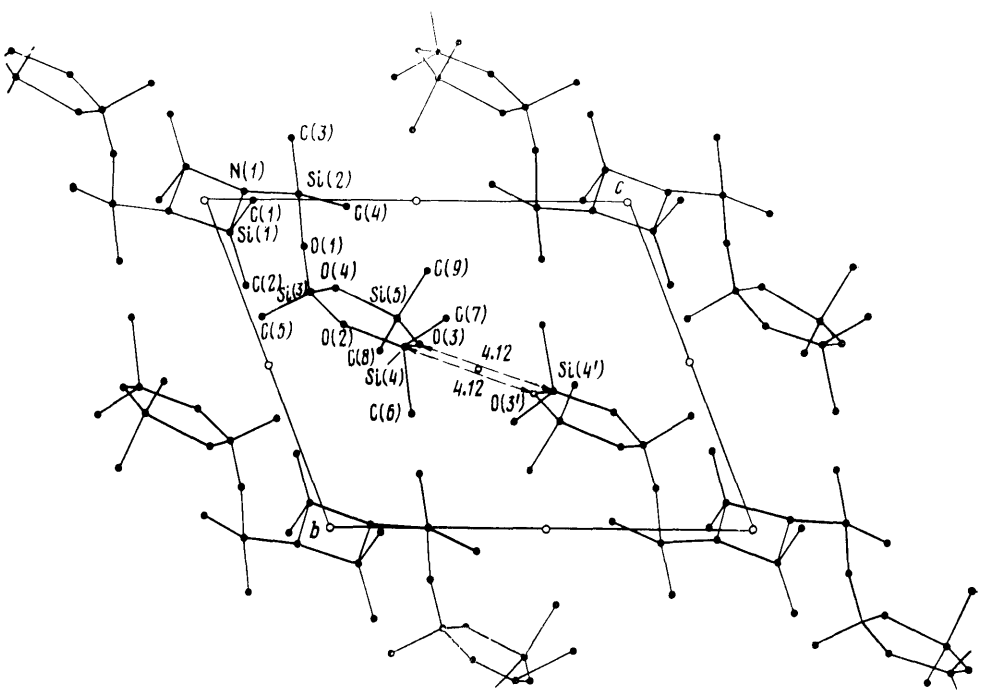

Figure 25. Projection (100) of structure (XXVII).[94]

†An analogous mechanism of initiation was suggested and confirmed by polarisation data and electron microscopy, as well as by measurements of infrared dichroism, for the solid-phase polymerisation of *p*-acetamidostyrene and *p*-benzamidostyrene, whose crystals also have a layer structure[93].

#A study is now being made of the possibility of radiation-induced solid-phase polymerisation of (XXVII), which would eliminate difficulties associated with the transfer of active centres: on exposure they are generated throughout the crystal.

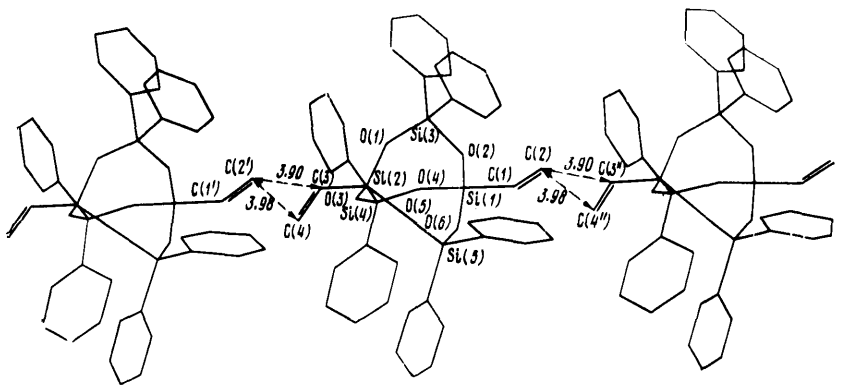

Figure 26. Diagram of chain of molecules in a crystal of (XXIV). Contacts C...C between vinyl groups in neighbouring molecules are indicated.

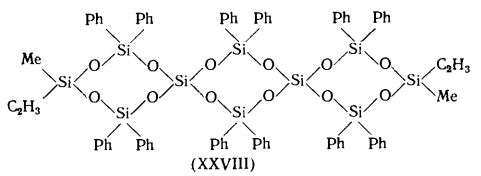
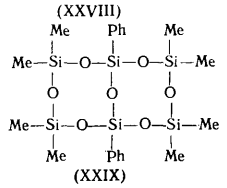


interact in the crystal by a topochemical mechanism[84]. It was therefore suggested[70] that (XXIV) is able to polymerise in the crystal through the vinyl groups with formation of a "bead" type of polymer. An attempt is now being made to confirm experimentally this crystal-chemical conclusion.

VII. CONCLUSION



It may be concluded not so much from the quantity of papers published on the crystal structure of organocyclosiloxanes (though it is quite convincing) as from the character of the problems tackled and the importance of several of the findings that X-ray structural (and physicochemical in general) investigation of this class of compounds is being vigorously pursued. Although it is difficult to expect the preparation of novel monomers in this field, while synthetic work is aimed mainly at improving and modifying known structures, the growth in the number of structural investigations on organocyclosiloxanes is undoubtedly justified, since it not only promotes further successful development of this field of macromolecular hetero-organic chemistry but also leads to the accumulation of the valuable factual and procedural information required for the analysis of novel or little-studied classes of hetero-organic monomers.

---o0o---

During the preparation of this Review for publication structural information has appeared on the spirocyclic siloxane (XXVIII),[95] the bicyclic siloxane (XXIX),[96]

(XXVIII)

(XXIX)

and also a tetragonal modification (XXX)[97] of octa(phenylsilsesquioxane) $(C_6H_5SiO_{1.5})_8$. The form of the tetrasiloxane rings in (XXVIII) and (XXIX) has been described by the Cremer–Pople method[98] and specified by the Hendrickson method[99].

In the centrosymmetric molecule (XXVIII) the outer D_3Q rings form dihedral angles of 83.2° with the plane of the inner D_2Q_2 ring. The latter ring has a form close to *LC*, and the outer rings are intermediate between *B* and *BB*. As in other spirocyclosiloxanes (Section III) the mean distance between a spiro-silicon atom and an oxygen atom (*Q* units) is 1.598(8) Å, rather less than the remaining silicon–oxygen distances (*D* units, 1.62(1) Å). The terminal vinyl groups, *trans* with respect to the tricyclic silicon–oxygen system, are disordered[95].

The form of the D_2T_2 rings constituting the molecule (XXIX) is close to *BB*, with a dihedral angle of 125.9°. The silicon–oxygen bond lengths in *D* and *T* units differ little (on the average they are respectively 1.630(8) and 1.62(1) Å).[96]

The $(C_6H_5SiO_{1.5})_8$ molecules in a crystal of (XXX) are situated on fourfold axes (in (XXI) at centres of symmetry). The mean silicon–oxygen and silicon–carbon distances (1.613 and 1.833 Å), and also the SiOSi bond angle (148.5°), are closely similar to those found in a crystal of the triclinic modification of (XXI). As in the latter compound, disordered solvent (acetone) molecules are found in a crystal of (XXX), which do not escape from the crystal in air, despite the absence of specific intermolecular interaction. The packing of molecules in a crystal of (XXX) is fairly free, with a shortest intermolecular C...C distance of 3.752 Å.[97]

Auto-oscillations in the Rates of Heterogeneous Catalytic Reactions

M.G.Slin'ko and M.M.Slin'ko

Experimental data on the auto-oscillations in the rates of heterogeneous catalytic reactions are surveyed and the physicochemical principles of the origin of this phenomenon are examined. It is shown that the auto-oscillations can be due to a change in the properties of the catalyst under the influence of adsorbed reactants or reactants dissolved in a thin surface layer of the catalyst. Kinetic models of the reaction of hydrogen with oxygen on nickel and platinum catalysts, the phase plots of which contain limiting cycles, are examined in detail and models are presented for the auto-oscillations in the rate of reaction of oxygen with carbon monoxide on platinum catalysts. The importance of the auto-oscillations in the reaction rate for the development of the theory of heterogeneous catalysis is discussed.
The bibliography includes 69 references.

I. INTRODUCTION

A necessary condition for the occurrence of auto-oscillations is the presence in the system of a sufficiently strong feedback. It ensures the supply to the system of sufficient energy which is regulated by the movement of the oscillating system itself. The theory of bifurcations in dynamic systems constitutes the mathematical basis of the theory of auto-oscillations[1,2].

Heterogeneous catalytic systems have all the characteristic features of non-linear dynamic systems, so that under certain conditions there is a possibility of auto-oscillations in the rate of a heterogeneous catalytic reaction. Since the auto-oscillations are very sensitive to the structure and properties of the system, they are of considerable interest for the understanding of the detailed mechanism of chemical reactions and for the establishment of the general features of reactions involving various types of catalysis: homogeneous, enzymatic, and heterogeneous. The auto-oscillations in the rates of reaction in homogeneous chemical and biological systems have been vigorously studied recently and there are a number of fairly complete reviews[3-8]. This review gives an account of studies devoted to the auto-oscillations in heterogeneous catalytic systems alone.

II. EXPERIMENTAL DATA

The oxidation of carbon monoxide on platinum catalysts is one of the first heterogeneous catalytic systems where auto-oscillations in the reaction rate were observed in the kinetic

region. This reaction has been studied[9] in a flow-circulation apparatus; the catalyst consisted of a platinum mesh prepared from wire 0.04 mm in diameter and having 3600 apertures per square centimetre. The reaction mixtures contained a large excess of air. At very low carbon monoxides pressures in air stable stationary states were observed in the system and the reaction was of second order with respect to carbon monoxide. With increase of carbon monoxide pressure, stable oscillations appeared. If the partial pressure of carbon monoxide rose, the amplitude and frequency of the oscillations increased, the average rate of reaction reaching a maximum. A further increase in the partial pressure of carbon monoxide led to a sharp fall of the rate of reaction and to the disappearance of the oscillations.

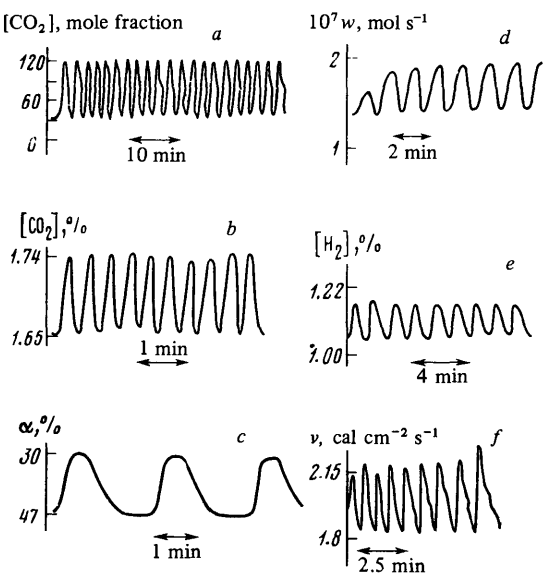

Figure 1. The overall form of the auto-oscillating processes in various heterogeneous catalytic systems: *a*) auto-oscillations in the rate of oxidation of carbon monoxide on a porous grain of platinised γ-alumina (180 °C; 1% CO; air)[10]; *b*) auto-oscillations in the rate of oxidation of CO on a Pt catalyst deposited on α-Al_2O_3;[11] *c*) auto-oscillations in the rate (degree of conversion α) of oxidation of CO on a Pt foil catalyst in an ideal mixing reactor (239 °C; 1.08% CO; air)[14]; *d*) auto-oscillations in the rate (*w*) of oxidation of hydrogen on a nickel foil (245 °C; 0.8% O_2; 99% H_2);[55] *e*) auto-oscillations in the rate of oxidation of hydrogen on a platinum wire (221 °C; 3.48% H_2; air)[53]; *f*) auto-oscillations in the rate of heat evolution in the oxidation of ethylene on a platinum wire (390 °C; 2% C_2H_4; 98% O_2).[24]

A similar dependence of the rate of reaction of carbon monoxide with oxygen on the carbon monoxide concentration in the gas phase was observed in another study[10] of this reaction on a catalyst grain containing 0.3% Pt deposited on γ-Al_2O_3. The reaction was carried out in a flow reactor in a stream of air containing small amounts of carbon monoxide. Fig. 1*a* illustrates the stable oscillations of the reaction rate observed in the region of the rate maximum. The period of the oscillations was several minutes. As in the oxidation of carbon monoxide on the platinum mesh, the amplitude of the oscillations increased with increase of the CO concentration in the initial mixture. As the catalyst temperature rose, the frequency of the oscillations increased and their amplitude fell. Above 250 °C the oscillation vanished. The authors[10] noted the high sensitivity of the characteristics of the oscillations to the properties of the catalyst. On passing from one catalyst grain to another, a change in the amplitude and period of the oscillations was noted.

McCarthy et al.[11] also investigated the reaction of CO and O_2 on a deposited catalyst containing 0.035% of platinum. At catalyst temperatures below 260 °C the dependence of the rate of reaction on the carbon monoxide concentration which they observed had a maximum corresponding to less than 0.5% of carbon monoxide in oxygen†; in the region of this maximum the author observed oscillations in the rate of reaction with a period of the order of 20 s (Fig. 1*b*).

In the study of the influence of the adsorption of carbon monoxide in oxygen on the contact potential difference (CPD) between the platinum electrode and the silicon reference electrode[12] a sharp change of CPD was noted for [CO] = 2%. The authors[12] showed that the maximum in the rate of reaction of CO with O_2 at 200 °C corresponds to this composition of the reaction mixture. In order to observe the auto-oscillations in the rate of this reaction, the authors employed two methods. In the first case CO was oxidised on a platinum wire 0.03 mm in diameter. The amplitude of the oscillations in the resistance of the wire induced by the oscillations in the rate of reaction corresponded to a change in the catalyst temperature by 5 °C. The oscillations were observed in a stream of oxygen containing 2% of carbon monoxide. In the second method CO was oxidised on an electrode made of *n*-type silicon on which a thin layer (100 Å) of platinum had been deposited. At 170 °C and [CO] = 1% the authors[12] observed oscillations in the photocurrent with a period of ~20 s, induced by the oscillations in the composition of the adsorbed layer in the oxidation of carbon monoxide on the platinum catalyst. It has been shown[13] that the amplitude of the oscillations reaches a maximum when the reactants distributed on the catalyst surface are in stoichiometric proportions.

The reaction of CO with O_2 on a platinum foil has been investigated[14]. It was carried out at atmospheric pressure in the temperature range 200–250 °C in a flow reactor free from temperature and concentration gradients. The authors investigated the dependence of the degree of conversion of carbon monoxide on the flow rate of the reaction mixture. The carbon monoxide concentration in air was varied from 1 to 4%. Depending on the experimental conditions, the establishment of either stable stationary states or auto-oscillations in the reaction rate was observed (Fig. 1*c*). The amplitude and period of the auto-oscillations increased with decrease in the degree of conversion at a constant CO pressure in the initial mixture. An analogous increase of the period and amplitude of the oscillations was observed with increase of the CO concentration in the initial mixture. As the temperature rose, the period and amplitude of the oscillations fell.

Virtually simultaneously with the auto-oscillations in the rate of oxidation of carbon monoxide on platinum catalysts, auto-oscillations were observed in the reaction of hydrogen with oxygen on a nickel foil[15,16] (Fig. 1*d*). The temperature

†Here and henceforth the concentrations of the reactants in the initial mixture are expressed in percentages by volume.

of the foil was kept constant to within 0.02 °C by means of a special thermoregulator. Above 180 °C, auto-oscillations in the rate of reaction were observed with a period ranging from 3 to 60 s. The reaction mixture contained a large excess of hydrogen and the oxygen concentration did not exceed 1 vol.%. With increase of temperature to 350 °C, an increase of the amplitude and frequency of the oscillations as well as an expansion of the range of pressures at which oscillations took place were observed. The maximum amplitude of the oscillations was 40% of the average rate of reaction. Simultaneously with the auto-oscillations in the rate of reaction, the authors[17] observed and investigated oscillations in the contact potential difference (CPD) for a nickel plate. Above 200 °C, oscillations were observed both in the reaction rate and in the CPD with a period ranging from 12 to 120 s. The amplitude and the frequency of the CPD oscillations were independent of the linear rate of flow of gases through the reactor.

Auto-oscillations in the reaction rate have also been found in the oxidation of hydrogen on platinum catalysts[18] (Fig. 1*e*). Owing to the difference between the types of influence of platinum and nickel catalysts on different reactants, the auto-oscillations in the rate on platinum catalysts were observed for other component ratios in the reaction mixture (in the presence of an excess of oxygen and small amounts of hydrogen). During the reaction on a platinum wire, auto-oscillations in the rate were observed at a catalyst temperature exceeding 135 °C for a reaction mixture containing 21.5% O_2 and >0.5% H_2. With increase of temperature from 160° to 200 °C, a decrease was observed in the amplitude and period of the auto-oscillations, the latter varying in the range from 220 to 6 s.

When hydrogen was oxidised on a platinum foil, oscillations in the CPD were noted simultaneously with oscillations in the reaction rate[18]. Auto-oscillations in the reaction rate were observed in the temperature range 85–130 °C for the same compositions of the reaction mixture as for the platinum wire. With increase of the hydrogen concentration in the reactor, the amplitude and period of the oscillations also increased, to maximum values, and then fell. When the temperature of the catalyst was varied in the range 85–130 °C, the period of the oscillations changed from 60 to 2 min.

Other workers[10,19] also observed auto-oscillations in the rate of oxidation of hydrogen on a catalyst grain containing 0.4% of platinum but under non-isothermal conditions. The period of the oscillations of the temperature of the centre of the platinum grain was 60 min and its amplitude was 60 °C. (about a mean value of 170 °C). The temperature of the gas stream, consisting of a mixture of air and 3.14% of hydrogen, was kept at 53 °C. The authors concluded that, despite the non-isothermal experimental conditions, the auto-oscillations are not associated with the characteristics of the interaction of the mass and heat transfer involving the catalyst grain. This conclusion was reached in the light of the long period of the oscillations and the absence of phase shift between the oscillations in the catalyst temperature and the concentration of the water formed.

The auto-oscillations in the rate of oxidation of ethylene by oxygen on a platinum wire have been studied[20] by the method of compensation electrothermography. The auto-oscillations in the rate were noted at a catalyst temperature exceeding 275 °C (Fig. 1*f*) in the presence of an excess of oxygen. The amplitude of the oscillations increased with increasing ethylene concentration and with decreasing catalyst temperature.

Auto-oscillations have been observed also in the rates of oxidation of cyclohexane on NaX, LiY, and KY zeolites[21,22] and of propene on the surfaces of CoO–MgO solid solutions[23]. The period of the auto-oscillations of the rate of oxidation of cyclohexane was ~0.5–10 min, the concentrations of the reactants and temperature varying periodically through the oscillations. Compounds of the peroxy-type were detected by infrared spectroscopy on the surface of the zeolite in the course of the reaction. The authors suggest that the oxidation of cyclohexane takes place by a heterogeneous-homogeneous mechanism.

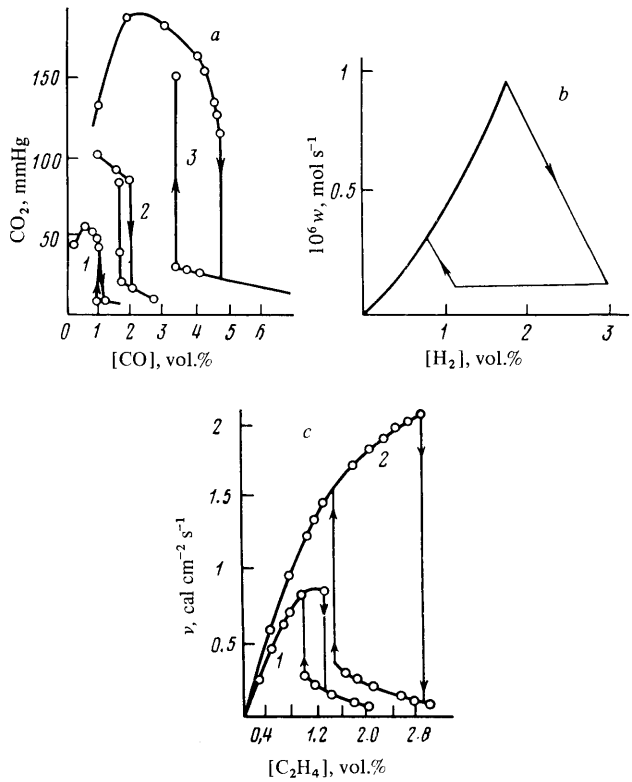

Figure 2. Dependence of the rate of reaction on the composition of the initial mixture for different heterogeneous catalytic systems: *a*) oxidation of CO on a deposited Pt catalyst[19] at different temperatures [temperature (°C): 1) 192; 2) 217; 3) 242]; *b*) oxidation of hydrogen on a platinum foil at 135 °C;[53] *c*) oxidation of ethylene on a platinum foil at different temperatures [temperature (°C): 1) 354; 2) 406].[20]

The data presented above show that auto-oscillations in the rate of reaction are observed in most cases in catalytic systems consisting of reactants differing sharply in their oxidation-reduction properties and containing a catalyst which is resistant to the formation of new bulk phases for a specified composition of the reaction mixture. For a number of heterogeneous catalytic systems, periodic conditions arise in the region of an uncertain dependence of the rate of reaction on the composition of the reaction mixture for a cyclic variation of the latter (i.e. in the region of hysteresis). Such phenomena have been observed in the oxidation of CO on platinum catalysts[9,10,19], in the oxidation of ethylene on a platinum wire[20], and in oxidation on a platinum

foil[53]. Fig.2 illustrates the dependence of the rates of the above reactions on the composition of the reaction mixtures; all the relations are similar. With increased concentration of a component which is present in the reaction mixture in a deficient amount, a gradual increase of the reaction rate is observed; above this the rate falls sharply. A decrease in the concentration of carbon monoxide, ethylene, or hydrogen leads to an increase of the rate of reaction, which, however, occurs at another (lower) concentration of the component present in a deficient amount.

Auto-oscillations in the rate have been observed either along the ascending branch or in the region of the maximum in the relation between the rate of reaction and the composition of the reaction mixture. Hysteresis has been observed[14] in the rate of oxidation of CO for a cyclic variation of the rate of flow of the reaction mixture through the reactor. The concentration of carbon monoxide at the inlet to the reactor was kept constant. Periodic changes in the rate of reaction have also been observed in the region of non-unique stationary states about an upper unstable stationary state.

Measurements of the contact potential difference in the course of the catalytic reaction have shown that the regions of maximum reaction rates and a multiplicity of stationary states are characterised by a high sensitivity of the activity of the catalyst to the composition of the gas phase and the surface layer. The marked influence of the composition of the adsorbed layer on the rate of the catalytic process is apparently one of the principal causes of the non-linear kinetic relations between the rate of reaction and the composition of the gas phase. Such complex relations, involving regions of non-unique stationary states, have been observed in reactions of carbon monoxide with hydrogen on a nickel catalyst[24] and in the oxidation of ammonia on platinum catalysts[25,26].

Fig.1 shows that the form of the oscillations observed in various reactions varies within wide limits from nearly harmonic to the form of relaxation oscillations (relaxation oscillations are characterised by an alternation of rapid and slow movements in the course of a single cycle). There is also a possibility of more complex oscillations. Fig.3*a* illustrates complex oscillations in the rate of oxidation of hydrogen on a platinum wire[53]. Fig.3*b* presents complex oscillations in the rate of heat evolution in the oxidation of ethylene on a platinum wire[20]. Complex irregular dynamic conditions in the oxidation of hydrogen on a platinum wire, illustrated in Fig.4, have also been observed[54]. Evidently oscillations with a small amplitude and a short period can be replaced by oscillations with larger values of these parameters (Fig.4*a*). After unequal time intervals, the oscillatory conditions can also be disturbed by a sharp decrease of the rate of reaction and can then return to the initial state (Fig.4*b*).

The auto-oscillations in the rates of heterogeneous catalytic reactions have been observed in reactors of different types on both deposited and metallic catalysts. In the study of the oxidation of CO on platinum catalysts this phenomenon was observed in flow reactors[10,12,13,19], in a gradient-free reactor

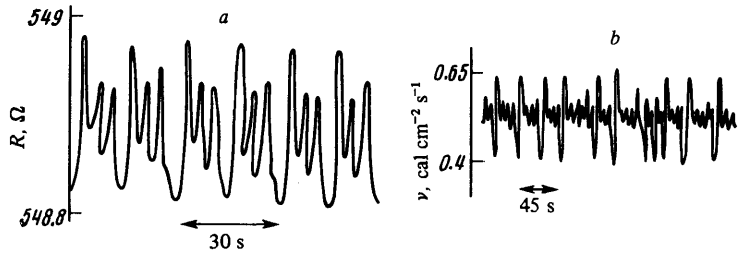

Figure 3. The form of the oscillations observed on platinum wire catalysts: *a*) variation of the resistance of the platinum wire R during the oxidation of hydrogen (2.8% H_2; 17.5% O_2; 79.7% N_2);[53] *b*) oscillations in the rate of heat evolution ν during the oxidation of ethylene (0.5% C_2H_4; 99.5% O_2).[20]

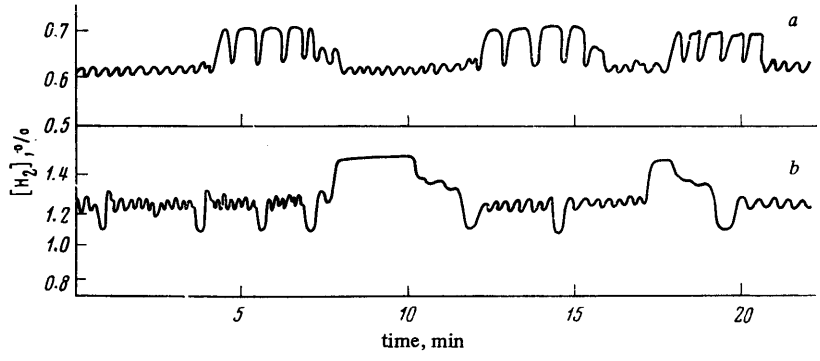

Figure 4. Complex oscillatory conditions observed on a platinum wire during the oxidation of hydrogen: *a*) 202 °C; 2.13% H_2, 21.5% O_2; *b*) 216 °C, 1.74% H_2, 15.6% O_2.[53]

with recycling[9], in a Carberry reactor[11], and in an ideal mixing reactor[14]. The auto-oscillations in the rates of oxidation of hydrogen on nickel and platinum catalysts[18], of ethylene on a platinum wire[20], and of cyclohexane on zeolite catalysts[21] have been studied in flow reactors.

In most cases auto-oscillations were detected under isothermal conditions or with a slight change in the catalyst temperature in the course of the oscillations. Thus, when CO was oxidised on a deposited catalyst, the temperature of the platinum grain changed by 2 °C [10,19] and in the study of the auto-oscillations in the rate of the same reaction on platinum catalysts in the form of a foil[14] and a wire[12] the change was by 3° and 5 °C respectively. Auto-oscillations in the rate of reaction of hydrogen with oxygen have been observed on a nickel foil whose temperature was kept constant in the course of the oscillations to within 0.02 °C.[16] This shows that the auto-oscillations in the rates of the above reactions are not associated with the influence of heat and material transport processes on the rate of reaction.

The nature of the observed auto-oscillations is determined by the catalyst temperature, the composition of the reaction mixture, and the composition of the catalyst surface. For all the oxidation reactions on metallic catalysts investigated, an increase of the rate of auto-oscillations with increasing temperature and the concentration of the component present in excess has been found. The frequency of the auto-oscillations depends much more on the concentration of the component present in the reaction mixture in a smaller amount. An increase of the period of the auto-oscillations in the rate of oxidation of carbon monoxide with increasing carbon monoxide concentration has been reported[11,14]. However, a decrease of the period of the auto-oscillations in the reaction rate for this process has been observed[9] with increase of the content of carbon monoxide in the initial mixture.

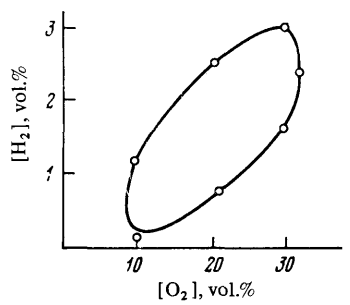

Figure 5. The region of the existence of auto-oscillations in the rate of oxidation of H_2 on a platinum foil in the plane corresponding to the variation of the hydrogen and oxygen concentrations at 85 °C.[18]

The variation of the period of the auto-oscillations in the rate of the hydrogen oxygen–reaction on a platinum foil with the initial concentration of hydrogen has a maximum whose height depends on the temperature[18]. With increase of the catalyst temperature, the amplitude of the auto-oscillations in the rate of reaction of hydrogen with oxygen on platinum catalysts fell. An analogous dependence of the amplitude of the oscillations in the rate on temperature has been noted in all studies of the reaction of carbon monoxide with oxygen.

On the other hand, on nickel catalysts an increase of the amplitude of the auto-oscillations in the rate of oxidation of hydrogen was observed with increase of temperature to 350 °C. The amplitude of the auto-oscillations depends also on the composition of the reaction mixture. With increase of the CO pressure, the amplitude of the auto-oscillations in the rate of oxidation of CO on a platinum catalyst increased. On nickel and platinum catalysts, a maximum has been observed in a number of experiments in the dependence of the amplitude of the auto-oscillation in the rate of oxidation of hydrogen on the composition of the reaction mixture. On a platinum foil, a closed region of auto-oscillations was found in the plane corresponding to changes in the concentrations of hydrogen and oxygen, illustrated in Fig.5.[18] The presence of critical concentrations of the reactants and a catalyst temperature for which auto-oscillations in the rate appear and vanish as well as the dependence of the amplitude and the frequency of the auto-oscillations on these parameters indicate the chemical nature of the observed phenomenon. A periodic variation of the contact potential difference, which was observed simultaneously with the auto-oscillations in the rate of reaction, indicates a change in the composition of the adsorbed layer. Fig.6 illustrates the auto-oscillations in the rate of reaction of hydrogen with oxygen on nickel (*a*) and platinum (*b*) catalysts measured simultaneously with the contact potential difference. Evidently the oscillations in the CPD have the same form and period as those in the rate of reaction. On a nickel catalyst, these quantities vary out of phase, while on a platinum foil there is no phase shift between the oscillations in the CPD and in the rate of reaction.

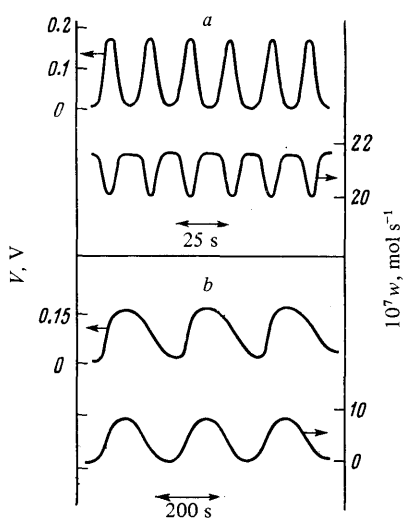

Figure 6. Auto-oscillations in the rate of oxidation of hydrogen on nickel (*a*) and platinum (*b*) catalysts recorded simultaneously with measurement of the changes in the CPD.[18]

Analysis of the CPD oscillations is difficult owing to the non-linear variation of the electron work function with the concentration of the adsorbed substances. However, it is known that the adsorption of oxygen on nickel and platinum leads to an increase of the electron work function and that this influence on the work function is stronger when the

influence of the hydrogen or carbon monoxide concentration is larger. Consequently, the form of the auto-oscillations in the rate of oxidation of hydrogen and in the CPD leads to the conclusion that an increase of the degree of surface coverage of nickel by oxygen and a decrease of the oxygen concentration on the platinum surface entail a decrease of the rate of reaction. The variation of the CPD between platinum and silicon with the ratio of carbon monoxide and oxygen in the reactor at different temperatures has been published[13]. It was shown that an increase of [CO] entails an increase of the CPD and a decrease of the rate of oxidation of CO. The form of the oscillations of the photocurrent, noted during this reaction on a platinum electrode, is analogous to the form of the oscillations of the CPD during the oxidation of hydrogen on a platinum foil. The rapid decrease in the amount of carbon monoxide or hydrogen on the surface, which leads to an increase of the rate of reaction, is replaced by a slower stage involving a return of the composition of the surface to the initial state.

III. PHYSICOCHEMICAL BASIS OF THE AUTO-OSCILLATIONS IN THE RATE OF REACTION

Auto-oscillating systems are well known in physics, engineering, and biology. Auto-oscillations are used particularly widely in radio-engineering, mechanics, and the control of technological processes. It is known from the theory of oscillations[2] that in most cases an auto-oscillating system should contain four fundamental elements: a constant (non-oscillating) source of energy or substance; an oscillating system, a device regulating the supply of energy or substance from the source to the oscillating system and feedback between the oscillating system and the regulating device (regulator), which acts by controlling the supply of the energy or substance. Auto-oscillating systems with a special feedback controlling the operation of a valve are called systems with an external feedback. External feedback can be absent and the valve can be controlled directly by the oscillating system. Such auto-oscillating systems are referred to as systems with internal feedback.

Auto-oscillating systems are divided into virtually harmonic systems and discontinuous or relaxation systems. The former have a high quality factor, a relatively small amount of energy is supplied during the period of the oscillation, and the energy in the oscillating system is exchanged between its elements. In systems of the second type dissipative forces play a significant role. In an oscillating system there exists one energy accumulator which either stores it or dissipates it. The period of the relaxation oscillations can frequently be divided into stages differing sharply in the rate of change of the state of the system. The boundary between the relaxation and harmonic auto-oscillations is not sharp and they can be regarded as a single physical phenomenon.

Auto-oscillatory conditions are impossible in linear systems and can arise only when there is a non-linearity in the system. In most cases the feedback is the source of the non-linearity. However, the presence of a feedback is not a sufficient condition for the occurrence of auto-oscillations; a definite force of this feedback is required.

In homogeneous chemical systems the feedback is determined by the auto-catalytic and inhibitory overall stages[5], as a result of which a closed sequence of stages appears in the system. Degn[6] indicated four possible types of feedback in homogeneous chemical systems. The presence of even one feedback in the system leads to the appearance of kinetic features different from the Law of Mass Action. However, Korzukhin[27] showed that, for any change in the concentrations of some of the reactants over a finite time interval, it is possible to construct a chemical system consisting of elementary stages whose rates are described by the Law of Mass Action.

The feedback in biochemical systems is in most cases achieved as a result of the influence of the substrate of the product on the activity of the enzyme and its properties[28].

Heterogeneous catalytic systems have many features in common with enzymatic systems. The reactants adsorbed on the catalyst surface can also exert a major influence on its catalytic properties. By considering the catalyst and the reaction medium as a single heterogeneous catalytic system, it can be shown that under certain conditions the heterogeneous catalytic system contains all the elements of an auto-oscillating system. The stationary flow of reactants entering the reactor in the direction of the catalyst surface constitutes a constant non-oscillating source of material. The oscillating system consists of a collection of adsorbed substances whose concentrations can vary periodically with time. By controlling the accumulation and consumption of the adsorbed substances as a result of adsorption and the reaction, the catalyst behaves as a regulator and the influence of the reactants on the properties of the catalyst can serve as the internal feedback from the system to the regulator.

In order to achieve non-decaying oscillations in the rate, it is necessary for accumulation to take place at each stage of the cycle, i.e. the rate of chemisorption of substances must exceed the rate of reaction, while in another stage the rate of reaction must be higher than the rate of accumulation. The catalyst as a regulator fulfills in this instant alternately the role of a source of negative and positive feedback. This is possible if the activity of the catalyst depends on the concentrations of the reactants on the catalyst surface. The application of the diffraction of slow electrons (LEED) in the study of catalytic systems made it possible to observe structural changes in the catalyst under the influence of the reactants in the course of adsorption and the reaction[29,30]. Such changes include a rearrangement and formation of new faces on the catalyst surface, the reconstruction of the surface with formation of mixed ordered surface layers containing the catalyst and reactant atoms, and the displacement of the positions of the atoms of the catalyst as a result of the formation of chemical bonds with the reactants. The formation of structures on the surface of platinum has been observed on different faces in the course of the adsorption of carbon monoxide[31] and hydrogen[32], while the adsorption of oxygen did not alter the surface structure of pure platinum up to complete saturation[31,33]. On the other hand, ordered surface structures were observed on nickel during the adsorption of oxygen[29,34,35] as a function of the face and the surface concentration, while hydrogen is capable of forming an ordered structure only on the (110) face of the nickel single crystal[36].

A period of increasing rate of reaction with decrease of the surface coverage by oxygen has been observed on the (110) and (100) faces of a nickel single crystal[37]. The authors[37] suggest that the development of the reaction requires the generation of "islands" of the pure nickel phase and that the rate of reaction is determined by the length of the boundary between these islands. An analogous topochemical type of reaction has been proposed[38] to account for the interaction of hydrogen with oxygen preadsorbed on the (110) nickel face and in another study[39] for the oxidation of hydrogen on a platinum catalyst.

The change in the properties of the catalyst as a result of adsorption in the reaction can be explained within the framework of the electron gas theory developed by Temkin[40]. According to this theory, the energetic properties of the surface are determined by the number of electrons in the surface layer of the catalyst and hence by a number of atoms adsorbed on the catalyst surface which supply and remove these electrons. A change in the amount of adsorbed substance entails a linear change in the activation energies for the adsorption process and the reaction on the catalyst surface. When substances with different donor–acceptor properties are adsorbed, the properties of the electron gas change, and this is reflected in the influence of the adsorption of one substance on that of the other. Thus the adsorption of carbon monoxide can alter the reaction properties of the hydrogen adsorbed on platinum[41]. In its presence a change in the rate of adsorption of oxygen on a platinum catalyst was also observed[31]. The influence of oxygen on the strength of the bond formed by hydrogen and carbon monoxide with the platinum surface has been observed[42]. With increase of the surface coverage by adsorbed oxygen, an increase of the amount of hydrogen or carbon monoxide, adsorbed in a state with much higher bond energies than on a clean surface, has been noted.

IV. MATHEMATICAL MODELS

The modelling of auto-oscillating systems is based mathematically on the general theory of oscillations, according to which auto-oscillations arise in non-linear systems with feedback. In order to elucidate the mechanism of the influence of feedback in heterogeneous catalysis, it is necessary to have an idea about the changes in the concentrations of the reactants on the catalyst surface during the reaction. In the studies discussed above such measurements could not be made and the construction of a detailed mathematical model is therefore difficult. One of the first mechanisms suggested for the operation of feedback in heterogeneous catalytic systems was one where the reactants influence the activity and properties of the catalyst[16]. The possibility of this mechanism of feedback is indicated by experimental data for the adsorption and reactions of a number of substances on metallic catalysts, which were described in the previous section. This type of feedback has been used[18] to construct a mathematical model of the reaction of hydrogen and oxygen on nickel and platinum catalysts.

The mathematical model of the oxidation of hydrogen on an element of the catalyst surface must reproduce the principal features of the process: the adsorption of hydrogen and oxygen and the interaction of the adsorbed substances, without specifying further the details of the mechanism:

$$\begin{gathered} O_2 + 2[M] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2[M{-}O], \\ H_2 + 2[M] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} 2[M{-}H], \\ [M{-}O] + 2[M{-}H] \xrightarrow{k_3} 3[M] + H_2O. \end{gathered} \tag{1}$$

where [M] is a free site on the catalyst surface, [M–O] and [M–H] represent the oxygen and hydrogen adsorbed on the free catalyst site, and k_i ($i = \pm 1$, ± 2, or ± 3) are the rate constants for the corresponding reaction stages.

Experimental studies of this reaction showed that there is only a slight dependence of the characteristics of the auto-oscillations on the rate of flow of the reactants through the reactor. Oscillations in the CPD have been observed for a relatively small change in the composition in the gas phase. Consequently one may claim that the auto-oscillations in the rate of reaction are due to periodic processes on the catalyst surface. This made it possible to treat the hydrogen and oxygen pressures as constant and to assume that they are equal to the average values for the period.

The kinetic model describing the changes in the surface concentrations of adsorbed oxygen (θ_O) and hydrogen (θ_H) is of the following type:

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - \theta_H)^2 - k_{-1}\theta_O^2 - k_3\theta_O\theta_H^2 = Q(\theta_O, \theta_H), \\ \frac{d\theta_H}{dt} = k_2 p_{H_2} (1 - \theta_O - \theta_H)^2 - k_{-2}\theta_H^2 - 2k_3\theta_O\theta_H^2 = P(\theta_O, \theta_H), \end{gathered} \tag{2}$$

where p_{O_2} and p_{H_2} are the oxygen and hydrogen pressures in the gas phase.

Eqns.(2) do not entail limiting cycles in the phase plane, since the Bendickson criterion holds for it: if the expression $\partial P/\partial x + \partial Q/\partial y$ has a constant sign in a single-phase region of the phase plane, then there are no closed contours in this region. It is readily seen that throughout the θ_O and θ_H phase plane the expression $\partial Q(\theta_O, \theta_H)/\partial P(\theta_O, \theta_H)/\partial\theta_H$ is always negative. In this case there is a unique stable stationary state of the type of a node or focus in system (2) for all values of the parameters. Auto-oscillations of the rate are impossible in the system, since one of the fundamental elements of an auto-oscillating system, namely the feedback, is absent.

The feedback arising from the influence of the reactants on the activity and properties of the catalyst can be expressed by the dependence of the activation energy for the adsorption and reaction stages on the hydrogen and oxygen concentrations on the catalyst surface. We shall analyse the simplest case where the concentrations of the adsorbed substances influence only the rate of the surface interaction of the reactants, the activation energy for this stage varying linearly with the degree of surface coverage by oxygen and hydrogen in accordance with the equation

$$E_3 = E_{30} + \alpha_1\theta_O + \alpha_2\theta_H. \tag{3}$$

The rate constant for the third stage can then be formulated as follows:

$$k_3 = k_{30}\, e^{(\mu_1\theta_O + \mu_2\theta_H)},$$

where the parameters $\mu_1 = \alpha_1/RT$ and $\mu_2 = \alpha_2/RT$ can be both greater and smaller than zero.

The variation of the rate of oxidation of hydrogen on nickel catalysts under the conditions of an excess of hydrogen and low oxygen concentrations in the gas phase can be due to the variation of the amount of adsorbed oxygen[37]. If the rate constant for the third stage varies with the degree of surface coverage by oxygen in accordance with the expression

$$k_3 = k_{30}\, e^{-\mu_1\theta_O}, \tag{4}$$

where $\mu_1 > 0$ and $\mu_2 = 0$, then, when account is taken of Eqn.(4), Eqns.(2) can be written as follows:

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - \theta_H)^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_H^2\, e^{-\mu_1\theta_O} = Q(\theta_O, \theta_H), \\ \frac{d\theta_H}{dt} = k_2 p_{H_2} (1 - \theta_O - \theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2\, e^{-\mu_1\theta_O} = P(\theta_O, \theta_H). \end{gathered} \tag{5}$$

Here the functions $Q(\theta_O, \theta_H)$ and $P(\theta_O, \theta_H)$ have been determined in the region $G = \{(\theta_O, \theta_H): \theta_O + \theta_H \leq 1;\ \theta_O \geq 0;\ \theta_H \geq 0\}$ and all the $k_i > 0$ ($i = \pm 1$, ± 2, or ± 3).

Eqns.(5) have been studied[55] by the phase plane method. Relations were found between the parameters for which a single unstable stationary state surrounded by stable limiting cycle is possible in the system. The following theorem was used to find periodic solutions of Eqns.(5).

Suppose that C is a cycle without contact and F is the region bounded by it. There exists at least one stable cycle if the following conditions are fulfilled: (1) all the trajectories intersecting C with increasing t enter F; (2) in the region F there is a single unstable stationary state of the type of a node or focus.

Linearisation of Eqns.(5) in the vicinity of the stationary state with θ_O^S and θ_H^S leads to algebraic expressions of the following type:

$$\frac{d\theta_O}{dt} = a_{11}(\theta_O - \theta_O^S) + a_{12}(\theta_H - \theta_H^S),$$
$$\frac{d\theta_H}{dt} = a_{21}(\theta_O - \theta_O^S) + a_{22}(\theta_H - \theta_H^S),$$

where

$$a_{11} = \left(\frac{\partial Q}{\partial \theta_O}\right)_{\theta_O^S, \theta_H^S}, \quad a_{12} = \left(\frac{\partial Q}{\partial \theta_H}\right)_{\theta_O^S, \theta_H^S},$$
$$a_{21} = \left(\frac{\partial P}{\partial \theta_O}\right)_{\theta_O^S, \theta_H^S}, \quad a_{22} = \left(\frac{\partial P}{\partial \theta_H}\right)_{\theta_O^S, \theta_H^S}$$

The stability of the stationary state is determined by the roots of the following characteristic equation:

$$\lambda^2 - (a_{11}+a_{22})\lambda + (a_{11}a_{22} - a_{12}a_{21}) = \lambda^2 - \sigma\lambda + \Delta = 0 . \quad (6)$$

A sufficient condition for the existence of a unique stationary state throughout the region of the parameters is

$$\frac{dQ(\theta_O, \theta_H)}{d\theta_O} < 0. \quad (7)$$

When the above condition holds, the following inequality is always valid: $\Delta(\theta_O, \theta_H) > 0$ along the curve

$$P(\theta_O, \theta_H) = 0 \quad (8)$$

Denoting the transport of oxygen to the surface by $k_1 p_{O_2}(1 - \theta_O - \theta_H)^2 - k_{-1}\theta_O^2 = G_O$ and the rate of reaction by $k_{30}\theta_O\theta_H^2 e^{-\mu_1\theta_O^2} = w$, condition (8) can be formulated thus:

$$\frac{dG_O}{d\theta_O} < \frac{dw}{d\theta_O}. \quad (9)$$

The physical significance of condition (9) is that in the stationary state the variation of the rate of reaction with oxygen concentration on the surface should be greater than the variation of the rate of transport of the latter to its surface. Condition (9) is valid when the following inequality holds:

$$2k_{-1} > k_{-2}(\mu_1 - 1). \quad (10)$$

In order that limiting cycles should arise in the system defined by Eqns.(5), the condition $\sigma(\theta_O^S, \theta_H^S) > 0$ must be fulfilled together with condition (10). This is achieved for $\mu_1 > 30$. The high values of μ_1 for which auto-oscillations in the rate of reaction arise in system (5) show that there must be a strong influence by the adsorbed substances on the properties of the catalyst.

System (2) has also been studied in the presence of various functional types of influence of the concentrations of the reactants on the properties of the catalyst. The form of the feedback was specified by the function $f_i(\theta_O)$ in the expression for the change in the rate constant for the third stage as a function of the degree of surface coverage by oxygen:

$$k_3 = k_{30} f_i(\theta_O).$$

For auto-oscillations to arise in system (2) with $f_1(\theta_O) = (1 - \theta_O)^{\mu_1}$ it is necessary that $\mu_1 > 20$, and for a feedback of the type $f_2(\theta_O) = (1 + \theta_O)^{-\mu_1}$, it is necessary that $\mu_1 > 37$.

A detailed study of a system of type (2) with the above types of feedback has been carried out in a general form for a system taking into account the different orders of the adsorption and desorption reactions of the reactants and its results can be used to find the conditions for the occurrence of auto-oscillations in kinetic models of both the hydrogen oxidation reaction on nickel and platinum catalysts and the carbon monoxide oxidation reaction on platinum catalysts.

The mathematical model of an auto-oscillating heterogeneous reaction of type (5) has many features in common with the system of differential equation describing the behaviour of a non-isothermal ideal mixing reactor[43]. The identical structure of the differential equations entails the similarity of the dynamic behaviour of the processes in the ideal mixing reactor and on a surface element of the catalyst. A detailed study of the properties of an ideal mixing flow reactor[44] revealed a multiplicity of phase plots observed in this system. The decisive parameters are the kinetic criterion and the adiabatic heating criterion, the Damköhler number, and the rate of removal of heat by the cooling unit. Depending on the values of these parameters, nine types of phase plots are possible, on five of which stable limiting cycles are possible. The cause of the auto-oscillations is the presence of a feedback via the influence of the temperature of the reaction mixture on the rate of reaction. This influence of the temperature is analogous to auto-catalysis. With increase of temperature, there is a sharp increase of the rate of reaction relative to the rate of supply of the reactants, which entails a decrease of the concentrations of the reactants in the reactor and a lowering of the temperature, which in its turn gives rise to a sharp fall of the rate of reaction relative to the rate of supply of the reactants. On subsequent increase of the amount of reactants in the reactor up to the critical concentration, a sharp increase of the rate begins again.

Condition (11), the fulfillment of which over the entire range of parameters guarantees a unique stationary state, is well known for thermokinetic oscillations:

$$\frac{dG_T}{dT} > \frac{dw}{dT}, \quad (11)$$

where G_T is the transport of heat to the reactor and w the rate of reaction. Conditions (9) and (11) are analogous in form and differ only by their signs due to the different influences of the adsorbed substances and temperature on the rate of reaction.

In an adiabatic ideal mixing reactor auto-oscillations of the rate of reaction are impossible. Additional removal of heat by the cooling unit is necessary for auto-oscillations to occur. Similarly additional removal of oxygen from the surface of the catalyst by desorption is essential for the auto-oscillations of the rate of reaction of hydrogen with oxygen on a nickel catalyst.

Sets of parameters for which limiting cycles arise have been found for system (5).[55] One of these limiting cycles, which exist about an unstable stationary state, is illustrated in Fig.7.

In conformity with the nature of the change in the degree of surface coverage by hydrogen and oxygen, it is possible to visualise the following mechanism of the generation of auto-oscillations. With increase in the amount of adsorbed oxygen on the surface of the nickel catalyst, the rate of reaction falls and the surface is covered by oxygen and hydrogen. Next, in consequence of the desorption of oxygen, there is a rapid decrease of its concentration on the catalyst surface. After

---

the attainment of the limiting value of θ_O, the quantity $e^{-\mu_1\theta_O}$ begins to increase rapidly as θ_O diminishes, the adsorbed hydrogen and oxygen react at a high rate, and the surface is almost completely freed from oxygen. Then the adsorption of oxygen begins again and leads to an increase of its concentration on the catalyst surface and the inhibition of the reaction. This process terminates the cycle. The above mechanism of the auto-oscillations of the rate of reaction is analogous to the mechanism of the thermokinetic auto-oscillations in an ideal mixing reactor with the difference that the reactants are supplied by chemisorption and the acceleration of the reaction is determined by the influence of the amount of adsorbed oxygen on the rate of formation of water.

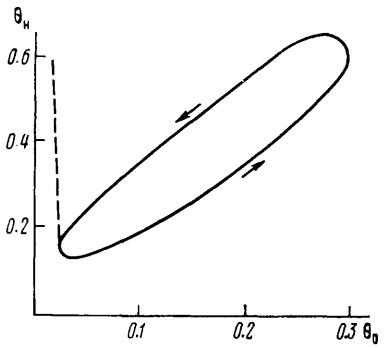

Figure 7. The limiting cycle of model (5) found for the following system parameters: $k_1 p_{O_2} = 15.6\ s^{-1}$; $k_{-1} = 1\ s^{-1}$; $k_2 p_{H_2} = 30\ s^{-1}$; $k_{-2} = 0$; $k_3 = 10^{-5}\ s^{-1}$; $\mu_1 = 40$.[55]

The auto-oscillations of the rate observed in the oxidation of hydrogen on platinum have also been described in terms of feedback of type (3).[53] However, in view of the different composition of the reaction mixture and the decrease of the stationary rate of reaction with increasing hydrogen pressure in the gas phase, the influence of the hydrogen concentration alone on the activation energy for the stage involving the interaction of the adsorbed substances was examined and α_1 was assumed to be zero. On the assumption that $\mu_2 = \alpha_2/RT$, the dependence of the rate constant for the third stage on the surface coverage by hydrogen can be written in a form analogous to Eqn.(4):

$$k_3 = k_{30}\, e^{-\mu_2\theta_H}. \qquad (12)$$

Taking into account Eqn.(12), Eqns.(2) can be written as follows:

$$\begin{aligned} \frac{d\theta_O}{dt} &= k_1 p_{O_2} (1 - \theta_O - \theta_H)^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_H^2\, e^{-\mu_2\theta_H} \\ \frac{d\theta_H}{dt} &= k_2 p_{H_2} (1 - \theta_O - \theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2\, e^{-\mu_2\theta_H} \end{aligned} \qquad (13)$$

The mechanism of the development of auto-oscillations in this system is analogous to that presented above for system (5).

Models (5) and (13) were compared with experimental data obtained for the interaction of hydrogen with oxygen on nickel and platinum catalysts respectively. These models reflect correctly the nature of the change in the amplitude and the critical conditions for the appearance and disappearance of auto-oscillations as the composition of the reaction mixture is varied. However, the models are of limited validity for the description of low-frequency oscillations. When the calculated and experimental rates averaged over the period of oscillations agreed, the maximum period of the auto-oscillations calculated on the basis of models (5) and (13) was ~1 s. Such frequencies were observed on a nickel foil and a platinum wire at high temperatures. At lower temperatures, low-frequency oscillations were noted, which cannot be described in terms of models (5) and (13). The maximum periods in models (5) and (13) are reached when k_{-1} and k_{-2} respectively are reduced. When these constants approach zero, the auto-oscillations in the rate of reaction vanish. This indicates the necessity for the existence of an additional removal of the substance influencing the catalytic activity of the metal from the surface of the catalyst.

Bearing in mind the low rates of desorption of oxygen from platinum[45] and nickel[46] catalysts, Zelenyak and Slin'ko[56] added to mechanism (1) a stage involving the Eley–Rideal impact mechanism, during which the adsorbed oxygen can be removed from the surface and can react with the gas-phase hydrogen:

$$[M - O] + H_2 \xrightarrow{k_4} [M] + H_2O. \qquad (14)$$

Allowance for this stage leads to the appearance of an additional term in the mathematical model (5), describing the removal of oxygen from the surface of nickel. The dynamic behaviour of the new system is unaltered if the rate constant for the fourth stage is independent of the degree of surface coverage by adsorbed substances. It is natural to suppose that the adsorbed oxygen decreases the rates of all the water formation stages in the oxidation of hydrogen on a nickel catalyst. Assuming that the activation energy for the fourth stage E_4 increases linearly with the degree of surface coverage by oxygen, i.e. $E_4 = E_{40} + \alpha_4\theta_O$, we obtain a mathematical model in the following form:

$$\begin{aligned} \frac{d\theta_O}{dt} &= k_1 p_{O_2} (1 - \theta_O - \theta_H)^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_H^2\, e^{-\mu_1\theta_O} - k_{40} p_{H_2}\theta_O\, e^{-\mu_4\theta_O}, \\ \frac{d\theta_H}{dt} &= k_2 p_{H_2} (1 - \theta_O - \theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2\, e^{-\mu_1\theta_O}. \end{aligned} \qquad (15)$$

With the aid of model (15), it is possible to obtain a much better agreement between the experimental and calculated data. Auto-oscillations at low frequencies for a high average rate during the period arise if the following relation between the constants holds:

$$k_1 p_{O_2},\ k_{40} \gg k_2 p_{H_2},\ k_{-2},\ k_{30}.$$

In this case the slow variation of the degree of surface coverage by hydrogen ensures a low oscillation frequency, while a high rate of reaction is attained as a result of the high rate of the impact stage.

A qualitative study of system (15) has been carried out by Belyaev, Chumakov, and Plikhta§. They showed that the introduction of an additional parameter, in relation to system (5), complicates the dynamic behaviour of the system. Fig.8 illustrates the types of phase plots which are possible in the given system. Evidently, depending on the values of the parameters, up to five stationary states and stable and unstable limiting cycles can arise in the system.

The dynamic behaviour of the hydrogen and carbon monoxide oxidation reactions is surprisingly similar. Attention was drawn to this by Langmuir as early as 1918 [47] and was confirmed by the experimental investigations of Kuchaev and Temkin[45,48], who observed that the kinetics of these two

§Quoted by T.I.Zelenyak and M.G.Slin'ko, Kinetika i Kataliz, **18**, 1235 (1977).

reactions have many features in common and can be described in terms of analogous mechanisms, including both impact and adsorption reaction pathways. The following mechanism has been proposed[48] for the oxidation of CO:

$$\begin{gathered} O_2 + 2\,[M] \overset{k_1}{\rightarrow} 2\,[M{-}O] \\ CO + [M] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} [M{-}CO] \\ [M{-}O] + [M{-}CO] \overset{k_3}{\rightarrow} 2\,[M] + CO_2 \\ [M{-}O] + CO \overset{k_4}{\rightarrow} [M] + CO_2 \end{gathered} \qquad (16)$$

The kinetic model corresponding to mechanism (16) has a form analogous to that of system (2) and differs from it only by the different orders of the adsorption and desorption reactions of one of the components of the reaction mixture and also by the additional term describing the interaction of the adsorbed oxygen with gaseous carbon monoxide:

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - \theta_{CO})^2 - k_{-1}\theta_O^2 - k_3\theta_O\theta_{CO} - k_4 p_{CO}\theta_O, \\ \frac{d\theta_{CO}}{dt} = k_2 p_{CO} (1 - \theta_O - \theta_{CO}) - k_{-2}\theta_{CO} - k_3\theta_O\theta_{CO} \end{gathered} \qquad (17)$$

The difference between the orders of adsorption and desorption reactions of the reactants is responsible for the possible appearance in system (17) of several stationary states, since condition (8) can break down. However, the Bendickson criterion remains negative over the entire range of parameters and auto-oscillations are therefore impossible. In order to explain the appearance of auto-oscillations, one must take into account, by analogy with the preceding systems, the experimental decrease of the rate of reaction with increasing CO pressure in the gas phase. One can then postulate the following dependence of the activation energies for the third and fourth stages on the degree of surface coverage of the catalyst by carbon monoxide:

$$\begin{aligned} E_3 &= E_{30} + \alpha_1\theta_{CO}, \\ E_4 &= E_{40} + \alpha_2\theta_{CO}. \end{aligned} \qquad (18)$$

Taking into account the influence of adsorbed carbon monoxide on the rate constants for the third and fourth stages, we obtain a kinetic model for the oxidation of carbon monoxide analogous to Eqns.(15):

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - \theta_{CO})^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_{CO} e^{-\mu_1\theta_{CO}} - k_{40} p_{CO}\theta_O e^{-\mu_2\theta_{CO}}, \\ \frac{d\theta_{CO}}{dt} = k_2 p_{CO} (1 - \theta_O - \theta_{CO}) - k_{-2}\theta_{CO} - k_{30}\theta_O\theta_{CO} e^{-\mu_1\theta_{CO}}. \end{gathered} \qquad (19)$$

This system can be used to compare the calculated and experimental parameters of the oscillations in the oxidation of CO on platinum.

Mechanism (16) and feedback of type (3) have also been used[14] to construct a kinetic model of the auto-oscillations of the rate of oxidation of CO on platinum catalysts. The authors examined four types of models consisting of two differential equations and differing in the choice of dynamic variables. Mathematical analysis of the model including the oxygen and carbon monoxide pressures in the gas phase as dynamic variables showed that auto-oscillations in the rate of reaction are possible only for unrealistic values of the parameters of the model. Oscillatory conditions were observed in models where the pressure of carbon monoxide in the gas phase was chosen as one of the dynamic variables while the degrees of surface coverage either by oxygen or by carbon monoxide or by one of the forms of adsorbed carbon monoxide served as the second dynamic variable. For this choice of dynamic variables, the surface concentration of the second reactant was assumed to correspond to equilibrium with respect to its pressure in the gas phase. The authors[14] in no way justified the choice of the dynamic variables of the models. It remains obscure why only one of the surface concentrations is stationary with respect to the gas phase. The experimental CPD and the photocurrent during the auto-oscillations of the rate of reaction show that a more probable cause of the development of auto-oscillations in the rate of reaction is oscillations in the composition of the surface of the catalyst,

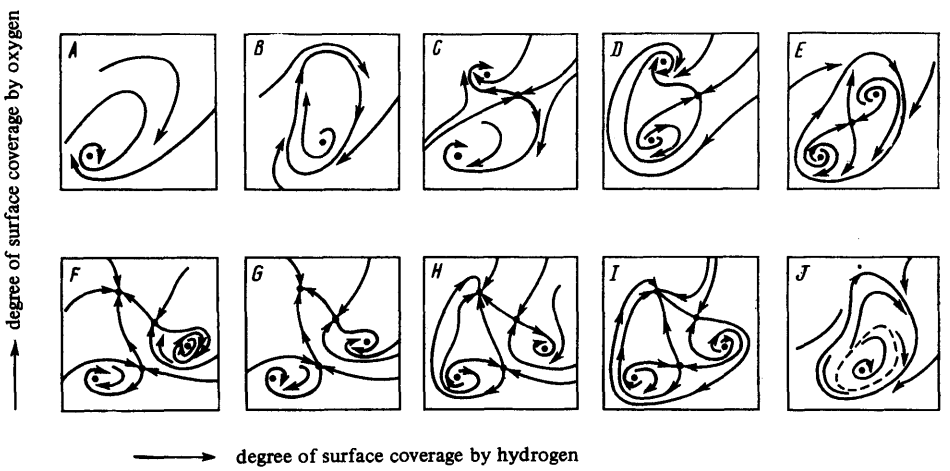

Figure 8. Phase plots for system (15) obtained for different values of the parameters of the model[56].

which can be non-stationary in relation to the composition of the gas phase.

The data obtained in the study of the auto-oscillations of the rates of heterogeneous catalytic reactions show that the periods of the auto-oscillations vary within wide limits—from 1 to 3600 s. The lower limit of this range is determined by the inertia and the upper limit by the stability of the instruments with the aid of which auto-oscillatory conditions are detected. The occurrence of auto-oscillations with long periods necessitates the assumption of the existence of phenomena which decrease the frequencies of the auto-oscillations. One of such causes may be the presence on the surface of an inactive form of the reactant, which constitutes a kind of buffer of the active form on the surface and can reduce the frequency of the auto-oscillations. It is known[49] that two forms of adsorbed hydrogen can exist on platinum catalysts. Presumably the adsorption of hydrogen on the surface of the platinum catalyst takes place with formation of an inactive form H_i. The latter can then be converted on the surface into the active form H_a, which interacts with the adsorbed oxygen. The reaction mechanism is formulated as follows:

$$\begin{gathered} O_2 + 2\,[M] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2\,[M{-}O]\ , \\ H_2 + 2\,[M] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} 2\,[M{-}H_i]\ , \\ [M{-}H_i] \cdot \underset{k_{-i}}{\overset{k_i}{\rightleftarrows}} [M{-}H_a]\ , \\ 2\,[M{-}H_a] + [M{-}O] \xrightarrow{k_3} 3\,[M] + H_2O\ . \end{gathered} \tag{20}$$

If the active hydrogen on the surface alters the rate constant for the third stage in accordance with the expression

$$k_3 = k_{30}\, e^{-\mu_3 \theta_{H_a}},$$

then the kinetic model can be formulated as follows in conformity with mechanism (20):

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - \theta_{H_a} - \theta_{H_H})^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_{H_a}^2 e^{-\mu_3\theta_{H_a}}, \\ \frac{d\theta_{H_H}}{dt} = k_2 p_{H_2} (1 - \theta_O - \theta_{H_a} - \theta_{H_H})^2 - k_{-2}\theta_{H_H}^2 - k_H\theta_{H_H} + k_{-H}\theta_{H_a}, \\ \frac{d\theta_{H_a}}{dt} = k_H\theta_{H_H} - k_{-H}\theta_{H_a} - 2k_{30}\theta_O\theta_{H_a}^2 e^{-\mu_3\theta_{H_a}}. \end{gathered} \tag{21}$$

If k_i, $k_{-i} \gg k_1$, k_{-1}, k_2, k_{-2}, k_3, then the active and inactive forms of hydrogen are in equilibrium and there is a linear relation between their surface concentrations:

$$\theta_{H_i} = K_p \theta_{H_a}, \tag{22}$$

where $K_p = k_{-i}/k_i$.

Taking into account Eqn.(22), it is possible to formulate a system of differential equations [Eqns.(23)] describing the variation of the concentration of surface oxygen and the overall concentration of the hydrogen adsorbed in two forms:

$$\begin{gathered} \frac{d\theta_O}{dt} = k_1 p_{O_2} (1 - \theta_O - (1 + K_p)\,\theta_{H_a})^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_{H_a}^2 e^{-\mu_3\theta_{H_a}}, \\ (1 + K_p)\frac{d\theta_{H_a}}{dt} = k_2 p_{H_2} (1 - \theta_O - (1 + K_p)\,\theta_{H_a})^2 - k_{-2}K_p^2\theta_{H_a}^2 - \\ - 2k_{30}\theta_O\theta_{H_a}^2 e^{-\mu_3\theta_{H_a}}. \end{gathered} \tag{23}$$

In Eqns.(23) there is an additional term on the left-hand side of the differential equation, compared with system (13), representing the inertia $(1 + K_p)$. The appearance of this term increases the period of the oscillations for values of the parameters close to those for system (13). Thus, when the amount of the active form of hydrogen is twice that of the inactive form ($K_p = 0.5$), the period of the auto-oscillations increases by a factor of two.

A possible mechanism of the development of auto-oscillations with participation of the active and inactive forms of one of the reactants was also examined by Eigenberger[50]. Assuming the existence of two forms of oxygen adsorbed on platinum, the author proposed the following mechanism for the oxidation of carbon monoxide on platinum catalysts:

$$\begin{gathered} CO + [M] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [M{-}CO]\ , \\ O_2 + 2\,[M] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} 2\,[M{-}O_a]\ , \\ 2\,[M{-}O_a] + 2\,[M{-}CO] \xrightarrow{k_3} 2CO_2 + 4\,[M]\ , \\ O_2 + 2\,[M] \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} [M{-}O_{2i}]\ . \end{gathered} \tag{24}$$

Next he assumes that the amount of oxygen adsorbed in an active form is in equilibrium with respect to its pressure in the gas phase and is small owing to the high rate of desorption ($k_{-2} \gg k_2 p_{O_2}$). With these postulates, mechanism (24) assumes the following form:

$$\begin{gathered} CO + [M] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [M{-}CO]\ , \\ 2\,[M{-}CO] + O_2 + 2\,[M] \xrightarrow{k_3} 2CO_2 + 4\,]M]\ , \\ O_2 + 2\,[M] \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} [M{-}O_{2i}]\ . \end{gathered} \tag{25}$$

The feedback in this sytem also occurs via the influence of the adsorbed substances on the rate of formation of carbon dioxide. However, it is assumed that this influence is not exerted by the adsorbed substances on the catalytic properties but occurs via the change in the number of active sections of the catalyst surface involved in the reaction. This form of feedback can occur subject to the author's assumption[50] that the concentration of the active form of oxygen is low owing to the high rate of its desorption from the surface of platinum. Despite the fact that this conflicts with experimental data showing low rates of desorption of oxygen from platinum, the author[50] was able to account for the region of development and the periods of the auto-oscillations in the rate of oxidation of CO on a platinum mesh observed by Hugo and Jakubith[9].

The buffer capacity for the adsorbed substance active in the reaction can be created not only on the catalyst surface as a result of substances inactive in the reaction but also in the surface layer of the catalyst due to the dissolved reactants. The high solubility of hydrogen in nickel[51] can lead to the saturation of the surface layer of the latter by hydrogen when the reaction takes place in an excess of this gas. If the rate of dissolution of hydrogen is assumed to be proportional to the rate of coverage of the catalyst by hydrogen and to the fraction of vacancies in the metal accessible to dissolved hydrogen while the rate of diffusion of hydrogen from the metal is assumed to be proportional to the amount of dissolved hydrogen and the fraction of surface free from adsorbed hydrogen, then the change in the fraction of hydrogen dissolved in nickel will be described by the following equation[55]:

$$\frac{dz_H}{dt} = K_5\theta_H (1 - z_H) - K_{-5} z_H (1 - \theta_H), \tag{26}$$

where $K_5 = k_5 NS/V$, $K_{-5} = k_{-5} NS/V$, z_H is the concentration of hydrogen dissolved in the surface layer of the catalyst and referred to the limiting concentration of the dissolved hydrogen, N the number of adsorbed atoms per cm^2 of the catalyst, S the catalyst area, and V the volume of the surface layer of the catalyst.

If $K_5 = K_{-5} = K \gg k_1$, k_{-1}, k_2, k_{-2}, k_3, then the fraction of hydrogen dissolved in the metal will be proportional to its surface concentration: $z_H = K\theta_H$.

If Eqn.(26) is added to mechanism (1), then system (5) can be formulated as follows:

$$\frac{d\theta_O}{dt} = k_1 p_{O_2}(1-\theta_O-\theta_H)^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_H^2 e^{-\mu_1\theta_O},$$
$$\frac{d\theta_H}{dt} = k_2 p_{H_2}(1-\theta_O-\theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2 e^{-\mu_1\theta_O} - \frac{dz_H}{dt}. \quad (27)$$

Since $dz_H/dt = Kd\theta_H/dt$, we obtain system (28), which differs from system (5) only by the inertia term. It appears in the equation describing the variation of the fraction of the surface covered by hydrogen:

$$\frac{d\theta_O}{dt} = k_1 p_{O_2}(1-\theta_O-\theta_H)^2 - k_{-1}\theta_O^2 - k_{30}\theta_O\theta_H^2 e^{-\mu_1\theta_O},$$
$$(1+K)\frac{d\theta_H}{dt} = k_2 p_{H_2}(1-\theta_O-\theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2 e^{-\mu_1\theta_O}. \quad (28)$$

With increase of K, there is an increase in the amount of dissolved hydrogen in equilibrium with adsorbed hydrogen, which increases the period of the auto-oscillations.

In the general case both components of the gas phase can dissolve in the surface layer of the metal and the overall mechanism of the interaction of hydrogen and oxygen includes the following stages in this case:

$$O_2 + 2[M] \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} 2[M{-}O],$$
$$H_2 + 2[M] \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} 2[M{-}H],$$
$$2[M{-}H] + [M{-}O] \xrightarrow{k_3} 3[M] + H_2O,$$
$$[M{-}O] + H_2 \xrightarrow{k_4} [M] + H_2O,$$
$$[M{-}H] + [M_V] \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} [M_V{-}H] + [M],$$
$$[M{-}O] + [M_V] \underset{k_{-6}}{\overset{k_6}{\rightleftarrows}} [M_V{-}O] + [M],$$

where $[M_V]$ is an atom in the surface layer of the metallic catalyst and $[M_V{-}H]$ and $[M_V{-}O]$ are the hydrogen and oxygen atoms dissolved in the surface layer.

Assuming that in a thin surface layer of the catalyst there is virtually complete mixing, one can formulate a generalised kinetic model as follows:

$$\frac{d\theta_O}{dt} = k_1 p_{O_2}(1-\theta_O-\theta_H)^n - k_{-1}\theta_O^p - k_4 p_{H_2}\theta_O - k_3\theta_O\theta_H^q - \beta_O\frac{dz_O}{dt},$$
$$\frac{d\theta_H}{dt} = k_2 p_{H_2}(1-\theta_O-\theta_H)^m - k_{-2}\theta_H^q - 2k_3\theta_O\theta_H^q - \beta_H\frac{dz_H}{dt},$$
$$\frac{dz_H}{dt} = k_5\theta_H(1-z_H) - k_{-5}z_H(1-\theta_H-\theta_O), \quad (29)$$
$$\frac{dz_O}{dt} = k_6\theta_O(1-z_O) - k_{-6}z_O(1-\theta_H-\theta_O),$$

where n, m, p, and q are the orders of the corresponding stages and β_O and β_H are the limiting amounts of oxygen and hydrogen dissolved in the surface layer of the catalyst and expressed in terms of the number of monolayers.

In the interpretation of the experimental data obtained in the study of the oxidation of hydrogen on platinum catalysts the following additional assumptions were made[57]: (1) the adsorption and desorption of hydrogen are second-order reactions, while the adsorption and desorption of oxygen are first-order reactions: $m=q=2$ and $n=p=1$; (2) the concentration of oxygen in the surface layer of the platinum catalyst changes little: $dz_0/dt \cong 0$; (3) the hydrogen dissolved in a thin surface layer of platinum increases linearly the activation energy for the water formation stages:

$$E_3 = E_{30} + \gamma_3 z_H,$$
$$E_4 = E_{40} + \gamma_4 z_H.$$

These assumptions lead to the following relations between the rate constants for the water formation stages and the amount of dissolved hydrogen:

$$k_3 = k_{30}e^{-\mu_1 z_H};\ k_4 = k_{40}e^{-\mu_2 z_H},$$

where $\mu_1 = \gamma_3/RT$ and $\mu_2 = \gamma_4/RT$. With these assumptions, the form of the kinetic model (29) is:

$$\frac{d\theta_O}{dt} = k_1 p_{O_2}(1-\theta_O-\theta_H) - k_{-1}\theta_O - k_{40}p_{H_2}\theta_O e^{-\mu_2 z_H} - k_{30}\theta_O\theta_H^2 e^{-\mu_1 z_H},$$
$$\frac{d\theta_H}{dt} = k_2 p_{H_2}(1-\theta_O-\theta_H)^2 - k_{-2}\theta_H^2 - 2k_{30}\theta_O\theta_H^2 e^{-\mu_1 z_H} - \beta_H\frac{dz_H}{dt}, \quad (30)$$
$$\frac{dz_H}{dt} = k_5\theta_H(1-z_H) - k_{-5}z_H(1-\theta_H-\theta_O).$$

Depending on the values of the parameters, system (30) makes it possible to describe both relaxation auto-oscillations and auto-oscillations which are nearly harmonic over a wide range of frequencies. The form of the auto-oscillations is determined by the relative values of the group of rate constants $k_1 p_{O_2}$, $k_2 p_{H_2}$, k_4, k_3, and k_{-2} for the processes occurring on the surface and the constants k_5 and k_{-5} characterising the involvement of the surface layer in the reaction. The period of the auto-oscillations depends on the rate of exchange between the surface and the bulk of the layer.

A novel mathematical model, also consisting of three differential equations, has been proposed[52] for the interpretation of the experimental auto-oscillations in the rate of oxidation of CO on platinum catalysts[12,13]. The authors[52] based their model on mechanism (16). In order to account for the development of auto-oscillations in the rate of reaction, they assumed a temperature difference between the first active layers of the catalyst and the external medium, whose temperature was assumed to be equal to that of the deep layers of the catalyst. It was also assumed that the rates of all the stages vary exponentially with the temperature of the surface layer of the catalyst. The mechanism of the development of auto-oscillations reduces in this case to the following: in the first instant the interaction of the adsorbed reactants proceeds at a low rate and the sites on the catalyst surface liberated by the reaction are immediately occupied by oxygen. The heat evolved in the reaction accelerates the surface interaction of carbon monoxide with oxygen and this autocatalytic process terminates only when the entire surface of the metal has been covered by oxygen. After this, the surface is rapidly cooled and the removal of oxygen from it begins as a result of its interaction with the carbon monoxide in the gas phase; this reaction takes place at a virtually constant temperature of the surface layer. As soon as the concentration of oxygen on the surface has been reduced and that of carbon monoxide increased, the surface interaction of these substances begins and leads to a new rise in the temperature of the surface layer and the cycle is repeated.

The above mechanism shows that the feedback arises in this case owing to the influence of the temperature of the surface layer on the rate of reaction. The mathematical model has a form analogous to that of model (30), but the third equation describes the change in the temperature of the surface layer of the catalyst and not the change in the concentration of hydrogen dissolved in the surface layer. Analysis of the mathematical model showed that the mechanism of the auto-oscillations in the rate described above is possible for long thermal relaxation times. Estimates of thermal relaxation times in the course of reactions on metals lead to much smaller values, so that the model described by the authors[52] is physically unsound.

V. CONCLUSION

The data presented above show that in recent years there has been a sharp increase of the number of studies and publications devoted to the auto-oscillations in the rates of heterogeneous catalytic reactions. This is because the discovery of this phenomenon is important for the development of the theory of the kinetics of heterogeneous catalytic reactions. The auto-oscillations in the rate observed in heterogeneous catalysis show that the catalytic properties of the surface vary under the influence of the catalytic process and that the composition of the surface can be non-stationary in relation to the composition of the gas phase. The auto-oscillations in the rate of reaction occur only under conditions remote from equilibrium. From this it follows that the mechanisms of heterogeneous catalytic reactions can be different in the vicinity of and far from equilibrium conditions. The reaction on different active sections of the catalyst surface remote from one another takes place synchronously.

The amplitude and period of the auto-oscillations in the rate of reaction are very sensitive to the structure of the catalytic system and to the values of its parameters. There is a possibility of quasi-harmonic, relaxation, complex, and random oscillatory conditions. The frequencies of the auto-oscillations vary within wide limits. The development of oscillations with low frequencies indicates the occurrence in the system of stages which are slower than that involving the formation of the final products.

The mathematical models of the auto-oscillations in the rates of heterogeneous catalytic reactions consist of systems of two or several non-linear differential equations. Their form and properties depend on the way which the results of the catalytic process influence its characteristics. This feedback can be due to various causes, namely: (a) the change in the reaction rate constant under the influence of the change in the concentrations of the reactants on the surface or in a thin surface layer of the catalyst; (b) competition by stages involving the adsorption of the reactants and a change in the number of active sites on the catalyst surface during the reaction; (c) superheating of a thin layer of the catalyst surface; (d) the development of homogeneous-heterogeneous stages in the catalytic process; (e) a complex sequence of three and more surface stages.

The present scope of experimental studies in the field of catalysis is limited owing to the lack of methods for the continuous observation of the composition and temperature of the surface and of the surface layer of the catalyst. At the present stage of investigations the choice of a particular type of feedback and a complete quantitative description of the auto-oscillations in the rates of heterogeneous catalytic reactions are therefore difficult. In order to develop a theory of the auto-oscillations, it is also necessary to establish a relation between the reaction at the molecular level and the observed rate and to elucidate the causes of the synchronisation of the oscillations on individual active sites of the surface. Thus one may hope that studies in the field of the auto-oscillations in the rate will permit a more complete investigation of the kinetics and will lead to the elucidation of the mechanisms of heterogeneous catalytic reactions.

During the preparation of the review for the press, studies on auto-oscillatory conditions have been combined into a new field of the kinetics of heterogeneous catalytic reactions. The first investigations of the auto-oscillations in the rates of heterogeneous catalytic reactions were part of the programme of an international congress devoted to the kinetics of physicochemical oscillations, which was held on 19th September 1979 in Aachen (German Federal Republic). During this period, there has been a significant increase of the number of heterogeneous catalytic systems in which the given phenomenon has been observed. These include the interaction of NO and CO on polycrystalline platinum[58], the oxidation of methanol on aluminosilicate catalysts containing palladium[59], the oxidation of ammonia on platinum–rhodium catalysts[60], and the oxidation of octane, hexane, and 1-propanol on platinum catalysts in the presence of organophosphorus compounds[61]. The oscillations in the rate of reaction of NO and CO are interesting because they arise at a pressure of only 5×10^{-4} mmHg, while the auto-oscillations in the rate in all other known systems have been observed only at atmospheric pressure.

Further investigation of the auto-oscillations in the rate of oxidation of CO on deposited and metallic platinum catalysts revealed a high sensitivity of the region where the oscillations occur and of their properties to the composition of the reaction mixture. It has been found that the addition of but-1-ene[62] and of organophosphorus compounds[61] to the initial reaction mixture induces the appearance of auto-oscillations in the rate of the reaction. It has been shown[63] that when electrolytic oxygen is used in the oxidation of carbon monoxide on deposited platinum catalysts, auto-oscillations arise in the rate of reaction whose properties are different from those of the oscillations in the rate of reaction involving oxygen obtained from air and containing a significantly larger amount of impurities. Modelling of the auto-oscillations in the rate of reaction in the given system has been continued[64,65]. The most complete interpretation of the experimental data published previously[9] has been achieved by Ali and Hugo[65]. The authors used model (17), having taken into account the activation energies for the third and fourth stages of mechanism (16) in the adsorption of both components of the reaction mixture. The model also takes into account the influence of the adsorbed oxygen on the activation energy for the CO desorption stage and the influence of both adsorbed components on the activation energy for the oxygen adsorption stage.

The study of the auto-oscillations in the rate of oxidation of hydrogen on platinum[66] and nickel[67] catalysts has also been continued. Particular attention has been devoted to the investigation of complex and irregular dynamic conditions, which have recently been referred to as random oscillations. Thorough experimental proof that the existence of random oscillations in the oxidation of hydrogen on a nickel foil has been published[67]. A mechanism has been proposed[68] for this reaction whose kinetic model can reflect the observed[67] random oscillations in the rate of reaction. The interest in complex and random oscillations can be explained by the fact that they can arise only in systems described by three and more differential equations. This imposes additional limitations on the possible reaction mechanism. Thus the reaction mechanism proposed by Schmiltz et al.[68] includes stages involving the alternate oxidation and reduction of the surface. It is suggested that the reduced surface is inactive, while the adsorption of the reactants and the reaction between them take place only on the oxidised surface. The mathematical model of the reaction also includes an equation describing the variation of the temperature of the catalyst surface. Random oscillations have been observed[66] in the rate of oxidation of H_2 on a platinum wire. The authors[66] believe that the random oscillations can be induced by the incomplete synchronisation of the rates of reaction on different catalyst surface sites.

A homogeneous-heterogeneous mechanism of the oxidation of cyclohexane on the NaX zeolite has been examined by Berman and Elinek[69]. They proposed a non-stationary kinetic model, which describes the variation of the gas-phase concentrations of the peroxy-compounds and peroxy-radicals

formed in the oxidation of cyclohexane. The model describes the earlier results qualitatively[22].

Polarographic Study of Complex Formation Equilibria in Solutions

E.A.Mambetkaziev and S.I.Zhdanov

Methods for the calculation of the coordination numbers and stability constants of complexes formed in solution from polarographic data are examined and methods for the determination of the parameters governing the formation of a single complex and stepwise complex formation as well as the formation of mixed and polynuclear complexes and complexonates are described. It is shown how kinetic and catalytic waves, the waves of the ligand, and the waves due to irreversible processes can be used for this purpose. Attention is drawn to the necessity to take into account the adsorption of the components of a system involving complex formation.

I. INTRODUCTION

The use of polarography for the study of the compositions, equilibrium formation constants, and dissociation constants of complexes in solution is based on the simple principles first formulated in 1935 by Heyrovský and Ilkovič[1]. The electrode reduction or oxidation of any depolariser at a mercury electrode is reflected in the polarogram by the corresponding wave whose principal parameters are the half-wave potential $E_{1/2}$ and the limiting current i_d. Heyrovský and Ilkovič introduced the equation of the wave $E = f(i)$ for a reversible electrode process with participation of n electrons and showed that the potential $E_{1/2}$ is in this case close to the normal value (E^0):

$$E_{1/2} = E^0 - \frac{RT}{nF} \ln \left(\frac{D_o}{D_r}\right)^{1/2},$$

where D_o and D_r are the diffusion coefficients of the oxidised and reduced forms of the depolariser ($cm^2\ s^{-1}$). According to the Nernst equation,

$$E = E^0 - \frac{RT}{nF} \ln \frac{[O]}{[B]},$$

the electrode potential is determined by the ratio of the concentrations (more precisely activities) of the components of the oxidation-reduction system. Complex formation leads to a decrease of the concentration of a particular form of the depolariser, which influences the position of the polarographic wave: it shifts along the potential axis. The direction and magnitude of the shift of the wave depend on which component of the redox system forms a more stable complex, the composition of the complex, and its equilibrium formation constant. This fact is in fact used in polarography to determine the complex formation parameters in solution enumerated above.

Thus the polarographic method for the study of complex formation equilibria is in essence close to the potentiometric method. In both cases one uses the dependence of the potential on the concentrations of the components of the redox system. The difference consists in the fact that in potentiometry the ratio of the concentrations of the system components is varied by altering the composition of the solution, while in polarography it is varied by electrolysis at a mercury dropping indicator electrode, which is technically much simpler. The polarographic method is somewhat inferior to the potentiometric method as regards accuracy, but an enormous amount of experimental data on complex formation in solutions has been obtained by the former method[2]. This was promoted by the fact that polarography makes it possible to obtain information not only about the equilibrium properties of the complexes but also about the mechanisms and kinetics of electrode processes involving them, the kinetics of the dissociation of the complexes, and their electrochemical activity as a function of structures.

In the course of the study of equilibria in solutions by the polarographic method, instances of simple and stepwise complex formation, the formation of mixed-ligand and polynuclear complexes, the formation of complexes by metal ions with ligands involved in complex acid–base interactions (for example, with complexones), and the formation of molecular organic complexes and ion pairs have been examined. Methods of calculation from experimental data, including computer calculations, have been greatly improved and methods have been proposed for the investigation of electrochemically inactive complexes with the aid of indicator ions; it has become possible to use kinetic and catalytic waves as well as waves due to irreversible processes. One may conclude that, overall, the level of development of the polarographic method in this field is high.

This review describes the present state of the methods for the investigation of complex formation equilibria in solution with the aid of polarography. The original literature was surveyed inadequately in previous reviews[3-12] and many important studies have been published only in recent years.

II. REVERSIBLE ELECTRODE PROCESSES

Reversible electrode processes involving complexes are more favourable for the study of the compositions of the complexes and their equilibrium formation constants, because it is possible to derive definite useful relations even for very complex systems. It is therefore desirable to select as far as possible experimental conditions which lead to the attainment of reversibility in electrode process. Naturally, before using the relations derived for a reversible process, it is necessary to make sure that the process is indeed reversible. If the process is fully or partly irreversible, the shift of the wave in consequence of complex formation is added to the shift due to the retardation of one of the stages of the electrode process, i.e. to the overvoltage, and the calculation leads to unduly high equilibrium formation constants for the complexes.

In polarography there are a number of criteria which are normally employed to test the reversibility of the process.

1. The equation of the wave of a reversible process is

$$E = E_{1/4} - \frac{2,3RT}{nF} \lg \frac{i}{(i_d - i)} \cdot \quad (1)$$

A linear relation is obtained by plotting $\lg [i/(i_d - i)]$ against E, whose slope is $\partial E/\partial \lg [i/(i_d - i)] = 2.3RT/nF$. At 25 °C the latter is $2.3RT/nF \cong 0.06(V)/n$. According to Tomeš's criterion, which is readily obtained from Eqn.(1), we have

$$E_{3/4} - E_{1/4},\ V = -\frac{0.06}{n} \lg 9 = -\frac{0.058}{n}.$$

2. The values of $E_{1/2}$ for the waves corresponding to the forward and reverse processes in reversible systems are equal. Cathodic and the corresponding anodic waves with humps of equal height arise on the cyclic voltamperogram for such a system when a stationary electrode is used, the peak potentials differing by $0.058/n$ volts.

3. For reversible processes the diffusion of the depolariser species to the electrode is the slowest stage at all points in the wave. The instantaneous diffusion current at any point in the wave is described by the Ilkovič equation:

$$i,\ \mu A = 706nD^{1/2}m^{2/3}t^{1/6}(c - c_0),$$

where m (mg s^{-1}) is the rate of flow of mercury from the capillary, t(s) the time elapsed from the start of the growth of the drop, and c and c_0 (10^{-3} M) are the concentrations of the depolariser in the bulk of the solution and at the electrode respectively. According to the Ilkovič equation, $i = kt^{1/6}$, along the rising section of the wave, which can be tested experimentally with the aid of an oscillographic polarograph (for irreversible processes, this equation is valid only for the upper part of the wave).

4. A distinct symmetric peak, the potential at the vertex of which consists only of the value of $E_{1/2}$ for the wave on a classical polarogram, arises on an a.c. polarogram for a reversible system. The peak width at half its height is $0.088/n$ volts. In phase-selective a.c. polarography such peaks have the same shapes and heights: $[(i_p)_R = (i_p)_C]$ are obtained on the curves relating the potentials to the active (i_R) and reactive (i_C) components of the alternating current.

To test the reversibility of this process, it is of course not necessary to employ all the criteria enumerated, which is laborious; however, the reliability of the conclusions is naturally higher the greater the number of criteria used.

In a system with complex formation a series of species are present simultaneously at equilibrium: free metal ions, complex species of various compositions, and the free ligand. In principle, not only free metal ions are discharged at the electrode, which is usually assumed for simplicity in the derivation of the quations, but also the complex species. However, if the process is reversible, and its overall rate is determined solely by diffusion, then experiment does not yield information about which particular species is reduced or oxidised at the electrode; the disappearance of an electrochemically active species at the electrode leads to a change in the concentrations of species of all types at the electrode owing to rapid equilibration.

On the basis of the accumulated experimental data, it is in some cases possible to predict the reversibility of the process involving complexes[5,9]. If a labile metal complex is reduced with preliminary dissociation and the free metal ions are discharged at the electrode, then the process as a whole will be reversible, provided that the metal ions are reduced reversibly[9]. The Tl^+/Tl, Hg^{2+}/Hg, Cu^+/Cu, Cu^{2+}/Cu, Cd^{2+}/Cd, and Pb^{2+}/Pb systems are reversible. Under certain conditions, the Sn^{2+}/Sn, Bi^{3+}/Bi, Sb^{3+}/Sb, and In^{3+}/In systems are also reversible. The labile complexes of these metals are likewise reduced reversibly. We may note that the metals enumerated form amalgams[5]

Sometimes free hydrated metal ions are reduced irreversibly, while in a system with complex formation the process becomes reversible. For example, the hydrated In^{3+} and Ni^{2+} ions are reduced irreversibly, while many of their complexes are reduced reversibly. In such cases one can apparently postulate that complex species and not free metal ions are reduced directly at the electrode.

If the complex is not reduced to the metallic state and the process involves merely a change in the valence of the central complex-forming ion, then it proceeds as a rule reversibly with participation of a single electron[5]. The Fe^{3+}/Fe^{2+}, Cu^{2+}/Cu^+, V^{3+}/V^{2+}, Ti^{4+}/Ti^{3+}, U(VI)/U(V), U^{4+}/U^{3+}, Eu^{3+}/Eu^{2+} and more rarely Cr^{3+}/Cr^{2+}, Mn^{3+}/Mn^{2+}, Co^{3+}/Co^{2+}, Ru^{3+}/Ru^{2+}, Nb(V)/Nb(IV), and Np^{4+}/Np^{3+} are reversible.

Reversibility is particularly characteristic of the reduction of inert complexes, whose oxidised and reduced forms have the same compositions. Thus the hexacyanoferrate(III)/hexacyanoferrate(II), ferrocenium cation/ferrocene, $Cr(CN)_6^{3-}/Cr(CN)_6^{4-}$, etc. systems are reversible. On the other hand, if the oxidised and reduced forms have different structures, then the system is in most cases irreversible. The simple empirical rules enumerated above are useful for the approximate assessment of the reversibility of the system investigated.

Solutions to which a large excess of an indifferent electrolyte has been added are used in polarography. A fairly high electrical conductivity of this solution is attained in this way and the ohmic potential losses can be neglected. At the same time one excludes the migration component of the current, whose presence would constitute an additional complication. Finally, the electrolyte is added also to maintain a constant ionic strength in the solution, ensuring thereby the constancy of the activity coefficients, which are usually difficult to meaure. This is why concentration equilibrium formation constants of the complexes and not their thermodynamic values are found by the polarographic method. The thermodynamic constant can also be estimated by extrapolating the relation between the concentration constant and ionic strength to zero value of the latter.

1. Systems with a Single Complex

The equations of the waves for this case were derived by von Stackelberg and von Freyhold in 1940 [13] and by Lingane in 1941.[14]

(a) Reduction of the complex with formation of an amalgam. In the derivation of the equations of the reduction wave of the complex by the Lingane method[14], one uses the equation for the equilibrium formation or dissociation constant of the complex, the Nernst equation, and the Ilkovič equation, whereby one converts the concentrations into the currents.

The reduction of the complex with formation of an amalgam

$$MX^{(n-pb)+} + ne + Hg \rightleftarrows M(Hg) + pX^{b-}$$

can be conveniently regarded as the sum of two partial reactions:

$$M^{n+} + pX^{b-} \rightleftarrows MX_p^{(n-pb)+}$$

and

$$M^{n+} + ne + Hg \rightleftarrows M(Hg)$$

(here X^{b-} is the ligand). If these reactions are fast and the process as a whole is reversible, then the potential of the indicator electrode will be described by the Nernst equation

for an amalgam electrode, which includes the concentrations at the surface of the electrode of the amalgam formed $[M(Hg)]_0$ and free metal ions $[M]_0$, their activity coefficients $f_{M(Hg)}$ and f_M, and the activity of mercury in the surface layer of the electrode a_{Hg}. Since a very dilute amalgam is formed on the mercury electrode, the activity of the mercury in the amalgam differs little from that of pure mercury and can be regarded as a constant.

The concentration of metal ions in terms of the complex formation equilibrium constant can be substituted in the Nernst equation. The concentration of the complex in solution and of the metal in the amalgam near the interface are found with the aid of the Ilkovič equations for the diffusion of the complex in the solution and of the metal in the amalgam. Since the ligand is liberated in the reduction of the complex, the concentration of the former at the surface of the electrode does not remain constant as the potential of the latter varies along the wave:

$$[X]_0=[X]+pi/\varkappa_X, \qquad (2)$$

where $\varkappa_X = 605nD_X^{1/2}m^{2/3}\tau^{1/6}$, D_X is the diffusion coefficient of the ligand, and τ is the drop time.

Allowance for the change in the ligand concentration at the electrode greatly complicates the equation of the wave. The ligand concentration in the bulk of the solution is therefore made considerably greater than that of the metal ions, whereupon the term $pi/\varkappa_X$ in Eqn.(2) can be neglected and one can assume that $[X]_0 = [X]$.

Ultimately we obtain

$$E = E_{1/2} - \frac{2.3RT}{nF}\lg\frac{i}{i_d - i} \qquad (3)$$

and

$$(E_{1/2})_c = E^0 - \frac{2.3RT}{nF}\lg\frac{K_p f_{M(Hg)}}{f_{MX_p}} - \frac{2.3RT}{2nF}\lg\frac{D_c}{D_a} - p\frac{2.3RT}{nF}\lg[X]f_X. \qquad (4)$$

In the derivation of Eqns.(3) and (4) account was taken of the diffusion to the electrode of complex species alone. If the diffusion of free ions M^{n+} is also taken into account, then instead of Eqn.(4) we obtain[5]:

$$(E_{1/2})_c = E^0 - \frac{2.3RT}{nF}\lg\frac{K_p f_{M(Hg)}}{f_{MX_p}} - \frac{2.3RT}{2nF}\lg\frac{D_c}{D_a} - \frac{2.3RT}{nF}\lg(1+K_p[X]^p f_X^p).$$

For stable complexes, the diffusion of M^{n+} ions to the electrode can be neglected.

Inspection of Eqn.(3) shows that the equation of the wave for the reversible reduction of the complex in no way differs from the equation of the wave for any reversible process. Consequently all the polarographic criteria of reversibility are applicable to the reduction of the complex.

Eqn.(4) does not include the concentration of the complex, so that $E_{1/2}$ is independent of the concentration of the depolariser, as should be the case for the wave corresponding to a reversible process.

It can be readily shown that the following equation is valid for the wave due to the discharge of simple ions:

$$(E_{1/2})_s = E^0 - \frac{2.3RT}{nF}\lg\frac{f_{M(Hg)}}{f_M} - \frac{2.3RT}{2nF}\lg\frac{D_M}{D_a}. \qquad (5)$$

From Eqns.(4) and (5), we obtain the difference between the half-wave potentials of the complex and the simple ion:

$$(E_{1/2})_c - (E_{1/2})_s = \frac{2.3RT}{nF}\lg\frac{f_{MX_p}}{K_p f_{M^{n+}}} + \frac{2.3RT}{2nF}\lg\frac{D_M}{D_c} - p\frac{2.3RT}{nF}\lg[X]f_X.$$

If the experiment is carried out under the conditions of a constant ionic strength, then the contribution of the activity coefficients is usually disregarded. The contribution of the term including the ratio of the diffusion coefficients is also rarely taken into account, although the latter can be readily determined experimentally as the ratio of the limiting currents. The final form of the equation for the shift of $E_{1/2}$ on complex formation is as follows:

$$(E_{1/2})_c - (E_{1/2})_s = \frac{2.3RT}{nF}\lg\frac{(i_d)_M}{(i_d)_c} - \frac{2.3RT}{nF}\lg K_p - p\frac{2.3RT}{nF}\lg[X]. \qquad (6)$$

According to Eqn.(6), the dependence of $\Delta E_{1/2}$ on $\lg[X]$ is represented by a straight line with a slope $2.3pRT/nF$; the coordination number of the complex p can be found from the slope. The straight line makes an intercept $(2.3RT/nF)\lg(1/K_p)(i_d)_M/i_d)_c$ on the ordinate axis, i.e. at $[X]=1$; hence it is easy to find the equilibrium formation constant for the complex K_p.

Lingane[14] used Eqn.(6) in the study of the hydroxo-complex of lead and established that, in the concentration range of alkali 0.01–1 *N*, the coordination number $p = 3$. The electrode process

$$HPbO_2^- + 2e + H_2O + Hg \rightleftarrows Pb(Hg)_f + 3OH^-$$

corresponds to the lead wave.

(b) The reduction of a complex involving the transition from one oxidation state of the complex-forming metal to another. We shall now consider the case of a reversible electrode process as a result of which the complex is not reduced to the metal but gives rise to a valence state of the complex-forming metal differing from the initial state:

$$MX_p^{(n-pb)+} + (n-m)e = MX_q^{(m-qb)+} + (p-q)X^{b-}.$$

Suppose that only one of two complexes, for example $MX_p^{(n-pb)+}$, is present in the bulk of the solution. Both complexes are labile and are involved in a mobile equilibrium with the metal ions in the ligand:

$$M^{n+} + pX^{b-} \underset{}{\overset{K_p}{\rightleftarrows}} MX_p^{(n-pb)+}, \qquad (I)$$

$$M^{m+} + qX^{b-} \underset{}{\overset{K_q}{\rightleftarrows}} MX_q^{(m-qb)+}. \qquad (II)$$

The ligand is taken in excess, so that $[X]_0 = [X]$.

Using the Nernst equation, the equations for the equilibrium constants of reactions (I) and (II), and the Ilkovič equations for the diffusion of the complexes $MX_p^{(n-pb)+}$ and $MX_q^{(m-qb)+}$, we obtain

$$E = E^0 - \frac{RT}{(n-m)F}\ln\frac{K_p}{K_q} - \frac{RT}{(n-m)F}\ln\frac{i}{i_d - i} - \frac{RT}{(n-m)F}\lg\frac{\varkappa_p}{\varkappa_q} - \frac{(p-q)}{(n-m)}\frac{RT}{F}\ln[X], \qquad (7)$$

$$(E_{1/2})_c = E^0 - \frac{RT}{(n-m)F}\ln\frac{K_p}{K_q} - \frac{RT}{(n-m)F}\ln\frac{\varkappa_p}{\varkappa_q} - \frac{(p-q)}{(n-m)}\frac{RT}{F}\ln[X] \qquad (8)$$

and

$$(E_{1/2})_c - (E_{1/2})_s = \frac{2.3RT}{(n-m)F}\lg\frac{\varkappa_{M^{n+}}+\varkappa_q}{\varkappa_{M^{m+}}+\varkappa_p} - \frac{2.3RT}{(n-m)F}\lg\frac{K_p}{K_q} - 2.3\frac{(p-q)}{(n-m)}\frac{RT}{F}\lg[X]. \qquad (9)$$

If both complexes are present in solution, then the term involving the currents in Eqn.(7) assumes the following form:

$$\frac{RT}{(n-m)F}\ln\frac{i-(i_d)_q}{(i_d)_p - i}$$

where $(i_d)_p$ is the limiting current of the complex $MX_p^{(n-pb)+}$ and $(i_d)_q$ is the limiting current of the complex $MX_q^{(m-qb)+}$; Eqns.(8) and (9) retain their previous form. A single

anodic–cathodic wave arises on the polarogram, its anodic component corresponding to the oxidation of the complex $MX_q^{(m-qb)+}$ and the cathodic component corresponding to the reduction of the complex $MX_p^{(n-pb)+}$.

Eqns.(8) and (9) show that, by studying the dependence of $E_{1/2}$ on lg [X], it is possible to find in this instance only the difference between the coordination numbers and the ratio of the stability constants of the two complexes in the system. In particular, if the composition of the complex does not change on reduction, i.e. $p-q=0$, then the potential $E_{1/2}$ will be independent of the ligand concentration; at the same time it will not be equal to $E_{1/2}$ for the reduction of the simple ion M^{n+}. On the other hand, following the addition of the first portion of the ligand in excess with respect to the M^{n+} ions, the reduction wave of the latter shifts in the cathodic or anodic direction depending on which complex is more stable, but a further change in ligand concentration does not entail a shift.

If the composition and the formation constant of one of the complexes are known, then it is possible to determine by Eqns.(8) and (9) the corresponding parameters for the other complex. As an illustration, we shall consider a system consisting of the oxalate complexes of bivalent and tervalent iron[13,14]:

$$Fe(C_2O_4)_3^{3-} + e \rightleftarrows Fe(C_2O_4)_q^{(3-2q)+} + (3-q)\,C_2O_4^{2-}.$$

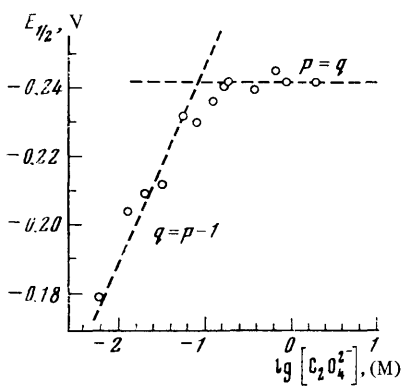

Figure 1. Dependence of the half-wave potential for the reduction of the complex $Fe(C_2O_4)_3^{3-}$ on the logarithm of the concentration of oxalate ions. Reference electrode—saturated calomel half-cell[14].

This system was investigated at 25 °C and an Fe^{3+} concentration of $(1–2)\times10^{-3}$ M. The $K_2C_2O_4$ concentration was varied[14] in the range 6.1×10^{-3}–1.76 M. The solutions also contained 0.3–0.6 M KCl. The dependence of $E_{1/2}$ of the reduction wave of the iron(III) oxalate complex on the logarithm of the oxalate concentration is illustrated in Fig.1. The plot consists of two sections. At an oxalate concentration in excess of ~0.15 M the half-wave potential $E_{1/2}$ is independent of $[C_2O_4^{2-}]$; consequently $p-q=0$ and the iron(II) and iron iron(III) complexes have the same compositions:

$$Fe(C_2O_4)_3^{3-} + e \rightleftarrows Fe(C_2O_4)_3^{4-}.$$

For $[C_2O_4^{2-}] < 0.15$ M, $E_{1/2}$ does depend on $[C_2O_4^{2-}]$ and $\partial E_{1/2}/\partial \lg [C_2O_4^{2-}] = 58$ mV, which corresponds to $p-q=1$ for $n-m=1$. Consequently, under these conditions, the reduction of the complex $Fe(C_2O_4)_3^{3-}$ leads to the formation of the complex $Fe(C_2O_4)_2^{2-}$:

$$Fe(C_2O_4)_3^{3-} + e \rightleftarrows Fe(C_2O_4)_2^{2-} + C_2O_4^{2-}.$$

The independence of $E_{1/2}$ of the ligand concentration for partial reduction of the complex is characteristic of the polarographic behaviour of metal complexonates which as a rule have the simplest composition, 1:1.

If the complex $MX_q^{(m-qb)+}$ is reduced with formation of an amalgam of the complex-forming metal at more negative potentials,

$$MX_q^{(m-qb)+} + m\,e + Hg \rightleftarrows M(Hg) + q\,X^{b-}$$

and a separate second wave arises on the polarogram, then both the composition and the stability constants of the two complexes can be determined by analysing the properties of the two waves. The properties of the first wave are fully consistent with Eqns.(7)–(9); those of the second wave are described by Eqns.(3), (4), and (6), but a number of corrections must be applied to them. Firstly, at the potentials of the second wave the current is determined by the rate of diffusion of the complex $MX_p^{(n-pb)+}$ and not $MX_q^{(m-qb)+}$ although its concentration does in fact fall almost to zero at the potentials of the first wave. Secondly, m electrons are involved in the process. Thirdly, at the potentials of the first and second waves the characteristics of the capillary differ owing to the influence of the potential on the drop time. Taking into account the above corrections, the following equations were obtained[13]

$$E'' = E''_{1/2} - \frac{2.3RT}{mF}\lg\frac{i''}{i''_d - i''},$$

$$(E''_{1/2})_c = E_2^0 - \frac{2.3RT}{mF}\lg K_q - \frac{2.3RT}{mF}\lg\frac{(n-m)}{m}\frac{\varkappa_q}{\varkappa_a} - q\frac{2.3RT}{mF}\lg[X],$$

and

$$(E''_{1/2})_c - (E''_{1/2})_s = \frac{2.3RT}{mF}\lg\frac{m}{(n-m)}\frac{\varkappa_{M^{m+}}}{\varkappa_q} - \frac{2.3RT}{mF}\lg K_q - q\frac{2.3RT}{mF}\lg[X].$$

In these equations E'' and $E''_{1/2}$ are respectively the potential of any point in the second wave and its half-wave potential, E_2^0 the normal potential for the process

$$M^m + me + Hg \rightleftarrows M(Hg);$$

i'' and i''_d are the current and the limiting current of the second wave reckoned from the limiting current of the first wave, K_q is the stability constant of the complex $MX_q^{(m-qb)+}$, $\varkappa_q$ the constant of the Ilkovič equation for the complex, $\varkappa_a$ the corresponding constant for the amalgam of M at the limiting current potential of the second wave, and $\varkappa_{M^{m+}}$ the corresponding parameter for the ion M^{m+} also at the limiting current potential of the second wave.

The reduction of certain copper complexes, particularly ammine complexes, serves as a striking example of a stepwise reduction process. Free copper(II) ions are reduced in one stage with formation of an amalgam, so that the normal potential for the process

$$Cu^+ + e + Hg \rightleftarrows Cu(Hg)$$

is more positive than that (and hence also $E_{1/2}$) for the process

$$Cu^{2+} + e \rightleftarrows Cu^+.$$

Ammine complexes of bivalent and univalent copper are formed in ammonia-containing solutions but the copper(I) complexes are more stable. The copper waves move apart; for this reason, at a fairly high ammonia concentration two waves arise on the polarogram of bivalent copper and can be used to investigate the composition and stabilities of the complexes of copper in both valence states. This system has been investigated by von Stackelberg and von Freyhold[13]; the experimental and calculated data obtained are illustrated in Fig.2. Evidently the stepwise reduction of the copper(II) ammine complex is observed at an ammonia concentration of 0.001 M and above. Fig.2 shows that the slopes of the plots of $E_{1/2}$ against lg $[NH_3]$ correspond to the complexes having this composition. In the reduction of the copper(II) complex this relation (curve *1*) has an anomalous form: along the initial section the increase of the ammonia concentration causes a shift of the wave in the positive direction. This is because at a very low ammonia concentration mainly complexes of Cu^{2+} with one or two ammonia molecules are formed, while copper(I) forms mostly a complex with two ammonia molecules under the same conditions. The ratio $K_p/K_q \ll 0$ and $\lg(K_p/K_q) < 0$, but this term has the minus sign in Eqn.(9). Furthermore, $p-q$ is either −1 or 0. As a result of the influence of these two parameters, the initial shift of the wave in the positive direction is observed. In the presence of ammonia the process

$$Cu^{2+} + 2e + Hg \rightleftarrows Cu\,(Hg)$$

does not occur (curve *2*).

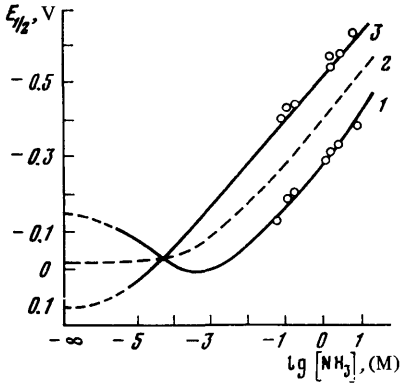

Figure 2. The influence of the concentration of ammonia on the half-wave potentials for different processes: 1) Cu^{2+}/Cu^{+} $[Cu(NH_3)_4^{2+}/Cu(NH_3)_2^{+}]$; 2) $Cu^{2+}/Cu(Hg)$; 3) Cu^{+}/Cu $[Cu(NH_3)_2^{+}/Cu(Hg)]$. Lines—calculations; circles—experimental data. Reference electrode—saturated calomel half-cell[13].

In the derivation of the equations of the reduction wave of the complex it was assumed that the ligand is present in solution in a fairly large excess. On the other hand, it is desirable to vary the concentration of the ligand within the widest possible limits. It is therefore necessary to know what excess is adequate. The change in the ligand concentration at the electrode as a result of the reduction of the complex is responsible for the undesirable shift of the wave. The excess of the ligand N, for which the error of the measurement of $E_{1/2}$ does not exceed $\Delta E_{1/2}$ for the reason discussed above, can be calculated by the equation (Heyrovský and Kuta[15], p.137)

$$N = \frac{p^2}{2} \cdot \frac{RT}{nF} \cdot \left(\frac{D_c}{D_X}\right)^{1/2} \cdot \frac{2}{\Delta E_{1/2}}.$$

Here $RT/F = 25$ mV at 25 °C. Thus, when $E_{1/2}$ is measured to within 2 mV, the excess of the ligand should be at least by a factor of 100 if $p = 4$ and $n = 1$ and a factor of 12 if $p = 2$, subject to the condition that $(D_C/D_X)^{1/2} = 1$. It follows from these calculations that a smaller excess of the ligand is required the smaller the value of p and the larger the value of n.

(c) Mercury complexes. The reduction waves of mercury complexes or the oxidation waves of metallic mercury involving the formation of a complex have an unusual form and properties. The explanation is that one of the components of the oxidation-reduction system is metallic mercury, whose activity is always constant. For this reason, the initial Nernst equation has a simpler form:

$$E = E^0 + \frac{RT}{2F} \ln [Hg^{2+}]_0.$$

Simple relations are also obtained where there is no excess of the ligand in solution.

The reasoning followed in the derivation of the equation of the wave is of the usual kind: the concentration of mercury ions is found from the equation for the stability constant of the complex and is substituted in the Nernst equation The concentrations are converted into the currented with the aid of the Ilkovič equation. It is therefore desirable to quote and discuss only the final equation in this instance (Heyrovský and Kuta, Ref.15, p.151).

The reduction of the mercury complexes will be considered in relation to the electrode process

$$Hg^{2+} + 2CN^- \overset{K}{\rightleftarrows} Hg(CN)_2,$$
$$Hg^{2+} + 2e \rightleftarrows Hg.$$

The equation of the wave is

$$E = E^0_{Hg^{2+}} - \frac{RT}{2F} \ln \frac{i^2}{(i_d - i)} \frac{\varkappa_c}{(\varkappa_X)^2} K, \qquad (10)$$

$$(E_{1/2})_c = E^0_{Hg^{2+}} - \frac{RT}{2F} \ln \frac{i_d}{2} \frac{\varkappa_c}{(\varkappa_X)^2} K. \qquad (11)$$

Eqns.(10) and (11) show that the wave of the mercury complex can be expressed in a linear form by plotting E against lg $[i^2(i_d - i)]$, the straight line intersecting the potential axis not at $E_{1/2}$ but at the potential

$$E^* = E^0_{Hg^{2+}} - \frac{2.3RT}{2F} \lg \frac{\varkappa_c}{(\varkappa_X)^2} - \frac{2.3RT}{2F} \lg K,$$

which depends on the characteristics of the capillary and the stability constant of the complex. The half-wave potential is a function of the concentration of the complex.

In the general case we have for the reduction of the complex HgX_p

$$E = E^0_{Hg^{2+}} - \frac{RT}{2F} \ln \frac{i^p}{(i_d - i)} \frac{\varkappa_c}{(\varkappa_X)^p} K_p$$

and

$$E_{1/2} = E^0_{Hg^{2+}} - \frac{RT}{2F} \ln \left(\frac{i_d}{2}\right)^{p-1} \frac{\varkappa_c}{(\varkappa_X)^p} K_p.$$

In the example under consideration CN^- is the anion of a weak acid, $K_a = [CN^-][H^+]/[HCN] = 7.2 \times 10^{-10}$. Taking this factor into account, we obtain somewhat different equations of the wave:

$$E = E^0_{Hg^{2+}} - \frac{RT}{2F} \ln \frac{i^2}{(i_d - i)} \frac{\varkappa_c}{(\varkappa_X)^2} K - \frac{RT}{F} \ln \frac{K_a}{K_a + [H^+]} .$$

When $[H^+] \gg K_a$ (i.e. at pH < 8) and a constant concentration of the complex $Hg(CN)_2$, we obtain

$$E_{1/2} = E^0_{Hg^{2+}} + \frac{RT}{F} \ln [H^+] + \text{const.}$$

Consequently at $[H^+] \gg K_a$ the half-wave potential $E_{1/2}$ is a function of the pH. On the other hand, if $[H^+] \ll K_a$ (i.e. at pH > 10), then $E_{1/2}$ is independent of the pH.

The principles governing the allowance for the acid–base equilibrium involving the ligand in simple complex formation equilibria without taking into account the participation of the protonated ligand in the complex formation reaction have been demonstrated in relation to the reduction of the complex $Hg(CN)_2$. More complicated cases will be considered below.

The equilibria in the formation of mercury complexes can be investigated also on the basis of the influence of the ligands on the anodic dissolution of mercury. Suppose that metallic mercury undergoes anodic dissolution in the presence of a small amount of CN^- ions;

$$Hg \rightleftarrows Hg^{2+} + 2e,$$
$$Hg^{2+} + 2CN^- \overset{K}{\rightleftarrows} Hg(CN)_2.$$

The CN^- ions bind the Hg^{2+} ions formed in a complex and the concentration of mercury ions at the electrode falls. As a result, an anodic wave arises on the polarogram, its height being determined by the diffusion of CN^- ions to the electrode and its position being related mainly to the stability constant of the mercury complex formed: the more stable the complex the more cathodic are the potentials at which the wave is located.

The equation of the anodic wave is

$$E = E^0_{Hg^{2+}} + \frac{RT}{2F} \ln \frac{i}{(i_d - i)^2} \frac{(\varkappa_X)^2}{\varkappa_c K} , \quad (12)$$

$$(E_{1/2})_c = E^0_{Hg^{2+}} + \frac{RT}{2F} \ln \frac{(\varkappa_X)^2}{\varkappa_c \cdot 0{,}5 i_d K} , \quad (13)$$

or

$$(E_{1/2})_c = E^0_{Hg^{2+}} + \frac{RT}{2F} \ln \left(\frac{D_X}{D_c}\right)^{1/2} \frac{2}{K[CN^-]} ,$$

since $i_d = \varkappa_X [CN^-]$. Comparison of Eqns.(10) and (11), on the one hand, and Eqns.(12) and (13), on the other, shows that the anodic wave for the formation of the mercury complex and the cathodic wave for its reduction have similar properties. This is understandable: the waves correspond to the forward and reverse processes of a single system.

The anodic waves of mercury are convenient for the investigation of mercury complexes. They have been used to study the equilibria in the formation of mercury complexes with the anions CN^-, SO_3^{2-}, $S_2O_3^{2-}$, SCN^- as well as complexones and ethylenediamine. In the presence of an excess of the ligand in solution, we obtain for the reduction wave of the mercury complex[15]

$$E = E^0 + \frac{RT}{2F} \ln (i_d - i) - \frac{RT}{2F} \ln \varkappa_c - \frac{RT}{2F} \ln K_p - p \frac{RT}{2F} \ln [X], \quad (14)$$

$$E_{1/2} = E^0 + \frac{RT}{2F} \ln \frac{i_d}{2} - \frac{RT}{2F} \ln \varkappa_c - \frac{RT}{2F} \ln K_p - p \frac{RT}{2F} \ln [X] \quad (15)$$

or

$$E_{1/2} = E^0 + \frac{RT}{2F} \ln \frac{[HgX_p]}{2} - \frac{RT}{2F} \ln K_p - p \frac{RT}{2F} \ln [X]. \quad (16)$$

Evidently the wave in this case is even more asymmetric, beginning from a sharp break at the potential

$$E_{i=0} = E^0 + \frac{RT}{2F} \ln [HgX_p] - \frac{RT}{2F} \ln K_p - p \frac{RT}{2F} \ln [X]. \quad (17)$$

The wave represents, as it were, the upper half of the normal reduction wave of a complex involving the formation of an amalgam. The half-wave potential is a function of the concentration of the complex, but is independent of the characteristics of the capillary; the equation can be expressed in a linear form by plotting E against $\lg (i_d - i)$.

If the complex is reduced with formation of a metal insoluble in mercury, then the wave has exactly the same shape and Eqns.(14)–(17) are valid for it.

(d) The displacement method[16]. If the solution contains only one ligand X and the two metal ions M and N, then the equilibrium mixture should contain the free ions M and N and the complexes MX and NX:

$$MX + N \rightleftarrows NX + M, \qquad K_{III} = [NX][M]/[MX][N] = K_{NX}/K_{MX} . \quad (III)$$

The additional unknowns in this equation are eliminated with the aid of the material balance equations

$$c_M = [M] + [MX],$$
$$c_N = [N] + [NX],$$
$$c_X = [MX] + [NX].$$

The relation is particularly simple if the experiment is carried out in such a way that $c_M = c_N = c_X = c$. Then

$$K_{III} = [M]^2/(c - [M])^2 = K_{NX}/K_{MX}.$$

[M] is determined polarographically and the ratio of the stability constants of the complexes NX and MX is calculated. If one of the constants is known, the other can be obtained from the ratio.

The experiment is carried out as follows[16]. A solution containing the complex MX, which is reduced with formation of a single wave on the polarogram, is treated with a salt containing the cation N. After the establishment of the new equilibrium, the reduction wave of the complex MX is preceded by the wave of the displaced free ions M. One of the conditions for the application of the displacement method is the slowness of the attainment of equilibrium (III). Only then is the reduction wave of the ions M of a purely diffusional type and its height characterises the equilibrium concentration of these ions. It is also necessary that the cation N and the complex NX are electrochemically more active than the ions M.

This procedure has been widely used[16] in the polarographic study of the formation of metal complexonates.

2. Stepwise Complex Formation

If several complexes are formed in solution, the dependence of the half-wave potential for the reduction of the complex-forming metal on the logarithm of the activity of the ligand will no longer be linear. In this case the plot of $E_{1/2}$ against lg [X] consists either of several linear sections (in accordance with the number of complexes formed, whose formation constants differ fairly appreciably) or of a smooth curve which is convex with respect to the abscissa axis, (with increase of the activity of the ligand, complexes with a larger coordination number are formed and the slope of the plot increases). The smooth curve is obtained when the stability constants of the complexes do not differ very markedly and the regions of

their existence overlap. In the former case the equations derived in the preceding section are applicable to the individual linear sections and it is possible to determine with their aid both the coordination number p and the formation constant K for each complex. The second case requires a more complicated analysis.

(a) Method based on the logarithmic Yatsimirskii plot[17–20]. We shall assume that at any ligand concentration not more than two complexes are formed in solution and these are in equilibrium:

$$MX_p + X \rightleftarrows MX_{p+1},$$
$$\beta_{p+1} = [MX_{p+1}]_0/[MX_p]_0[X].$$

(β_{p+1} is the successive formation constant of the complex MX_{p+1}). The ligand is again present in solution in a fairly large excess.

An expression for $[MX_{p+1}]_0$ and then for $[M]_0$ can be obtained from the equation for β_{p+1}. Having substituted $[M]_0$ in the Nernst equation and having replaced the concentrations by the currents with the aid of the Ilkovič equation, we arrive at the following equations for the wave, $E_{1/2}$, and $\Delta E_{1/2}$:

$$E = E^0 - \frac{RT}{nF}\ln\frac{i}{(i_d - i)} - \frac{RT}{nF}\ln\frac{\varkappa_c}{\varkappa_a} - \frac{RT}{nF}\ln[X]^p(1 + \beta_{p+1}[X]),$$

$$E_{1/2} = E^0 - \frac{RT}{nF}\ln\frac{\varkappa_c}{\varkappa_a} - \frac{RT}{nF}\ln K_p - \frac{RT}{nF}\ln[X]^p(1 + \beta_{p+1}[X]),$$

$$(E_{1/2})_s - (E_{1/2})_c = \Delta E_{1/2} = \frac{RT}{nF}\ln[X]^p(1 + \beta_{p+1}[X]) + \frac{RT}{nF}\ln K_p + \frac{RT}{nF}\ln\frac{\varkappa_c}{\varkappa_M}. \quad (18)$$

According to Eqn.(18), the function $\Delta E_{1/2} = f\{\ln[X]\}$ is represented by a curve whose slope at any point is determined by the derivative

$$\frac{\partial \Delta E_{1/2}}{\partial \ln[X]} = \frac{RT}{nF}\left(p + \frac{[X]}{\beta_{p+1}^{-1} + [X]}\right).$$

When $[X] \gg \beta_{p+1}^{-1}$, we have $\partial \Delta E_{1/2}/\partial \ln[X] = RT(p+1)/nF$ and Eqn.(18) is converted into Eqn.(6); the complex MX_{p+1} predominates in the solution. When $[X] \ll \beta_{p+1}^{-1}$, we have $\partial \Delta E_{1/2}/\partial \ln[X] = RTp/nF$ and Eqn.(18) is again transformed into Eqn.(6); the complex MX_p predominates in the solution.

When the concentrations of the two complexes are equal, i.e. $[X] = \beta_{p+1}^{-1}$, we have

$$\Delta E_{1/2} = \frac{RT}{nF}\ln[X]^p + \frac{RT}{nF}\ln K_p - \frac{RT}{nF}\ln\frac{\varkappa_M}{\varkappa_c} + \frac{RT}{nF}\ln 2, \quad (19)$$

$$\frac{\partial \Delta E_{1/2}}{\partial \lg[X]} = \frac{2.3RT}{nF}\left(p + \frac{1}{2}\right). \quad (20)$$

In conformity with these derivations, the experimental data are represented by a plot of $\Delta E_{1/2}$ against $\lg[X]$ and a series of tangents are drawn; their slopes are defined by Eqn.(20) in which integral values of p are substituted (1, 2, 3, etc.). The tangential points correspond to the equality of the concentrations of the complexes MX_p and MX_{p+1}, while the ligand concentrations at these points are numerically equal to β^{-1}. Knowing p and the corresponding values of $[X]$, it is possible to calculate the constants K_p by Eqn.(19). Yatsimirskii called this method the logarithmic plot method.

If a tangent is drawn having put $p = 0$, then the tangential point will correspond to the equality of the concentrations of the free ions M^{n+} and the complex MX, while the concentration of the ligand at this point is equal to the instability constant of the complex MX.[21]

Adamovich and Novakovskii[22] and also Tur'yan[23] considered the conditions under which the logarithmic plot method is applicable. According to these workers, the method can be used to determine the parameters p, K, and β even for non-existent complexes in those cases where for some reason ligands do not add to the metal ion solely one by one. Adamovich and Novakovskii therefore recommend that the method be used only for complexes whose existence has been demonstrated independently. However, real complex formation is reflected in the form of the relation between $E_{1/2}$ and $\lg[X]$ and for a non-existent complex the Yatsimirskii method should in principle yield the corresponding successive formation constants.

Tur'yan[23] pointed out that the logarithmic plot method is an approximation, so that the hypothesis that two adjacent complexes predominate when their concentrations are equal does not correspond exactly to reality. Sometimes it is altogether invalid and the situation depends on the ratio of the formation constants of the complexes. For this reason, the stability constants of the complexes determined by the logarithmic plot method are approximate. Nevertheless the method merits attention in view of its simplicity.

The method of tangents[9] is similar to the logarithmic plot method. In this procedure tangents are also drawn to the $\Delta E_{1/2} = f\{\lg[X]\}$ curve, but with the slope defined by Eqn.(6), i.e. $\partial \Delta E_{1/2}/\partial \lg[X] = 2.3RTp/nF$ with integral values of p. The tangential points correspond to the ligand concentrations at which a single complex MX_p predominates in the solution. The method of tangents is also approximate and practice has shown[9] that it leads to less accurate stability constants than the logarithmic plot method. The explanation is that the condition governing the predominance of two adjacent complexes usually holds better than the condition governing the predominance of a single complex.

(b) The graphical method of De Ford and Hume[24]. If n complexes are formed in solution, then each causes a shift of $E_{1/2}$ in accordance with Eqns.(6). The overall shift of $E_{1/2}$ can therefore be determined by adding together the shifts of $E_{1/2}$ corresponding to all the complexes:

$$(E_{1/2})_s - (E_{1/2})_c = \frac{RT}{nF}\lg\sum_{p=0}^{p=n} K_p[X]^p + \frac{RT}{nF}\ln\frac{\varkappa_c}{\varkappa_M},$$

$$\sum_{p=0}^{p=n} K_p[X]^p = F_0([X]) = \text{anti lg}\left\{\frac{nF}{2.3RT}[(E_{1/2})_s - (E_{1/2})_R] + \lg\frac{(i_d)_M}{(i_d)_c}\right\}, \quad (21)$$

$$F_0([X]) = 1 + K_1[X] + K_2[X]^2 + \ldots + K_n[X]^n. \quad (22)$$

The right-hand side of Eqn.(21) contains quantities which are determined experimentally. If $F_0\{[X]\}$ is plotted against $[X]$ then, according to Eqn.(22), one obtains a curve whose extrapolation to $[X] = 0$ yields unity, i.e. the formation constant of the zeroth complex.

In order to find K_1, we introduce the function $F_1\{[X]\}$:

$$E_1([X]) = \frac{F_0([X]) - 1}{[X]} = K_1 + K_2[X] + \ldots + K_n[X]^{n-1} \quad (23)$$

The plot of this function is also curved and its extrapolation to $[X] = 0$ yields K_1.

The plot of the function

$$F_2([X]) = \frac{F_1([X]) - K_1}{[X]} = K_2 + K_3[X] + \ldots + K_n[X]^{n-2} \quad (24)$$

and its extrapolation to $[X] = 0$ yield K_2, etc. The plot of the penultimate function against $[X]$ consists of an inclined straight line and that for the last function is represented by a straight line parallel to the abscissa axis.

It follows from Eqns.(22)–(24) that the slope of the plot of the function is initially equal to the next stability constant of the complex:

$$\left(\frac{\partial F_0([X])}{\partial [X]}\right)_{[X]\to 0} = K_1;\ \left(\frac{\partial F_1([X])}{\partial [X]}\right)_{[X]\to 0} = K_2, \text{etc.}$$

Graphical analysis of the Leden functions $F\{[X]\}$ by the method of De Ford and Hume makes it possible to determine how many and what complexes are formed in the solution and to determine their formation constants.

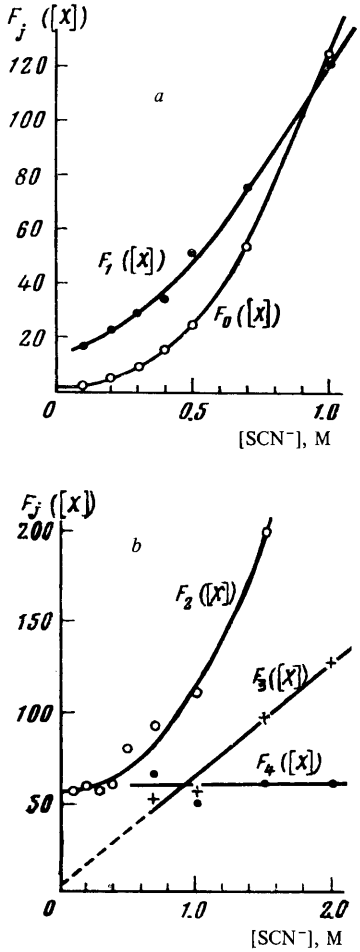

Figure 3. The De Ford and Hume analysis of the functions $F_j\{[X]\}$ for the Cd^{2+}/SCN^- system at an ionic strength $I = 2$ (established by the addition of KNO_3).[25]

Fig.3 illustrates plots of the functions $F\{[X]\}$ for the Cd^{2+}/SCN^- system at a constant ionic strength of 2. Evidently four complexes are formed in this system: $CdSCN^+$, $Cd(SCN)_2$, $Cd(SCN)_3^-$, and $Cd(SCN)_4^{2-}$, with the stability constants $K_1 = 11 \pm 0.5$, $K_2 = 56 \pm 2$, $K_3 = 6 \pm 5$, and $K_4 = 60 \pm 10$. This example demonstrates the fruitfulness of the method of graphical analysis, but at the same time it reveals its weak aspect, namely the increase of the error with increasing complexity of the complex. The existence of the complex $Cd(SCN)_3^-$ is doubtful. It is noteworthy that the reliability of the conclusions arrived at is greater the more stable the complex.

Hume et al.[25] determined $E_{1/2}$ to within 1 mV. A significant improvement of the accuracy of the measurements can be achieved by improving the experimental technique. Piljac et al.[26] prepared the solutions directly in the cell and introduced the ligand-containing solution with the aid of an accurate microburette. The potential was applied to the cell by means of a polarograph and the potential of the mercury dropping electrode relative to the reference electrode was measured by a precision pH-meter. The current was measured at the instant of separation of the drop with the aid of an undamped mirror galvanometer. All the measurements were made by hand and not automatically. The reproducibility of the measurement of the potential in these experiments was to within 0.2 mV.

More accurate stability constants are obtained by calculation and not by the graphical analysis of the Leden function. The problem reduces to the solution of a system of linear equations of type (22), the number of equations equal to the number of measurements of $F_0\{[X]\}$ exceeding the number of unknowns, i.e. the formation constants of the complexes:

$$1 + K_1[X]_1 + K_2[X]_1^2 + \ldots + K_n[X]_1^n - F_0([X])_1 = 0, \quad (25)$$

$$1 + K_1[X]_2 + K_2[X]_2^2 + \ldots + K_n[X]_2^n - F_0([X])_2 = 0, \quad (26)$$

$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$

$$1 + K_1[X]_m + K_2[X]_m^2 + \ldots + K_n[X]_m^n - F_0([X])_m = 0 \quad (27)$$

$(m > n)$. The calculations are performed mainly by the method of least squares[27–29], whereby the number of equations is reduced to the number of unknowns. The system of equations obtained is then solved by matrix algebra.

If the experiment has been formulated in such a way that

$$[X]_2 - [X]_1 = [X]_3 - [X]_2 = [X]_4 - [X]_3 = \ldots = [X]_m - [X]_{m-1},$$

i.e. $\Delta[X] = \text{const.}$, then calculations by the method of least squares are less laborious[28,29].

When the method of least squares is used, one must make an assumption about the number of complexes formed in solution. If the assumption is wrong, some of the calculated formation constants of the complexes are negative, which lacks physical significance. Calculations are therefore repeated for another postulated number of complexes and this is continued until all the constants obtained are positive. It is therefore desirable to combine calculations by the method of least squares with a graphical method whereby one determines initially the number of complexes and the approximate values of the constants.

Calculations using iterative or successive approximation methods, particularly the relaxation method, are much less laborious[30]. In the last method Eqns.(25)–(27) are solved by trying different values of the constants K_1–K_n until the left-hand sides of all the equations differ from zero by fairly small amounts. Computers are used successfully in the calculation of the stability constants for stepwise complex formation processes[26,31].

3. Mixed Complexes

If only one mixed complex is formed in solution,

$$M^{n+} + pX + qY \rightleftarrows MX_pY_q,$$

we obtain from the shift of the half-wave potential[32] $E_{1/2}$

$$(E_{1/2})_c - (E_{1/2})_s = \frac{RT}{nF}\ln\frac{\varkappa_M}{\varkappa_c} - \frac{RT}{nF}\ln K_{pq} - p\frac{RT}{nF}\ln[X] - q\frac{RT}{nF}\ln[Y].$$

The coordination numbers p and q can be determined by measuring experimentally the dependence of $\Delta E_{1/2}$ on lg [X] for [Y] = const., and on lg [Y] for [X] = const.:

$$\left(\frac{\partial \Delta E_{1/2}}{\partial \lg [X]}\right)_{[Y]=\text{const}} = -p\frac{2.3RT}{nF},$$

$$\left(\frac{\partial \Delta E_{1/2}}{\partial \lg [Y]}\right)_{[X]=\text{const}} = -q\frac{2.3RT}{nF}.$$

In the general case, involving the stepwise formation of simple and mixed complexes, Leden functions can also be used to analyse the data[33,34]:

$$F_{00}([X][Y]) = \sum_{p=0}^{p=m}\sum_{q=0}^{q=n} K_{pq}[X]^p[Y]^q.$$

The functions can be analysed by the graphical method of De Ford and Hume. For this purpose, one finds the dependence of $E_{1/2}$ on the concentration of one ligand corresponding to the constant concentration of the other and conversely, and it is necessary to consider series of constant concentrations of each ligand in order to investigate the system fully.

4. Metal Complexonates

A characteristic feature of complexones is their polydentate nature, so that more than one ligand only comparatively rarely interacts with a single metal ion. On the other hand, the complexones are polybasic acids which are characterised by the formation of protonated complexes, the number of protons attached to them increasing with increasing acidity of the medium.

In order to determine the stability constants of normal and protonated complexes of complexones, Gorelov[35] suggested a procedure based on the analysis of the dependence of $E_{1/2}$ on pH at constant metal and complexone concentrations.

When 1 : 1 complexes are formed, the following equilibria obtain in solution:

$$M + H_pX \overset{K_p}{\rightleftarrows} MH_pX.$$

Using the expressions for the equilibrium constants, one can obtain:

$$[M] = \frac{\sum_{p=0}^{p=n}[MH_pX]}{[X]\sum_{p=0}^{p=n} K_p[H]^p/k_nk_{n-1}\cdots k_{n-p+1}},$$

where K_p is the formation constant of the complex, MH_pX and

$$k_n = \frac{[H][X]}{[HX]},$$

$$k_{n-1} = \frac{[H][HX]}{[H_2X]} = \frac{[H]^2[X]}{k_n[H_2X]},$$

$$k_{n-2} = \frac{[H][H_2X]}{[H_3X]} = \frac{[H]^3[X]}{k_nk_{n-1}[H_3X]},$$

etc. are the successive dissociation constants of the complexone. The sum $\sum_{p=0}^{p=n} K_p[H]^p/k_nk_{n-1}\cdots k_{n-p+1}$ will be denoted by $F_0\{[H]\}$:

$$F_0([H]) = K_0 + K_1\frac{[H]}{k_n} + K_2\frac{[H]^2}{k_nk_{n-1}} + \ldots + K_n\frac{[H]^n}{k_nk_{n-1}\cdots k_1}.$$

Having substituted the expression for [M] in the Nernst equation and having carried out the usual transformations (the complexonate is reduced with formation of an amalgam), we obtain

$$F_0([H]) = \text{anti lg}\left\{\frac{nF}{2.3RT}\Delta E_{1/2} + \lg\frac{\varkappa_M}{\varkappa_c} - \lg(c_X - c_M) + \lg\alpha\right\}, \quad (28)$$

where c_X and c_M are the analytical concentrations of the complexone and the metal ions, while

$$\alpha = 1 + \frac{[H]}{k_n} + \frac{[H]^2}{k_nk_{n-1}} + \ldots + \frac{[H]^n}{k_n\cdots k_1}. \quad (29)$$

Eqns. (28) and (29) make it possible to determine $F_0\{[H]\}$ at a given hydrogen ion concentration. The formation constants of the complexes are found graphically: $F_0\{[H]\}$ is plotted against [H] and K_0 is found by extrapolating the plot to [H] = 0.

The new function

$$F_1([H]) = \frac{\{F_0([H]) - K_0\}k_n}{[H]} = K_1 + K_2\frac{[H]}{k_{n-1}} + K_3\frac{[H]^2}{k_{n-1}k_{n-2}} + \ldots.$$

is then calculated. The extrapolation of the plot of $F_1\{[H]\}$ to [H] = 0 yields K_1. By calculating the successive functions, it is possible to find the formation constants of all the protonated complexes.

If the species H_pX forms a 1 : 2 complex, i.e.

$$M + 2H_pX \overset{K_p}{\rightleftarrows} M(H_pX)_2,$$

then analogous reasoning[36] shows that one must calculate the functions $F_j\{[H]^2\}$:

$$F_0([H]^2) = K_0 + K_1\frac{[H]^2}{k_n^2} + K_2\frac{[H]^4}{k_n^2k_{n-1}^2} + \ldots + K_n\frac{[H]^{2n}}{k_n^2\cdots k_1^2}.$$

The final expression for $F_0\{[H]^2\}$ is

$$F_0([H]^2) = \text{antilg}\left[\frac{nF}{2.3RT}\Delta E_{1/2} + \lg\frac{\varkappa_M}{\varkappa_c} - 2\lg(c_X - 0.5c_M) + 2\lg\alpha\right].$$

When 2 : 1 complexes are formed,

$$2M + H_pX \overset{K_p}{\rightleftarrows} M_2H_pX$$

one analyses the same function $F_0\{[H]\}$ as in the formation of 1 : 1 complex but the final expression for $F_0\{[H]\}$ assumes a somewhat different form[36]:

$$F_0([H]) = \text{antilg}\left[0.903 + \frac{2nF}{RT}\Delta E_{1/2} + \lg\frac{D_M}{D_c} - 2\lg c_M - \lg(c_X - 2c_M) + \lg\alpha\right].$$

The composition of the complex is again found from the dependence of $E_{1/2}$ on the logarithm of the analytical concentration of the ligand.

Using the method described, Gorelov[35] investigated the formation of thallium complexes of ethylenediaminetetraacetic and ethylenediamine-*N*,*N*'-disuccinic acids. Only normal and monoprotonated complexes are formed in these systems. More complex phenomena are observed[36] in the Cd^{2+}–hydroxyethylidenediphosphonic acid (HEDPA) system. 1 : 1 complexes are formed in this system at concentrations in the range 10^{-3}–10^{-2} M HEDPA and 1 : 2 complexes are formed at higher concentrations. Fig. 4 presents the functions $F_j\{[H]\}$ for the 1 : 1 complex. Evidently Cd^{2+} ions form not only the normal complex but also four protonated complexes with HEDPA (HEDPA is a pentabasic acid). Furthermore, Fig. 4 shows that each specific complex must have its own extrapolation region of the function $F_j\{[H]\}$ closely adjoining the pH range corresponding to the existence of the given ligand. If the metal ion has a high affinity for hydroxide ions, then the region of high pH values becomes inaccessible to measurements. In this case the constants of certain protonated

complexes can nevertheless be determined by analysing the incomplete function $F_j\{[H]\}$.

5. Polynuclear Complexes

The formation of polynuclear complexes, for example M_mX_p, can be investigated polarographically:

$$m\,M + p\,X \overset{K_{mp}}{\rightleftarrows} M_mX_p,$$

$$\Delta E_{1/2} = -\frac{2.3RT}{mnF}\lg\frac{mK_{mp}}{2^{n-1}} - \left(1-\frac{1}{m}\right)\frac{2.3RT}{nF}\lg[M] - \frac{p}{m}\frac{2.3RT}{nF}\lg[X],$$

$$\frac{\partial\Delta E_{1/2}}{\partial\lg[M]} = -\frac{2.3RT}{nF}\left(1-\frac{1}{m}\right)$$

These relations were obtained by Souchay and Faucherre[32], who identified with their aid polymeric copper complexes of tartaric acid in alkaline media. The stepwise formation of polymeric complexes can be also examined in principle.

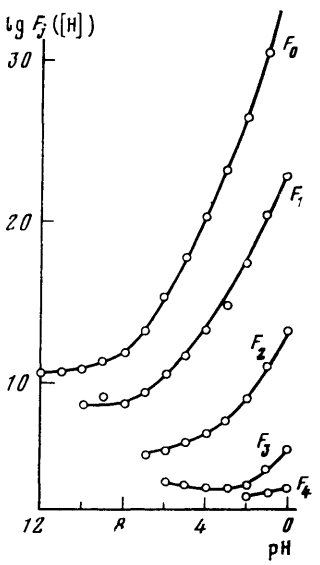

Figure 4. Dependence of the functions $\lg F_j\{[H]\}$ on the pH for the Cd^{2+}–hydroxyethylidenediphosphonic acid system at a complexone concentration of 0.004 M. Cd^{2+} concentration 1×10^{-4} M.[36]

6. Kinetic Waves

Hitherto we have considered cases where the complex species and the metal ions are involved in a rapid equilibrium. However, systems are encountered in which one of the dissociation stages is slow and a kinetic wave arises on the polarogram. The limiting current of the kinetic wave i_c is smaller than the limiting current of the usual diffusion wave i_d. Koryta[37] solved this problem under the condition where free metal ions are reduced reversibly with formation of an amalgam and the ligand is present in excess. The equation for the difference between the half-wave potentials $E_{1/2}$ is as follows:

$$(E_{1/2})_c - (E_{1/2})_s = \frac{RT}{nF}\ln\frac{i_d}{i_c} - \frac{RT}{nF}\ln\sum_{p=0}^{p=n}K_p[X]^p. \qquad (30)$$

In this equation $(E_{1/2})_c$ is the half-wave potential of the kinetic wave. Eqn.(30) is common to diffusion and kinetic waves for the reduction of complexes with formation of an amalgam in stepwise complex formation. It differs from the equation of De Ford and Hume only by the correction term $\ln(i_d/i_c)$, which corrects $E_{1/2}$ for the kinetic wave:

$$(E_{1/2})_d = (E_{1/2})_c - \frac{RT}{nF}\ln\frac{i_d}{i_c}.$$

When $i_c = i_d$, Eqn.(30) is transformed into the equation of De Ford and Hume.

7. Catalytic Waves

Yatsimirskii and Budarin[38–40] showed that the complex formation reaction can be identified and investigated from the decrease of the catalytic activity of metals in polarography. For example, molybdenum in acid solutions catalyses the reduction of hydrogen peroxide, but the introduction of phosphoric acid lowers the limiting current of the catalytic wave.

The catalytic activity of molybdenum is explained by the fact that the product of its interaction with hydrogen peroxide is reduced more readily than free hydrogen peroxide:

$$\begin{aligned} &H_2MoO_4 + H_2O_2 \rightleftarrows H_2MoO_5 + H_2O,\\ &H_2MoO_5 + 2\,H^+ + 2\,e \rightarrow H_2MoO_4 + H_2O. \end{aligned} \qquad (IV)$$

In the presence of phosphoric acid, the complex interacts with hydrogen peroxide:

$$H_2MoO_4 + H_3PO_4 \rightleftarrows MoO_2HPO_4 + 2\,H_2O, \qquad (V)$$

$$\begin{aligned} &MoO_2HPO_4 + H_2O_2 \rightleftarrows H_2O_2MoO_2HPO_4,\\ &H_2O_2MoO_2HPO_4 + 2\,e + 2\,H^+ \rightarrow MoO_2HPO_4 + 2\,H_2O, \end{aligned} \qquad (VI)$$

reaction (VI) being slower than reaction (IV). With increase of phosphoric acid concentration, the limiting current of the catalytic wave therefore diminishes, but not to zero, reaching a limiting value. Hence it follows that the complex $MnO_2.HPO_4$ also exhibits a catalytic activity, albeit smaller than that of free molybdic acid.

In the presence of a large excess of H_2O_2 and in the absence of H_3PO_4, we have

$$(i_c)_1 = A_1 c_{H_2O_2}[Mo].$$

In the presence of a sufficiently large excess of H_3PO_4 (for example 0.113 M at a hydrogen ion concentration of 0.444 M and an H_2MoO_4 concentration of 5.95×10^{-6} M), when the reduction of H_2O_2 is catalysed solely by the complex MoO_2. $.HPO_4$ (designated by convention as MoP), we have

$$(i_c)_2 = A_2 c_{H_2O_2}[MoP].$$

If the amount of phosphoric acid is insufficient to bind the entire molybdenum in a complex, then

$$i_c = c_{H_2O_2}(A_1[Mo] + A_2[MoP]).$$

Furthermore,

$$[MoP] = \alpha_1 c_{Mo},$$

$$[Mo] = (1-\alpha_1)c_{Mo}$$

where [Mo] and [MoP] are the equilibrium concentrations, c_{Mo} is the analytical concentration of H_2MoO_4, and α_1 is the fraction of complex formed:

$$i_c = c_{H_2O_2}c_{Mo}[\alpha_1 A_2 + (1-\alpha_1)A_1].$$

Hence

$$\alpha_1 = [(i_c)_1 - i_c]/[(i_c)_1 - (i_c)_2].$$

Having determined α_1, it is possible to calculate the equilibrium constant for reaction (V):

$$K = \alpha_1/(1-\alpha_1)(c_{H_3PO_4} - \alpha_1 c_{Mo}).$$

At still higher phosphoric acid concentration the catalytic wave again begins to fall and ultimately vanishes completely. This means that a more complex compound is produced:

$$MoO_2HPO_4 + H_3PO_4 \rightleftarrows H_4MoO_2(PO_4)_2,$$

which no longer exhibits a catalytic activity. By repeating the above reasoning, we obtain

$$\alpha_2 = [(i_c)_2 - i_c]/(i_c)_2.$$

In the general case, in the presence of stepwise complex formation, there should be a relation between the catalytic current and the ligand concentration[40]:

$$i_c = \frac{(i_c)_0 + (i_c)_1 K_1[X] + (i_c)_2 K_2[X]^2 + \ldots}{1 + K_1[X] + K_2[X]^2 + \ldots}, \quad (31)$$

where $(i_c)_0$ is the catalytic current and $[X] = 0$, $(i_c)_1$ and $(i_c)_2$, ... are the catalytic activities of the complexes MX_1, MX_2, ... The stability constants of the complexes and their catalytic activities can be determined from the relation between i_c and [X]. For this purpose, Eqn.(31) is transformed into an equation of the type

$$i_c = (i_c)_1 + \varphi_1/K_1 + [(i_c)_2 - i_c]\beta_2[X] + [(i_c)_3 - i_c]\beta_2\beta_3[X]^2 + \ldots$$

$$i_c = (i_c)_2 + \varphi_2/\beta_2 + [(i_c)_3 - i_c]\beta_3[X] + \ldots,$$

where β are successive stability constants:

$$\varphi_1 = [(i_c)_0 - i_c]/[X],$$

$$\varphi_2 = [(i_c)_0 - i_c]/K_1[X]^2 + [(i_c)_1 - i_c]/[X].$$

The quantities $(i_c)_1$ and K_1 can be determined graphically from the relation between i_c and ϕ_1 by extrapolation to $[X] \to 0$ and $(i_c)_2$ and β_2 can be determined from the relation between i_c and ϕ_2. $(i_c)_3$ and β_3 can be calculated analogously, etc. The quantities $(i_c)_1$, $(i_c)_2$, β_1, β_2, ... can also be found by another procedure. For this purpose, Eqn.(31) is transformed by substituting $y = [X]^{-1}$:

$$i_c = \frac{(i_c)_n K_n + (i_c)_{n-1} K_{n-1} y + (i_c)_{n-2} K_{n-2} y^2 + \ldots + (i_c)_0 y^n}{K_n + K_{n-1} y + K_{n-2} y^2 + \ldots + y^n}. \quad (32)$$

By extrapolating the relation between i_c and y to $y \to 0\{[X] \to \infty\}$, we find $(i_c)_n$.

Eqn.(32) can be put in the form

$$i_c = (i_c)_{n-1} + \psi_1\beta_n + [(i_c)_{n-2} - i_c]\frac{y}{\beta_{n-1}} + \ldots,$$

$$i_c = (i_c)_{n-2} + \psi_2\beta_{n-1}[(i_c)_{n-3} - i_c]\frac{y}{\beta_{n-2}} + \ldots,$$

where $\psi_1 = [(i_c)_n - i_c]/y$ and $\psi_2 = [(i_c)_{n-1} - i_c]/y - [i_c - (i_c)_n] \cdot \beta_n/y^2$. $(i_c)_{n-1}$ and β_n are determined graphically from the relation between i_c and ψ_1 and $(i_c)_{n-2}$ and β_{n-1} are found from the relation between i_c and ψ_2. All the quantities $(i_c)_i$ and β_i can be obtained similarly.

8. Determination of the Characteristics of the Complex from the Shift of the Ligand Wave

If the ligand, particularly an organic compound, is reduced more readily than the central metal ion, then inferences about complex formation can be drawn from the shift of the ligand wave. An equation has been derived[41] for the shift of the ligand wave subject to the condition that the ligand is reduced reversibly, that the complexes are dissociated rapidly, that metal ions are present in large excess, and that the ligand reduction product does not form complexes with the metal ions:

$$F_0([M]) = \text{antilg}\left(\frac{nF}{2.3RT}\Delta E_{1/2} - \lg\frac{(i_d)_c}{(i_d)_s}\right),$$

$$F_0([M]) = 1 + K_1[M] + K_{1/2}[M]^{1/2} + K_{1/3}[M]^{1/3} + \ldots.$$

In these equations $(i_d)_s$ and $(i_d)_c$ are the limiting currents of the ligand reduction waves in the absence of a metal ion and in its presence respectively and K_1, $K_{1/2}$, $K_{1/3}$, ... are the equilibrium constants of the complex formation reaction

$$X + pM \overset{K_p}{\rightleftarrows} M_pX.$$

($p = 1$, 1/2, 1/3, ...). The formation constants of the complexes are found by the graphical analysis of the relation between $\Delta E_{1/2}$ and [X] or by computational methods. This case is of limited applicability because only the 1:1 complex is formed as a rule in the presence of an excess of metal ions.

9. Organic Molecular Charge Transfer Complexes and Ionic Associated Species

The formation of organic molecular complexes and ionic associated species has been studied successfully by the polarographic method[42-45]. These phenomena are more distinctive in solvents with a low dielectric constant. Furthermore, the solvent must be aprotic in order that the reduction of the organic compound proceeds reversibly. The formation of molecular complexes was therefore studied in chloroform and methylene chloride.

Aromatic compounds are reduced reversibly in an aprotic medium:

$$A + e \rightleftarrows A^{\cdot-}.$$

The initial molecule A is a much stronger electron acceptor than the radical-anion $A^{\cdot-}$. After the addition of an electron donor, a complex is therefore formed with A and not with $A^{\cdot-}$ and the overall mechanism of the electrode process is as follows:

$$DA \overset{K}{\rightleftarrows} D + A \overset{e}{\rightleftarrows} D + A^{\cdot-}.$$

Complex formation shifts the wave of A in the cathodic direction and the composition and stability constant of the complex can be determined from the dependence of $E_{1/2}$ on the concentration of D either by calculation or graphically. The shift of the wave of the acceptor A can be due in principle not only to complex formation but also to a change in the potential of the liquid compound as well as a change in solvation. However, since experiment has shown that $E_{1/2}$ of the second wave of A does not change following the introduction of D, these effects must be insignificant. Studies have shown[44] that, in methylene chloride in the presence of 0.5 M $(C_4H_9)_4NClO_4$ as the supporting electrolyte, 2,3-dichloro-5,6-dicyanoquinone forms two complexes, 1:1 and 1:2, with hexamethylbenzene; 7,7',8,8'-tetracyanoquinodimethane also forms two complexes with pyrene. Only one complex is formed in each of the systems tetracyanoethylene/hexamethylbenzene, 7,7',8,8'-tetracyanoquinodimethane/hexamethylbenzene, chloranil/hexamethylbenzene, chloranil/pyrene, 1,2,4,5-tetracyanobenzene/hexamethylbenzene, and 1,2,4,5-tetracyanobenzene/pyrene. The stability constants as a rule differ significantly from the spectroscopic values. It has been noted in the literature that the spectroscopic determination of the equilibrium formation constants of charge-transfer

complexes is difficult, since the situation is complicated by the energy levels of the molecules of complex formation. In polarography this complication does not exist, since the acceptor molecule is reduced in a free state. It is therefore postulated that the stability constants of charge-transfer complexes found by the polarographic method are closer to the true values than the constant determined spectroscopically.

In aprotic solvents the radical-anions $A^{\cdot-}$, generated on reduction of the organic compound, interact with the counterions of the indifferent electrolyte, forming ionic associated species. As a result, the reduction wave shifts towards less negative potentials. Experiment shows[44] that the cations with a smaller crystallographic radius and with a larger charge are more effective. In dimethylformamide tetraalkylammonium cations do not interact with the radical-anions of quinones, while the anthraquinone radical-anion interacts with the lithium cation to form a 1:1 associated species having $K = 39$ litre mol^{-1}. Dianions interact with cations more strongly. For example, the anthraquinone dianion forms an associated species with three lithium ions. Very large effects are observed when polyvalent cations are introduced into the solution. Thus the addition of neodymium at a concentration of 0.002 M shifts the first wave of the quinone at a concentration of 0.003 M by 550 mV and the second wave by 950 mV (in acetonitrile). These equilibria have also been studied successfully by the polarographic method[44].

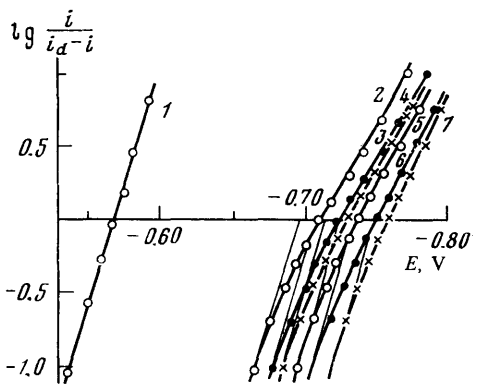

Figure 5. Logarithmic analysis of the waves of the Cd^{2+} ion and of its 2,2'-bipyridyl complex in aqueous solutions; molar concentration of 2,2'-bipyridyl: 1) 0; 2) 0.005; 3) 0.0063; 4) 0.00795; 5) 0.01; 6) 0.0126; 7) 0.02. Cd^{2+} concentration 1×10^{-4} M.[46]

10. The Influence of Adsorption

Organic ligands and complexes are adsorbed on mercury from aqueous solutions. It is therefore to be expected that the reduction waves of the complexes will in certain cases be complicated by the autoinhibition of the electrode process. Insufficient attention has been devoted to this problem in the literature. Autoinhibition is responsible for the additional shift of the wave of the complex in the cathodic direction and, if it is disregarded, the calculation leads to an unduly high stability constant of the complex. Autoinhibition is fully or partly eliminated by the addition of an organic solvent, since organic substances are adsorbed on mercury much less strongly from organic and mixed solvents. However, one should bear in mind that the addition of non-aqueous solvents influences the complex formation equilibrium.

If the autoinhibition phenomenon is not too pronounced, then in certain cases it is nevertheless possible to find the true stability constants. For example, the reduction wave of the trisbipyridylcadmium complex is only partly deformed and its lower part retains its original shape. The semilogarithmic plot of the wave is curved, but its lower part has a slope which approaches asymptotically the theoretical value $2.3RT/2F \cong 0.03$ V (Fig.5). This makes it possible to determine, by drawing tangents to the lower sections of the $\lg [i/(i_d - i)] - E$ plot, the values of $E_{1/2}$ unaltered by autoinhibition and to calculate the true stability constant[46]. A.c. measurements showed that 2,2'-bipyridyl exhibits a higher surface activity than its cadmium complexes. On this basis, it was concluded that the autoinhibition is due to the adsorption of free 2,2'-bipyridyl and the 2,2'-bipyridyl liberated on reduction of the complex[47].

Bond and Hefter observed[48] that the stability constants of the lead iodide and bromide complexes found by the polarographic method are significantly greater than the values obtained by other procedures. The authors suggested that, owing to the adsorption of the anions on mercury, the phenomenon of "additional complex formation" in the electrical double layer, where the ligand concentration is higher than in the bulk of the solution, is observed in this case. However, the experimental justification of this conclusion is open to objection. Thus it follows from a number of studies[49,50,51] that lead complexes and not free halide ions exhibit a higher surface activity in the Pb^{2+}/Br^- and Pb^{2+}/I^- systems. The additional complex formation effect could not therefore occur. It is more likely that the discrepancy between the stability constants observed by Bond and Hefter is in fact due to autoinhibition (the adsorption of the complex). It has been shown[52] that the phenomenon of "additional complex formation" postulated by Bond and Hefter is ruled out by its incompatibility with the thermodynamics of reversible processes.

III. IRREVERSIBLE ELECTRODE PROCESSES

In those cases where the criteria of reversibility enumerated in section II show that the reduction of the complex is irreversible overall, the use of the equations derived for reversible processes becomes impossible: the position of the wave is influenced not only by the equilibrium properties of the complexes but also by the kinetics of electrode processes. Kinetic analysis of irreversible waves yields very interesting information about the nature of the species which are reduced directly at the electrode[53-58]. This leads to the possibility of studying the relation between the reactivity of complexes and their structure.

Several approaches, permitting the study also of the equilibrium properties of complexes which are reduced irreversibly at the dropping mercury electrode, have been developed.

1. Determination of the Characteristics of the Complex from the Shift of the Half-Wave Potential

The principles of the study of the equilibria in the formation of complexes under conditions where the reduction is fully irreversible have been examined in detail[59]. Equations

have been derived for the current at any point in the polarographic wave and for the half-wave potential under the following conditions: (1) only mononuclear complexes are formed in solution; (2) the complex formation is rapid; (3) each complex can be reduced at the electrode independently with formation of an amalgam; (4) there is no specific adsorption in the experimental range of potentials.

The initial equation is that of the fully irreversible wave:

$$\frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} = \frac{0.886 k^0 \tau^{1/3}}{D^{1/3}} \exp\left[-\frac{\alpha n F}{RT}(E - E^0)\right]. \qquad (33)$$

where k^0 is the rate constant at the normal potential E^0, τ the drop time, and i_{irrev} the current at the potential E of the irreversible wave.

The rate of the process $\nu = kc$ is equal to the sum of the rates of reduction of each complex:

$$kc = k_0[\text{M}] + k_1[\text{MX}] + k_2[\text{MX}_2] + \ \ldots\ + k_n[\text{MX}_n],$$

whence, taking into account the complex formation equilibria, we have

$$k = \frac{k_0 + k_1 K_1 [\text{X}] + k_2 K_2 [\text{X}]^2 + \ \ldots\ + k_n K_n [\text{X}]^n}{1 + K_1 [\text{X}] + K_2 [\text{X}]^2 + \ \ldots\ + K_n [\text{X}]^n}.$$

Since

$$k_p = k_p^0 \exp\left[-\frac{\alpha_p n F}{RT}(E - E^0)\right],$$

it follows that

$$k = \frac{\sum_{p=0}^{p=n} k_p^0 K_p [\text{X}]^p \exp\left[-\frac{\alpha_p n F}{RT}(E - E^0)\right]}{\sum_{p=0}^{p=n} K_p [\text{X}]^p}.$$

On substituting the expression for k in the initial Eqn.(33), we obtain

$$\frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} = 0.886 \left(\frac{\tau}{D_c}\right)^{1/3} \frac{\sum_{p=0}^{p=n} k_p^0 K_p [\text{X}]^p \exp\left[-\frac{\alpha_p n F}{RT}(E - E^0)\right]}{\sum_{p=0}^{p=n} K_p [\text{X}]^p}, \qquad (34)$$

where D_c is the average diffusion coefficient of the complex.

The partial derivatives A, B, and C can be used conveniently for the analysis of experimental data:

$$A = \left(\frac{\partial}{\partial E} \ln \frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}}\right)_{[\text{X}]=\text{const}} = -\frac{\alpha n F}{RT},$$

where α is the average transfer coefficient. If the number of electrons is known (and this is frequently the case), α can be found from the derivative A. This quantity is useful for the elucidation of the mechanism of the electrode process: if it is independent of E and [X], then, on changing the ligand concentration and the potential along the wave, the mechanism remains unaltered, i.e. the same species is reduced, and the calculations are simplified. On the other hand, if α does depend on E, the implication is that two reactions with different α take place at the electrode.

The derivative B is of the form

$$B = \left(\partial \frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} \Big/ \partial \ln [\text{X}]\right)_{E=\text{const}} = p_{\text{el}} - p,$$

where p_{el} is the average coordination number of the complexes being reduced and p is the average coordination number of the complexes formed in solution. If the difference $p - p_{\text{el}}$ for the maximum [X] is equal to the maximum coordination number for the given cation, then free cations are reduced at the electrode. At any rate, if p can be found independently, it is possible to discover from the derivative B which complex is reduced at the electrode.

The derivative C is

$$C = -\left(\frac{\partial E}{\partial \ln [\text{X}]}\right)_{i_{\text{irrev}}=\text{const}} = p - p_{\text{el}}.$$

If the difference $p - p_{\text{el}}$ over a range of values of [X] remains constant, then presumably only one complex predominates in solution and only one complex is reduced.

The overall equation of the wave for the fully irreversible reduction of the complexes is extremely involved. However, in reality frequently simpler cases are encountered where only one of the species involved in the equilibrium is reduced at the electrode.

If it has been established by studying A, B, and C that free cations are reduced at the electrode, then Eqn.(34) simplifies:

$$\frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} = 0.886 \left(\frac{\tau}{D_c}\right)^{1/3} k_0^0 \frac{\exp\left[-\frac{\alpha n F}{RT}(E - E^0)\right]}{\sum_{p=0}^{p=n} K_p [\text{X}]^p}.$$

Hence

$$(E_{1/3})_c = E^0 + \frac{RT}{\alpha n F} \ln\left(0.886 \left(\frac{\tau}{D_c}\right)^{1/3} k_0^0\right) - \frac{RT}{\alpha n F} \ln \sum_{p=0}^{p=n} K_p [\text{X}]^p,$$

$$(E_{1/3})_s - (E_{1/3})_c = \Delta E_{1/3} = \frac{RT}{\alpha n F} \ln \sum_{p=0}^{p=n} K_p [\text{X}]^p - \frac{RT}{\alpha n F} \ln \frac{(i_d)_s}{(i_d)_c}.$$

This expression is similar to the equation for $\Delta E_{1/2}$ in the case of the reversible reduction of complexes and can be analysed in exactly the same way, i.e. by the graphical De Ford and Hume analysis, by computational methods, or by the method based on the Yatsimirskii logarithmic plot.

On the other hand, if the analysis of the derivatives A, B, and C shows that one of the complexes MX_i and not free cations, is reduced, then Eqn.(34) becomes

$$\frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} = 0.886 \left(\frac{\tau}{D_c}\right)^{1/3} k_i^0 \frac{\exp\left[-\frac{\alpha_i n F}{RT}(E - E^0)\right]}{\sum_{0}^{n} K_j K_i^{-1} [\text{X}]^{(j-i)}}. \qquad (35)$$

The sum in Eqn.(35) is of the following form:

$$\sum_{0}^{n} \frac{K_j}{K_i} [\text{X}]^{(j-i)} = \frac{1}{\beta_1 \beta_2 \ \ldots\ \beta_i [\text{X}]} + \frac{1}{\beta_2 \beta_3 \ \ldots\ \beta_i [\text{X}]^{(i-1)}} + \ \ldots\ +$$

$$+ \frac{1}{\beta_i [\text{X}]} + 1 + \beta_{i+1} [\text{X}] + \beta_{i+1}\beta_{i+2} [\text{X}]^2 + \ \ldots\ + \beta_{i+1}\beta_{i+2} \ \ldots\ \beta_{n-1} [\text{X}]^{(n-i)},$$

where β_i are the successive stability constants of the complexes. The sum can be significantly simplified by making the reasonable assumption that the concentrations of complexes simpler than the complex MX_i being reduced at the electrode are negligible. Then

$$\frac{i_{\text{irrev}}}{i_d - i_{\text{irrev}}} = 0.886 \left(\frac{\tau}{D_c}\right)^{1/3} k_i^0 \frac{\exp\left[-\frac{\alpha n F}{RT}(E - E^0)\right]}{\sum_{i}^{n} [\text{X}]^{(j-i)} \prod_{i+1}^{j} \beta_m},$$

$$(E_{1/3})_c = E_i^0 + \frac{RT}{\alpha n F} \ln\left(0.886 \left(\frac{\tau}{D_c}\right)^{1/3} k_i^0\right) - \frac{RT}{\alpha n F} \ln \sum_{i}^{n} [\text{X}]^{(j-i)} \prod_{i+1}^{n} \beta_m$$

and

$$\Delta E_{1/3} = \frac{RT}{\alpha n F} \ln \sum_{i}^{n} [\text{X}]^{(j-i)} \prod_{i+1}^{j} \beta_m - \frac{RT}{\alpha n F} \ln \frac{(i_d)_i}{(i_d)_c}. \qquad (36)$$

Eqn.(36) can be solved particularly simply if the difference between the maximum coordination number and the coordination number of the complex being reduced $(n - i)$ does not exceed 2 {in this case the dependence of $\Delta E_{1/2}$ on ln [X] is linear}. When a mixture of complexes with $(n - i) > 2$ is present in solution, the logarithmic plot method can be used.

2. The Study of Complex Formation on the Basis of Limiting Diffusion Currents

The limiting diffusion current is the second source of information about complex formation in classical polarography. In fact, complex formation leads to a significant change in the size of the species; one must then bear in mind not only the dimensions of the central ions and the ligands but also those of the solvation shell around the complex species. This alters the diffusion coefficient of the species. The dependence of the limiting current on the ligand concentration is frequently of the expected type and can be used to determine the stability constants of the complexes[60,61]. Thus, when only one complex MX_1 is formed in solution, the average diffusion coefficient D is

$$D = (D_M + D_{MX}K_{MX}[X])/(1 + K_{MX}[X]).$$

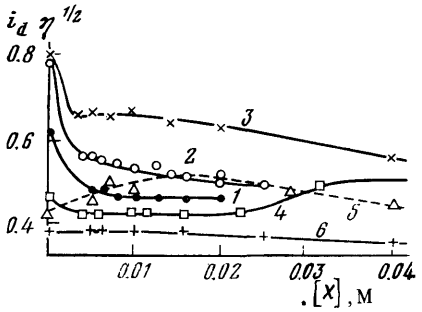

Figure 6. Dependence of the Cd^{2+} limiting current corrected for the viscosity of the medium ($i_d\eta^{1/2}$) on the 2,2'-bipyridyl concentration; ethanol content (vol.%): 1) 0; 2) 20; 3) 40; 4) 60; 5) 80; 6) ~100.[46]

The average diffusion coefficient is determined from the limiting current at the given ligand concentration, the diffusion coefficient of the free metal ions D_M can be found from the limiting current in the absence of the ligand, and the diffusion coefficient of the complex D_{MX} can be found from the limiting current in the presence of a large excess of the ligand, whereupon virtually only one complex is present in solution. The transition from the case involving the formation of only one complex to the more general case of stepwise complex formation does not give rise to fundamental difficulties.

The use of limiting diffusion currents for the calculation of equilibrium constants has an advantage over methods based on the measurement of half-wave potentials, which consists in the fact that it is applicable to all processes regardless of their reversibility. Instances of the successful application of this method in the study of the equilibria in the formation of ionic associated species have been described in a review[12].

However, when calculations based on limiting diffusion currents are used, caution must be exercised because there are frequent instances of anomalous relations between the diffusion coefficients and the ligand concentration. For example, an unusual type of influence of the ligand concentration has been observed in the Cd^{2+}–2,2'-bipyridyl system in a mixed aqueous alcoholic solvent (Fig.6) and the employment of the given method becomes difficult[46].

3. The Indicator Method

An indicator method has been proposed[62] for the determination of the stability constants, which is suitable when the complex is reduced irreversibly or is altogether electrochemically inactive. Its essential feature is as follows. One selects an indicator ion whose complexes with the given ligand are reduced reversibly and at less negative potentials than the complex investigated. The dependence of $E_{1/2}$ for the indicator ion on the ligand concentration is plotted on the basis of experimental or calculated (if the stability constants are known) data, and then the test cation is introduced into the solution and the change in $E_{1/2}$ for the indicator ion, occurring as a result of the formation of a complex by the test ion with the given ligand, is measured. The concentration of the free ligand is found from the plot of $E_{1/2} = f\{[X]\}$ for the indicator ion. Knowing the equilibrium concentration of the ligand [X] and the analytical concentrations of the ligand (c_X) and the test metal (c_M), it is possible to calculate the formation function for the given metal at the half-wave potential:

$$\bar{n} = \left(c_X - [X] - \frac{1}{2} n_i c_i\right) / c_M,$$

where $\bar{n}_i$ is the formation function of the indicator ion and c_i the analytical concentration of the latter. The stability constants can be determined from the formation functions of the test ion by the Bjerrum or Fronaeus methods[20]. The indicator ion method has been frequently tested[61,63,64].

---o0o---

Thus, a survey of the literature shows that a wide variety of problems, associated with the equilibria in the formation of complexes and ionic associated species in solution, can be studied by the method of classical polarography virtually without limitations arising from the complexity of the equilibria and the reversibility of the electrode processes. One must note that many relations derived for classical polarography are applicable (without modifications or with certain non-fundamental changes) also when other varieties of polarography are used (oscillographic and a.c. polarography, chronopotentiometry, etc.)[12].

The Volumes of Mixing of Liquids and Their Importance for the Modern Theory of Solutions

A.A.Tager and L.V.Adamova

The results of studies on volumes of mixing in liquid-liquid systems and in polymer solutions are surveyed and the causes of the volume change and its influence on the thermodynamic parameters of dissolution are examined.
The bibliography includes 131 references

I. GENERAL IDEAS CONCERNING THE INFLUENCE ON THERMODYNAMIC PARAMETERS OF THE VOLUME CHANGE ON MIXING

The first studies on the volumes of mixing of liquids were carried out by Mendeleev[1,2] whose doctoral thesis was devoted to proving the fundamental postulates of his theory of solutions, particularly his ideas concerning the volume change on mixing the components. Subsequently many related data were obtained, which, however, did not receive due attention, since the volumes of mixing are small and it was believed possible to neglect them. All the theories of solutions (Hildebrand's theory of regular solutions, Guggenheim's theory of strictly regular solutions, etc.) were therefore based on the assumption that the volume is constant on dissolution. Theoretical internal energies of mixing (ΔU) were set equal to the enthalpy of mixing (ΔH). For example, the widely familiar Scatchard–Hildebrand equation was obtained on this basis[3]:

$$\Delta U=\Delta H=V(\delta_1-\delta_2)^2\varphi_1\varphi_2, \qquad (1)$$

where V is the volume of the solution, ϕ_1 and ϕ_2 are the volume fractions of the components of the solution, and δ_1 and δ_2 are the solubility parameters of the components equal to the square roots of the densities of their cohesion energies (DCE): $\delta=(\Delta E/V)^{1/2}$.

According to Eqns(1), dissolution can only be an endothermic process ($\Delta H>0$) and, when their values of δ are equal, the components should mix with a zero heat change. In reality neither the first nor the second postulate are valid. One of the causes of this is the volume change on mixing; the magnitude and sign of which have a significant influence on the thermodyanmic parameters. This can be readily shown using the equation of state[4]

$$\left(\frac{\partial U}{\partial V}\right)_T=-p+T\left(\frac{\partial p}{\partial T}\right)_V. \qquad (2)$$

On substituting Eqn.(2) in the expression

$$(\Delta H^m)_p=(\Delta U)_p+p(\Delta V^m)_p, \qquad (3)$$

we obtain

$$(\Delta H^m)_p=(\Delta U^m)_V+T\left(\frac{\partial p}{\partial T}\right)_V\cdot(\Delta V^m)_p. \qquad (4)$$

The derivative $(\partial U/\partial V)_T\equiv p$ is the internal pressure in the liquid or a real gas, which depends on the extent of the intermolecular interaction. The pressure p_i amounts to ~3500 atm for not unduly polar organic liquids, 12000 atm for water, and ~40000 atm for mercury[5]. The derivative $(\partial p/\partial T)_V\equiv\gamma$ is the temperature coefficient of pressure, related to the isothermal compressibility β_T and the coefficient of thermal expansion α_p by the expression

$$\gamma=\alpha_p/\beta_T. \qquad (5)$$

For liquids, γ varies from 10 to 14 atm K^{-1}. Consequently, even if the volume change on dissolution $(\Delta V^m)_p$ is indeed very small, the second term in Eqns.(4) is $(\Delta V^m)_p\times 3000$ (atm cm^3) (at room temperature) and makes a considerable contribution to $(\Delta H^m)_p$. $(\Delta U^m)_V$, which is calculated theoretically or determined experimentally at constant volume, can therefore differ significantly from the value of $(\Delta H^m)_p$ determined at constant pressure. For example, $(\Delta V^m)_p=0.65$ cm^3, $(\Delta H^m)_p=182$ cal, and $(\Delta U^m)_V=131$ cal for the benzene–cyclohexane system containing 0.5 mole of each component[6].

The entropies of mixing measured at constant volume and pressure also differ[4]. They are linked by the relation

$$T(\Delta S^m)_p=T(\Delta S^m)_V+T\left(\frac{\partial p}{\partial T}\right)_V(\Delta V^m)_p. \qquad (6)$$

Negative enthalpies or heats of mixing are frequently due to the negative sign of $(\Delta V^m)_p$, i.e. the decrease of volume on dissolution.

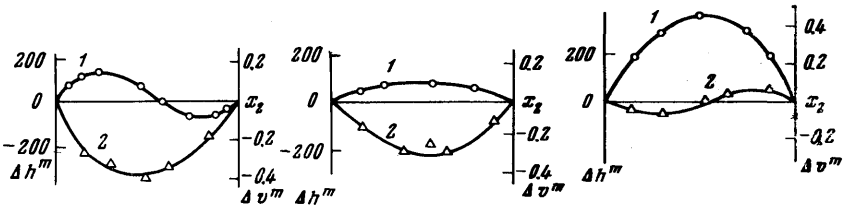

Figure 1. Dependence of the enthalpies Δh^m (curves *1*) and average volumes Δv^m (curves *2*) of mixing on the mole fraction of the second component x_2 for different systems: *a*) acetone–isopropyl alcohol; *b*) isopropyl alcohol–propionitrile; *c*) ethanol–acetonitrile[19].

The volume change observed on mixing liquids is the cause of the lower consolute temperature (LCT) of a special type, discovered by Rowlinson[7,8] for solutions of components with a similar chemical structure but differing in molecular size. Systems such as dodecane–ethane and n-hexadecane–n-hexane split into separate layers on heating to temperatures greatly exceeding the boiling point of the more volatile component. This type of LCT is characteristic of polymer solutions, since in this case the difference between the molecular sizes of the components is particularly marked[8]. The mechanism of layer formation in polymeric systems will be examined below.

Thus the volume change on dissolution or mixing plays an extremely great role. This is understandable, because negligible changes in distances between molecules can be the cause of enormous changes in the interaction energy, which is inversely proportional to the sixth power of the distance. In recent years there has therefore been a sharp growth of interest in measurements of the volume changes on mixing low-molecular-weigth liquids and on dissolution of polymers.

II. VOLUMES OF MIXING AND THE FREE VOLUME

The volume change on mixing substances is a consequence of the change in the free volume, since the intrinsic volume of the molecules hardly changes. The free volume is understood as the volume unoccupied by the intrinsic volume of the molecules of the given substance. We believe that it can be defined most correctly, as suggested by Hildebrand[9] and by Bondi[10], as the difference between the volume of one mole of the substance measured at a given temperature (V_T) and the intrinsic volume of the molecules contained in one mole (V_W):

$$V_E = V_T - V_w. \qquad (7)$$

The volume V_W is calculated as the sum of the volumes of the constituent atoms of the molecule and atomic groups taking into account the overlap of the shells of the atoms involved in the chemical bond. A scheme for such a calculation has been described[11] and the same communication contains tabulated volume increments, i.e. the volumes of different atomic groups. Hildebrand[9] calls the free volume calculated by Eqn.(7) the "empty volume" or the volume of vacancies V_E. Frenkel[12] proposed another method of calculating the free volume—as the difference between the volume of a body at a given temperature V_T and its volume V_0 at 0 K (on the assumption of maximum close packing):

$$V_f = V_T - V_0. \qquad (8)$$

The volume V_f calculated by Eqn.(8), which according to Hildebrand represents the "volume of expansion", differs from the values of V_E calculated by Eqn.(7).

According to modern ideas, the change in free volume on mixing liquids or on dissolution of solids can be due to three causes: (1) the difference in the cohesion energy between the molecules of the components; (2) the difference between the molecular sizes; (3) the differences between the molecular shapes. The latter two factors are referred to as geometrical. Attention to their role was first drawn by Mendeleev, who wrote that processes similar to the mixing of grains or spheres of different dimensions can occur on dissolution: "the smaller grains or spheres are accommodated in the gaps between the large spheres in a certain manner and the decrease in volume can then be readily demonstrated"[2].

The overall volume change observed on dissolution is represented by the sum of two components[13,14]:

$$\Delta V^m_{tot} = \Delta V^m_{inter} + \Delta V^m_{geom}$$

(ΔV^m_{inter} is the volume change due to the first cause).

III. THE VOLUME CHANGE ON MIXING LIQUIDS

The available data on the volumes of mixing for 800 liquid–liquid systems have been arranged systematically[15]. The Table compiled by the authors shows that only 20 systems are formed without a volume change (i.e. $\Delta v^m = 0$)†. These are systems whose components have both similar chemical structures and similar molecular sizes and shapes (the toluene–xylene, o-xylene–p-xylene, etc. systems). For the vast majority of two-component systems, $\Delta v^m \neq 0$. The volume changes can differ by three orders of magnitude (from 0.002 $cm^3\ mol^{-1}$ for the benzene–carbon tetrachloride system to 2.23 $cm^3\ mol^{-1}$ for a solution of triethylamine in methanol) and can have different signs.

It was assumed initially that the volume change on dissolution is caused only by the difference between the cohesion energies of the components. Thus, if the cohesion energy between unlike molecules $2\varepsilon_{12}$ is greater than between like molecules ($\varepsilon_{11} + \varepsilon_{22}$), unlike molecules should be attracted more strongly to one another, which should lead to a decrease of the volume (i.e. $\Delta v^m < 0$). Conversely, if the cohesion energy between like molecules is greater than

† Average thermodynamic parameters are normally employed when solutions are considered: the average molar enthalpy of mixing $\Delta h^m = \Delta H^m/(n_1 + n_2)$ and the average molar volume of mixing $\Delta v^m = \Delta V^m/(n_1 + n_2)$, where n_1 and n_2 are the numbers of moles of the components in the solution.

between unlike molecules, the molecules should be at greater distances in solution than in the pure substances, which should entail an expansion on dissolution ($\Delta v^m > 0$). At the same time, there may be a change in the internal energy of the system:

$$-\Delta u^m \simeq K[-\varepsilon_{11}-\varepsilon_{22}+2\varepsilon_{12}];$$
$$\text{if } |2\varepsilon_{12}| > |\varepsilon_{11}+\varepsilon_{22}|, \text{ then } \Delta u^m < 0;$$
$$\text{if } |2\varepsilon_{12}| < |\varepsilon_{11}+\varepsilon_{22}|, \text{ then } \Delta u^m > 0 .$$

Consequently, the signs of Δu^m and Δv^m should be identical.

Since $\Delta h^m = \Delta u^m + P\Delta v^m$, it was assumed that the signs of the heats and volumes of mixing should be identical, i.e. that contraction corresponds to exothermic mixing and expansion corresponds to endothermic mixing[2,16-18].

It has been shown[19] that this is not the case. There are data (Fig.1) demonstrating that the difference between the cohesion energies of the components is not the only cause of the volume change on dissolution; it is determined also by geometrical factors. The role of the latter was demonstrated in relation to a number of systems. Thus Marsh[20-22] used octamethylcyclotetrasiloxane as a model substance with large spherical molecules and benzene and carbon tetrachloride as substances with small molecules. Endothermic mixing and contraction, which in this case is a result solely of greater close packing, were observed for these systems.

The role of the geometrical factor in a "pure" form is manifested clearly in systems where the molecules have identical chemical structures but different dimensions, for example, in solutions of normal alkanes. The mixing of alkanes at room temperature is accompanied by the absorption of heat, which is greater the greater the difference between the molecular sizes of the mixed components[23,24]. On the basis of this experimental fact, Brønsted[25] formulated the principle of congruence, expressed by the equation

$$\Delta h^m = B(n_1-n_2)^2 x_1 x_2, \qquad (9)$$

where x_1 and x_2 are the mole fractions of the components in the solution, n_1 and n_2 are the numbers of carbon atoms in the molecules of n-alkanes, and B is a constant.

Table 1. The average energies (Δu^m, cal mol^{-1}), volumes (Δv^m, cm^3 mol^{-1}), and enthalpies (Δh^m, cal mol^{-1}) of mixing for mixtures of cyclic hydrocarbons[33].

System	Δu^m	Δv^m	Δh^m
Cycloheptane–cyclooctane	1.7	−0.03	−0.7
Cyclopentane–cyclohexane	3.1	0.042	6.2
Cyclohexane–cycloheptane	4.3	−0.034	1.7
Cyclopentane–cycloheptane	6.9	−0.102	−0.4
Cyclohexane–cyclooctane	12.0	−0.128	1.7
Cyclopentane–cyclooctane	13.2	−0.30	−10.1

If only cohesion energies were concerned, then expansion might be expected on mixing n-alkanes. In reality, the mixing of n-alkanes is accompanied by contraction, which is greater the greater the difference between the molecular sizes of the mixed components[26-30], as illustrated in Fig.2. Consequently, for mixtures of alkanes, $\Delta h^m > 0$ and $\Delta v^m < 0$. The ratio of these quantities is such that the internal energy of mixing, calculated from the equation $\Delta h^m = \Delta u^m + P\Delta v^m$, is always positive, i.e. the internal energy of the systems increases on mixing alkanes[24]. The positive value of Δu^m in such systems is due to the fact that the main type of interaction between the components is dispersion interaction, which is additive with respect to the length of chain molecules. The cohesion energy increses in the homologous series of n-alkanes, while the energy of contact between unlike molecules $2\varepsilon_{12}$ is smaller than for like molecules ($\varepsilon_{11} + \varepsilon_{22}$). The contraction in such systems is caused solely by geometrical factors; however, at room temperature, it is not large enough to alter the sign of the heat of solution, i.e. the Δu^m and Δh^m are positive.

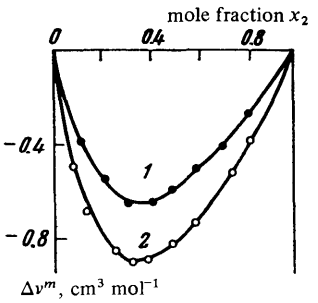

Figure 2. The average volumes of mixing Δv^m in different systems: 1) n-hexane–n-hexadecane; 2) n-pentane–n-hexadecane[26].

Positive internal energies of mixing and negative volumes of mixing are observed also on mixing cyclic hydrocarbons[33,34] (Table 1). Consequently, in this case the contraction is also due to geometrical causes. Thus, when two adjacent homologues are mixed, Δu^m is comparatively small, but increases with increase of the difference between the numbers of carbon atoms in the hydrocarbon molecule; under these conditions, there is as a rule an increase in the extent of contraction. The cyclopentane–cyclohexane system, whose formation involves expansion, constitutes an exception. However, the ratio of the absolute values of Δu^m and Δv^m is such that the signs of the Δh^m for these systems are different and it is very difficult to discover any kind of regularity.

The role of the geometrical factor is manifested also on mixing liquids between the molecules of which a dipole–dipole interaction takes place in addition to the dispersion interaction. This was demonstrated very clearly by Meares[35] in a study of the volumes and heats of mixing of two isomeric diesters: butylene diacetate (BDA) and diethyl succinate, the molecules of which are in essence dimers of ethyl acetate. The methylene group CH_2 and the oxygen atom have the same numbers of electrons in the outer orbital. The dispersion interaction in each contact between the molecules of these two diesters is therefore the same. They exhibit the same dipole–dipole interactions and their molecules have the same dimensions. The diesters therefore mix athermally and without a volume change. The heat of mixing of each with ethyl acetate is also zero, but there is a contraction due to the difference between the sizes of the mixed molecules.

All these findings show that, when systems having similar chemical structures but differing in molecular size are mixed, contraction is observed ($\Delta v^m < 0$), while $\Delta h^m \geqslant 0$. Thus the mixing of acetone with acetylacetone and acetonylacetone is accompaned by the absorption of heat and contraction[36] (Fig.3). In all these cases the contraction is due to purely geometrical factors.

When substances differing in chemical structure are mixed, the signs of the enthalpies and volumes of mixing are as a rule the same. Thus the mixing of alkanes with aliphatic ethers is accompanied by the absorption of heat and expansion, the values of which increase with increasing length of the hydrocarbon molecule or group[37]. The absorption of heat and expansion are also observed when carbon tetrachloride is mixed with chloroform and chlorobenzene and when n-hexane is mixed with acetone[23,38,39]. In all the systems enumerated, one of the components is more polar than the other and the energy expended on the rupture of bonds between the dipoles exceeds the energy gain due to the greater cohesion energy between unlike molecules. As a result, the internal energy of the system increases and the process is at the same time accompanied by expansion ($\Delta h^m > 0$ and $\Delta v^m > 0$).

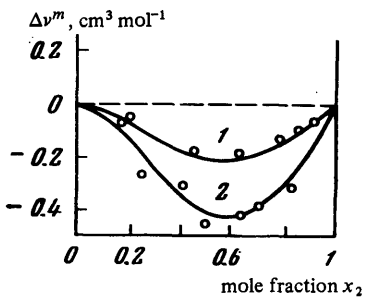

Figure 3. The average volumes of mixing Δv^m in different systems: 1) acetone–acetylacetone; 2) acetone–acetonylacetone[36].

More complex relations are observed for systems where there is a possibility of the formation of solvated complexes via hydrogen bonding or the interaction of π electrons. Systems in which hydrogen bonds can be formed can be divided into four groups in accordance with the classification of Belousov and Morachevskii[23], which is the same as the classification of Pimentel and McClellan[40].

1. Systems in which only one component tends to form hydrogen bonds (mixtures of alcohols, acids, and amines with straight-chain hydrocarbons and CCl_4). Endothermic heat changes are characteristic of such systems, because the decisive process in the formation of the solution is the rupture of hydrogen bonds between the molecules of the polar component. However, the volumes of mixing can have different signs. Thus the dissolution of straight-chain alcohols in straight-chain hydrocarbons is accompanied by expansion caused by the smaller cohesion energy between unlike molecules compared with like molecules. This is seen particularly clearly when an alcohol and a hydrocarbon having molecules of the same size are mixed. In this case the role of the geometrical factor is reduced to a minimum and the effect is determined solely by the difference between the cohesion energies, so that $\Delta h^m > 0$ and $\Delta v^m > 0$.[41,42]

If unlike molecules differ not only in chemical structure but also in shape, the geometrical factor again becomes decisive: contraction accompanies the mixing of alcohols and amines with carbon tetrachloride despite the fact that $\Delta h^m > 0$.[43–46]

2. Systems in which one of the components contains only proton-donating and the other only proton-accepting groups, i.e. hydrogen bonds can arise only between unlike molecules. These are solutions of ketones, aldehydes, and tertiary amines in chloroform and similar compounds. They are always formed exothermically ($\Delta h^m < 0$) and as a rule with contraction[15,23,47]. However, there are also exceptions. Thus the exothermic mixing of chloroform with methyl acetate is accompanied by expansion. In this case the geometrical factor again plays a dominant role: the chloroform molecule apparently cannot form a sufficiently close-packed structure with methyl acetate molecules ($\Delta V^m_{geom} > 0$, $\Delta V^m_{inter} < 0$, $\Delta V^m_{tot} > 0$).

3. Systems where one component contains simultaneously proton-donating and proton-accepting groups (acids, alcohols, water, and secondary amines) while the other contains only groups of one of these types (acetone, chloroform, etc.). In such systems the dissociation of the hydrogen bonds between like molecules can be partly or completely compensated by the formation of new hydrogen bonds between molecules of different kinds. The signs of the heat changes can therefore be different and can vary with the composition of the solution. The volume changes are also complex. For example, the mixing of straight-chain alcohols with acetone is accompanied by the absorption of heat due to the disruption of the alcohol structure, but this is accompanied by contraction and not expansion. Consequently $|\Delta V^m_{geom}| > |\Delta V^m_{inter}|$. When alcohols are mixed with chloroform, Δh^m changes sign as the solution composition is varied and over a large range of compositions exothermic mixing accompanied by expansion is observed[48].

4. Systems in which both components contain both proton-donating and proton-accepting groups. These are mixtures of alcohols with one another and mixtures of alcohols with acids and amines. When such substances are mixed, the size of the alkyl group plays the main role. The larger the group, the greater the dispersion interaction energy and properties characteristic of alkanes are manifested. Alcohols therefore mix with one another with absorption of heat, like n-alkanes. However, in contrast to mixtures of n-alkanes, expansion takes place in this instance, i.e. the interaction effect predominates over the geometrical factor ($\Delta V^m_{inter} > 0$ and $|\Delta V^m_{inter}| > |\Delta V^m_{geom}|$). The expansion is greater the greater the difference between the molecular sizes of the alcohols[49].

Aqueous solutions are of special interest. Water molecules are known to be capable of forming a three-dimensional network of hydrogen bonds, as a result of which water has a fairly distinct tetrahedral structure[50] with large cavities which can be penetrated by the molecules of other components. The dissolution of most substances in water is therefore accompanied by contraction[15]. This applies to aqueous solutions of alcohols, acetone, and even hydrocarbons. The mixing of water with methanol and ethanol is accompanied by the evolution of much heat and a marked contraction[51,52]. Evidently, in this case both $\Delta V^m_{inter} < 0$ and $\Delta V^m_{geom} < 0$. With increase in the size of the alkyl group, the exothermic effect and the degree of contraction diminish: 1-butanol is partially miscible with water and the mixing process is accompanied by the absorption of heat but there is again contraction, as in the mixing of water with alcohols having longer molecules[15]. The dominant role of the geometrical factor is manifested once more.

In all the previous examples the evolution of heat (decrease of enthalpy) was caused either by the greater interaction energy between unlike molecules or by the greater degree of contraction. A different situation arises when n-alkanes interact with water. They dissolve in water in very small

amounts and the process is accompanied by the evolution of heat and contraction, which is caused by the formation of very small crystalline clusters of water around hydrocarbon molecules[53,54] (so called hydrophobic bonds) and not by a strong interaction between unlike molecules.

In conclusion we shall consider solutions whose components are aromatic substances capable of strong donor–acceptor interactions involving the π electrons of the benzene ring. Aromatic compounds are self associated liquids and the energy expended on the disruption of these associated species on dissolution in straight-chain hydrocarbons is not compensated. The mixing of aromatic hydrocarbons with aliphatic and alicyclic hydrocarbons and with one another is usually accompanied by expansion and the absorption of heat[55–58]. This is observed even in a system such as benzene–toluene[58], which is frequently classified as ideal. However, $\Delta v^m = 0.35$ cm^3 mole^{-1} and $\Delta h^m = 15$ cal mol^{-1} for this system. A typical plot of the concentration dependence of Δh^m and Δv^m for mixutres of aromatic hydrocarbons is illustrated in Fig.4. However, the mixing with benzene of aromatic hydrocarbons which are elongated is accompanied by contraction. For example, there is a zero heat change in the mixing of benzene and bibenzyl and the process involves contraction[15,23]; the geometrical factor again plays the main role.

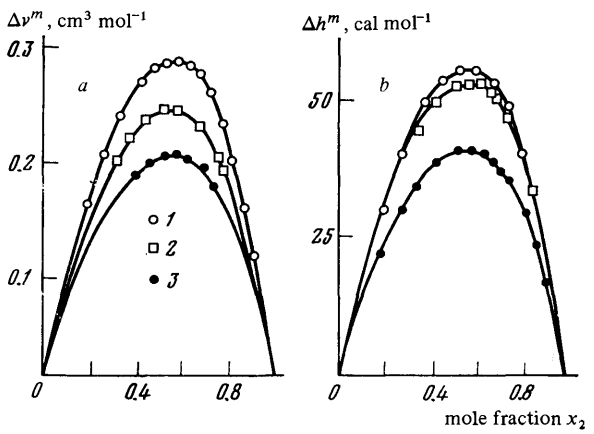

Figure 4. The average volumes Δv^m (*a*) and enthalpies Δh^m (*b*) of mixing for benzene–isomeric xylenes systems[55]: 1) *m*-xylene; 2) *o*-xylene; 3) *p*-xylene.

When benzene dissolves in carbon tetrachloride, the enthalpy and volume of mixing are positive and increase with temperature: $\partial \Delta h^m/\partial T > 0$ and $\partial \Delta v^m/\partial T > 0$ (Fig.5), which is attributed[59] to the formation of a compound at 239 K due to the interaction of the π electrons of the benzene ring and the vacant *d* levels of the chlorine atoms in the CCl_4 molecule, this compound dissociating on increase of temperature.

When aromatic hydrocarbons are mixed with substances whose molecules contain polar groups, complexes may be formed due to the interaction of the π electrons of the aromatic rings with the proton-donating groups. For this reason, these complexes are also not very stable at normal temperatures and the interaction between unlike molecules is weaker than between like molecules. The mixing of benzene with ethyl acetate is therefore accompanied by the absorption of heat and expansion, although these effects are much smaller than for solutions of ethyl acetate in n-alkanes[37]. The positive enthalpies of mixing are reduced still more in the benzene–ethyl benzoate system owing to the interaction between the aromatic rings of the components, the mixing process being accompanied by contraction.

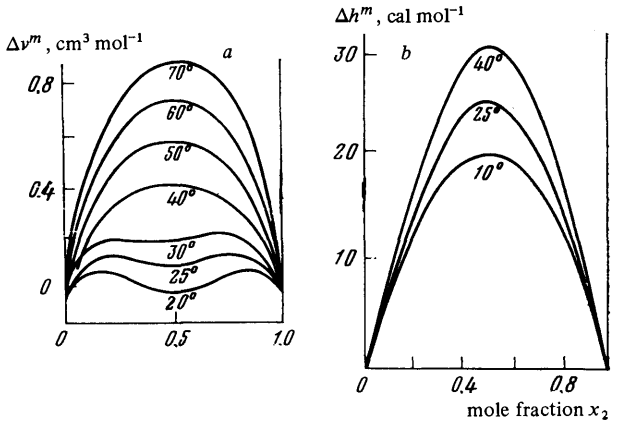

Figure 5. The ratios of the volumes of the solutions V^m to the sums of the volumes of the components V^0 (*a*)[59] and the average enthalpies of mixing Δh^m (*b*)[60] for the benzene–carbon tetrachloride system at different temperatures.

The presence of methyl substituents in the ring, which enhances the electron-donating capacity of the aromatic compound and gives rise to a dipole moment, is responsible for the possibility of additional interactions in solution. The mixing of ethyl benzoate with toluene is therefore less endothermic and involves a greater degree of contraction than the mixing with benzene[37].

The volumes and heats of mixing of aromatic hydrocarbons with aromatic amines have been measured in a series of studies[61–66]. For the majority of the compounds investigated, the signs of the excess volumes and heats are positive. According to the authors, this means that the energy expended on the dissociation of the hydrogen bonds N–H...N in the amines and the π–π bonds in the aromatic hydrocarbons themselves exceeds the energy of formation of new contacts of the N–π type.

If the bond dissociation energy in the pure components is compensated by the energy of formation of π-bonds between different aromatic compounds, then athermal mixing is observed. An example is provided by the benzene–pyridine system, which, however, is formed with contraction.

The molecules of aromatic compounds, which have electron-donating (proton-accepting) properties, are capable of forming hydrogen bonds with alcohols, but these are much weaker than the hydrogen bonds between the alcohol molecules. The mixing of benzene with alcohol therefore involves the absorption of heat and expansion[23,67].

All the facts enumerated above show that the volume changes in the mixing of the vast majority of liquids are non-additive and that geometrical factors play a major role in this process.

IV. THE VOLUMES OF MIXING IN THE DISSOLUTION OF POLYMERS

The first studies on the volumes of mixing of polymeric solutions, published in 1958,[68] showed that the dissolution of polyisobutylene (PIB) in n-heptane and of polystyrene (PS) in ethylbenzene is accompanied by contraction. Subsequently the volumes of mixing were measured also for other polymeric solutions[69-71]. Table 2 gives the signs of the volumes and enthalpies of mixing for certain polymeric solutions. In the first place there is a striking failure of solutions of high-molecular-weight hydrocarbons in lower alkanes to obey the Brønsted congruence rule [Eqn.(9)], according to which a very large endothermic effect should be observed for $n_1 \gg n_2$.[25] In reality the dissolution of polymers is frequently accompanied by the evolution of heat, which was first demonstrated by Delmas et al.[72]; at the same time, $\Delta u^m > 0$.[69] This shows undoubtedly that the negative values of Δh^m are caused by the negative values of Δv^m, which arise in this instance solely because of the difference between the molecular sizes of the mixed component.

Table 2. The consolute* temperature and the average enthalpies (Δh^m) and volumes (Δv^m) of mixing for polymer–solvent systems.

Polymer	Solvent	UCT, °C	LCT, °C	Δh^m	Δv^m
Polyisobutylene (PIB)	Isooctane	—	162[92]	<0[72]	<0[71]
PIB	Benzene	23[92]	160[92]	>0[104]	>0[71]
Polystyrene (PS)	Ethylbenzene	—	295[96]	<0[105]	<0[71]
PS	Cyclohexane	32[95]	206.5[95]	<0[104,106]	<0[71]
Poly(vinyl acetate) (PVA)	Ethyl acetate	—	204[96]	<0[86]	<0[71]
PVA	Methanol	−3[96]	209[103]	>0[106]	<0[71]
Polyoxypropylenediol (POPD)	Hexane	44[102]		>0[82]	=0[82]
POPD	Water	—	45[82]	<0[82]	<0[82]

* UCT and LCT are respectively the upper and lower consolute temperatures.

The free volume of the polymer is always smaller than that of its low-molecular-weight analogue, since intermolecular bonds 3–4 Å long are replaced by chemical bonds on polymerisation. When a polymer is mixed with a low-molecular-weight liquid and a solution is formed, the polymer expands (the free volume of the solvent is supplied to it), while the solvent contracts. However, these effects are not balanced. If the second effect predominates, the dissolution involves contraction, while if the first effect predominates expansion takes place.

For identical structures of the polymer and solvent molecules, when the cohesion energies are identical for like and unlike molecules, the geometrical factor plays the main role and the process involves contraction[69-71,73,74], which is the cause of the exothermicity. If the units of the polymer molecules differ in their chemical structure from those of the solvent molecules, the difference between the cohesion energies begins to play a role. The weaker interaction between unlike molecules than between like molecules leads to positive changes in the internal energy, volume, and enthalpy. The same polymer therefore dissolves with contraction in some solvents and with expansion in others. This can be seen from the data presented in Fig.6, which were obtained by Bianchi and Guniberty[69].

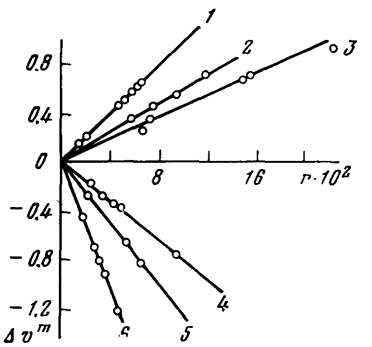

Figure 6. Variation of the volumes of polyisobutylene solutions[69]; solvent: 1) benzene; 2) toluene; 3) chlorobenzene; 4) cyclohexane; 5) methyl-cyclohexane; 6) n-heptane.

Natural rubber dissolves in benzene with expansion like low-molecular-weight hydrocarbons. Contraction is usually observed on dissolution of loosely packed polymers, for example PS[71,75-77], and also on dissolution of polyesters in water and carbon tetrachloride[68-83]. For example, polyoxyethylene and polyoxypropylene-diols dissolve in water with contraction[82], which may be due to the incorporation of their molecules into the water structure. The contraction observed when they dissolve in carbon tetrachloride is evidently associated with the formation of a more close-packed molecular arrangement in consequence of the difference between their dimensions[80,83].

Thus, like low-molecular-weight substances, polymers dissolve either with contraction or expansion.

V. THE INFLUENCE OF TEMPERATURE ON THE VOLUMES OF MIXING AND CONSOLUTE TEMPERATURES

The volume of mixing depends on temperature and Δv^m can become both more negative and more positive as the temperature increases. Thus the negative values of Δv^m for solutions of liquid alkanes increase with increasing temperature. This has been clearly shown by Davenport et al.[84] and is illustrated in Fig.7. A similar behaviour is observed in the n-hexane–n-hexadecane system. In these systems the main type of interaction is the dispersion interaction which is independent of temperature[85]. Consequently, Δu^m should not vary with temperature and an increase of the negative values of Δv^m alters the enthalpy of mixing. Thus at room temperature n-hexane mixes with n-hexadecane

with absorption of heat, the extent of which diminishes as the temperature rises[86,87]; Δh^m changes sign at 64 °C and at higher temperatures the dissolution becomes exothermic.

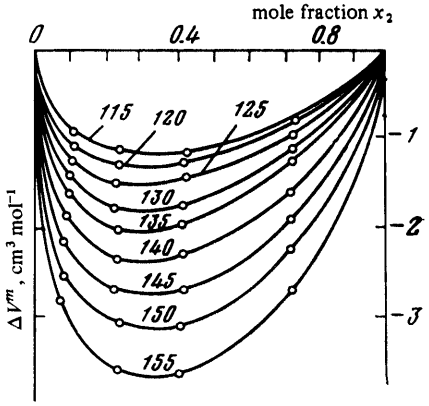

Figure 7. The average volumes of mixing of the methane–isopentane system (the numerals opposite the curves indicate the temperature in K)[84].

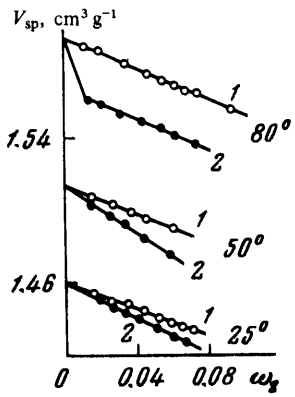

Figure 8. Dependence of the specific volumes of the polyisobutylene–isooctane system on the weight fraction of the polymer in solutions ω_2: 1) additive specific volumes of the solutions V^{sp}_{ad}; 2) experimental specific volumes of the solutions V^{sp}_{exp}.

The increase of the contraction at higher temperatures is caused by the difference between the coefficients of thermal volume expansion for the components, which depends on the difference between their free volumes. The free volume of the component having the higher molecular weight is smaller than that of the low-molecular-weight component, so that the thermal coefficient of the second component is greater than that of the first. However, in solution the low-molecular-weight component cannot expand on heating, as in the free state; with increase of temperature, it is therefore in a state close to that of a condensed gas, which leads to the association of its molecule and ultimately to the separation of the single-phase solution into two phases, i.e. to the appearance of a lower consolute temperature, which is in the temperature range above the boiling point of the more volatile component. The existence of the LCT of this type has been observed for solutions of hydrocarbons (n-hexane–n-hexadecane); this type of LCT is characteristic of solutions of all polymers, since the coefficient of volume expansion of the latter is smaller by an order of magnitude than that of low-molecular-weight liquids. For many polymeric solutions, the degree of contraction increases with increasing temperature (Fig. 8) and the thermodynamic criteria of the LCT, in particular $\Delta h^m < 0$, are valid.

LCT of this type in the range 160–300 °C have been observed for many polymer–solvent systems[90–100].

For solutions of low-molecular-weight substances containing polar components, the degree of contraction diminishes with increase of temperature; this behaviour has been observed, in particular, for mixtures of alcohols with phenols, aniline, and formaldehyde[44]. This is usually attributed to the dissociation of the hydrogen bond between unlike molecules.

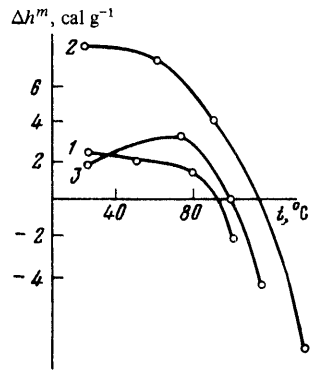

Figure 9. Temperature variation of the average enthalpies of mixing Δh^m in different systems: 1) polyisobutylene–benzene; 2) poly(vinyl acetate)–methanol; 3) polystyrene–cyclohexane (the weight fraction of the polymer in solution is $\omega_2 = 0.8$).

Prigogine and Defay[101] analysed the relation between the sign of the volume of mixing and the type of consolute temperature. They concluded that four cases can be observed for solutions of low-molecular-weight compounds:

1. UCT#: $\Delta h^m > 0$; $\Delta S^m > 0$; *a*) $\Delta v^m > 0$; *b*) $\Delta v^m < 0$.
2. LCT: $\Delta h^m < 0$; $\Delta S^m < 0$; *a*) $\Delta v^m > 0$; *b*) $\Delta v^m < 0$.

Systems of types 1*a* and 2*b* are encountered most frequently and there are also a certain number of systems of types 1*b*; examples of systems of types 2*a* are not known. The data presented in Table 2 show that, among polymer–solvent systems, exothermic systems with LCT involving contraction and systems with UCT, formed with absorption of heat and expansion, are typical; there are also systems with UCT, for which $\Delta h^m > 0$ and $\Delta v^m < 0$.

UCT = upper consolute temperature (Editor of Translation).

If the system has both a UCT and an LCT, then Δh^m must change sign as the temperature is varied (Fig.9).

VI. THEORIES OF SOLUTIONS AND VOLUMES OF MIXING

Despite the enormous amount of experimental data indicating the absence of additivity of the volume of the solution, most of the theories of solutions are based on the assumption that the volume remains unchanged on mixing. This is one of the causes of the discrepancies between theoretical results and experiment. The volume change exerts an influence in those cases where the remaining thermodynamic parameters of the dissolution process are measured at constant pressure (the commonest case). This question is discussed in the third edition of the book by Hildebrand et al.[109]. It is well known that the Scatchard–Hildebrand equation is valid only for the simplest systems of the type CCl_4–$SiCl_4$.[110] The equation does not hold even for mixtures of hydrocarbons, let alone more complex systems. It is therefore evidently necessary to take into account the volume change.

This was first done by Prigogine[111–113], who applied the principle of corresponding states to liquids with chain molecules. Prigogine's theory in its initial form was very complex and was not used for a long time, until Hijmans[114] and Patterson and coworkers[115] expressed it in a simpler form, which is described in a number of articles and books[85,116]. In Prigogine's theory a chain molecule is regarded as a sequence of r rigid quasi-spherical segments, whose behaviour differs from that of the free segments owing to the presence of chemical bonds between them. This leads to significant characteristic features of such systems, namely:

1. The surface of each segment is only partly free for intermolecular interactions, the remainder being blocked by neighbouring segments of the same molecule linked by valence forces to the given segment. The number of outer contacts between the molecules is therefore smaller than for free spherical segments.

2. The presence of chemical bonds between the segments limits their mobility, so that the number of degrees of freedom of each segment linked by valence forces (c) is smaller than the number of degrees of freedom of the free segment.

The theory deals only with external or configurational properties of liquids, i.e. properties which depend on the external degrees of freedom (translational and rotational movement) as well as hindered internal rotation in the molecule, which the authors[115] represent as a superposition of torsional vibrations on the transitions between different states of the rotational isomers. The idea of the outer contacts of the segments is expressed by the Lennard-Jones potential

$$\varphi(R)=4\varepsilon^*[(\sigma^*/R)^{12}-(\sigma^*/R)^6], \qquad (10)$$

where ε^* is the energy of the contact between the segments at 0 °C, σ^* the distance over which this contact is achieved (the diameter of the sphere of action), and R the distance between the molecules.

The normalising parameters are the so-called molecular units: for the internal energy–the quantity $u_0=Nq\varepsilon^*z$, which represents the energy of the contacts of all N molecules (z is the coordination number); for the volume—the quantity $v_0=Nr\sigma^{*3}$; for the entropy—the quantity $s_0=3NcR$ (R is the Boltzmann constant), etc. The above quantities can be expressed as follows:

Reduced free energy	$\tilde{U}=U/Nqz\varepsilon^*$;
Reduced volume	$\tilde{V}=V/Nr\sigma^{*3}$;
Reduced entropy	$\tilde{S}=S/3NcR$;
Reduced temperature	$\tilde{T}=T/T_0=3cRT/qz\varepsilon^*$.

The reduced temperature is defined as the ratio of the kinetic energy of the substance to its cohesion energy $z\varepsilon^*$. It depends on the parameter c/q, which Prigogine calls the structure factor, since this ratio is linked directly to the free volume, which is the most important characteristic of the structure of matter.

On passing to solutions, it is assumed that all the normalising parameters are additive. Thus

$$\langle v_0\rangle=x_1v_{01}+x_2v_{02} \qquad (11)$$

$$\langle u_0\rangle=x_1u_{01}+x_2u_{02} \qquad (12)$$

where x_1 and x_2 are the mole fractions of the components, v_{01}, v_{02}, u_{01}, and u_{02} are the corresponding reduced parameters, and $\langle v_0\rangle$ and $\langle u_0\rangle$ are the reduced parameters for the solution. With these assumptions, the reduced temperature of the solution $\langle\tilde{T}\rangle$ can be expressed by the equation

$$\langle\tilde{T}\rangle=\varphi_1\tilde{T}_1+\varphi_2\tilde{T}_2, \qquad (13)$$

where $\tilde{T}_1$ and $\tilde{T}_2$ are the reduced temperatures of the components and ϕ_1 and ϕ_2 are their volume fractions.

The volume of mixing is calculated from the equation

$$\Delta v^m=\langle v_0\rangle\{\tilde{V}-[\varphi_1\tilde{V}_1+\varphi_2\tilde{V}_2]\}, \qquad (14)$$

where $\tilde{V}$, $\tilde{V}_1$, and $\tilde{V}_2$ are the reduced volumes of the solution and the components respectively. Calculations by Eqn.(14) have shown that the mixing of substances consisting of molecules having similar chemical structures but differing in the dimensions of their chains should be accompanied by contraction.

For the homologous series of alkanes (from methane to polyethylene), polystyrene (from the dimer to infinite molecular weight), poly(ethylene oxides), polydimethylsiloxanes, and fluorinated alkanes, it has been shown[117–120] that the experimental data for the temperature variation of the volumes of mixing fit on a single curve. Consequently the principle of corresponding states can be applied also to polymeric liquids and even to polymeric glasses. It follows from the calculation carried out for solutions of certain polymers that they are formed with contraction[116].

Thus Prigogine's theory demonstrated the possibility, in principle, of calculating the volume of mixing as well as other thermodynamic functions. However, these calculations are difficult, owing to the difficulty of a quantitative choice of the parameters q, c, ε^*, and σ^*.

The theory of solutions developed by Flory and coworkers[121–124], which is based on all the postulates of Prigogine's theory but in which the reduced parameters have a clear physical significance and can be obtained from Tables, constituted a considerable step forward. The main reduced parameter in the so-called new Flory theory or the Flory–Prigogine theory is the intrinsic volume of the segment v^*, which is the sum of the volumes of all its constituent atoms, or the intrinsic volume of the molecules $V^*=rv^*$ (r is the number of segments in the molecule); it differs from the actual volume of the molecule by the free volume.

According to Hildebrand[9], the volume of one mole of a substance can be represented by the sum of the intrinsic volume of its molcules V_W and the free volume or the volume of the vacancies V_E (see above). If the overall volume occupied by N chain molecules is divided by the number of segments in this volume (Nr), then the local volume corresponding to a segment is obtained:

$$v=V/Nr. \qquad (15)$$

The reduced volume is

$$\tilde{v}=v/v^*=V/V^*=M/dV^*, \quad (16)$$

where V is the volume of one mole of the substance, M its molecular weight, and d the density.

Using the Tonks distribution function[125] for a two-dimensional system of N rigid species and having applied it to a one-dimensional system made up of a single chain of rigid segments, the authors[114,115] obtained the equation of state for a liquid with non-spherical chain molecules:

$$\frac{\tilde{p}\tilde{V}}{\tilde{T}}=\frac{\tilde{v}^{1/3}}{\tilde{v}^{1/3}-1}-\frac{1}{\tilde{v}\tilde{T}}; \quad (17)$$

at $p=0$ (this is close to the atmospheric pressure $p=1$) Eqn.(17) assumes a simpler form:

$$\tilde{T}=\frac{\tilde{v}^{1/3}-1}{\tilde{v}^{4/3}}. \quad (18)$$

Differentiation of Eqn.(18) with respect to temperature leads to an expression involving the derivative $\partial V/\partial T$, which is related to the volume by the coefficient of thermal expansion α; as a result, we obtain the equation

$$\tilde{v}^{1/3}-1=\frac{\alpha T}{3(1+\alpha T)}. \quad (19)$$

When α for the substance and the experimental temperature are known, Eqn.(19) makes it possible to calculate the reduced volume $\tilde{v}$. Next, the intrinsic volume of the segment is calculated by Eqn.(16) and the reduced temperature is calculated by Eqn.(18).

The talks formulated by the authors[114,115] reduces to the calculation of the thermodynamic properties of solutions from those of the components. Two parameters are then introduced to express the concentration of the solution: the fraction of the segments ϕ_i and the fraction of sites θ_i. The parameters ϕ_2 and θ_2 of the second component are calculated by the equations

$$\varphi_2=m_2v^*_{sp2}/(m_1v^*_{sp1}+m_2v^*_{sp2}), \quad (20)$$

$$\theta_2=1-\theta_1=(S_2/S_1)\varphi_2/[\varphi_1+(S_2/S_1)\varphi_2], \quad (21)$$

where m_2 and m_1 are the masses of components, $v^*{}_{sp}{}^1$ and $v^*{}_{sp}{}^2$ are the reduction parameters for the specific volume, and S_2/S_1 is the ratio of the sufrace areas of the molecules being mixed, which is calculated from model representations. For example, an alkane molecule is modelled by a cylinder with an average radius 2.49 Å and a length $l^*=1.19n+1.32$, where n is the number of carbon atoms. These dimensions are consistent with the crystallographic radii and the intrinsic volumes V^* of n-alkane molecules.

The reduced volume of the solution is calculated by the equation

$$\frac{\tilde{v}^{1/3}-1}{\tilde{v}^{4/3}}=\tilde{T}=(\varphi_1p^*_1T^*_1+\varphi_2p^*_2T^*_2)/(\varphi_1p^*_1+\varphi_2p^*_2-\varphi_1\theta_2X_{12}), \quad (22)$$

where X_{12} is the energy parameter of the interaction of the components and the additive volume of the solution is found from the equation

$$\tilde{v}_0=\varphi_1\tilde{v}_1+\varphi_2\tilde{v}_2. \quad (23)$$

The reduced volume of mixing is calculated as the difference between the reduced volume of the solution $\tilde{v}$ and the reduced additive value:

$$\Delta\tilde{v}^m=\tilde{v}-\tilde{v}_0. \quad (24)$$

Flory and coworkers[121–123] proposed equations, which make it possible to calculate the partial enthalpies and entropies of mixing ($\overline{\Delta H_1}$ and $\overline{\Delta S_1}$) and the difference between the chemical potentials of the components $\Delta\mu_1$, while Abe and Flory[124] showed that all these theoretical equations can be applied to mixtures of not only chain molecules but also spherical molecules (CCl_4, benzene, cyclohexane, neopentane, $TiCl_4$, $SnCl_4$, etc.).

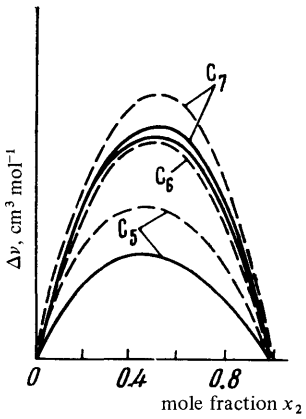

Figure 10. The volumes of mixing of benzene–alicyclic hydrocarbon systems[130]: continuous curves–experimental data; dashed curves–theoretical data.

The new Flory theory has been tested for a large number of mixtures of low-molecular-weight liquids and for solutions of polymers. It has been shown that, for mixtures of n-alkanes[121,122] and alkanes with cyclic hydrocarbons[124], mixtures of spherical molecules[124], mixtures of hydrocarbons with fluoro-derivatives, solution[3] of isooctane in CCl_4 and cyclohexane[126–129], and solutions of benzene and CCl_4 in toluene and xylene[55], the Flory theory always predicts the correct sign of the volume change and in most cases the calculated values of Δv^m are close to the experimental values (Fig.10). Fig.11 shows that the theory describes satisfactorily the experimental data also for solutions of polymers: in particular, the values of Δv^m for the natural rubber–benzene system[73], calculated by Eqn.(24), virtually agree with experiment; for solutions of poly-isobutylene in n-alkanes[74], the theory predicts the correct sign of the volume of mixing, but the values of Δv^m do not agree. An even greater discrepancy between the experimental and calculated Δv^m has been observed for solutions of polystyrene[76], although the theory predicts correctly the sign of Δv^m.

All the foregoing considerations show that the mixing of liquids and the dissolution of polymers are accompanied by a volume change which makes a significant contribution to all the thermodynamic potentials. Even a small contribution of the volume change can induce marked effects, for example, phase separation when the solution is heated.

The contraction effect on mixing liquids and on dissolving polymers leads to the occurrence of concentration fluctuations in solution, whose further growth leads to the formation of organised structures such as associated species or solvates. These organised structures, which are formed spontaneously, are classified as the so-called dissopative structures, considered in the modern thermodynamics of irreversible processes[130–131].

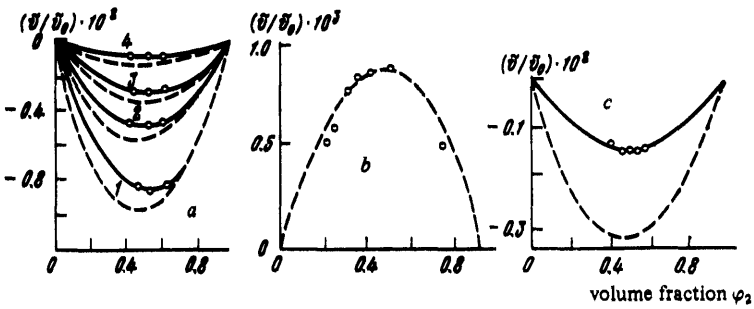

Figure 11. The relative volumes of mixing for different solutions: *a*) of polyisobutylene in n-alkanes[74] [1) in n-hexane; 2) in n-octane; 3) in n-decane; 4) in n-hexadecane]; *b*) of natural rubber in benzene[75]; c) of polystyrene in cyclohexane[76]. Continuous lines—experimental data; dashed lines—calculation based on the Flory theory.

Advances in the Chemistry of Pernitriles

N.S.Zefirov and D.I.Makhon'kov

The problems of a formal systematic treatment of nitrogen-carbon structures as well as the methods of synthesis, chemical properties, and applications of the most familiar representative of the class of nitrogen-carbon compounds, namely pernitriles, are examined.
The bibliography includes 298 references.

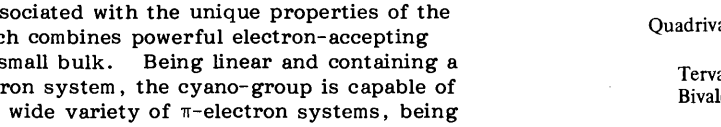
I. INTRODUCTION

Approximately 30 organic compounds, whose molecules consist solely of nitrogen and carbon atoms, and approximately the same number of anions of percyanohydrocarbon derivatives containing one or several acid C–H bonds—the so-called cyanocarbonic acids (see Appendix)—are now known. However, it is of interest that, although the majority of these acids form stable salts, for example dicyanamide, pentacyanocyclopentadiene etc., it has so far been impossible to synthesise compounds such as hexacyanocyclopentadiene, or tricyanamide, which are extremely interesting from both theoretical and possibly practical points of view.

Analysis of literature data shows that during the last 15 years the number of compounds of the "nitrogen–carbon" class synthesised has not only increased almost by a factor of nine[1], but every year there is an increase in the number of publications devoted to the investigation of the physicochemical and chemical properties of these compounds.

By virtue of advances in synthesis, the majority of representatives of this class have become relatively readily available and the intense development of quantum-chemical methods permitted a theoretical prediction of the existence of molecules of this type. This applies primarily to polycyano-compounds or pernitriles, which have recently become the objects of constant attention by investigators. The unusual properties of polynitriles are associated with the unique properties of the cyano-group, which combines powerful electron-accepting properties with a small bulk. Being linear and containing a cylindrical π-electron system, the cyano-group is capable of conjugation with a wide variety of π-electron systems, being favoured in this respect compared with other strong electron-accepting substituents such as the nitro- and sulphonyl groups.



As an illustration, we may note that the electrical conductivities of salts of the tetracyanoquinodimethane radical-ion are virtually equal to the conductivity of graphite, pentacyanocyclopentadiene is a stronger acid than perchloric acid, tetracyanoquinone oxidises water, and tetracyano-oxiran adds to olefins and even to aromatic compounds, like ozone[2].

Despite the relative novelty of nitrogen–carbon compounds, certain representatives of this class of compounds have become quite familiar chemically. For example, the bibliography on the chemistry of tetracyanoethylene already numbers more than a thousand studies and there has been no slackening of the interest in this compound. Furthermore, each year new types of reactions of tetracyanoethylene are reported. On the other hand, the chemistry of many polynitriles has been studied very superficially, although it is of considerable theoretical and even practical interest.

The present review is devoted to advances in the chemistry of pernitriles and covers the literature up to 1976 inclusive. The section devoted to the systematic treatment of nitrogen–carbon molecules deals with an examination of literature data.

II. A FORMAL SYSTEMATIC TREATMENT OF NITROGEN–CARBON STRUCTURES

We shall consider a formal combinatorial approach to structures consisting of carbon and nitrogen atoms. Both these elements have coordination numbers ranging from unity to four depending on the oxidation state and are capable of forming double and triple bonds. On this basis, it is easy to deduce all possible monatomic fragments, which are illustrated below:

Any structure of a nitrogen–carbon compound can be obtained by scanning all possible combinations of these fragments, provided that the following requirements are fulfilled: all the valences are saturated and the molecule is electrically neutral overall. The role of the homologous modulus (cm^3)

† The list does not include bivalent carbon, because isonitriles can be described in terms of the fragment $-N\equiv\overline{C}$.

can be fulfilled either by homogroups of the type $-C\equiv C-$ and $-N=N-$ (there is also a possibility of the formation of cumulene carbon chains) or by heterogroups such as, for example, $-N=C=N-$. Among these, only the azo-group has a geometry suitable for inclusion in a ring and for the formation of cyclic azaheterocycles. It is readily seen that the combination of the above atomic fragments permits a large variety of nitrogen–carbon skeletons, which can be divided into two types: (1) those with single free valences and (2) those with unused double bonds ("exo-double bonds").

The fundamental problem in the determination of molecular structures consists in finding the end group. Evidently, only two monatomic fragments, $Y\equiv$ and $Z=$, can play the role of an end group and neither is univalent. A bivalent end group can be derived from the diatomic fragment $=X=Z$; the diazo-group $=\overset{+}{N}=\overline{N}$ corresponds to such a fragment. In hydrocarbons the terminal valence is usually saturated by a univalent atom—hydrogen. Evidently, in a systematic treatment of nitrogen–carbon compounds it is essential to find univalent fragments capable of "covering" the unused valences; a nitrogen–carbon structure can then be derived by means of a systematic treatment of hydrocarbons involving the replacement of hydrogen atoms by the appropriate univalent nitrogen–carbon group. Among diatomic electrically neutral combinations, it is possible to obtain only one, $-X\equiv Y$, satisfying the requirement for a univalent state. The $-C\equiv N$ and $-\overset{+}{N}\equiv C^-$ functional groups, i.e. the nitrile and isonitrile groups, correspond to this combination. The azido-group $N\equiv\overset{+}{N}-\overline{N}- \leftrightarrow N=\overset{+}{N}=N-$ corresponds to the univalent triatomic fragments $Y\equiv X-Z-$ or $Z=X=Y-$. Thus the molecules of nitrogen–carbon compounds (with the exception of unsaturated cyclic structures consisting of azo- and acetylenic groups) should belong to the class of diazo-compounds, nitriles, isonitriles, and azides.

Molecules containing more than two isonitrile or diazo-groups are apparently unknown. On the other hand, pernitriles and perazides have been described in the literature. However, whereas there are only isolated publications on perazides[4–9], the literature on pernitriles is fairly extensive; the properties of pernitriles are the subject of the succeeding sections of the review.

III. PERCYANOALKANES

1. Tetracyanomethane

The only stable representative of the percyanoalkane series is tetracyanomethane (TCM). The first attempt to synthesise TCM from silver tricyanomethide and chlorocyanogen was undertaken by Schmidtmann[10] in 1896. Three years later Hantzch and Osswald[11] tried to obtain TCM by Schmidtmann's method having replaced chlorocyanogen by iodocyanogen. The attempts to synthesise TCM from bromotricyanomethane and potassium cyanide[12] and from the compounds $C(CH_2N{=}CHC_6H_5)_4$ and $C(CH_2NCl_2)_4$ were also unsuccessful[13].

It was not until 1969 that Mayer[14] succeeded in synthesising TCM in accordance with Schmidtmann's scheme:

$$AgC(CN)_3 + ClCN \xrightarrow{100^\circ} AgCl + C(CN)_4 \ . \qquad (1)$$

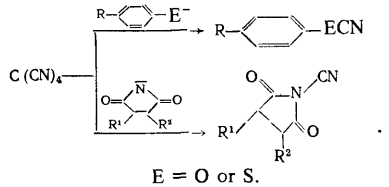
Mayer's product was a colourless crystalline compound, soluble in polar solvents, and decomposing fairly rapidly on storage with formation of an unidentified orange-yellow amorphous substance. Mayer described certain chemical properties of TCM, in particular its alkaline and acid hydrolysis:

$$C(CN)_4 + 2OH^- \rightarrow C(CN)_3^- + OCN^- + H_2O \ ,$$
$$C(CN)_4 + 2H_2O \rightarrow C(CN)_3^- + NH_4^+ + CO_2 \ .$$

Systematic study of the chemistry of TCM began as soon as it was shown[15] that the stability of this compound depends greatly on the conditions of its synthesis, particularly on the absence of traces of chlorine in chlorocyanogen and of traces of moisture in silver tricyanomethide (which catalyse the trimerisation of chlorocyanogen). The presence of an admixture of cyanuric chloride was in fact responsible for the instability of the first TCM specimens. The enthalpy of formation of TCM from the elements has been determined[16], its molecular geometry has been studied by electron diffraction[17] and X-ray diffraction[18], and its photoelectron[19], ^{13}C NMR[13,20], and infrared and Raman spectra[21] have been studied.

As was to be expected, TCM proved to be extremely reactive in relation to nucleophiles. Comparison of the thermochemical properties of TCM and polyhalogenomethanes showed that the accumulation of four cyano-groups at a saturated carbon atom leads to an appreciable destabilisation of the TCM molecule. The "bond separation" energy, the existence of which is reflected in a tendency towards reaction involving the formation of the nitrile cation and the tricyanomethyl anion, is 23.5 kcal mol^{-1}.[20]

Tetracyanomethane reacts readily with inorganic chlorides, for example:



$$C(CN)_4 + LiCl \rightarrow LiC(CN)_3 + ClCN \ .$$

Formally, this reaction can be regarded as electrophilic substitution at a saturated carbon atom (the cyano-group is replaced by the lithium cation). However, the "cyanophilic" mechanism, involving attack by the nucleophile on the carbon atom of the cyano-group, is believed nowadays to hold for these reactions:

$$B^- + N\equiv C-C(CN)_3 \longrightarrow B-CN + C(CN)_3^- \ .$$

This mechanism is related to that of the so-called "halogenophilic" reactions of polyhalides[15,22,23].

The reaction of TCM with caesium fluoride has been used successfully as a method for the preparation of fluorocyanogen[24], but attempts to synthesise dicyanogen oxide by the analogous reaction with potassium and caesium cyanates led to the isolation of an unidentified polymer[25]. The reactions of TCM with the anions of dibasic acid imides[23] and phenoxide and thiophenoxide anions[22] take place under mild conditions (THF, 10–15 min) and lead respectively to *N*-cyanoimides, cyanates, and thiocyanates:

E = O or S.

Thus TCM behaves as a powerful cyanating agent in reactions with nucleophiles of this type.

The reactions of TCM with tertiary amines and phosphines, which in most cases lead to unidentified mixtures of products, proceed in a much more complex manner. It is believed[15] that in this case the primary reaction products are trisubstituted *N*-cyanoammonium or *P*-cyanophosphonium tricyanomethides [mechanism (2)]—extremely reactive compounds which undergo subsequent hydrolysis with elimination of the cyano-group from the cation or undergo intramolecular transformations involving attack on the cation by the ambident cyanoform anion:

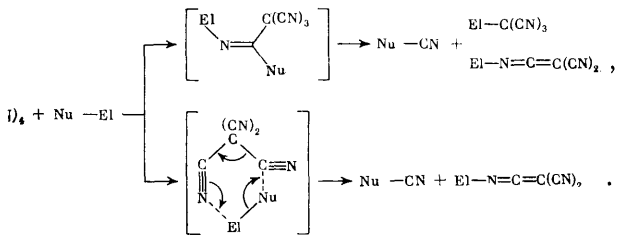
$$R_3E + C(CN)_4 \rightarrow [R_3\overset{+}{E}CN]\,\bar{C}(CN)_3 \ ; \qquad (2)$$
$$E = N \text{ or } P \ .$$

The products of secondary reactions of the first type—tribenzylammonium and triphenylphosphonium tricyanomethides—have been isolated in yields of 90 and 20% respectively[15]. The reaction of TCM with triphenylphosphine complexes of transition metals have been reported[26] to proceed via the mechanism

$$Pt(Ph_3P)_4 + C(CN)_4 \rightarrow 2Ph_3P + Pt(Ph_3P)_2(CN)C(CN)_3 \ .$$

However, in the light of later studies of the reactions of TCM with nucleophiles, the above reaction probably requires a more detailed investigation.

The ability of an electrophile such as TCM to react with compounds which are usually classified as electrophiles (hydrogen chloride and the halides of sulphur and phosphorus acid) was very much unexpected[15]:



$$C(CN)_4 + HCl \rightarrow ClCN + HC(CN)_3 \xrightarrow{HCl} (NC)_2C{=}C\langle^{NH_2}_{Cl} \ ,$$

$$C(CN)_4 + SO_2Cl_2 \rightarrow ClCN + ClC(CN)_3 + SO_2 \ ,$$

$$C(CN)_4 + SOCl_2 \rightarrow ClCN + (NC)_2C{=}C\langle^{N{=}S{=}O}_{Cl} \ ,$$

$$C(CN)_4 + PCl_5 \rightarrow ClCN + (NC)_2C{=}C\langle^{N{=}PCl_3}_{Cl} \ .$$

Alternative mechanisms of the above reactions are presented below[15]:

us TCM is a unique compound in which a regular tetral structure and the consequent equivalence of all the ›-groups are combined with a high mobility of one of the ›-groups, since TCM reacts with equal ease with both nucleophiles and electroph'les.

Reactions of the first type are particularly useful when anions of different kinds are used as nucleophiles. The transfer of the cyano-group to an atom with a negative charge takes place under extremely mild conditions and leads to cyanation products in almost quantitative yields.

Reactions of the second type with compounds containing a mobile chlorine atom are also extremely convenient for the synthesis of compounds having four electron-accepting groups at a saturated carbon atom (for example, of chlorotricyanomethane) and derivatives of the keten imine form of the tricyanomethide anion such as thionylamino- and phosphazo-2,2-dicyanoethylenes.

2. Hexacyanoethane

In 1928 the first and unsuccessful attempt was made to obtain hexacyanoethane (HCE) by treating silver tricyanomethide with chlorine[27]. The synthesis of HCE was achieved in 1968 by the reaction of chlorocyanogen with pentacyanoethylsodium, obtained by treating tetracyanoethylene with sodium cyanide[28]. The yield of product was only 17%. The discoverers of this synthesis note that the success of the reaction depends on the absence of a solvent (apart from chlorocyanogen itself). The best results were obtained in the presence of aluminium chloride. Both in solutions and in crystalline state HCE decomposes rapidly (the process is catalysed by bases) with formation of tetracyanoethylene. As in many other reactions of pernitriles, dicyanogen, which theoretically should be formed in this reaction, could not be detected[28].

IV. PERCYANOALKENES

1. Tetracyanoethylene (TCE)

A number of reviews, both general[2,29] and concerned with certain specific questions, for example, the reactions of TCE with amines and aminoacids[30], the alkylation of TCE[31], transition metal complexes of pernitriles[32], the properties of polymeric compounds of metallic derivatives of TCE[33], and molecular complexes[34], have been devoted to the chemistry of tetracyanoethylene. The present review therefore deals solely with the most interesting studies carried out in the last eight years.

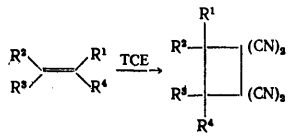
Vigorous investigation of the synthetic aspects of the chemistry of TCE led to the publication of new reports on the physicochemical properties of this compound. Thus the molecular constants[35] and molecular orbitals[36] of TCE have been calculated and studies have been made on the NMR[37] and NQR[38] spectra, mass spectra (of negative ions)[39], photoelectron spectra[40], and the relation between the ionisation potentials and electron affinities, on the one hand, and the reactivity of TCE, on the other[41].

(a) Molecular Complexes of TCE

The presence of four powerful electron-accepting groups is responsible for the extremely high tendency of TCE to form molecular complexes with a wide variety of classes of electron-donating molecules, among which complexes with aromatic compounds[34] and polymeric complexes of TCE have been most thoroughly investigated[42].

The formation of complexes of TCE with π-donors precedes as a rule the cycloaddition, tricyanovinylation, and cyanation reactions. Thus the interaction of TCE with ferrocene is not limited to the formation of a π-complex, which was believed for a long time, but leads to a mixture of cyanoferrocene (40%) and tricyanovinylferrocene (16%) (150 °C, sulpholane or acetonitrile as solvents)[43]. The analogous reaction with ferrocenylmercury chloride yields mainly tricyanovinylferrocene and the absence of the directing effect in the reaction with ethylferrocene indicates a radical mechanism of this reaction[43].

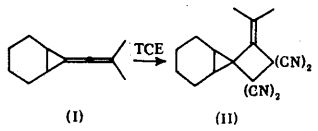
In the presence of bases TCE reacts with 2,4,6-trinitroanisole and 1,3,5-trinitrobenzene to form anionic σ-complexes, whose structure has been confirmed by NMR[44]. It has been shown recently that TCE forms molecular complexes also with saturated compounds of Group IVB metals (permethylpolysilanes[45], polygermanes[46], hexa-alkyldistannanes[46], and tetraalkyl derivatives of germanium, tin, and lead[47]) and even with saturated hydrocarbons—hexamethylethane, cyclohexane, bicyclohexyl, decalin, adamantane, and 1,1-biadamantyl[48].



(b) Reactions Involving Addition to the C=C Bond of TCE

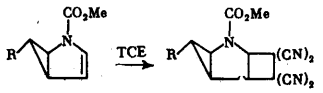
The vast majority of reactions of TCE (probably with the sole exception of reactions involving the cyano-group and the cracking reaction) include the stage in which the substrate adds to the C=C bond of TCE, leading as a rule to a zwitterionic intermediate, which then cyclises intramolecularly or undergoes intermolecular reactions, frequently accompanied by fragmentation processes of different types. In particular, this factor is responsible for the wide variety and complexity of the chemistry of TCE.

Another type of addition reaction (in the presence of a mobile hydrogen atom in the substrate molecule) involves the formation of substituted tetracyanoethanes, which are in many instances the final products, but which usually decompose with elimination of an HCN molecule, malononitrile, or tetracyanoethane.



The reactions of TCE with olefins, the principal pathway of which in the case of monoalkenes involves the formation of cyclic 1,2-adducts, have apparently been most thoroughly investigated. When the molecule contains a large number of double bonds (particularly conjugated double bonds or bonds with a suitable steric arrangement), the reaction products are 1,*n*-adducts. In the simplest case of conjugated donors $n = 4$ (the Diels–Alder reaction), but in more complex systems there is a possibility of the formation of adducts with $n = 3$, 5, 6, 8, and higher values, the reactions being usually accompanied by different kinds of rearrangements and leading as a rule to mixtures of isomers. The study of reactions of this type is extremely interesting for the investigation of problems of reactivity.

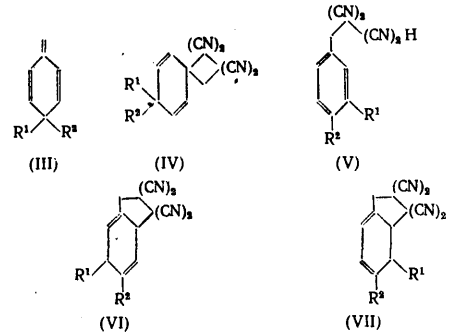
1,2-Cycloaddition reactions. The activation of the double bond by steric strain or by electron-donating substituents entails addition to TCE with formation of cyclobutane derivatives. Vinyl sulphides, *N*-vinylamides, *N*-vinylsulphonamides[29], vinyl ethers, and vinylcyclopropanes react via the general mechanism



(3)

In the last case, however, the reaction is complicated by the ability of TCE to react with cyclopropane via the $[2\pi + 2\sigma]$ mechanism (see below). Nevertheless, the reaction with allene (I) yields both isomers of the spiro-compound (II):[49]

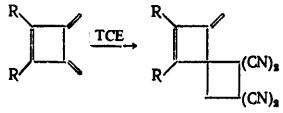
(I) (II)



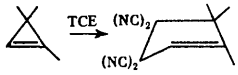
Nor is the three-membered ring involved in reactions of derivatives of 2-azabicyclo[3,1,0]hex-3-ene[50]:

Aryl-substituted olefins, namely styrenes[51], acenaphthylene[52,53], 1-vinylpyrene[53], as well as indene and vinylferrocene react with TCE in accordance with the $[2\pi + 2\pi]$ mechanism[53,54]. However, in many cases the reaction involves the aromatic system and leads to 1,4-addition products (see below).

1,3-Dienes incapable of undergoing the Diels–Alder reaction (for example, cyclic olefins with an exomethylene group and polymethylated butadienes) also form 1,2-adducts as a rule. Reactions of this kind have been reviewed[55].

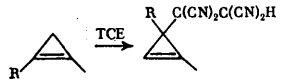


The reaction of TCE with 6,6-disubstituted 3-methylenecyclohexa-1,4-dienes greatly depends on the structure of the triene. Whereas the dimethyl derivative (IIIa) forms adducts (IV) and (V) [adduct (IV) rearranges to adduct (V) in polar solvents], the corresponding aryl derivatives (IIIb) and (IIIc) give rise to adduct (V) and a further two adducts (VI) and (VII), the relative amounts of which depend on the polarity of the solvent[56]:



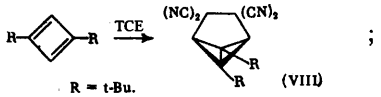
(III) (IV) (V) (VI) (VII)

(a) $R^1 = R^2 = CH_3$; (b) $R^1 = Ph$, $R^2 = CH_3$; (c) $R^1 = R^2 = Ph$.

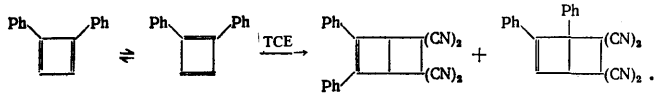


The reactions of diphenyl- and dimethyl-dimethylenecyclobutenes take place via the 1,2-cycloaddition mechanism[29]:

The reaction of TCE with cyclopropenes depends on the presence or absence of an allylic hydrogen atom. In the latter case ring opening occurs (via the stage involving the addition of TCE to the double bond), while in the former case a substituted tetracyanoethane is produced[57]:

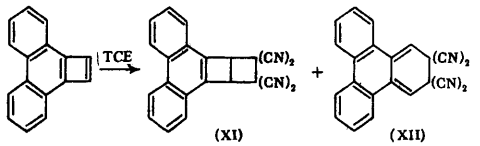


;



.

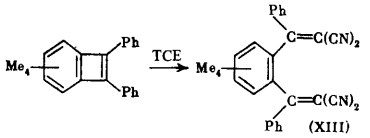
1,3-Di-(t-butyl)cyclobutadiene reacts with TCE to form a derivative of dihydrobenzvalene (VIII) in a high yield[58]:



;

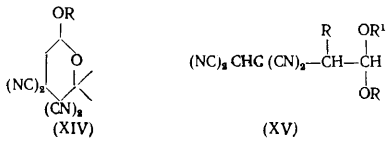
On the other hand, the existence of *o*-diphenylcyclobutadiene as an equilibrium mixture of two isomers was confirmed by the formation of adducts (IX) and (X) in proportions of 1 : 7:[59]

(IX) (X)



The reaction of phenanthro[*l*]cyclobutadiene with TCE leads to a mixture of adducts (XI) and (XII), the former being unstable and rearranging to the latter on heating[60]:

(XI) (XII)



The reaction of benzocyclobutenes proceeds differently[61,62]. The addition of one equivalent of TCE leads to the formation

of adducts with structure (XIII)[62]:

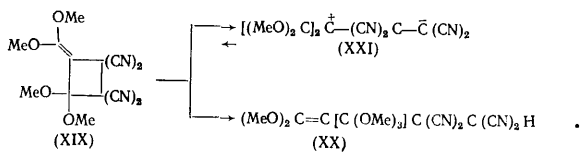
(XIII)

The cycloaddition of TCE to vinyl ethers proceeds via the stage of a 1,4-dipolar intermediate, which has been convincingly demonstrated by Schug and Huisgen[63], who isolated compound (XIV) after the reaction of ethoxyethylene with TCE in acetone[63]. Tetrahydropyridines and piperidines respectively are formed analogously in the presence of nitriles and amines[63]. The products (XV) of the reaction of the zwitter-ionic intermediate with alcohols have also been isolated and conformational and kinetic studies on this process have been carried out[64,65]:

(XIV) (XV)

The cyclobutanes obtained by the reaction of TCE with ring-substituted phenyl vinyl ethers decompose slowly with loss of HCN and the formation of 4-aryloxy-1,1,2-tricyanobuta-1,3-dienes[66]. Metalloalkylolefins (XVI), containing Group IV elements, behave analogously to vinyl ethers[67]:

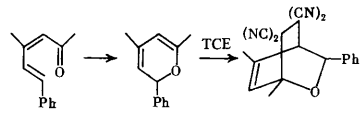
$$CH_2{=}CH{-}CH_2{-}MR_3 \ (M = Si,\ Ge,\ or\ Sn;\ R = Me\ or\ Ph)\ .$$



(XVI)

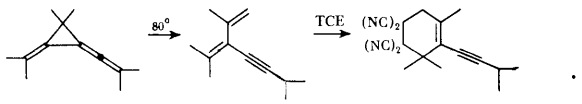
The coordination of an olefin to transition metals (Fe, Co, ', Mo)[68] leads, as in the case of polyenes (see below), to a ange in the reaction pathway and to the formation (for yl and allenyl derivatives) of rearranged products of types VII) and (XVIII):

(XVII) (XVIII)



The reaction of TCE with tetramethoxyethylene leads to the normal [2 + 2]-adduct[69], while the analogous reaction with tetramethoxyallene gives an equilibrium mixture of compound (XIX) [which gives rise to compound (XX) on treatment with methanol] and the betaine (XXI)—the principal component at room temperature[70]:

(XIX) (XXI) (XX)



Conjugated dienes and polyenes. After it had been found that TCE is such a powerful dienophile that it can be used for the quantitative determination of dienes[71], the formation of the corresponding adducts became a virtually permanent feature of studies on the synthesis of compounds containing a diene or heterodiene fragment. This led to the publication of a whole series of reports dealing with the study of the mechanism, kinetics, and thermochemistry of the Diels–Alder reaction with TCE[72–77].

TCE proved to be extremely useful for the trapping of various kinds of intermediates containing a diene system [for example, the pyran (XXII), formed in the isomerisation of 4-methyl-6-phenylhexa-3,5-dien-2-one, was identified in this way[78] (scheme (IV)] and also for the investigation of problems of electrocyclic tautomerism (particularly for the quantitative estimation of the content of isomers):
