The collector does not necessarily have to be added to the solution: it can be part of the matrix. This type of concentration method was studied by Chuiko[47,48], Jackwerth[49], and others. The method is specially convenient with hydroxides. In the deposition of other precipitates the charge on the trace elements has to be "controlled", for example by converting them into complex anions. This is because when part of the matrix is precipitated as an insoluble crystalline compound the surface of the precipitate is usually positively charged. On the other hand nydroxides tend to sorb hydroxyl ions, and are not included in this rule.

Some very interesting organic coprecipitants were introduced into analytical practice in the 1950's, mainly by Kuznetsov and Myasoedova[50-52]. Organic collectors are easily eliminated, they are available in a variety of forms, and they minimise the uncontrolled coprecipitation of unwanted trace elements and of the matrix. In contrast to extraction methods, these organic reagents are needed in small amounts only. In the case of atomic-absorption or photometric end-determination the collector can be dissolved in a suitable organic solvent instead of being ashed: the solution thus obtained can be used directly for analysis. Hydroxyquinoline, Cupferron, and other reagents have been used as coprecipitants; they can be used in conjunction with indifferent coprecipitants of the naphthalene type. Many examples of concentration by using organic coprecipitants are quoted in Kuznetsov and Akimova's monograph[52]. Among the more recent work we should note that concentration of a large number of elements on germanium and aluminium salicylfluoronates[53], and the concentration of gold and palladium with dithizone before flameless atomic-absorption determination[54].

Deposition of the matrix leaving the trace elements in solution requires large amounts of reagents, usually involves a relatively large "blank" correction, and can be laborious. The large mass of precipitate can cause loss of the trace elements by coprecipitation. However in special cases many of these difficulties can be avoided, and many methods of concentration by precipitation of the matrix have been proposed. For example, in the analysis of high-purity lead the best method of concentrating impurities is to precipitate the lead as its nitrate from concentrated nitric acid solution[55]. Various methods of this type were developed by Karabash and coworkers[56], such as precipitation of bismuth iodide in the spectroscopic analysis of impurities in bismuth.

4. Evaporation Methods

Several variants of the evaporation method are used: simple thermal evaporation of the trace elements, evaporation after conversion of the trace elements into volatile compounds, and sublimation or distillation of the matrix either directly or after chemical reactions to convert it into volatile compounds.

Simple thermal evaporation is relatively free from contamination, but when reagents are used to produce volatile compounds the contamination problem increases, especially in the case of volatilisation of the matrix. Loss of the wanted elements is always possible, and can be serious when the matrix is evaporated. Usually only one element (or a small number of elements) is concentrated in the impurity evaporation variant. Evaporation of the matrix produces group concentration of the trace elements in the residue (either with or without a collector).

The evaporation of traces from a solid matrix requires the sample to be very finely divided, and this is a serious drawback of the method. Furthermore only small samples can be handled (50–100 mg). For many impurities vacuum distillation is effective, but it makes the method more complex. Evaporation of the trace elements in a stream of carrier gas has also been used. In the analysis of high-purity silicon dioxide the trace elements have been distilled in a stream of hydrogen chloride (an example of the removal of impurities at relatively low temperatures[57]). In that experiment the following impurities were distilled off and determined spectrometrically: Fe, Ni, Co, Al, Ti, Sn, Mn, In, Ga, and Be. The elements were condensed on a pure graphite tube which was cooled with water. Meyer and coworkers[58] developed a very sensitive method of determining selenium in high-purity copper by gas chromatography after evaporating the impurity in a stream of oxygen. The condensate (selenium dioxide) was converted into 5-nitropiaselenole [by reaction with 4-nitro-o-phenylene diamine, (Ed of Translation)], which was extracted with toluene and determined gas-chromatographically. The evaporation method is often used to evolve mercury vapour, especially before atomic-absorption analysis (see, for example, Refs.59 and 60).

Evaporation of the matrix is used when the matrix is much more volatile than the impurity elements being analysed. Under atmospheric pressure simple evaporation of the matrix can be difficult: the rate of evaporation increases with temperature, but temperatures in excess of 800 °C are not recommended because of the danger of losing the trace elements and of oxidising the matrix elements. However the evaporation of a large sample at low temperature is very time-consuming. The only matrices which are easily removed by evaporation are iodine, arsenic, antimony, and zinc. Both vacuum evaporation and evaporation in a stream of inert gas have been used, but the commonest variant is evaporation after chemical reactions to convert the matrix into a more volatile form. A simple and widely used method is dry ashing, i.e. combustion in air or in a stream of oxygen (in the case of organic materials and carbons). Ashing is often used as the final stage of a concentration procedure involving a different method. Ashing of the matrix is possible either in the presence or in the absence of a collector. The collector (e.g. graphite powder) helps to minimise the loss of trace constituents. Sulphur, arsenic, selenium, and osmium can also be removed by combustion. In addition to oxygen, the following can be used as chemical agents: hydrogen fluoride, hydrogen chloride, chlorine, and carbon monoxide. These produce volatile fluorides, chlorides, and carbonyls respectively. The carbonyls (e.g. nickel carbonyl) are formed under difficult conditions, and both carbon monoxide and the carbonyls are highly toxic.

Removal of the matrix from the liquid into the gas phase is widely used in practice. The commonest application of this method is the evaporation of a large liquid sample for analysis, with or without a collector: for example in the analysis of water, acids, liquid organic compounds, and a series of liquid inorganic compounds such as tin or silicon tetrachlorides. A similar method is the wet ashing of organic compounds, which requires large amounts of reagents and therefore suffers from contamination problems, but usually results in losses of trace elements lower than those produced by dry ashing.

5. Electrochemical Methods

Electrochemical methods are used occasionally (electrolysis on a solid electrode (metal or carbon), or on a mercury electrode, cementation, etc.). One of the most practical variants of this method is the electrolytic deposition of the trace elements on graphite disks or rods, which are used directly for spectroscopic or flameless atomic-absorption determination. Some workers[61–64] have deposited the trace elements either on carbon disks 4 mm in diameter and 1 mm thick, attached to a special holder, or on the end-face of a carbon rod (Fig.1). Deposition occurs at the cathode, and a platinum wire is used as the anode. The separated trace elements were then determined spectroscopically, using the carbon rod as the arc electrode. This method has been used in the analysis of compounds of the alkali metals, aluminium, organic acids, etc., in which Bi, In, Cd, Co, Cu, Ni, Pb, Zn, and Mn were determined. In another series of experiments[65–67] a similar method of concentration was used to determine trace elements by flameless atomic absorption spectroscopy. The trace elements were deposited on a platinum or tungsten wire, or on a graphite electrode.

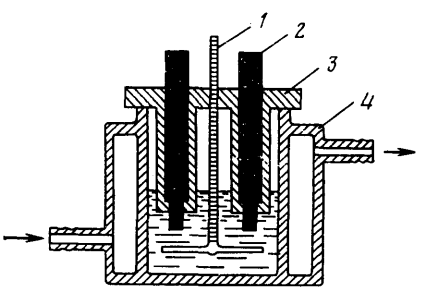

Figure 1. Electrolytic cell for depositing impurities on carbon rods: *1*) platinum anode, *2*) graphite cathodes, *3*) Teflon holder, *4*) quartz cell. Water circulation indicated by arrows.

The electro-osmosis method[68,69] is useful for concentrating ions from very dilute solutions, or from solutions of non-electrolytes. When membranes of aluminium oxide and polytetrafluoroethylene are used the concentration coefficient can be as high as 10^3–10^4, and the extent of extraction of the trace components is 85–99%. A special group of electrochemical concentration methods has been used as the basis of the inverse voltammetry method[70]. We shall refer to some of these methods below.

6. Crystallisation Methods

The reagentless concentration methods include the crystallisation methods (directional freezing and zone melting[71]).

The advantages of these methods are their universal application to all trace elements (i.e. they are group methods), the ease of automation, and the freedom from contamination (if the process is carried out in a closed apparatus at not too high temperature). Most of the sample can be recovered and re-used if necessary. However the methods have also some shortcomings: they are time-consuming, and the segregation coefficient tends to decrease at very low concentrations of the element being analysed, especially if this element is isomorphous with the main component.

The directional freezing method consists in melting the ingot completely and allowing it to crystallise from one end: as the crystallisation proceeds the impurities concentrate in the last part of the ingot to freeze. Directional freezing is much easier to carry out than zone melting. It can be applied to water–salt eutectics and crystal hydrates as well as to high-temperature melts. Various methods of concentrating impurities in metal halides have been developed at the All-Union Single Crystals Institute in Khar'kov (see, for example, Ref.72). Vertical directional freezing is used, and the melt is stirred by the strong convection currents.

7. Partial Dissolution of the Matrix

An unusual concentration method developed by Jackwerth[73] relies on dissolving part of the matrix under conditions such that the impurities do not go into solution but remain in the residue of the matrix. This is done by amalgamating the surface of metallic sample being dissolved. For example, in order to concentrate the impurities in high-purity zinc the sample (up to 100 g) is coated with 1–5% of the mercury. The zinc is then dissolved in hydrochloric acid until only a small residue is left, containing the Bi, Cd, Co, Pb, Ni, In, Tl, Sn, Ag, Au, and Pd in a concentrated form. Similar methods have been developed for the analysis of cadmium, lead (after assay melting), gallium, and aluminium (Table 2). In the case of aluminium[74] the extent of extraction of the impurities was >95%, and the concentration coefficient was ~10^3.

Table 2. Methods of concentrating trace elements in high-purity metals by partial dissolution of the matrix.

Matrix	Trace elements to be concentrated	Method of determination	Reference
Zinc	Ag, Au, Bi, Cd, Co, In, Ni, Pb, Pd, Sn, Tl	various	73
Aluminium	Bi, Cd, Ga, In, Pb, Tl, Zn	atomic absorption	74
Lead*	Precious metals	atomic absorption	75
Gallium	Ag, Au, Bi, Cu, Fe, Hg, Ni, Pb, Pd, Sn, Zn	atomic absorption	76
Mercury	Au, Pd	photometric	77
Cadmium	Ag, Au, Bi, Cu, Ni, Pb, Pd	atomic absorption	78

*After assay melting.

8. Assay Melting

Assay melting is a special form of pre-concentration. It combines, in a single operation, decomposition of the sample and concentration of the precious metals (for example, in molten lead). The result is a separation of the precious metals from their accompanying elements, which enables a large (and therefore representative) sample to be used in the analysis of ores and products of ore treatment. Concentration coefficients of 10^2–10^3 can be obtained. Assay melting is a convenient method of separation and concentration when combined with one of the modern, high-sensitivity methods of determination such as spectroscopic or activation analysis. Assay melting is valuable for the analysis of samples containing 10^{-7}–10^{-4}% of the precious metals. The method of concentrating the wanted elements into molten lead gives good results in the determination of gold, silver, platinum, and palladium. Metallic tin, and nickel sulphide, have been used as an alternative to lead. Conditions for concentrating iridium and rhodium have been found. The theory of assay melting continues to be poorly developed, though this is the oldest method of concentration (not counting evaporation).

9. Other Methods

Other methods have been used for the pre-concentration of trace elements. One of these is flotation, which can be used either to extract the matrix or to extract the trace components. The matrix can be floated after being precipitated, as an alternative to filtration. Examples of the separation of trace components by flotation include the extraction of silver[79], vanadium[80], and a group of nine elements[81] from seawater. Ultrafiltration, lyophilic drying, thermo-diffusion, and other methods have also been used.

As stated above, several concentration methods are often used in series, sometimes in unorthodox combinations. In the analysis of organic and biological materials the concentration of trace elements by any method is usually preceded by ashing. There are many examples of the combined use of extraction and sorption, precipitation and flotation, extraction and ashing, etc. Andrianov and Poladyan[82] concentrated traces of germanium by combining coprecipitation on iron(III) hydroxide with extraction of the iron by solutions of fatty acids in light petroleum. The germanium was co-extracted with the iron from the hydroxide precipitate.

A combined method of concentrating precious metals for their determination in natural and industrial materials has been developed[83]. After decomposition of the sample the traces of precious metals are coprecipitated from solution on copper sulphide in the presence of 2-mercapto-benzotriazole. In a second concentration stage the wanted elements are separated from the copper by sorption on a chelating sorbent. After concentration the precious metals are determined by spectral, atomic-absorption, or neutron activation methods.

10. Comparison of Methods

It is difficult to arrange the methods of concentrating trace components in order of merit. No comparison is significant without reference to the type of sample and to the method of analysis of the concentrate. However if allowance is made for these factors the order of merit can change radically. Yudelevich[84] compared matrix extraction, distillation, ion exchange, and directional freezing as methods of concentrating trace elements in the analysis of high-purity antimony with spectroscopic end-determination. From the sum of the indicators he concluded that matrix extraction is the best method of concentration.

The concentration coefficient is one of the main characteristics of concentration methods. The writer has tried to compare methods on the basis of this indicator (Fig.2). However it is important to note that this is only one of the relevant indicators: the other coefficients can be equally important on occasions.

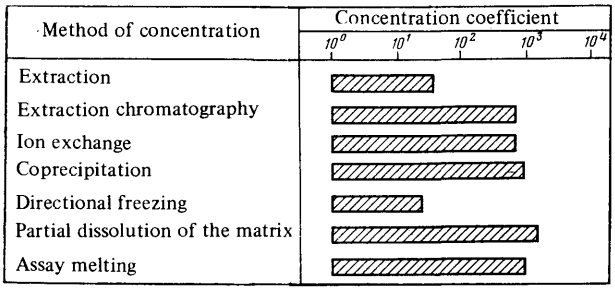

Figure 2. Concentration coefficients achieved by using various methods of pre-concentration.

III. COMBINED CONCENTRATION AND DETERMINATION METHODS

We shall now discuss rational ways of combining concentration methods and methods of end-determination, Evidently, non-specific (multi-element) determination methods should be used in conjunction with group concentration methods. The collector (i.e. the matrix of the concentrate) should be chosen so as to satisfy the requirements of the method of determination as far as possible: thus graphite powder is best for spectroscopic analysis, an organic extract for flame atomic-absorption spectroscopy, etc. It is useless to combine a high-precision method of determination with a method of concentration lacking adequate reproducibility, or *vice-versa*.

We can distinguish two groups of analytical procedures resulting from the combination of a concentration method and a determination method. In the first group the concentration and determination are not specially related: more or less independent methods of concentration and of determination are applied sequentially. The determination is not significantly affected by the properties of the concentrate. In these cases the method chosen for the concentration is immaterial from the standpoint of the determination: ion exchange, extraction (with or without re-extraction), or other methods are all equally suitable. The concentrate to be used in the determination can be, for example, an aqueous solution bearing little similarity to the original sample. Such a solution can be analysed by a variety of methods. Clearly, combinations of concentration and analysis methods of this type do not need to be specially discussed, though they have been used for a very long time and their applications are very widespread.

However on occasions the properties of the concentrate do have a substantial effect on the subsequent determination. In these cases we have to consider the special features of the combination, which can no longer be treated simply as the application of two methods in succession: a new qualitative aspect has appeared. For example, whereas with flame atomic-absorption analysis of aqueous solutions the method of extracting the trace elements is unimportant, substantial effects are observed in the atomic-absorption analysis of organic extracts. These effects arise from the difference in viscosity between organic solvents and water, and of course from the fact that the former are combustible. These differences can substantially affect the mechanism of processes in the flame. The effects are so marked that the methods are often placed in a class of their own. The situation is very similar in the combined extraction and photometric determination procedure when the organic phase is used directly for the determination. There have been recent attempts at combining extraction with direct polarographic analysis of the extract. Evidently the polarography of these organic solutions differs very substantially from the polarography of aqueous solutions.

The very close link between separation and determination methods is evident also from a different standpoint. Combinations of separation and determination methods in a single apparatus have been described (e.g. in gas chromatographs). Comparable unification is achieved in modern high-pressure liquid chromatographs. The need to separate the methods within a particular group is demonstrated most clearly by the gas chromatographic approach. Combined procedures of the second group can be termed hybrid methods.

We shall now discuss some specific examples of the combination of a pre-concentration method with some of the most important methods of determination.

Concentration is very important when *spectral analysis* is used: it has been applied for the past 25 years since the work of Semples, Pohl, and others[85,89]. Concentration is resorted to when direct analysis cannot reach the required limit of detection, and also for other reasons mentioned above. It is desirable to remove the matrix fully when its presence interferes with the determination of the trace elements because of overlapping spectral lines or if the excitation potential of the main element is unfavourable. All the samples should be converted into the same physicochemical form, so that a single series of reference standards can be used. The greater concentration of the trace elements in the concentrate (as compared with the original sample) avoids the need to use unreliable reference standards with extremely low concentrations of the wanted elements. Concentration also minimises the fluctuations of the spectroscopic results produced by uneven distribution of the trace elements in the sample[2]. All these reasons account for the very wide use currently made of these particular combinations. (In the USSR these combinations are termed chemico-spectral methods).

Group concentration of all the wanted trace elements is very desirable in these methods. In some cases complete removal of the matrix is unnecessary, and enrichment is sufficient. However the concentrate must always be in a form suitable for direct excitation of the spectrum of the trace elements: these elements must be concentrated on a small mass of the collector or on a small-area electrode.

Spectral analysis places a number of special requirements on the collector (i.e.on the matrix of the concentrate). It must be stable when stored, non-hygroscopic, and its constituent elements must have a simple emission spectrum. The collector material must be easily prepared in a reproducible form by a small number of simple operations. It should also be relatively involatile to ensure uniform access of the trace elements to the electric discharge during the spectral analysis. All these requirements are met by carbon (graphite) powder, often used in a mixture with sodium chloride. Very many specific methods of chemico-spectral analysis based on the use of this collector have been developed. Examples are given in Table 3.

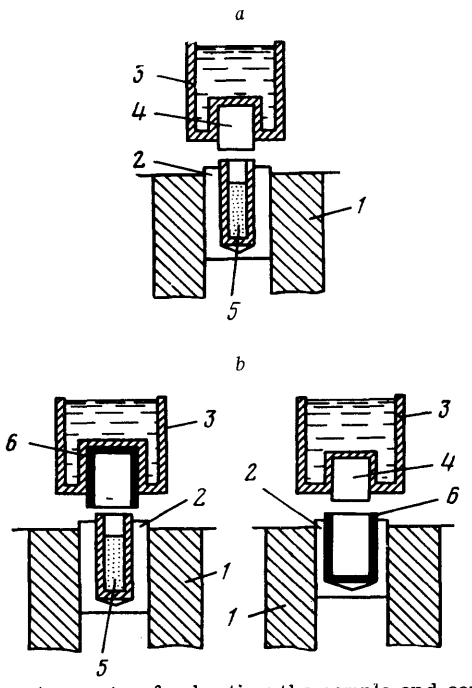
One of the methods listed in Table 3 deserves special mention[90]. The aim was to determine small impurities (10^{-6}–10^{-4}%) of antimony, tin, lead, bismuth, zinc, cadmium, and copper in alloy steels. The above elements were extracted by methyl isobutyl ketone from a solution of 1 *M* ammonium iodide and 2.3 *M* sulphuric acid, and they were then re-extracted by 15% hydrogen peroxide into a 2.5 *M* solution of sulphuric acid. The re-extract was evaporated to dryness

with 10 mg of graphite powder, and the final concentrate was baked at 350–400 °C. The spectral determination was carried out by a fractional distillation method, using potassium iodide as a carrier. The limits of detection on a medium-dispersion spectrograph were 10^{-6}–10^{-4}%, the relative standard deviation 0.09–0.36. By using a high-dispersion spectrograph the limit of detection could be lowered to 10^{-7}–10^{-5}%.

Table 3. Examples of spectroscopic determinations with pre-concentration of the trace elements*.

Sample	Method of concentration	Elements to be concentrated	Limit of detection, %	Refs.
High-purity silver	matrix extraction	Al, As, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Ga, Fe, In, Mg, Mn, Ni, Pb, Sn, Te, Ti, V, Zn, Zr	10^{-7}–$2\cdot10^{-6}$	25
Alloy steels	trace element extraction	Bi, Cd, Cu, Pb, Sb, Sn, Zn	10^{-6}–10^{-4}	90
Aqueous solutions	trace element extraction	Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Ti, V	—	17
Sodium iodide	trace element extraction	Ag, Al, Bi, Ca, Cd, Co, Cr, Cu, Fe, Mg, Mn, Mo, Ni, Pb, Sb, Sn, Ti, Zn	10^{-7}–10^{-5}	10
Solutions from dedompn. of ores and concentrates	trace element extraction	Ag, Au, Ir, Pb, Pt, Rh, Ru	10^{-6}–10^{-4}	19
Ditto	sorption on CuS and chelating resin	Ag, Au, Ir, Pd, Pt, Rh, Ru	10^{-7}–10^{-5}	83
Aluminium, gallium gallium arsenide, indium phosphide	coprecipitation on Bi_2S_3, $Bi(OH)_3$, In_2S_3	Ag, Au, Cd, Co, Cr, Cu, Mn, Ni, Pb, Sn, Zn	10^{-7}–10^{-5}	91
Ores and minerals	trace element extraction	Au, Ag	$5\cdot10^{-8}$–$5\cdot10^{-5}$	92

*Powdered graphite used as collector in all cases.



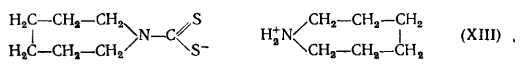


Figure 3. Apparatus for heating the sample and condensing the elements in the one-stage (*a*) and two-stage (*b*) method of evaporation: *1*) graphite flanges of water-cooled copper electrodes, *2*) graphite crucible, *3*) water-cooled holder for condensate receivers, *4*) condensate capsule, *5*) graphite beaker containing powdered sample, *6*) first condensate receiver.

A specific concentration procedure for spectral analysis is the evaporation method, a classical example of which is the fractional distillation method[93]. The evaporation method was proposed[94,95] for the analysis of pure materials used in the atomic energy industry. Two variants were described: evaporation in air and in a vacuum. An infusible powdered sample (usually oxides) is placed in a graphite cup (Fig.3) and heated by passing a heavy current through a graphite heater pressed between the graphite flanges of two water-cooled copper electrodes. The vapours of the evaporating trace elements are condensed on a cooled graphite or copper capsule which is then used as a spectrographic electrode. With samples of intermediate volatility (for example, silicon) a two-stage distillation of the trace elements can be carried out: the first stage uses a cooled graphite cup as the collector, and in the second stage the trace elements are distilled from this cup to the capsule electrode. This procedure offers a more complete separation of the matrix. Some workers have converted volatile matrices (for example, molybdenum or chromium oxide) into involatile carbides before this procedure.

The combination of pre-concentration and *atomic absorption spectrometry* is most often exploited in the extraction–flame atomic absorption variant, with direct atomisation of the extract into the flame. The main advantages of this method (as compared with the determination of elements in aqueous solution by atomic absorption) are a lower limit of detection and a faster and simpler analysis. The method avoids evaporation of the extracts, re-extraction, and other operations which result in higher blank corrections when widely occurring elements are being determined. In some procedures, using a highly combustible organic solvent, even the fuel gas can be dispensed with. Concentration is used also in conjunction with flameless atomic-absorption spectroscopy.

The high selectivity of the atomic-absorption determination allows the group concentration of the trace elements (for example, into an extract). Therefore group extraction is used as an alternative to individual extraction. The extraction of chelates is widely used for this purpose (i.e. complexes with hydroxyquinoline, β-diketones, xanthogenates, and especially dithiocarbamates). Chloroform and carbon tetrachloride, like benzene, are now rarely used as solvents because of their toxicity. Suitable solvents for flame atomic-absorption spectroscopy are methyl isobutyl ketone (MIBK) and butyl acetate. The ammonium pyrrolidinedithiocarbamate (PDTC)–methyl isobutyl ketone system is widely used for the group separation of trace elements, and many methods of analysis of waters, biological samples, and other materials have been based on this system. For example, Anders and Hailer[96] describe a method of direct extraction of cadmium and lead from wine which does not extract the sugars and acids of the wine.

Some workers[97,98] have successfully used hexamethylammonium hexamethylenedithiocarbamate (XIII) instead of PDTC:

(XIII)

This reagent is prepared from hexamethyleneimine, which is obtained as a side-product in the manufacture of Nylon and is therefore readily available. Several methods using this reagent have been developed, including the determination of Co, Cu, Fe, Mn, Ni, Pb, and Zn in sea-water[98].

Automatic apparatus for concentration by extraction has become available commercially: in particular, the model marketed by the firm "Technicon" has a throughput of 60 samples per hour[99]. Another variant of concentration by

extraction, developed for use in conjunction with a six-channel atomic fluorescence spectrophotometer, can handle 25 samples per hour[100]. Another useful method for determining traces of various elements and for analysing concentrates has been termed the "injection" method[101].

Typical atomic-absorption methods of determining trace elements in various materials are listed in Table 4. The special features of the combination of extraction and atomic absorption are discussed in detail in the recent monograph[58,105] and review literature[106].

Table 4. Examples of atomic-absorption determination with pre-concentration of trace elements by extraction.

Elements to be determined	Sample	Main extraction reagent	Detection limit, %	Refs.
Ag	minerals, ores, concentrates	diphenylthiourea	10^{-6}	20
Ag, Cu, Tl	metal halides	diphenylthiourea	10^{-7}—10^{-5}	21
Ag	ores and minerals	triphenylphosphine	10^{-6}	15
Au	minerals, cyanide solutions	triphenylphosphine	10^{-4} (2×10^{-3} $\mu g\ ml^{-1}$)	14
Cu, Fe, Mo, V, Zn	titanium tetrachloride	trioctylamine	$2 \cdot 10^{-5}$—$2 \cdot 10^{-5}$	102
Bi, Cu, Fe, Pb, Sb, Sn, Zn	alloy steels	trioctylamine	10^{-5}—10^{-4}	103
Fe	sodium and potassium halides	dithizone, sodium tetraphenylborate	—	104

In *X-ray fluorescence analysis* group concentration is used more often than individual concentration. In this case the concentrate should be a solid, which can be analysed directly. If the concentrate is liquid several additional operations are required: for example, after extraction the organic phase is often decomposed and the trace elements are sorbed on cellulose powder or on silica gel with grafted functional groups. Whenever possible the extraction is carried out with low-melting extractants at high temperature: the concentrate can then be simply pelleted and analysed. In some methods[43-45] of water analysis the trace elements are sorbed on silica gel microspheres with grafted chelating groups.

A widely used combination is concentration (usually by extraction) followed by *spectrophotometric determination* in the visible and u.v. regions of the spectrum. Individual concentration is often employed, or several elements are extracted sequentially. The matrix is very seldom removed in these methods. Usually the same reagent which gives a coloured complex is used also for concentrating the trace element. However two different reagents are used on occasions: a selective reagent is used first, to extract the trace element, and then a reagent not necessarily selective but having the most favourable photometric properties is added to the extract. This latter variant usually implies re-extraction, or decomposition of the extract. We should mention a method of concentrating copper, zinc, cadmium, mercury, manganese, and nickel as their 1-(2-pyridylazo)-2-naphthol (PAN) complexes: concentration occurs on an optically transparent membrane consisting of poly(vinyl chloride), tricresyl phosphate, and PAN.[107] The membrane is immersed into the solution for analysis, it is washed and dried, and its optical absorption is measured with a photometer.

Pre-concentration methods have been used also in combination with *spark source mass spectrometry*[108,109]. After being separated from the matrix (by extraction) the trace elements are deposited on a collector (usually high-purity alumina). In a determination[108] of eight trace elements in steel the impurities were extracted from an iodide solution into methyl isobutyl ketone, and they were then re-extracted by a dilute solution of sulphuric acid in the presence of hydrogen peroxide and evaporated on alumina. The concentrate was baked and analysed with a double-focussing mass spectrometer. A similar method was developed to determine impurities in sulphuric acid. A different, more specialised variant was proposed[109] for the determination of traces of the precious metals in both natural and technical materials. The precious metals are extracted from a solution in hydrochloride acid containing copper and other non-ferrous metals in the form of their hexamethylenephenylthiourea complexes. Copper(I) is co-extracted by this reagent. The extract is evaporated and baked to give a concentrate on copper oxide suitable for direct analysis in the mass spectrometer, since copper does not interfere with this determination.

Spark source mass spectrometry can be used to determine small quantities of at least 60–70 elements, and therefore it is most conveniently combined with concentration methods relying on removal of the matrix.

Concentration is used also in *activation analysis*. There are two basically different methods of concentrating trace elements in this method: concentration before irradiation and concentration after irradiation. Removal of the matrix before irradiation is essential when strong activation of the matrix would otherwise occur with production of long-lived radioisotopes. The concentration procedure can be used also to remove trace components liable to be strongly activated which are not being determined. However concentration before irradiation invalidates the main advantage of activation analysis: the absence of a blank correction. On the other hand this advantage is retained when concentration is carried out after irradiation. Both methods are used in analytical practice, though the second is by far the more common.

Two main types of pre-concentration method can be identified also in *electrochemical methods* of analysis. The first is inverse voltammetry. The trace elements are pre-concentrated electrochemically on a solid or a mercury electrode, and they are then determined by anodic dissolution. Cations produce a metallic deposit on the electrode: this deposit is conveniently handled by using a vitreous carbon electrode, which is chemically stable and mechanically strong. The concentration method used in the determination of anions consists in forming a film of an insoluble compound on a metallic (e.g. silver) electrode by the reaction between the electrode material and the anion being determined.

The alternative approach is polarography of extracts containing the trace elements. A background electrolyte and a homogenising solvent (for example, methanol) are added to the extract before polarographic analysis. This combination makes the analysis faster by avoiding the need for decomposition of the extract or for re-extraction. Furthermore it combines the selectivity of the polarographic method with that of concentration by extraction. For example, a method of determining indium doping impurities in the compound semiconductor $CdSiAs_2$ has been described[110]: the indium is extracted by chloroform at pH 1.2 as its chelate with 1-phenyl-3-methyl-4-benzoylpyrazol-5-one, and the cadmium and arsenic do not interfere with the extraction of indium. A solution of ammonium bromide in methanol is used as background electrolyte. Several developments of this type have been reported[111,112]. The first review of extraction-polarographic methods was published in 1939,[113] and it was followed by several other reviews.

An interesting "double" concentration is described by Karbainov[114]: concentration by extraction is followed by electrochemical concentration on an electrode. Both the approaches mentioned above are used in this variant.

IV. CONCENTRATION METHODS IN THE ANALYSIS OF SPECIFIC SUBSTANCES

It is interesting to examine the special features of concentration methods in the analysis of some important materials. In most cases concentration is applied in the analysis of high-purity materials, natural waters, and geological samples.

In the analysis of high-purity materials the purity of the air, of the glassware, of the apparatus, and of the reagents is of the utmost importance. Methods of concentration which do not require the use of reagents are often preferred (thermal evaporation of the matrix, crystallisation methods, etc). When choosing a concentration method it is important to know the previous history of the pure sample: if possible the concentration method should be different from the purification method used in the preparation of the sample.

The blank problem has a special significance in the analysis of pure materials. Usually the blank experiment includes all the reagents used in the concentration experiment, in the same amounts and under the same conditions, but without the sample for analysis. The amount of the wanted element determined in the blank experiment is a correction which is subtracted from the analysis result. Blank experiments of this type are often carried out, but they are not entirely correct: the degree of contamination by (or of loss of) the trace element in the presence of the main constituent of the sample may not be the same as in the blank experiment. Furthermore the residue of the matrix in the real concentrate may produce conditions for the determination of the trace element different from those which apply to the concentrate of the blank experiment, which is free from these residues. Several ways of overcoming these inconsistencies have been proposed, but space does not allow us to discuss them here. We will only stress the importance of using a method capable of handling different weights of the sample for analysis.

There are interesting reports[6,7] of the avoidance or minimisation of errors introduced by concentration methods. One of the recommended procedures involves very close integration (in both time and space) of the decomposition, concentration, and detection stages, preferably within a single enclosure. The adoption of micro- and ultra-micro methods is also recommended.

Natural waters are another important type of material whose analysis involves concentration methods. Without going into this problem in depth, we shall only stress the importance of the state of the trace elements in the water, which is often ignored. Often the trace elements are present as soluble complexes with naturally occurring or industrial organic substances, or alternatively they can be present as colloids.

Some methods allow direct concentration of the trace elements without previous treatment of the water: for example, Cu, Co, Zn, Mn, Cd, and In can be extracted as their complexes with hexamethyleneammonium hexamethylenedithiocarbamate without any preliminary operation. However in most cases a preliminary decomposition of the complexes is required, and the water is therefore treated with an oxidising agent (e.g. persulphate).

The complex formation problem is even more important in the analysis of surface fresh waters. The complexes formed by metal ions with humic and fulvic acid and with other organic compounds present in natural waters can strongly influence the extent of concentration of the trace elements achieved by extraction, sorption, and coprecipitation methods. Full concentration is usually possible only after decomposition of these organic materials.

In conclusion we note that this review has dealt with only a small part of the problem of the analytical concentration of trace elements. No mention was made, for example, of the validity and the reproducibility of the analysis, or of the effect of the concentration procedure on these characteristics, of the problem of controlling the degree of concentration, of the need to specify the concentration method used, etc. Among the important problems still to be solved are the development of automated methods of concentrating trace elements, the creation of unified procedures for the decomposition of the sample and the concentration and final analysis of the trace elements, and the development of new, simple, and rapid reagentless methods of concentration.

Possible Approaches to the Development of Photo-catalytic Solar Energy Converters

K.I.Zamaraev and V.N.Parmon

Possible approaches to the development of photo-catalytic solar energy converters, and their perspectives, are discussed with special reference to the conversion of solar energy into chemical energy by the photo-catalytic decomposition of water into hydrogen and oxygen. 408 references.

I. INTRODUCTION

According to recent estimates[1-4] the annual consumption of energy by mankind is currently 5×10^{16} kcal, rising rapidly and doubling every 15–20 years. On the other hand the known reserves of mineral fuels, which at present form the basis of our energy balance, are limited to an estimated energy equivalent of 10^{19} kcal. Thus the search for new sources of energy is a problem of fundamental importance. The most promising approaches appear to be the use of thermonuclear energy (based on deuterium) and the use of solar energy[1-18]. The large-scale exploitation of both these sources of energy presents serious difficulties, but it is important to note that whereas controlled thermonuclear fusion is still at the research stage solar energy is continuously reaching the Earth in amounts far exceeding the rapidly growing needs of mankind.

Thus the amount of solar energy which is incident on our planet is estimated[1,16,17] to be 1.2×10^{21} kcal per annum, but some of this energy is reflected by the atmosphere and by the Earth's surface and is irreversibly lost, while the remainder is absorbed by the atmosphere (2×10^{20} kcal), by the oceans and seas (4.2×10^{20} kcal), and by the land masses (1.8×10^{20} kcal). Part of this absorbed energy (6×10^{17} kcal per annum) is converted into chemical energy by the photosynthetic process in plants and micro-organisms. However, only a very small part of this energy is used by mankind: 8×10^{15} kcal per annum as fuel and other materials and 4×10^{15} kcal per annum as food. The amount of solar energy converted into electrical energy by hydroelectric and wind-operated power stations is also quite small: 4×10^{15} kcal per annum.

The most important attribute of solar energy is its ecological purity, i.e. the possibility of carrying out energy cycles without emitting harmful products into the surroundings and without additional heating of the Earth.

The wide-scale exploitation of solar energy must await practical solutions to the following three problems: 1) the relative diffuseness of solar energy (even outside the Earth's

atmosphere the flux of solar energy is only 1.395 kW m^{-2} = 12260 kW-h m^{-2} $year^{-1}$ = 3.33×10^{-5} kcal cm^{-2} s^{-1}),[19-24] 2) the annual, seasonal, and daily variations of the energy flow reaching the Earth's surface, and 3) the need to convert the energy of the light quanta into a more convenient form.

Let us consider the importance of the first two of the above factors. In the vicinity of the Earth a power of 1 GW (typical of a modern electric power station) is carried by the Sun's rays falling on a square 850 m in side: the area of such a square is comparable to that occupied by a thermal power station having that output. Of course, on the Earth's surface the insolation is much lower, since the Sun shines for only part of the day, and its rays are partly reflected by the atmosphere. But even in the middle latitudes of the USSR—in the region of Moscow or of Novosibirsk, say—the total amount of radiation falling on the surface of the Earth is staggeringly large: more than 1000 kW-h m^{-2} $year^{-1}$.[19,20] This is only 2.5 times lower than the radiation in the sunniest region of the Earth (near the Red Sea[20,22]). In Soviet Central Asia the total solar radiation is as high as 1600 kW-h m^{-2} $year^{-1}$. A simple calculation shows that an amount of energy equal to the annual output of a 1 GW electric power station is contained in the Sun's rays falling on a square 3 km in side in the middle latitudes of the USSR or 2.3 km in side in Central Asia. It is equally easy to show that the amount of energy produced by the combustion of 600 million tonnes of petroleum (the annual production of the USSR) is contained in the Sun's rays falling on a square 67.4 km in side in Central Asia: we note that just the Kara-Kum desert can accommodate over 60 of these squares.

An amount of energy of 1300 billion kW-h, equal to the annual output of electrical energy planned for 1980 in the USSR, could be collected in Central Asia from a square 64.7×64.7 km^2 in area assuming a conversion efficiency of 20%. Even in the region of Novosibirsk the annual output of electrical energy of the Novosibirsk hydro-electric station (1.7×10^9 kW-h)[25] could be matched with a square 2.9 km in side (again, assuming 20% conversion efficiency), which is very much less than the area of the Ob' sea which feeds the hydroelectric station (1070 km^2). For comparison we may note that in the USA the area of the existing network of hard-surfaced roads (having a total length of 6 million km in 1972[26]) is greater than the area of a square 150 km in side. Thus, in spite of the relatively low density of the solar energy flux and of its dependence on local conditions, even a complete change-over of our energy consumption to solar energy is not (in principle) an engineering impossibility. More detailed estimates have confirmed the economic justification for the development of energetics based on solar radiation[27-59]. However, the effective exploitation of solar energy awaits the development of economically acceptable methods of concentration, conversion, and storage of the Sun's energy.

II. METHODS OF SOLAR ENERGY CONVERSION

Existing methods of conversion of the Sun's energy can be arbitrarily classified into four types: 1) thermal, 2) photophysical, 3) photochemical (including photo-electrolysis), and 4) photobiological (based on natural photosynthesis).

The thermal conversion of solar energy is the simplest: it consists in heating heat-transfer media with ordinary or with concentrated Sun's rays. Many variants of the thermal method are currently in use, or are being developed: they are used for cooling or heating buildings, in solar kitchens and high-temperature furnaces, for powering mechanical engines and electrical generators, for feeding thermo-electric converters, in the desalination of water, etc. (see previous reviews[4,12,27-39]). In principle the efficiency of the conversion of the Sun's radiant energy into heat is quite high, and with a very simple concentrator it can reach 50–70% at noon[23,27,28,38,39,60]. Therefore even in the near future we can expect relatively large-scale use of thermal methods of solar energy conversion, matched to local needs. However, in the subsequent conversion of thermal into electrical or mechanical energy the efficiency (daily average) falls to 3–5% because of the low efficiency of heat engines and of the low effectiveness of the concentrators except at noon[23,27]. For these reasons thermal conversion of solar energy is still not being used for large-scale energy production.

Recent advances in the direct conversion of solar energy into electrical or chemical (fuel) energy have made these methods potentially more attractive for large-scale energy production.

The direct photophysical conversion of solar into electrical energy is most effectively realised in semiconductor p–n junction converters[4,22,28,51-55,61,62]. In these devices the absorption of a light quantum of energy $h\nu$ (greater than the energy gap) transfers an electron from the valence to the conduction band. The resulting hole–electron pair is separated by the electric field of the p–n function (see Fig. 1), causing electrical polarisation of the semiconductor wafer and thus producing an e.m.f. and a current i. Semiconductor converters based on crystalline silicon, with efficiencies up to 14%, have been developed and are being used successfully[51-55,61,62]. Even more effective semiconductor converters based on hetero-junctions (e.g. gallium arsenide) are also being developed: their efficiency can be as high as 20% or more[52-55]. This method of converting solar into electrical energy is attracting most of the research effort at the moment, and it appears to offer the best prospect of success†. A plan to set up a semiconductor electrical power station in space capable of re-transmitting the energy to the Earth in the form of UHF radiation is also being discussed[24].

The widespread use of semiconductor converters awaits practical solutions to two main problems: the high cost of the semiconductor converters themselves (currently[53-55] 10–15 thousand dollars per kW of power production capability), and the difficulty of combining semiconductor photo-electric converters with high-power electrical circuits. The former problem will be rapidly overcome by current advances in semiconductor production technology (it is estimated[53-55] that economically acceptable converters costing 200–250 dollars per kW, i.e. matching the cost of modern thermal converters, will be available in the mid-1980's). However, the second limiting factor, which applies to all Earth stations, is more serious. It stems from the annual, seasonal, and daily

† Work is proceeding also on photo-electrochemical converters of solar into electrical energy ("wet photocells"). According to their operating mechanism, these can be classified into two types: the photosensitive semiconductor electrode type[11,59,63-93] and the photosensitive electrolyte type[94-110]. Recent converters of the photosensitive electrode type have shown very promising efficiencies (up to 7.5% for CdSe with a polysulphide electrolyte[88]). However, much more work is needed before the true potential of the method can be assessed. The All-Union Research and Technical Information Institute (VINITI) issues a special bulletin entitled "Ekspress-informatsiya. Pryamoe Preobrazovanie Teplovoi i Khimicheskoi Energii v Elektrichestvo" (Express Information. The Direct Conversion of Thermal and Chemical Energy into Electricity), which summarises current foreign publications on the conversion of solar energy into electrical energy by photo-electric cells (including "wet cells").

variations of the energy output of the semiconductor converters. The consumption of electrical energy cannot be tailored to suit these variations. Energy accumulators (or buffers) have been based on the chemical energy of fuels or on the potential energy of water in reservoirs. The large-scale use of solar energy will also require some form of *accumulation* of this energy, preferably in the most effective form currently known (i.e. as a *chemical fuel*).

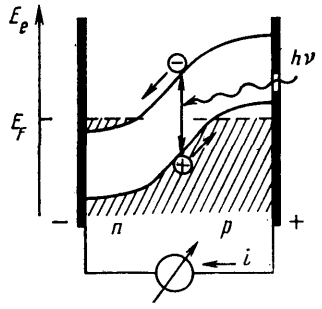

Figure 1. Basic operation of the semiconductor element. The potential energy of the current carriers (E_e) is plotted vertically. The thin full lines are the edges of the energy gap; the cross-hatched region denotes the energy levels filled with electrons; E_F is the Fermi level. The arrows show the direction of motion of the charges (electrons and holes) separated by the light in the region of the step in electrical potential.

Many experts consider hydrogen to be the most promising fuel[1,13-15,56-59,111-116]. Hydrogen is not only an exceptionally good fuel, whose combustion does not contaminate the environment, but it is also a valuable chemical product. The current world production of hydrogen is more than 30 million tonnes per annum, with an annual growth rate of 10%.[14,57] Given solar energy converters having an efficiency of 20% this amount of hydrogen could be produced in Central Asia from a square with 55.4 km sides.

One possible way of converting solar energy into chemical energy in the form of hydrogen is the electrolysis of water, using the electrical energy produced by semiconductor $p-n$ junction converters. Assuming an efficiency of 14% for the conversion of solar into electrical energy (which has already been achieved in modern silicon photocells), and an efficiency of 70% for the conversion of electrical into chemical energy (i.e. the efficiency of present-day industrial apparatus for the electrolysis of water), the overall efficiency for the conversion of solar energy into the chemical energy of hydrogen is 10%. This is an encouraging figure, especially since there are very real prospects of further improvements in the efficiency of semiconductor converters of radiant into electrical energy. Converters based on this two-stage scheme could in principle be operating now, but so far they have not been economically viable because of the existence of cheaper (natural) organic and nuclear fuels.

In addition to this two-stage method we can envisage the direct photochemical conversion of solar energy into fuel energy without intermediate production of electrical energy. Most of the photochemical conversion methods rely on the use of *photo-catalytic* processes. One of these methods is the photo-electrolysis of water on a semiconductor surface (e.g. an oxide), acting as a heterogeneous catalyst for the decomposition of water[117-119]. This method is attracting a great deal of attention at the moment[11,59,117-188] (see also Refs. 63–93).

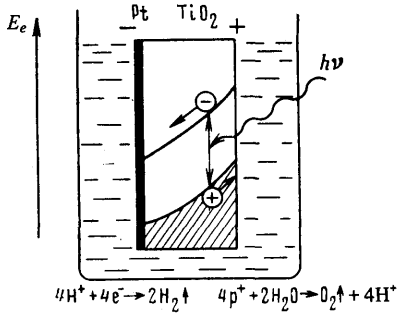

Figure 2. Operation of a semiconductor photo-catalyst for the decomposition of water; symbols as in Fig. 1.

In the most thoroughly investigated system, which uses titanium dioxide as the photo-catalytic semiconductor, the photo-electrolysis process can be described as follows[87,178]. The light generates a conduction electron and a hole in the semiconductor, and the two carriers are separated by the electric field at the semiconductor–electrolyte interface. The holes diffuse to the surface of the semiconductor catalyst, where they oxidise the water with evolution of molecular oxygen (see Fig. 2), and the conduction electrons reach the metal electrode (e.g. platinum) where they reduce the water with evolution of molecular hydrogen. Unfortunately the efficiency of the conversion of solar into chemical energy on TiO_2 is quite low (less than 1%) because this oxide has a wide band-gap (~ 3 eV) and hence the photo-catalytic process in this case requires u.v. quanta, which are present in small numbers in the Sun's spectrum.

Worthwhile progress in this area can be made only by changing to semiconductors which can decompose water under the influence of visible radiation, such as iron oxide[116,182,183] and tungsten oxide[182,183], though other semiconductors also could be used. However, in the absence of reliable quantitative measurements we cannot yet assess the efficiency of solar energy conversion with hydrogen accumulation on these photo-catalysts. Furthermore, most of these materials suffer strong photo-corrosion in aqueous solutions. There is evidence that the photo-corrosion of semiconductor photo-catalysts may be suppressed by chemical modification of the semiconductor surface (by introducing surface impurities, or by adsorption of special reagents). Surface modification can be used also to control the surface field which separates the photo-generated charge pairs.

Thus any progress in the exploitation of these converters will be determined to a large extent by advances in the surface chemistry of semiconductors.

Another method of direct conversion of solar energy into chemical energy relies on molecular photo-catalytic systems. These systems are found, for example, in natural photobiological converters such as plants and bacteria capable of photosynthesis[7,13,56,189-192]. In plants the energy of the Sun's radiation is converted mainly into chemical energy of

carbohydrates, synthesised by the reduction of carbon dioxide and the oxidation of water. The initial step of the photosynthesis is reminiscent of the formation of a conduction electron and a hole in semiconductors. The light quantum absorbed by a chlorophyll molecule (Chl) transfers one electron from the ground state to an excited level (Fig. 3), from which it can fall into the lower-lying levels of other molecules (the acceptors, A). On the other hand the hole which is formed at the same time in the ground level of the Chl molecule can accept an electron from the higher-lying levels of other molecules (the donors, D). As a result, the initial step of the photosynthesis process

$$A + D \xrightarrow[Chl]{h\nu} A^- + D^+ , \qquad (1)$$

produces a pair of particles (the reducing agent A^- and the oxidising agent D^+) analogous to the hole–electron pair of semiconductors.

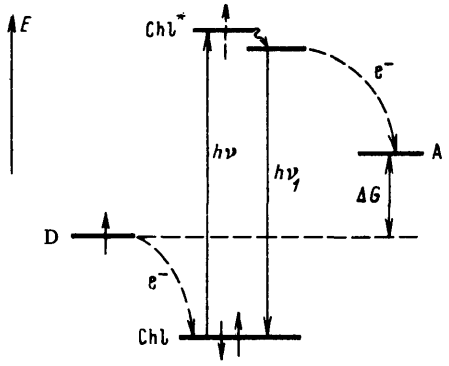

Figure 3. Charge separation by an electronically excited dye molecule (chlorophyll, Chl). Electron energy is plotted vertically, $h\nu$ is the absorbed light quantum, the wavy arrow denotes the conversion into a longer lived excited state, $h\nu_1$ is the luminescence quantum, and ΔG is the chemical energy stored as a result of the process.

During photosynthesis in plants the reducing agent A^- is used (through a complicated chain of catalytic reactions) to reduce CO_2 to sugars:

$$4A^- + 3H_2O + CO_2 \rightarrow 4A + {}^1/_6(C_6H_{12}O_6) + 4OH^- , \qquad (2)$$

and the oxidising agent D^+ completes the cycle of reactions by oxidising water to molecular oxygen:

$$4D^+ + 4OH^- \rightarrow 4D + 2H_2O + O_2\uparrow . \qquad (3)$$

Thus the overall photosynthesis process in plants can be described by the catalytic reaction scheme

$$H_2O + CO_2 \xrightarrow[Chl,\,A,\,D]{h\nu} 1/6\,(C_6H_{12}O_6) + O_2\uparrow \qquad (4)$$

in which an amount of free energy $\Delta G \cong 120$ kcal mole^{-1} O_2 is stored. In order to carry out one such cycle a plant needs no fewer than eight quanta of red light, each with an energy of ~40 kcal Einstein^{-1}.[7]

Theoretical calculations (see below) suggest that the maximum possible efficiency of the conversion of solar energy by the eight-quantum reaction (4) is 15% of the incident Sun's light. This value can be treated as the theoretical limit of the efficiency of photo-biological energy converters. In some water plants (e.g. *chlorellae*) the experimentally measured efficiency of solar energy conversion is as high as 6%.[12,193–195] Among cultivated (agricultural) plants the highest efficiencies are found in maize (3.2%), sorghum (3.2%), and sugar cane (2.4%).[194] Thus the best cultures of water plants offer an acceptably efficient conversion of solar into chemical energy. Economically sound processes for the microbiological fermentation of the products of plant photosynthesis to give convenient forms of fuel for large-scale energy production have already been suggested: hydrogen (see Fig. 4), methane, or ethanol[13,50,196–200]. Large Government programmes aimed at replacing hydrocarbon motor fuels by ethanol (obtained from sugar cane) are already in progress in Brazil and in the Philippines.[13]

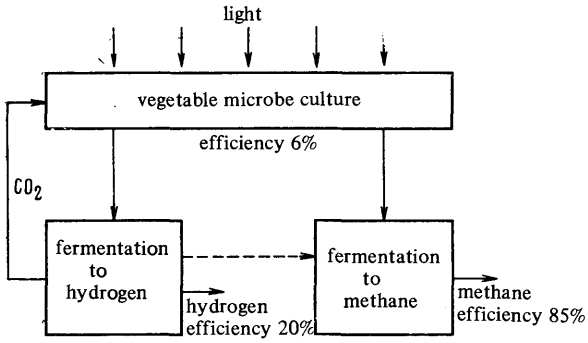

Figure 4. Microbiological conversion of solar energy and efficiencies achieved in the different steps.

Obviously, a major advance in the conversion of solar into chemical energy would be the development of synthetic molecular photo-catalytic systems with a narrow "chemical specialisation", which could be more efficient than plants[1]. If these systems could be handled in simple industrial plant, and manufactured from cheap starting materials, they could even be cheaper than existing semiconductor p–n junction devices. The problem of designing molecular photo-catalytic systems for the conversion of solar into chemical energy was fully formulated only recently[1], and is still in its initial stages of development. The various approaches to its solution are the main theme of the present review.

As will be shown below, molecular and semiconductor photo-catalytic converters have very similar mechanisms. Hence many of the data quoted in this paper can be applied also to calculations involving semiconductor photo-catalytic systems.

III. POSSIBLE PROCESSES FOR THE CONVERSION OF SOLAR INTO CHEMICAL ENERGY

The basic thermodynamic requirement which applies to chemical reactions for accumulating solar energy in the form of chemical energy is that the reaction should be endothermic in the dark. The condition is $\Delta H > 0$ (if the stored energy is to be used for the production of heat) or $\Delta G > 0$ (if the energy is being stored for the production of a more "noble" form of energy, e.g. the electrical energy of fuel cells). In order to allow their storage, transport, and use in practical situations the photo-reaction products must be stable, i.e. the reverse (exothermic) reactions must be slow.

Chemical energy can be stored either directly as the internal energy of molecules (for example, by converting a substance under the influence of light into an energy-enriched form such as a valency isomer), or as reaction products which can be used as fuels (combustibles and oxidisers), and which interact with evolution of energy in a useful form[13,56-59,122,179,201-208].

The exploitation of photochemical converters for large-scale energy production implies the storage and transport of hundreds of millions of tonnes of photo-catalytic reaction products in the form of useful fuels. Therefore the starting materials used in these reactions should be readily available, cheap, convenient to use, and easily transportable. The accumulation of energy in an intramolecular form obviously implies the use of fairly complex compounds[122,179,201,208-216], and this method will probably be limited to satisfying local needs even if very efficient forms of the method are developed. The same is true of converters relying on phase transitions[217,218] or on corrosive or dangerous materials such as SO_2, Cl_2, etc.[208]

Within the Earth's atmosphere the most convenient way to exploit chemical energy is to allow a fuel to react with the atmospheric oxygen. Hence the most attractive working processes for the conversion of solar energy are those leading to the reduction of readily available materials (as in natural photosynthesis).

Table 1. Possible reactions for the storage of solar energy as fuel.

No.	Reaction	n	ΔG^0_{298}, kcal mole^{-1}	ΔH^0_{298}, kcal mole^{-1}	ΔG^0_{298} (for 1 electron), eV	λ_{thr}, nm
1	$H_2O \rightarrow H_2 + {}^1/_2 O_2$	2	56.71	68.25	1.23	1008
2	$2H_2O + CO_2 \rightarrow CH_4 + 2O_2$	4	195.54	212.8	2.12	588
3	$2H_2O + CO_2 \rightarrow CH_3OH + {}^3/_2 O_2$	6	167.92	173.64	1.21	1025
4	$3H_2O + 2CO_2 \rightarrow C_2H_5OH + 3O_2$	12	318.34	336.82	1.15	1077
5	${}^3/_2 H_2O + {}^1/_2 N_2 \rightarrow NH_3 + {}^3/_4 O_2$	3	81.09	91.44	1.17	1059
6	$2H_2O + N_2 \rightarrow N_2H_4 + O_2$	4	181.33	148.74	1.97	629

Note. The thermodynamic data quoted are for liquid H_2O, CH_3OH, C_2H_5OH, and N_2H_4; n is the number of electrons transferred; λ_{thr} is the threshold wave length for the n-quantum mechanism (see Section IV).

In the light of the requirements outlined above the most convenient starting materials are water and atmospheric gases, and we must turn towards these materials (at least, initially) in our search for large-tonnage photo-catalytic energy production methods. Some processes potentially suitable for the storage of energy in a chemical form are listed in Table 1. In every case the product is a valuable chemical raw material. All these processes take place in living organisms (photosynthesis followed by fermentation of the photosynthesis products to H_2, CH_4, or alcohols, or fixation of atmospheric nitrogen). As was pointed out above, reaction No.1 of Table 1 has been achieved under artificial conditions on semiconductor photo-catalysts. Reactions No.2[219] and Nos.5 and 6[220] have also been observed on TiO_2 and $SrTiO_3$ photo-catalysts under the influence of u.v. light, though their quantum efficiency is still very low. The distinguishing feature which all these processes have in common is the oxidation of water with evolution of molecular oxygen. As we shall show below, this reaction step is the most difficult to implement.

The absorption of solar energy by the compounds listed in Table 1 is negligibly small, and photochemical conversion is necessary: this is provided by an additional intermediate agent (the photo-catalyst) which strongly absorbs the Sun's light and which is fully regenerated at the end of the working cycle. Many photo-catalytic reactions, both homogeneous and heterogeneous, have been described (see, for example, Refs.221 and 222 respectively). However, the effort currently devoted to the search for really effective catalytic processes for the conversion of solar energy is still inadequate.

The most promising chemical process for the conversion of solar energy at present is the photo-catalytic decomposition of water into hydrogen and oxygen. Water, of course, is a universally available, cheap, and very convenient starting material. The product of the reaction—hydrogen—is not only an excellent fuel but also an important raw material for the chemical industry, used on an enormous scale. Furthermore, existing information on chemical reaction mechanisms suggests that the photo-dissociation of water may be the most easily implemented of all the processes so far proposed for the accumulation of solar energy. Therefore we shall examine in detail the problems posed by the conversion of solar into chemical energy by this process.

IV. MAXIMUM THEORETICAL EFFICIENCY OF THE CONVERSION OF SOLAR INTO CHEMICAL ENERGY

The efficiency of the conversion of solar energy (η) is defined as the ratio of the amount of energy stored to the total amount of solar energy (E_0) falling on the converter. The latter quantity is equal to the product of the area of the system (S) and of the total flux of solar energy (i.e. of the flux of light quanta of all energies).

For thermal methods of solar energy conversion the efficiency is limited essentially by the use of the Carnot cycle for heating the working fluid in the first stage of the process, and by the conversion of heat into mechanical, electrical, or chemical energy in the later stages[23,60]. Other losses (such as incomplete absorption of radiation) are avoidable in principle to a large extent, and are being overcome as new technological improvements are introduced.

The photo-catalytic conversion of light energy also suffers losses of different types: incomplete absorption of the light by the system (or ineffective absorption by photochemically inactive parts of the system), partial recombination of the useful intermediates during the photochemical reaction, partial loss of energy (as heat) in overcoming activational barriers or in forming energy-consuming intermediates, etc. All these losses can be avoided to a large extent by improved photo-reactor design and by choosing a more effective cycle of chemical reactions.

However, the maximum theoretical efficiency of the photochemical conversion of solar into chemical energy is limited by a factor which is unavoidable in principle and is unrelated to the Carnot cycle: the same factor which sets a limit to the maximum theoretical efficiency of semiconductor p–n junction energy converters. This is the quantum character of the photochemical and photophysical changes[7,59,223].

The elementary endo-energetic photochemical processes all require the absorption of a quantum of light energy greater than some threshold value determined by the free energy ΔG of the process: $h\nu_{thr} = \Delta G$. The only exceptions are the multi-photon processes which take place in high-intensity light fluxes such as laser beams. The real threshold value $h\nu'_{thr}$ can be higher than $h\nu_{thr}$, since the activational barrier may have to be overcome in a system which does not absorb at the frequency ν_{thr}.

All the light quanta having an energy $< h\nu'_{thr}$ fail to induce the photochemical reaction and are wasted; on the other hand when quanta having an energy $> h\nu'_{thr}$ are absorbed only a fraction of their energy ($h\nu_{thr}$) is converted into chemical energy.

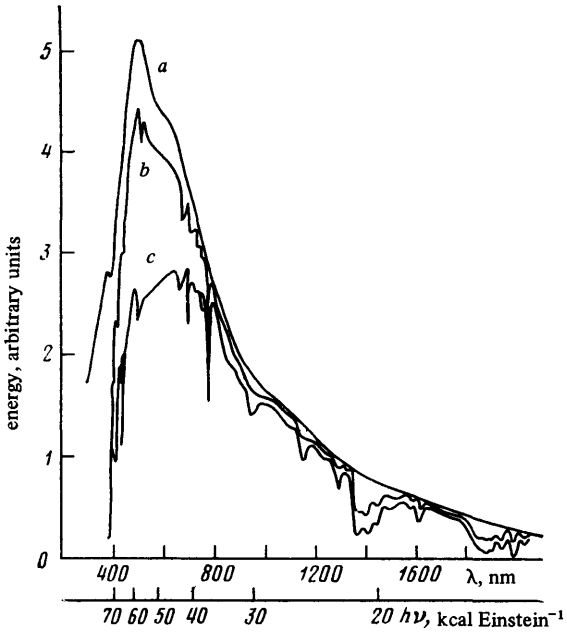

Figure 5. Spectral composition of solar radiation outside the atmosphere (*a*) and on the Earth's surface on a clear summer day at noon (*b*) and in the evening (c)[21].

Knowing the energy distribution function $\rho(\nu)$ of the quanta of solar energy (see Fig.5) we can easily calculate the maximum possible efficiency of a photochemical conversion for different assumed mechanisms. Thus in the simplest case of a one-quantum chemical reaction the stored useful energy E is equal to the product of the number N of acts of reaction (which under optimum conditions is given by the number of incident quanta with an energy $> h\nu'_{thr}$) and of ΔG or ΔH (depending on the final use of the stored energy) for a single act. For example, if the product is to be used in the production of electrical energy we can write $E = \Delta G \cdot N$, where $N = S\int_{\nu'_{thr}}^{\infty} \rho(\nu) d\nu$; furthermore $E_0 = S\int_0^{\infty} h\nu\rho(\nu) d\nu$, so that

$$\eta = \Delta G \int_{\nu'_{thr}}^{\infty} \rho(\nu)\, d\nu \Big/ \int_0^{\infty} h\nu\rho(\nu)\, d\nu.$$

The maximum efficiency theoretically achievable in the complete absence of losses#, i.e. for $h\nu'_{thr} = h\nu_{thr} = \Delta G$,[223] is

$$\eta = \Delta G \int_{\nu_{thr}}^{\infty} \rho(\nu) d\nu \Big/ \int_0^{\infty} h\nu\rho(\nu)\, d\nu = \nu_{thr} \int_{\nu_{thr}}^{\infty} \rho(\nu)\, d\nu \Big/ \int_0^{\infty} \nu\rho(\nu)\, d\nu. \quad (5)$$

According to the second law of thermodynamics we should decrease η by a factor of $\sim (T_0 - T)/T_0$, where $T_0 \cong 5800$ K is the Sun's temperature and T is the temperature of the absorber of quanta. However, this correction is unimportant in practice because $T_0 \gg T$.

Plots of the efficiency calculated by this formula against the threshold quantum energy for the $\rho(\nu)$ distributions which describe the solar spectrum outside the Earth's atmosphere and on the Earth's surface respectively are shown in Fig.6. These plots go through a maximum, where the efficiency reaches ~40% for photochemical processes with threshold energies corresponding to quanta in the red and near-i.r. regions. The existence of an optimum value of ν_{thr} indicates the interplay of two opposing tendencies as ν_{thr} increases: a decrease in the total number of quanta absorbed and an increase in the degree of utilisation of the energy of each of the quanta absorbed.

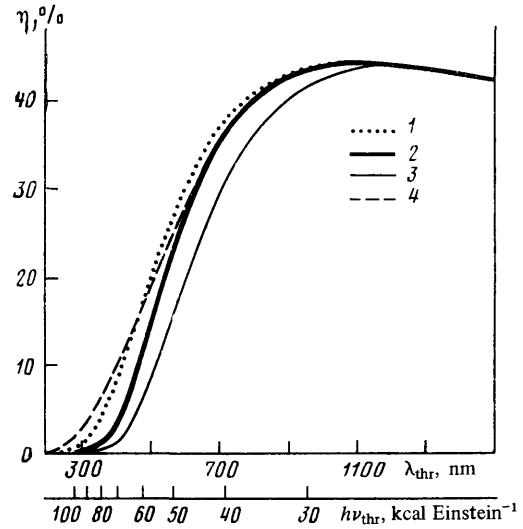

Figure 6. Maximum theoretical efficiency (η) of the one-quantum photochemical reaction against wave length of the threshold light quantum ($\lambda_{thr} = c/\nu_{thr}$) for solar radiation outside the Earth's atmosphere (*1*), on a clear summer day at noon (*2*) and in the evening (*3*), and for a perfect black body at 5800 K (*4*). Data on the solar spectrum taken from Refs.21 and 20.

In another possible situation (which exists, for example, during photosynthesis in plants) n quanta are needed for the chemical change, each quantum producing one particular active compound (the cation radicals of chlorophyll in the case of photosynthesis), and therefore we have

$$\eta = \Delta G \int_{\nu'_{thr}}^{\infty} \rho(\nu)\, d\nu / n \int_0^{\infty} h\nu\rho(\nu)\, d\nu, \quad (6)$$

where $h\nu'_{thr}$ is the threshold energy quantum for an individual photochemical reaction (for example, for the production of Chl^+), and ΔG is the energy stored as a result of the overall process [for example, as a result of reaction (4)].[7,224] In the optimum case $h\nu'_{thr} = h\nu_{thr} = \Delta G/n$, and formula (5) again applies. The following parameters apply to photosynthesis in plants (see Section II): $\Delta G \cong 120$ kcal mole^{-1} O_2, $n = 8$, $h\nu'_{thr} \cong 40$ kcal Einstein^{-1} (the red edge of the chlorophyll absorption band active in photosynthesis). Inserting into formula (6) these values together with the function $\rho(\nu)$

calculated from Fig.5*b* or 5*c* we arrive at $\eta \cong 15\%$ as the maximum efficiency of the photosynthesis process in plants. For the four-quantum ($n = 4$) dissociation of water discussed below ($\Delta G = 113.4$ kcal mole^{-1} O_2) the threshold quantum $h\nu_{thr} = \Delta G/4 = 28.4$ kcal Einstein^{-1} ($\lambda_{thr} = 1008$ nm) lies exactly at the maximum of the curve in Fig.6. This means that a maximum solar energy conversion efficiency of $\eta \cong 40\%$ could be achieved in the decomposition of water by a four-quantum mechanism.

The maximum conversion efficiency could be increased by using several endo-energetic reactions, with different ΔG, in the converter. In this case the photo-catalytic apparatus could be designed in such a way that quanta of low and of high energy are used in reactions with low and with high ΔG respectively. An analogous method of raising the efficiency has been proposed[225] for semiconductor photo-cells. However, there is a danger that chemical systems of this type will be so complex that their usefulness will suffer (as compared to that of the single endo-energetic process). Therefore an efficiency of $\eta \cong 30-40\%$ is perhaps the most realistic estimate which can be made at present.

Table 2. Standard electrode potentials of reactions involving water and its fragments in aqueous solutions.

No.	Reaction	E^0, V	ΔG^0_{298}, kcal mole^{-1}	Refs.

11	$2OH^- = H_2O + {}^1/_2O_2 + 2e^-$	0.401	18.5	226
12	$H_2O_2 = O_2 + 2H^+ + 2e^-$	0.682	31.5	228
13	$\dot{O}H + H_2O = H_2O_2 + H^+ + e^-$	0.72	17	228
14	$2H_2O = O_2 + 4H^+ + 4e^-$	1.228	113.4	226
15	$O_2 + 2OH^- = O_3 + H_2O + 2e^-$	1.24	57.2	226
16	$H_2O_2 = H\dot{O}_2 + H^+ + e^-$	1.5	35	228
17	$3H_2O = O_3 + 6H^+ + 6e^-$	1.511	209.3	229
18	$OH^- + H_2O = HO_2^- + 2H^+ + 2e^-$	1.706	78.76	229
19	$2H_2O = H_2O_2 + 2H^+ + 2e^-$	1.776	81.72	229
20	$OH^- = \dot{O}H + e^-$	2.02	46.6	226
21	$O_2 + H_2O = O_3 + 2H^+ + 2e^-$	2.076	95.56	226
22	$H_2 = H + H^+ + e^-$	2.106	48.61	229
23	$H_2O = \dot{O}'(g)' + 2H^+ + 2e^-$	2.421	111.72	226
24	$H_2O = \dot{O}H + H^+ + e^-$	2.8	65	228

It is often suggested that the use of thermal processes in photochemical converters is irrational because of the low efficiency of the conversion of thermal into chemical energy. However, this shortcoming is compensated by the possibility of full conversion into heat of all the quanta contained in the Sun's light. As a result the overall losses may be lower than those encountered in quantum converters, in which we know that more than half of the energy can be lost. Evidently, photo-catalytic systems which exploit the advantages of the thermal and of the quantum conversion methods at the same time could be designed, thus overcoming their disadvantages to some extent. For example, a system could be designed in which the chemical equilibrium at various stages of the photo-catalytic process is shifted towards useful products by heating the system (or part of it) with photochemically inactive i.r. light. Several possible conversion systems with heating will be considered in the following Section.

V. THE PHOTO-CATALYTIC DECOMPOSITION OF WATER

1. Thermodynamics of the Water Decomposition Processes

The decomposition processes in the gaseous and the liquid phase are accompanied by the following changes in free energy and in enthalpy[226]:

$$H_2O(g) \rightarrow H_2(g) + {}^1/_2O_2(g);\ \Delta G^\circ_{298} = 54.6 \text{ kcal mole}^{-1},\ \Delta H^\circ_{298} = 57.8 \text{ kcal mole}^{-1};$$
$$H_2O(l) \rightarrow H_2(g) + {}^1/_2O_2(g);\ \Delta G^\circ_{298} = 56.7 \text{ kcal mole}^{-1},\ \Delta H^\circ_{298} = 68.3 \text{ kcal mole}^{-1}.$$

For the reaction involving the liquid phase ΔG decreases by ~ 3 kcal mole^{-1} when the temperature is increased from 25 to 100 °C.

The standard electrode potentials E^0 and the corresponding values of ΔG°_{298} for a number of one-electron and multi-electron reduction and oxidation processes involving water and its reaction products in aqueous solutions are listed in Table 2. We can see from the Table that from the electrochemical standpoint the decomposition of water into H_2 and O_2 is a four-electron process§ with a potential difference $\Delta E^0 = 1.23$ V and $\Delta G^0 = 113.4$ kcal mole^{-1} (obtained by combining reactions No.8 and No.14 of Table 2).

Most of the reactions in Table 2 involve the ions H^+ and OH^-. The electrode potentials of these reactions depend on the pH of the medium. The standard potentials listed in Table 2 correspond to pH = 0 for reactions involving H^+ and pH = 14 for reactions involving OH^-. At other pH values the E^0 values should be replaced by the formal oxidation–reduction potentials (ORP) E_m.[228]

Plots of E_m against pH for reactions No.14 and No.8 (evolution of oxygen and of hydrogen respectively) are shown in Fig.7.[229] Since the H^+ ions do not appear in the overall equation

$$H_2O \rightarrow H_2 + {}^1/_2O_2,$$

the difference between the E_m values for reactions No.14 and No.8 is independent of pH (1.23 V). Any oxidising agent with an E_m value lying above the "oxygen" line is thermodynamically able to evolve O_2 from water, and similarly any reducing agent with E_m below the "hydrogen" line can evolve H_2 from water[228–230].

As usual, removal of the reaction products assists the reaction: a rise in the "hydrogen" line and a fall in the "oxygen" line are clearly shown in Fig.7 in response to a decrease in the hydrogen and the oxygen pressure over the solution respectively.

§ The terms "one-electron" and "multi-electron" process are often used in a different context: they are applied to the number of electrons transferred through the electrical circuit in order to carry out the stated reaction by electrolysis. In papers on electron transfer reactions the same terms denote the number of electrons transferred in each elementary act. In this review we shall use the terms "one-electron" and "multi-electron processes (or reactions)" in the electrochemical sense, and the terms "one-electron" and "multi-electron mechanisms" with reference to the mechanism of the elementary act.

2. Requirements for Photo-catalysts for the Decomposition of Water by Visible Light

By comparing the above thermodynamic data with the photochemical properties of water and with the spectral characteristics of solar radiation we can formulate the most important requirements for photo-catalytic systems for the decomposition of water.

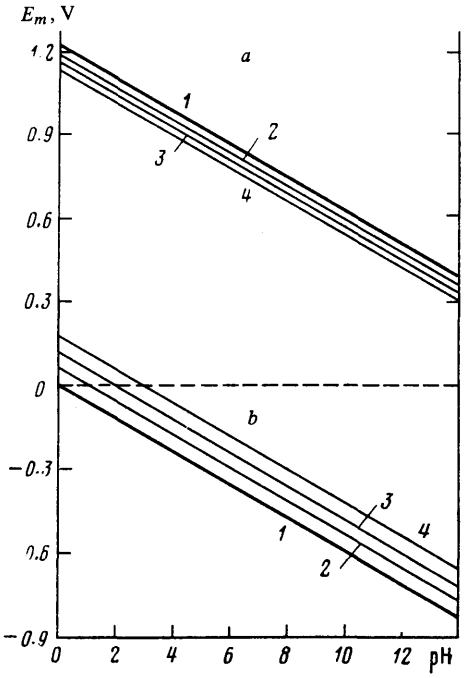

Figure 7. Formal ORP for the evolution of oxygen (*a*) and hydrogen (*b*) from water against the pH of the solution for different partial pressures of oxygen and hydrogen[229]: *1*) 1, *2*) 10^{-2}, *3*) 10^{-4}, *4*) 10^{-6} atm.

As Fig.5 shows, the solar spectrum at the Earth's surface contains practically no quanta corresponding to wave lengths < 300 nm, i.e. with an energy > 95 kcal Einstein^{-1}. At the same time the least endothermic of the possible monomolecular photo-dissociation processes

$$H_2O \rightarrow H_2 + O\ ,$$

requires an energy of 116 kcal mole^{-1} for a gas-phase reaction[222,231-233]. The lowest electronically excited state of water ($^3B_1$) is stated[234,235] to have an excitation energy $\geq$116 kcal mole^{-1}. This means that neither the direct nor the sensitised (by excited states) photolysis of water can be used for the conversion of solar into chemical energy. For the same reason it would be useless to try known heterogeneous photo-catalysts for the decomposition of water by hard u.v. radiation with λ < 250 nm (such as BeO and Al_2O_3[222,231,232]).

Thus the key element of any effective molecular system for the decomposition of water by solar radiation is the photo-catalyst: a dye K which can absorb the Sun's light without itself being decomposed by it and initiate a cycle of reactions in which water is reduced and oxidised. In natural photosynthesis the photo-catalyst is based on chlorophyll.

From the thermodynamic point of view any electronically excited K molecule (like chlorophyll, see Fig.3) can induce the photo-catalytic redox reaction

$$D + A \xrightarrow[K]{h\nu} D^+ + A^- \ . \qquad (7)$$

However, in practice these reactions take place only if the dye is excited into the "charge transfer bands"[202,236]. Hence the search for photo-catalysts should be confined to compounds which possess charge transfer bands in the visible region. This property is found in many organic dyes, though transition-metal compounds also seem promising in this respect. The latter compounds offer not only suitable absorption bands but also the ability to change their state of oxidation by several units, which should favour many-electron changes. Lastly, transition-metal compounds are able (in principle) to coordinate the Ḣ and ȮH free radicals formed by the one-electron reduction and oxidation of water. As will be shown below, this should lower the energy losses accompanying the photo-decomposition of water.

Since two molecules of H_2O have to be decomposed in order to produce one molecule of O_2 the total energy expenditure of a catalytic cycle cannot be less than 113.4 kcal mole^{-1}: in other words, the photo-catalytic decomposition of water cannot be a single-quantum process. A two-quantum process would need light of wave length < 504 nm (in the green region of the spectrum). As Fig.6 shows, the maximum efficiency at this wave length is less than the optimum by a factor of 2 or 3. The threshold wave length for a three-quantum process is 756 nm. Light of this wave length is found to offer the optimum conversion efficiency, but the decomposition of water involving fewer than four photons implies the simultaneous transfer of more than one electron under the influence of a single quantum. Until recently no such process had been reported, and therefore a serious discussion of three-quantum and two-quantum mechanisms for the decomposition of water would be inappropriate at present. However, there is no fundamental reason why one quantum should not induce the transfer of several electrons, and therefore we should continue to search for systems capable of reactions of this type[204].

The most rational process for the decomposition of water at present appears to be a four-quantum, sequential mechanism induced by red light, in which each light quantum is used to transfer one electron. As we have already pointed out, the threshold wave length for the decomposition of water in this case is $\lambda_{thr} = 1008$ nm, which corresponds to the optimum efficiency value. The fact that a non-optimum eight-quantum scheme is used in natural plant photosynthesis has been explained by the need to compensate for energy losses in long chains of redox reactions, or by evolutionary effects[192,237]. There is no reason to assume that an eight-quantum scheme is essential also in artificial photo-catalytic systems for the decomposition of water[1].

The energy ΔG stored by the photo-catalyst K for the absorption of one light quantum is equal to the difference in energy between the excited and the ground state of the photo-catalyst. However, the energy available for subsequent reactions is usually less than the energy of the light quantum because of the fast, spontaneous transition (conversion) of the K molecule from the primary excited state to some lower and longer-lived state, which then takes part in the chemical changes. The long life-times of these metastable excited states are due to the difference between their spin multiplicity and that of the ground state. These chemically active excited states are often luminescent, and therefore the energy stored by the photo-catalyst ($\Delta G = h\nu_1$) can

be determined by measuring the wave length ν_1 of the emitted light.

Knowing the formal redox potentials E_m for the ground state of the photo-catalyst, and the energies of its excited states, we can calculate the E_m values for the latter states. Obviously, in order to decompose water we must select a photo-catalyst whose excited states have E_m values consistent with the evolution of H_2 or O_2 from water. For example, in the case of isolated molecules of chlorophyll-*a* (Chl) we know[238] the formation potentials of the Chl^+ cation radical ($E^+ = +0.72$ V) and of the anion radical Chl^- ($E^- = -0.88$ V), and also the energies of the singlet (S) and of the triplet (T) excited state ($E_S = 1.86$ eV, $E_T = 1.26$ eV). The formal oxidation potential of the excited chlorophyll singlet state, i.e. the potential of the reaction

$$^{S}Chl + e^- \rightarrow Chl^{\div} ,$$

with respect to the normal hydrogen electrode, is $E_S^- = E^- + E_S = +0.98$ V, and the reduction potential of the same state, i.e. the potential of the reaction

$$^{S}Chl \rightarrow Chl^{+} + e^- ,$$

is $E_S^+ = E^+ - E_S = -1.14$ V. Similarly we find for the triplet state $E_T^- = +0.38$ V and $E_T^+ = -0.54$ V. These values agree exactly with direct electrochemical measurements of the potentials of the excited states of chlorophyll[238].

It follows from the relative values of E^+ and E^- that both the singlet and the triplet state of chlorophyll are potentially capable of reducing water with evolution of hydrogen, whereas only the singlet state (or the cation radical) can oxidise water with evolution of oxygen, at pH $\gtrsim$4 or 8 respectively (see Fig. 7).¶ The E_m value for the anion radical Chl^- obtained in the first reaction is sufficient in principle for the reduction of water, i.e. it is able to initiate the decomposition cycle.

We should note that many thermodynamically strong one-electron oxidising agents such as Ce^{4+}(aq), with $E^0(Ce^{4+}/Ce^{3+}) = 1.61$ V, cannot in practice cause oxidation of water because the reaction rate is very low. Their potential is probably not high enough to give a high enough rate to the first energetically unfavourable step. (This step is the one-electron oxidation of water to the $\dot{O}H$ free radical, which we shall discuss below in detail.) However, in the presence of catalysts (such as metallic platinum, or manganese or cobalt oxide) which allow the reaction to take place without formation of $\dot{O}H$ radicals in the free state the oxidation of water by Ce^{4+}(aq) is fairly fast[242].

3. Possible Mechanisms for the Decomposition of Water

The data listed in Table 2 allow us to compare the efficiencies of various theoretically possible mechanisms for the photo-catalytic decomposition of water. Thus we note that the reduction or oxidation of water by successive one-electron transfer reactions to give $\dot{H}$ or $\dot{O}H$ radicals in the free state require large (and unproductive) consumptions of energy, since in the subsequent reactions of these particles a significant fraction of their chemical energy is uselessly converted into heat. For example, the one-electron reaction

$$H_2O \rightarrow \dot{H} + \dot{O}H$$

(the difference between reactions No. 24 and No. 3) requires a heat input of 4.9 eV = 113 kcal mole^{-1}. At the same time the overall reaction

$$2H_2O \rightarrow 2H_2 + O_2$$

can store only 1.23 eV = 28.4 kcal mole^{-1} of energy for each transferred electron. In other words, ~75% of the chemical energy of the $\dot{H}$ and $\dot{O}H$ radicals is unavoidably converted into heat.

The effectiveness of the process may be increased in two ways: 1) by carrying out the reaction so that the $\dot{H}$ and $\dot{O}H$ particles are formed in a coordinated or adsorbed state as opposed to a free state, which lowers their energy of formation by an amount equal to the free energy of coordination (complex formation or adsorption), and 2) by avoiding the formation of $\dot{H}$ and $\dot{O}H$ particles through the use of multi-electron elementary acts. The possibility of two-electron transfer processes has been demonstrated[243,244], and even more complex, four-electron processes are believed[245,246] to be possible.

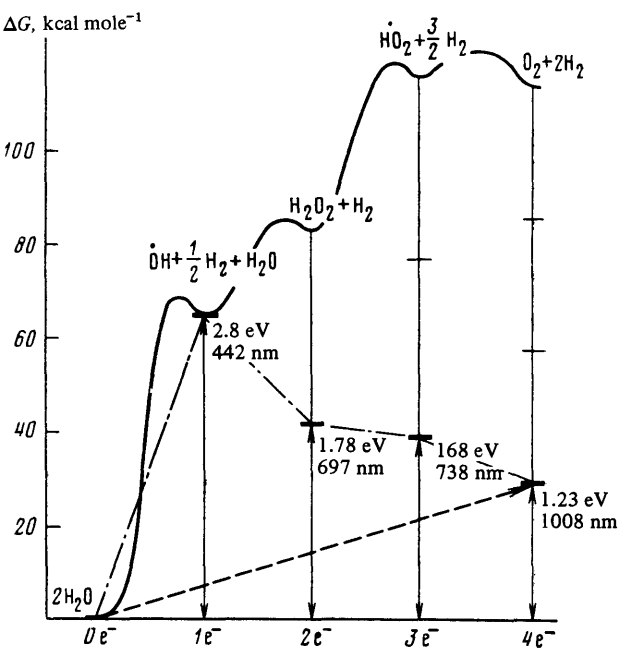

Figure 8. Energy profile of the decomposition of water to molecular hydrogen and the products of its one-, two-, three-, and four-electron oxidation. The numbers denote the energies and wave lengths of the threshold quanta for the transfer of one electron by the four-quantum mechanism of decomposition of water. The dot-and-dash line and the broken line show the changes in stored free energy (expressed for one transferred electron) attending the decomposition of water through the intermediate formation of $\dot{O}H$, H_2O_2, and $H\dot{O}_2$, and by its decomposition directly into H_2 and O_2 respectively.

As an illustration of the use of the data in Table 2 for estimating the effectiveness of various theoretically possible mechanisms of water decomposition we have shown in Fig. 8 an energy profile for conditions in which water is reduced

¶ According to the most recent views, the oxidation of water in natural photosynthesis occurs not on isolated molecules of chlorophyll-*a* but on associated groups of the dihydrated molecule $(Chl\text{-}a \cdot 2H_2O)_n$, with $n \geq 2$ and $E^+ = +0.92$ V[239-241].

directly to H_2 by a two-electron mechanism, and oxidised by sequential one-electron processes with formation of free $\dot{O}H$, H_2O_2, and $H\dot{O}_2$. It is evident from Fig. 8 that hydrogen peroxide (when formed through $\dot{O}H(ads)$ or by a two-electron mechanism) is a far more effective intermediate than the $\dot{O}H$ free radical. Over 70% of the stored chemical energy is retained when this intermediate decomposes with evolution of O_2. Active catalysts for the decomposition of hydrogen peroxide are well known[244]. The same approach can be used to estimate the effectiveness of other possible mechanisms.

We conclude from Table 2 and Fig. 8 that the most favourable energy profile is obtained if the water is decomposed directly into H_2 and O_2, without going through the intermediate formation of free $\dot{H}$, $\dot{O}H$, H_2O_2, HO_2, etc. The possibility of reducing water to H_2 (and of oxidising it to O_2) on the surface of heterogeneous catalysts while avoiding the formation of free $\dot{H}$ and $\dot{O}H$ particles follows directly from data on the electrolysis of water on metal electrodes. Thus at low current densities the overvoltage for the evolution of H_2 on a platinum cathode is of the order of 0.01 V, and the O_2 overvoltage of a cobalt anode is 0.2 V. These potentials are insufficient for the formation of $\dot{H}$ and $\dot{O}H$ in significant quantities.

It has recently been suggested[247,248] that the first step in the electrolytic reduction of water is the formation of adsorbed (as opposed to free) $\dot{H}$ particles:

$$H_3O^+ + e^- \rightleftarrows \dot{H}(ads) + H_2O ,$$

and that molecular hydrogen is formed directly from these particles by the reactions

$$2\dot{H}(ads) \rightleftarrows H_2\uparrow \text{ or } \dot{H}(ads) + H_3O^+ + e^- \rightleftarrows H_2\uparrow + H_2O .$$

The stronger the adsorption of atomic hydrogen on the electrode, the faster is the hydrogen evolution and the lower the overvoltage.

The first (and slowest) step in the oxidation of water on precious metal electrodes is thought to be[247]

$$OH^-(ads) \rightarrow \dot{O}H(ads) + e^- \text{ or } H_2O(ads) \rightarrow \dot{O}H(ads) + H^+ + e^- ,$$

This is followed by the fast step

$$2\dot{O}H(ads) \rightarrow \dot{O}(ads) + H_2O$$

or

$$\dot{O}H(ads) \rightarrow \dot{O}(ads) + H^+ + e^-$$

and finally

$$2\dot{O}(ads) \rightarrow O_2\uparrow .$$

On common metal electrodes the oxide film which covers the electrode can take part in the oxygen evolution process: for example,

$$MO + H_2O \rightarrow MO_2 + 2H^+ + 2e^-$$
$$2MO_2 \rightarrow 2MO + O_2\uparrow .$$

Thus the water electrolysis processes are essentially heterogeneous catalytic reactions taking place on the electrodes through the formation of adsorbed active particles. Effective heterogeneous catalytic systems for the conversion of electrical into chemical energy by the electrolysis of water are known, and therefore it should be possible in principle to develop similar systems for the conversion of solar energy.

4. Possible Organisation Schemes for the Photo-catalytic Process

Four different organisation schemes for the photo-catalytic decomposition of water can be suggested.

Scheme 1. The primary electron donor (or acceptor) for the excited state of the photo-catalyst is the water molecule itself, or its fragments OH^- and H^+, and the primary oxidation (or reduction) product goes into the solution, where it undergoes further reactions whilst the reduced (or oxidised) state of the photo-catalyst is potentially able to complete the water decomposition cycle in the dark, i.e. this species is a strong enough reducing (or oxidising) agent.

Scheme 2. Analogous to scheme 1 except that the oxidation (or reduction) product does not go into solution but remains coordinated (adsorbed) either on the photo-catalyst or on another compound until it takes part in further reactions.

Scheme 3. The primary photochemical reaction does not cause oxidation (or reduction) of water or its fragments, but it forms a strong oxidising agent and a strong reducing agent at the same time, which can decompose water in the dark.

All the three cases listed above imply a sequential four-quantum mechanism for the decomposition of water, and in every case the effectiveness of the process as a whole is determined by the effectiveness of the electrochemical charge separation process (to form a strong oxidising agent and a strong reducing agent), and of the evolution of hydrogen and of oxygen.

Scheme 4. In the initial step water is dissociated on the surface of a heterogeneous catalyst [for example, with formation of $\dot{H}(ads)$, $\dot{O}H(ads)$, or $\dot{O}(ads)$], or in the coordination sphere of a homogeneous catalyst. The light is used to cause recombination of the adsorbed (coordinated) intermediates with formation of H_2 and O_2 molecules and the photodesorption of these molecules.

Combinations of these schemes may be used in real water decomposition processes.

a) Photo-catalytic Decomposition of Water by Scheme 1

The main advantage of this scheme is its simplicity. Since one-electron oxidation or reduction of water is assumed even in the initial act of the photochemical reaction the use of a catalyst for the H_2 or O_2 evolution step becomes unnecessary, and the catalyst can consist (in principle) of a single component: the dye. The fast (and uncatalysed) recombination of the $\dot{O}H$ and $\dot{H}$ free radicals leads to evolution of O_2 or H_2, and the reduced or the oxidised form of the dye can be used to produce H_2 or O_2 if this is allowed by the redox potential. The need for stability of the dye in the presence of very reactive free radicals suggests that the most effective photo-catalysts will be found among inorganic compounds.

Data on the complexes and on the organic compounds which can evolve hydrogen (as H_2 or H) or oxygen as O_2 or $\dot{O}H$) from water under the influence of light are summarised in Tables 3 and 4. Unfortunately most of these materials are photochemically active only in the ultraviolet region of the spectrum. Photo-oxidation and photo-reduction processes in water have been reported also in the presence of inorganic anions (halide ions, S^{2-}, SO_4^{2-}, etc.)[202,249,278], but these too require energetic u.v. radiation. It is convenient to examine separately the formation of the oxidised (K^+) and of the reduced (K^-) form of the catalyst in the primary photochemical act (the oxidation and the reduction case).

Photo-oxidation in aqueous solutions with evolution of gaseous hydrogen is well known in aquo complexes of the transition metals in their lower states of oxidation (see Table 3).

The quantum yield of hydrogen in these reactions can be quite high: for example, a yield of 80% has been observed[255] for $Cu^+(aq)$. This suggests that both steps of the process have a high efficiency: the charge separation in the primary photochemical reaction and the evolution of H_2 in the subsequent dark reactions†. The effectiveness of charge separation is determined by the quantum yield of the formation of K^+ and $\dot{H}$ in the primary photochemical act:

$$K + H^+ \xrightarrow{h\nu} K^+ + \dot{H} ,$$

and by the relative rates of the different reactions which consume $\dot{H}$ particles:

$$\dot{H} + \dot{H} \rightarrow H_2\uparrow \quad (8)$$

$$K^+ + \dot{H} \rightarrow K + H^+ \quad (9)$$

$$4K^+ + 2H_2O \rightarrow 4K + O_2\uparrow + 4H^+ , \quad (10)$$

* Depends on the nature of the counter-ion and on the pH of the medium.
** Depends on the nature of the counter-ion.
*** Only the photo-oxidation of K was reported.

The probability of formation of radicals from electronically excited states of molecules cannot yet be predicted theoretically. Therefore photo-catalysts offering a high quantum yield can be chosen only empirically at present.

As regards the relative rates of the subsequent reactions of the free radicals, that for scheme 1 should favour the formation of useful final products. For example, in the case of oxidation (which we are considering) the rate constant of reaction (8) ($\sim 10^{10}$ litre mole^{-1} s^{-1})[279] is usually not less than, and often significantly greater than, the rate constant of reaction (9),[227] and the H radicals formed under the influence of light will be evolved from the solution as gaseous hydrogen in high yield and without the need for a catalyst as long as accumulation of the oxidised form of the dye (K^+) is avoided.

† We should note that direct experimental proof of the formation of $\dot{H}$ (or $\dot{O}H$) free radicals is not available for all the systems listed in Tables 3 and 4. Hence (in some cases at least) the reaction may follow scheme 2 rather than scheme 1.

In the photo-catalytic decomposition of water under static conditions accumulation of K^+ is unavoidable, because of the slowness of reaction (10), even if an active catalyst is used to accelerate the multi-electron process. Therefore the practical realisation of scheme 1 implies the use of flow conditions, arranged so that the evolution of O_2 (or H_2) in the light and the complementary evolution of H_2 (or O_2) in the dark take place in different parts of the apparatus [for example, by pumping the solution enriched in the K^+ (or K^-) form through a reactor containing a catalyst for the evolution of O_2 (or H_2)].

*** Only the photo-reduction of K was reported.

Of the systems listed in Table 3 the following aquo-complexes have a redox potential E_m high enough to complete the water decomposition cycle: Ce^{4+}(aq), Co^{3+}(aq), and Mn^{3+}(aq), the oxidised forms of Ce^{3+}(aq), Co^{2+}(aq), and Mn^{2+}(aq). For the Ce^3(aq)−Ce^{4+}(aq) system the photo-catalytic decomposition of water was observed and fully investigated[251,252] in the 1950's. It was shown that water is decomposed under the influence of u.v. light and in low yield, but we should note that the low quantum yield may have been due to the failure to use flow conditions in those experiments.

Methods of completing the cycle have been suggested even for systems in which the oxidised form K^+ is thermodynamically unable to evolve oxygen from water under normal conditions (for example, for the Cu^+(aq)−Cu^{2+}(aq) system[254]). Thus the E_m value of the K/K^+ couple can be increased by changing the temperature in the dark part of the apparatus. For aquo-complexes, say, the large (up to 20–40 e.u.) difference in entropy between the oxidised and the original form causes a shift in the equilibrium towards the evolution of oxygen upon heating.

In principle the oxidation photo-catalyst could also be a compound which yields a hydrated electron under illumination, since in acid solutions this species is immediately converted into the $\dot{H}$ radical[236,249,260,280]:

$$H_3O^+ + e^-(aq) \rightarrow \dot{H} + H_2O .$$

However, because of the large reduction potential ($E^0 = -2.7$ V), the energy losses in processes involving $e^-(aq)$ can be expected to be even greater than those of processes involving radicals. There is a report[281] of the production of hydrated electrons by green light (as opposed to u.v. light) in micellar heterophase systems. Of course, under these conditions the ORP of K^+ is not high enough to evolve O_2 from water, but it may be high enough in a photo-excited state of K^+. Thus the scheme could be realised in practice only for the decomposition of water by an eight-quantum mechanism.

Photo-reduction (the evolution of oxygen or ȮH radicals by light) has been observed in aqueous solutions of some transition-metal complexes in a higher state of oxidation as well as in some organic compounds (see Table 4). In this case the evolution of oxygen is the fast step as a result of the high chemical activity of the ȮH radicals[279]:

$$2\dot{O}H \rightarrow H_2O_2,\ 2H_2O_2 \rightarrow 2H_2O + O_2\uparrow .$$

As regards completing the cycle of the water decomposition process the most promising systems are UO_2^{2+}–UO_2^+, $U^{4+}(aq)$–$U^{3+}(aq)$, and MV^{2+}–$M\dot{V}^+$, according to the E_m values in Table 4, but the photo-catalytic decomposition of water has not so far been observed in these systems (though ȮH radicals have been detected in the UO_2^{2+} and MV^{2+} systems).

It is generally thought that the generation of free radicals in an aqueous solution must necessarily imply the use of u.v. radiation, with a disastrous effect on the efficiency of the solar energy conversion. In fact, the ȮH radical can be formed in an acid solution (pH = 0) at room temperature and for a zero value of E_m of the K/K^- couple by a quantum of $\lambda = 442$ nm (blue light), with an efficiency of $\eta \cong 5\%$, and furthermore the same radical can be formed in an alkaline solution (pH = 14) by a quantum of $\lambda = 612$ nm (orange light) with a very adequate conversion efficiency ($\eta \cong 20\%$, see Fig.6). Of course, in order to complete the cycle of water decomposition reactions in this solution at room temperature we have to use light with $\lambda \leq 442$ nm, since a reducing agent with $E_m < -0.828$ V is needed for the evolution of hydrogen in alkaline solutions.

The formation of Ḣ in acid solution (pH = 0) is also possible in light of reasonably long wave length ($\lambda = 558$ nm), but it is again impossible to complete the cycle at constant temperature without using u.v. light, because an oxidising agent with $E_m > +1.23$ V has to be generated in addition to the Ḣ radicals, and light with $\lambda = 371$ nm is required for this.

Nevertheless the decomposition of water by this mechanism under the influence of light of reasonably long wave length is possible in principle if the H_2 and O_2 evolution steps are separated. This can be attempted in two ways: by arranging for the H_2 and O_2 evolutions to occur at different pH, or at the same pH but different temperatures. The latter approach is the more attractive because it does not require unrecoverable additions of acids and alkalis. The rise in temperature of the solution needed to shift the equilibrium in the required direction could be obtained by exploiting the photochemically inactive long-wave quanta of the solar spectrum, thus raising the efficiency of the overall conversion. We also note that the lower energy losses expected from the relative simplicity of scheme 1 should compensate (at least partially) for the loss in efficiency associated with the irreversible conversion into heat of some of the energy of the Ḣ and ȮH radicals.

Thus the main problem to be overcome before scheme 1 can be used in practice is to find photochemically active dyes with charge transfer bands at sufficiently long wave lengths. All the compounds examined so far, listed in Tables 3 and 4, have this band in the u.v. region of the spectrum. It may be necessary to sensitise the evolution of H_2 and O_2 by adding to the solution an auxiliary dye which absorbs strongly in the visible region and can transfer this absorbed radiant energy to the chemically active excited levels of the photo-catalyst.

b) Photo-catalytic Decomposition of Water by Scheme 2

As we have already pointed out, the effectiveness of the utilisation of the solar spectrum could be substantially increased by arranging for the Ḣ and ȮH radicals produced in the primary photochemical act to be in the coordinated or adsorbed state (as opposed to the free state). The absence of free radicals would also make it easier to use organic photo-catalysts (as compared with scheme 1).

Complexes of the active intermediates of the decomposition of water with transition-metal compounds in excited states have recently been detected experimentally. These include hydroxylated chromium(III) complexes in an electronically excited state[282] and protonated complexes of the aquo uranyl ion (UO_2H^{2+}),[283,284] bipyridyl ruthenium(II) complexes[285,286], and binuclear molybdenum complexes[259].

Kinetic data on the photochemical evolution of hydrogen from acid aqueous solutions of the aquo complexes $Eu^{2+}(aq)$[253–255] are consistent with the hypothesis that the active role in this process is played by complexes of the metal with free radicals:

$$\begin{gathered} Eu^{2+}(aq) + H_2O \xrightarrow{h\nu} [EuOH \cdot H]^{2+} \\ [EuOH \cdot OH]^{2+} + H^+ + Eu^{2+}(aq) \rightarrow EuOH^{2+} + Eu^{3+}(aq) + H_2\uparrow . \end{gathered} \qquad (11)$$

A similar scheme applies to the photochemical evolution of hydrogen from acid solutions of the $Fe^{2+}(aq)$ aquo complex[287]. Detailed studies of acidity changes in organic dyes during electronic excitation are also in progress[277,288–290].

Existing experimental data are insufficient for a meaningful discussion of the application of scheme 2 to homogeneous reactions. We shall only point out that hydrogen evolution from a protonated excited state

$$K^* + H^+ \rightarrow KH^+$$

requires the collision of these protonated forms either in pairs

$$2KH^+ \rightarrow 2K^+ + H_2\uparrow$$

or with a strong reducing agent [e.g. as in reaction (11)], or alternatively it requires further protonation in a secondary excitation:

$$KH^+ + H^+ \xrightarrow{h\nu} KH_2^{3+} \rightarrow K^{3+} + H_2\uparrow .$$

In the first case the effectiveness of the process may be raised by adding a dehydrogenation catalyst, and in the second by choosing a compound in which the protonated excited forms are long-lived.

The most promising media for the realisation of scheme 2 may be heterogeneous systems, especially supported catalysts and zeolites containing adsorbed, attached, or interstitial dye molecules (organic or inorganic). The affinity of Ḣ and ȮH radicals for adsorption on these heterogeneous surfaces should favour the charge separation in the primary photochemical act and the subsequent recombination of the adsorbed radicals with evolution of H_2 and O_2 (as in catalytic electrodes during electrolysis).

The formation of ȮH radicals in the adsorbed state during irradiation with visible or near-u.v. light has been observed in suspensions of ZnO, TiO_2, and V_2O_5 in water[118,291], and in Aerosil containing adsorbed Methyl Viologen bi-cations[276]. Hydrogen evolution by illumination of freshly precipitated iron(II) hydroxide has also been reported[292], but the mechanism of this process was not studied in detail.

Some recent papers describe the decomposition of water under the influence of solar radiation in the presence of silver-substituted type Y and A zeolites[208,293,294]. The following reaction is assumed to take place with a high quantum yield:

$$2Ag^+ + 2ZO^- + H_2O \xrightarrow{h\nu} 2Ag^0 + 2ZOH + {}^1/_2O_2\uparrow .$$

The water decomposition cycle is completed in the dark by heating the system to 600 °C. Clusters are thought to be formed in the zeolite under these conditions, and these clusters are assumed to have an enhanced reducing power:

$$2Ag_n^0 + 2n\ ZOH \xrightarrow{T} 2n\ Ag^+ + 2nZO^- + n\,H_2\uparrow .$$

The main advantage of this type of scheme is the ease with which the final products (H_2 and O_2) can be separated. Furthermore these catalysts can be operated over a much wider range of temperature than homogeneous catalysts.

By replacing the silver by a metal with a greater reducing power in its lower state of oxidation it may be possible to avoid the need for a high temperature during the dark step. Auxiliary dyes may also be added to the zeolite to improve the sensitivity to long-wavelength light.

Another possibility is the photo-catalytic decomposition of water on metal-containing zeolites without the participation of electronically excited states. As in aqueous solutions, the entropy of interstitial transition-metal ions in zeolites is very sensitive to the degree of oxidation of the ions. Therefore a change in temperature will strongly affect the redox properties of the ions, and this should allow the decomposition of water by cyclic changes in the temperature of the catalyst (for example, using concentrated solar radiation). There is evidence[295] that such a cyclic process would be thermodynamically possible in zeolites containing Cr^{3+}, In^{3+}, or Cu^{2+} ions.

Table 5. Systems which evolve hydrogen by scheme 3.

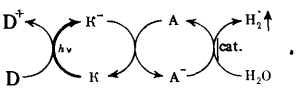
No.	Dye (K)	Acceptor (A)	Donor (D)	Catalyst	Refs.
1	Proflavin; Acridine Orange	MV^{2+}	ethylenediamine-tetra-acetic acid (EDTA)	hydrogenase	296
2	Methylene Blue, acridine	cytochrome → acridine → MV^{2+}*	Fe^{2+}(aq), allyl-thiourea, isopropanol, ethanol, toluene, ascorbic acid, EDTA	not stated	297
3	Acridine Yellow, tripaflavin	salicylato complexes of V(III) and Eu(III)	cysteine, triethanol-amine, EDTA, H_2S	PtO_2, colloidal Pt	298
4	Acridine Yellow	MV^{2+}	EDTA	Pt	298
5	Benzophenone	V^{3+}(aq), Cr^{3+}(aq), Eu^{3+}(aq)	ethanol, isopropanol	PtO_2	299
6	Immobilised chloroplast	MV^{2+}	glycerol, H_2O	hydrogenase, metallic Pt	224
7	Immobilised chloroplast	immobilised ferredoxin	H_2O	hydrogenase	300
8	$Ru(bipy)_3^{2+}$	MV^{2+}	EDTA	hydrogenase	296
9	$Ru(bipy)_3^{2+}$	$Rh(bipy)_2Cl_2^+$	triethanolamine	collodial Pt	301

* A chain of acceptor was used.
** The scheme proposed for completing the cycle involves O_2 evolution by heating the system with Fe^{3+} to 50–350 °C.

In principle scheme 2 can offer the maximum efficiency for the conversion of solar energy. Therefore further work on these problems is of the utmost importance.

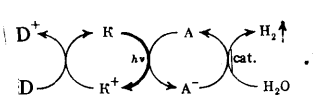
c) Photo-catalytic Decomposition of Water by Scheme 3

In spite of the simplicity of schemes 1 and 2, most of the research now in progress is devoted to scheme 3, in which the primary photochemical act does not decompose the water but produces strong one-electron oxidising (D^+) and reducing agents (A^-) simultaneously, able to evolve oxygen and hydrogen from water in the absence of light. The interest in this scheme is not fortuitous: it stems from its similarity to natural photosynthesis.



The main difficulty in the practical implementation of scheme 3 is that the complex multi-electron processes leading to the evolution of oxygen and hydrogen from water by the D^+ and A^- species have to compete with the recombination of D^+ and A^-. Therefore the reduction to practice of scheme 3 is possible only if an adequate method of charge separation is available.

Many photo-catalytic systems able to evolve hydrogen from water with a good quantum yield are known (see Table 5). However, in every case the electron donor is not water but a special reducing agent which is consumed irreversibly. Photo-catalytic systems for the evolution of oxygen from water have also been described: chlorophyll and coproporphyrin of iron(III) adsorbed at an octane–water interface[302] or on a vesicle membrane[303]. But in this case the electron acceptor is not water but $Fe(CN)_6^{3-}$, which is again consumed irreversibly. Thus it has not yet been possible to complete the water decomposition cycle without using structures of biological origin#.



All the systems listed in Table 5 attempt to model the photosynthetic system of bacteria and the "photo-system I" of plant photosynthesis, which synthesises reduced forms of carbon from CO_2 by using good electron donors[189–192].

We note that in system No. 3 of Table 5 (as in the photosynthesis of sulphur bacteria) the electron donor is hydrogen sulphide (an analogue of water, but with more marked reducing properties), which can be oxidised fully by the transfer of only two (as opposed to four) electrons.

The choice of an appropriate photo-catalyst is of the utmost importance for the decomposition of water by scheme 3. Thus, in systems Nos. 1–5 of Table 5 (using benzophenone and organic dyes of the xanthene, acridine, and fluorescein type as the photo-catalyst, i.e. compounds with a fairly high oxidation potential in their initial state) the reaction takes place by the "reduction mechanism"§

However, even the excited form of the photo-catalyst could not bring about the oxidation of water. In systems Nos. 6–9 of Table 5 [for which the photo-catalysts are chloroplasts immobilised in micelles, or the *tris*-bipyridyl complex of ruthenium(II)] the reaction took place by the "oxidation mechanism":

A complete water decomposition cycle has been reported[304] for monolayers of the surface-active bipyridyl complex of ruthenium(II), but many attempts at repeating the experiment have proved unsuccessful[305–310].

§ The double arrow denotes the instant when radiant energy is stored.

The range of compounds potentially suitable as photo-catalysts for the decomposition of water by scheme 3 is still very narrow. It includes chlorophyll and its nearest analogues, and also bipyridyl (and similar) complexes of ruthenium(II)[311-341], osmium(II)[311,312,320,342,343], and probably also iron(II)[344-347] and chromium(III)[330,348]. Thus the field is wide open for further research.

There are qualitative reports of the production of the very strong oxidising agents Co^{3+}(aq), Mn^{3+}(aq), Ce^{4+}(aq), and Ag^{2+}(aq) by the excited state of uranyl[349-351], and of the reduction of Zn^{2+}(aq) to Zn^0 by the excited state of Mn^{2+}(aq), which becomes oxidised to MnO_2.[352] If a charge separation process with an acceptable quantum yield were available these systems could be of interest as components of the photo-catalytic system.

Special mention is due of the *tris*-bipyridyl complexes of ruthenium, which are not decomposed under the action of light, are not hydrolysed, and offer a unique set of redox properties in their ground and their triplet excited state: as a result, they can take part in both the "oxidation" and the "reduction" mechanism of decomposition of water in solutions of practically any acidity. For the *tris*-bipyridyl complex of ruthenium(II) the following energy levels have been reported[333]: $E^- = -1.3$, $E^+ = +1.3$, $E_T^+ = +0.8$, and $E_T^- = -0.8$ V. The evolution of oxygen from water in the dark by the oxidised states of these[353] and of the corresponding iron complexes[354-358] is well characterised.

Fairly rigid limits are imposed on the intermediate donor D and acceptor A. For example, the E_m value of the acceptor must lie below the "hydrogen" line of Fig.7, but it must also be higher than the E_m value of the K^-/K couple (for the "reduction mechanism") or of the K/K^+ couple (for the "oxidation mechanism"). In the systems listed in Table 5 the intermediate acceptors which satisfy this condition are V(III) and Eu(III) complexes [for example, V^{3+}(aq) and Eu^{3+}(aq)], and also the bipyridyl complex of rhodium(III) and the organic bi-cation[359] Methyl Viologen (MV^{2+})

Reduced forms of all these acceptors in the presence of a catalyst can evolve hydrogen from water at the appropriate pH. Intermediate donors D for the oxidation of water are still unknown.

Let us consider possible ways of increasing the efficiency of charge separation in the primary photochemical reaction. The effective charge separation in natural chloroplasts (systems Nos.6 and 7 of Table 5) is evidently the result of their rigid structure. The molecules of chlorophyll and of the primary electron acceptor (still not definitely identified) are separated by a significant distance (>13 Å) in the chloroplast membranes[360]. Fast charge separation in this system (the process $Chl^* + A \rightarrow Chl^+ + A^-$) can only occur by a tunnel mechanism[360,361]. The reverse process (the tunnelling transfer of an electron from A^- to Chl^+) is much slower[360]. This may be due to the rapid conversion into heat of part of the energy stored in the Chl^+ and A^- particles (since changes in the energy of the system can disturb the conditions favourable to tunnelling transitions[361-363]), or alternatively it may be due to rapid conformational changes in the membrane produced by the forward reaction, which can increase the distance between the reactants[360,362,363].

By analogy with natural photosynthesis we can expect that a spatial separation of the photo-catalyst from the primary acceptor by ~10–20 Å (on a solid carrier surface, in a lipid membrane, or in a micellar solution) will improve the efficiency of charge separation in artificial systems also. Stabilisation of the charge separation by the "tunnel" principle can be attempted also in a homogeneous solution, for example by using rigid molecules within which charge transfer can occur (from one fragment to another) under the influence of light[364-381]. After charge separation of this type the molecule can behave bifunctionally, i.e. both as an oxidising agent and as a reducing agent.

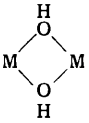
It has been found experimentally that charge separation is assisted by fast chemical changes (for example, protonation or deprotonation) of the D^+, A^-, K^+, or K^- species. Thus fast protonation of the reduced form of the dye in reactions Nos.1–5 of Table 5 is the most probable explanation of the substantial decrease in the recombination rates of D^+ and K^-; furthermore, protonation leading to the formation of hydride complexes of rhodium may occur also in system No.9 of Table 5.

Effective chemical stabilisation of the separated charges by deprotonation of the phenothiazine cation radical has been observed[382] as a result of the interaction with the *tris*-bipyridyl complex of ruthenium(II) in an excited state.

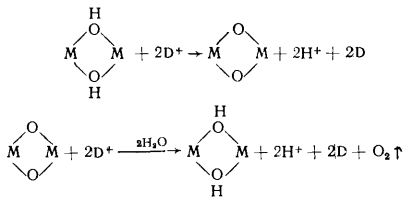
Since chemical stabilisation requires a stabilisation rate greater than the recombination rate the only likely candidates are the fast stabilisation processes involving unimolecular decomposition, conformational transitions, or interactions with substances present in very high concentration (e.g. the solvent).

Stabilisation mechanisms other than the tunnel mechanism and the chemical mechanism discussed above may be considered. One of these consists in precipitating as a solid phase (or extracting from the aqueous solution) the product of the primary photochemical act (e.g. A^-). Thus the elemental sulphur produced by the oxidation of hydrogen sulphide in system No.3 of Table 5 is precipitated into a solid phase. Precipitation as a hydroxide may also be effective: for example, by varying the state of oxidation of metal aquo ion used in the cycle. Stabilisation of the separated charges by extraction was demonstrated in the 1960's for a system consisting of thionine (an organic dye) and the iron(II) aquo ion[383]: the same stabilisation mechanism was later applied to the thionine–thallium(I) aquo ion system[384].

However, phase transformations and extraction are relatively slow processes. Hence we may assume that an initial stabilisation is provided by chemical effects in every case (reconstruction of the solvation shells, dimerisation, etc.), followed at a later stage by the phase transformation.

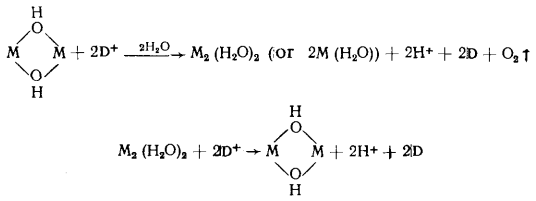


Yet another stabilisation method depends on using an electric field for charge separation, as in the semiconductor energy converters. In liquids, very high electric field gradients are easily obtained at the surface of colloidal particles (for example, the micelles of ionogenic surface-active particles, knots of polymer chains containing ions, etc.)[385,386]; high electric field gradients can exist also in zeolite holes[387]. Thus if singly charged cations are used as the initial forms of the photo-catalyst and of the electron acceptor, and if these cations are adsorbed on the surface of anionic micelles in the form of a Stern layer[385], the doubly charged cation of the photo-catalyst formed by the transfer of an electron under the influence of light will be adsorbed even more strongly in the Stern layer whereas the uncharged form of the acceptor will pass into the bulk of the solution. In this way charge stabilisation may be obtained as a result of the increase in the rate of reaction of the excited photo-catalyst with the acceptor produced by the increased local concentrations resulting from adsorption on the micelle (micellar catalysis)[388,389], combined with the decrease in the rate of recombination of the reaction products. This stabilisation mechanism was studied for a reaction in aqueous solutions containing an anionic surface-active compound or an ion-containing polymer[334,335]:



$$Ru(bipy)_3^{2+} + Cu^{2+}(aq) \xrightarrow{h\nu} Ru(bipy)_3^{3+} + Cu^{+}(aq) \cdot$$

No fundamental difficulties can be foreseen in the evolution of hydrogen from a solution containing a strong one-electron reducing agent. Effective catalysts for this process are known: for example, finely divided or colloidal platinum, or the enzymes nitrogenase and hydrogenase (see Table 5). Of course, the main problem is to choose the most effective and stable catalyst for the specific experimental conditions.



More serious difficulties are found in the oxygen evolution step. In the absence of a catalyst this step proceeds very slowly if at all, even if very strong oxidising agents such as $Ce^{4+}(aq)$ or PbO_2 are present. On metallic catalysts (such as platinum) the reaction takes place only if the oxidation potential is raised well above the thermodynamic minimum value[242]: this is true even in the presence of an oxidising agent as strong as $Ru(bipy)_3^{3+}$. Heterogeneous catalysts of the PtO_2, IrO_2, and RuO_2 type are also not very effective towards the oxidation of water by Ce^{4+} and $Ru(bipy)_3^{3+}$ ions: in this case quantitative evolution of oxygen in acid solutions is observed only after several hours[390,391].

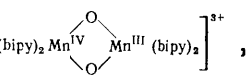
There are reports that the O_2 evolution catalyst in plant photosynthesis systems includes polynuclear manganese and copper complexes[1,13,392], but neither their composition nor their structure has yet been determined. Homogeneous O_2 evolution catalysts were unknown until quite recently. Thus the development of catalysts for the evolution of oxygen from water under mild conditions is the most difficult of the problems which must be solved before photo-catalytic converters relying on scheme 3 can be used in practice.

The writers have recently developed effective homogeneous catalysts for the evolution of oxygen from water by one-electron oxidising agents (D^+) of the $Ru(bipy)_3^{3+}$ type[393]. The mechanism of the action of these catalysts is still being investigated, but there is evidence of a catalytically active intermediate with the binuclear μ-dihydroxo  structure (where M is a metal atom), so that the evolution of oxygen and the regeneration of the intermediate occur by successive one-electron oxidations. For example, the catalytic action of partially hydrolysed bipyridyl complexes of iron(III)[296] could be described by one of the following schemes:

or

so that the overall equation is

$$4D^+ + 2H_2O \xrightarrow{cat} 4H^+ + 4D + O_2\uparrow$$



[where M = Fe(III), and $D^+ = Ru(bipy)_3^{3+}$, $Fe(bipy)_3^{3+}$, or $Fe(phen)_3^{3+}$].

We have also observed[393] catalytic effects in some compounds of Co(II) (see also Ref. 394), Cu(II), Ni(II), Mn(II), Ir(III), and Ru(III). Especially interesting catalytic effects were found[393] in the water-soluble cobalt(II) phthalocyanines: we should note that the cobalt(II) and iron(III) phthalocyanines are now considered to be the most effective catalysts for the cathodic (electrolytic) reduction of oxygen in aqueous solutions (i.e. for the reverse of the oxygen evolution reaction)[395].

The evolution of oxygen from water should be favoured by alkaline conditions (see Fig. 7), and therefore the search for photo-catalytic systems operating in alkaline solutions is of interest. Data on the photochemical oxidation of water by iron[292,263,265] or cerium[252] hydroxides are relevant in this context. We note that the ability of hydroxo complexes to form polynuclear structures may be an important factor in the development of multi-electron processes for the decomposition of water.

The mechanism of oxygen evolution from water by oxidising agents (such as MnO_4^- [358,396,397]) stronger than $Ru(bipy)_3^{3+}$ is currently being studied, and so is the mechanism of the electro-catalytic oxidation of water[394,398].

The work on the intermediate steps of the decomposition of water has generated a great deal of interest in the photochemical reduction of binuclear complexes of the type of[56,204,399,400]

as well as in the light-induced generation of hydrogen from solutions of hydride complexes such as[204,401–403]

$$\text{iso-Co(phen)}(PR_3)_2H_2^+ \xrightarrow{h\nu} \text{Co(phen)}(PR_3)_2^+ + H_2\uparrow$$

$$2HIr(PF_3)_4 \xrightarrow{h\nu} (PF_3)_4Ir{-}Ir(PF_3)_4 + H_2\uparrow$$

$$[Rh_2(AA)_4H]Cl^{2+} + H^+(aq) + Cl^- \xrightarrow{h\nu} [Rh_2(AA)_4Cl_2]^{2+} + H_2\uparrow$$

$$[Mo(\eta^5\text{-}C_5H_5)_2H_2] \xrightarrow{h\nu} [Mo(\eta^5\text{-}C_5H_5)_2] + H_2\uparrow$$

(where phen = 1,10-o-phenanthroline, and AA = 1,3-diisocyanopropane), and also in the reaction[258,259]

$$Mo_2(SO_4)_2^{4-} + H^+(aq) \xrightarrow{h\nu} Mo_2(SO_4)_2^{3-} + {}^1/_2H_2\uparrow.$$

The binuclear complex $[(\eta^5\text{-}C_5H_5)Fe(CO)_2]_2$ has also been found[404] to evolve hydrogen from potential donors under the influence of light.

The semiconductor photo-catalysts discussed in Section II (e.g. TiO_2) can also be classified with the converters operating by scheme 3.

The main distinguishing feature of semiconductor converters (as opposed to molecular converters) is the primary charge separation by electronic transitions between the collective levels (bands) of the solid under the influence of light, as opposed to transition between levels in individual molecules. With this exception, however, the mode of action of semiconductor converters is not very different from that of molecular converters. Thus the electron and the hole formed by the charge separation in semiconductors contribute to the decomposition of water in exactly the same way as the A^- and D^+ particles formed in molecular systems.

The spatial separation of the electron and hole is assisted by the internal electric field in the surface layer of the semiconductor (i.e. in the region where the light is absorbed). As was stated above, separation of the A^- and D^+ particles by an electric field is one method of stabilisation in molecular converters. The electrons and holes which have failed to recombine diffuse to the electrode surface where (as in molecular systems) they can take part in catalytic reactions leading to the reduction of water with hydrogen evolution

(in the case of the electron) or to the oxidation of water with oxygen evolution (in the case of the hole).

The main shortcomings of the present semiconductor photo-catalysts (see Section II) are their low photosensitivity in the visible region, and also inadequate charge separation in the surface field and low catalytic activity towards the later steps (oxygen and hydrogen evolution). In order to suppress the recombination of electrons and holes, and to impose on them an oxidation–reduction potential sufficient to decompose water at an acceptable rate, additional potentials must be applied from an external voltage source to the semiconductors in existing systems.

These shortcomings may be overcome by the use of semiconductors with a narrower (1–1.5 eV) energy gap and by doping their surface layer (see Section II). The addition of electron donor or acceptor species to the surface layer may generate stronger electric fields and thus allow effective charge separation without resorting to an external source of potential. Sensitisation by adsorbed or "grafted" dye molecules could produce sensitivity to visible light even in wide-gap semiconductors. Lastly, it may be possible to raise the catalytic activity of the semiconductor surface towards hydrogen and oxygen evolution by doping it with suitable impurities.

Thus there is no fundamental difference between the mechanisms of semiconductor and of molecular photo-catalytic converters, and current approaches to the development of molecular photo-catalysts may be expected to apply equally to the development of semiconductor photo-catalysts.

d) Photo-catalytic Decomposition of Water by Scheme 4

Very few data are available on the photo-catalytic decomposition of water by scheme 4. Nevertheless this scheme seems extremely promising. It was recently shown[219] that the following reaction can take place on illuminated single crystals of the semiconductors TiO_2 and $SrTiO_3$:

$$2H_2O\ (gas) + CO_2 \xrightarrow{h\nu} CH_4 + 2O_2 .$$

The first step of this reaction is believed to be the dark dissociative adsorption of water, followed by light-induced desorption of the products. There are also reports[405,406] of the photo-decomposition of gaseous water by visible light on the surface of another semiconductor (monocrystalline germanium).

The dissociative chemisorption of water on metal surfaces (e.g. Raney nickel[407], and possibly iron[408]) is well known. It is assisted by the high heats of adsorption of hydrogen and oxygen atoms on some metals. These results suggest at least the possibility of practical exploitation of scheme 4 on metallic catalysts in the future.

At the present stage of development in science and technology a substantial penetration of solar energy into the energy balance of mankind seems to be a soluble problem, deserving very serious study. At the moment the semiconductor (p–n junction) and thermal methods of solar energy conversion are nearest to large-scale practical application. Existing information on the mechanisms of catalytic and photochemical reactions confirm the reality (in principle) of photo-catalytic energy conversion (using both molecular and semiconductor systems), initially at least as applied to the photo-catalytic decomposition of water. Semiconductor photo-catalysts able to decompose water into hydrogen and oxygen are already known. Though their efficiency is still low, the way is clear to the achievement of higher efficiencies by varying the chemical composition of the surface layer and by using narrow-gap semiconductors. Another realistic (though difficult) goal is the development of molecular photo-catalytic systems for the conversion of solar energy: simpler analogues of the photosynthetic systems found in living organisms.

From the practical view-point—the development of energy converters offering the maximum possible efficiency—the most promising systems are those which do not depend on the formation of free radicals and atoms in the intermediate steps. Nevertheless we should not dismiss the systems in which radicals are formed in the free state. They are simpler, and therefore they may (at least initially) offer more favourable efficiencies than the more complex systems. Hence, elements developed on simple systems may in future find applications in more advanced types of converter.

Combined energy converters, in which visible light is used to induce photochemical changes and infrared light to heat the reactants in order to displace chemical equilibria in the desired direction, are a particularly imaginative development. The maximum theoretical efficiency of these converters must be greater than that of systems relying purely on quantum effects, since the Sun's light is more fully utilised in them.

The decomposition of water on molecular as well as on semiconductor photo-catalysts occurs in three steps: light-induced charge separation (to give a strong oxidising agent and a strong reducing agent), evolution of oxygen from the water by the strong oxidising agent, and evolution of hydrogen from the water by the strong reducing agent.

The main stumbling block on the way to the realisation of the first step is the fast recombination of the strong oxidising agent and the strong reducing agent, which uselessly converts the stored energy into heat. However, it may be assumed that means will be found to suppress this recombination by one of the methods of stabilising charge separation discussed above (based on tunnelling, chemical, phase separation, or electrostatic effects). Of the remaining two steps the evolution of oxygen is the more difficult to carry out in practice. Whereas effective catalysts for the evolution of hydrogen from water by strong reducing agents are already known, equally effective catalysts for oxygen evolution have not yet been reported. The search for these catalysts has become a problem of the greatest importance.

Work on the photo-catalytic conversion of solar energy began only recently, and is still in the research stage. This review has attempted to examine the essential aspects of the problem against the background of the general state of solar energy conversion, and to point out possible solutions. There is every reason to believe that the photo-catalytic method will lead to the development of systems for the conversion of solar energy into chemical fuel (hydrogen) energy with an acceptable efficiency. However, the problem is not an easy one, and its solution needs further extensive studies in the fields of catalysis, photochemistry, and photophysics.

Only the future can show which of the many theoretically possible methods of solar energy conversion will prove to be the most economical.

Electrocatalysis on Metalloporphyrins

M.R.Tarasevich and K.A.Radyushkina

Results of theoretical and applied research on electrocatalytic reactions—the cathodic reduction of oxygen, hydrogen peroxide, and carbon dioxide and the anodic oxidation of organic and inorganic substances—on metalloporphyrins are analysed with a list of 132 references.

I. INTRODUCTION

Organic complexes of metals constitute a novel and extremely promising class of electrocatalysts. Among them compounds containing as ligands various porphyrin derivatives (metal phthalocyanines, tetra-arylporphyrins) attract especial attention. The possibility of using these compounds as electrode materials is due to three main factors—great activity in various heterogeneous redox reactions, semiconductor properties, and high chemical and thermal stability—and would provide a method for replacing catalysts based on precious metals. Enlargement of the scale of application of new technical electrochemical processes, e.g. in sources of current, the photoelectrochemical transformation of solar energy, etc., will largely depend on solving this problem.

Investigation of the mechanism and the kinetics of chemical and electrochemical reactions on organic metal complexes is also of considerable theoretical interest, as it helps to reveal the role of collective and local effects in electrocatalysis and to establish the relation between chemical structure and catalytic activity. These results may be useful also for understanding several aspects of enzymic catalysis. Molecular complexes containing a porphyrin group serve as active centres in protein macromolecules—enzymes and electron-carriers in respiratory chains in living organisms—and play a decisive part in photosynthesis.

The most important task of current research on electrocatalysis is to establish rules for the selection of catalytically active systems. The importance of this problem is increasing especially as a consequence of the almost unlimited number of possible organic compounds.

The present Review, covering the literature to January 1977, examines in the greatest detail published information on the mechanism and the kinetics of the electroreduction of molecular oxygen. Other electrocatalytic and photocatalytic reactions, whose investigation is only beginning, are considered in less detail.

II. ELECTROPHYSICAL AND CATALYTIC PROPERTIES OF METALLOPORPHYRINS

Among organic metal complexes possessing semiconductor properties compounds of the porphyrin series occupy an important place in electrocatalytic investigations. Results on their chemical, electrophysical, and catalytic characteristics have been summarised in several monographs[1-4] and reviews[5-8]. In the present Review, therefore, we shall very briefly consider only those properties that are necessary for an interpretation of the electrocatalytic phenomena.

The two hydrogen atoms attached to nitrogen in the porphyrin molecule can be replaced by a metal to form coordination complexes. The three main groups of porphyrin derivatives are—(i) reduced porphyrins, (ii) porphyrins with substituents at positions 5, 10, 15, and 20, e.g. tetraphenylporphyrin (TPhP), and (iii) porphyrins with benzene rings attached at outer bonds, e.g. tetrabenzoporphyrin (TBP).

Among tetra-azaporphyrin derivatives phthalocyanines (Phth) are especially well known. X-Ray structural investigations have established[1,9] that phthalocyanines of bivalent metals (copper, nickel, iron, cobalt) belong to the monoclinic system, symmetry group D_4h; such high symmetry is a consequence of conjugation effects. Several polymeric metal phthalocyanines are known[1]. Polyphthalocyanines ($Phth_i$) are compounds of high molecular weight having a strip, network, or three-dimensional structure and containing tetra-azaporphyrin macrorings C_8N_8 alternating in a definite sequence. The joining of monomer units into a polymer can occur either through benzene rings (without disruption of conjugation) or through bridging groups (methylene, oxygen, nitrogen, etc.), which are either isolators or weak transmitters of conjugation. The unbroken chain of conjugation in polyphthalocyanines is short (4–6 units).

Monomeric phthalocyanines can exist in more than one modification differing in crystal structure and electrical properties[1]. The monoclinic unit cell comprises two molecules, and the distance between parallel molecules (e.g. in a crystal of copper phthalocyanine) is 3.38 Å; the area occupied by one molecule is 123 Å^2. The α-form has a tetragonal structure and is formed by precipitation from concentrated sulphuric acid or sublimation at high vapour pressures; the β-form can be obtained by heating the α-form above 300 °C. The transition occurs more rapidly and at a lower temperature in a vacuum than in air[1]. In the β-form the phthalocyanine molecules are more densely packed, which leads to stronger interplanar interactions than in the α-modification. For example, the interplanar spacings are 11.8 and 9.8 Å, while the size of the crystals increases from 100–200 Å to 1 μm for the α- and β-modifications of copper phthalocyanine respectively[1].

Porphyrin and its derivatives are characterised by a developed system of conjugated double bonds covering the whole molecule. The changes occurring in metal porphyrins during chemical reactions are associated with electronic transitions in the conjugated system of the ligand and in the electron system of the central metal ion. Therefore an understanding of the nature of catalytic and electrocatalytic processes on organic metal complexes requires a detailed study of their electronic structure.

Quantum-chemical calculations on porphyrin complexes of transition metals have shown[9-14] that the orbitals of the metal, other than those of copper and zinc, interact weakly with the π-system of porphyrin. Zinc and nickel porphyrins are diamagnetic, and those of copper and cobalt are paramagnetic; with iron and manganese several variants of the spin state are possible, because the energies of their obitals are so close to that of the $a_{2u}(\pi)$ molecular orbital. Similar results were obtained[12] for the phthalocyanines of bivalent nickel, cobalt, and iron; a somewhat different electronic configuration was found for manganese phthalocyanine.

The appearance of excited states in the visible and the ultraviolet was attributed[11] to the orbital transitions

$$a_{2u}(\pi)\rightarrow e_g^*(\pi) \qquad a_{1u}\rightarrow e_g^*(\pi).$$

The strong degeneracy and mixing of these energy levels leads to a low-energy state *Q* in the visible and a high-energy state in the region of the Soret band. The *Q*-bands approximate to a one-electron transition in the sequence

porphyrin > tetra-azoporphyrin > tetrabenzoporphyrin > > phthalocyanine.

The results of quantum-chemical calculations correlate satisfactorily with the electronic absorption spectra of porphyrin and its derivatives, although the participation of a large number of orbitals of the ligand system and perhaps *d*-orbitals of the metal must be taken into account in order to intepret the fine structure of these spectra[11,14].

The electronic absorption spectra of polyphthalocyanines on the whole are similar to the spectra of the monomers[15], but the less intense bands become flattened on polymerisation. The invariability of the long-wavelength band, representing the energy levels of the ground and lowest excited states of phthalocyanine, indicates that polymerisation does not affect the character of the π-electron interaction of the benzene and tetra-azaporphyrin rings of phthalocyanine.

A more detailed analysis of the electronic structure of metal derivatives of porphyrin, in particular of the spin state of the central metal ion, is made by comparing theoretical calculations[9,11,12] with experimental results obtained by electron spin resonance[4,5,16-18], Mössbauer spectroscopy[19,20], and measurements of magnetic susceptibility[21,22]. The e.s.r. data show that the unpaired electron in copper and cobalt phthalocyanines is located in $d_{x^2-y^2}$ [16] and d_{z^2} [17] orbitals respectively, which is consistent with the above results of quantum-chemical calculations.

An especially large number of studies have been made on the electronic state of iron ions in porphyrin complexes. However, this question has not yet been clarified. Thus some workers[19] have found the electronic configuration

$$(d_{xy})^2(d_{yz}d_{xz})^3(d_{z^2})^1,$$

but others[21] have found

$$(d_{xy,\ xz})^4(d_{xy})^1(d_{z^2})^1.$$

Calculations[11] indicate that the energy of the orbitals usually increases in the sequence

$$d_{xy}<d_\pi<d_{z^2}<d_{x^2-y^2}.$$

However, experimental and calculated positions for the band corresponding to electron transfer from metal to ligand have suggested[13,14] the alternative sequence

$$d_{z^2}<a_{xy}<d_\pi<d_{x^2-y^2}.$$

In view of the peculiarities of the electronic structure of manganese and iron porphyrins the distribution of d-electrons in these central ions is probably strongly dependent on the mode of preparation and the specific experimental conditions[20,23].

The porphyrin ring is amphoteric: in acid medium the lone pairs of the nitrogen atoms enable it to add one or two protons to form singly or doubly charged cations, and in alkaline medium singly and doubly charged anions can be formed[2]. Protons add to the central nitrogen atoms even at pH 2–3, and the excess charges are uniformly distributed throughout the whole π-electron system of the molecule[24]. In phthalocyanine the first proton is added at considerably lower pH values ($pK \cong 1.8$), probably at a bridging nitrogen atom[25]. The number and positions of protons added to phthalocyanines are still matters of controversy.

Important features of metalloporphyrins, of great value for the interpretation of their catalyic and electrocatalytic properties, are their ability to add additional ligands (extra coordination) and to exist in ionic forms. Possible participation of the latter in catalysis and electrocatalysis makes it necessary to establish the redox potentials of the ring and of the central ions in non-aqueous and aqueous solutions and to identify the path of electronic transfers (ring, metal). The two problems are solved respectively by polarography and by combined study of electron spin resonance[17,18,26,27], electronic[17,18,27-29], and infrared[27,30] spectra. The general approach to these questions and a comprehensive bibliography will be found in Refs.27 and 31.

In contrast to metalloporphyrins, which form singly and doubly charged anions, the molecules of most metal phthalocyanines are capable of adding up to four electrons[12]. Porphyrin complexes in which the metal ion cannot be oxidised (zinc, magnesium, cadmium, copper) undergo oxidation in two one-electron stages[26] with formation of singly and doubly charged cations. In cobalt and iron complexes an electron is probably first detached from the metal, after which the porphyrin ring is oxidised[17,18]. Localisation of the charge depends substantially on the nature of the central metal ion: in singly charged anions of metal-free phthalocyanine and tetraphenylporphyrin the excess charge is localised on the ligand; in both of the cobalt complexes the electron is localised on the central atom[5,28,31]; and in the anions $[FePhth]^-$ and $[FePhth]^{2-}$ the negative charge is shared between the iron atom and the ligand[5,28].

The coordination of additional ligands by planar-coordinated metal porphyrins, termed "extra coordination", is their important property. In relation to heterogeneous catalysis and electrocatalysis it consists merely in the reversible adsorption interaction of reactants and components of the medium with the active centre of the catalyst. For specific aspects of catalysis and electrocatalysis it is of the greatest interest to examine the axial bonding of several simple electrochemically active molecules—oxygen, carbon monoxide, nitric oxide, sulphur dioxide, water—and also component ions of the electrolyte.

Nitric oxide is coordinated to iron, cobalt, and manganese porphyrins in the presence of axially bound ligands containing nitrogen[32-37]. The complex of cobalt porphyrin with nitric oxide can be regarded formally as Co^{III}–NO^- with charge transfer from the $3d_{xz}$ or $3d_{yz}$ orbitals of cobalt to anti-bonding $2p\pi^*$ molecular orbitals of the nitrosyl ligand. π-Interaction of these metalloporphyrins with nitric oxide weakens from manganese to iron and then to cobalt. The same porphyrins form mono- and di-adducts with carbon monoxide[38-41]. Adsorption of the latter gas is more stable than that of oxygen: if they are present together, oxygen is coordinated first, and is then displaced by carbon monoxide. The coordinating power for carbon monoxide falls in the sequence[38]

protoporphyrin > tetraphenylporphyrin > tetrabenzoporphyrin > phthalocyanine.

Electron spin resonance indicates the fully reversible formation of an almost axially symmetric complex by sulphur dioxide with cobalt tetraphenylporphyrin in toluene solution[42].

Optical and e.s.r. measurements have shown that cobalt phthalocyanines, tetraphenylporphyrins, and tetra-*p*-methoxyphenylporphyrins in anhydrous medium (e.g. toluene) at low temperatures (−80 °C) form equimolecular oxygen adducts reversibly[43–47]. In the presence of a strong donor (e.g. imidazole) a mononuclear adduct is formed even at room temperature. The e.s.r. spectra indicate that the oxygen complex of cobalt tetraphenylporphyrin has the electronic configuration $Co^{III}...O_2^-$: i.e. considerable delocalisation of the unpaired electron and partial charge transfer to the oxygen atom take place.

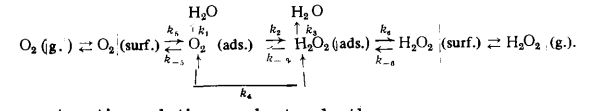
Two models—parallel and unsymmetrical or bent (the Griffiths and Pauling models respectively)—have been used in a quantum-chemical calculation[11] of the coordination of an oxygen molecule with iron porphyrins. With parallel orientation the π_x-orbital of oxygen will overlap the d_{z^2}-orbital of the metal, and the anti-bonding π_x^*-orbital of oxygen the $d_{xz}d_{yz}$-orbitals of the metal. The calculation showed that such coordination should be accompanied by transfer of negative charge (−0.53) from iron to oxygen, which should result in formation of the O_2^- ion in a vibrationally excited state. According to the Pauling version, on formation of a bond between oxygen and iron porphyrin the bent orientation is stabilised by formation of a σ-bond with the d_{z^2}-orbital. Maximum σ-bonding is achieved with an M–O–O angle of 120°. An approximation to this structure is found in oxyhaemoglobin.

A considerable quantity of experimental information has now accumulated on the heterogeneous catalysis of several reactions on metalloporphyrins, detailed accounts of which will be found in reviews[6–8,48]. The range of reactions activated by these complexes is extraordinarily wide; most of the studies have been made on the oxidation of organic compounds—mild oxidation of hydrocarbons (cumene[6,7,49–51], propene[48], mesitylene[52]), oxidative dehydrogenation (of alcohols[8,32,53–55] and cyclohexadiene[56–59])—and on decarboxylation[6,8], processes probably involving a stage of activated adsorption of molecular oxygen on the catalyst with formation of O_2^- or O^- ions. They are therefore of interest for predicting electrocatalytic activity in the cathodic reduction of molecular oxygen, as well as in other electrode reactions involving the adsorption of oxygen as an intermediate stage.

The main effects on the rate and the selectivity of redox reactions are attributed to the nature of the central metal ion[6,8,49,51,55–59], the chemical structure of the organic complex (effect of substituents in the ligand[56–59], polymerisation[6,7,48]), and the crystal structure[6,8,60]. The catalytic activities of phthalocyanines and tetraphenylporphyrins of transition metals—iron, cobalt, manganese, copper, nickel—in the oxidative dehydrogenation of cyclohexadiene have been compared[56–59] with the first oxidation potentials of the catalyst[17]. The catalytic activity of a phthalocyanine complex is greater the lower the first oxidation potential:

manganese > iron > cobalt > nickel, copper.

However, such comparison may well be ambiguous, since the localisation of charge accompanying the oxidation takes place in different regions of the complex—in the electronic system of the central ion in the iron, cobalt, and manganese complexes, or in the ligand in the copper and nickel complexes.



Such correlation is not observed at all for the catalytic properties of tetraphenylporphyrin complexes: the cobalt complex is more active than the iron complex, although their first oxidation potentials are respectively 0.52 and −0.32 V. This is probably connected with the complicated interrelated effects of organic ligand and metal on redox processes, and may indicate that not only the central atom but also the ligand is catalytically active. The latter has recently been convincingly shown[8] for the oxidation of isopropyl alcohol and the decomposition of oxalic acid. It must also be borne in mind that chemisorption bonds may differ in different redox processes, e.g. not only a π-bond with transition-metal ions of a chelate complex but also a bond using unpaired electrons. In the latter case the catalytic activity may correlate with the concentration of paramagnetic centres, as was found[61] for the ortho–para conversion of hydrogen on copper phthalocyanines.

The decomposition of hydrogen peroxide is very often used as model in investigations of the catalytic properties of organic semiconductors. This reaction is especially interesting for electrocatalysis, since in many cases hydrogen peroxide is formed as intermediate in the electroreduction of oxygen. Studies of the decomposition of hydrogen peroxide on phthalocyanines of various metals (iron, cobalt, nickel, copper, manganese, platinum, palladium, ruthenium, osmium, rhodium, and iridium)[6,7,48,62–64] have shown that monomeric ruthenium, osmium, and iron phthalocyanines[62] and polymeric copper phthalocyanine[7,48] are most active. They show also that neither the presence of unpaired *d*-electrons in the central atom nor oxidisability of the latter is a condition of catalase activity by metallophthalocyanines, which is probably due to the ability of certain such compounds to form intermediate complexes with hydrogen peroxide. The activity of a powdered metal (cobalt, copper, nickel) coated with a thin (10^{-5}–10^{-6} cm) continuous film of a phthalocyanine of the same metal far exceeds those of the individual components towards the decomposition of hydrogen peroxide[63]. This can be explained, in terms of the electronic theory of catalysis[65], by injection of electrons from the metal into the phthalocyanine film (when the thickness of the latter does not exceed the depth of shielding) with a consequent displacement of the Fermi level on the phthalocyanine surface.

This example is evidence of the contribution by collective electronic properties to the catalytic activity of organic metal complexes. However, most of the experimental results that have accumulated indicate a definite role for local electron transfers determined by the chemical properties of the catalytic complex organometallic molecule and its electronic structure. In organic semiconductors the interaction between separate molecules is considerably weaker than that between component parts of the same molecule, and every molecule in the crystal lattice is able to retain its individuality. This must probably be taken into account in the first place when catalytic and electrocatalytic research results are examined.

III. KINETICS AND MECHANISM OF THE ELECTROREDUCTION OF OXYGEN ON METALLOPORPHYRINS

The electroreduction of molecular oxygen, studied in the greatest detail with organic metal complexes, takes place on air or oxygen cathodes in chemical sources of current. Reduction of oxygen can follow different paths depending on the nature of the electrocatalyst[66]:

On the most active platinum electrode the process goes mainly via dissociative adsorption of oxygen directly to water (with rate constant k_1).[67,68] Hydrogen peroxide can be formed only in a parallel reaction (k_2). On a carbon electrode molecularly adsorbed oxygen undergoes reduction[69]. Hydrogen peroxide is formed in a two-electron reaction, and

its further transformation occurs at considerably more negative potentials, since $k_3 \ll k_2$. On several electrode materials hydrogen peroxide can be catalytically decomposed (k_4),[67,70] and oxidised by a reverse reaction (k_{-2}). The adsorption and desorption of oxygen (k_5 and k_{-5}) or of hydrogen peroxide (k_6 and k_{-6}) can also be slow stages[71,72]. Electrocatalysis can in principle consist in the acceleration of any stage of this process.

In view of the many-electron character of the electroreduction of molecular oxygen a study of this process should include two main stages—(i) elucidation of the mechanism or path of the process, i.e. establishment of the relation between the partial reactions in the overall process, and (ii) kinetic analysis of the most important partial reactions with the aim of elucidating the nature of the slow stage.

1. Model Systems

Organic metal complexes have low conductance, and are therefore deposited as a thin film on an electrically conducting carrier for the study of their electrocatalytic reactions. Several model systems have been designed for investigations under purely kinetic or strictly defined hydrodynamic conditions.

1. Thin films (10^2–10^4 Å) of organic metal complexes on a smooth, electrically conducting support, which are applied from solution[73–75] or by vacuum sputtering[20,76,77]. Gold or pyrographite is most often used as the support.

2. Extremely thin layers of catalysts comprising a highly dispersed (usually carbon) carrier coated with the organic metal complexes[78–88]. This system is more active than the first and is often used in investigations using a disc electrode with a ring. This method makes it possible to fix on the annular electrode an intermediate product (in the present case hydrogen peroxide) in the reaction occurring on the disc, and is most informative with respect to separation of the process into partial reactions and determination of kinetic parameters for each of the latter[89].

3. Suspension electrodes[82–86], enabling diffusion restraints to be eliminated and electrocatalytic activities of organic metal complexes deposited on a dispersed carrier to be compared under kinetic conditions. A disadvantage is the complicated character of the transfer of charge from particles of the suspension to the current leads[90], a stage which under certain conditions may become rate-determining.

4. Porous gas-diffusion electrodes promoted by organic complexes[58,88,91]. Comparisons of catalytic activity by this method are qualitative, since the characteristics of such electrodes depend significantly on several macrokinetic parameters[92].

Kinetic analysis of electrochemical reactions on organic metal complexes must take into account structural features of the electrical double layer on semiconducting materials, specifically the possible distribution of electrode potential between the Helmholtz layer in the electrolyte and the space charge in the semiconductor[93]. The potential distribution depends on the concentration and mobility of free charge carriers, the concentration of surface states, etc. If the thickness of the semiconductor film is less than the depth of shielding (for organic metal complexes it is 10^{-6}–10^{-5} cm), additional effects are possible as a consequence of injection of charge carriers from the conductor (support) into the semiconductor (catalyst)[65]. This requires investigation of the structure of the complex–electrolyte interface for the above specific systems.

Measurements of differential capacitance on cobalt, iron, and metal-free phthalocyanine films sputtered on to pyrographite have shown that the presence of the film lowers the electrode capacitance to some 10% of that of the support, to ~0.5–0.7 μF cm^{-2} (Fig. 1c).[78,93] The capacitance depends significantly on the a.c. frequency, which probably indicates that the measured capacitance is determined not by the charge of the depleted layer in the semiconductor but by rapid surface states. This suggests that migration of charge in a film is a rapid process.

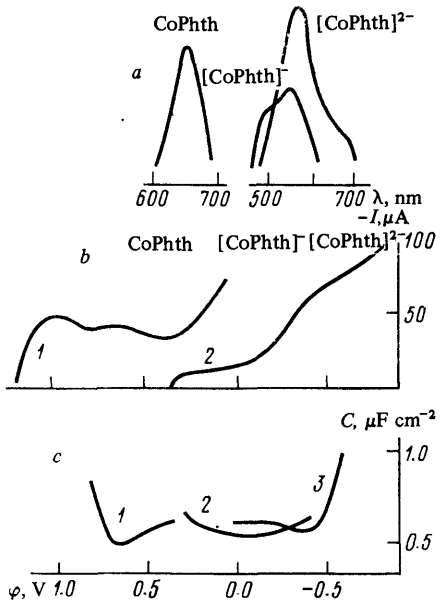


Figure 1. Investigation of cobalt phthalocyanine films at various pH.[78,93]
(*a*) Specular reflectance spectra.
(*b*) Potentiodynamic I–ϕ curves determined on film at pH: 1) 0.3; 2) 14.
(*c*) Dependence of differential capacitance of CoPhth on potential at pH: 1) 0.3; 2) 6.8; 3) 14.

The electronic structure of the neutral state of organic complexes is considered when the nature of catalytic and electrocatalytic activities is discussed. Under the conditions of electrochemical reactions, however, the charge on the complexes may vary (with formation of ionic modifications) as the pH and the electrode potential change. Interesting conclusions follow from a study of the surface state of cobalt phthalocyanine based on comparison of electrochemical and spectral measurements in aqueous solutions at pH 0.3 and 14 (Figs. 1*a* and 1*b*): independently of the pH the potentiodynamic current–potential (I–ϕ) curves of the complex contain several plateaux or maxima, from which to a first approximation three can be isolated in the potential ϕ_r ranges 1.2–0.75, 0.75–0.4, and 0.4–0 V†.

† Here ϕ_r is the potential relative to a hydrogen electrode in the same solution and ϕ the potential relative to a normal hydrogen electrode.

In order to identify electrochemical changes undergone by cobalt phthalocyanine in aqueous solution spectral studies have been made[93] by specular reflectance directly under conditions of electrochemical polarisation. A film of this complex, like all neutral metal phthalocyanines, has an absorption band in the range 600–670 nm. On cathodic polarisation ($\phi < -0.4$ V) the band due to the neutral molecule becomes weaker, and a double band appears at 400–500 nm (Fig. 1*a*). This indicates formation of a singly charged anion of cobalt phthalocyanine with the charge localised on the central cobalt ion. At large negative potentials ($\phi < -0.8$ V) in alkaline aqueous solution a broad band appears representing a doubly charged anion with the second electron localised on the ligand. The reflectance spectrum of iron phthalocyanines undergoes reversible changes under the influence of an electrolyte[94]. A qualitative correlation has been established[20] between the position of the main absorption peak and the spin state of the iron atom in phthalocyanines prepared by different methods. Thus over the potential range of electroreduction of the oxygen molecule the phthalocyanine molecule may be present in various electronic states depending on the pH and the nature of the central ion.

At present information on the structure of the interface between organic metal complex and electrolyte is extremely limited and is related only to a few specific systems used in studying the electroreduction of oxygen. From these results it can be suggested that the potential drop is mainly located in the electrolyte and that charge transfer in the semiconducting film is rapid[20].

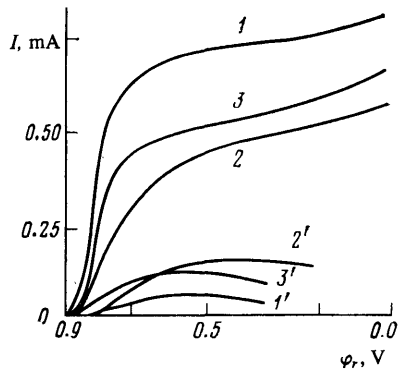

Figure 2. Polarisation curves for the reduction in 0.1 *N* KOH of oxygen on: 1) $CoPhth_i$; 2) CoTPhP; 3) CoTMPhP; 1′–3′) corresponding curves for the oxidation of hydrogen peroxide on a platinised platinum ring ($m = 680$ rev/min).

2. Mechanism of the Electroreduction of Oxygen

Published work reveals the effect of the structure of organic metal complex catalysts, their crystal structure, and the composition of the solution on the mechanism and the rate of the electroreduction of molecular oxygen. The most important factor is the chemical structure of the catalyst molecule—the type of ligand and substituents and the degree of polymerisation on the one hand, and the nature of the central ion on the other.

Macrocyclic complexes containing a system of conjugated π-electrons—phthalocyanines[73–88,95], tetraphenylporphyrins [58,80,81,83–85], dibenzotetra-aza-annulenes (DBTAA)[86,87]—exhibit greater or less activity in the electroreduction of oxygen both in acid and in alkaline solutions. (The number of π-electrons in the inner conjugated system of these complexes is roughly the same at ~18.) Polarisation curves for the reduction of oxygen at a rotating disc electrode coated with a thin layer of polymeric cobalt phthalocyanine, of cobalt tetraphenylporphyrin, or of cobalt tetrakismethoxyphenylporphyrin (CoTMPhP) in alkaline solution have a single wave (Fig. 2),[80,81] in contrast to those of pyrographite[69] or carbon black[96]. Fig. 2 includes for the above compounds the variation of the limiting currents for the oxidation of hydrogen peroxide on the ring. Numerical calculations applied to the results by the method of Ref. 89 have shown that the mechanism of the reduction of molecular oxygen on these organic metal complexes is different: on cobalt tetraphenylporphyrin reaction takes place only with intermediate formation of hydrogen peroxide ($k_1 = 0$);[80,81] on polymeric cobalt phthalocyanine and on cobalt tetrakismethoxyphenylporphyrin parallel direct reduction to water takes place, its contribution to the total process being respectively 50% and 30%.[80,81]

In acid solution only the reaction involving intermediate formation of hydrogen peroxide occurs on all the complexes investigated. The constant k_2 decreases in the sequence[80,81]

$$CoTMPhP > CoTPhP > CoPhth_i > CoPhth.$$

Phthalocyanines are less active in acid solutions than are tetraphenylporphyrin complexes[58,80,81,83–85]. The introduction of electron-donors into the phenyl groups increases the activity of cobalt tetraphenylporphyrin in the sequence[85]

$$-OCH_3 > \langle\bigcirc\rangle > H\ .$$

However, the method of preparation of the chelate is probably quite important. For example, the catalytic activity of cobalt tetraphenylporphyrin was unaffected[58] by the introduction of *p*-methoxy- and *p*-nitro-substituents. Electron-acceptors, e.g. the fluoride ion, do not influence the electrocatalytic activity of cobalt phthalocyanine[58], but lower that of iron phthalocyanine[58,82]. Cobalt dibenzotetra-aza-annulene is more active than the tetraphenylporphyrin chelate in acid solutions[86,87], and neither donor nor acceptor substitutents affect the rate of electroreduction of oxygen on this complex.

Thus, in relation to the electroreduction of molecular oxygen, the organic ligands investigated form the sequences

Phth > TPhP > DBTAA in alkaline solutions
DBTAA > TPhP > Phth in acid solutions.

The nature of the central metal ion has a still more substantial influence on the rate and the mechanism of the ionisation of molecular oxygen on the organic complexes[75–88,95]. In relation to the rate of electroreduction of molecular oxygen (independently of pH) the activity of the metal phthalocyanines varies in the seqence

$$Fe\ (II),\ Fe\ (III) > Co\ (II),\ Mn\ (II) > Ni\ (II) \geqslant Cu\ (II) > 2H\ .$$

With tetraphenylporphyrins at all pH [58,80,81,83–85] and with dibenzotetra-aza-annulenes in acid and alkaline solutions[86,87] the bivalent cobalt complexes are more active than the bi- and ter-valent iron complexes:

$$Co\ (II) > Fe\ (II,\ III) > Ni\ (II),\ Cu\ (II)\ \text{(on TPhP)}\ ,$$
$$Co\ (II) > Mn\ (II) > Fe\ (II,\ III) > Ni\ (II),\ Cu\ (II)\ \text{(on DBTAA)}\ .$$

Systematic investigations using a disc electrode with a ring[75,78–81] have established which reactions in the complicated reduction of molecular oxygen are catalysed by organic metal complexes and how their relative rates vary with the chemical structure of the catalyst. In acid solutions the reaction yielding hydrogen peroxide is accelerated in the presence of metal complexes of phthalocyanine, tetraphenylporphyrin, and tetrakismethoxyphenylporphyrin. In alkaline solutions this is accompanied, in the presence of monomeric and polymeric iron and manganese phthalocyanines, polymeric cobalt phthalocyanine, and cobalt tetrakismethoxyphenylporphyrin, by the direct reaction involving rupture of the O–O bond. Reduction of oxygen to water without intermediate formation of hydrogen peroxide[79] diverges significantly from conclusions reached by other workers[73,74,76,77,82–87], who accept that in all cases reaction occurs only via this intermediate stage.

A correlation has been found[97] between the electrocatalytic activity of metal phthalocyanines and their magnetic properties determined by the spin state of the central ion. In the view of other workers[91], however, no direct relation exists between magnetic moment and electrocatalytic activity. It should be noted that the latter workers[91] use results obtained on porous gas-diffusion electrodes, which diminishes the reliability of the conclusions because of possible distortion by macrokinetic effects.

The nature of the carrier has a considerable effect on the electrocatalytic activity of metal chelates. The greatest activity is achieved by the use of various forms of carbon, with the maximum effect when alkaline groups are present on the carbon surface[82]. The mechanism of these phenomena is still obscure. The electrocatalytic activity of the α-modification of iron(II) phthalocyanine is greater than that of the β-form[76,94]. The electronic spectra of transmitted and reflected light show a ~15 000-cm^{-1} shift of the band to longer wavelengths on passing from the β- to the α-modification, which is attributed[76,94], in agreement with Ref.13, to a greater concentration of high-spin iron(III) phthalocyanine in the latter form. This is due to adsorption of oxygen in the bulk of the α-form and transition of the greater part of the iron(II) complex into a high-spin form. Cathodic polarisation of a specimen of the α-modification leads to an irreversible loss of activity. The enhanced electrochemical activity is attributed to a complex $Fe^{III}Phth-O_2^-$, on which occurs secondary adsorption of the oxygen molecule involved in the electrochemical reaction[76,94].

Detailed investigations of the effect of the method of preparation of monomeric and polymeric iron phthalocyanines on their electrocatalytic activity and the spin state of the central ion have established[20] that a polymer formed on a carrier and containing iron(III) of intermediate spin is the most active; the least active is the iron(II) monomer in the triplet state. However, the state of iron phthalocyanine at the interface with the electrolyte and the mechanism of adsorption of molecular oxygen remain obscure.

The above discussion shows that the main factor in electrocatalysis of the oxygen reaction is local interaction between an oxygen molecule and a catalyst molecule: collective interaction effects may be of secondary importance, at least in the above specific model systems. This conclusion is supported[88] by the lack of correlation between the electrocatalytic activity of phthalocyanines of several metals and their electrical conductivity.

Thus the reaction path of the cathodic reduction of oxygen on organic complexes of metals is now in general clear. On all the metal porphyrins investigated at all pH molecular oxygen is reduced by a consecutive mechanism involving intermediate formation of hydrogen peroxide. On several organic complexes in alkaline solutions (pH 10–14) this is accompanied by simultaneous reduction of oxygen directly to water without intermediate formation of hydrogen peroxide, i.e. involving rupture of the oxygen–oxygen bond either in an oxygen molecule or more probably in the molecular ion O_2^-. In the case of iron phthalocyanine direct formation of water is the main reaction.

3. Kinetics of the Reduction of Oxygen

Investigation of the kinetics of the reduction of oxygen over a wide pH range is necessary in order to ascertain the nature of the slow stage, which has been undertaken for metal-free phthalocyanine, monomeric and polymeric cobalt phthalocyanines, and cobalt tetraphenylporphyrin (Fig.3).[80,81] Table 1 gives typical variations in the kinetic parameters $\partial\phi/\partial \lg i$ and $\partial\phi/\partial$pH for the catalysts under different experimental conditions. Throughout the pH range 0–14 the rate of reduction of molecular oxygen to hydrogen peroxide is higher in the presence of the organic complexes than with carbon black as carrier. With the exception of cobalt tetraphenylporphyrin in acid medium the kinetic parameters of the reduction on the various catalysts are closely similar to those on carbon black. Such coincidence indicates a similar mechanism for the slow stage. Investigations on carbon black[96] and other carbonaceous materials[69,98] have shown that the cathodic reduction of oxygen is governed by the slowness of transfer of the first electron to an adsorbed oxygen molecule (or from an O_2^- ion in the reverse anodic oxidation of hydrogen peroxide):

$$(ML) + O_2 \rightarrow (ML)O_2,$$
$$(ML)O_2 + e \rightarrow (ML)O_2^- \text{ (slow stage)},$$
$$(ML)O_2^- + H_2O \rightarrow (ML)HO_2 + OH^-,$$
$$(ML)HO_2 + e \rightarrow (ML)HO_2^-,$$
$$[(ML)HO_2^- + H_2O \rightarrow (ML) + H_2O_2 + OH^-].$$

The remaining stages, leading to formation of hydrogen peroxide or HO_2^- in acid or alkaline solution respectively, are rapid. In acid and neutral solutions the reaction is irreversible, with $(\partial\phi/\partial\,\text{pH})_{i=\text{const}} = 0$, $\partial\phi/\partial \lg i = 120$ mV, and the transmission or Brønsted coefficient $\alpha = 0.5$. With rise in pH the rate of the reverse reaction increases, and the O_2–$H_2O_2(HO_2^-)$ system approaches reversibility, with a consequent negative shift in potential and decrease in $\partial\phi/\partial \lg i$. It can quite justifiably be assumed that the reduction of oxygen has a similar mechanism on the organic complexes (except for cobalt tetraphenylporphyrin in acid solutions)[80,81].

The behaviour of cobalt tetraphenylporphyrin departs completely from the above scheme, a very interesting phenomenon that merits special attention. A formal explanation can be based on the hypothetical slow stage

$$(ML)O_2 + H^+ + e \rightarrow (ML)HO_2$$

with $\partial\phi/\partial \lg i = \partial\phi/\partial\,\text{pH} = 120$ mV when $\alpha = 0.5$. The change in the mechanism of the reduction of oxygen on cobalt tetraphenylporphyrin and tetrakismethoxyphenylporphyrin in acid solutions may exist because their protonation may differ in character from that of the phthalocyanines.

The kinetics of the reduction of oxygen at various pH has been investigated also on monomeric and polymeric cobalt and iron phthalocyanines[20,94]. Detailed comparison of these results with those of other workers[75,79–81] shows a certain parallelism: in both cases the reaction is of first order with respect to molecular oxygen, the derivative $\partial\phi/\partial \lg i$ decreases with increase in pH to reach ~40 mV at pH > 13, in alkaline solutions the potential becomes more negative with increase in pH, and the slopes of the polarisation curves on promoted

and unpromoted carbonaceous materials coincide. However, it is concluded[20], in contrast to the other workers[75,79–81], that in alkaline solutions chemical cleavage of the O–O bond

$$HO_2^- \text{ (ads.)} + H_2O \rightarrow 2OH + OH^-$$

is the slow stage. This mechanism is clearly of limited value, since it does not explain all the experimental results, especially in non-alkaline media.

Table 1. Kinetic parameters of the reduction of oxygen to hydrogen peroxide on carbon black in the presence of organic complexes*.[80,81]

pH	$\partial\varphi/\partial$ pH, mV	$\partial\varphi/\partial \lg i$, mV
	carbon black	
2—10	0	—90—120
10—14	—60—30	—40—50
	cobalt phthalocyanine	
2—10	0	—100—120
10—14	—60—30	—40—50
	cobalt tetraphenylporphyrin	
0—4	—110	—100—120
4—10	0—10	—100—120
10—14	—60	—40—60

*Closely similar values of the kinetic parameters were observed on films of the phthalocyanines 500–1000 Å thick sputtered on a pyrographite electrode.

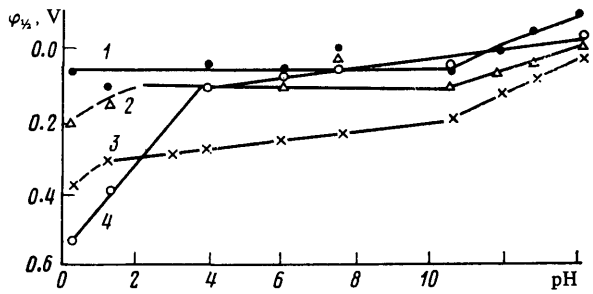

Figure 3. Dependence of half-wave potential on pH for the reduction of oxygen[80,81] on: 1) carbon black; 2) metal-free and cobalt phthalocyanine monomers; 3) cobalt phthalocyanine polymer; 4) cobalt tetraphenylporphyrin.

Several attempts have been made to explain the electrocatalytic action of metal porphyrins on the cathodic reduction of oxygen. The simplest approach is to establish a correlation between electrocatalytic activity and oxidisability[58], the latter measured by the first oxidation potential of the complex. Indeed, if the slow stage is electron transfer from the central ion, these reactions are similar. Good correlation between electrocatalytic activity and oxidation potential actually exists for monomeric iron, cobalt, and copper phthalocyanines, but the situation is considerably impaired with other ligands.

In the mechanism of "redox catalysis"[86,87] the activity of the complexes is related to the tendency of the central metal ion to pass into a higher valency state, i.e. to the third ionisation potential. The metal chelate is oxidised chemically by oxygen or an intermediate product to the cation, which then undergoes the electrochemical stage of cathodic reduction to the original compound. Such an approach does not actually consider the reduction of oxygen. Furthermore, it ignores the mutual influence of ligand and metal ion, which is evident e.g. in the difference in the activity series for phthalocyanines and tetraphenylporphyrins.

The effect of the central ion on the rate of the electroreduction of oxygen has been explained[20,77,78,84,85,94] on the basis of the quantum-chemical calculations of the electronic structure of metalloporphyrins and their oxygen complexes briefly considered in Section II. Stable complexes of oxygen with metal (e.g. iron) porphyrins are formed[11] by adsorption of the oxygen in a lateral position. The d_{z^2} orbital of the cobalt ion is most favourable for bonding an oxygen molecule, since its symmetry ensures the necessary overlap of orbitals[85]. It is assumed that the adsorption of an oxygen molecule on a metal phthalocyanine (tetraphenylporphyrin) is accompanied by formation of a $\sigma-\pi$ double bond between the $d_{xz}d_{yz}$ and d_{z^2} orbitals of the central ion and the π^* molecular orbital of the oxygen molecule. Partial electron transfer from the central metal ion to the antibonding π^* orbitals of the oxygen atom weakens the O–O bond in the molecule. This tends to accelerate the cathodic reduction of oxygen.

Since formation of a donor–acceptor bond requires interaction of filled oxygen orbitals with vacant d_{z^2} metal orbitals, iron(II, III), cobalt(II), and manganese(II) complexes should exhibit the greatest activity, whereas only weak or completely absent catalytic activity can be expected for nickel(II) and copper(II) complexes#. Augmenting the number of delocalised π electrons (polymerising phthalocyanines or introducing donor groups into tetraphenylporphyrin) increases the electron density on the central ion, which facilitates electron transfer to the oxygen molecule and accelerates its reduction. On the other hand, increasing the degree of localisation of the electron on the adsorbed oxygen molecule weakens the O–O bond until it ruptures with direct formation of water. To explain the change in the activity sequence of ligands on passing from acid to alkaline solutions account must be taken of the possible occurrence of reaction on charged forms of the organic complexes (anions, cations), which may be present on the electrode surface within certain pH and potential ranges, as shown at the beginning of this Section.

Discussion of the nature of the electrocatalytic effects on the basis of approximate quantum-chemical calculations is, of course, only qualitative and leaves aside many experimental factors, e.g. the effects of the support or carrier[58,74,82], the crystalline modification[76,94], and the mode of preparation of the organic metal complex[58,78,80]. Their explanation requires a more profound (both theoretical and experimental) study of the adsorption interaction of such complexes with the reactants and investigation of the structure of the catalyst–electrolyte interface and the electronic structure of the adsorbed state.

The validity of this deduction depends on the adequacy of the quantum-chemical calculations in relation to the experimental results. Several discrepancies between them have been mentioned in Section II.

IV. USE OF ORGANIC COMPLEXES OF METALS TO PRODUCE GAS-DIFFUSION ELECTRODES

The great activity of several organic complexes of metals in the electroreduction of molecular oxygen has enabled them to be used to activate oxygen (air) electrodes in electrochemical sources of current[82,88,91,99–114], transducers[115], and other electrochemical devices. The production of active and stable gas-diffusion electrodes requires the solution of several macrokinetic problems in the optimum distribution of catalyst, electrolyte, and gas in a porous electrically conducting matrix with the aim of maximum development of the surface available for the electrochemical reaction[92]. Only results bearing directly on the use of organic metal complexes will be considered here.

Because of the low electrical conductivity of organic metal complexes they are used in combination with a highly dispersed carrier (a carbonaceous material or nickel powder). The catalyst is introduced into the carrier either by mechanical mixing[99,100] or by impregnating the carrier with a solution of the organic complex in concentrated sulphuric acid or other appropriate solvent (pyridine, dimethylformamide, etc.)[101–114]. The latter method is the most usual, since it will give a uniform distribution of the catalyst on the carrier surface. Another method is to form the organic metal complex directly on the carrier surface[91,108,116]. The chief design feature of the electrodes employed in work with these complexes is their water-repellancy, with a stable interface between gas and electrolyte achieved by introducing into the active mass a water-repellant agent (polyethylene or fluoroplastic), which is also a binder. The active mass is applied to a wire-gauze or porous metal base serving as current lead. Other details of the design and technique of preparation of the electrodes will be found in the literature[99–114].

Table 2. Electrochemical activity of oxygen electrodes comprising carbon black promoted with 20% of monomeric metal phthalocyanines in 12 *N* potassium hydroxide at 90 °C.[102]

Catalyst	–	H_2Phth	NiPhth	CuPhth	MoO_2Phth	CoPhth	FePhth	MnPhth	PtPhth	PdPhth
i, mA cm^{-2}, at φ_r = 0.80 V	40	60	8	60	70	130	120	140	110	140

Many monomeric phthalocyanines display extremely high electrochemical activity in porous gas-diffusion electrodes in an alkaline electrolyte. The rates of the electroreduction of oxygen on iron, cobalt, manganese, platinum, and palladium phthalocyanines are several times higher than that on pure carbon black. It is interesting that the introduction of metal-free phthalocyanine into carbon black increases the reaction velocity by ~50%. In the case of cobalt, molybdenyl, and copper phthalocyanines the change from monomer to polymer increases the current density by 100–200% (Fig.4).[102] A similar effect has been observed[108] with polymeric iron phthalocyanine. The influence of method of preparation on the activity of gas-diffusion electrodes has been investigated[102] for polymeric cobalt phthalocyanine.

The activity and the stability of gas-diffusion electrodes depend significantly also on their macrokinetic parameters, which are determined by the porous structure of the water-repellent active layer and the distribution of electrolyte and gas in the latter. These aspects have been investigated in the greatest detail[117,118] on water-repellent electrodes based on carbon black promoted with polymeric cobalt phthalocyanine. Mercury porosimetry indicates that contents of the polymer up to 10 mass % have no effect on the electrode structure; 20 mass % increases the total porosity; and up to 40 mass % some of the narrow pores become blocked. Application of this method to a frozen electrolyte has shown[119] that introduction of the polymer with the same fluoroplastic content leads to a considerable growth of liquid porosity.

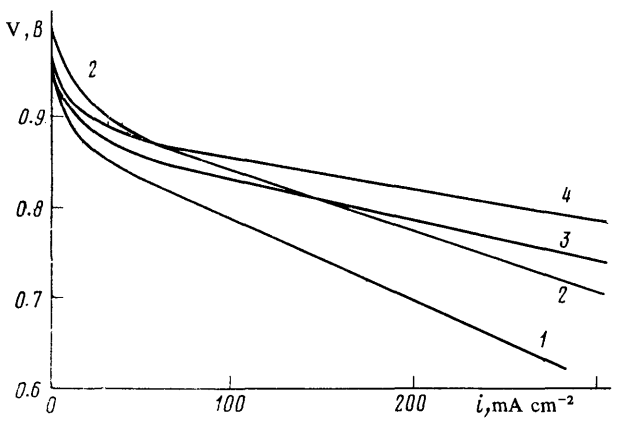

Figure 4. Polarisation curves for the reduction of oxygen, in 12 *N* KOH at 90 °C, on porous carbon electrodes promoted with polyphthalocyanines[102]: 1) $MnPhth_i$; 2) $CuPhth_i$; 3) MoO_2Phth_i; 4) $CoPhth_i$.

The correlation between current density at a gas-diffusion electrode and liquid porosity indicates a direct relation between the structure and the electrochemical activity of an electrode. Optimisation of the structure of the active layer [102,118] has enabled current to be generated under conditions close to optimum, i.e. inner kinetic[92]. The apparent activation energy for porous electrodes promoted with iron and polymeric cobalt phthalocyanines at $\phi_r = 0.83$ V is 4–5 kcal mole^{-1}, which confirms the predominantly kinetic character of the process. Carbon electrodes promoted with a cobalt phthalocyanine polymer have the highest electrochemical parameters in an alkaline electrolyte (0.3 A cm^{-2} at ϕ_r = 0.80 V).

An urgent problem in connection with electrochemical current sources is to develop an oxygen (air) cathode for acid media that does not contain scarce metals, which would avoid the complications associated with the carbonisation of alkaline electrolytes involved in the use of organic fuels or contaminated hydrogen with atmospheric oxygen as oxidant. However, no inorganic catalysts not containing precious metals and sufficiently stable in acid media have yet been reported. Certain organic metal complexes are very promising in this respect.

Table 3 compares the electrochemical characteristics of carbon–oxygen electrodes promoted with organic metal complexes (for acid media)[82,85,103–107,109,111–114,120,121]. The potential of such an electrode promoted with polymeric iron phthalocyanine is 0.85 V at a current density of 10 mA cm^{-2}, but the electrodes are unstable[82]. Some stabilisation of their

functioning could be achieved by varying the mode of preparation of the iron polyphthalocyanine[88,106,107]. The instability in acid solution of the electrochemical characteristics of carbon–oxygen electrodes containing phthalocyanines is probably due to partial dissociation of tetrabenzotetra-aza-porphyrin complexes in acid solutions. Hydrogen peroxide, formed in acid solutions as intermediate in the reduction of oxygen, may also have an adverse effect[80,81]. It oxidises metal phthalocyanines with cleavage of the macroring[1]. This probably limits the direct use of metal-containing porphyrin complexes in acid electrolytes.

Table 3. Electrochemical characteristics of carbon electrodes promoted with organic metal complexes in 3–6 *N* H_2SO_4 at 25–30 °C (τ = duration of functioning).

Active layer	φ_r, V, at i, mA cm^{-2}				τ, h	Ref.
	10	20	40	50		
Carbon black + $CoPhth_f$ + polyethylene	0.70	0.60	0.50	0.43	—	82
Carbon black + $FePhth_f$ + polyethylene	0.85	0.78	0.72	0.70	—	82
Norit BRX + 50% $FePhth_f$ + fluoroplastic	—	0.80	0.75	—	400	88, 106
Carbon + $FePhth_f$ + fluoroplastic	0.78	0.71	0.60	0.56	1000	107
Norit BRX + $CoPhth_f$ + fluoroplastic	0.72	0.69	0.64	—	150	103, 104
Norit FNX + CoTMPhP + fluoroplastic	0.75	0.70	0.65	0.63	300	85
Carbon AG-3 + macromolecular cpd. based on CoTMPhP	0.82	0.79	0.76	0.75	10000	120, 121

Heat-treatment of organic semiconductors at temperatures up to 1200 °C yields pyropolymers characterised by a narrow forbidden gap and significantly higher conductivity. The polymers are probably formed from highly unsaturated aromatic molecules[122] and possess great chemical stability. This group of polymeric compounds is extremely promising for electrolcatalysis.

Table 4. Effect of heat-treatment temperature t on durability τ of oxygen–carbon electrodes containing 5 mass % CoTMPhP in 4.5 *N* H_2SO_4 at 10 mA cm^{-2}.

t, °C	400	600	700	800	900	1000
τ, h	150	350	500	10000	10000	10000

Polyacrylonitrile pyrolysed at 600–1000 °C has been used[123] to activate an oxygen electrode in an acid electrolyte. At current densities of 50–80 mA cm^{-2} the potential of such an electrode was 0.7 V, but in durability tests it fell appreciably.

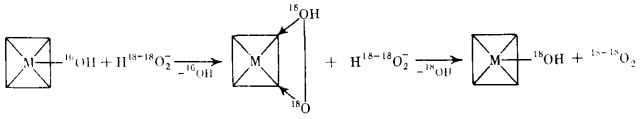
A method has been proposed[121] for preparing a catalyst based on carbon promoted with organic cobalt complexes (tetraphenylporphyrin, tetrakismethoxyphenylporphyrin, phthalocyanine) to ensure prolonged (>10 000 h) stable functioning of oxygen (air) electrodes in an acid electrolyte (4.5 *N* sulphuric acid). A mixture of carbon and the organic complex (e.g. cobalt tetrakismethoxyphenylporphyrin) is subjected to heat-treatment in an inert gas (helium) at 800° to 900 °C, which does not affect the initial activity of the catalysts, but has a substantial effect on the stability of their operation [Table 4].[120] X-Ray structural examination and elementary analyses have shown that the heat-treatment of cobalt chelates yields new macromolecular compounds whose chemical stability in sulphuric acid exceeds considerably that of the original compounds.

These investigations have shown that the principal parameters of the porous active layer—the total porosity and also the ratio of liquid and gas pores—are not affected by heat-treatment. Results obtained by means of a disc electrode with a ring indicate that microkinetic factors have a decisive role in stabilising the electrochemical characteristics of electrodes having heat-treated catalysts. The rate of conversion of hydrogen peroxide in the presence of thermally stabilised catalysts is increased some tenfold in comparison with the initial organic complexes, which lowers its concentration in the pores of the active layer and stabilises the working of oxygen electrodes in an acid electrolyte.

V. ELECTROCHEMICAL REACTIONS OF HYDROGEN PEROXIDE AND OTHER ELECTROCATALYTIC REACTIONS

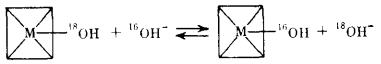
Other electrocatalytic reactions on organic metal complexes have been studied in less detail than the electroreduction of molecular oxygen.

1. Reactions of Hydrogen Peroxide



It is of interest from various points of view to investigate the electrode behaviour of hydrogen peroxide. As shown above, in several cases this compound is formed as intermediate in the reduction of oxygen, and its subsequent transformation determines the efficiency of operation of the oxygen (air) cathode. On the other hand, the decomposition of hydrogen peroxide is used as a model in investigations of heterogeneous catalysis on organic complexes. The possibility that it may undergo electrochemical reactions on complexes possessing semiconductor properties is usually ignored§.

Qualitative studies have been made of the cathodic reduction of hydrogen peroxide on phthalocyanines of several metals[73,88,106]. Comparisons have been made[88,106] between the catalytic activity and the conductivity of polymeric cobalt and iron phthalocyanines. The lack of correlation between these parameters led to the catalase activity of phthalocyanines being attributed to acceptor sites, assumed to be defects, dislocations, etc.



A combination of polarisation measurements, gasometry, and isotopic analysis of the oxygen evolved by the decomposition of hydrogen peroxide labelled with oxygen-18 has permitted[124] separate examination of the chemical and the electrochemical reactions of hydrogen peroxide on monomeric iron and cobalt phthalocyanines. Typical polarisation and gasometric curves are shown in Fig. 5 for cobalt phthalocyanine. Cathodic polarisation of the electrode entails reduction of the peroxide, and anodic polarisation its oxidation with evolution of molecular oxygen (curves *1* and *2*). Decomposition occurs also by a chemical mechanism, as is indicated by the maximum in the potential dependence of gas evolution, in the region of which the decomposition is bimolecular. At more anodic and more cathodic potentials the

§ The work of Roginskii and his colleagues[7] forms an exception.

order of the reaction decreases to unity. The oxygen evolved on decomposition of the labelled peroxide indicates that the peroxy-bond remains unbroken. These results suggest that the mechanism of the breakdown of hydrogen peroxide (e.g. in alkaline solutions) at a steady potential is

which is followed by rapid isotope exchange

so that the evolved oxygen has the same isotopic composition as the original hydrogen peroxide. The phthalocyanine molecule can function only after the chain is complete. Intermediate compounds—complexes of phthalocyanine with one or two adsorbed molecules (ions) of hydrogen peroxide—are essentially the Chance–Ogura complexes formed in the decomposition of hydrogen peroxide by catalase.

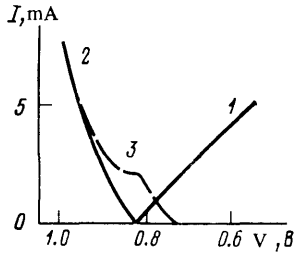


Figure 5. Curves obtained on a pyrographite electrode coated with CoPhth in 1 *N* KOH + 0.005 *N* H_2O_2:[80] 1, 2) polarisation; 3) gasometric.

On the application of electrochemical polarisation the central metal ion becomes able either to donate or to accept electrons, which permits the occurrence of a stationary electrochemical reaction with a consequent change in the order of the reaction to unity. A mechanism for the anodic oxidation and the cathodic reduction of hydrogen peroxide on cobalt and iron phthalocyanines has been suggested[124] on the basis of kinetic results. The pH dependence of the kinetics of the cathodic process enables two regions to be distinguished: $\partial\phi_C/\partial pH \cong 0$ or 120 mV according as the pH is below or above 12. This indicates that the cathodic reaction is controlled by the slowness of the stage

$$H_2O_2 + e \rightarrow OH + OH^- .$$

With respect both to chemical (catalase) and to electrochemical activity the phthalocyanines investigated form the sequence

polymeric cobalt > monomeric iron > monomeric cobalt phthalocyanines.

2. Photocatalytic Reactions

As noted in Section II, phthalocyanines are photoconductors. When thin layers are illuminated in the wavelength range 0.5–0.8 μm, free charge carriers are formed: an internal photoeffect arises. The concentration of free carriers may increase more than hundredfold[1,65] in metal-free phthalocyanine. Recently the effect of illumination on the electroreduction of oxygen has been studied on metalfree, copper, cobalt, and iron phthalocyanines either sputtered on to a support (pyrographite, gold, platinum, etc.)[125,126,128] or deposited from solution on the surface of a mercury drop[127]. Both photoactivity and dark activity are greatly influenced by the nature of the central ion[125,127], the material of the support[125–128], and the solution pH.[125]

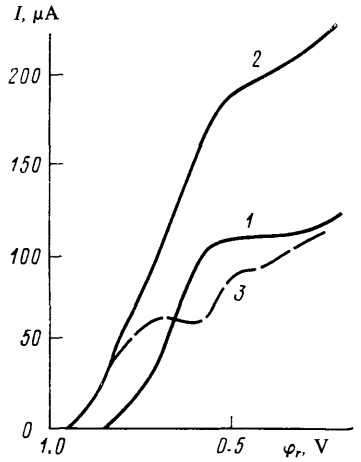

Figure 6. Polarisation curves for the reduction of oxygen on an H_2Phth film (100 Å) in 0.1 *N* KOH: 1) without illumination; 2) illumination with white light; 3) photocurrent[80].

Light has the greatest effect on the rate of the electroreduction of oxygen on metal-free phthalocyanine, the photoelectrochemical activity diminishing in the sequence of phthalocyanines

metal-free > copper > cobalt, iron.

Thus the sequence of electrocatalytic activity of phthalocyanines in the reduction of oxygen with the electrode illuminated has been opposite to that observed under dark conditions. It has been suggested[125,126,128] that light increases the concentration of O_2^- ions without changing the mechanism of the electroreduction of oxygen. According to other workers[127] it increases the rate of cathodic reduction of hydrogen peroxide. Fig.6 shows polarisation curves obtained in 0.1 *N* aqueous potassium hydroxide for the reduction of oxygen on a thin film of metal-free phthalocyanine sputtered on pyrographite. The photocurrent (curve 3) exceeds or equals the dark current, which probably indicates a change in reaction mechanism on illumination of the phthalocyanine—occurrence of the direct reaction to water.

3. Other Reactions

According to the patent literature organic complexes of metals are beginning to be used for activation of the electrooxidation of carbon monoxide[129], hydrogen[110,130], hydrazine [129,130], and several organic compounds (methanol[130], and

formic[129,131] and oxalic[129] acids) and of the electroreduction of carbon dioxide[132] (Table 5). As in the electroreduction of oxygen, phthalocyanines, tetraphenylporphyrins, and dibenzotetra-aza-annulenes of several metals are used. The oxidation of organic and inorganic compounds is catalysed by metal-free, copper, palladium, chromium, and vanadyl phthalocyanines and by nickel, zinc, and platinum tetraphenylporphyrins, i.e. by compounds that are relatively inactive towards the electroreduction of oxygen. Monomeric cobalt, nickel, manganese, palladium, copper, and iron phthalocyanines have been investigated for the electroreduction of carbon dioxide[132]. A high rate of electroreduction to oxalic and gluconic acids was observed only in the presence of cobalt and nickel phthalocyanines. The mechanism of these reactions was not investigated, but this work is evidently promising and will be developed both theoretically and by extending the ranges of electrochemical reactions and catalytically active organic compounds.

Table 5. Electrochemical activities of organic complexes towards oxidation.

Cpd.	Catalyst	Rate of oxidation	Ref.
HCOOH	CoDBTAA	11.0 mA mg^{-1} (φ_r = 0.5 V), 2 *N* H_2SO_4	129
	CoDBTAA, heat-treated	6.8 mA mg^{-1} (φ_r = 0.35 V), 2 *N* H_2SO_4	131
N_2H_4	CoDBTAA	7.5 mA mg^{-1} (φ_r = 0.5 V), 2 *N* H_2SO_4	129
	Co bis-1-hydroxy-anthraquinone	10 mA cm^{-2} ($\Delta\varphi$ = 0.1 V), KOH	130
H_2	PdPhth	500 mA cm^{-2} (φ_r = 0.5 V), 2 M H_2SO_4	130

---o0o---

Intensive reserach on electrocatalysis by organic complexes of metals has been undertaken during the past five years, but appreciable progress has already been made during this short period, both in understanding the nature of electrocatalytic activity and in elucidating the possible practical application of organic catalysts for the activation of electrochemical reactions. Local interaction of the electrochemical reactants with the catalyst molecule is shown to play the chief part. In the electroreduction of oxygen the direction and the rate are determined by the nature of the central metal ion in the organic complex and hence by the character of the adsorption interaction of an oxygen molecule with it. Detailed kinetic investigations have suggested phenomenological schemes for electrode reactions. Several metalloporphyrins are promising electrocatalysts for alkaline electrolytes. New possibilities, especially in acid media, are opened up by the use of thermally stabilised macromolecular compounds.

The task of future research is to extend the range of electrocatalytically active systems and electrocatalytic reactions. A more profound theoretical study is required of the adsorption interaction of reactants and catalyst, which governs the main effects of electrocatalysis. This needs the development of combined physical and electrochemical methods for determining the structure of the interface between organic catalyst and electrolyte.

Determination of the Useful Lifetime of a Polymeric Material as a Physicochemical Problem

O.N.Karpukhin

The principal problems of the determination of the useful lifetime of a polymeric material under various operating conditions in a given article are formulated, the disadvantages of the traditional simplified empirical approaches to solutions of problems of this kind are analysed, and the principal trends in physicochemical research, which lead to success in solving the given problem, are discussed.
The bibliography includes 50 references.

I. INTRODUCTION

The quality of a material consists of the set of its properties which are important in practice. However, not only the properties of the material at a given instant, as it were, its instantaneous properties, but also the way in which the properties of the material vary under different operating conditions are of practical importance; this characteristic of the quality of the polymeric material (PM) in fact determines its useful lifetime.

The instantaneous properties of the material can be measured in different ways and the number of such methods is large and they have been thoroughly developed. At the present time one can characterise quantitatively virtually any instantaneous property of the material, it is possible to determine any of its mechanical or rheological characteristics, its spectrum of mechanical or dielectric losses or its absorption or luminescence spectra can be characterised, the composition of the material and that of its impurities can be determined, and it is even possible to determine the composition of the active species formed in the material under any conditions.

Unfortunately however, apparatus for measuring one extremely important property of the material, which determines the kinetics of the variation of its instantaneous properties under any conditions and hence its useful lifetime under these conditions, does not and apparently cannot exist. The solution of this problem, which requires investigation, is sometimes simple and sometimes fairly complex. The present review is devoted to problems of the methodology of such investigations. They are of urgent importance at the present time by virtue of two causes of different kinds.

On the one hand, the assortment of polymeric materials with different properties, materials which are either already produced industrially or whose industrial production can be achieved, has increased. In this connection the problem arises of the optimum application of the given material or the optimum material for a given article, and not simply the problem of the determination of the useful lifetime of the given material. Materials with enhanced stability are not always best for a given article, since an increase of stability usually entails also an increased cost of the material and excessive stability of the material creates the additional problem of the disposal of the residue after the given article has failed. Therefore if, as commonly occurs, the predicted useful lifetime of the material is too short, the result may be large unnecessary expenditure on excessive stabilisation of the material or reinforcement of the constructions produced from the material.

On the other hand, the present state of the theory of the ageing of polymeric materials makes it possible to pose the question of a more rigorous formulation of problems associated with the determination of their useful lifetime. More than ten years ago the principal problems of the fundamental research into the question of the ageing of polymeric materials were formulated[1,2] and a long series of studies on these lines was initiated. Considerable experience in work with polymeric materials has now accumulated, extensive experimental studies have been carried out, the foundations have been created for a theory of the ageing of polymeric materials, methods have been developed for the determination of the quantitative characteristics of this process, and the first successes have been achieved in the description of the kinetics of the variation of properties of polymeric materials of practical importance in the course of ageing on the basis of data on the mechanisms of the processes occurring in polymeric materials[3]. All these factors suggest that it is already possible to pose the question of the replacement of what is actually an empirical method of forecasting generally used at the present time by a scientific approach to the problem based on the understanding of the fundamental features of the mechanisms of the processes occurring in the ageing of polymeric materials.

II. FORMULATION OF THE PROBLEM

1. The Necessary Initial Data

The instantaneous properties of the material can be characterised quantitatively by a point in the multidimensional space of properties or by a vector **Y** directed to this point. The components of vector **Y** are quantitative characteristics of the instantaneous properties of the material, its composition, strength (σ), dielectric losses tan δ, optical density, etc.

The polymeric material should possess a set of properties in order to be suitable for use in a given article. This means that in the space of the instantaneous properties of the material there exists a region of operational suitability of the material S_0. If the vertex of the vector **Y** falls within this region, then such a material can fulfill its necessary functions in the given article at the given instant.

However, the condition that the vector Y falls within the region S_0 is itself insufficient for the material to be used in the given article. It is necessary that throughout the entire useful lifetime of the article the vertex of the vector **Y** does not leave the region of the operational suitability of the material. In the course of use and storage the properties of the material Y gradually change as a result of the ageing processes occurring in it. The vertex of the vector Y gradually shifts in the space of properties (Fig.1). The way in which it shifts depends not only on the properties of the material, but is also determined by the conditions under which the material is used. In the course of ageing the relative contributions of the properties change and the vertex of the vector Y shifts along different trajectories, which depend on the process conditions.

In the general case these conditions can be characterised by another vector **X** in the space of operating conditions. Its components will be, for example, temperature, stress, intensity and spectral composition of the incident radiation, humidity, oxygen pressure, etc. Thus the problem of the determination of the useful lifetime of the polymeric material is a special case of the more general problem of the determination of the kinetics of the variation of the properties of such a material under any conditions, i.e. the problem is to find the function

$$\mathbf{Y}=\mathrm{f}(\mathbf{X}, t). \qquad (1)$$

In this treatment the breakdown of the polymeric material in a given article is characterised by the time during which the vertex of the vector Y reaches the limit of the region of the operating suitability S_0 under conditions **X**.

Consequently the useful lifetime of the polymeric material is determined by (1) the properties of the material, (2) the operating conditions **X**, and (3) the requirements which the material must meet or the region of its operating suitability S_0.

Accordingly, the accuracy of the determination of the useful lifetime of the polymeric material depends not only on the extent to which the characteristics of the instantaneous properties of different specimens of a given material are uniform, but also on the accuracy of the determination of its operating conditions and of the characteristics of its operating suitability.

2. The Purpose of Prediction

When the question of the prediction of the useful lifetime of a material is considered, one usually examines two different problems: the problem of determining the useful lifetime of the given material under specified conditions of its use and storage and the problem of determining the guaranteed lifetime of the material in articles of a particular type.

The solution of the first problem is directed towards the determination of the most probable useful lifetime of the material under operating conditions which are known beforehand and have been determined accurately. This is in essence a physicochemical problem which must be solved on the basis of current ideas concerning the physicochemical ageing processes in the material and on the basis of the results of accelerated tests of the material carried out under rigorously controlled conditions.

The determination of the guaranteed lifetime of the material is a qualitatively different problem. In the course of the guaranteed lifetime the material can exist in a certain range of operating conditions and it is necessary that the probability of the loss of its operating suitability under these conditions should not exceed a certain quantity corresponding to a specified coefficient of reliability of the article made from this material[4,5]. In solving this problem, one must take into account the possible variability of the properties of different batches of the material or of the material in different articles, the possible differences in their operating conditions, and even the possible differences in the requirements which must be met by different articles of a given type.

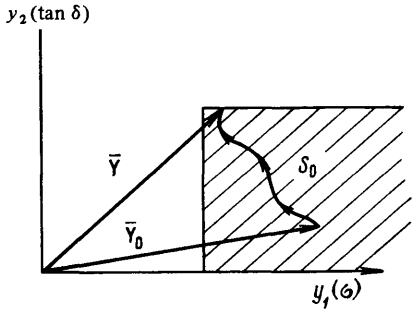

Figure 1. Trajectory of the variation of the properties of the polymeric material. For the significance of the notation, see text.

The basis of the problem is statistical and belongs to the theory of reliability. If the first problem has been solved, then the second can also be solved by statistical mathematical methods, provided that the distributions of the properties of the material, its operating conditions, and its operating suitability have been specified.

This review deals mainly with questions associated with the solution of the first problem. Problems of reliability are involved only in connection with the experimental error in the measurement of the rate of change of the properties of the material and in connection with the problem of averaging the time-variable operating conditions of the material.

3. Principal Ways of Determining the Useful Lifetime of a Polymeric Material

There exist two idealised ways of determining the useful lifetime of a polymeric material.

1. Modelling of the operating conditions of the polymeric material in the laboratory, i.e. laboratory tests on the material under conditions identical with its operating conditions in the given article.

2. The study of the detailed mechanisms of all the processes occurring in the material and calculation from these data of the useful lifetime of the material under any conditions.

Neither of these procedures can be recommended in the pure form as a realistic method for the solution of the problem of prediction.

Modelling cannot in essence be regarded as a method for the prediction of the useful lifetime of the material. With the aid of modelling, one can really only determine the useful lifetime of the material under the given conditions and one need know nothing about the processes which lead to an alteration of the properties of the material. It is sufficient to reproduce satisfactorily the operating conditions of the material in the laboratory, to place the material under these conditions, and to measure its useful lifetime. The accuracy of the determination of the useful lifetime depends in this case only on the accuracy with which the operating conditions are simulated.

However, not all operating conditions can be modelled in the laboratory and in choosing the material for a given article one can hardly seriously entertain the procedure involving the preparation of the article from all possible combinations of materials. Therefore modelling is usually employed in the last stages of the investigation when the material for the article has been chosen by some other methods and it only remains to refine its useful lifetime. In essence, the procedure involving the modelling of the operating conditions in the laboratory or the determination of the useful lifetime by interpolating the results of laboratory tests does not constitute prediction—with its aid one can only conclude what the result of the test is. This method in essence lacks any predictive power.

Nevertheless prediction is necessary, since one must know how all the properties of materials, which must be used for many years or under unique conditions, will vary. The question of the prediction of the stability of a polymeric material arises when one must decide whether a given material is or is not to be manufactured, or whether or not a given article is to be made from this material. A number of examples of problems the solution of which require the prediction of the useful lifetime of the polymeric material are listed below.

1. Determination of the useful lifetime of articles to be stored and used for a long time:
   (a) Constructional materials (medicine, building industry);
   (b) Specialised engineering applications (photographic materials, electronics);
   (c) Conservation of articles (spare parts, stock of spare articles).
2. Construction of articles:
   (a) Optimum materials for articles;
   (b) Optimum applications for the material.
3. New materials:
   (a) The search for applications of given materials;
   (b) Estimation of the scale of manufacture.
4. Mass applications of materials:
   (a) Estimation of the relative scales of industrial manufacture;
   (b) Elucidation of the time and extent of repairs;
   (c) Utilisation of waste.

In all these cases extrapolation of the results of preliminary tests to conditions under which the material has never been tested is required and not the interpolation of the results of tests on polymeric materials. In essence, the difference between the problem of the prediction of the useful lifetime of a polymeric material and the problem of the modelling of the operating conditions in the laboratory is the same as the difference between the problems of extrapolation and interpolation.

The second idealised method for the solution of the problem is also unrealistic. Evidently, a detailed study of the mechanism of ageing leads to the solution of the problem and ultimately makes it possible to determine the useful lifetime of the given material under any conditions, and usually with any degree of accuracy. However, this procedure is known to be laborious and long. Despite the fact that polymer chemistry has already existed for several decades, there are only a few materials whose useful lifetime can be predicted from the knowledge of the mechanism of their ageing and only under certain conditions. Nevertheless, this way of solving the problem is in fact used in the leading laboratories in the world in which fundamental research is being carried out, and this research actually determines the level of our knowledge about the mechanisms of the ageing processes in the polymeric material and makes it possible to cover the entire wide variety of materials, the methods for their synthesis, and the ways in which they can be modified and adapted to the solution of particular problems. The second method of solution therefore predominates in the initial stages of the study and in choosing the material.

Most of the work on the determination of the useful lifetime of polymeric materials is performed by methods which lie somewhere between these two idealised procedures. In real prediction both empirical methods involving the extrapolation of the results of laboratory tests on the material and the available information about the ageing mechanism are widely used. If the prediction is based largely on the results of tests on the given material, then one speaks of empirical and semiempirical methods of prediction; on the other hand, if information about the fundamental features of the mechanism of the ageing of the material predominates, then one speaks of describing the kinetics of the variation of the properties of the material on the basis of complete or incomplete knowledge of the process mechanism[6].

In both cases the prediction is based on the extrapolation of the results of laboratory tests on the material to its operating conditions, but extrapolation and laboratory tests are understood to have the same broad significance. The result of a test on the polymeric material includes not only the results of its study but also the set of all the accumulated experimental and theoretical information about the given material as well as any of its analogues, while extrapolation includes the development of methods of adjusting the results of tests for any operating conditions, which are as fully characterised as is possible.

III. EXTRAPOLATION OF THE RESULTS OF TESTS ON THE POLYMERIC MATERIAL TO OPERATING CONDITIONS

1. Mathematical Difficulties

In predicting the useful lifetime of the polymeric material one must solve the following problem. There exists a region Z_0 in the conditions governing the tests on the material. In this region of conditions the tests are carried out. On their basis, one obtains in some way, for example, by interpolation, a mathematical description of the kinetics of the change in the properties of the material $\mathbf{Y}(\mathbf{X}, t)$. It is necessary to extrapolate this relation outside the limits of the region Z_0.

In this formulation of the tast, problems of a mathematical nature immediately arise. In mathematics the task formulated in this way is invalid[7]. In the general case any problem of extrapolation is invalid because one can always select a function which describes adequately all the available experimental data and which behaves arbitrarily outside the region of the tests.

On the other hand, common sense suggests that such absolute invalidity of the extrapolation problem is probably too extreme. In the vicinity of the region in which the tests are carried out there is bound to be a region in which extrapolation is possible. The problem formulated must not

concern the existence or non-existence of such a region and must deal with the information required to extend this region and to increase the accuracy of a well-founded extrapolation within this region.

The possibility of validating the problem which is invalid from the mathematical point of view by relatively straightforward methods can be seen from the following simplest example. Suppose that it is necessary to extrapolate over a long time interval the decreasing relation $Y(t)$ illustrated in Fig.2. The conditions are constant throughout the process and the extrapolation must be carried out on the basis of the results of tests indicated by points in Fig.2.

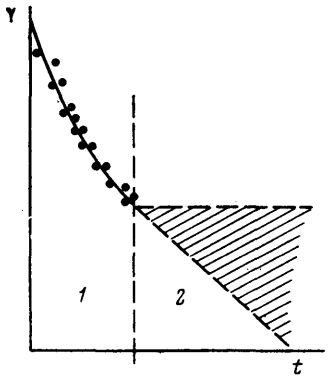

Figure 2. Example of the simplest extrapolation: 1) region of tests Z_0; 2) region of extrapolation. The shaded region represents the possible extrapolation in accordance with Eqn.(3).

If no limitations are imposed on the extrapolated relation, then, outside the range of measurements, it can vary arbitrarily. Indeed, the relation can be continued through any point outside the range of measurements, using, for example, a polynomial function containing more parameters than the number of experimental points. However, even a simple limitation, which is natural for many chemical processes, namely

$$Y<Y(0),\ \frac{dY}{dt}<0,\ \frac{d^2Y}{dt^2}>0, \tag{2}$$

and which postulates that the relation must decrease monotonically and must have no points of inflection, makes it possible to produce a well-founded prediction for virtually any time.

When $t>t_0$, any solution can be found between two straight lines:

$$f_1(t)=f(t_0);$$
$$f_2(t)=f(t_0)+(t-t_0)\left(\frac{df}{dt}\right)_{t=t_0}. \tag{3}$$

It appears that, when one specifies a narrower class of functions which can describe the given relation, then the accuracy of the extrapolation can be increased compared with Eqn.(3), and it is also possible to obtain data concerning the possible distribution of the error of the extrapolation for any t.

Thus the introduction of a series of such very simple constraints made the invalid extrapolation problem entirely valid and susceptible to solution by methods of modern mathematical statistics and computer techniques.

Unfortunately the region where such problems can be solved has so far been poorly worked out. Only problems in which the form of the $Y(X, t)$ relation is known exactly are solved. It is then possible to find not only the most probable extrapolation and the distribution of the expected error, but also to specify the optimum plan of tests whereby one can carry out the extrapolation with the minimum error[8].

When the mechanism of the ageing of the given material has not been established, it is usually impossible to predict exactly the form of the kinetic curve. However, the general understanding of the essential features of the processes occurring during ageing frequently makes it possible to specify the general characteristics of the expected relation. In some cases one may expect a monotonically decreasing relation analogous to that illustrated in Fig.2, while in others one can postulate a curve with a point of inflection or a relation with a characteristic induction period, etc. One can hardly assume that the $Y(X, t)$ relation will undergo a large number of oscillations for time-invariant external conditions X. All this qualitative information makes the problem of extrapolation valid from the mathematical point of view.

The greater the amount of the information available about the ageing mechanism, the more fully and more accurately can one describe the form of the kinetic curve and the greater the accuracy of the useful lifetime predicted by extrapolation.

This general consideration of the extrapolation problem shows that the problem of the characteristics of the form of the kinetic curves for the variation of the properties of the polymeric material under various conditions, i.e. the problem of the classification of the mechanisms of the ageing of polymeric materials and the characteristic features of each class of mechanisms, is particularly important for the prediction of the useful lifetime of polymeric materials. On the other hand, the mathematical problem reduces to ensuring that in the course of extrapolation there is the smallest possible loss of information accumulated both in the tests on the polymeric material and in the compilation of the *a priori* information about it.

2. Traditional Predictive Methods

For the majority of materials, the ageing mechanism has not yet been established. Therefore in predicting the useful lifetimes of such materials one frequently (see, for example Elizavetin[9]) uses methods based on the simplest hypothesis that the ageing of the polymeric material can be formally described as an elementary chemical reaction. The rate of this reaction is determined by a rate constant, which varies with temperature according to the Arrhenius law and which varies under the influence of mechanical stresses in accordance with Zhurkov's equation; in the presence of radiation, the constant increases in proportion to the intensity of the latter:

$$k=k_0 I e^{-(E-\gamma\sigma)/RT}, \tag{4}$$

where E is the activation energy for the process, σ the mechanical stress, I the intensity of light, and γ and k_0 are proportionality coefficients. The majority of methods for the useful lifetimes of polymeric materials used at present have been based on this hypothesis.

According to a USSR Government Standard (GOST),[10,11] it is recommended that the temperature dependence of the useful lifetime of the polymeric material be described in terms of the Arrhenius equation. The lifetime of the polymeric material under mechanical forces is described by the Zhurkov equation:

$$\tau = \tau_0 \exp\left(\frac{E - \gamma\sigma}{RT}\right). \quad (5)$$

The principle of the summation of the faults arising in the course of the ageing in the polymeric material, otherwise known as the principle of superposition, is widely used[12,13]. The mathematical expression of this principle is Bailey's equation[14], according to which, under the conditions of a time-variable influence on the polymer, its useful lifetime τ is defined by the equation

$$\int_0^\tau \frac{dt}{\tau_0(\mathbf{X}(t))} = 1, \quad (6)$$

where $\tau_0(\mathbf{X})$ is a function characterising the relation between the useful lifetime of the material and its operating conditions for constant $\mathbf{X}$ and $\tau_0\mathbf{X}(t)$ is the same function where the time-variable characteristic of the operating conditions $\mathbf{X}(t)$ has been substituted as the argument. On the other hand, the useful lifetime τ to be determined is involved in this equation as the integration limit.

Combination of the Arrhenius equation with Bailey's equation leads to the familiar principle of the temperature–time superposition, which establishes the equivalence of the influence of temperature and the duration of that influence. Thus in the field of mechanical stresses the useful lifetime of a polymeric material should be defined by the equation

$$\int_0^\tau k_0 e^{-[E-\gamma\sigma(t)]/RT(t)}\, dt = 1. \quad (7)$$

The superposition principle is valid when the change in the properties of the material is irreversible and when these properties vary in the space of properties along a single trajectory whatever the operating conditions. This also shows that the ageing of the material proceeds to the same extent whatever the sequence in which the operating conditions are altered.

A corollary of the superposition principle is that constant conditions, equivalent to variable operating conditions exist. Thus Eqns.(4) and (7) show that the time of accelerated tests (τ_{equiv}), at the chosen temperature T_0 and under the conditions of a stress σ_0, which is equivalent to operation during a period τ at an arbitrary temperature $T(t)$ and stress $\sigma(t)$, is determined by the relation

$$\tau_{equiv} = \int_0^\tau e^{-\left(\frac{E-\gamma\sigma(t)}{RT(t)} - \frac{E-\gamma\sigma_0}{RT_0}\right)} dt. \quad (8)$$

By means of simple rearrangements, it is possible to obtain from Eqn.(8) the familiar equation for the equivalent temperature[15–17]

$$T_{equiv} = \frac{E}{R \ln\left(\frac{1}{\tau}\int_0^\tau e^{-E/RT(t)}\, dt\right)}, \quad (9)$$

at which the properties of the material change would change by the same amount during the period τ as they do with a variable temperature $T(t)$.

All these principles and equations are valid for the determination of the useful lifetime of materials whose ageing can be described as a single elementary chemical reaction of any order. Even in the presence of two parallel stages one may expect the breakdown of the Arrhenius law and the failure of Bailey's equation. These questions will be examined in greater detail in the following Sections.

Nevertheless the principles discussed above have been used successfully to describe the kinetics of the variation of the strength and viscoelastic characteristic of polymeric materials under conditions such that the mechanical stress is the principal factor responsible for the change in the properties of the material. For example, Zhurkov's equation describes the lifetime of many polymeric materials acted upon by mechanical loads[18]. However, over a wide range of stresses, particularly under conditions such that, apart from the stress, the ageing process is influenced also by other factors (such as oxygen, light, ozone, etc.), Eqn.(6) does not hold. Even the "fatigue" characteristics of the material are very difficult to describe by these methods, let alone the "static fatigue" which causes the material to break down regardless of the applied stress. This is apparently due to the fact that the "fatigue" of the polymeric material, i.e. its breakdown when acted upon by small stresses, is determined mainly by the irreversible physicochemical transformations of the material, induced by other causes such as oxidation, photochemical transformation, interaction with a corrosive medium, etc., and not by stresses. The mechanism of these processes is usually fairly complex and cannot be described at the level of empirical functions of the susceptibility of the material to damage, which vary with time in the same way as in a pseudoelementary nth order reaction and it is therefore necessary to take into account the influence of the stress on each elementary step of the complex ageing process. A relatively wide range of studies has now been carried out[20,21] in which an attempt has been made to predict the useful lifetime of polymeric materials while retaining the principles of the above methods. For example, the breakdown of the linearity of the plot of the logarithm of the lifetime against the reciprocal of temperature is treated as the variation of the activation energy for a process, and the physical causes of this variation are sought. The so-called pole in Zhurkov's equation is displaced and the physical nature of this displacement is elucidated. The essence of these phenomena is probably associated with the non-elementary nature of the ageing of polymeric materials under these conditions. It is hardly possible to solve successfully the problems arising by assuming that the ageing process of the polymeric material and hence the kinetics of the variation of its properties can be formally regarded as a single chemical reaction.

A radical-chain mechanism of the mechanothermal degradation of a polymer, including a chain initiation stage involving the rupture of strained bonds in the macromolecules, depolymerisation, chain transfer with formation of a central radical, the decomposition of this radical under the influence of stresses, the migration of the free valence along the central radical, and chain termination, has been examined[22]:

$$\begin{aligned}
&\text{Polymer} \xrightarrow{k_1\sigma} 2\dot{R}_t \text{ (initiation)},\\
&\dot{R}_t \xrightarrow{k_2} \dot{R}_t + \text{monomer (depolymerisation)},\\
&\dot{R}_t + \text{polymer} \xrightarrow{k_3} \text{polymer} + \dot{R}_c \text{ (chain transfer)},\\
&\dot{R}_c \xrightarrow{k_4(\sigma)} \dot{R}_t + \text{polymer (radical decomposition)},\\
&\dot{R}_c \xrightarrow{k_5(\sigma)} \dot{R}_t \text{ (migration of free valence)},\\
&2\dot{R}_c \xrightarrow{k_6} \text{polymer (chain termination)}.
\end{aligned} \quad (10)$$

The stress has the most significant influence on the constants k_1, k_4, and k_5.

Analysis of the corresponding kinetic equations shows that, over relatively narrow ranges of variation of the stresses, the Zhurkov equation holds formally, but τ_0, E, and γ are effective quantities which do not characterise a single elementary reaction but refer to a complex combination of several rate constants for different elementary reactions. Consequently, for an arbitrary material, it is impossible to relate τ_0 to the vibration period of any bonds in the molecule and E cannot be related to the activation energy for any one elementary step of the chemical process. These quantities do not characterise the elementary step, but refer to decomposition of the material as a whole. Accordingly, these quantities are not constant and depend on the process conditions. When the mechanism of the ageing of the material is unknown, the terminology frequently employed[17,20] becomes only a jargon. There is no more point in speaking of the activation energy for the ageing process than there would be in speaking of the activation energy for thermal expansion.

Thus calculation shows that, for the example under consideration, over a wide range of stresses, the semilogarithmic form of the relation between the lifetime of polypropylene and the stress should be concave. Fig.3 shows that the results of the calculation using the rate constants for the mechanothermal degradation of polypropylene obtained independently agree satisfatorily with the experimental values[23]. These results have been examined in greater detail elsewhere[24].

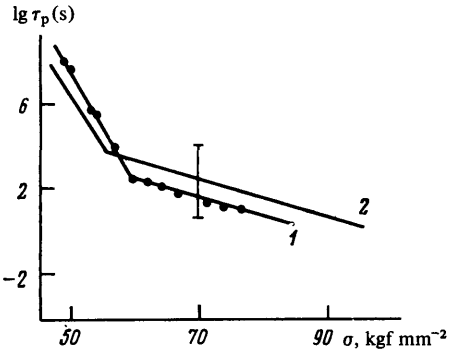

Figure 3. The influence of stresses on the useful lifetime of polypropylene: 1) experimental data[23]; 2) calculation[22] based on mechanism (10) with indication of the error of the calculation.

Analogous breaks in the semilogarithmic relations between the lifetime and the stress can be observed under the conditions of the joint action of oxygen and the stress, light and the stress, etc. In this case the relations become convex[25], since the polymer acted upon by small stresses breaks down almost independently of the kind of stress it is subjected to.

Over a wide range of temperatures, Eqn.(6) also does not hold. For example[26], E for many polymers varies sharply in the vicinity of their brittle temperatures T_{br}, which is due to the fact that the relaxation processes at $T > T_{br}$ become capable of competing with the mechanical dissociation of the macromolecule.

IV. THE "CHANGE IN THE MECHANISM" OF THE AGEING OF A POLYMERIC MATERIAL ON PASSING FROM TEST CONDITIONS TO OPERATING CONDITIONS

1. The Causes of the "Change in Mechanism"

In the determination of the useful lifetime of a polymeric material by extrapolation from the more severe conditions of accelerated tests to the milder operating conditions, the greatest difficulties do not arise from the extrapolation itself but from the fact that the ageing mechanism changes along the extrapolation path. Strictly speaking there is usually no actual "change in the mechanism" along the extrapolation path. Critical changes in the mechanism are extremely rare. They are normally observed probably only in the liquid–crystal phase transition, which is hardly ever observed in a pure form in polymeric materials. Even after crystallisation of polymers, the chemical changes usually involve the same mechanism as in the melt and in the remaining amorphous phase of the polymeric material.

There is usually a change not in the ageing mechanism but merely in the rate-limiting stage of the ageing process. For example, in a study[27] of the kinetics of the thermal oxidation of polyethylene at elevated temperatures the effective activation energy for the process was found, and on the basis of these data it was predicted that the insulation made of this polyethylene on pipes at 60 °C would be suitable for use over a period of approximately 15 years. However, in this prediction, no account was taken of the fact that at high temperatures the kinetics of the consumption of the thermal stabiliser are determined by its involvement in the oxidation process, while at a low temperature, where the oxidation process, which has a relatively high activation energy is sharply retarded, the thermal stabiliser begins to be consumed mainly by its diffusion from the specimen, which is a low activation energy process, and not due to the chemical transformation. As a result, it was found that the insulation of pipes breaks down after only $1\frac{1}{2}$ years, and not after 15 years.

An analogous effect was observed in a study of the lifetime of polymeric materials subjected to low stresses[25]. Under the conditions of high stresses, the rate of the process is limited by the step involving the dissociation of the macromolecules under the influence of the mechanical stress. Under these conditions, Zhurkov's equation holds satisfactorily and the logarithm of the lifetime of the material τ is linearly related to the stress σ and the parameter E/RT of the Arrhenius equation. For low stresses, the rate of this process becomes insignificant and other processes determine the variation of the properties of the material, for example, its chain oxidation. As a result, a sharp break is observed in the $\lg \tau - \sigma$ relation in the region of low stresses.

In neither case was there any change in the ageing mechanism either at low temperatures or under the conditions of low stresses. The thermal stabiliser diffused with an unchanged activation energy over the entire temperature range and also at higher temperatures, but under the latter conditions the rate of the process was negligible compared with the rate of oxidation and therefore could not be taken into account in the prediction. Similarly, for high stresses, the oxidation of the polymer proceeds in the same way as for low stresses, but in the former case the rate of the process can be neglected compared with the rate of dissociation of the strained molecules. Both effects described are associated with the usual phenomenon involving the competition of several elementary chemical or physical processes constituting the essential feature of the ageing mechanism,

the rate constants for these reactions varying monotonically along the extrapolation section in conformity with the Arrhenius or Zhurkov equations.

A somewhat more complex situation arises when there is a sharp change in the conditions for the elementary steps of either the chemical transformation of the substance or if there is a physical alteration in the structure of the material along the extrapolation section. This difficulty can be sometimes overcome when the features of the variation of quantitative characteristics of the elementary step are known for this change of conditions.

Thus it is known that the rate constants for bimolecular reactions are to a large extent determined by the nature of the molecular mobility in the medium. Molecular mobility influences both the transport of the reactants towards one another and the probability of the chemical interaction at the site where the reactants meet. It has been shown[28] that, on passing from liquid-phase systems to vitreous polymeric matrices, there is the so-called levelling of reactivity for series of molecules with different chemical structure participating in isotypical chemical reactions. Molecules whose reactivity in the liquid phase differs by 2–4 orders of magnitude have reactivities differing by only 1–2 orders of magnitude in the solid polymer. This phenomenon is associated with the sharp alteration of the molecular mobility in the medium and is independent of the chemical structure of the molecules of the latter.

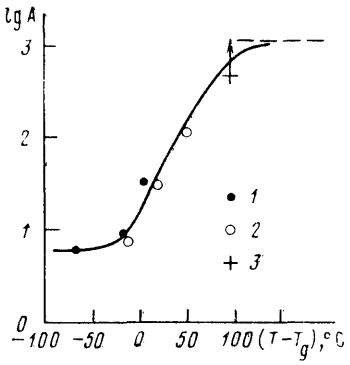

Figure 4. The influence of the molecular mobility of the medium on the relative rate constant (A) for the quenching of singlet oxygen. Polymeric matrices: 1) polystyrene; 2) butyl methacrylate–methacrylic acid copolymer (BMK-5, $T_g \approx 35$ °C); 3) polybutadiene. The dashed straight line corresponds to the liquid phase[29].

Fig.4 shows that the relative reactivity of the reactants in different polymeric matrices is determined by the difference between the experimental temperature and the glass point of the medium T_g, which is known[30] to be a measure of the molecular mobility of the medium over a wide temperature range. With the aid of a model taking into account the relative movement of the reactants in the cage where they meet, it has been shown[31] that the levelling phenomenon can be described quantitatively by the relation

$$\left(\frac{k_1}{k_2}\right)_S = \sqrt{\left(\frac{k_1}{k_2}\right)_L}, \qquad (11)$$

where k_1 and k_2 are the probabilities of the chemical transformation of two different substances in an isotypical chemical reaction when the transport of the reactants towards one another and the activation energy for the process can be neglected. The subscripts show that the process takes place in the solid polymer at $T < Tg$ or in the liquid phase.

Using Eqn.(11) and the data for the variation of the diffusion coefficients of the reactants and the molecular mobilities of the medium, it is possible to calculate the change in the reaction rate constant along the extrapolation path and to estimate the ratio of the rates of different processes under operating conditions. However, one should not forget here that Eqn.(11) refers to the elementary step of the chemical reaction and not to the ageing process as a whole and similar relations can therefore be applied in a real process when the kinetic mechanism of the ageing of polymeric material is known.

Not only chemical reactions in the polymeric material are responsible for its ageing. The change in its properties can be caused by physical processes which do not alter the chemical nature of the polymeric material. For example, a distinctive feature of the polymeric material is that it is frequently used in a thermodynamically non-equilibrium state. The great length of the polymer molecule sharply retards the occurrence of many physical processes, which makes it possible to use for a long time polymers in a state far from equilibrium from the physical point of view. Thus crystallising polymers are used in a partially amorphous state, the preliminary orientation of the polymer persisting for many years and the stresses arising in the polymer sometimes relaxing in the course of the entire useful lifetime of the material[27,32].

During the ageing of the polymeric material, chemical reactions are accompanied by its physical rearrangement and both processes can proceed at comparable rates. The change in the ratio of these rates can be one of the causes of the apparent "change in the mechanism" of the ageing of the polymeric material. Thus, when the polymer is used in the vitreous state, then owing to the non-uniformity of the chemical process in the bulk of the specimen local internal stresses arise which alter in their turn the rate constants for the elementary reactions. At higher temperatures the relaxation of stresses can be significantly faster than the chemical reaction of the substance, while in accelerated tests of the polymeric material this phenomenon could not be observed at all.

The solution of the problem of the possible occurrence of such phenomena along the extrapolation section is determined by the state of research into the problem of the influence of mechanical stresses on the kinetics of the ageing of polymeric materials, which is an important fundamental problem in chemical kinetics, as well as the question of the mechanism of the generation of internal stresses and the kinetics of their alteration in the course of the ageing of the polymeric material. Whereas relatively much attention has been devoted to the first problem at the present time[33], particularly in connection with the use of polymeric materials under load, only few studies have been undertaken on the second problem, despite its undoubted importance[34].

As a second example, complicating the influence of physical kinetics on the solution of the problem of the prediction of the useful lifetime of a polymeric material, one may examine the physical disorientation of the amorphous component of the half-crystallised polymer. Under operating conditions, the physical disorientation of the polymer filament proceeds at a negligibly low rate. Nevertheless it has been shown[35,36] that the chemical ageing process in such a highly oriented filament frequently differs qualitatively from the ageing of an isotropic non-oriented polymer. At the same time any

increase of temperature leads not only to the acceleration of the chemical process but also to the acceleration of the physical disorientation of the amorphous phase of the polymer and hence to a real qualitative change in the chemical mechanism of the ageing process. Thus, in accelerated tests processes whose role under operating conditions is negligible can begin to affect the ageing process.

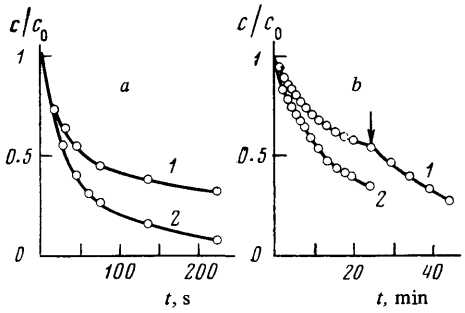

Figure 5. Kinetics of the photochemical oxidation of naphthacene (0.025%) (*a*) and anthracene (0.5%) (*b*) in polystyrene films in air under irradiation: 1) without intermediate heating; 2) with intermediate 15 min heating at 90 °C at instants indicated by circles. Intermediate heating was also applied at the instant designated by an arrow[37].

Fig.5 presents another example of a process in the polymer matrix in which the chemical transformation of the substance and the physical rearrangement of the local environment of the reactive species compete. The photochemical reaction of hydrocarbons with condensed nuclei within a vitreous polymer is inhibited sharply under conditions where the concentration of the reactants has altered relatively little—the so-called kinetic process arrest has occurred[37,38]. The reason for this phenomenon is that the photochemical process is significantly faster than the physical rearrangement of the local environment of the reacting species, the molecules existing under conditions favourable for the chemical reaction are rapidly consumed, and the photochemical process is retarded, since only molecules existing under conditions unfavourable for reaction remain in the specimen.

Under the real conditions of the employment of a polymeric material in which hydrocarbons with condensed nuclei have been introduced as special additives, for example, in photochromic materials or carriers of information, photochemically active light is less intense than in accelerated tests and does not operate all the time, while the physical rearrangement of the matrix proceeds continuously at the same rate and does not therefore limit the photochemical decomposition of the additive. As a result, no kinetic arrest is observed and the process is significantly faster than might have been expected on the basis of a formal inspection of the results of accelerated tests[39].

Thus at least three causes of the "change of the mechanism" of the ageing of polymeric materials when the ageing conditions are altered can be specified.

1. Competition between different elementary reactions constituting the ageing mechanism. A change in conditions can direct the ageing process via another pathway.

2. The influence of the physical structure of the polymer matrix on the elementary step of the chemical reaction. A change in this structure under different conditions can alter significantly the ratio of the rate constants for the elementary reactions.

3. Competition between the chemical transformation of the polymeric material and the physical change in its temperature.

In all the instances examined there is no actual change in the process mechanism and there is only change in its rate-limiting stage. Fundamental study of the ageing of the material might in fact render greatest assistance in the observation of such possible changes in the rate-limiting change of the process.

Even qualitative ideas about the process mechanism can sometimes help to solve the problem of a well-founded prediction. There is a possibility of a multistage extrapolation of different elementary processes proceeding independently in the polymer. For example, in the thermal oxidation of a stabilised polymer one must take into account not only the consumption of the thermal stabiliser in the oxidation reaction, but also its consumption as a result of its diffusion from the polymer. On the other hand, the rate of diffusion can be measured by independent methods. On comparing subsequently the results of the extrapolation of both rates to the operating conditions, it is possible to discover the process which determines the rate of consumption of the stabiliser. If there is a kinetic arrest in the photochemical process, the rates of rearrangement of the local environment of the species can also be obtained by an independent method[40] and hence one can estimate the role of this process under operating conditions.

Thus even a qualitative understanding of the principal stages of the ageing of a polymeric material significantly facilitates the solution of the problem of the prediction of the useful lifetime of the material.

2. Prediction of the Useful Lifetime of Polymeric Materials as a Kinetic Study

The possibility of "a change in the mechanism" of the ageing of a polymeric material makes the solution of the problem of the prediction of its useful lifetime extremely indefinite. One can actually claim that there should exist instances where a well-founded prediction is altogether impossible and in many cases the degree of risk cannot apparently be characterised quantitatively; nevertheless, since the problem of the determination of the useful lifetime exists, one must seek ways for its optimum solution.

The problem reduces in fact to the observation of a possible "change in the mechanism" of ageing already during tests on the polymeric material. A trivial procedure consists in carrying out tests under conditions as close as possible to the operating conditions. Naturally, all the possibilities of this procedure must be utilised but the method does not solve the problem of prediction, but merely reduces it to the modelling of the operating conditions in the laboratory, which is not always possible, as mentioned previously.

There remains a single method—the derivation of maximum possible information from the results of tests on the polymeric material.

A characteristic feature of the polymeric material is that in the latter there are virtually no abrupt changes in structure, characteristic of, for example, phase transitions in low-molecular-weight compounds. This gives rise to the hope that the "change in the mechanism" of the ageing of a polymeric material does not take place abruptly either. However, the "change in mechanism" can occur not only by virtue of a change in external conditions, but also as the ageing process proceeds and at different stages of the transformation of the material the process will be limited by different

steps. Therefore the study of the kinetics of the change in the properties of the polymeric material up to advanced stages of the transformation yields much more information than a simple determination of the useful lifetime of the material, since it can reveal signs of a "change in the ageing mechanism" under conditions where this change still does not determine the useful lifetime of the material.

We shall consider the advantages of the kinetic approach in relation to this formal example. Suppose that the kinetics of the change in the properties of the material can be described by the sum of two exponential functions:

$$U/U_0 = \gamma e^{-k_1 t} + (1-\gamma) e^{-k_2 t}, \qquad (12)$$

the constants k_1 and k_2 varying with temperature in accordance with the Arrhenius law with different activation energies, while the coefficient γ is independent of temperature. For example, γ can characterise the fraction of one of the components of a composite material when the quantitative characteristic of the property of the material U is a result of the additive effect of the two components which exhibit different thermal stabilities.

If the useful lifetime of such a material is characterised in terms of the time taken for the decrease of U to a certain limite U^0, then evidently the effect of activation energy for the useful lifetime measured in this way will depend on U^0 (Fig.6). Fig.6*a* shows how the effective activation energy E_{eff} for the useful lifetime of such a material varies for different values of U^0. Evidently, depending on the ratio of the activation energies and the pre-exponential factors for the constants k_1 and k_2, the quantity E_{eff} can both increase and decrease as U^0 varies.

Fig.6*b* shows how accurately the Arrhenius law holds under these conditions. The difference between the calculated activation energies δE at 360 and 400 K was adopted as a measure of its validity. Evidently, appreciable deviations from the Arrhenius law, for example $\delta E = 1$ kcal, are observed over relatively narrow ranges of values of U^0, while for the remaining values of U^0 the Arrhenius law holds satisfactorily and it is virtually impossible to observe the complex variation of the useful lifetime of the material as a function of temperature.

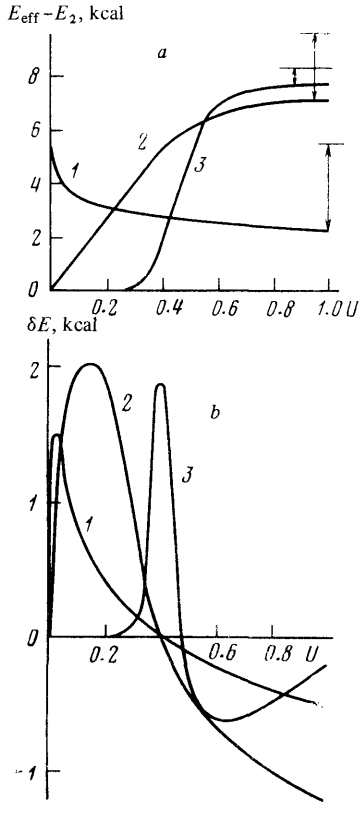

Figure 6. *a*) Variation of the effective activation energy for the attainment of a quantity U^0, the kinetics of the variation of which are described by Eqn.(13); temperature range 360–400 K; *b*) deviation from the Arrhenius law. The calculation was performed for $E_1 - E_2 = 5.5$ (curve *1*), 9.6 (curve *2*), and 8.3 kcal mol^{-1} (curve *3*) and $\chi = (k_1/k_2)\exp(E_1 - E_2)/400R = 10^3$ (curve *1*) and 10^6 (curves *2* and *3*). The values of the quantity $E_1 - E_2$ are indicated by arrows next to the corresponding curves.

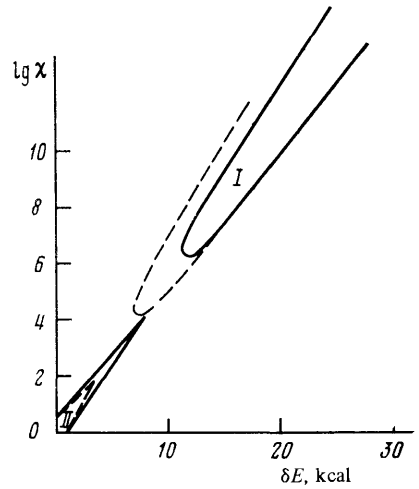

Figure 7. Conditions governing the observation of deviations from the Arrhenius law for process kinetics described by Eqn.(13); $\chi = (k_1/k_2)\exp(E_1 - E_2)/400R$; I is the region where $\delta E > 0.8$ kcal mol^{-1} in the measurement of the initial rates; II is the region where deviations from the exponential law governing the variation of U are not observed. The continuous lines correspond to the temperature range 360–400 K and the dashed lines correspond to 320–400 K; $\gamma = 0.5$.

If only the initial rates of change of U are measured, then deviations from the Arrhenius law can be observed only when the rates of change of both terms in Eqn.(12) are comparable. Fig.7 presents the results of the numerical calculations, showing that, even over a fairly wide temperature range of the measurements in the coordinate plane $\chi - \delta E$, where $\chi = (k_1/k_2)e^{\delta E/RT}$ and $\delta E = E_1 - E_2$, there is only a small region in which it is possible to observe deviations from the Arrhenius law (the shaded region in Fig.7, where $\delta E > 1$ kcal mol^{-1} in the temperature range 360–400 K). If the process kinetics are followed up to a degree of conversion of only 75%, then $\gamma = 0.5$ and, for a 5% accuracy of the

measurement, deviations from the exponential law governing the variation of U (and hence the deviations from the Arrhenius law) can be observed for almost all ratios of the constants. An exception is a small region of low values of δE and χ.

The above example shows how much more information can be derived from kinetic measurements compared with "point" measurements of the useful lifetime of the material. Therefore prediction of the useful lifetime of materials should be based on extrapolation of the parameters which describe the kinetics of the variation of the properties of the material under different conditions and not on extrapolation of the dependence of the useful lifetime of the material on the conditions of the tests. It is desirable to have data not only for the small "permissible" changes in the properties of the material but also for the kinetics of the variation of these properties up to stages which are as advanced as possible.

It may be that such measurements of the rate of change of the properties of a polymer subject to mechanical forces would make it possible to observe the features of the influence of mechanical stresses on the ageing of the polymer for small loads and of the oxidation process for high loads and there would be no question of a change in the process mechanism. It may also be that a study of, for example, the kinetics of the consumption of the thermal stabiliser in the high-temperature oxidation of polyethylene would make it possible to observe the diffusional component of its consumption and to make a correct prediction of the thermal stability of polyethylene under operating conditions.

V. ALLOWANCE FOR THE VARIABILITY OF OPERATING CONDITIONS

1. Formulation of the Problem

Extrapolation of the results of severe, forced, and accelerated tests on the polymeric material to mild conditions under which it is used, i.e. transition from high to low temperatures and from high irradiation intensities or high loads to low values of these parameters—all these constitute only one aspect of the problem of the prediction of the useful lifetime of the polymeric material. It is no less difficult to take into account the fact that during use the material usually exists under continuously varying conditions, and not simply the change in the operating conditions compared with accelerated tests. Day changes to night, a moist period is replaced by a dry one, intensive use is followed by a period of storage, etc.

Usually in accelerated tests the material is tested under conditions which remain constant throughout the test. By carrying out such tests under various conditions, it is possible to obtain a mathematical description of the process under any conditions. If the operating conditions are within the range of the conditions of the tests, then the problem of prediction is apparently solved, since, in contrast to extrapolation, interpolation can be carried out with any degree of accuracy and it is only necessary to have a sufficient amount of experimental data. However, this is true only if one predicts the variation of the properties of the material under constant conditions, as in the tests. On the other hand, the problem of the way in which the properties of the material should vary under variable conditions remains in essence open.

We shall assume that the kinetics of the variation of a property of the material Y are described by the following equation under constant conditions:

$$Y = k_1(1 - e^{-k_2 t}), \tag{13}$$

where k_1 and k_2 are effective constants, which vary with temperature in accordance with the Arrhenius equation. We shall examine the problem of the description of this process under variable conditions—at a variable temperature. There is hardly any point in substituting the time-variable values of k_1 and k_2 in Eqn.(14), since a decrease of temperature, resulting in a decrease of k_2, usually does not lead to the same decrease in Y and conversely the process kinetics at high temperatures are usually independent of the time during which the specimen remains at a low temperature, where k_2 is close to zero. It is not always possible to substitute an average temperature in Eqn.(13). For example, the question arises of an average temperature which must be invoked if it is necessary to discover how the properties of the polymeric material vary when the latter cools or conversely when it is heated at a constant rate.

The problem is complicated still further when the polymeric material is acted upon by several factors. For example[25], in the initial stage of the photochemical oxidation of polyolefins the kinetics of the variation of their mechanical properties are determined by the parameter

$$\Omega = kI^2 t^3, \tag{14}$$

where k is a constant which varies with temperature in accordance with the Arrhenius law and I is a quantity proportional to the intensity of the light incident on the specimen.

It is also not permissible to substitute the average temperature and light intensity in Eqn.(14), since one must take into account, on the one hand, the fact that the temperature and light intensity are usually strongly correlated and, on the other hand, it is evident that one can neglect the time intervals during which the light intensity and temperature are sufficiently small.

Some workers[6] suggest that Eqns.(13) and (14) be differentiated with respect to time and that time be subsequently eliminated from the resulting expression or that one seek from the very beginning a mathematical description of the process not in the form of a dependence of the rate of change of the properties on time but in the form of the dependence of the rate of the process on the current properties of the material, i.e. that one carry out transformations of the type

$$\begin{gathered}\mathbf{Y} = \mathrm{f}(\mathbf{X}, t),\ \mathbf{X} = \text{const},\ t = \varphi(\mathbf{X}, t);\\ \frac{\partial \mathbf{Y}}{\partial t} = \frac{\partial \mathrm{f}}{\partial t}(\mathbf{X}, \varphi(\mathbf{X}, \mathbf{Y})) = \psi(\mathbf{X}, \mathbf{Y}).\end{gathered} \tag{15}$$

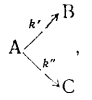
We may replace the partial derivative by the total derivative, and obtain

$$\frac{\mathrm{d}\mathbf{Y}}{\mathrm{d}t} = \psi(\mathbf{X}(t), \mathbf{Y}). \tag{16}$$

Thus, instead of Eqns.(14) and (15), we obtain the expressions

$$\frac{\mathrm{d}Y}{\mathrm{d}t} = k_2(k_1 - Y), \tag{17}$$

$$\frac{\mathrm{d}\Omega}{\mathrm{d}t} = 3(kI^2\Omega^2)^{1/3}. \tag{18}$$



On solving similar equations under variable conditions, it is possible to find a mathematical description of the variation of the properties Y and Ω with time:

$$Y = \mathrm{e}^{-\int_0^\tau k_2\,\mathrm{d}t} \int_0^\tau k_1 k_2\, \mathrm{e}^{\int_0^\tau k_2\,\mathrm{d}t}\,\mathrm{d}t, \tag{19}$$

$$\Omega = \left(\int_0^\tau (kI^2)^{1/3}\,\mathrm{d}t\right)^3. \tag{20}$$

In the general case, in the description of the kinetics of the variation of the properties of the polymeric material, one cannot arbitrarily apply any one of the procedures described. In essence, in this case one is faced with the same problem as the cybernetic problem of the prediction of the behaviour of a "black box", which cannot be solved when data for its behaviour are available only under constant conditions. Thus Eqn.(14) discussed above can describe the kinetics of the accumulation of the reaction product formed via two different kinetic mechanisms.

1. The accumulation of the reaction product of one of two parallel reactions:

(21)

$$[B] = \frac{k'}{k'+k''}[A]_0(1-e^{-(k'+k'')t}). \quad (22)$$

The kinetic mechanism (22) can model the ageing process initiated by radicals formed in the decomposition of some initiator. In this case C are the products of the interaction of active centres within the cage which do not alter the properties of the material.

2. The accumulation of an unstable product in a zero-order reaction:

$$\xrightarrow{w_i} B \xrightarrow{k_d}, \quad (23)$$

$$[B] = \frac{w_i}{k_d}(1-e^{-k_d t}). \quad (24)$$

The kinetic mechanism (23) can also model the ageing process, B being an unstable reaction product capable of reverting to the initial state.

Thus two qualitatively different kinetic mechanisms lead to formally the same description of the process kinetics under constant conditions. However, under variable conditions, mechanisms (21) and (23) lead to different solutions. We obtain from Eqn.(21)

$$[B] = \int_0^\tau k'[A]_0 e^{-\int_0^t (k'+k'')dt} dt, \quad (25)$$

or, on converting to the notation defined by Eqn.(14), we have

$$[B] = \int_0^\tau k_1 k_2 e^{-\int_0^t k_a dt} dt. \quad (26)$$

We obtain from Eqn.(23)

$$[B] = e^{-\int_0^\tau k_d dt} \int_0^\tau w_i e^{\int_0^t k_d dt} dt = e^{-\int_0^\tau k_a dt} \int_0^\tau k_1 k_2 e^{\int_0^t k_a dt} dt. \quad (27)$$

Evidently there is also a qualitative difference in the kinetics of the variation of the quantity [B] under variable conditions. According to mechanism (21), the concentration of B under any conditions can only increase irreversibly. On the other hand, the establishment of a steady-state concentration of B under constant conditions according to Eqn.(23) is a consequence of the equality of the rates of formation and consumption of this product, so that under variable conditions the concentration of B can both increase and decrease.

The above considerations can be illustrated by the following numerical calculations. Suppose that the specimen is heated instantaneously to a temperature T_0 and is then slowly cooled, so that the temperature varies in accordance with the equation

$$T = T_0/(1+\gamma t). \quad (28)$$

If the variation of temperature is governed by this law, Eqn.(26) and (27) can be solved by the method of quadratures, provided that the rate constants k_1 and k_2 vary with temperature in accordance with the Arrhenius law.

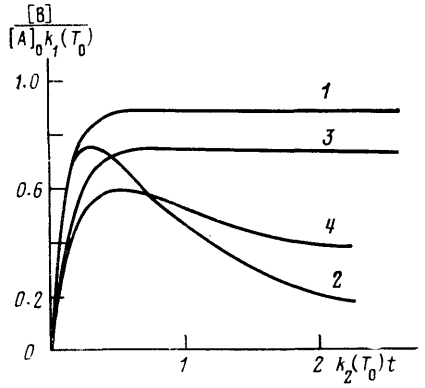


Figure 8. Kinetics of the variation of the concentration of B with temperature according to Eqn.(28) and subject to the kinetic mechanisms (21) (curves *1* and *3*) and (23) (curves *2* and *4*). Calculation performed for $k_2RT_0/E_2\gamma = 4$ (curves *1* and *2*) and 10 s^{-1} (curves *3* and *4*) and for $E_1 = E_2$ ($E' = 2E''$, $E_w = 2E_d$).

In this case, when the specimen is cooled fairly slowly, i.e. when

$$\gamma < \frac{k_2(T_0)RT_0}{E_2},$$

the kinetic curve for the variation of [B], described by Eqn.(27), passes through a maximum, which can be in no way expected when the final product B accumulates in accordance with mechanism (21). Fig.8 presents a numerical example of the calculation of the kinetic curves from Eqn.(26) and (27). Thus, for the extrapolation of the results of laboratory tests to variable operating conditions, the results of tests under constant conditions are insufficient and one must develop special programs whereby the kinetics of the ageing of the material under variable conditions can be described.

2. The Superposition Principle or the Principle of the Summation Defects

In the practical determination of the useful lifetime of the polymeric material one can frequently employ the so-called superposition principle or the principle of the summation of defects arising in the course of ageing[12,14]. This principle is based on the hypothesis that the breakdown of the material under any conditions takes place irreversibly and independently of the previous history of the specimen. Depending on the conditions, only the efficiency of the decomposition of the material changes. In conformity with

this principle, it is assumed[8] that for each material there should exist a single-valued function, the damage to the material ω, which increases monotonically in the course of ageing. Here the increment of ω is proportional to the efficiency of the ageing of the material under the given conditions and to the time during which the material has been exposed to these conditions:

$$\Delta\omega=\psi(\mathbf{X})\Delta t. \tag{29}$$

Accordingly, under variable conditions the quantity ω is obtained as a result of the summation of different influences $\mathbf{X}_i$:

$$\omega=\Sigma\psi(\mathbf{X}_i)\Delta t_i. \tag{30}$$

Since a change in the properties of the material represents the results of the independent action of different conditions, it is postulated that ageing proceeds with the same efficiency regardless of the sequences in which the material is acted upon by different influences.

Eqn.(30) can be formulated in a differential form for a continuous variation of operating conditions:

$$\frac{\mathrm{d}\omega}{\mathrm{d}t}=\psi(\mathbf{X}) \tag{31}$$

and can be extended to the case of multidimensional operating conditions for the materials:

$$\frac{\mathrm{d}\mathbf{Y}}{\mathrm{d}t}=\varphi(\mathbf{Y})\psi(\mathbf{X}). \tag{32}$$

The necessary feature for the applicability of the superposition principle follows from Eqn.(32), namely the presence of a single unambiguous trajectory along which the properties of the material vary under any operating conditions. Indeed it follows from Eqn.(32) that

$$\frac{\partial y_i}{\partial y_j}=\frac{\varphi_i(\mathbf{Y})}{\varphi_j(\mathbf{Y})}, \tag{33}$$

where subscripts i and j denote components of the vectors $\mathbf{Y}$ and $\phi(\mathbf{Y})$.

The material is finally damaged when the vector $\mathbf{Y}$ reaches a certain value $\mathbf{Y}_z$† i.e.

$$\int_{Y_0}^{Y_z}\frac{\mathrm{d}\mathbf{Y}}{\varphi(\mathbf{Y})}=\int_0^{\tau}\psi(\mathbf{X})\,\mathrm{d}t, \tag{34}$$

where the upper integration limit τ represents the useful lifetime of the material.

If the operating conditions are constant, then

$$\tau=\tau_0=\frac{1}{\psi(\mathbf{X})}\int_{Y_0}^{Y_z}\frac{\mathrm{d}\mathbf{Y}}{\varphi(\mathbf{Y})}; \tag{35}$$

We shall now express $\psi(\mathbf{X})$ in terms of τ_0 and shall substitute the resulting expression in Eqn.(24) assuming that the argument $\mathbf{X}$ varies with time. After cancelling out, we arrive at the familiar Bailey equation:

$$\int_0^{\tau}\frac{\mathrm{d}t}{\tau_0(\boldsymbol{X}(t))}=1. \tag{36}$$

Thus Bailey's equation can be used only in processes whose mechanism can also be described in the form of Eqn.(32). In particular, it follows from Eqn.(32) that the superposition principle is applicable to all processes whose kinetics are determined by a single elementary step. However, it ceases to be applicable even for the description of the kinetics of the accumulation of reaction products in a process consisting of two parallel reactions (21), since the partial derivative is a function of temperature; for example, it follows from Eqn.(21) that

$$\frac{\partial[\mathrm{B}]}{\partial[\mathrm{A}]}=\frac{k'}{k'+k''}.$$

The superposition principle is frequently applicable when one considers the ageing of materials used under critical conditions where a small change in the properties of the material lead to the breakdown of the latter. In this case there is a sharp diminution of the requirement for a single-valued trajectory along which the properties of the material vary. In fact, the current properties of the material in the equation describing the variation of its properties can be replaced by the initial values. The superposition principle can then be always employed when the rate of ageing is determined by the initial properties of the material.

Thus it is applicable to a process consisting of two parallel reactions. Indeed the rate of accumulation is determined solely by the initial concentration of substance A:

$$\frac{\mathrm{d}[\mathrm{B}]}{\mathrm{d}t}=k'[\mathrm{A}]_0.$$

Nevertheless one cannot describe with its aid the accumulation of the product of a consecutive reaction or any reaction which takes place in accordance with the autocatalytic law.

In particular, it is generally accepted[3,41] that the ageing of any polymeric materials is a chain process with degenerate branching. The kinetics of this process are clearly autocatalytic. The ratio of the rates of accumulation of the branching product, usually formed in the chain propagation reaction, and the products formed in the chain initiation steps—the effective chain length—usually depends strongly on the process conditions, which leads to failure of Eqn.(33) and hence to a non-single-valued trajectory for the variation of the properties of the material. Bailey's equation is therefore usually inapplicable to branched-chain processes.

In connection with the relatively wide use of prediction methods based on the superposition principle, the problem of discovering the features of the process mechanism and the characteristics of variable operating conditions, for which the application of this principle can lead to significant errors, has now become particularly acute. It is especially important to be able to observe these features in the course of accelerated tests on materials, the mechanism of the ageing of which is virtually unknown.

3. Optimisation of the Superposition Principle

The superposition principle is a special case of a more general procedure examined above (Section V, 1), which consists in the measurement of the rate of change of the properties of the material under different conditions. Eqn.(32) is a special case of Eqn.(16). However, as shown above, the formal application of even the general Eqn.(16) could not always permit the prediction of the variation of the properties of the material under variable conditions.

Nevertheless, it is evident that, when the instantaneous rates of change of all the properties of the material have been measured for all possible combination of these properties,

$$w(\mathbf{Y},\mathbf{X})=\left(\frac{\partial\boldsymbol{Y}}{\partial t}\right)_{\substack{\mathbf{Y}=\mathbf{Y}_0\\ t=0}}, \tag{37}$$

†In the general case $\mathbf{Y}_z$ represents a characteristic of the limit of the region of the operational suitability of the material and not a point.

then the kinetics of the variation of the properties of this material under any conditions can be described by solving the differential equation

$$\frac{d\mathbf{Y}}{dt} = w[\mathbf{Y}, \mathbf{X}(t)]. \quad (38)$$

In essence, Eqns.(16) and (38) have the same significance; the only different feature of Eqn.(38) is that the vector **Y**, which it includes, must characterise all the properties of the material determining the kinetics of the ageing process and not only some of them (for example, those important for practical purposes). On the other hand, in the derivation of Eqn.(16) the partial derivative was replaced by the total derivative without any justification. A rigorous application of Eqn.(16) or (38) implies that Eqn.(16) represents a system of differential equations taking into account not only the kinetics of the accumulation of B and Ω in the examples discussed above, but also the kinetics of the consumption of the initial substance and the kinetics of the variation of the concentration of the chain branching product.

As a result we obtain a system of equations identical to a system of chemical kinetic equations. Instead of Eqn.(17), we obtain from the kinetic scheme (21)

$$\frac{d[B]}{dt} = k_1 k_2 \frac{[A]}{[A_0]}, \quad \frac{d[A]}{dt} = -k_2[A], \quad (39)$$

and, instead of Eqn.(18), we have for the photochemical oxidation of polyolefins

$$\frac{d\Omega}{dt} = I[P], \quad \frac{d[P]}{dt} = \sqrt{kI[P]}, \quad (40)$$

where [P] is the concentration of the branching product.

In the general case the systems of equations obtained can differ in form from systems of chemical kinetic equations, but their structure must reflect, as it were, the logic of the process occurring and must take into account the variation of all the properties of the material which actually determine the process kinetics.

Unfortunately data on the variation of all the necessary properties of the material cannot always be obtained. For example, in a chain process it is sometimes difficult to follow the kinetics of the variation of the concentration of the branching product, since its nature may be unknown and, when it is known, its concentration may be below the sensitivity of the analysis.

At the present time there is no rigorous method whereby one can discover the properties whose variation is the primary cause of the variation of the remaining properties of the material. Nor is it clear whether it is at all possible to devise such a general method or whether the solution of this problem will remain for a long time in the hands of highly qualified specialists greatly experienced in the study of polymeric materials of a given class. The methods for the estimation of the significance of various factors employing factorial analysis[42] are as yet hardly applicable in this field, since they do not make it possible to elucidate the causal relation between different external factors and the properties of the material. On the other hand, the derivation of equations analogous to Eqn.(38), which take into account the variation of all the properties of the material and all the factors associated with the external conditions, is too laborious.

Thus the generalised superposition principle shows that there exists a possibility, in principle, of solving the problem of extrapolating the results of laboratory tests to any variable operating conditions. However, this principle shows how difficult it is to solve this problem without using information about the mechanism of the ageing of the material.

From the experimental point of view, it follows from the superposition principle that the measurement of the rate of change of the properties of material aged in different ways is most significant for prediction, and not the kinetics of the change of these properties under some conditions even if they do model fairly satisfactorily the operating conditions of the material from some particular point of view.

VI. INITIAL DATA FOR THE FORMULATION OF THE PROBLEM OF THE PREDICTION OF THE USEFUL LIFETIME

The accuracy of the determination of the useful lifetime of a material is usually not restricted solely by the difficulty of extrapolation of the results of tests to arbitrarily complex operating conditions. It is to a large extent determined by the accuracy with which the operating conditions of the material are known beforehand and how well the requirements which must be met by the material in a particular article have been formulated.

These at first sight simple tasks are in practice fairly complex, because one must understand which operating conditions in fact determine the kinetics of the ageing of the polymeric material and hence one can recognise how accurately these conditions are known beforehand only by having some idea about the factors which determine the variation of the properties of the material in the course of ageing. Only if it is known how the different properties of the material are inter-related can one formulate exactly the requirements which must be met by the stability of the article made of the given material.

Several examples illustrating this essential feature of the problem are discussed below.

1. Relation Between the Kinetics of the Variation of Practically Important Properties of a Polymeric Material and the Mechanism of the Ageing Process

Any polymeric material is characterised by a set of properties. From the practical point of view, the "external" properties of the material are important: its strength, lustre, permeability to moisture or gas, transparency, dielectric losses, combustibility, etc. These are not usually properties which determine the kinetics of the ageing of the material; their variation is a consequence of the physicochemical processes occurring in the material during its ageing. In order to record the kinetics of the ageing of the material and to elucidate the mechanism of this process, one usually measures quite different properties of the material: the variation of its composition, the formation and destruction of active species in it, the characteristics of the mobility of individual fragments of macromolecules, etc. Nevertheless, the useful lifetime of the material is determined by the kinetics of the variation of properties of practical importance. In this connection, the solution of the problem of the interrelation of different properties of the polymeric material is of primary importance in predicting its useful lifetime.

Relatively numerous studies have now been carried out in which the kinetics of the variation of properties of practical importance have been followed in the course of the ageing of many polymers[43]. The relation between certain properties of polymeric materials is known. For example, the dielectric losses are correlated with the number of polar groups in the polymer[44] and the elasticity of the polymer is related to the fraction and chemical structure of its amorphous phase[45].

However, unfortunately there have been virtually no studies on the quantitative relation between the kinetics of the variation of the properties of a polymeric material and the mechanism of its ageing. Such a relation has been established in a study[46] dealing with the kinetics of the variation of properties in the ageing of polyolefins. It has been shown that the variation of any physicomechanical characteristics of polyolefins is determined not only by the amount of light incident on the specimen but depends significantly also on the intensity of the photochemically active light. The higher the intensity of the light, the less effective (per quantum of light incident on the specimen) is the variation of the properties.

This result can be readily explained on the basis of data for the mechanism of the oxidation of the given polymer. The oxidation of polyolefins is a chain reaction with degenerate light-induced branching by the reaction products and with quadratic chain termination[45]. This process also proceeds more effectively at lower light intensities, since one of the principal branching products, the hydroperoxide, accumulates in the reaction which involves the propagation of a chain whose length, under conditions of quadratic chain termination, is known to be greater the lower the rate of initiation, i.e. the lower the intensity of the light.

An ambiguous quantitative relation has been established[46] between the kinetics of the variation of the mechanical properties of polypropylene and the total number of oxidation chain initiation steps occurring in the polymer throughout the process (the yield of radicals). This relation is purely empirical; neither its cause nor its characteristics are known exactly. Furthermore, it has actually been shown that the form of the relations between the mechanical characteristics and the yield of radicals is different for polymer specimens prepared in different ways. Nevertheless, the unambiguous nature of the relation already established made it possible to calculate the rate of change of mechanical properties under any conditions. The details of this study have been described by Slobodetskaya[36].

2. The Characteristics of Operating Conditions

The accuracy of the determination of the useful lifetime is governed to a large extent by the accuracy with which the operating conditions of a given material in the article have been specified. It is sometimes believed that the determination of the characteristics of the operating conditions is a simple task, attention being concentrated only on the difficulty of determination of internal stresses in the specimen or of the dynamics of the loads applied to it.

However, in practice there are too many factors acting on the polymer in the course of its use, so that even factorial design methods cannot always reveal which are the most significant. For example, only special studies revealed that the rate of atmospheric corrosion of metals is to a large extent determined by the concentration of sulphur compounds in the atmosphere[47].

Frequently only an understanding of the fundamental features of the mechanism of the ageing of the polymeric material makes it possible to discover the principal factors which determine its useful lifetime. It is then sometimes found that the determination of the characteristics of the operating conditions becomes an independent scientific task. For example, at the beginning of the 1970s the principal features of the mechanism of the ageing of polyolefins under atmospheric conditions became clear and all the necessary rate constants for the elementary reactions were found. However, even this could not lead to the solution of the problem of the determination of the useful lifetime of these polymers in different climatic zones. The point is that the ageing of polyolefins in open air takes place mainly as a result of the absorption of light by aliphatic hydroperoxides. On the other hand, aliphatic hydroperoxides absorb light only in the extreme ultraviolet region of the solar spectrum and the intensity of this component depends greatly on the angle of the sun above the horizon and on the latitude of the given site. Regular direct measurements of the ultraviolet component of the solar spectrum have not been made anywhere in the world except at the meteorological station of Moscow University. The problem of predicting the useful lifetime of polyolefins under real conditions therefore remained unsolved until a special study was carried out[48] showing how the average characteristics of the intensity and spectral composition of solar radiation in the ultraviolet can be calculated theoretically from data on the cloud cover and the geographical position of the given location. As a result, a special computer program was developed whereby it was possible to calculate the rate of change of the properties of olefins at any point on earth from data supplied by ordinary meteorological stations[49].

A completely different problem arose when prediction of the useful lifetime of polyolefins used to insulate pipes, already mentioned above, was considered[27]. The failure of the initial prediction is associated in this instance with the fact that no account was taken of the contact between the polymer and the environment.

An unusual characteristic of the operating conditions of a polymer may prove to be the size of the given article. Many polymeric materials are used in a plasticised state. The increase in the size of the articles made from such a material leads to two opposed phenomena. On the one hand, intense stresses arise in large articles which reduces the useful life of the latter. On the other hand, the plasticiser diffuses less from a large article and its initial properties are retained for a longer time.

The prediction of the useful lifetime of the material in such an article is a fairly difficult problem and the question arises of the extrapolation of the results of laboratory tests not only to the normal characteristics of the operating conditions (temperature, humidity, stress) but also to parameters of the size of the specimen.

The aim of this Section was not to consider comprehensively the problem of the formulation of initial data required for the determination of the useful lifetime of a polymeric material; this is an independent and fairly complex problem. The examples quoted merely illustrate the importance of this problem, to which inadequate attention is being devoted.

VII. KINETIC CLASSIFICATION OF AGEING MECHANISMS

The analysis described in previous sections shows that simplified approaches to prediction, which are suitable when the ageing of the polymeric material is determined by one elementary step, are usually inapplicable to the prediction of the variation of the properties of real materials, the mechanism of the ageing of which involves a complex set of different elementary processes.

Well-founded prediction must therefore be based, on the one hand, on the determination of the fundamental features of the possible mechanism of the ageing of the material, and, on the other hand, on the development of a series of type-specific methods of prediction suitable for the most common ageing mechanisms. Thus the prediction must be based on the classification of the possible mechanisms of the ageing of polymeric materials in terms of features essential for such prediction.

Unfortunately, at present it is impossible to point to any one study in which a sufficiently complete classification of the mechanisms of the ageing of polymeric materials has been given. Nevertheless, such a classification is being set up, albeit somewhat sporadically. Ageing processes are divided into classes based on different features: the chemical structure of the polymer, the ageing conditions, the physical and chemical nature of the processes predominating in the course of ageing, and the properties of the polymer which are of greatest practical importance. Examples of different processes associated with different methods of classification are presented in the Table.

Methods of classification of ageing processes.

Feature on which classification is based	Examples of processes
Chemical nature of material	Ageing of polyolefins Ageing of poly(vinyl chloride) Ageing of polyamides Ageing of natural rubbers and elastomers Ageing of polyurethanes Ageing of epoxy-compounds
Influences acting on materials	Oxidative degradation Photochemical oxidation Thermal degradation Photolysis Mechanical degradation Chemical degradation Radiation-induced degradation
Nature of physicochemical process	Radical transformations in polymer Photochemical transformations Structure formation in polymers Crystallisation Relaxation processes
Properties essential for practical purposes	Variation of mechanical properties Variation of dielectric properties Gas evolution Cracking

However, these are not the features which must underlie the classification of ageing processes necessary for the determination of the useful lifetime of the polymeric material. A kinetic classification of the mechanisms of the ageing processes is essential. The beginnings of such a classification already exist.

It is known that the ageing of a polymeric material is frequently not a simple irreversible reaction. In many instances there is a chain process and the prediction of the rate of change of the properties of the material decomposing via a chain mechanism requires, as we have seen in the previous Sections, a qualitatively different approach from that for a simple irreversible reaction. Furthermore the kinetics of the chain process in different polymeric materials and under different conditions can be also qualitatively different. Thus pure polyolefins and apparently many natural rubbers are oxidised via the mechanism involving a chain reaction with degenerate branching and quadratic termination[36,41].

The introduction of a thermal stabiliser into the olefin leads to the appearance in the kinetic process mechanism of what is in fact only one additional elementary reaction—the interaction of the thermal stabiliser and the peroxy-radical. However, the process kinetics do not change qualitatively, since chain termination becomes linear. The relatively slow change in the rate of accumulation of the hydroperoxide along a quadratic parabola in pure polyolefins is replaced in the thermally stabilised polyolefin by a characteristic relation with a so-called induction period. At the beginning of the process, during a prolonged time interval, the branching product (the hydroperoxide) hardly accumulates and then its concentration increases almost exponentially[50]. Despite the chemical similarity of both processes, they are very different kinetically.

An unbranched chain process has altogether different kinetic features. Under constant conditions, its rate is almost unaltered, but its dependence on temperature and the rate of initiation may be complex. The photochemical decomposition of many polymers occurring as a result of the absorption of light by the polymer molecule itself may serve as an example of processes of this kind.

Different kinds of photochemical processes can be treated in the same way. Together with processes proceeding as ordinary single-quantum reactions, two-quantum processes, which take place with the consecutive absorption of two light quanta, and even multiquantum chain processes, in which each chain propagation step requires the absorption of a new light quantum, are known. From the kinetic point of view, all these are qualitatively different.

Together with chemical changes, physical processes also take place in the course of ageing: crystallisation and recrystallisation as well as diffusion of different components of the polymeric material and the reaction products. Different kinds of stresses arise in the polymer and relax, and the polymer undergoes orientation or disorientation. The role of all these processes must be taken into account in classifying the possible kinetic features of ageing processes.

The ain of current studies on the ageing processes of polymeric materials is usually to demonstrate the existence and to determine the quantitative characteristics of individual elementary steps of the process; one may say that they are designed to discover sufficient evidence that the elementary steps do occur. On the other hand, for the prediction of the useful lifetime, it is necessary to have the characteristics of the ageing process of the polymeric material as a whole. Naturally these essential process characteristics consist of the characteristics of individual elementary steps. When the characteristics of all the elementary steps are known, the prediction of the useful lifetime of the material does not involve fundamental difficulties, as already stated. However, usually, particularly at the beginning of the study, such characteristics are not available and even the ageing mechanism is largely obscure. In this case on must solve the "converse" problem: it is necessary to discover the type of the mechanism of ageing from a set of certain features and then to seek on this basis the quantitative characteristics of the process necessary for the determination of the useful lifetime of the material.

We are thus faced, for example, with the problem of the features of experiments with the aid of which one can decide whether Bailey's equation for the determination of the useful lifetime of the material under variable conditions is applicable to the given material. Evidently the applicability or inapplicability of this equation is determined both by the mechanism of the ageing of the material and by the nature of the changes in its operating conditions. Under conditions which change little, the equation is always applicable, while in the case of an extensive variation of conditions it is not easy to decide whether the equation is applicable or not.

Thus the kinetic classification of ageing processes must be based not only on data for the mechanism of the ageing of the polymeric material but also on the basis of information concerning the operating conditions of the material in the given article. Unfortunately the solution of problems of this kind is only just beginning and the necessity for their solution

becomes apparent only when the use of traditional simplified methods leads to emergencies.

---o0o---

Summarising what has been said above, one can formulate the tasks for fundamental research on the performance of which depends the successful prediction of the useful lifetime of polymeric materials.

Firstly, it is necessary to discover, classify, and estimate the distribution of typical mechanisms for the variation of the properties of polymers under different conditions. The determination of the qualitative features of a particular mechanism is of greater importance than the detemrination of the rate constants for elementary processes. This makes it possible to discover on the basis of laboratory tests the type of the mechanism for the decomposition of the material and hence one can devise both a mathematical description of the ageing process of the material and a programme of accelerated tests directed to the determination of its useful lifetime.

Secondly, fundamental research should indicate the conditions governing the variation of the process mechanism. This will make it possible to establish the possible limits of the correct extrapolation of data obtained in accelerated tests or under conditions more severe than the operating conditions.

Thirdly, fundamental research should reveal the complete set of the properties of the polymeric material which determine the kinetics of the variation of its practically important characteristics in the course of its use. Only if the set of such properties and the way in which they can be characterised quantitatively are known will it be possible to compare two materials or to specify the variation of the properties of the material during its use.

Fourthly, fundamental research should indicate which factors in the operating conditions of the polymer induce changes in its properties and which can be characterised quantitatively.

Fifthly and finally, it is necessary to develop methods for the investigation of complex non-linear systems whereby one can predict their behaviour on the basis of preliminary studies and qualitative data on the relation between their properties.

On this basis, one must set up a method for the development of an optimum programme of preliminary studies on the material. The first four tasks refer to the field of chemical physics and that part of it where the kinetics and mechanisms of chemical processes are studied. The fifth task can be assigned to the field of applied mathematics, on the border between computational mathematics or mathematical statistics and experimental design.

A characteristic feature of the problem of prediction is the necessity for its daily solution. It is continually faced by various organisations occupied with problems of the application of polymeric materials. It arises when it is necessary to determine the guaranteed useful lifetime of articles produced by the new technology, when it is necessary to select the material for an article still only in the planning stage, and finally when one must devise a plan using a material already manufactured in various articles and in various branches of industry.

Errors in the solution of problems of this kind can cost the National Economy many millions of roubles and they can vitiate the efforts of many teams, directed towards the development of new articles and materials. Therefore the time available for the solution of the problem of prediction is usually dictated by practical considerations and the solution must be achieved regardless of the level, which, for example, studies on the mechanism for the variation of the properties of the given material have reached at the instant of the formulation of the given task.

Prediction of the Variation of the Properties of Polymeric Materials after Prolonged Storage and Use

B.D.Goikhman and T.P.Smekhunova

The fundamental problems of the prediction of the changes in the properties of polymeric materials (in consequence of ageing, mass transfer, and the application of stresses) after prolonged storage and use are examined. The experimental conditions and the methods of interpretation of experimental data as well as characteristics of the method of accelerated tests on articles made from polymeric materials are discussed.
The bibliography includes 66 references.

I. INTRODUCTION

The increasing application of polymeric materials (PM) in various branches of the National Economy and the necessity to optimise their properties have given rise to the problem of improving the accuracy in predicting the duration of the technical suitability of the relevant articles.

On storage and during use, articles made of polymeric materials are acted upon by various factors: temperature, moisture, oxygen, ozone, light, radiation, corrosive media, biological factors, and applied forces. Depending on the duration and intensity of the influence, these factors lead to reversible and irreversible physicochemical processes, which include the following:

(a) thermal, radiation-induced, and light-induced ageing (chemical degradation and structure formation reactions, structural rearrangements at a supermolecular level), leading to irreversible changes in the properties of the polymeric material.

(b) Phase transformations in the polymeric material, which give rise to reversible changes in its properties.

(c) Mass transfer (relative migration of plasticisers in various elements of the articles, the removal of volatile components, the diffusion of moisture, etc.), causing changes in various properties of the articles.

(d) The accumulation of defects in the articles (constructions) owing to stresses active during storage and use, which lead to an alteration of the properties of the polymeric material, a change in its geometry, and the breakdown of the integrity of the constructions.

The influence of the above environmental factors on the polymeric material must be considered in terms of interrelations between them. For example, the simultaneous influence of heat, oxygen, and moisture gives rise to thermo-oxidative degradation (structure formation) in the material and hydrolytic degradation via different types of bonds, which is the reason for the complex variation of the properties of the polymeric material. The reversible and irreversible processes occurring in the polymeric material under the influence of the environment can be greatly accelerated if the articles are in a strained-deformed state.

In the problem of the estimation of the capacity for retention of the operational characteristics of the given articles the direct and converse tasks are distinguished. The direct task consists in estimating the storage times of the articles in terms of the permissible changes in their operational characteristics. The converse task consists in determining the required level of operational characteristics of the given articles to ensure their usability during a specified time. Formally, both problems are solved on the basis of the following condition:

$$Y_j(0)\rho_j(t) \geqslant [Y_j], \qquad (1)$$

where $[Y_j]$ and $Y_j(0)$ are respectively the maximum permissible and the initial characteristics of the article and $\rho_j(t)$ is the coefficient of the change in the characteristic Y_j with time (relative to the initial value).

The index of reliability, taking into account the sum total of the operational characteristics of the articles, is a generalised characteristic of the usability of the given articles. In view of the variation in the characteristics of the materials with time and the accumulation of defects in the articles under the influence of external conditions, the reliability index is a function of the storage time or the time during which the given articles are used. If this function has been determined quantitatively, the storage time can be found as the time required to attain the limiting permissible level of reliability; on the other hand, if the storage time has been specified, then the level of change in reliability can be determined from the above relation. In other words, in this case the problem also reduces to the solution of Eqn.(1), in which Y_j is the reliability index and $\rho_j(t)$ is the coefficient of its time variation. Here one should note that a certain excess reliability of the article at the beginning of the storage time is an inevitable "advance contribution" necessary to ensure the usability of the article within the limits of the specified time.

The correct solution of the kinetic problem of reliability involves considerable difficulties in most cases. For this reason, the following approach has come to be widely used in engineering practise. Eqn.(1) is solved for each of the characteristics which determine the usability of the article. To ensure the specified useful lifetime, the standardised requirements to be met by the characteristics are specified taking into account their time variation.

A characteristic feature of the problem of predicting the changes in the properties of a polymeric material is the short duration of laboratory tests at the stage involving

the development of the articles, i.e. under conditions where no direct experience in the use of the article can be gained. The problem can only be solved on the basis of the laws of chemical and physical kinetics and thermodynamics.

The majority of studies devoted to the prediction of changes in the operational properties of polymeric materials are characterised by an endeavour to simplify to the maximum possible extent the methods of interpretation of the kinetic $Y_j(t)$ curves. This frequently leads to the unjustified exclusion from consideration of a number of processes and hence to errors in prediction. This review deals with a series of practically most important aspects of the problem of prediction of the changes in the properties of polymeric materials on prolonged storage and use.

II. THE EQUIVALENT TEMPERATURE AS A CHARACTERISTIC OF NATURAL CLIMATIC CONDITIONS UNDER WHICH ARTICLES ARE STORED AND USED

In terms of thermal and other natural influences, the territory of the USSR can be divided into zones of cold, temperate, and hot climates. The climatic regions of the USSR differ considerably in terms of temperature, relative humidity, intensity of solar radiation, and other factors[1]. For example, the average diurnal temperature varies in the range from −50° to +40 °C, the hourly temperatures range from −60° to +45 °C, the maximum daily temperature amplitudes range from 20° to 30 °C, the average annual relative humidity is between 40 and 75%, the overall solar radiation intensity is between 87.7 and 158.5 kcal cm^{-2}, and the annual atmospheric precipitation ranges from 202 to 2788 mm.

The temperatures at which articles are stored, which in many respects determine the intensity of physicochemical processes, are particularly important. Furthermore, in many instances a change in the temperature of ambient air leads to the appearance and stresses in the articles (for example, diurnal variations in temperature induce non-stationary temperature stresses, while seasonal variations give rise to stationary stresses when there is a difference between the coefficients of thermal expansion of the constructional elements).

Variation of the temperature of ambient air during the storage of the articles within wide limits (up to 100 °C) makes it necessary to take into account the non-isothermal conditions in predicting the properties of the materials. The solution of kinetic equations under the conditions of a non-stationary temperature field may be carried out on a computer using the known laws governing the variation of temperature with time[2].

One of the ways in which non-stationary temperature conditions can be taken into account involves the introduction of the so-called equivalent temperature[3,4]. This term is understood as a conventional constant temperature at which the same changes take place in the given material during the time under consideration as under non-stationary temperature conditions. For chemical reactions described by the relation

$$\frac{dc}{dt} = -A_0 \exp\left(-\frac{U}{RT}\right) f(c) , \qquad (2)$$

where c is the concentration of the reactant, U the apparent process activation energy (in the general case the temperature coefficient of the rate of the process), A_0 the pre-exponential factor, R the gas constant, and $f(c)$ a function independent of temperature, the present authors[4] found an

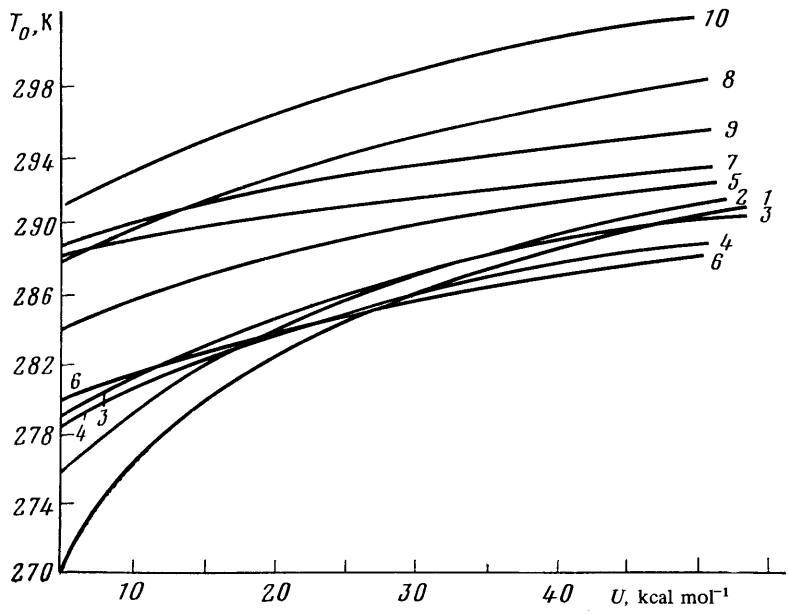

Figure 1. The $T_0(U)$ relation for representative points according to the results of observations carried out at specified times in different climatic regions: 1) very cold; 2) cold; 3) moderately cold; 4) moderately cold and moist; 5) moderately warm; 6) moderately warm and moist; 8) hot and dry; 9) moderately hot and moist; 10) very hot and dry.

expression describing the equivalent temperature:

$$T_0 = -\frac{U}{R}\left\{\ln\left[\frac{1}{t_0}\sum_{j=1}^{n}\Delta t_j \exp\left(-\frac{U}{RT_j}\right)\right]\right\}^{-1}, \qquad (3)$$

where n is the number of intervals Δt_j with an average temperature T_j during the time interval t_0 under consideration.

This expression for the equivalent temperature was obtained for decomposition processes, creep, the relaxation of stresses, etc.[4] The identity of the expressions for the equivalent temperature is due to the fact that the temperature dependence of the rates of different chemical and physical processes is described by analogous relations of the Arrhenius type.

It follows from Eqn.(3) that the equivalent temperature is a function of the apparent process activation energy and of the distribution of temperatures. For a known distribution of temperatures, the dependence of T_0 on U can be calculated beforehand. Fig.1 presents plots of T_0 against U calculated by Eqn.(3) for different climatic zones in the USSR using data from Ref.1†.

One should note that the equivalent average temperatures are not the same and in many cases there is not even a qualitative correlation between them. For example, the average annual temperature in the zone of the temperate, warm, and moist climate is 6.0 °C, while in the zone of the very cold climate it is −12.5 °C.[1] For the same climatic zones, the equivalent temperatures for $U = 35$ kcal mol^{-1} are respectively 13.3° and 14.3 °C (Fig.1), i.e. a higher equivalent temperature corresponds to a lower average annual temperature. Therefore treatment based on average annual temperatures can lead to significant errors in calculations in view of the considerable dependence of the rates of the processes on temperature.

The equivalent temperature found from Eqn.(3) can be regarded not only as the extrapolation temperature in predicting the changes in the properties of materials but also as a generalised characteristic of the temperature conditions in the storage and use of materials. It follows from the $T_0(U)$ relations in Fig.1 that the values of T_0 for different climatic zones are significantly different (up to 20 °C). In view of the significant dependence of the rates of processes on temperature, a difference of 3–4 °C in the equivalent temperature leads to a considerable difference in the rates of processes and the storage time.

The Table presents the values of T_0 and the relative rates (w/w_{cold}) of physicochemical processes in different climatic zones of the USSR. The rate of processes in the zone of the cold climate (w_{cold}) has been adopted arbitrarily as unity. Evidently the rates of physicochemical processes in different climatic regions can differ severalfold. Nevertheless the specified storage and utilisation times for articles are as a rule stated to be the same for the entire territory of the USSR (they are calculated for the most severe conditions). After this time has elapsed, the stock of given articles can differ severalfold depending on the storage conditions.

Bearing in mind that the zone of the dry, hot climate constitutes only ~10% of the territory of the USSR (the zones of the cold and temperate climates constitute 67 and 23% of the territory of the USSR respectively)[1], the desirability and economic efficiency of differentiating the storage times as a function of temperate conditions, at least for large and expensive articles used under the conditions of a single climatic region, becomes evident.

The relative rates of processes in different climatic regions of the USSR.

Climatic region	$U = 15$ kcal mol^{-1}		$U = 25$ kcal mol^{-1}		$U = 35$ kcal mol^{-1}	
	T_0, K	w/w_{cold}	T_0, K	w/w_{cold}	T_0, K	w/w_{cold}
Cold	281.9	1.0	285.6	1.0	288.3	1.0
Moderately warm	287.0	1.58	289.0	1.65	290.6	1.7
Dry and hot	291.2	2.46	294.0	3.5	296.0	4.8

III. CHANGES IN THE PROPERTIES OF POLYMERIC MATERIALS ON AGEING

The experimental methods for the prediction of the changes in the properties of polymeric materials during ageing are based on accelerated tests under conditions of increased temperature, moisture concentration, oxygen, radiation intensity, stresses, etc.

A survey of studies[6–16] during recent years in the Soviet literature shows that the curves describing the variation of the characteristics of materials during ageing under forced conditions are complex. Nevertheless, the authors of these studies used simplified methods for the interpretation of experimental kinetic curves in calculating the expected changes in the properties of materials or their storage times. This approach can lead to contradictory estimates of the expected changes[10] and also, as will be shown below, to not only quantitative but also qualitative errors. This leads in its turn to errors in the determination of the times of technical suitability of articles or unjustifiably high specifications which must be met by the operational characteristics.

In the general case the characteristic of a material investigated can be expressed in the form

$$Y_j = f_i(c_1, c_2, \ldots, c_n), \qquad (4)$$

where Y_j is the characteristic of the material under consideration and c_i the concentration of bonds of the ith type (chemical, physical) which determine the level of Y_j.

The time variation of the characteristic Y_j is evidently determined by the law governing the variation of concentration:

$$c_i = c_i(t, T, \xi), \; i = 1, 2 \ldots n \qquad (5)$$

(here t is the time, T the temperature, ξ the stress, radiation dose, the concentration of oxygen, etc.).

When the mechanism of ageing, which determines the form of function (5), and the law governing the establishment of properties (4) are known, the relation $Y_j = f(t, T, \xi)$ is unambiguously defined and the problem of prediction reduces to the corresponding analytical calculations at the storage and operating temperatures of the material. This in turn indicates the need to investigate and determine the quantitative relations between the rate of ageing and different factors. The determination of the mechanism of ageing and the

† In the absence of data on the distribution of temperature in the given climatic region, the equivalent temperature can be estimated from average minimum and maximum monthly temperatures[5]. The distribution of temperature on the surface and in the bulk of the articles differ somewhat from the distribution of temperature in the ambient air. In the absence of the effect of solar radiation, the corresponding values of T_0 will be lower than those in Fig.1.

law governing the establishment of properties would be the best guarantee of a reliable prediction.

However, in most cases the investigator does not have the necessary information concerning the structure of Eqns.(4) and (5) and the corresponding kintic constants. The generally accepted approach therefore consists in the study of the kinetics of the variation of the characteristics of the material under investigation $Y_j(t, T)$ with subsequent extrapolation of the results to the real temperature conditions.

We shall analyse the possible features of the variation of the characteristic $Y_j(t)$ (for example, in thermal ageing). We shall assume that relation (4) can be represented by the fairly general expression

$$Y_j = \sum_{i=1}^{n} \alpha_{ji} c_i^{m_{ji}}, \qquad (6)$$

where α_{ij} and m_{ji} are coefficients.

It follows from Eqns.(5) and (6) that, even under the conditions of simple kinetic laws governing the variation of the concentrations of bonds, the Y_j characteristic varies with time in a complex manner. The identity of the kinetic laws governing the variation of Y_j and c_i in terms of relative units obtains only for $n = 1$ and $m_{ji} = 1$ (in this case the kinetic parameters of the changes in the above quantities are identical). For $n = 1$ and $m_{ji} \neq 1$, the kinetic parameters of the variation of the bond concentration and of the characteristic are not identical even in the simple case where the bond concentration varies in accordance with the first-order law. For $n = 2$ and $m_{ji} = 1$, the above kinetic parameters also differ.

The different operating characteristics of the material are different functions of the concentration of the same bonds. In other words, the coefficients of Eqn.(6) for different characteristics of the material can be different. Therefore the same chemical and physical transformations in the material can lead to different changes in particular operating characteristics. The kinetic parameters of the variation of different characteristics can therefore also differ. In particular, the apparent activation energy U—the temperature coefficient of the rate of change of the characteristics—may not be the same as the true activation energy for the physicochemical process. The presence of stable bonds and the occurrence of recombination processes lead to a limiting value of the characteristic Y_j^{∞}.

For parallel competing first-order processes (structure formation and degradation) with $n = 2$ and $m_{ji} = 1$, we have

$$c_1 = c_1^0 \exp(-k_1 t); \quad c_2 = c_2^{\infty} - (c_2^{\infty} - c_2^0)\exp(-k_2 t) \qquad (7)$$

and

$$Y_j = \gamma_1 \exp(-k_1 t) - \gamma_2 \exp(-k_2 t) + Y_j^{\infty}, \qquad (8)$$

where k_1 and k_2 are rate constants, c_1^0 and c_2^0 are the concentrations at time $t = 0$, c_2^{∞} is the limiting concentration of bonds, and γ_1 and γ_2 are coefficients which are functions of c_1^0, c_2^0, and c_2^{∞}.

The plot of function (8) has an extremum and the corresponding asymptotic section. Thus for relatively simple hypotheses, the curves describing the variation of the characteristics of materials during ageing have a complex form. Nevertheless, in practical predictions of the changes in operating characteristics during thermal ageing, one normally employs elementary kinetic equations (of zero, first, and second orders), the treatment being limited in the case of complex $Y_j(t)$ curves to the description of their initial sections only[9-11,15]. There is a similar possibility of qualitative errors. This can be readily shown in relation to Eqn.(8). We shall assume that in the range of the temperatures of forced tests $k_1 > k_2$; the $Y_j(t)$ curves are then characterised by a minimum. The prediction based on the initial sections of these curves indicates a decrease of Y_j under real conditions. However, in consequence of the difference between the activation energies, there is also a possibility of a change in the ratio of the rates in the temperature range where the materials are used ($k_2 > k_1$). In this case there is a change also in the nature of the $Y_j(t)$ curve under real conditions (a maximum appears).

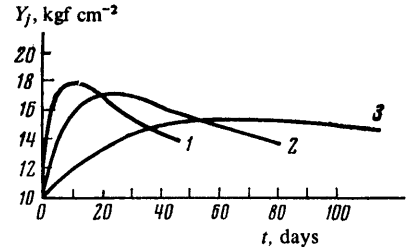

Figure 2. Calculated $Y_j(t)$ curves at different temperatures (°C): 1) 90; 2) 80; 3) 70.

We shall illustrate this by the following example. Suppose that the variation of the characteristic Y_j (for example, the short-term strength) is described by Eqn.(8) with $\gamma_1 = 13.8$, $\gamma_2 = 9.8$, $Y_j^{\infty} = 6$ kgf cm^{-2}, $k_1 = 7.4 \times 10^{-6} \exp(-14\,700/RT)$ days^{-1}, and $k_2 = 3.2 \times 10^{17} \exp(-30\,000/RT)$ days^{-1}. The calculated $Y_j(t)$ curves at 90°, 80°, and 70 °C have the form shown in Fig.2. The prediction based on the initial sections of these curves (up to the $Y_j = 12$ kgf cm^{-2} level), fitted by a first-order equation, indicates an increase of Y_j to 11.1 kgf cm^{-2} after ten years at 20 °C. On the other hand, calculation of the predicted $Y_j(t)$ curve by the initial Eqn.(8) indicates a decrease of the characteristic from 10.0 kgf cm^{-2} to 6.6 kgf cm^{-2} (Fig.3).

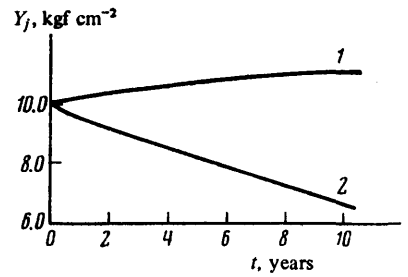

Figure 3. Predicted $Y_j(t)$ curves at 20 °C: 1) calculated from the initial sections of the curves in Fig.2; 2) calculated from the Eqn.(8).

Another common method of predicting the change in the properties of a polymeric material on thermal ageing is the so-called graphoanalytical method[10-14,21,22]. The essence of the method consists in the determination of the time t_{Y_j} for the attainment of identical values of Y_j from experimental

$Y_j(t)$ curves at different temperatures. The results are used to plot $\ln t_{Y_j} = f(1/T)$ and to find the time at the operating temperature by a linear extrapolation. The predicted $Y_j(t)$ curve at the operating temperature can be constructed on the basis of the complete set of values obtained.

It is easy to show that the linear relation between $\ln t_{Y_j}$ and $1/T$ is possible only in the case where the change in the characteristics is described by the kinetic equation

$$\frac{dY_j}{dt} = -A_0 \exp\left(-\frac{U}{RT}\right) f(Y_j). \qquad (9)$$

This postulates in its turn that the parameter U is independent of Y_j, i.e. that the $\ln t_{Y_j} = f(1/T)$ linear plots are parallel for different Y_j. This limits the region of applicability of the combined graphical and analytical method. The same limitation applies also to the familiar method of transformation coefficients[23]. In the case of curves with extrema, the application of these methods can also lead to qualitative errors in predicting the changes in the properties of materials.

It follows from the foregoing that, when the mechanism of ageing is unknown, in order to increase the reliability of the prediction of the changes in the properties of a polymeric material one must endeavour to discover the principal components of the process involving a change in Y_j and to obtain an analytical description of the latter. For this purpose, one can use the procedures of formal kinetics[23,24]. Frequently the form of the $Y_j(t)$ curves can be suggested by a version of the analytical curve fitting method. For example, in the case of S-shaped curves one can use formally the autocatalytic[23,24] or Kolmogorov–Erofeev[25,27] equation; experimental curves with asymptotic sections can be described by Eqn.(8). In the latter case, in particular, the parameters of the equation can be found by graphical or analytical methods[28,29] and Y_j^∞ is obtained by extrapolating the linearised relation $dY_j/dt = f(Y_j)$, corresponding to the last section of the $Y_j(t)$ curve, to the zero value of dY_j/dt or by the method# quoted by Shenk[30].

Naturally, mathematical modelling methods can be used for prediction on the basis of $Y_j(t)$ curves when the ageing mechanism is unknown[31].

We shall indicate yet another method whereby experimental $Y_j(t)$ curves can be fitted. Applying the methods for the expansion of functions, it is easy to show that Eqn.(6), corresponding to different varieties of relation (5), leads to a possible representation of the function $Y_j(t)$ by the experimental series

$$Y_j = Y_j^\infty + \sum_{i=1}^{n} \gamma_i \exp(-k_i t), \qquad (10)$$

where γ_i can be both positive and negative. The coefficients of Eqn.(10) naturally cannot always have a clear-cut physical significance, but, by fitting this equation to experimental data, one increases significantly the accuracy of the prediction and the determination of the principal components of the process involving the variation of $Y_j(t)$ is to some extent guaranteed. The coefficients of Eqn.(10) can be determined by the above procedure for Eqn.(8). Here the procedure used to search for the coefficients of the equation can reveal the fundamental stages (components) of the process involving the variation of $Y_j(t)$.

The method is based on the solution of the $Y_j = f(t)$ relation linearised with respect to t.

As an example, we shall consider the ageing of rubber based on SKMS-10 raw rubber. Fig.4 presents data for the accumulation of the residual deformation (ε_{res}) of the rubber under natural conditions. Analysis shows that the experimental data for the ageing of this rubber at 50–90 °C[32] are described satisfactorily by the equation

$$\varepsilon_{res} = \varepsilon_{res}^\infty - \gamma_1 \exp(-k_1 t) - \gamma_2 \exp(-k_2 t), \qquad (11)$$

where $\varepsilon_{res}^\infty = 97.5\%$, $\gamma_1 = 68.5\%$, $\gamma_2 = 29.0\%$, $k_1 = 3.2 \times 10^8 \exp(-16\,300/RT)$ days^{-1}, and $k_2 = 2.5 \times 10^{10} \exp(-17\,400/RT)$ days^{-1}. The $\varepsilon_{res}(t)$ for the regions of Central Asia and Transbaikal were calculated from the relations obtained. Fig.4 shows that the prediction is confirmed satisfactorily by observations carried out over many years.

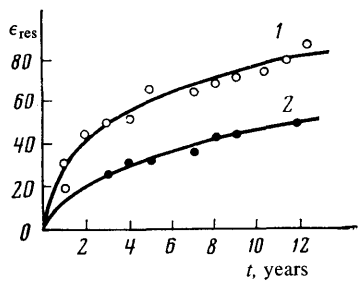

Figure 4. Kinetics of the accumulation of the residual deformation in rubber on storage in the regions of Central Asia (curve *1*) and Transbaikal (curve *2*) [the calculated curves were plotted on the basis of Eqn.(11) for $T_0 = 295.5$ K (curve *1*) and 283 K (curve *2*); the experimental points are based on the data of Dobrosklonskaya et al.[32]].

Mechanical stresses can have a significant influence on the rates of chemical reactions[33]. Under the influence of mechanical loads, chemical bonds are ruptured in polymers and free radicals are formed, giving rise to a chain of subsequent reactions[34]. The accelerating effect of mechanical stresses on thermal degradation processes in low-pressure polyethylene has been studied experimentally[35]. It has been shown[36] that mechanical stresses influence the apparent activation energy and the pre-exponential factor for the ageing of rubbers. According to the theory of absolute reaction rates[33], this implies that the stresses influence not only the energy barrier for the reactions but also the entropy of activation, which reflects the necessity for a specific orientation of the macromolecules.

Since the activation energy depends on the extent of the stresses, it is useful to study the ageing of materials in the stressed state at different temperatures under the conditions of constant stresses. The rates of processes then obey the Arrhenius equation, which can be used for extrapolation in the prediction. Tests under conditions of constant deformation complicate the task involved in the prediction owing to the temperature dependence of the rate of relaxation of stresses. Because of this, the level of stresses is different at different temperatures and hence there is a change in the apparent activation energy for the process. The use of the simple Arrhenius equation for prediction is in this case illegitimate.

The establishment of exact quantitative relations between the rate of ageing, on the one hand, and temperature and the extent of the stress on the other, makes it possible to calculate by numerical integration methods the predicted changes in the characteristics of materials under conditions of non-stationary stresses and temperatures[36].

IV. CHANGES IN THE PROPERTIES OF MATERIALS DUE TO MASS TRANSFER PROCESSES

Mass transfer phenomena are due to contact between the polymeric material and the surrounding medium and with other elements of the given articles. There is then a possibility of both physical and chemical transformations. Physical transformations are due to plasticisation, swelling, the formation of pores, etc.; chemical transformations are caused by the interaction of the diffusing substance with different functional groups of the polymer.

In the study of the interaction of a given article with the environment one usually investigates the changes of characteristics as a function of the duration of the influence of the medium (for example, increase in moisture content)[16-18]. The results of such tests indicate a sensitivity of articles to particular influences, but they are insufficient for the solution of the problems of prediction, since they refer to a specific geometry of the specimen, degree of penetration, etc.

For predictions of the changes due to physical transformations, it is necessary to establish the law governing the variation of the concentration of the diffusing substance with time at any point within the article:

$$a_i = a_i(r, t) \tag{12}$$

(here a_i is the concentration and r the flux coordinate) and the dependence of the characteristic of the material on concentration:

$$Y_j = Y_j(a_i). \tag{13}$$

By solving the mass transfer equation[29]

$$\frac{\partial \mu}{\partial t} = D\nabla^2\mu, \tag{14}$$

where μ is the chemical potential and D the diffusion coefficient, one determines the law governing the variation of concentration $a_i(r, t)$. The dependence of the characteristics of the material on the concentration $Y_j(a_i)$ is established experimentally. Simultaneous solution of Eqns.(12) and (13) yield the relation

$$Y_j = f(r, t). \tag{15}$$

If the diffusing substance participates in the chemical reactions responsible for the changes in the properties of the material) for example, water in hydrolytic degradation reactions[37-41]), then in the prediction one must solve the non-stationary kinetic problem taking into account the diffusion of the reactants:

$$\frac{\partial \mu}{\partial t} = D\nabla^2\mu - g(\mu), \tag{16}$$

where $g(\mu)$ is the rate of loss of the diffusing reactant (in units of chemical potential) owing to the chemical reaction. An evident condition for the solution of the problem is the determination of the mechanism and kinetics of the chemical reaction involving the diffusing reactant, which determine the $g(\mu)$ relation and the $Y_j = f(c_1, c_2, \ldots, c_n, a_i)$ relations.

The problem of the influence of atmospheric moisture is particularly important. It is known that, for many constructional polymeric materials, a change in humidity by several hundredths per cent leads to significant changes in operating properties. The endeavour to take into account the influence of moisture in accelerated tests for ageing (the so-called thermal-humidity ageing) is frequently expressed by the fact that tests at elevated temperatures are carried out at the level of the real relative humidity[42-44] (for example, 80 °C and a humidity of 80%). While the humidity under storage conditions is apparently reproduced, such tests can lead to considerable errors since the limiting (equilibrium) moisture content of the material changes significantly as the temperature is altered. This leads to non-equivalent changes in the properties of the material for purely physical reasons.

In order to separate chemical and physical transformations in thermal-humidity ageing, one can employ the method of conditioning the specimens, which consists in the fact that before and during thermal-humidity tests the specimens are maintained at the same relative humidity and temperature until the attainment of a state of equilibrium before measuring the characteristics. The conditioning method is based on the reversibility of the changes in the properties of the material due to physical transformations. The changes in properties detected in the course of tests on the material are due solely to chemical transformations.

The tests involved in estimating the changes in the properties of materials due to physical transformations are carried out by maintaining the specimens at different humidities at a low temperature (20–25 °C). Under these conditions, chemical transformations are hardly manifested during the experiment. The experiments are used to determine the sorption isotherms, the diffusion coefficients, and the $Y_j(a_i)$ relation.

We shall consider the changes in the operating properties of polymeric materials due to chemical transformations in thermal-humidity ageing. The simplest example is the case where the characteristic of the material Y_j investigated is determined by a single type of bond subject to hydrolytic degradation. Assuming that

$$Y_j = \alpha c^n, \quad \frac{dc}{dt} = -k_1 cW, \quad \frac{dW}{dt} = -k_1 cW + k_2(W_e - W), \tag{17}$$

where W and W_e are the current and limiting (equilibrium) moisture contents of the material and k_2 is the mass exchange rate constant, we obtain for the quasi-stationary state ($dW/dt \cong 0$) [45]

$$W = \frac{k_2 W_e}{k_1 c + k_2}, \quad \frac{dc}{dt} = -\frac{k_1 c k_2 W_e}{k_1 c + k_2}. \tag{18}$$

When the process takes place in the kinetic region (for example, in the case of film materials), we have

$$k_2 \gg k_1 c, \quad \frac{dc}{dt} = -k_1 W_e c; \quad \frac{dY_j}{dt} = -\tilde{k}_1 Y_j; \quad \tilde{k}_1 = nk_1 W_e. \tag{19}$$

In the diffusion region

$$k_2 \ll k_1 c, \quad \frac{dc}{dt} = -k_2 W_e; \quad \frac{dY_j}{dt} = -\tilde{k}_2 Y_j^{1-1/n}, \quad \tilde{k}_2 = n\alpha^{1/n} k_2 W_e. \tag{20}$$

Using the equation of the Freundlich isotherm

$$W_e = \chi p^{1/\nu}, \tag{21}$$

the Clausius–Clapeyron equation for equilibrium systems

$$\frac{d \ln p}{d(1/T)} = -\frac{Q}{R} \tag{22}$$

(p is the water vapour pressure, Q the heat of sorption, and χ and ν are coefficients), and the equation for the temperature dependence of the constants k_1 and k_2, it is easy to show that

$$\tilde{k}_1 = a_1 p^{1/\nu} \exp\left(-\frac{U - Q/\nu}{RT}\right); \quad \tilde{k}_2 = a_2 p^{1/\nu} \exp\left(-\frac{E - Q/\nu}{RT}\right), \tag{23}$$

where U and E are respectively the apparent activation energy for the reaction and diffusion and a_1 and a_2 are coefficients.

Eqns.(23) determine the temperature dependence of the effective rate constants $\tilde{k}_1$ and $\tilde{k}_2$ for the variation of the characteristic Y_j. If tests at different temperatures are carried out at $p = \text{const}$., then it follows from Eqn.(23) that the dependences of $\ln \tilde{k}_1$ and $\ln \tilde{k}_2$ on $1/T$ are linear, which makes it possible to employ them for the prediction of the rate of change of Y_j when the material is stored under real conditions. The apparent activation energy is then determined by the differences $U - Q/\nu$ and $E - Q/\nu$ respectively.

If the materials are tested at a constant relative humidity of air ϕ, then, bearing in mind that

$$p = p_{sat} \cdot \varphi; \quad p_{sat} = \lambda \exp(-L/RT) \tag{24}$$

(p_{sat} is the water vapour pressure, L the heat of vaporisation, and λ a coefficient), we obtain

$$\tilde{k}_1 = b_1 \varphi^{1/\nu} \exp\left(-\frac{U - Q/\nu + L/\nu}{RT}\right); \quad \tilde{k}_2 = b_2 \varphi^{1/\nu} \exp\left(-\frac{E - Q/\nu + L/\nu}{RT}\right), \tag{25}$$

where b_1 and b_2 are coefficients. Eqns.(25) also make it possible to use for prediction the linear dependences of $\ln \tilde{k}_1$ and $\ln \tilde{k}_2$ on $1/T$, but naturally with coefficients different to those in Eqn.(23).

The above relations (17)–(25) describe the changes in characteristics occurring in consequence of chemical transformations under the influence of water. The corresponding coefficients can be found from experimental $Y_j(t)$ curves obtained by the method of conditioning the specimens. The overall change in the properties of the material is determined as the sum of the changes due to chemical and physical transformations.

One must note that Eqns.(17)–(25) refer to certain limiting situations. In the general case a correct prediction of the changes in the properties of the material is possible on the basis of the diffusion-kinetic model defined by Eqn.(16).

V. PREDICTION OF THE LIFETIMES OF MATERIALS

Ideas concerning the breakdown of materials as a process occurring in time have come to be generally accepted[47–53]. The breakdown of bodies under the influence of stresses can be regarded as a chemical degradation reaction activated by the stress. Different types of reactions have been analysed in a number of studies[54–58] and in the review of Deyun et al.§

The time before the breakdown of the material under the influence of a constant stress σ under the conditions of a constant temperature is referred to as the lifetime of the material τ. Experimental $\tau(\sigma)$ relations constitute the basis for the prediction of the lifetime. The empirical relations (at $T = \text{const}$.)

$$\tau = A \exp(-\alpha\sigma), \tag{26}$$

$$\tau = B\sigma^{-m}, \tag{27}$$

where α, m, A, and B are coefficients, have come to be most widely used.

Eqn.(26) usually holds for rigid polymeric materials, while Eqn.(27) is valid for elastomers. It has been shown[55,60] that Eqns.(26) and (27) constitute limiting cases of more general $\tau(\sigma)$ relations; the region of their applicability is determined by the extent of the stresses. Eqn.(27) holds as a rule in the region of low stresses and Eqn.(26) in the region of higher stresses. Since in experiments involving the determination of the $\tau(\sigma)$ relation one measures the time before the breakdown of the specimen under the influence of the stress, τ is frequently referred to as the mechanical lifetime.

During storage and use, articles made from polymeric materials are subjected to stresses and temperatures which vary with time. Under these conditions, the lifetime can be calculated on the basis of particular models of the process (physical, chemical, and mechanical)[48,49,55–58,60,61].

The breakdown of the material is characterised by the degree of accumulation of defects. From the standpoint of chemical kinetics, the degree of accumulation of defects in the material is measured by the ratio of the amount of ruptured bonds to the total number of bonds per unit cross-sectional area of the specimen. In the mechanics of continuous media, the ratio of the time of application of the load to the lifetime or ratio of the acting stress to the breaking stress as well as other criteria serve as measures of the extent of damage at a constant acting stress, while under non-stationary conditions the corresponding integral functions serve as the relevant measures. The limiting degree of accumulation of defects, usually set equal to unity, serves as a criterion of the breakdown.

The criteria of Bailey[48,49]

$$\int_0^{t_b} \frac{dt}{\tau(\sigma, T)} = 1, \tag{28}$$

Il'yushin[60]

$$\int_0^{t_b} \frac{d\sigma}{S(t_b - t)} = 1 \tag{29}$$

and others[61,62] have come to be most widely used in engineering practice [in these relations t is the time of application of the load, t_b the time before breakdown, and S the breaking (constant) stress]. Being of phenomenological origin, these criteria have a physical basis in many instances. For example, the applicability of Bailey's criterion has been examined from the standpoint of the kinetics of the development of cracks[63].

Much experience has been gained in engineering practice as regards these criteria and the limitis of their applicability have been established. Bailey's criterion, defined by Eqn. (28), which expresses the principle of the summation of defects but does not take into account the history of the applied load, is the simplest.

In contrast to Bailey's criterion, Il'yushin's criterion, defined by Eqn.(29), reflects the history of the applied load, while non-linear criteria examined in a number of studies[60–62] make it possible to take into account more accurately the complex laws governing the effect of the load and the mechanical behaviour of bodies in terms of empirical coefficients.

As already stated, the breakdown criteria are used to estimate the lifetime of the material (article) under the conditions of a non-stationary stress. The properties of the material are then assumed to be unchanged. Under real storage and operating conditions, the properties of the polymeric material vary owing to ageing, mass transfer, etc. processes. The real lifetime of the material can then differ significantly from the lifetime predicted on the basis of the results of mechanical tests in which the effect of factors other than stresses is usually excluded[63].

§ See E.V.Deyun, G.B.Manelis, E.V.Polianchuk, and L.P.Smirnov, Uspekhi Khim., **49**, 1574 (1980) [Russ.Chem. Rev., No.8 (1980)].

The criteria of long-term strength, extended to the case of physicochemical transformations, will be used to predict the real lifetime. As a simple example, we shall examine Bailey's criterion, which can be formulated as follows in this instance:

$$\int_0^{t_b} \frac{dt}{\tau(\sigma, T, \eta)} = 1, \qquad (30)$$

where η is the extent of the change in the properties of the material owing to physicochemical transformations. Assuming, in accordance with Eqn.(27), that

$$\tau = B(\eta)\sigma^{-m(\eta)} \qquad (31)$$

and taking into account the fact that $\eta = \eta(t)$, we obtain from Eqn.(30) for σ, $T = \text{const.}$,

$$\int_0^{\tau_s} B^{-1}(t)\,\sigma^{m(t)}\,dt = 1, \qquad (32)$$

where τ_s is the time before the breakdown of the material for constant stresses and at a constant temperature (the lifetime). Having established the characteristics of the variation of $B(t)$ and $m(t)$ during ageing, mass exchange, and other transformations, it is possible to calculate the lifetime from Eqn.(32). In the general case calculations by Eqn.(30) or (32) are performed by numerical integration.

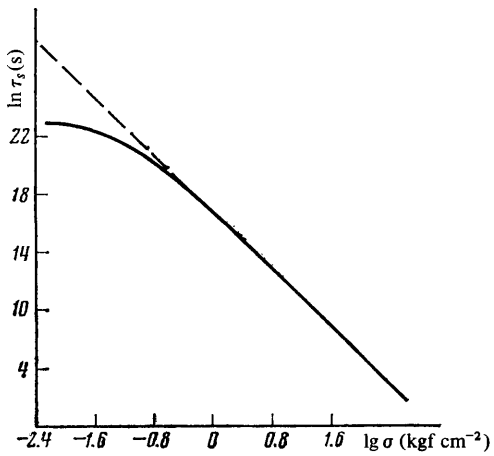

Figure 5. Dependence of $\ln \tau_s$ on $\ln \sigma$ for $B_0 = 10^7$ s, $m = 5$, and $k = 5.7 \times 10^{-9}$ s^{-1} (the curve in the absence of transformations is shown dashed)[64].

In order to elucidate the fundamental characteristics of the $\tau_s(t)$ relation, we shall consider the following example. It is known that, in the ageing of many polymeric materials up to a degree of conversion of 25–50%, the exponent m in Eqn.(27) hardly changes; the variation of the lifetime is due to the variation of the coefficient B. Assuming that the coefficient B changes as a result of ageing in accordance with the first-order equation

$$B = B_0 \exp(-kt), \qquad (33)$$

where k is the rate constant for the ageing process, we obtain, after integrating Eqn.(32),

$$\tau_s = k^{-1} \cdot \ln(1 + kB_0\sigma^{-m}) = k^{-1} \ln(1 + k\tau_0), \qquad (34)$$

where $\tau_0 = B_0\sigma^{-m}$ is the lifetime determined by the action of mechanical stresses. For $k\tau_0(\sigma) \ll 1$, we have

$$\ln(1 + k\tau_0) \simeq k\tau_0; \quad \tau_s \simeq \tau_0. \qquad (35)$$

This condition limits the region where Eqns.(26) and (27) can be used to predict the strength and lifetime of the materials. When $k\tau_0 \gg 1$, we have $\tau_s < \tau_0$, i.e. the real lifetime is shorter than the mechanical lifetime.

Evidently, when $\sigma \gg (kB_0)^{1/m}$, we have

$$\ln \tau_s = \ln B_0 - m \ln \sigma, \qquad (36)$$

and, when $\sigma \ll (kB_0)^{1/m}$, we have

$$\tau_s = k^{-1} \ln(kB_0) - mk^{-1} \ln \sigma\,. \qquad (37)$$

Thus the linear relation $\ln \tau_s = f(\ln \sigma)$ is converted into the linear relation $\tau_s = f(\ln \sigma)$. The lifetime curve constructed by plotting $\ln \tau_s$ against $\ln \sigma$ shows a characteristic inflection (Fig.5). Fig.5 shows that the difference between the lifetimes τ_s and τ_0 for low stresses can reach two decadic orders of magnitude.

This approach to the prediction of the lifetime of a polymeric material under the conditions of physicochemical transformations can be used virtually whatever the law governing the variation of the parameters of the mechanical lifetime and whatever other criteria of long-term strength are employed. A necessary condition for this purpose is the study of the kinetics of the physicochemical transformations and the determination of the relation between the parameters of the mechanical lifetime and the degree of transformation.

VI. ACCELERATED TESTS ON ARTICLES MADE FROM POLYMERIC MATERIALS

Articles made from polymeric materials differ from specimens of the materials in the first place by the presence of stresses due to the geometry and size of the articles and also the external influences to which they are subjected. In order to estimate the lifetime of articles made from polymeric materials, accelerated tests are frequently resorted to, i.e. tests are made on the whole article or on its individual components for the influence of various operating factors (temperature and humidity of the surrounding air, temperature differences, radiation, and applied loads).

Accelerated tests on an article without a detailed elucidation of the characteristic features of the variation of the properties of the relevant materials are frequently regarded as the only method of predicting their lifetime. The task to be performed in selecting the conditions for such tests is believed to involve the modelling of the operating conditions[65]. This approach can hardly be regarded as useful, since a well-founded choice of conditions for the tests is impossible without knowing the characteristics of the variation of the properties of the materials. Furthermore, there is a possibility of the case where the predicted changes in the characteristics of the article under storage and operating conditions can amount to a fraction per cent and complex and expensive tests are then pointless.

We believe that the task of accelerated tests is not the modelling of external factors but the reproduction of the changes in the characteristics of the articles which are to be expected during storage and use. These tests are carried out in order to confirm the predicted changes in the characteristics of the articles under the influence of various factors only in those cases where the predicted changes are significant and have a negative influence on the suitability of the material for its purpose and when allowance for the changes in all the characteristics of the article is difficult. The conditions of accelerated tests on articles can be chosen only on

the basis of the study of the kinetics of the variation of the characteristics of the materials. The parameters of the tests are selected on the basis of the condition that identical changes in the operating properties of the polymeric material under operating conditions are reproduced in the accelerated tests:

$$\Delta Y_j(t_0, \chi_0) = \Delta Y_j(t_a, \chi_a). \quad (38)$$

where t_0 and t_a are the storage time and the duration of accelerated tests and χ_0 and χ_a are the parameters of the storage conditions and the conditions of the accelerated tests (temperature, stress, relative humidity, radiation dose, etc.). Tests designed to reproduce the changes in the properties of the material during ageing, mass transfer, and under the influence of stresses are special cases.

Tests for thermal ageing are carried out by maintaining the article at a specified constant temperature T_a during the so-called equivalent time t_a. In simple cases where the change in Y_j is described by Eqn.(9), the time t_a can be calculated from the relation[65,66]

$$t_a = t_0 \exp\left[\frac{U}{R}\left(\frac{1}{T_a} - \frac{1}{T_0}\right)\right]. \quad (39)$$

Calculation of the equivalent time t_a by Eqn.(39) without taking into account the specific kinetic features of $Y_j(t)$ can lead to significant errors. The most general method for the determination of t_a therefore consists of the following steps. On the basis of the known kinetics of the variation of the characteristic of the material during ageing, one plots the predicted curve $Y_j(t)$ for specified storage conditions ($T = T_0$) and the curve $Y_j(t)$ under forced conditions ($T = T_a$). The greatest changes in Y_j are determined from the predicted curve and the time t_a corresponding to the attainment of these changes at $T = T_a$ is found (Fig.6). One must then bear in mind that in the case of complex processes the maximum changes in properties cannot always be reproduced in accelerated tests. Thus, for processes described by Eqn.(8), there exists a temperature T_* above which no changes occurring under real storage conditions can be reproduced owing to the inversion of the curves $Y_j(t)$. This is in no way caused by a change in the mechanism of the processes but is due to a change in the ratio of their rate constants. The quantity T_* is defined by the expression

$$T_* = \frac{U_1 - U_2}{R \ln (A_1/A_2)}, \quad (40)$$

where U_1 and U_2 are apparent activation energies and A_1 and A_2 are the pre-exponential factors associated with the corresponding rate constants. One should bear in mind that, when $T < T_*$, it is possible to reproduce only those changes which do not exceed the level corresponding to T_a.

In accelerated tests on articles made from different polymeric materials the problem of the simulation of several processes arises. The choice of the equivalent times t_a on the basis of the apparent activation energy for a certain process in any given material can lead to unduly extensive or, conversely, insufficient transformations in other materials. Analysis shows that the problem of the reproduction of the real changes in Y_j in a multielement article can be solved rigorously only in a few instances. These include cases where Eqn.(9) holds for each element (material) and there is a definite relation between the kinetic parameters[66].

The parameters of the conditions of accelerated tests for the influence of mass transfer processes can also be chosen from the condition for the attainment of identical changes in properties during storage and accelerated tests. For this purpose, one calculates from the solution of mass transfer equations the change in the concentration of the diffusing substance under storage conditions and in accelerated tests: $a_i = f(t, r)$. Using the relation $Y_j = f(a_i)$, one plots on the basis of the data obtained the curves $Y_j = f(t, r)$ from which one determines the duration of the tests in accordance with the scheme illustrated in Fig.6. In this case accelerated tests are carried out at an elevated temperature and concentration of the diffusing substance (for example, atmospheric moisture). These tests can be combined with tests of the reproducibility of the changes in the properties of the material during ageing.

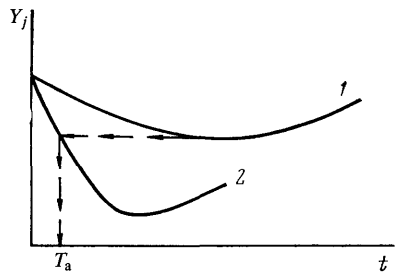

Figure 6. Selection of the duration of tests: 1) predicted $Y_j(t)$ curve describing the variation of the characteristics of the material under the conditions of storage or use at $T = T_0$; 2) the curve describing the variation of the characteristics of the material under the conditions of accelerated tests at $T = T_a$.

Under the storage conditions, articles made from polymeric materials are subjected to prolonged stresses. These include stresses due to gravitational forces, stationary and non-stationary temperature stresses induced by seasonal and diurnal changes in temperature, etc. Well-founded conditions for accelerated tests, designed to check the influence of various forces (the level of stresses, amplitude, temperature, duration), are selected on the basis of identity conditions in the accumulation of defects during storage and accelerated tests[66]:

$$\pi(T_0, \sigma_0^e, \eta_0, t_0) = \pi(T_a, \sigma_a^e, \eta_a, t_a), \quad (41)$$

where π is the level of accumulated defects and σ^e are equivalent stresses in the article. When Bailey's integral is used as a measure of the accumulation of defects (π), the above condition is formulated as follows:

$$\int_0^{t_0} \frac{dt}{\tau(\sigma_0^e, T_0, \eta_0)} = \int_0^{t_a} \frac{dt}{\tau(\sigma_a^e, T_a, \eta_a)}. \quad (42)$$

Consider the following example. We assume that the article made from a polymeric material is stored at a temperature T_0 and is subjected to a stress σ_0^e during a period t_0. The corresponding quantities σ_a^e and T_a are chosen for the accelerated tests. Assuming for simplicity that $\eta_0 = \eta_a = 0$, we obtain from Eqn.(42)

$$t_a = t_0 \frac{\tau(\sigma_a^e, T_a)}{\tau(\sigma_0^e, T_0)}. \quad (43)$$

In this case, when the relation $\tau(\sigma)$ is determined by Eqn. (27), we have, for $T_a = T_0$,

$$t_a = t_0 \left(\frac{\sigma_0^e}{\sigma_a^e}\right)^m. \quad (44)$$

Since for a polymeric material we usually have $m > 6$, the increase of stresses under the conditions of accelerated tests makes it possible to reduce greatly their duration. For example, for $\sigma_a^e = 2\sigma_0^e$ and $m = 7$, we obtain $t_a < 0.01 t_0$ when $T_a = T_0$.

For an exponential relation between the lifetime and σ [Eqn. (26)], it follows from Eqn.(43) that

$$t_a = t_0 \exp [\alpha (\sigma_0^e - \sigma_a^e)]. \quad (45)$$

When $\sigma = \text{const.}$, the following relation usually holds[48,49]:

$$\tau = p \exp (U_b/RT) \quad (46)$$

where U_b is the apparent activation energy for the breakdown and p a coefficient. It follows from Eqns.(43) and (46) that, when $\sigma_a^e = \sigma_0^e$,

$$t_a = t_0 \exp \left[\frac{U_b}{R} \left(\frac{1}{T_a} - \frac{1}{T_0} \right) \right]. \quad (47)$$

The above relations indicate the possibility of intensifying accelerated tests on articles by the application of forces and elevated temperatures.

This approach can be used also in tests for cyclic influences of forces[66]. From Eqn.(41), one can calculate the time during which articles must be thermostatted at negative temperatures and the number of cycles simulating the influence of diurnal oscillations in temperature.

---o0o---

It follows from the foregoing that the endeavour to simplify unduly the methods for the interpretation of kinetic curves and the determination of the parameters of accelerated tests can lead to gross errors, including qualitative errors.

A correct prediction is based on the study of the kinetics of the variation of the properties of materials under the influence of various factors and the mechanisms of the processes taking place.

Kinetic Models for the Prediction of the Lifetime of Polymeric Materials

E.V.Deyun, G.B.Manelis, E.B.Polianchik, and L.P.Smirnov

Theoretical and experimental data for the degradation of polymers under the influence of mechanical stresses are surveyed from the standpoints of chemical physics. Kinetic models for the bulk-phase breakdown of polymers are examined and an approach is formulated to the prediction of the lifetime of articles made from polymeric materials.
The bibliography includes 123 references.

I. INTRODUCTION

One of the principal problems which the theory and practical applications of polymeric materials face as a result of progress in science and engineering is a quantitative prediction of the useful lifetime of polymeric materials and control of their stability[1]. The urgency of these problems is due to the expansion of the fields in which polymeric materials are applied, the wide variety of types of polymeric articles, the regimes and conditions under which they are employed, and the increase in the number of classes of polymers used; it is also associated with the need to solve problems involving ways of insuring the reliability of polymeric articles, the choice of the optimum polymeric material for a particular article, the design of a polymeric material, etc.

In technology, medicine, and other fields polymers are used mainly as constructional materials. The stability (lifetime) of a particular construction comprising a given polymer under specified conditions and operating regimes can be characterised by the time during which the article either breaks down or undergoes significant changes in its shape and dimensions, as a result of which the construction loses its suitability for the prescribed purpose. Problems of the stability of polymeric articles are considered below from the standpoint of their breakdown under the influence of mechanical forces.

The review does not deal with the characteristics of the breakdown of composite polymeric materials. Experimental and theoretical studies devoted to this problem are being published with an increasing frequency and their analysis requires a special survey.

II. THEORY OF THE BREAKDOWN OF SOLIDS

There is at present no unanimous view on the breakdown of solids, particularly polymers; there is therefore no generally accepted mathematical procedure whereby one could estimate quantitatively the strength characteristics, predict their changes during use, and determine the conditions under which breakdown occurs. It is possible to distinguish two main and to a large extent conflicting views on the breakdown process—static and kinetic[2-4].

The traditional view on the breakdown process is that breakdown is a critical event. In the mechanics of continuous media and in physical theories taking into account the atomic-molecular structure of bodies the static approach to the problem of strength involves the introduction of concepts of limiting states and ultimate strengths[3,5]. There is a whole series of theories of the limiting state, each of which is based on specific hypotheses concerning the breakdown condition. A common feature of all these theories is the claim that the breakdown of any body occurs when a certain function of the components of the stresses and deformation tensors or the deformation energy exceeds a specific quantity $C_{\lim}$, which is believed to be a fundamental physical constant of the given body[2,3,6]. In practice it is very often assumed that breakdown occurs if one of the principal stresses reaches its limiting value $\sigma_{\lim}$, which can be determined experimentally by testing a material for rupture on extension and under so-called standard conditions (at a specified constant temperature, pressure, and rate of deformation).[3,7] Together with $\sigma_{\lim}$, $\varepsilon_{\lim}$—the maximum deformation determined under standard conditions—is used as the ultimate strength[3,8].

The experimental studies of the breakdown of many materials established a series of facts indicating the kinetic nature of the process: it has been shown that the limiting characteristics ($\sigma_{\lim}$, $\varepsilon_{\lim}$) depend on the regime and conditions under which the tests are carried out (preliminary load, rate of deformation, and temperature)[7-10]; it has been established that the breakdown of a body occurs also following the application of stresses weaker than the ultimate strength $\sigma_{\lim}$; under these conditions, the weaker the stress the longer the lifetime of the specimen under load, until the instant of rupture t_r.[4,11-13] Systematic studies on hundreds of objects (inorganic salts, metals, alloys, polymers, and composite materials) established that the dependence of t_r on the temperature T and on the stress σ for materials of different chemical types is the same and can be described by the equation

$$t_r = t_0 \exp \frac{U_0 - \gamma\sigma}{RT}, \qquad (1)$$

where t_0, U_0, and γ are constants of the material.

Attempts to explain the conflict between the assumption of the critical nature of breakdown and the time dependence of strength and hence to develop a mathematical procedure which could take into account the fact that the breakdown is a function of time, whilst retaining the static approach, have been frequently made[14-18].

Thus the kinetic nature of the breakdown of polymers is frequently related to the characteristic features of the behaviour of polymeric materials, consisting in a significant alteration of their limiting characteristics as a function of time under the influence of heat, moisture, and many other factors[7,19-21]. The decrease of the limiting characteristics $C_{\lim}$ is usually defined as the ageing of the material and its increase is believed to be due to structure formation processes (crystallisation, orientation of macromolecules, etc). In the

prediction of the time corresponding to the breakdown of the polymeric structure within the framework of the static approach to breakdown, but with allowance for thermal ageing, the kinetic parameters describing the time variation of C_{lim} are usually determined experimentally by accelerated tests[7,22]. The method consists in maintaining specimens at elevated temperatures for specified periods without the application of mechanical stresses, this being followed by the determination of the limiting characteristics under standard conditions and by the calculation from the $C_{lim}(t)$ kinetic curves obtained, of the activation energy and the pre-exponential factor and the determination of the kinetic law of the reaction. When the results are extrapolated to the temperature range in which the given polymeric material is actually used, it is assumed that the characteristics of the variation of C_{lim} determined in the tests are maintained.

In order to describe the kinetics of the ageing and structure formation process, the combined graphical and analytical method[23,24] is used together with the mathematical procedure employed in describing the kinetics of chemical reactions[22,25], which, incidentally, is not justified from the theoretical point of view, because the relation between the limiting properties and the concentration of the chemical groups and bonds has not been established. The time of the breakdown of the object is determined in this approach as the time of attainment at any point in the construction of equality between C_{lim}, calculated for the operating conditions and regime for the given construction, and the value of this characteristic calculated in the analysis of the strained-deformed state of the construction under the given conditions (Fig.1). We emphasise that here one assumes in essence that the kinetics of the variation of the limiting characteristic $C_{lim}(t)$ are determined solely by the law governing the variation of the temperature $T(t)$ and are independent of the stress $\sigma(t)$.

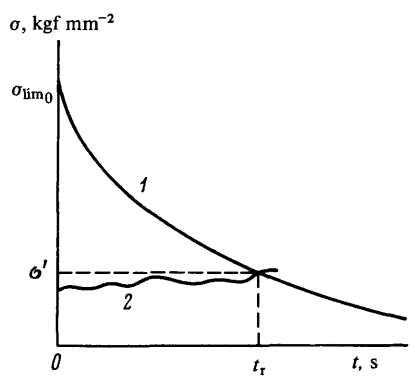

Figure 1. Scheme for the prediction of the breakdown time of a polymeric object taking into account the thermal ageing of the polymer: *1*) kinetic $\sigma_{lim}(t)$ curve for the given polymeric material under the operating conditions and regime of a specific construction; *2*) law governing the variation of the stress $\sigma(t)$ at a characteristic point for the given object under specified operating conditions and regime.

It can be shown that in this approach the activation energy for the breakdown process is equal to the activation energy for the ageing process E_{age} and is independent of σ, while the $t_r(\sigma)$ relation is much less pronounced than the relation described by Eqn.(1). Indeed, it is evident, for example, in the case of the variation of σ_{lim} during ageing in accordance with the first-order equation $\sigma_{lim} = \sigma_{lim_0}\exp(-kt)$, where $k = k_0\exp(-E_{age}/RT)$, that the relation $t_r(T, \sigma)$ should be described by the equation

$$t_r = \frac{\ln \lim 0/\sigma'}{k_0} \exp \frac{E_{age}}{RT}, \qquad (2)$$

where σ' is the stress at the instant of breakdown and σ_{lim0} is the ultimate strength of the initial "non-aged" material. Thus allowance for the thermal ageing of polymeric materials does not explain satisfactorily the inconsistency between the concept of breakdown as a critical, limiting event and the experimental time variation of strength described by Eqn.(1).

It has been suggested that the kinetic nature of breakdown be taken into account by introducing into Griffith's formula[26] for the ultimate strength of a solid with a crack of length l_{cr}, i.e.

$$\sigma_{lim} = [2wE/\pi(1-\nu^2)l_{cr}]^{0,5} \qquad (3)$$

the relation between Young's modulus E and the rate of deformation[14] or by replacing Young's modulus by the relaxation modulus $E(t)$ and taking into account the time variation of the cohesive energy of breakdown w.[15]

Detailed analysis of the time variation of the strength of solids and direct studies of the elementary reactions occurring in polymers subjected to a mechanical load led to the conclusion[4] that the time variation is not determined by the accompanying processes (such as the sorption of moisture[16], the redistribution of stresses in heterogeneous materials[17], etc.) but is inherent in the very mechanism of the breakdown. Experimental study of the $t_r(T, \sigma)$ relation together with theoretical ideas concerning the decrease of the energy barrier in the force field served as a basis for the creation of a kinetic theory of the strength of solids, which constitutes the second of the possible approaches to the breakdown process. According to this theory[4], the external mechanical force does not as a rule itself lead to the rupture of interatomic bonds; by deforming these bonds, it merely accelerates the breakdown process, reducing the activation barrier. The rupture of strained interatomic bonds takes place as a function of time under the influence of the thermal movement of atoms (thermal fluctuations).

III. KINETIC MODELS OF THE BULK PHASE BREAKDOWN OF POLYMERS

In a number of studies the kinetics of the bulk-phase breakdown of solids are described on the basis of a phenomenological approach[2,27-31]. Some investigators, for example, Il'yushin and Pobedrya[2] and Moskvitin[3], introduced the concept of the vulnerability of the material ω; the physical significance of the vulnerability is not defined, but it is assumed that during the breakdown process the ω increases from 0 to 1 and that on breakdown $\omega = 1$.

On the basis of general considerations, according to which the rate of change of vulnerability should increase with increase of σ and should tend to a maximum reached directly before macroscopic breakdown, it has been suggested that the kinetic equations for the vulnerability be formulated as follows[27,28]:

$$\frac{d\omega}{dt} = A\sigma^{\beta}/(1-\gamma\omega)^{p}, \qquad (4)$$

where A, p, β, and γ are constants.

Since it has been noted[2] that Eqn.(4) does not agree well with experimental data for $\sigma \neq$ const., it has been suggested[29] that a new parameter q, the rate of change of which is related to the rate of change of σ, be introduced into this formula.

The theory of long-term strength described in the monograph of Il'yushin and Pobedrya[2], introduces the concept of the vulnerability (susceptibility to damage) tensor $P(p_{ij})$ with the components

$$p_{ij} = \int_0^t \varphi_{ijkl}(t-\tau)\,\sigma_{kl}(\tau)\,d\tau, \qquad (5)$$

and it is suggested that in the absence of stresses during a time interval $0 \leq t \leq t'$ all the components of the tensor P are zero, i.e. the breakdown of a "non-ageing" material is considered.

Although breakdown is considered in the above and similar studies as a process developing as a function of time, its physicochemical nature is not taken into consideration. This is responsible for limitations in the employment of relations of this kind, which are characteristic of phenomenological theories[32].

Attempts have been made frequently to create a mathematical procedure for the description of the kinetics of breakdown which would be able to take into account adequately and physicochemical processes occurring in the solid when the latter is acted upon by external mechanical forces[4,33-45]. However, while postulating a particular dependence on temperature and applied stress of the probability of the breakdown of strained interatomic bonds, the authors of these studies confined themselves to determining the type of relation $t_r(t, \sigma)$; furthermore, they considered (with a single exception[46]) only simple kinetic schemes. In some of these studies arbitrary and sometimes contradictory assumptions were made: in particular, in formulating the expression for the rate of rupture of strained bonds at constant T and σ, account was taken of the dependence of this rate on the current concentration of the strained bonds, but the increased number of ruptured bonds was disregarded[41-43].

Together with the differential relations for the description of the bulk-phase breakdown, integral equations have also been proposed[4,47,48]. Thus, in predicting the lifetime of polymers on extension with time-dependent stress and temperature, the principle of the summation of the contributions to breakdown is used in the form of the relation

$$\int_0^{t_r} \frac{dt}{t_r[\sigma(t), T(t)]} = 1, \qquad (6)$$

called Bailey's integral. Eqn.(1) or the expression

$$t_r = B\sigma^{-b} \exp \frac{U_0}{RT}, \qquad (7)$$

proposed for the description of the lifetime of elastomers[12], is then used normally as the function $t_r(T, \sigma)$. However, it has been noted that, in this approach to the prediction of the useful lifetime of polymeric materials under load, the error is low only for a single application of a load with a complex relation $\sigma(t)$ and also for the application of a load for a small number of cycles[4,47,48]. It must be emphasised that the use of integral relations of type (6) for the description of the kinetic process under variable conditions, which determine its rate (particularly for the determination of t_r with $\sigma \neq$ const. or $T \neq$ const) is possible, according to the principal postulates of chemical kinetics, only when the rate of the given process is independent of the degree of completion of the process.

A sufficient amount of experimental data, demonstrating convincingly the common features of the mechanisms of different types of degradation of polymers, particularly mechanical breakdown and thermal degradation, has now accumulated. The application of modern physicochemical research techniques and comparison of the experimental relations governing mechanical breakdown and thermal degradation made it possible to show that, in polymers acted upon by stretching stresses, chemical reactions take place whose nature is identical to that of the reactions occurring in the thermal degradation of the polymers[4]. Thus, in many of the instances investigated, the activation energy for the mechanical breakdown of the polymer U_0 proved to be close to the activation energy for its thermal decomposition E_T[4,49-52]. The identity of the intermediate and final products of these processes has been observed[4,53-60] and it has been shown that the variation of the molecular weight distribution is identical[4,61-62]; the increase of the lifetime following the introduction of inhibitors and antioxidants[21,63-65] and the decrease of the lifetime after the addition of sources of free radicals[4,66,67] have been demonstrated.

Thus the mechanical breakdown of polymers can be regarded as a chemical reaction involving the dissociation of interatomic bonds subjected to a mechanical load and the rate of dissociation of the strained bonds is determined not only by the temperature and degree of reaction, as in thermal degradation, but also by the magnitude of the stretching stress. We may note that an analogous influence on the rate of the process is shown by mechanical stresses also for other types of degradation of polymers (hydrolytic[68-70], thermo-oxidative[71], and photothermal[4]). The mechanical initiation of chemical reactions in solids has been examined in a series of studies[72-75].

Thus, from the standpoint of chemical physics, the degradation of polymers is a multifactorial process, the rate of which depends on temperature, the action of various chemical agents (water, oxygen, etc.), irradiation, and mechanical stresses. Depending on the combination of these factors acting on the polymer, it is possible to distinguish thermal, thermo-oxidative, hydrolytic, photothermal, and other types of degradation, and among them different types of mechanical degradation of polymers (mechanothermal, mechanothermo-oxidative, mechano-hydrolytic etc.). In conformity with the foregoing, one can assume that mechanical stresses (and apparently also irradiation[76]) cannot alter the mechanism of the reactions involving the degradation of polymers and that the corresponding types of mechanical degradation include the same elementary stages as degradation in the absence of stresses; however, the ratio of the rates of the individual stages changes significantly under these conditions as a function of the active factors determined by external conditions. For example, mechanical stresses under the conditions of a radical chain degradation mechanism activate the chain initiation process and apparently, to a lesser extent, the chain propagation process. Accordingly, the rate of chain initiation is much higher as a rule in photothermal degradation than in thermal degradation of polymers.

Thus in the most general case the problem of predicting the lifetime of a polymeric object requires, firstly, the determination of the chemical mechanism of the degradation of the given polymer, and the elucidation of the set of elementary stages of the process and of the dependence of the rates of these stages on the temperature T and the stress σ, the irradiation intensity I, and the concentrations c_i of the possible reactants and reaction products, and secondly, the determination from the operating conditions and regime for the given object of the laws governing the variation of $T(t)$, $\sigma(t)$, $I(t)$, and $c(t)$ at the characteristic points of the object. The determination of the stability of the polymeric object

must be based on the solution of the appropriate equations for the degradation kinetics subject to the observed laws governing the time variation of T, σ, I, and c_i.

In the general case this problem is extremely complex; comparatively simple special cases of the problem have now been analysed[77-88]. In the analysis it was assumed that the influence of the mechanical field on the rate of reaction reduces to the alteration of the energy barrier to the dissociation of the interatomic bond E_0. We may note that calculations performed taking into account the interaction between the atoms with the aid of the Morse potential[44,89-91] established that the dependence of the energy barrier E on the tension f in the chemical bond is non-linear, but allows a linear fit within a comparatively wide range of values of f. Then, assuming that the load is uniformly distributed along all the bearing bonds and taking into account the fact that, for a constant σ, the accumulation of breaks in the bonds leads to an increase of the tension in the surviving bonds, one can write

$$E(\sigma) = E_0 - \alpha\sigma n_0/n, \qquad (8)$$

where n_0 is the initial concentration of the bearing bonds, n the current concentration of the bearing bonds, and α a coefficient determined by the nature and structure of the substance.

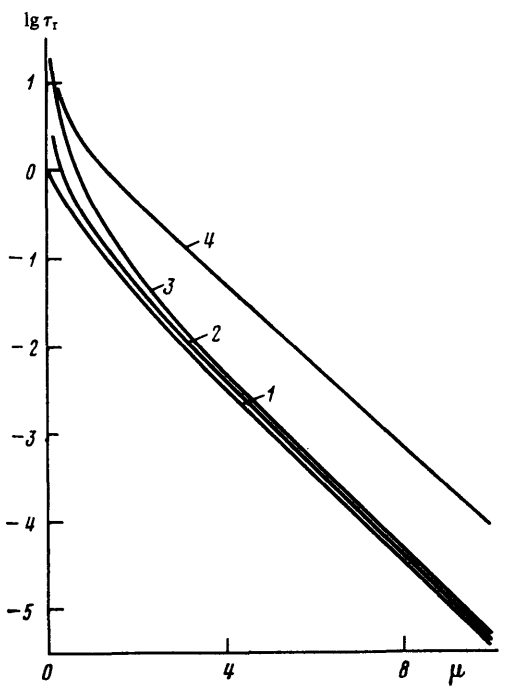

Figure 2. The $\lg \tau_r(\mu)$ relation for $\phi(\Pi) = 1$ (curve *1*), $1-\Pi$ (curve *2*), $(1-\Pi)^2$ (curve 3), and $(1-\Pi)(0.01+\Pi)$ (curve *4*).[77,78]

In the case of a simple irreversible reaction, the rate of mechanical degradation at constant T and σ can be described by the following dimensionless equation[77-79]:

$$\frac{d\Pi}{d\tau} = \varphi(\Pi)\exp\frac{\mu}{1-\Pi}, \qquad (9)$$

where $\Pi = 1-n/n_0$ is the relative concentration of the broken bearing bonds (the degree of accumulation of defects), $\mu = \alpha\sigma/RT$ the parameter characterising the intensity of the mechanical field, $\phi(\Pi)$ the kinetic law governing the reaction, $\tau = ktn_0^{m-1}$ the dimensionless time, $k = k_0\exp(-E_0/RT)$ the rate constant for the chemical reaction, k_0 the pre-exponential factor, and m the order of the reaction.

Eqn.(9) can be readily integrated. The dimensionless lifetime τ_r (corresponding to $\Pi = 1$) is determined solely by μ and $\phi(\Pi)$, i.e. the dependence of $\tau_r(\mu)$ for the given type of $\phi(\Pi)$ is universal. The $\lg \tau_r(\mu)$ curves plotted for different $\phi(\Pi)$ are non-linear for low values of μ and, when $\mu > 2$, they can be described with satisfactory accuracy by a linear equation (Fig.2), i.e. the following expression can be formulated in a dimensional form for the time variation in the region of high stresses ($\mu > 2$):

$$t_r = \frac{a}{k_0}\exp\frac{E_0 - b\alpha\sigma}{RT}, \qquad (10)$$

the expression being analogous to Eqn.(1). In the region where $\mu < 2$ the observed $\tau_r(\mu)$ relations are described satisfactorily by Eqn.(7). We may note that the deviation of the $\lg t_r(\sigma)$ relation from linearity under the conditions of low stresses has been observed experimentally in all the cases investigated[4].

The $\Pi(\tau)$ kinetic curves are of the self-accelerating type regardless of the form of $\phi(\Pi)$ and it is possible to distinguish qualitatively two stages in the development of the process: at the beginning a comparatively slow increase in the concentration of the ruptured bearing bonds, proceeding almost at a constant rate, followed by a rapid "avalanche like" increase. The degree of accumulation of defects Π^* for which there is a transition from the slow to the rapid stage of the process diminishes with increase of the parameter μ. The kinetic curves for the formation of volatile products[92] and for the change in light transmission[93] in the mechanothermal degradation of polystyrene are identical in form to the $\Pi(\tau)$ curve for a simple irreversible reaction.

The rate of thermal degradation of polymers is frequently described by equations for *two simultaneous first-order reactions*, which can be accounted for by the presence in the initial polymer of kinetically non-equivalent so-called strong and weak bonds. the difference between the activation energies for the radical-chain thermal degradation involving initiation via the strong and weak bonds being capable of reaching from 1–3 to several tens kcal mol^{-1}, while the initiation of degradation via the rupture of weak bonds give rise to a conversion of the polymer up to 10–30%.[40-52,94-96]

The equations for the mechanothermal degradation in the case under consideration can be formulated in a dimensionless form in the following way[78,79]:

$$\frac{d\Pi_1}{d\tau} = (1-\Pi_1)\exp\frac{\mu_1}{1-\Pi}, \qquad \frac{d\Pi_2}{d\tau} = \varkappa(1-\Pi_2)\exp\frac{\mu_2}{1-\Pi}, \qquad (11)$$

where $\Pi_1 = 1-n_1/n_0$ is the extent of accumulation of defects in the strong bonds, $\Pi_2 = 1-n_2/n_0$ the extent of accumulation of defects in the weak bonds, $\tau = k_1 t$ the dimensionless time, $\varkappa = k_2/k_1$ a parameter equal to the ratio of the rate constants for the degradation of the weak and strong bonds, $\Pi = c\Pi_1 + (1-c)\Pi_2$ the overall extent of accumulation of defects, and c the fraction of the strong bonds.

For comparatively low values of $\varkappa$(~10), the $\Pi(\tau)$ curves do not differ qualitatively from the corresponding curves in the case of a single simple reaction. For $\varkappa > 10^2$–10^3, the kinetic $\Pi(\tau)$ curves have three sections: initially the rate of accumulation of defects gradually diminishes with time, then there is

a more or less low-slope section of the curve, and at the end of the process the accumulation of defects proceeds at a very high rate. The first stage is largely determined by the rupture of the weak bonds: hence the $\Pi_2(\tau)$ relation can be described by a first-order equation. The length of the low-slope section of the $\Pi(\tau)$ curve diminishes with decrease of c and, when $c < 1-\Pi^*$, the $\Pi(\tau)$ curve degenerates into one characteristic of the model with kinetically equivalent bonds. The lifetime τ_r is then determined by the kinetic parameters of the weak bonds.

For low values of κ, the $\lg \tau_r(\mu)$ relation for all values of the parameter c retains the same nature as in the case of a simple unidirectional reaction. When the fractions of the weak and strong bonds are approximately equal, then, for sufficiently high values of $\kappa(\kappa \geq 10^3)$, the relation becomes non-linear over a wider range of variation of the parameter μ and can be described by two linear sections, the slope of the linear section of the $\lg \tau_r(\mu)$ relation being higher for low values of μ than for high values of μ.

The hypothesis that the mechanothermal degradation is reversible has been put forward in connection with the discussion of certain characteristics of the variation of the lifetime of solids of different chemical types observed under the conditions of relatively small stresses and high temperatures[97]. Previously an analogous degradative recombination mechanism had been proposed to describe the so-called chemical flow of cross-linked elastomers[98]. For a reversible reaction, the rate of mechanothermal degradation can be described by the following dimensionless equation[78-81]:

$$\frac{d\Pi}{d\tau} = (1-\Pi)^{m_1} \exp\left(\frac{\mu}{1-\Pi}\right) - \frac{\Pi^{m_2}}{\kappa}, \qquad (12)$$

where $\tau = k' t n_0^{m_1-1}$ is the dimensionless time, $\kappa = k' n_0^{m_1-1}$. .$^2/k''$ a dimensionless parameter characterising the ratio of the dissociation (k') and recombination (k'') rate constants, and m_1 and m_2 are the orders of the bond dissociation reaction and of the reaction involving the recombination and rupture of bonds respectively.

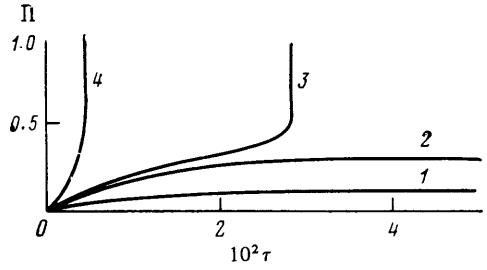

Figure 3. Kinetic curves for the accumulation of defects $\Pi(\tau)$ with $m_1 = 1$, $m_2 = 2$, $\kappa = 1.7 \times 10^{-3}$ and different values of μ: *1*) 2; *2*) 3; *3*) 3.1; *4*) 4.[78,79]

For this system, described by Eqn.(12), there exists a range of parameters μ and κ in which there is a possibility of a transition from a stationary to a non-stationary regime for a small change in external conditions, i.e., critical phenomena can arise. The specific form of the critical conditions $\mu_{cr} = \mu(\kappa)$ for specified pairs of values m_1 and m_2 can be readily found with the aid of Semenova's method. The nature of the $\Pi(\tau)$ curves changes sharply when μ passes through μ_{cr}: for $\mu < \mu_{cr}$, a stationary concentration of the ruptured bonds is established and there is no breakdown (the region of safe stresses); for $\mu > \mu_{cr}$, the process terminates with complete rupture of the bearing bonds (Fig.3). The influence of the reaction involving the recombination of the ruptured bonds on τ_r is significant only for values of μ slightly exceeding μ_{cr}: in this case the time taken to traverse a small (with respect to the values of Π) region, where the overall rate of breakdown is minimal, makes the main contribution to the lifetime of this specimen. For large values of μ (when $e^{\mu} \gg \kappa^{-1}$), the influence of the recombination of the ruptured bonds on the mechanothermal degradation becomes insignificant, and the $\tau_r(\mu)$ relation can be represented by Eqn.(10), obtained for a simple unidirectional reaction (Fig.4). We may note that the existence of safe stresses has been observed experimentally in the study of the mechanothermal degradation of cross-linked elastomers[99].

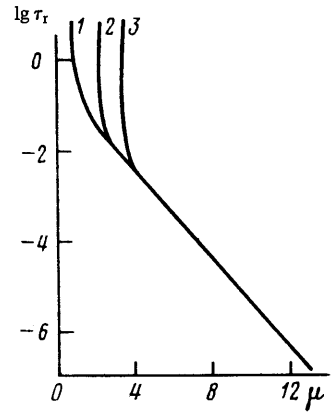

Figure 4. The $\lg \tau_r(\mu)$ relation with $m_1 = 1$, $m_2 = 2$, and different values of κ: *1*) 0.2; *2*) 10^{-2}; *3*) 10^{-3}.[78,79]

A radical-chain mechanism was proposed for the first time by Zakrevskii[46] in order to describe the kinetic characteristics of the breakdown of polymers. However, it dealt only with the initial stage of the process and no account was taken of the redistribution of the load on the surviving bearing bonds with increase of the number of ruptured bonds. The breakdown process proceeding via a radical-chain mechanism has been modelled in a number of studies[82-85]. The kinetic scheme for the process examined by Deyun et al.[83] includes the following stages: (1) the stress-activated initiation of the kinetic chain via the rupture of strained bonds in the macromolecules P_n, leading to the formation of terminal radicals R_t; (2) the depolymerisation of R_t as a result of the abstraction of the monomer P_2; (3) chain transfer in the interaction of R_t with P_n involving the formation of a central radical R_{ce}; (4) the stress-activated decomposition of R_{ce} with formation of R_t and molecules containing a double bond: (5) the migration of the free valence in R_{ce}, hindered by stresses, as a result of which R_{ce} is converted into R_t; (6) termination of the kinetic chain via the disproportionation or recombination of R_t.

Analysis of the corresponding kinetic equations using the method of quasi-stationary concentrations showed that, depending on the ratio of the parameters of the above equations, it is possible to distinguish three ranges of stresses

within the limits of which the $t_r(T, \sigma)$ relation is described by Eqn.(1) but with different values of U_0, t_0, and γ for each section, the values being complex combinations of the corresponding parameters of the elementary stages (see Table). A characteristic feature of the model of the breakdown of polymers under consideration is the establishment of quasi-stationary radical concentrations for relatively low stresses (regimes I and II); here the rate of mechanothermodegradation in regime I is limited by the decomposition of R_{ce} (stage 4), and that in regime II is limited by chain transfer (stage 3). For fairly large stresses (regime III), the radical concentrations are non-stationary throughout the process whose rate is determined by the initiation stage; thus in regime III the radical-chain process mechanism degenerates into a radical mechanism. The existence of the above three regimes in the mechanothermodegradation of polymers has been confirmed in a whole series of studies[62,100-107] and both types of breaks in the $\lg t_r(\sigma)$ relation, indicated in Fig.5, were noted. The presence of such breaks is usually attributed not to a radical-chain process mechanism but to the existence of a functional relation between the coefficient γ of Eqn.(1) and the temperature and stress due to the sharp alteration of the mobility of the side groups of the macromolecules[100,102].

Relation between the parameters of Eqn.(1) for the time variation of the strength and the constants of the elementary stages of mechanothermodegradation proceeding via a radical-chain mechanism*.[84]

Regime	U_0	t_0	γ
I	$\frac{E_{01}-E_{06}}{2}+E_{03}+E_{04}-E_{05}$	$\frac{(k_{06}/k_{01}P_0)^{0.5}RTk_{05}}{2^{1.5}k_{03}k_{04}n_0^{2.5}(0.5\alpha_1+\alpha_4+\alpha_5)\sigma}$	$\frac{\alpha_1}{2}+\alpha_4+\alpha_5$
II	$\frac{E_{01}-E_{06}}{2}+E_{03}$	$\frac{(k_{06}/k_{01}P_0)^{0.5}RT}{2^{1.5}k_{03}n_0^{1.5}\alpha_1\sigma}$	$\frac{\alpha_1}{2}$
III	E_{01}	$\frac{RT}{k_{01}n_0\alpha_1\sigma}$	α_1

*E_{0i}, k_{0i}, and α_i are respectively the activation energy, pre-exponential factor, and the structure-sensitive coefficient of the ith elementary stage and P_0 is the initial concentration of macromolecules.

The results of the calculation by the tabulated formulae of the values of U_0 and t_0 for a series of polymers [polyethylene, polypropylene, poly(vinyl chloride), polystyrene, poly(methyl methacrylate), and polyacrylonitrile], obtained using the literature values of the rate constants for the elementary stages of the thermal degradation of the corresponding polymers, in most cases agree satisfactorily with the experimental values of U_0 and t_0.[82] Thus the difference between the values of U_0 obtained in the study of the lifetime of the same polymer can be accounted for by the change in the rate-determining stages of mechanothermodegradation involving a radical-chain mechanism, when the stress is altered. In this connection one should note that comparison of the activation energies for thermal degradation and mechanothermodegradation (with the exception of regime I) is fairly conventional.

According to Regel' et al.[4], the quantity $t_0 = 10^{-12}-10^{-13}$ s for polymers, which is attributed to the period of the thermal vibrations of the atoms[108]. Thus the $t_r(T, \sigma)$ relation, defined by Eqn.(1), in essence involves only two constants (U_0, γ) characterising the polymer. However, the results of the analysis (see Table) have shown that such universality of the values of t_0 should not occur for mechanothermodegradation via a radical-chain mechanism. Indeed, for polymers listed above, calculation in the case of regimes I and III yields values of t_0 differing significantly from $10^{-12}-10^{-13}$ s. Apparently t_0 is frequently[4] assumed to be equal to 10^{-13} s in order to facilitate the calculation. One should also note that the use of the method of secants for the determination of t_0, recommended by Regel' et al[4], involves a long-range double extrapolation of experimental data on the logarithmic scale, which can also be a source of errors. These principles probably lead in many instances to the "pole redisplacement" effect[4].

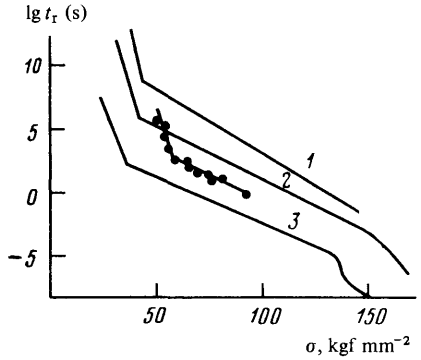

Figure 5. The $\lg t_r(\sigma)$ relation for polypropylene; calculation[84] using the tabulated formulae at different temperatures (K): *1*) 250; *2*) 300; *3*) 400. Circles—experimental data[4] at 300 K.

In the presence of a monofunctional stable radical In, termination of the kinetic chain is possible when In interacts with R_t or R_{ce}. It has been shown[85] that in this case there is a possibility of two regions in which inhibited and non-inhibited mechanothermodegradation develops, whose boundary is defined by the equation

$$[\mathrm{In}]^* = \frac{2(k_1k_6P_0\exp\mu)^{0.5}}{k_7+k_8k_7'/\left[k_4\exp\frac{\alpha_4\mu}{\alpha_1}+k_5\exp\left(-\frac{\alpha_5\mu}{\alpha_1}\right)\right]}, \qquad (13)$$

where k_7 and k'_7 are the rate constants for the interaction of In with R_t or R_{ce} respectively.

Depending on the ratio of the parameters of Eqn.(13), the critical concentration of the inhibitor [In]* either increases monotonically with increase of μ, passes through a minimum, or passes through a local maximum and then through a minimum. The nature of the [In]* (μ) curve determines the form of the relation $\lg \tau_r(\mu)$ (Fig.6). For given inhibitor concentration, there exists a maximum stress for which the inhibitor influences the breakdown process; starting from a certain inhibitor concentration, this test depends little on the latter. The qualitative nature of the theoretical $\lg t_r(\sigma)$ relation agrees with experimental data obtained in a study[62] of the breakdown of nitrocellulose in the presence of the 4-ethyl-4-hydroxy-2,2,6,6-tetramethylpiperidenyloxy-radical.

An analysis of the characteristics of the mechanothermodegradation taking into account the distribution of macromolecules with respect to chain lengths has been carried out[82] for a kinetic process mechanism involving the following stages: (1) initiation of the kinetic chain by the rupture of strained bonds in the macromolecules P_n* (n is the number of atoms in the chain of the macromolecule) with a rate constant k_1; (2) depolymerisation of the radical R_t with a rate constant k_2; (3) stress-activated chain transfer in the interaction of R_t with P_n involving the formation of R_{ce} and subsequent decomposition of the latter with a rate constant k_3; (4) termination of the kinetic chain via the disproportionation or recombination of R_t with a rate constant k_6. Unlike the kinetic degradation mechanism examined by Deyun et al[83], in this model the stages involving chain transfer and the decomposition of R_c have been combined into a single stage in order to simplify the calculation and the stage in which the free valence migrates is missing.

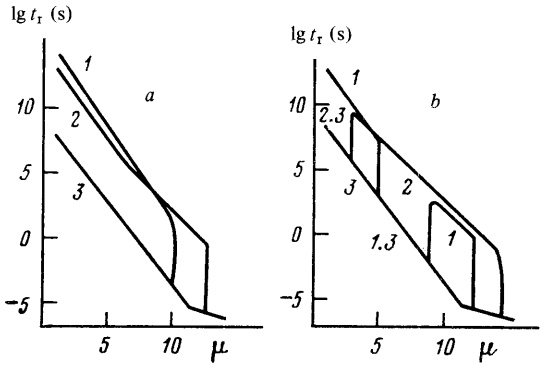

Figure 6. The lg $t_r(\mu)$ relation for the mechanothermodegradation of polymers in the presence of a monofunctional inhibitor[85] with $k_5/k_4 = 10^{10}$ and $\{k_1k_6[P_0]\}^{0.5}/k_7 = 5 \times 10^{-7}$: *a*) $k_3k'_7[P_0]/k_4k_7 = 10^4$ (curve *1*), 10^7 (curve *2*), and zero (curve *3*) and $[In] = 1.6 \times 10^{-4}$ (curve *1*), 1.6×10^{-5} (curve *2*), and zero (curve *3*); *b*) $k_3k'_7[P_0]/k_4k_7 = 10^7$ (curve *1*), 10^{10} (curve *2*), and zero (curve *3*) and $[In] = 10^{-5}$ (curve *1*), 2×10^{-7} (curve *2*), and zero (curve *3*).

The system of kinetic equations, formulated in accordance with the chosen reaction mechanism, agrees in broad outline with the system examined in the analysis of the thermodegradation of polymers[105]; the principal difference is that in mechanothermodegradation one takes into account the dependence of the rate of the initiation and chain transfer stages on the mechanical stresses. The system of equations has been converted into a dimensionless form by introducing the dimensionless time $\tau = k_1t$, the dimensionless concentrations of macromolecules $P_n(\tau) = \bar{P}_n(t)/\bar{P}_{n_0}(0)$ and radicals $R_n(\tau) = \bar{R}_n(t)/\bar{P}_{n_0}(0)$, and the dimensionless depolymerisation ($\kappa_2 = k_2/k_1$), chain transfer [$\kappa_3 = k_3\bar{P}_{n_0}(0)/k_1$], and chain termination [$\kappa_6 = k_6\bar{P}_{n_0}(0)/k_1$] rate constants ($n_0$ is the maximum number of atoms in the main chain of the macromolecule).

It has been shown that the kinetic curves for the variation of the overall concentration of radicals $R(\tau)$ are fairly complex (Fig.7). Radicals are initially accumulated at a decreasing rate; the subsequent shape of their $R(\tau)$ curves depends on the ratios of the parameter μ, κ_3, κ_6, and n_0. In a certain range of values of these parameters, it is possible to distinguish a section of the $R(\tau)$ curve along which the radical concentration remains virtually constant. The length of the quasi-stationary section is up to $(0.8-0.9)\tau_r$. The transition to the $R(\tau)$ curves without a quasi-stationary section takes place fairly abruptly as μ increases.

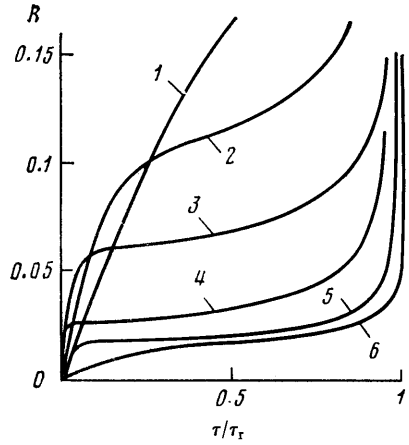

Figure 7. Kinetic curves for the variation of the overall concentration of free radicals $R(\tau)$ in the mechanothermodegradation of polymers by a radical-chain kinetic mechanism[84] with $n_t = 10$, $\alpha_3/\alpha_1 = 1$, $\kappa_2 = 10^2$, $\kappa_3 = 10$ (curves *1*–*5*) and 10^3 (curve *6*), $\kappa_6 = 10^6$ (curves *1*–*3*) and 10^8 (curves *4*–*6*), $\mu = 5$ (curves *1* and *4*–*6*), 4 (curve *2*), and 3 (curve *3*), and $n_0 = 100$ (curves *1*–*3* and *5* and *6*) and 200 (curve *4*) (n_t is the number of non-loaded atoms in the terminal sections of the main macromolecular chain).

The calculated $R(\tau)$ curves agree satisfactorily with the experimental characteristics of the accumulation of radicals in mechanothermodegradation[4,110]. The form of the calculated kinetic curves $P_n(\tau)$ depends on n; if n is small, then the induction period for the corresponding $P_n(\tau)$ curve is most distinct and the entire change in the concentration of the given product takes place virtually near the time of attainment of the maximum concentration P_n, which depends little on the process parameters and is largely determined by the value of n. We may note that the yield of the monomer $P_2(\tau_r)$ decreases with decrease of the parameter κ_2 and with increase of μ and κ_3. In the case of chain termination by the recombination of R_t the decrease of the number-average molecular weight $\bar{M}_n$ proceeds at a constantly increasing rate for all values of the parameter μ. On the other hand, if chain termination takes place via the disproportionation of R_t, then only for fairly large values of μ do the $\bar{M}_n(\tau)$ curves have the same form as in the previous case. For low values of the parameter μ, the kinetic curves $\bar{M}_n(\tau)$ have three sections: along the first and third sections $\bar{M}_n$ decreases at a gradually increasing rate, while along the second section the rate falls (Fig.8). The form of the kinetic $\Pi(\tau)$ curve is analogous to that of the $\bar{M}_n(\tau)$ curves.

IV. THE ROLE OF THE MECHANICAL MODEL IN THE KINETIC THEORY OF STRENGTH

The results of the analysis of certain kinetic models of the bulk-phase (quasi-homogeneous) breakdown, occurring over a wide range of conditions and regimes in the breakdown of polymers which are of practical importance, were examined above. Any theoretical model proposed to describe the breakdown kinetics involves (explicitly or implicitly) certain assumptions concerning the mechanical picture of the processes occurring in the loaded material, since each step involving the rupture of an interatomic bond constitutes at the same time a step in the rearrangement of the microstructure of the material.

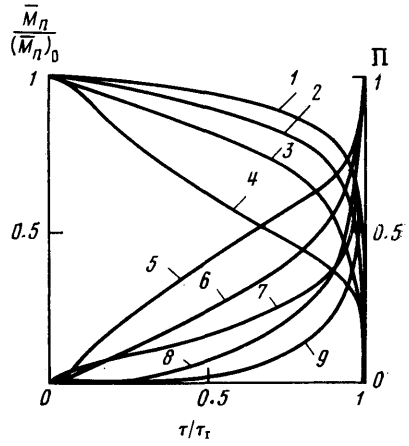

Figure 8. Kinetic curves for the variation of the number-average molecular weight (curves *1–4*) and for the degree of accumulation of defects (curves *5–9*) in the mechanothermodegradation of polymers by a radical-chain kinetic mechanism[84] with $n_t = 10$, $\alpha_3/\alpha_1 = 1$, $\kappa_2 = 10^2$, $\kappa_3 = 10$, and $\kappa_6 = 10^6$ (curves *1–5* and *7–9*) and 10^8 (curve *6*), $\mu = 3$ (curves *3–5* and *7*), 6 (curves *2, 6,* and *8*), and 9 (curves *1* and *9*), and $n_0 = 100$. The kinetic chain is terminated via recombination (curves *1–3, 5, 6, 8,* and *9*) and disproportionation (curves *4* and *7*).

Breakdown models, in which it is suggested that breakdown takes place throughout the bulk of the specimen, that the strength characteristics of the bonds are identical, and, in addition, that in most of the models mentioned above the load applied to the ruptured bonds is redistributed uniformly among the surviving bonds, have been examined in Refs. 33 to 45, 77–85, and others. Next it is assumed that the probability dp_i of the rupture of a bond under the influence of a force f_i during a time interval dt is described by an equation of the Arrhenius type:

$$dp_i = k_i \exp\left(-\frac{U_0 - \alpha f_i}{RT}\right) dt. \qquad (14)$$

Together with these models, others have been proposed[86,111] in which the non-equivalence of the chains with respect to strength characteristics and their non-uniform loading were assumed, but it was also postulated that the distribution of the load applied to the ruptured bonds among the residual surviving bearing bonds is uniform.

In particular, the influence of the non-uniformity of the load applied to the bonds on the kinetics of mechanothermodegradation was taken into account[86] subject to the following main assumptions: (1) throughout almost the entire lifetime of the specimen under load, the material remains linearly elastic; (2) a dimensionless parameter $x \geq 0$ can be assigned to each bond in such a way that all the strength characteristics (i.e. elastic constants and the parameters of the degradation kinetics) are functions of x and not of the time t; (3) the rupture of the bonds is described by the equation for an irreversible first-order reaction:

$$\dot{H}(x, t) = -H(x, t) k_0(x) \exp\{-[U_0(x) - \alpha(x)\Omega]/RT\}, \qquad (15)$$

where $H(x,t)$ is the density of the distribution of bonds with respect to x and Ω is the force acting on the bond.

If the rigidity of the bond is $\phi_1(x)$, then the stretching stress in the cross-section of the specimen is

$$\sigma(t) = \int_0^\infty H(x, t) \varphi_1(x) \varepsilon_{33}(t)\, dx, \qquad (16)$$

where ε_{33} is the elongation of the specimen.

Eqns. (15) and (16) can be written as follows in a dimensionless form:

$$\dot{h}(x, \tau) = -h(x, \tau) \varkappa(x) \exp[\omega(x) \varepsilon(\tau)], \qquad (17)$$

$$\mu(\tau) = \varepsilon(\tau) \int_0^\infty h(x, \tau) \varphi(x)\, dx, \qquad (18)$$

where $\tau = tk_0 \exp(-\tilde{U}_0/RT)$ is the dimensionless time, $\mu = \alpha\sigma/N_0RT$ the average dimensionless tension in the bonds, $h(x, \tau) = H(x, t)/N_0$ the relative density of the distribution of bonds with respect to the parameter x, $\kappa(x) = k_0(x)\exp.(\tilde{U}_0/RT)/\tilde{k}_0 \exp[U_0(x)/RT]$ the dimensionless breakdown strengths for thermal degradation, $\phi(x) = \phi_1(x) = \phi_1(x)N_0/A$ the dimensionless rigidity of the bonds, $\varepsilon = \varepsilon_{33}A/N_0RT$ the dimensionless deformation of the specimen, $\omega(x) = \Omega_1(x)RTN_0/A\tilde{\alpha}$ the dimensionless decrease of the activation energy, $\Omega_1(x)$ the decrease of the activation energy corresponding to $\varepsilon = 1$, N_0 the initial number of bonds in the given cross-section $\tilde{U}_0$, $\tilde{k}_0$, and $\tilde{\alpha}$ are certain characteristics of U_0, k_0, and α respectively, $A = \int_0^\infty H(x,0)\phi_1(x)dx$, and $\int_0^\infty h(x,0)\phi(x)dx = 1$.

Eqns. (17) and (18) make it possible to deduce the expression

$$\mu(\tau) = \varepsilon(\tau) \int_0^\infty h(x, 0) \varphi(x) \exp\left\{-\varkappa(x) \int_0^\tau \exp[\omega(x) \varepsilon(\tau')]\, d\tau'\right\} dx, \qquad (19)$$

which fully describes the evolution of a specimen for an arbitrary law governing the deformation or the application of a load. The study of Eqn. (19) showed that, for a constant load at fairly high values μ (in the sense that $e^\mu \gg 1$), we obtain

$$\tau_r = \tau_0 \exp(-\rho\mu), \qquad (20)$$

where $\rho \gg 1$, i.e. a non-distribution of the load among the bearing bonds leads to a decrease of the lifetime compared with a uniform distribution; at the same time, the $\tau_r(\mu)$ relation remains exponential.

The calculated evolution of the distribution function $h(x, \tau)$ reflects qualitatively the course of the breakdown process observed experimentally[4,112]. The shape of the $\varepsilon(\tau)$ creep curves for high values of μ depends on the form of the function $h(x, 0)$ (Fig. 9). If $h(x, 0)$ has a rectangular shape, then the $\varepsilon(\mu)$ curves consist of two sections, while in other cases they have three sections. For low values of the parameter μ, the creep curves cease to depend on the form of $h(x, 0)$;

in this case the decrease in the number of bearing bonds in consequence of purely thermal degradation makes a major contribution to the development of creep. The $\Pi(\tau)$ curves are similar in form to the $\varepsilon(\tau)$ curves. For high values of μ, the lifetime is determined by the rupture of a relatively small number of bearing bonds. The decrease in the rate of increase of the concentration of broken bonds for low values of μ is related to the decrease in the total number of bonds as a consequence of thermal degradation.

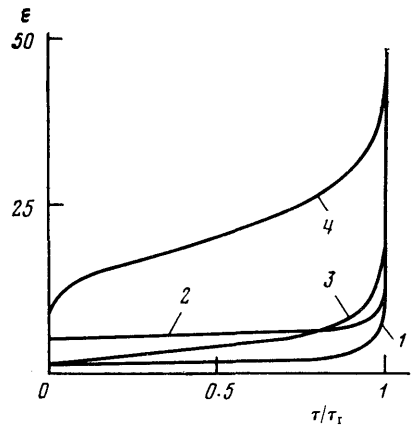

Figure 9. Creep curves $\varepsilon(\tau)$ for a non-uniform loading of the bearing bonds in mechanothermodegradation[86] with $\mu = 1$ (curve *1*), 5 (curve *2*), 1.2 (curve *3*), and 6 (curve *4*). The $h(x,0)$ curves *1* and *2* have a rectangular shape; the $h(x,0)$ curves *3* and *4* correspond to oriented capron[4,112].

One of the principal features of the mechanothermodegradation of real bodies is that the process as a rule develops initially as a homogeneous reaction, while in the concluding stage it is localised and terminates by the growth of a crack right through the specimen. Although the model discussed above and similar models[39,113] make it possible to explain qualitatively a whole series of features typical for mechanothermodegradation, they nevertheless do not provide an answer to the question which of the elementary steps in the breakdown process constitute the macroscopic breakdown of the given body[4,114] The initiation of a crack from single breaks, occurring on average uniformly throughout the bulk of the specimen, has still not been investigated. The study of the conditions under which the interaction of closely spaced continuity microdefects (bond breaks, submicrocracks) is significant and of the conditions under which breakdown occurs as a result of the growth of a single microdefect is complicated by the lack of effective solutions for the distributions of stresses and deformations in the vicinity of microdefects with allowance for the kinetics of the accumulation of microdefects and for the real structure of the polymer. The solution of the problem of the localisation of breakdown should, in principle, yield also an answer to the question how justified is the assumption, used in models describing quasi-homogeneous breakdown, that the transition from the bulk-phase breakdown to the growth of a crack right through the specimen coincides with a sharp increase of the rate of accumulation of defects.

In this connection mention should be made of the study[115] of the statistics of an *ensemble* of microdefects, the probability of the formation and growth of which depends on the local stresses in accordance with Eqn.(14). However, one then uses the solution of the problem of the distribution of stresses for an infinite crack extrapolated to the region of the typical dimensions of the microdefect. The same can also be said of a study[116] whose results are largely a repetition of those of the previous investigation. A direct solution of this problem by modelling the breakdown process using the Monte Carlo method on a computer has been attempted[117].

Several models, for instance[87,88,118-121], have been proposed to describe the kinetics of the growth of cracks right through the specimen. In most of these investigations the solutions of the theory of elasticity for a crack (section) through a continuous body were used together with particular assumptions whereby the specific features of the solution near the end of the crack (infinite stresses) can be eliminated. A correct formulation of the mechanical problem concerning the equilibrium governing the crack (it is assumed that a slowly growing crack corresponds to mechanical equilibrium) requires an explicit introduction of a parameter having the dimensions of length, i.e. it is necessary to invoke hypotheses concerning the structure of the material[118-121]. Together with the details of the structure of the material, the description of the kinetics of the growth of a crack right through the specimen requires the formulation of the kinetics of the elementary processes involving the rupture of interatomic bonds near the end of the crack, where, by virtue of the marked dependence of the rate of the process on the stresses, the breakdown is localised[87,88].

Thus the problems of the micromechanics of breakdown cannot be eliminated from kinetic models for the breakdown process. The attempts to disregard the structure of the material lead to implicit hypotheses concerning the structure[122] or the treatment remains open-ended[123].

---o0o---

A theoretical relation has been established for different kinetic degradation schemes[77-88] between the lifetime in mechanothermodegradation and the parameter μ characterising the intensity of the mechanical field. Comparison of the results of the calculation showed that the $\lg \tau_r(\mu)$ relations obtained are qualitatively the same in the region of small values of μ, although they differ quantitatively. For sufficiently large values of μ, the relation between the logarithm of the lifetime and the applied stress can be represented by a single straight line, i.e. can be described by Eqn.(1) only for a simple reaction mechanism. As a result of the occurrence of two parallel reactions, the above relation is in some cases represented by two linear sections over a wide range of stresses. For a radical-chain kinetic mechanism of the degradation process, the dependence of the logarithm of the lifetime on the stress is most complex and, with the exception of the initial section, is represented in the general case by three linear sections, the ratios of the slopes of which are 5 : 1 : 2 (when the structure-sensitive coefficients of the elementary stages are equal). For a reversible reaction, critical phenomona are possible in mechanothermodegradation, and the range of "safe" stresses is determined by the ratio of the rate constants for the forward and reverse reactions. The non-uniformity of the distribution of bonds with respect to tensions leads to a decrease of the lifetime without altering the general form of the $\lg \tau_r(\mu)$ relation.

The results of the theoretical analysis[77-88] agree with experimental data, which makes it possible to employ the mathematical procedures developed in the above studies for the prediction of the useful lifetimes of polymeric articles. The problem of the prediction of the stability of polymeric articles can be simplified in the case of a complex radical-chain mechanism and the prediction itself can be made more exact. Theoretical analysis shows that in this case one must employ in calculations of the lifetime not the rate constants for the individual elementary stages of the degradation process, which are as a rule still not known with adequate accuracy, but the corresponding functions of the above constants, in terms of which the parameters of the mechanothermodegradation equations are expressed. The functions of the constants can be determined with the necessary accuracy from experimental lifetimes of polymeric materials. In extrapolating the results thus obtained to the operating conditions of the corresponding polymeric article, it is, however, necessary to bear in mind that when the kinetic mechanism of the degradation process is complex, the combination of elementary constants determining the macroscopic parameters of the mechanothermodegradation (U_0, t_0, γ) varies with the applied stress.

Photochemical Oxidation of Polyolefins and Prediction of Their Useful Lifetime

E.M.Slobodetskaya (deceased)

By analysing the experimental data for individual elementary steps in the photochemical oxidation of pure polyolefins and by considering the kinetics of the process as a whole, it is shown that the latter is a chain reaction with degenerate photobranching by hydroperoxides and carbonyl compounds and quadratic chain termination. The available data are sufficient to describe the process at a quantitative level under any conditions. The use of this reaction as a model made it possible to elucidate the characteristic features of the photochemical oxidation of thermally stabilised and oriented polyolefins.
The bibliography includes 68 references.

I. INTRODUCTION

Polyolefins have been used traditionally to study the ageing of polymeric materials. Tens of original studies devoted to the degradation, oxidation, thermal, and photo- and radiation-induced ageing of polyolefins (PO) and several reviews are published annually. The interest in polyolefins as objects of study is due to a number of causes. On the one hand, polyolefins are some of the simplest polymeric molecules with thoroughly investigated low-molecular weight analogues—aliphatic hydrocarbons. On the other hand, polyolefins, particularly polypropylene (PP) are comparatively readily oxidised, which makes the problem of the stabilisation of these polymeric materials particularly urgent and at the same time facilitates the study of this process. Furthermore polyolefins are produced industrially on a wide scale and are used in practice in a comparatively pure form—in the presence of added stabilisers only. This permits an easy comparison of laboratory studies with the results of tests on a real polymeric material under natural conditions.

Polyolefins are usually employed at a temperature much higher than their glass point. Therefore, in describing the mechanism of the ageing of polyolefins, there are almost no difficulties characteristic of the description of solid-phase reactions. The formal process kinetics remain the same as in a viscous liquid or in the melt.

Several years ago, the present author published a review[1] in which a general mechanism of the entire polypropylene photooxidation process was "synthesised" on the basis of data for the mechanisms of individual elementary steps of the photochemical oxidation reaction and it was shown that the data available at the time for this process could be described at a quantitative level within the framework of the mechanism proposed. Despite the comparatively short period which has elapsed since the publication of the earlier review[1], a large amount of new experimental data, confirming the earlier hypothesis concerning the mechanism of the photooxidation of polypropylene has now accumulated. They now make it possible to regard the photochemical oxidation of polypropylene as a model reaction whose mechanism has been elucidated at a quantitative level.

The present review deals with the question of how this model reaction can be used to describe the kinetics of the variation of properties of polyolefins of practical importance, to elucidate the fundamental features of the mechanism of the action of various stabilisers, and to investigate the mechanism of the oxidation of polymers in an oriented state. The study of all these problems will permit a close approach to the performance of one of the fundamental tasks in the study of the ageing of polymers—the determination of the useful lifetime of polymeric materials—in the present instance those based on polyolefins.

II. KINETICS OF THE PHOTOCHEMICAL OXIDATION OF POLYPROPYLENE

By analysing the experimental data available at the time, it was shown in the earlier review[1] that the photochemical oxidation of polyolefins is a chain process with quadratic chain termination and degenerate photobranching by the hydroperoxide. The kinetic mechanism of this process can be formulated thus:

$$S \xrightarrow{w_0} PO_2^{\cdot}, \quad (1)$$

$$PO_2^{\cdot} + PH \xrightarrow{k_p} POOH + P^{\cdot}, \quad (2)$$

$$P^{\cdot} + O_2 \xrightarrow{k_2} PO_2^{\cdot},$$

$$PO_2^{\cdot} + PO_2^{\cdot} \xrightarrow{k_t} (C{=}O), \quad (3)$$

$$POOH + h\nu \xrightarrow{\alpha} PO^{\cdot} + OH^{\cdot} \xrightarrow{PH} (C{=}O) + 2PO_2^{\cdot}, \quad (4)$$

$$(C{=}O) + h\nu \xrightarrow{\alpha'} f\,PO_2^{\cdot}. \quad (5)$$

where S is the sensitiser present in the polymer and ensuring the primary initiation, $PO_2^{\cdot}$ are peroxy-radicals derived from the polymer PH, POOH is the hydroperoxide, (C=O) are carbonyl compounds, and f is the probability of the release of the radicals into the bulk phase on photolysis of the carbonyl compound. The rate constants for the corresponding reactions are indicated above the arrows, those for the photochemical reactions (α and α') characterising the probability of the decomposition of the given

substance per unit time under the influence of light having an intensity I subject to the condition that light is absorbed uniformly throughout the thickness of the specimen. The quantity α is related to the quantum yield of the decomposition into radicals ϕ and the extinction coefficient ε:

$$\alpha = \int \varphi I \varepsilon \, d\lambda. \qquad (6)$$

A change in the concentration of carbonyl compounds in the specimen is known to have no appreciable influence on the rate of photochemical oxidation[2,3] and the formation of radicals in the decomposition of C=O can therefore be neglected.

In this case the kinetics of the process are analogous to those of the familiar thermal oxidation of hydrocarbons[4]. If it is assumed that the principle of quasi-stationary concentrations of peroxy-radicals holds throughout the process, then, at a constant light intensity, the kinetics of the accumulation of reaction products are determined[1] solely by the parameter $k_p/\sqrt{k_t}$ and the probabilities of the photochemical decomposition of peroxides and carbonyl compounds—α and α':

$$[\mathrm{POOH}] = [\mathrm{POOH}]_\infty (1 - e^{-\alpha t/2})^2, \qquad (7)$$

$$[\mathrm{C{=}O}] = \frac{2\alpha}{\alpha'}[\mathrm{POOH}]_\infty \left(1 - e^{-\alpha t} - \frac{4\alpha'}{2\alpha' - \alpha}(e^{-\alpha t/2} - e^{-\alpha' t}) + \frac{\alpha'}{\alpha' - \alpha}(e^{-\alpha t} - e^{-\alpha' t})\right). \qquad (8)$$

For $\alpha' = 0$, we obtain

$$[\mathrm{C{=}O}] = 2[\mathrm{POOH}]_\infty (\alpha t - (3 - e^{-\alpha t/2})(1 - e^{-\alpha t/2})),$$

where

$$[\mathrm{POOH}]_\infty = (2k_p^2/\alpha k_t)[\mathrm{PH}]^2.$$

All the parameters in Eqns.(7) and (8) can be determined independently. It is known[5] that aliphatic hydroperoxides decompose into radicals in the step involving the absorption of each light quantum and α can therefore be calculated from spectroscopic data. Apart from spectroscopic data for carbonyl compounds, it is necessary to know the quantum yield ϕ_I of their decomposition via a Norrish type I reaction in order to determine α' †. The yields ϕ_I for different types of (C=O) in polyolefins are available in the literature (see, for example, Carlsson and Wiles[6] and Hartley and Guillet[7]).

The parameter $k_p/\sqrt{k_t}$ is determined from data for the initiated oxidation of the polymer. The calculation[1] yielded a satisfactory agreement with the results of experiments on the oxidation of pure polypropylene[8]; at that time only isolated data were available for the kinetics of the photochemical oxidation of polypropylene in which all the necessary characteristics of the process conditions were indicated: temperature and the intensity and spectral composition of the effective radiation.

Detailed studies have been made on the kinetics of the photochemical oxidation of polypropylene under the influence of light of different intensity and different spectral composition[9], the range of temperatures in which the parameters $k_p/\sqrt{k_t}$ were measured has been significantly extended, and the absolute values of the constants k_p and k_t have been determined (Table 1). All the results obtained concern the validity of the proposed mechanism. As an example, Fig.1 shows how the calculation agrees with data for the accumulation of (C=O) in the photochemical oxidation of different polypropylene specimens under the influence of light at a wavelength of 254 nm.

*All the parameters were calculated taking into account the fact that the oxidation develops only in the amorphous component of the polymer[13].

Thus it has become possible to treat the photochemical oxidation of polypropylene from a single standpoint as a model process whose mechanism has been fully elucidated also at a quantitative level and the rate constants for all the elementary processes have been determined by independent methods. A characteristic feature of this process is a non-linear relation between the rate of reaction and the rate of formation of active centres. As a result of this non-linearity, the kinetics of the given process are qualitatively different from the kinetics of processes described as elementary nth order reactions.

For example, polypropylene does not absorb light at a wavelength greater than 200 nm; nevertheless, it is effectively oxidised under the influence of this light. The explanation is not inadequate purity of the polymer but the fact that the destruction of radicals proceeds via a second-order reaction. At low rates of initiation the oxidation chain length tends to affinity. Because of this, the solution of the differential equation describing the process kinetics is unstable at low rates of initiation and even at low rates of side processes the concentration of the hydroperoxide increases fairly rapidly; the quasi-stationary concentration of peroxy-radicals is also rapidly established.

A rigorous analysis of the kinetic scheme showed[14] that, for the majority of hydrocarbons and polymers, the decrease of the rate of primary initiation cannot alter significantly the induction period of the oxidation reaction, which is defined as the time required to accumulate the hydroperoxide at a concentration of $\sim 10^{-2}$ M.

† Norrish type II decomposition actually leads to the decomposition of the macromolecule and not to the consumption of the carbonyl group.

Another unusual consequence of the quadratic termination of the oxidation chains is a weak dependence of the stationary rate of photochemical oxidation on light intensity. Some time after the onset of oxidation (at $t \gg 1/\alpha$) the accumulation of the hydroperoxide virtually ceases completely and its quasi-stationary concentration is established. According to Eqn.(8), the concentration is inversely proportional to the light intensity. On the other hand, the rate of formation of carbonyl compounds, which under the given conditions is a measure of the rate of oxidation, is proportional to the concentration of the peroxide and the light intensity, i.e. [the hydroperoxide concentration] is independent of the light intensity#.

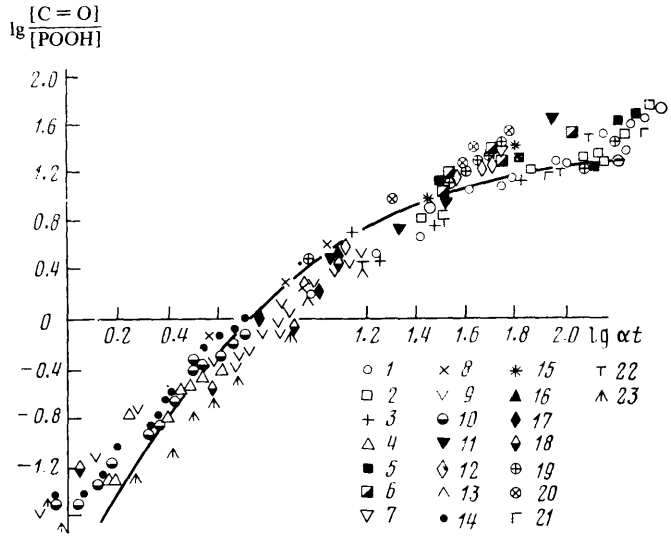

Figure 1. The logarithmic forms of kinetic curves for the accumulation of carbonyl compounds in the photochemical oxidation of different polypropylene specimens. Intensity of incident light 10^{-15} I (quanta cm^2 s^{-1}): 1), 5), 11), and 15) 4; 2), 6), 12), and 16) 2; 3), 7), 13), and 17) 0.5; 19) 0.7; 8) 0.44; 4), 9), and 18) 0.16; 10) and 14) 0.04; 20) 0.63; 21) 4; 22) 2; 23) 0.04 [21)–23) specimens consisting of large spherolites]; continuous line—calculation[9].

Within the framework of the mechanism under consideration, the stationary concentrations of the peroxide and carbonyl compounds are defined by the relations

$$[\mathrm{POOH}]_{\mathrm{stat}} = [\mathrm{POOH}]_\infty \frac{2\theta + f}{2\theta - f}, \qquad (9)$$

$$[\mathrm{C=O}]_{\mathrm{stat}} = [\mathrm{POOH}]_\infty \frac{\alpha}{\alpha'} 4 \frac{2\theta + f}{(\theta - f)^2}, \qquad (10)$$

where θ is the probability of the destruction of the carbonyl compound in the cage on decomposition via a Norrish type I reaction. With the aid of Eqns.(9) and (10), the values of θ and f have been determined for polypropylene[15] ($\theta = 0.75$ and $f = 0.15$).

It has been shown[16] that this treatment, which does not take into account the consumption of the substance oxidised, is valid only when one considers photochemical oxidation; in thermal oxidation $[\mathrm{POOH}]_\infty$ is usually comparable to [PH].

Thus the photochemical oxidation of polypropylene is a process which proceeds despite the fact that the initial substance does not absorb light and its stationary rate is independent of the light intensity.

III. CHARACTERISTICS OF THE ELEMENTARY STEPS AND THEIR INFLUENCE ON THE PHOTOCHEMICAL OXIDATION OF POLYOLEFINS

In the course of the study of the elementary reactions in polyolefins, certain features of their occurrence and quantitative characteristics were elucidated. This section deals with the conditions under which these features can influence the photochemical oxidation of polyolefins and the way in which this can be done.

1. Primary Initiation

According to a number of workers, the cause of the low stability of polyolefins with respect to the action of light is the sensitising role of impurities contaminating the polymer in the course of synthesis and processing[17,18]. Charge-transfer complexes between the polymer and oxygen[19–21], singlet oxygen donors[22–25], admixtures of aromatic compounds[26–28,34], residual amounts of catalysts[29–31], and unsaturated carbonyl compounds[18] have been considered as sensitisers of this kind. It has been shown that under certain conditions these compounds can serve as sources of free radicals. However, in estimating the influence of these impurities on the photochemical oxidation of polyolefins, it is necessary to compare the efficiency of their action with the efficiency of other stages of the process—in the first place the branching stage.

In the majority of cases such estimates were not made, which led to an apparent conflict between the available literature data. For example, it has been shown that, in the photolysis of aromatic[34] or carbonyl compounds, free radicals are formed. On the other hand it has also been shown that in many instances the presence of these impurities does not affect the photochemical oxidation[18]. This apparent contradiction is due to the fact that free radicals are formed from aromatic compounds at low temperatures in two-quantum processes, which do not occur in the photochemical oxidation of polyolefins close to room temperature. Carbonyl compounds are indeed sources of free radicals, but, together with these, photochemical oxidation of polyolefins gives rise to a much more effective source of free radicals—the hydroperoxide, and the role of sensitisation by carbonyl compounds is therefore insignificant.

A special analysis of the possible role of singlet oxygen donors in the photochemical oxidation of polyolefins and natural rubbers has been carried out[33]. It was assumed that the initiating function of $^1O_2$ consists in the fact that its interaction with unsaturated compounds can give rise to a hydroperoxide, which serves as an additional source of free radicals. It was shown[33] that the introduction of singlet oxygen donors does not accelerate the photochemical oxidation of the polymers investigated, occurring under the influence of ultraviolet radiation at fairly short wavelengths.

#In fact the increase of the concentration of carbonyl compounds is limited by their photochemical decomposition, which results in the formation of a certain amount of free radicals and this leads to some increase of the quasi-stationary concentration of the hydroperoxide.

On this basis, the authors[33] concluded that $^1O_2$ is not involved in the photochemical oxidation of natural rubbers and polyolefins. They showed[33] that this conclusion is valid only when the polymer is acted upon by ultraviolet radiation of sufficiently short wavelengths, which is effectively absorbed by the hydroperoxide. For a quantitative estimate of the influence of singlet oxygen, it is necessary to compare the rate w_0 at which it forms the hydroperoxide with the rate of its formation in the chain propagation reaction. For the photochemical oxidation of polypropylene, the influence of $^1O_2$ may be neglected if

$$\frac{k_p}{\sqrt{k_t}}\sqrt{2\alpha[\mathrm{POOH}]} \gg w_0. \qquad (11)$$

Consequently in the initial stages of the process the influence of singlet oxygen can be manifested throughout; it disappears under the condition

$$(1-e^{-\alpha t/2}) \simeq \frac{\alpha t}{2} \gg \frac{w_0 k_t}{2k_p^2}. \qquad (12)$$

Accordingly, the role of singlet oxygen donors can be neglected when the concentration of reaction products z exceeds a certain limit

$$[\mathrm{POOH}] > \frac{w_0^2 k_t}{2\alpha k_p^2}, \qquad (13)$$

$$z > \frac{w_0^2 k_t^2}{2\alpha k_p^4},$$

where z is the concentration of the products formed in the chain termination reaction.

The sensitising activity of the impurities generating free radicals can be estimated similarly. It has been shown[1] that the role of these impurities becomes insignificant when

$$\alpha t \gg \frac{\sqrt{w_i}}{k_p/\sqrt{k_t}}. \qquad (14)$$

Instead of Eqn.(13), we have in this case

$$[\mathrm{POOH}] > \frac{w_i}{2\alpha}, \qquad (15)$$

$$z > \frac{w_i^{3/2}}{\alpha k_p/\sqrt{k_t}}.$$

There are virtually no data at present based on a quantitative estimate of the role of sensitising impurities in photochemical oxidation. Therefore, as in the study of Karpukhin and Slobodetskaya[1], one can only say that, in the photochemical oxidation under the influence of ultraviolet radiation absorbed by peroxides, the role of sensitisation and $^1O_2$ is insignificant, since the available data can be accounted for without allowance for them and since the kinetic curves for the accumulation of the reaction products clearly reveal an acceleration of the process, which is impossible in the case of a process sensitised by impurities.

Photochemical oxidation cannot become sensitised under the influence of near ultraviolet (>360 nm) and visible light, which is not absorbed by hydroperoxides. This is indicated also by the examination of the criteria defined by Eqns.(12)–(15) which were discussed above.

2. Propagation and Termination of the Kinetic Chain

The kinetics of chain oxidation usually depend little on the absolute rate constants for chain propagation (k_p) and termination (k_t). When the principle of quasi-stationary radical concentrations holds, the kinetics are determined by the parameter $k_p/\sqrt{k_t}$. This parameter can be determined in different ways from the kinetics of the thermal and photochemical oxidation of polyolefins.

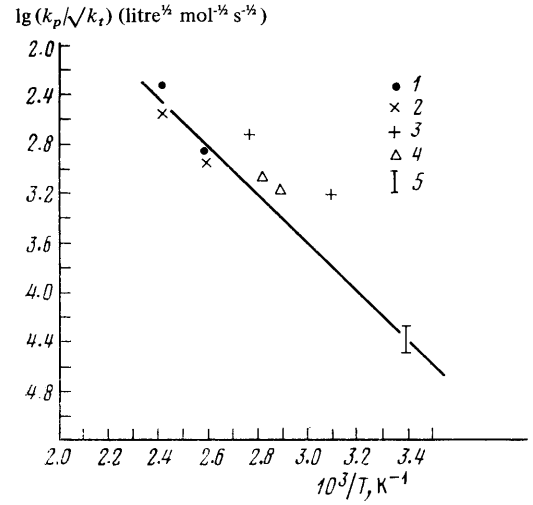

Figure 2. Temperature dependence of the parameter $k_p/\sqrt{k_t}$ for the oxidation of polypropylene according to different data: 1) Chien and Boss[68]; 2) Pudov et al.[16]; 3) Shanina et al.[11]; 4) Rapoport et al.[10]; 5) Karpukhin and Slobodetskaya[9].

The range of temperatures in which this parameter has been measured for polypropylene has been greatly extended recently. Fig.2 presents the data in terms of the variables of the Arrhenius equation. Evidently almost all the available data can be described by a single relation§; only at low temperatures is there some tendency towards an increase of the activation energy.

Table 2. The influence of the plasticiser and the hydroperoxide on the kinetic parameters of the oxidation of polypropylene[36].

Parameter*	Value of the parameter
	in the presence of 1 M *o*-dichlorobenzene
$k_p/(k_p)_0$	5.3
$k_t/(k_t)_0$	11
$(k_p/\sqrt{k_t})/(k_p/\sqrt{k_t})_0$	1.6
	in the presence of POOH**
k_t, litre mol^{-1} s^{-1}	170 (0.25); 12 (2.5); 5.2 (10)

*Subscript 0 refers to polypropylene without a plasticiser.
**The values of 10^2 [POOH] (M) are given in brackets.

§Only the data of Shanina et al.[11] deviate somewhat from the relation.

The absolute chain termination rate constants have been measured by EPR. It was observed that the rate of chain termination depends greatly on temperature[12,35] and is influenced by the molecular mobility of the medium[36] and the concentration of hydroperoxy-groups in the polymer[37]. The simultaneous measurement of the parameter $k_p/\sqrt{k_t}$ in the same systems showed[36] that all these factors have little effect on its value. The cause of this kind of compensation effect has not so far been established. Nevertheless the kinetics of the oxidation of polypropylene can be described under virtually any conditions using a single value of the parameter $k_p/\sqrt{k_t}$.

The parameters $k_p/\sqrt{k_t}$ for other polyolefins are much smaller. It is known that in the case of polyethylene (PE) the parameter has different values for low-pressure polyethylene (LPPE) and high pressure polyethylene (HPPE). This is explained by the fact that HPPE contains a greater number of tertiary hydrogen atoms, which react more effectively with the peroxy-radicals[38]. It is also known that a much smaller amount of hydroperoxides is formed in the photochemical oxidation of polyethylene than for polypropylene. This is associated with the lower value of the parameter $k_p/\sqrt{k_t}$ for polyethylene. In the thermal oxidation the parameter $k_p/\sqrt{k_t}$ for HPPE was measured in the melt[39]; furthermore, data have been published[40] on the accumulation of the HPPE hydroperoxide at 150–170 °C. The above parameter for HPPE was determined[41] from these results:

$$\frac{k_p}{\sqrt{k_t}}[\mathrm{PH}] = 34e^{-7000/RT}.$$

Photochemical oxidation of HPPE and LPPE was studied[41] at room temperature. The quantity $(k_p/\sqrt{k_t})[\mathrm{PH}]$ proved to be 1×10^{-4} (mol litre^{-1} s^{-1})$^{1/2}$, which virtually agrees with the value of this parameter extrapolated to room temperature in the study of Chokraborty and Scott[40].

3. Photobranching

The fundamental photoinitiation reaction in the photochemical oxidation of polyolefins is the photolysis of POOH. This reaction proceeds with a quantum yield of unity and with formation of two free radicals[5]. The presence of carbonyl compounds has no influence on the rate of this reaction. Thus a change in the concentration of carbonyl compounds by an order of magnitude does not affect the photolysis of POOH in polypropylene[42].

The absence of an initiating effect of (C=O) in polypropylene is associated with the low degree of liberation of radicals into space during their photolysis ($f_{20^\circ}=0.15$).[2] The situation is somewhat more complex in the case of polyethylene. Since the concentration of the hydroperoxide in polyethylene is very low and frequently cannot be determined analytically, it has been suggested in a number of studies that (C=O) is in fact a branching agent in polyethylene[43].

It is known[44] that, if 1% of C=O groups is introduced into polyethylene, the polymer becomes susceptible to decomposition by light and loses its strength characteristics much faster than pure polyethylene. On the other hand, it has been shown[40,45] that the rate of oxidation of specimens subjected to preliminary thermal oxidation varies in parallel with their hydroperoxide content (the hydroperoxide concentration in them was varied from 1×10^{-2} to 5×10^{-2} M). According to the data of Karpukhin et al.[41], when polyethylene is irradiated by light at a wavelength of 254 nm, the principal branching agents are also hydroperoxides. Analysis of literature data shows that the cause of this is (as for polypropylene) the low yield of radicals in the photolysis of carbonyl compounds (Table 3).

The observed contradictions can be resolved as follows. The photolysis of carbonyl compounds on irradiation of polyethylene by short-wavelength and particularly long-wavelength light proceeds extremely effectively. The photolysis of "central" ketones via a Norrish type II reaction involves the rupture of polymer chain. Thus the decomposition of the polymer takes place in two parallel processes: in the radical photochemical oxidation reaction and in the non-radical decomposition of ketones. Evidently the relative contributions of these processes will be determined by the irradiation conditions and by the concentration of ketones in the polyethylene. For example, calculation¶ for polyethylene used in practice, containing 10^{-2} M ketones, has shown that the role of the second process is small whatever the spectral composition of the incident light. When polyethylene containing ~0.5 M ketones is irradiated with long-wavelength light, the contributions of the two processes are comparable. This in fact explains the rapid decomposition of the ethylene–carbon monoxide copolymer. On the other hand, the degree of liberation of radicals into space during the photolysis of ketones is small; they make a small contribution to the rate of formation of radicals in polyethylene and a particular consequence of this is therefore that they have virtually no influence on the rate of photochemical oxidation of polyethylene.

Table 3. The quantum yields in the photochemical decomposition of aliphatic ketones in polyolefins.

Polymer	Ketone	φ_I	φ_{II}^*	f	$f\varphi_I$	Method of determination of φ	Refs.
PP	central	0.08	0.007	0.15	0.01	analysis of volatile products and weight loss on photolysis	6
PP	terminal	0.008	0.09	—	—	ditto	6
PE	central		0.025	—	0.003	change in molecular weight	46

*Here ϕ_{II} is the quantum yield of the decomposition via a Norrish type II reaction.

Thus the above analysis of data for the mechanisms and the quantitative characteristics of the elementary reactions which may occur in the photochemical oxidation of polyolefins showed that, under the usual conditions, the kinetics of this process are determined solely by the characteristics of the photochemical decomposition of hydroperoxides and carbonyl compounds and by the parameter $k_p/\sqrt{k_t}$.

IV. THE USE OF THE MODEL POLYPROPYLENE PHOTOCHEMICAL OXIDATION REACTION FOR THE STUDY OF THE INFLUENCE OF STABILISERS AND ORIENTING EXTRUSION ON THE PHOTOCHEMICAL OXIDATION OF POLYOLEFINS AND FOR PREDICTING THE USEFUL LIFETIME OF THE POLYMERS

The knowledge of the mechanism of the photochemical oxidation of pure polypropylene at a quantitative level makes it possible to use this reaction as a model whereby one

¶For the calculation, see E.M.Slobodetskaya, T.V.Magomedova, O.N.Karpukhin, and V.G.Protasov, Vysokomol.Soed. (in the Press).

can elucidate the details of more complex processes occurring both in the given polymer matrix and in other matrices with a similar structure.

1. Characteristics of the Oxidation of Oriented Polyolefins

Orienting extrusion is widely used in industry to obtain highly modular or specially strong fibres and films[47], which are used in various branches of technology. In particular, oriented polypropylene (OPP) films are used as packing materials in the food industry, for the packing of hygroscopic reagents and medicines, as insulating and protecting materials, etc.[48] The practical employment of these materials has shown that, compared with isotropic polypropylenes (IPP), they have not only more effective physicomechanical properties but are also more resistant to thermal oxidation[47]. A number of studies have been published recently whose authors attempt to discover the causes of this unusual structural stabilisation[49–51].

It is shown below that the data for the mechanism of the photochemical oxidation of isotropic polyolefins have been used to explain the fundamental stages of the oxidation of oriented polymers (OPO).

Polyolefins are semicrystalline polymers, the degree of crystallinity of which is usually in the range 60–70%. When crystalline polyolefins are extruded, their crystalline and amorphous components are oriented and the orientation of crystallites is virtually completed for low extrusion factors ($\bar{\lambda} = 4-5$), while for high extrusion factors all the changes occur in the amorphous part of the material[52].

The oriented fibres and films have a fibrillar structure, i.e. the polymer consists of microfibrils ~100 Å in diameter and several microns long, in which the amorphous and crystalline components alternate. The average periodicity in the polyolefin fibrils (the so-called long period) is ~100 Å and depends mainly on the extrusion temperature. The fraction of amorphous regions in the long period is inversely proportional to the degree of crystallinity of the polymer and usually amounts to 0.3–0.5 of the latter in industrial polyolefins. The composition of the crystallite usually includes several macromolecules. Consequently a large number of molecules in the amorphous region are "transient", i.e. pass from one crystallite to another through the amorphous layer. Indeed, according to Marikhin[53] 80–90% of the molecules in the amorphous region are transient and only 10–20% form the free ends and loops of the polymeric molecules projecting outside the limits of a single crystallite. Thus various parts of almost every macromolecule are incorporated simultaneously in several crystallites and contain several transient chains. The presence of a large number of transient chains is responsible for the increase in the stength of oriented polymers relative to isotropic polymers; according to Zhurkov et al.[52], the strength of fibres varies in parallel with the degree of orientation of macromolecules in the amorphous part.

Since the crystalline component of the specimens is not oxidised because the oxygen molecule cannot penetrate a crystallite, the oxidation of oriented polyolefins develops in their amorphous region[13]. According to Tochin et al.[54], considerable changes in the diffusion coefficients and in the solubility of gases in the amorphous portion of oriented polyethylene are observed only for $\bar{\lambda} > 12$. This shows, that, for $\bar{\lambda} = 4-5$, the orientation involves only a small fraction of the transient chains, while the rest remain in the same state as before orientation. When the oriented polymer is heated to a high temperature, its amorphous component undergoes partial disorientation, the degree of which depends on the annealing conditions—temperature, duration of annealing, and the strain in the macromolecule. This disorientation is caused by the "tearing out" of the transient chains from the crystallites or their "slip" relative to one another. Isometric annealing also leads to the disorientation of the amorphous part of the polymer, but here the width and the thickness of the specimen contract. The disorientation of the amorphous component of oriented polyolefins is indicated by the decrease of their contraction strain[55], the extent of which can serve as a measure of the orientation of the amorphous component of the polymer.

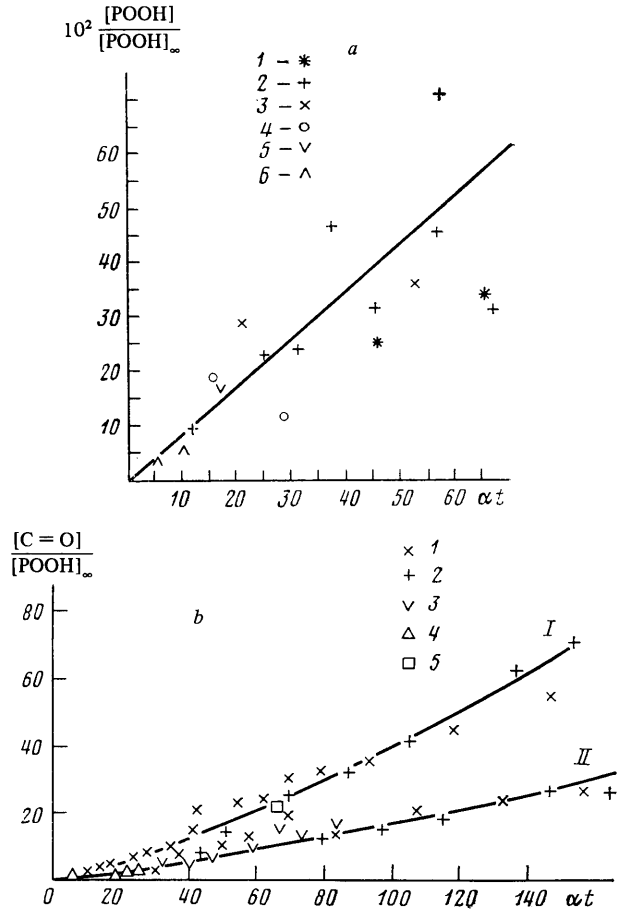

Figure 3. Kinetics of the accumulation of POOH (*a*) and carbonyl compounds (*b*) in the photochemical oxidation of OPP by light at a wavelength of 254 nm.[15] *a*) Intensity of incident light 10^{-15} *I* (quanta cm^2 s^{-1}): 1) 3.3; 2) 1.5; 3) 0.75; 4) 0.6; 5) 0.46; 6) 0.15; extrusion factor $\bar{\lambda} = 4-5$; *b*) intensity of incident light 10^{-15} *I* (quanta cm^2 s^{-1}): 1) 4; 2) 1; 3) 0.74; 4) 0.3; 5) 0.08; extrusion factor $\bar{\lambda}$: I) 4–5; II) 9–10.

A characteristic feature of the oxidation of oriented polypropylene compared with the isotropic material (IPP) is that, other conditions being equal, POOH accumulates in it at a much lower concentration. The decrease of the rate of accumulation of POOH is not related to the overall decrease of the rate of the process, which also occurs in thermal

oxidation, but is due to a qualitative change in the composition of the oxidation products.

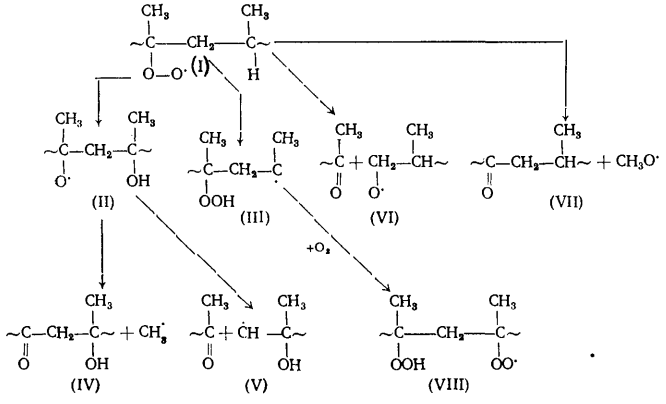
In thermal oxidation of oriented polypropylene the yield of hydroperoxide per mole of absorbed oxygen decreases from virtually unity for IPP to 0.13 for OPP with $\bar{\lambda}=4-5$ and to 0.05 for OPP with $\bar{\lambda}=9$.[51] In the photochemical oxidation of OPP with $\bar{\lambda}=4-5$ the rate of accumulation of POOH at the beginning of the process decreases compared with IPP by a factor of hundreds, while the rate of formation of carbonyl compounds hardly changes (Fig.3). Isometric annealing at 165 °C fully eliminates the characteristics of the oxidation of OPP.[50] These results show that the changes in the physical structure of the amorphous component of polypropylene alter radically the mechanism of the oxidation process.

The small change in the rate of accumulation of carbonyl compounds on photochemical oxidation of OPP compared with IPP in the almost complete absence of POOH at the beginning of the process can be explained by assuming that in this case the photochemical decomposition of carbonyl compounds becomes an important source of free radicals or that the carbonyl compounds are formed in the chain propagation reaction on photochemical oxidation of OPP. The increase of the release of radicals into space on photolysis of strained polymers is indicated by the results of studies[57-59], where the increase of the concentration of radicals on photolysis of strained PA and PMMA compared with unstrained polymers was observed by EPR. The degree of liberation of radicals into space in the photolysis of ketones in OPP was determined[15] on the assumption that two kinds of carbonyl compounds are present in the OPP. Some of the carbonyl groups are distributed along the extended polymer chains and in their photochemical decomposition $f=2$, while others are distributed along non-extended chains and have the same properties as in IPP. The effective value of f was found by comparing the rate of accumulation of carbonyl compounds with the current concentration of POOH in the OPP. It was found that f increases compared with IPP almost by an order of magnitude and reaches $f=2$ at the beginning of the process.

As a result of the appearance of a second source of free radicals in the OPP, namely carbonyl compounds, the orientation of polypropylene does not always increase its stability. Thus, under the influence of light with $\lambda=254$ nm, the rates of accumulation of carbonyl compounds in OPP ($\bar{\lambda}=4.5$) and in IPP are virtually the same, while under the influence of light with $\lambda>300$ the photochemical oxidation of OPP is significantly faster than that of IPP.[56] This result can be readily explained by the fact that the extinction coefficients of POOH and carbonyl compounds at a wavelength of 254 nm are almost identical, while at $\lambda>300$ nm carbonyl compounds absorb light almost 20 times more effectively than POOH (Table 1).

In the thermal oxidation of polyolefins orientation always increases their stability, since a new source of free radicals does not appear in this process.

In the course of the oxidation of OPP the oriented macromolecules are ruptured with a consequent gradual disorientation of the amorphous component (chemical relaxation); the rate of accumulation of POOH increases, its yield per mole of absorbed oxygen also increases[50], while the effective liberation of free radicals into space in the photochemical decomposition of carbonyl compounds diminishes[56]. However, despite the fact that extensive and varied data have been obtained for the oxidation of OPP, at the present time the mechanism of this process has not been established at a quantitative level and only its fundamental features are clear.



1. OPP is oxidised via a chain mechanism with quadratic chain termination.

2. The formation of free radicals by the photochemical decomposition of carbonyl compounds plays an important role in the photochemical oxidation of OPP, so that, depending on the intensity and spectral composition of the light acting on the polymer, the orientation of polypropylene can lead to both a decrease and an increase of the rate of photochemical oxidation, while thermal oxidation of polypropylene is always inhibited when the latter is oriented.

3. In the course of oxidation there is a gradual disorientation of the amorphous component of the OPP and the qualitative differences in the oxidation of OPP and IPP gradually diminish.

The results could be seemingly accounted for on the hypothesis that the oriented transient chains in OPP play a role akin to inhibitors which terminate the oxidation chains. However, under the conditions of this process mechanism, the kinetics of the photochemical oxidation should be determined by the dose of the light incident on the specimen, since in linear chain termination the rate of formation of any reaction product is linearly related to the rate of initiation. Furthermore, this conclusion is inconsistent with the available experimental data. Thus in the photochemical oxidation of OPP the efficiency of the formation of carbonyl compounds (per quantum of the light incident on the specimen) is higher the lower the irradiation intensity[56]. This result can be explained only by assuming that the branched products (carbonyl compounds) accumulate in the chain propagation reaction with quadratic termination or in accordance with a more complex kinetic mechanism in which the interaction between the reaction products plays an important role. This mechanism of the formation of carbonyl compounds in the chain propagation reaction can be set up by postulating that the peroxy-radical group on the strained chain is unstable and isomerises or decomposes, yielding ultimately a carbonyl compound.

Formally one can postulate the following different pathways leading to such isomerisation:

The consecutive isomerisation of the radicals (I) → (III) → (II), involved in competition with the oxidation of radical (III) leading to the formation of POOH (VIII) has been considered[49-51]. The authors believe that their observation of an increase of the yield of hydroperoxide per mole of absorbed oxygen with increase of O_2 pressure from 150 to 600 mmHg constitutes proof of this mechanism[60]. This conclusion appears to be ambiguous, since oxygen accelerates the oxidation of any alkyl radicals and the increase of the yield of POOH can be accounted for by competition between the oxidation of labile alkyl radicals and their interaction with strained polymer chains. The rate constant for the latter reaction should greatly exceed that for the

chain propagation in IPP, since otherwise the rates of oxidation of OPP and IPP would differ insignificantly, because the majority of chains in OPP are unstrained. Therefore the role of the competition between these reactions should be effective at considerably higher oxygen pressures than in the case of competition between analogous reactions in IPP involving an unstrained chain. This reaction is known[4] to be significant in IPP only at $p_{O_2} < 100$ mmHg. At higher p_{O_2} the influence of oxygen is determined by the competition between the reactions involving the formation of block hydroperoxides and the transfer of valence by the alkyl radical to another macromolecule[60]. In the oxidation of OPP these reactions are apparently less important, since the formation of POOH does not constitute the main pathway to the oxidation of OPP.

2. Prediction of the Kinetics of the Variation of the Practically Important Properties of a Polyolefin on the Basis of the Known Mechanism of Its Ageing

The data described above show that studies of the mechanism of the ageing of polyolefins have usually been directed towards the investigation of the changes in their chemical composition. Studies were made of the interconversion of the active centres propagating the process and of the accumulation of reaction products. However, for practical purposes, the variation of the physicomechanical characteristics of polyolefins is usually of interest and not the variation of their composition.

At the same time it is known that the kinetics of the variation of the physicomechanical properties of polyolefins are frequently not determined by the variation of their composition. Evidently, the variation of the physicomechanical properties of polyolefins and the variation of their composition in the course of ageing are caused by the same elementary processes, so that, in order to predict the kinetics of the variation of the practically important properties of the polymer, it is necessary to discover which elementary process is the primary determinant of its properties. This was achieved in the study of the photochemical oxidation of polypropylene and polyethylene.

A characteristic feature of this process is the fact that the reaction products accumulate more effectively at lower light intensities, where the branching product (the hydroperoxide) is formed in a process with longer chains. The available literature data show[41] that this feature holds qualitatively when one considers the kinetics of the variation of the molecular weight and the mechanical characteristics [the strength σ and the elongation on rupture ε (%)] of polypropylene and polyethylene.

The nature of the relation between the physicomechanical properties of polyolefins and their composition and the causes of the differences in the form of the kinetic curves for the variation of ε(%) in the case of specimens prepared in different ways are unknown, but the available data are in good qualitative agreement with the data for the mechanism of the photochemical oxidation of polyolefins. The lower the light intensity, the greater the chain length in the formation of the branching product (POOH), and consequently the higher the efficiency of all the processes occurring in the polymer.

Fig.4 presents the same relations for polypropylene obtained by plotting along the abscissa axis the amount of radicals formed in the specimen by a given instant and not the amount of light incident on the specimen:

$$\Omega = \int_0^t (2\alpha[\text{POOH}] + f\alpha'[\text{C=O}])\,dt. \qquad (16)$$

Evidently, in terms of these coordinates, the data obtained at different light intensities fit the same relation. The quantity Ω can be calculated with the aid of a system of equations for any variable operating conditions, while the relation between ε(%), σ and Ω, can be obtained empirically for different polypropylene specimens.

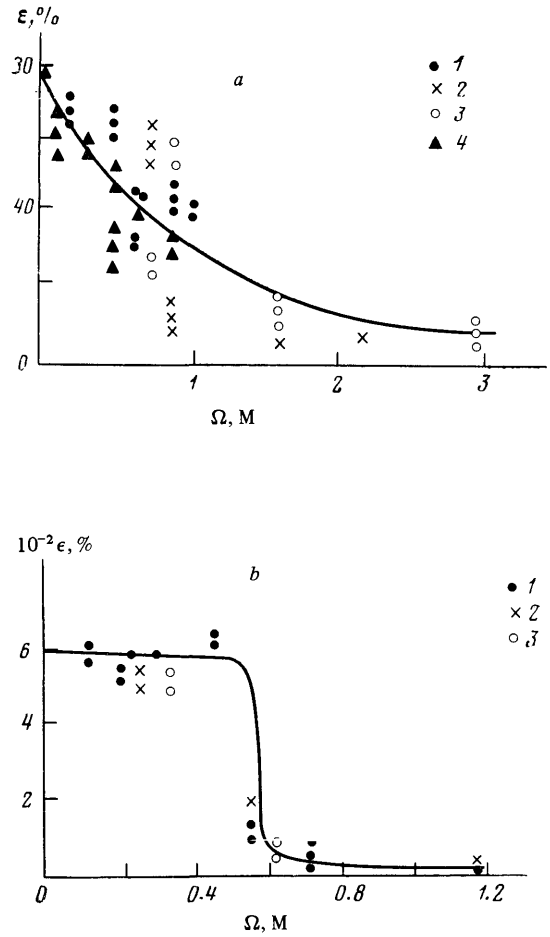


Figure 4. Dependence of the relative elongation on the dose of radicals Ω: *a*) triply oriented and annealed specimen; *b*) IPP. Intensity of incident light 10^{-15} I (quanta cm^2 s^{-1}): 1) 4; 2) 0.7; 3) 0.24; 4) 4 (in the presence of 0.15 M Methylox)[9].

Polyethylene is a much more stable polymer than polypropylene and its photochemical decomposition time is several times longer than the time required to decompose polypropylene. Analysis of Eqn.(16) shows that, for high values of t, the rate of accumulation of Ω is independent of the intensity of the incident light. Fig.5 illustrates the kinetics of the variation of ε(%) and σ for polyethylene at different light intensities. Evidently the results fit a single relation, as in the case of polypropylene. Thus on the basis of the known mechanism of the accumulation of the products of the photochemical oxidation of pure polyolefins,

it was possible to describe the kinetics of the variation of their physicomechanical characteristics.

As stated above, the mechanism of the photochemical oxidation of OPP has not been established at all hitherto. Nevertheless it has been shown[15] that the variation of the physicomechanical characteristics of OPP is correlated with the variation of Ω. The difference relative to the oxidation of IPP discussed above consists in the fact that Ω was calculated from experimental kinetic curves for the accumulation of POOH and carbonyl compounds and not on the basis of a known oxidation mechanism. Thus, even when the mechanism of the photochemical oxidation of the polymer is not known completely, it is possible to describe the kinetics of the variation of its physicomechanical properties in this process.

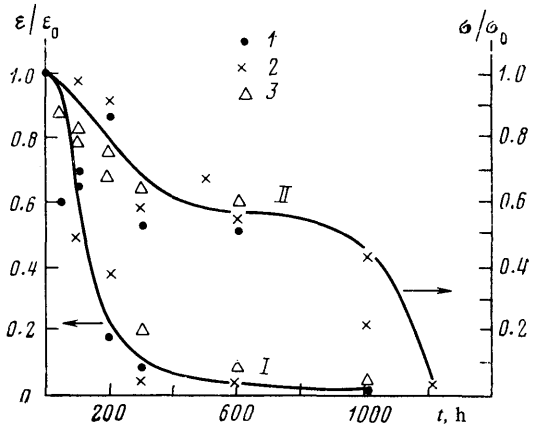

Figure 5. Dependence of the relative elongation (I) and strength (II) on the radical dose in the photochemical oxidation of HPPE.[41] Intensity of incident light 10^{-15} I (quanta cm^2 s^{-1}): 1) 2; 2) 1; 3) 0.3.

3. Photochemical Oxidation of Polypropylene Thermally Stabilised by Sterically Hindered Phenols

The example of the photochemical oxidation of pure polypropylene discussed above is to a large extent of academic interest. Only polypropylenes containing thermal and light stabilisers, which increase their useful lifetime, are used in practice. The widely employed stabilisers of the phenolic type are acceptors of the free radicals which inhibit the dark stages of the oxidation process. At the same time these stabilisers absorb the short-wavelength component of sunlight fairly effectively and function as photosensitisers of the oxidation process. Therefore, in the study of the photochemical oxidation of polymers in the presence of phenols, it is necessary to take into account not only the inhibiting effect of the antioxidant but also its initiating capacity. Furthermore, one must take into account the initiating activity of the inhibitor conversion products. For example, it has been shown[61] that the methylenequinone formed in the oxidation of ionol can dehydrogenate decane, increasing at the same time the rate of initiation. The mechanism of the sensitisation of the photochemical oxidation by phenols is complex and has not so far been ultimately established[62,63].

The photochemical transformation of the thermal stabiliser Methylox [the methyl ester of β-(3,5-di-t-butyl-4-hydroxyphenyl)propionic acid] in polypropylene has been investigated[63]. It was shown that the photochemical oxidation of Methylox results in the formation of two different photochemically active products A and B. Product A absorbs light in the longer-wavelength part of the spectrum than Methylox and many of its characteristics (the form of the absorption spectrum, the quantum yield of the photochemical decomposition) correspond to 2,6-di-t-butyl-4-methylmethylenequinone. Product A sensitises the photochemical decomposition of Methylox. Under the influence of light, products A and B decompose with different quantum yields and in the presence of large radiation doses both products are consumed almost completely and the specimen ceases to absorb light with $\lambda > 220$ nm.

Despite the very complex mechanism of the photochemical transformation of phenols in the polymer, the knowledge of the principal features of the mechanism of the photochemical transformation of pure polypropylene made it possible to discover the fundamental stages of the process which determine the photochemical decomposition of the thermally stabilised polymer.

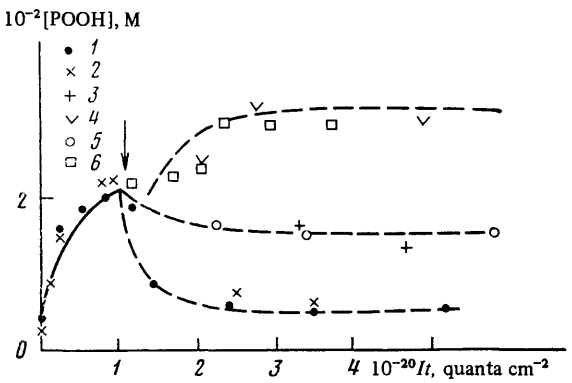

Figure 6. Kinetic curves for the accumulation of POOH in specimens containing 0.15 M Methylox[63]. Intensity of incident light 10^{-15} I (quanta cm^2 s^{-1}): 1) and 2) 4; 3) and 5) 1.4; 4) and 6) 0.7. The calculated curves are shown dashed. In plotting curves *3* and *4* the irradiation dose $It = 1.2 \times 10^{20}$ quanta cm^{-2} was attained at $I = 4 \times 10^{-15}$ quanta cm^2 s^{-1}. The arrow indicates the instant at which Methylox is consumed.

Fig.6 illustrates the kinetics of the variation of the concentration of POOH in the photochemical oxidation of polypropylene thermally stabilised by Methylox. Evidently, at different light intensities the amount of accumulated POOH at the beginning of the process is determined by the amount of light incident on the specimen. By the time of the virtually complete consumption of the phenol, the kinetic curves describing the variation of the POOH concentration begin to diverge. At low light intensities POOH continues to accumulate, while at high light intensities the POOH concentration falls.

The observed features can be readily explained within the framework of the kinetic mechanism of the photochemical oxidation of pure polypropylene with a certain initial concentration of POOH accumulated at the beginning of the process. If the initial POOH concentration is higher than the limiting value for the given intensity, then, after the consumption of the phenol, the POOH concentration will diminish; if it is lower, then POOH will continue to accumulate. The kinetics of the variation of the POOH concentration should then be described by the equation

$$[\mathrm{POOH}] = [\mathrm{POOH}]_\infty (1-(1-\sqrt{[\mathrm{POOH}]/[\mathrm{POOH}]_\infty}) \times e^{-\alpha t/2})^2. \quad (17)$$

Fig.6 shows that Eqn.(17) describes satisfactorily the kinetics of the accumulation of POOH after the consumption of Methylox. This shows that the products of the photochemical transformation of Methylox do not function as sensitisers of the photochemical oxidation process.

The variation of the physicomechanical properties of the thermally stabilised polypropylene is described by the same relation as for the pure polymer; the dose of the radicals formed in the photochemical decomposition of POOH is then calculated from the data for the kinetics of the variation of the concentration of POOH. The identity of the two relations (for the pure and thermally stabilised polymers) show that the variation of the physicomechanical properties is determined in both cases by the kinetics of the same radical reactions.

Thus, in order to develop a method for predicting the kinetics of the variation of the properties of thermally stabilised polypropylene, it is only necessary to calculate the kinetics of the consumption of Methylox and to discover at which concentration of the latter the process mechanism begins to be described by the kinetic mechanism for the photochemical oxidation of pure polypropylene. The latter problem is solved relatively simply: it is sufficient to assume that, as long as Methylox is present in the polymer, it is consumed both via its intrinsic photochemical decomposition and in terminating all the oxidation chains initiated as a result of the decomposition of POOH. Presumably, as long as the polymer contains Methylox, POOH is not effectively consumed in the photochemical decomposition steps, since it is constantly regenerated by the interaction of Methylox with peroxy-radicals.

On the basis of the foregoing, it is possible to obtain the following system of differential equations describing the kinetics of the formation of POOH in polypropylene in the presence of Methylox:

$$\frac{d[\mathrm{M}]}{dt} = -\alpha_\mathrm{M}[\mathrm{M}],$$
$$\frac{d[\mathrm{POOH}]}{dt} = f_\mathrm{M}\alpha_\mathrm{M}[\mathrm{M}], \quad (18)$$

where [M] is the concentration of Methylox, f_M the yield of hydroperoxide per Methylox destruction step, $\alpha_\mathrm{M} = \int_\lambda \phi_\mathrm{M}\varepsilon_\mathrm{M} I d\lambda$, ε_M the extinction coefficient of Methylox, and ϕ_M the quantum yield in the consumption of Methylox. The quantity ϕ_M has been included in the integral, since the consumption of Methylox is not an elementary photochemical reaction[63] and ϕ_M can therefore depend on the wavelength of the acting radiation. Under the influence of light with $\lambda = 254$ nm, we have $\phi_\mathrm{M} = 2.7 \times 10^{-2}$ and $f_\mathrm{M} = 0.14$.

After the consumption of the thermal stabiliser, the kinetics of the variation of the POOH concentration are described by Eqn.(17) for an initial non-zero POOH concentration calculated with the aid of Eqn.(18).

Thus, despite the fact that the mechanism of the sensitising effect of phenols in the polyolefin has not been established and the nature of the relation between the composition of the photochemical oxidation products and the kinetics of the variation of the physicomechanical properties of the polymer is unknown, it was possible to put forward, on the basis of ideas concerning the fundamental features of the process mechanism, a method for the prediction of the kinetics of the variation of the properties of a thermally stabilised polymer.

4. Prediction of the Useful Lifetimes of Polyolefins under Natural Conditions

The elucidation of the mechanism of the photochemical oxidation of polypropylene and the determination of the correlation between the kinetics of this process and the kinetics of the variation of the physicomechanical properties led to the formulation of the problem of the calculation of the rate of change of these properties in the course of the natural ageing of polypropylene.

As shown above, the kinetics of the variation of the physicochemical mechanical properties of polypropylene are determined unambiguously by the amount of radicals formed in the polymer throughout the process—the dose of the radicals Ω. Consequently the determination of the useful lifetime of polypropylene reduces to the calculation of Ω under the operating conditions. Two problems arise in the calculation of this quantity.

1. Eqns.(7) and (8), describing the kinetics of the photochemical oxidation of polypropylene, are non-linear and the kinetics of the variation of Ω under conditions varying with time cannot therefore be reduced to the kinetics of the variation of this quantity under equivalent conditions which are constant in time. Indeed, under variable conditions, even when the condition of a quasi-stationary concentration of free radicals holds, the kinetics of the variation of Ω in the photochemical oxidation of IPP are desdribed by the integral equation

$$\Omega = \int_0^t e^{-D}\left(\int_0^t k_p[\mathrm{PH}]\sqrt{\alpha/k_t}\, e^{D/2} dt\right)^2 \alpha\, dt, \quad (19)$$

where $D = \int_0^t \alpha dt$. Evidently one cannot replace the variable characteristics of the conditions by average quantities. In this case one can speak of an average temperature, provided that the intensity of the light and the temperature are in no way correlated. The average light intensity can in principle characterise the quantity D; however, the light intensity also enters into the integrand independently of D.

Analogous relations should apparently hold also in thermal oxidation. The activation energies for the thermal decomposition of POOH and for the process described by the integrand may not be the same; this means that the process kinetics cannot be described within the framework of the same activation energy and it is therefore also not always possible to adjust the thermal process to an equivalent temperature.

The above calculation is illustrated in Fig.7, where the kinetic curves for the variation of Ω at different constant light intensities are shown. In the calculation it was assumed† that the light intensity varied periodically; during approximately one tenth of the period, the light intensity

†O.N.Karpukhin and E.M.Slobodetskaya, J.Polymer Sci., Polymer Chem.Ed., 17, 3687 (1979).

was I_0 (and $\alpha = \alpha_0$), while in the course of the remaining nine tenths of the period it was 100 times lower.

It is seen from the data presented that, under the conditions of a variable intensity the process proceeds in accordance with a qualitatively different law. The limiting rate of increase of Ω, which is independent of light intensity under constant conditions, under variable conditions does depend on the law governing the time variation of I. In the example under consideration it is almost three times smaller than for the average intensity.

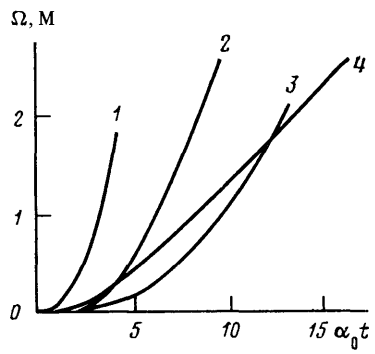

Figure 7. Calculated curves based on the measurement of Ω in the photochemical oxidation of polypropylene for variable (cruve 4) and constant (curves 1–3) light intensities[64]. The law governing the variation of I is described in the text: 1) $0.1I_0$; 2) $0.03I_0$; 3) $0.015I_0$.

Thus the calculation requires data for the dynamics of the variation of the light intensity and temperature in the course of ageing and not simply the average characteristics of the operating conditions of the polyolefin.

2. Modern computer techniques permit the calculation of Ω after substituting in the initial system of equations the primary data for the variation of the temperature and the intensity and spectral composition of the effective radiation. However, it has been found that, apart from Moscow, systematic regular measurements (over a period of many years) of the ultraviolet component of sunlight, which largely determines Ω, have hardly been made anywhere.

It is therefore necessary to resort to the advances in modern meteorology in order to set up a program for the calculation of Ω on the basis of the available meteorological data. This program includes the following initial data[64]: (a) the physicochemical characteristics of the process (the rate constants for the elementary reactions of the Arrhenius form, the absorption spectra, and the quantum yields of the decomposition of POOH and carbonyl compounds); (b) the spectral characteristics of the sun and the Earth's atmosphere (the spectrum of the sun at the outer edge of the atmosphere, the absorption spectrum of the ozone layer of the atmosphere, and the characteristics of the light scattering by the atmosphere); (c) the results of meteorological observations (temperature, thickness of the ozone layer, and the characteristics of the cloud cover); (d) geographical coordinates of the site where the tests are performed and the geometry of the arrangement of the polymer specimens (the angle with respect to the horizon and the direction of inclination).

In the calculation it was assumed that the variation with respect to the spectral composition of the solar radiation occurs only due to the change in the effective thickness of the ozone layer, while clouds play the role of an absolutely grey light filter. Fig.8 presents kinetic curves, calculated from meteorological data (Moscow, 1974)[64], for the variation of Ω and the accumulation of the products of the oxidation of free horizontally arranged polypropylene specimens exposed on the first of each month. Evidently the useful lifetime of the specimens varies with the time of the beginning of the exposure, since during cold months the photochemical oxidation is extremely slow. Fig.8 also shows that the same value of Ω, i.e. the same degree of change in the mechanical properties of polypropylene, is obtained at different concentrations of hydroperoxy- and carbonyl groups.

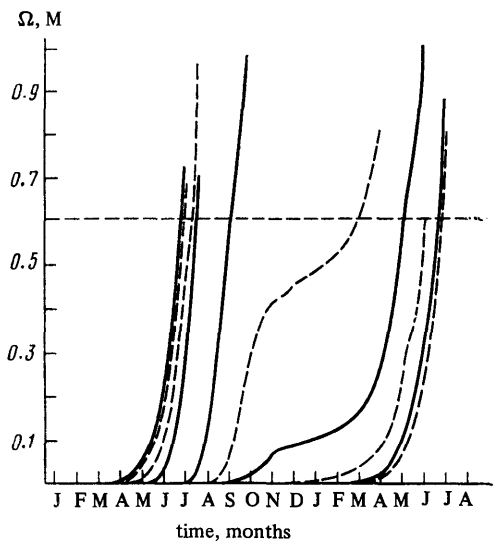

Figure 8. Calculated kinetic curves for the variation of Ω on exposure of polypropylene. Ω = 0.6 M corresponds to the loss of useful operating properties by the polypropylene.

A special computational experiment shows[64] that, in order to determine the useful lifetime of the polymer in the given case, one can employ the average monthly temperatures and average monthly coefficients of the screening of ultraviolet radiation by clouds. The average monthly coefficient of the screening of ultraviolet radiation by clouds K is calculated from the empirical formula proposed by Belinskii et al:[65]

$$K = \frac{n_1 + 0.8n_2 + 0.6n_3 + 0.35n_4}{N},$$

where N, n_1, n_2, n_3, and n_4 are respectively the total number of days, the total number of clear days, the number of days with a variable cloud cover, the number of cloudy days, and the number of days without sunshine. The quantities n_1, n_2, n_3, and n_4 are recorded systematically in the course of meteorological observations.

Comparison of the results of the calculation with the results of tests under natural conditions showed that the experimental useful lifetime is systematically shorter than the calculated lifetime. This arises apparently because the temperature of the exposed polymer specimens is always higher than the temperature of the ambient layer, since they are heated as a result of the absorption of light by the support on which the specimen rests. According to the results of Kurzhenkova and Pashchenko[66], for example, films stretched on agricultural implements age preferentially at the sites of contact with the frame, which is due to the higher temperature at these sites compared with the free film. It has been shown[67] that the film exposed under natural conditions on a black support is heated to 40–50 °C, while on a white support its temperature is 25–27 °C. It is also known that the films used for fencing in seed beds are at a temperature higher by 10–15 °C than that of the surrounding medium[67].

Thus the data presented show that in the given case the exact determination of the useful lifetime of the polymeric material is limited by the lack of exact data concerning its operating conditions.

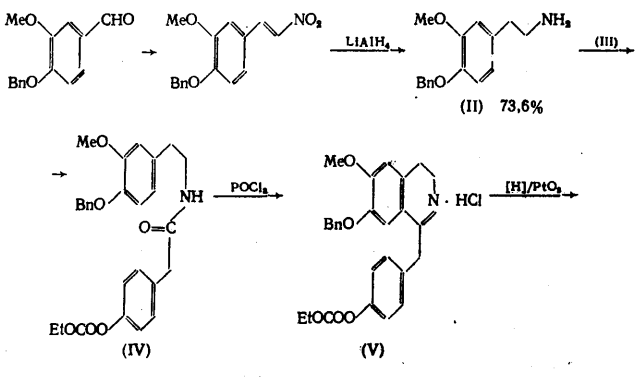
Synthesis of Bisbenzylisoquinoline Alkaloids

O.N.Tolkachev, E.P.Nakova, and R.P.Evstigneeva

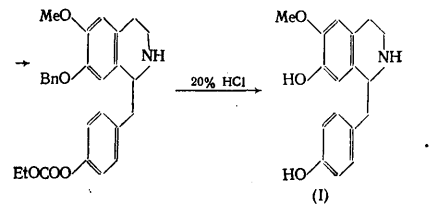
Methods for the synthesis of bisbenzylisoquinoline alkaloids and also 1-benzylisoquinoline bases, which are biogenetic precursors of the dimeric alkaloids, are surveyed in the biogenetic sequence of the alkaloids. Not only total but also partial and biomimetic syntheses of bisbenzylisoquinoline bases are covered. A list of 153 references is included.

CONTENTS



I. Introduction 784
II. Synthesis of coclaurine and its derivatives 784
III. Synthesis of bisbenzylisoquinoline alkaloids containing one diphenyl ether link 785
IV. Synthesis of bisbenzylisoquinoline alkaloids containing two diphenyl ether bridges 787
V. Synthesis of bisbenzylisoquinoline alkaloids containing three diphenyl ether links 795

I. INTRODUCTION



Bisbenzylisoquinoline alkaloids form a large group (>150) of naturally occurring compounds in which two benzylisoquinoline moieties are joined by one, two, or three ether links. More rarely a diphenylated carbon–carbon bond is encountered. The number and positions of the ether links are used to classify these alkaloids[1], and this classification has great value for the choice of method of synthesis. During recent years great attention has been paid to these alkaloids in connection with the discovery of their great and diverse biological activity—antitubercular, anti-inflammatory, antitumour, etc. (see reviews[2–4]).

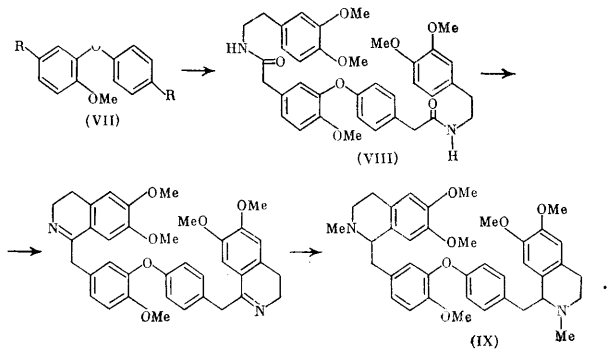
II. SYNTHESIS OF COCLAURINE AND ITS DERIVATIVES

Since coclaurine (I) and its derivatives accompany bisbenzylisoquinoline alkaloids in plants, besides being precursors and also structural fragments, their synthesis is a necessary stage in obtaining the dimeric alkaloids. The method of synthesising coclaurine suggested originally consists in the condensation of *p*-benzyloxy-*m*-methoxyphenethylamine (II) with *p*-chloroformylphenyl ethyl oxalate (III), Bischler–Napieralski cyclisation of the resulting amide (IV) to give the dihydroisoquinoline derivative (V), reduction of the double bond over platinum dioxide, and removal of the protective groups by acid hydrolysis[5]:†

† Here and subsequently the abbreviations Me = CH_3, Et = C_2H_5, and Bn = $C_6H_5CH_2$ are employed.

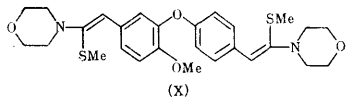
This scheme has since been only slightly modified. For example, racemic coclaurine has been synthesised via the corresponding dibenzyl derivative, with the free amine (II) replaced by its *N*-formyl derivative[6]; the double bond in the dihydroisoquinoline derivative is then reduced with zinc dust in acetic acid. It has also been proposed[7] to use homovanillylamine for condensation with the acid component followed by temporary protection of the phenolic hydroxyl in the resulting amide by acetylation, which makes it possible to have fewer stages and increase the overall yield of coclaurine.

Several coclaurine derivatives—intermediates in the synthesis of bisbenzylisoquinoline alkaloids—have been synthesied similarly[8–10]. The initial amines are obtained by reducing the corresponding nitrostyrenes with lithium tetrahydroaluminate[5,11], over palladium–carbon to the oxime and then over platinum dioxide to the amine[5] or over palladium black to homovanillylamine[12]. It has been proposed[13,14] to reduce an unsubstituted or a substituted nitrostyrene with amalgamated zinc dust in acid. The reduction of *p*-benzyloxy-*m*-methoxyphenylacetonitrile with lithium tetrahydroaluminate has been described[15]. Cyclisation to dihydroisoquinoline is effected with phosphoryl chloride in various solvents, e.g. toluene[5], chloroform[6,15], or acetonitrile[16], in the last of which a good yield was obtained. Phosphorus pentachloride[15] and other phosphorus compounds, such as polyphosphoric acid and phosphorus pentoxide[17], have also been used as condensing agents.



The synthesis of (±)-coclaurine has been accomplished also by Arndt–Eistert condensation of a 4-methylsulphonyloxy-ω-diazoketone with (II) to give the corresponding amide[18].

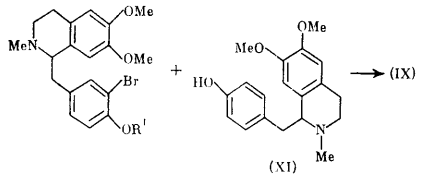
(±)-*N*-Methylcoclaurine has been obtained by the methylation of coclaurine with formaldehyde and formic acid[19], and also by reduction of the urethane derivative of dibenzylcoclaurine with lithium tetrahydroaluminate followed by hydrogenolysis[20]. Resolution of *N*-methylcoclaurine into optical antipodes was achieved by means of (+)- and (−)-di-*p*-tolyltartaric acids[21]. (±)-Armepavine and its derivatives have been resolved similarly[22,23].



III. SYNTHESIS OF BISBENZYLISOQUINOLINE ALKALOIDS CONTAINING ONE DIPHENYL ETHER LINK

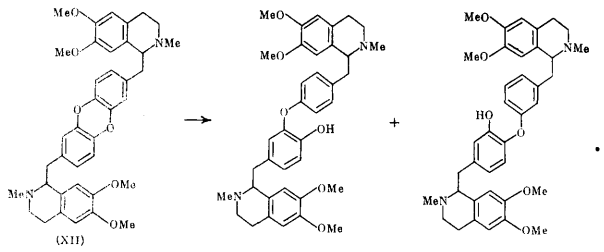
The simplest bisbenzylisoquinoline alkaloids are bases of monoether type—magnoline and dauricine—at which were aimed the first synthetic attempts. There exist two fundamental synthetic routes to such alkaloids—(*a*) from substituted diphenyl ethers by the addition of appropriate isoquinoline fragments using known methods and (*b*) by linking substituted benzylisoquinoline bases by means of ether bridges.

The first attempt to synthesise a bisbenzylisoquinoline alkaloid was made in 1935,[24] when a scheme was worked out for obtaining *O*-methyldauricine (IX)# via the intermediate 4-methoxy-3-phenoxybenzene-1,4'-dicarboxylic acid (VII: R =COOH), which was converted into the acid chloride, aldehyde, azlactone, and then the bisacetic acid (VII: R = CH_2. .COOH); the isoquinoline fragments were obtained by Bischler–Napieralski cyclisation of the corresponding bishomoveratrylamides (VIII) with subsequent conversion into the tetrahydro-*N*-methylisoquinoline derivative by the usual method:



Since, however, the required compound was non-crystalline, it was converted into a methine base identical with the compound obtained from the natural alkaloid[24]. This scheme was subsequently improved by modifying the method of obtaining the initial acid (VII: R = CH_2COOH): *o*-methoxydiphenyl ether was chloromethylated, the halogen atom replaced by a cyano-group, and the latter was hydrolysed[28]; alternatively the corresponding diacetyl derivative was subjected to the Willgerodt–Kindler reaction, and the resulting bisthiomorpholide was hydrolysed[29]. The intermediate bisamide (VIII) has been obtained also by condensing homoveratrylamine with the bisenaminothioether structure[30]

Application of this scheme to the benzylated diacid gave a diastereomeric dauricine mixture[31]. Another scheme for the synthesis of (±)-dauricine was based on the Arndt–Eistert reaction of a bisdiazoketone with homoveratrylamine[32,33], which also gave a diastereomeric racemic mixture.

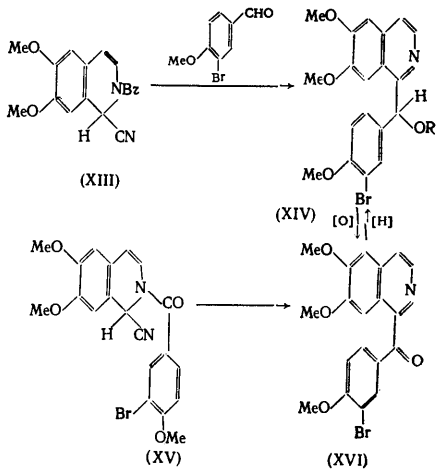


O-Methyldauricine was originally obtained by methylating natural dauricine with diazomethane. It was first detected in plant sources (*Colubrina asiatica*, etc.) only in 1970.[25–27]

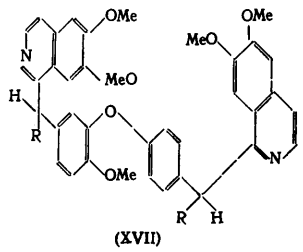
Racemic magnoline was synthesised from appropriate benzyl or ethoxycarbonyl derivatives of the acid (VII).[34–36] In view of the difficulties encountered in removing the benzyl group, preference was given to the ethoxycarbonyl group. A diastereomeric mixture of (±)-cuspidaline was synthesised similarly[37,38]. A different route—condensation of (–)-armepavine with (–)-1-*m*-bromo-*p*-methoxybenzyl-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methylisoquinoline, obtained by the bromination of armepavine (XI)—was used to synthesised *O*-methyldauricine in 24% yield[39]:

(±)-Dauricine[31,40,41], daurinoline[42], magnoline[43], (±)-magnoline[44], and berbamunine[45] have been obtained by the same synthetic method.

Dauricine is formed, together with an isomer differing in the position of the ether link, when the dibenzodioxin ring of compound (XII) undergoes fission in the presence of sodium in liquid ammonia[46]:



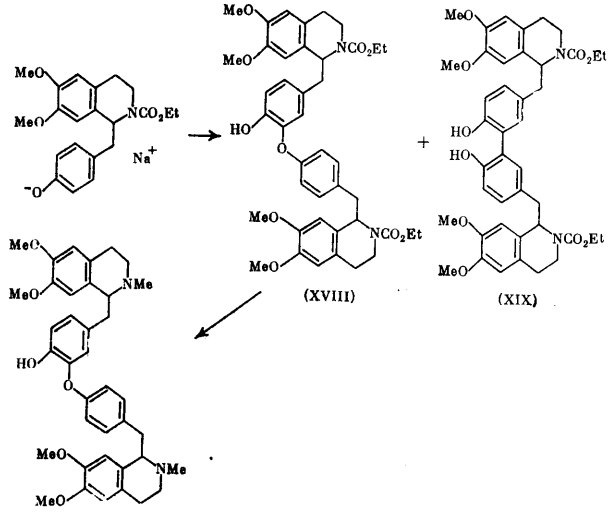
The intermediate (XII) was synthesised from the corresponding diacetyldibenzodioxin via the stages of bisthiomorpholide, diacid, diamide, bisdihydrosioquinoline derivative, and dihydric secondary base.



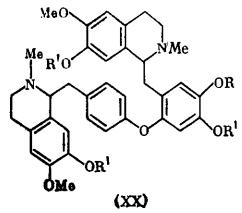
Dauricine has been obtained, in low yield, also by selective demethylation with butylmagnesium bromide of the methoxy-group in the diphenyl ether portion of *O*-methyldauricine[47].

An original sythesis of *O*-methyldauricine[48,49] consisted in reaction between 2-benzoyl-1,2-dihydro-6,7-dimethoxyisoquinolyl cyanide (Reissert's compound, XIII) and *m*-bromo-*p*-methoxybenzaldehyde, hydrolysis of the resulting *O*-benzoyl derivatives (XIV: R = C_6H_5CO) to the carbinol (XIV: R = H) in 87% yield, and reduction of this product with zinc dust in hydrobromic acid to 1-*m*-bromo-*p*-methoxybenzyl-6,7-dimethoxyisoquinoline (yield 78%), whose methiodide was reduced with sodium tetrahydroborate to 1-*m*-bromo-*p*-methoxybenzyl-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methylisoquinoline and then condensed with (±)-armepavine, as mentioned above; in a modification of this synthesis 1-*m*-bromo-*p*-methoxybenzoyl-1,2-dihydro-6,7-dimethoxyisoquinolyl cyanide (XV) was converted into 1-*m*-bromo-*p*-methoxybenzoyl-6,7-dimethoxyisoquinoline (XVI) in the presence of sodium hydride in dimethylformamide (yield 49%)

and then reduced to the carbinol with sodium tetrahydroborate:



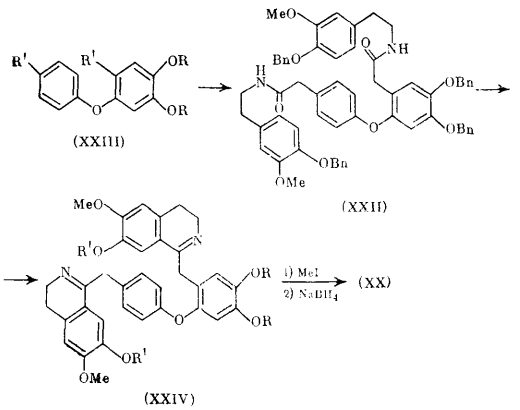
A shorter synthetic route to (±)-*O*-methyldauricine involves condensation of the diphenyl ether (VII: R = CHO) with Reissert's compound to give the bisisoquinoline base



with R = C_6H_5COO in 83% yield. The latter was hydrolysed with aqueous–alcoholic alkali to the diol (XVII: R = OH), which was reduced with zinc dust in a mixture of hydrobromic and acetic acids to give a 91% yield of a product from which the methiodide was obtained and further reduced with sodium tetrahydroborate to an 81% yield of *O*-methyldauricine (overall yield 52% based on Reissert's compound)[48]. Yet another alternative was to condense Reissert's compound with 5,4'-bischloromethyl-2-methoxydiphenyl ether (VII: R = CH_2Cl) and hydrolyse the product with aqueous–alcoholic alkali to the bisisoquinoline derivative (XVII: R = H), whose methiodide was similarly reduced to *O*-methyldauricine[50].

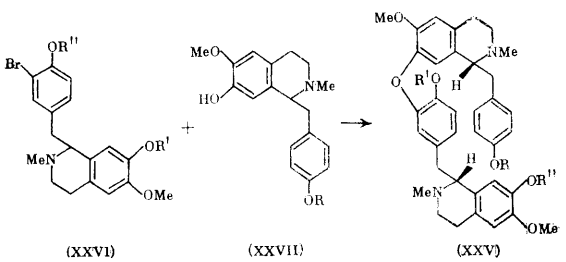
Theoretical interest attaches also to the biomimetic synthesis of (±)-dauricine by the electrochemical oxidation of salts of *N*-ethoxycarbonyl-*N*-norarmepavine to the compound (XVIII) followed by reduction of the ethoxycarbonyl to an *N*-methyl group; the dimer (XIX) was isolated as a by-product[51]:

Magnolamine is an alkaloid closely similar to those already discussed: it differs in the presence of an additional oxygen function and in the location of the diphenyl ether link. It was originally assumed to contain four hydroxy-groups (XX: R = R' = H) [52–55]



but it has now been proved that only three hydroxyls are present (XX: R = CH_3; R' = H).[56]

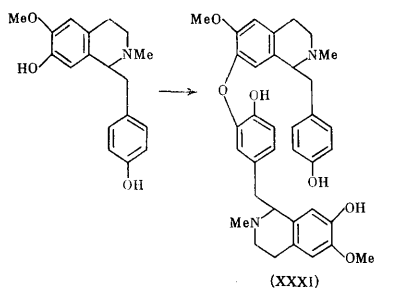
The antipode and the diastereomer of methylmagnolamine have been obtained by the condensation of (–)-6'-bromolaudanosine (XXI) with respectively (–)- and (+)-armepavine, which confirmed the *SS*-configuration of the natural alkaloid [57,58]. Similarly, condensation of the corresponding benzylated components[59] gave a stereoisomeric mixture of the tetraol having the formula originally suggested for magnolamine. Ullmann condensation in its classic form gives a very low yield (~2%). Replacement of copper powder and pyridine by pentafluorophenylcopper enables the yield of the methyl ether of magnolamine to be raised to 53%. In this case the reaction involves intermediate formation of copper phenoxide[60].



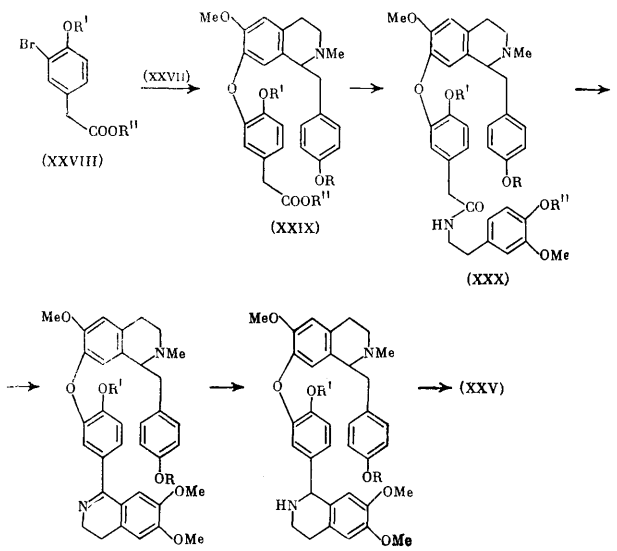
A total synthesis of a diastereomeric mixture of "magnolamine" (XX: R = R' = H) (*O*-demethylmagnolamine) was also accomplished by route (*b*) [see below], in which the bisamide (XXII) was obtained by the Arndt–Eistert method from

(II) and the bisdiazoketone (XXIII: $R = C_6H_5CH_2$; $R' = N_2CHCO$):

As in other cases, the diastereomeric mixture could not be resolved[51,62]. The tetradehydro-derivative (XXIV: $R = CH_3$: $R' = C_6H_5CH_2$) was also synthesised by a method involving formation of an intermediate bisamide[63]. Here the initial dicarboxylic acid (XXIII: $R = CH_3$; $R' = CH_2COOH$) was obtained in two ways—(*a*) chloromethylation of *mp*-dimethoxydiphenyl ether with subsequent replacement of the chlorine atoms by cyano-groups followed by hydrolysis, and (*b*) Ullmann condensation of two substituted esters of phenylacetic acids.



Another type of monoether base, in which benzylisoquinoline fragments are linked "head to tail", is represented by liensinine (XXV: $R = R' = H$; $R'' = CH_3$) and isoliensinine (XXV: $R = CH_3$; $R' = R'' = H$). The former was synthesised by condensation of the bromobenzylisoquinoline component (XXVI: $R' = CH_3$; $R'' = C_6H_5CH_2$) with the *p*-benzyl ether or the *p*-toluene-*p'*-sulphonic ester of *N*-methylcoclaurine (XXVII):[64,65]

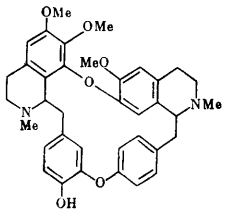


Condensation of the bases (XXVI: $R' = R'' = C_6H_5CH_2$) and (XXVII: $R = CH_3$) or their optically active forms gave (±)- and (−,−)-isoliensinine[65–69].

In another synthesis (Scheme 1) the *p*-methyl ether of *N*-methylcoclaurine (XXVII: $R = CH_3$) is condensed with the bromophenylacetic ester (XXVIII: $R' = CH_3$; $R'' = CH_3$, C_2H_5), and then the diphenyl ether (XXIX: $R = R' = CH_3$; $R'' = H$, CH_3, C_2H_5) is converted by the action of homoveratrylamine into the amide (XXX), which after cyclisation to the dihydroisoquinoline derivative, reduction, and *N*-methylation gives *OO'*-dimethyl-liensinine[70].

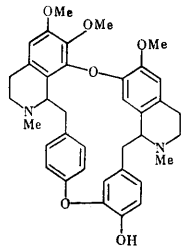
The enzymatic oxidative dimerisation of *N*-methylcoclaurine has been achieved, with the isolation of 7″-*O*-demethylliensinine (XXXI) together with the corresponding trimer[71]:

Scheme 1



IV. SYNTHESIS OF BISBENZYLISOQUINOLINE ALKALOIDS CONTAINING TWO DIPHENYL ETHER BRIDGES

This group of alkaloids, which are formed in plants by enzymatic double dehydrogenation of two molecules of coclaurine or its derivatives, can be divided into four types of compounds differing in the location of the ether bonds.

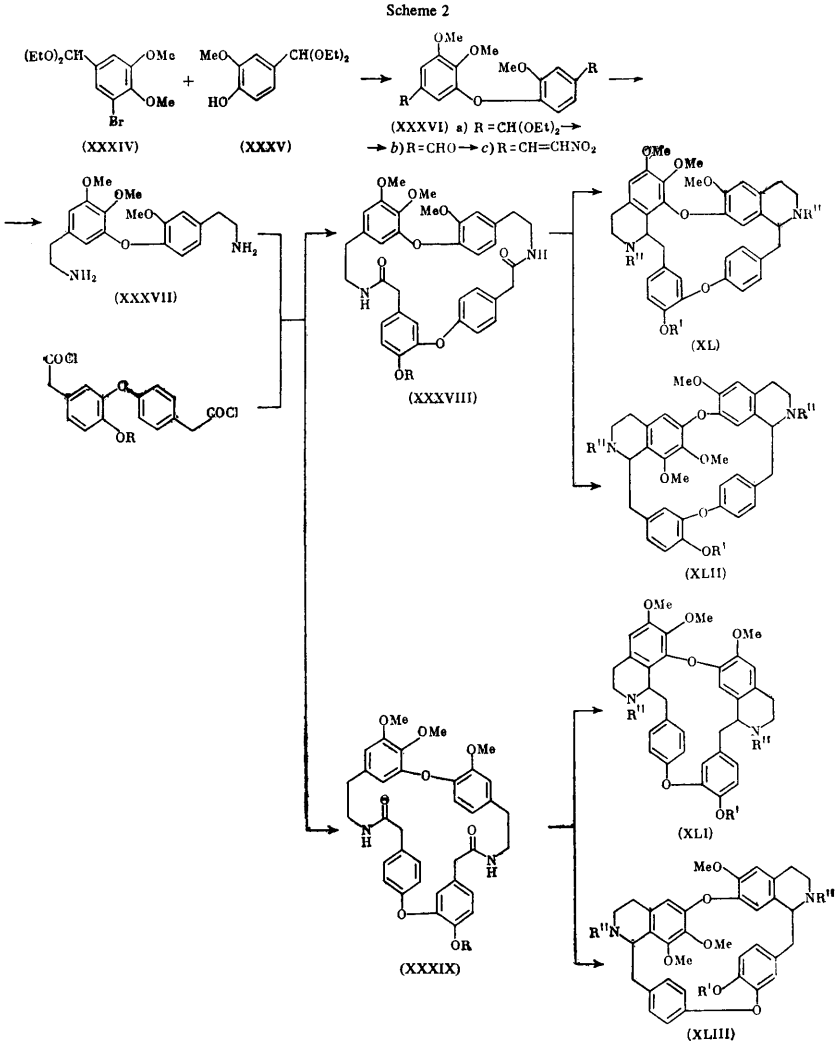


1. Oxyacanthine–Berbamine Type of Alkaloids

This group of natural bases includes the structural isomers berbamine (XXXII) (*RS*), oxyacanthine (XXXIII) (*SR*), their stereoisomers—pycnamine (XXXII) (*RR*) and repandine

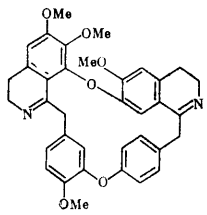
(XXXII), (*SS*)—and also their derivatives.

(XXXII)

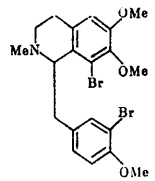


(XXXIII)

The synthesis of berbamine and oxyacanthine (Scheme 2) consists in condensation of the acetals of 5-bromoveratraldehyde and vanillin (XXXIV and XXXV) to give the diacetal (XXXVIa) of diphenyl ether (in 53% yield), which is converted by acid hydrolysis into the dialdehyde (XXXVIb) and then into the oxybisnitrostyrene (XXXVIc). The latter is reduced with lithium tetrahydroaluminate to the diamine (XXXVII).



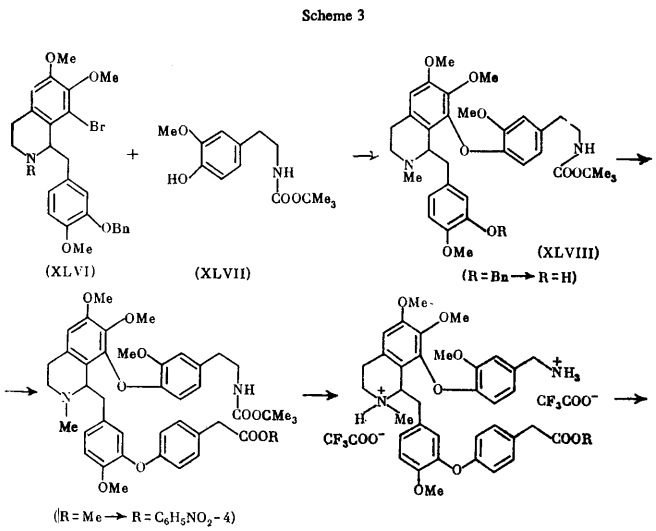
The Schotten–Baumann reaction with 2-benzyloxy-4',5-oxybisphenylacetyl chloride gives an isomeric mixture of the amides (XXXVIII) and (XXXIX), which are separated chromatographically and then subjected to Bischler–Napieralski cyclisation. Each amide forms a mixture of isomeric dihydroisoquinoline bases, which are converted without resolution into the methiodides, reduced, and then debenzylated. After cyclisation of the final products the compounds (XL)–(XLIII) were isolated, two of which were identified with berbamine and oxyacanthine[72,73].



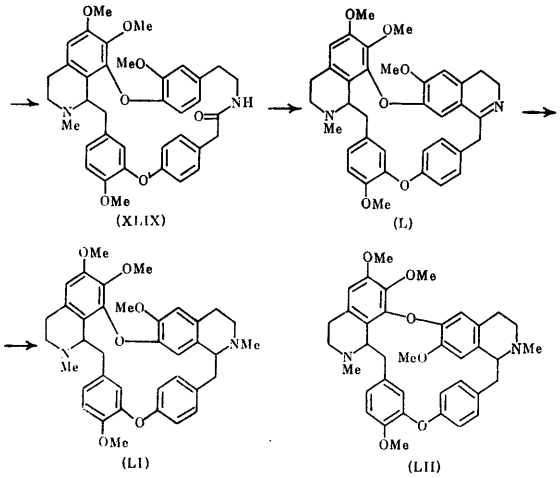
The non-phenolic alkaloids obaberine (*O*-methyloxyacanthine) and tetrandrine have been synthesised by a similar route[74]. In this case the bisamide (XXXVIII: $R = CH_3$), after cyclisation to the bisdihydroisoquinoline bases, was first reduced to the tetrahydroisoquinoline derivatives, which were separated and then methylated. One of the final compounds was identified with *O*-methyloxyacanthine. Tetrandrine was obtained (Scheme 2) from the other bisamide (XXXIX: $R = CH_3$). In the early attempts to synthesise this alkaloid by a similar scheme the dihydroisoquinoline derivatives could not be isolated[75–78]. Other schemes were also proposed, in which the initial diacid was obtained e.g. by Willgerodt rearrangement of the corresponding acetophenone

Scheme 2

[75,79]. Direct condensation of *p*-hydroxyphenylacetic and *m*-bromo-*p*-methoxyphenylacetic esters gives a low yield of the expected diphenyl ether. Obtaining the acid component by Arndt–Eistert chain lengthening has no advantages over the first method[81]. The second component for the synthesis—the diamine (XXXVII)—was also obtained by several methods, e.g. from the corresponding diacid (formed in low yield by Ullmann condensation of substituted aromatic esters) by reduction of ester to hydroxymethyl groups, replacement of the hyroxyls by chlorine and then by cyano-groups, and subsequent reduction with lithium tetrahydroaluminate[80–82]. On the other hand, the dialdehyde (XXXVIb), obtained from the corresponding acid dichloride by Rosenmund reduction, was further converted via the corresponding nitrostyrene (as described above) into the diamine (XXXVII).[75,81] This compound was synthesised from the corresponding bispropionic acid via the isopropylidene hydrazide[83].

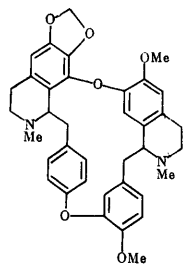


(XLIV)

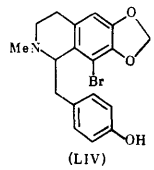


(XLV)

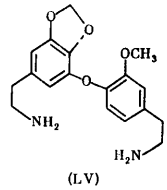
The alkaloid stebisimine, a bisdehydro-derivative (XLIV) isolated from *Stephania japonica*[84], was identified with an intermediate in the synthesis of obaberine[85,86].



Another synthesis of tetrandrine was the condensation of *N*-methylcoclaurine with its 3′,8-dibromo-*OO*′-dimethyl derivative (XLV).[87] However, all syntheses of this type are at present merely of theoretical interest, because of the very low yields.



Scheme 3

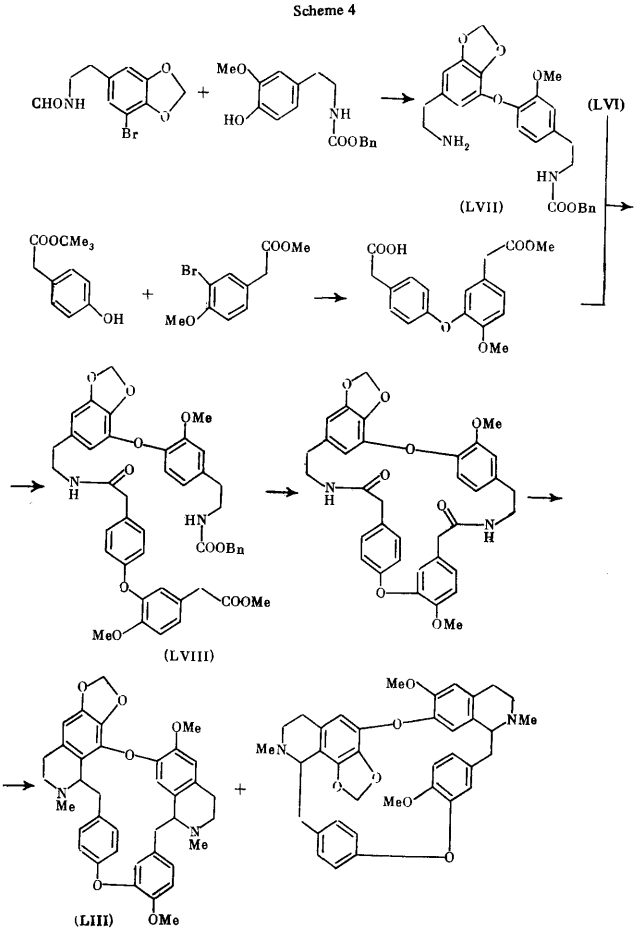


(R = Me → R = $C_6H_5NO_2$-4)

(XLIX) (L) (LI) (LII)

The first total synthesis of the optically active alkaloids—tetrandrine, isotetrandrine, and pheanthine—was accomplished in 1968 from *O*-benzyl-8-bromolaudanine (XLVI: R = H) (Scheme 3),[88,89] which was obtained from 5-bromohomoveratrylamine and *O*-benzylhomoisovanillic acid by classic methods. The tetrahydroisoquinoline derivative was resolved into its optical antipodes by means of (+)-tartaric acid, and after *N*-methylation subjected to Ullmann condensation with t-butyl *N*-*p*-hydroxy-*m*-methoxyphenethylcarbamate (XLVII) to give the diphenyl ether (XLVIII: R = $C_6H_5CH_2$) in 50% yield. After debenzylation (by hydrogenolysis) and condensation with methyl *p*-bromophenylacetate the protecting group in the diphenyl ether was removed, and the cycloamide (XLIX) isolated in 54% yield. Cyclisation to the dihydroisoquinoline (L), reduction, and *N*-methylation gave a mixture of isotetrandine and pheanthine (LI), which were separated by crystallisation of the picrates. (±)-Tetrandrine, which had previously been resolved[90], and *O*-methylthalicberine (LII) [91] were synthesised similarly. Japanese chemists have patented this synthesis of tetrandrine, isotetrandrine, and pheanthine[92].

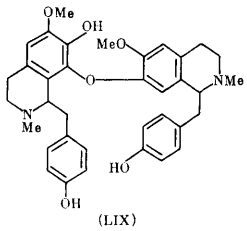
(LIII)



(LIV)

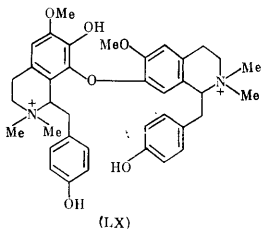
(LV)

The first attempts to synthesise the alkaloid cepharanthine (LIII) by double Ullmann condensation of the two tetrahydroisoquinoline fragments (LIV) and (XXVI: R′ = H; R″ = CH_3) were unsuccessful owing to difficulties in obtaining an 8-bromo-derivative with a methylenedioxy-group (LIV).[93] An attempt to synthesise this alkaloid by the scheme of double amide condensation of diacid and the diamine (LV) described



for tetrandrine gave a mixture of cyclobisamides, one of which when isolated could not be cyclised to the expected bis-dihydroisoquinoline[79,80,93–95]. Spectral results indicated that merely products of the oxidation and partial cyclisation of the bisamide had been isolated[96].

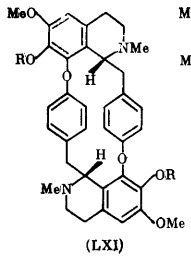
Scheme 4



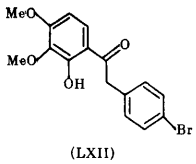
The first successful synthesis of cepharanthine was accomplished by Japanese workers, with successive formation of amide links to obtain the intermediate cyclobisamide[87,98]. Monosubstituted components—the monoether (LVI) and the benzyl *N*-aminoethylphenoxyphenethylcarbamate (LVII)—were synthesised for condensation in the presence of dicyclohexylcarbodi-imide to form initially the monoamide (LVIII) (Scheme 4). The second amide link was formed by means of activated esters. This multistage synthesis of cepharanthine has also been patented by Japanese workers[99]. As in the preceding syntheses, the Bischler–Napieralski cyclisation produces two isomeric dihydroisoquinoline bases, so that not only cepharanthine (LIII) but also its isomeric 6,7′-ether was isolated. Cepharanthine can be converted into obaberine (*O*-methylhydroxyacanthine) by removing the methylene group with a mixture of phloroglucinol and sulphuric acid and then methylating the phenolic product[100].

An attempted double oxidative coupling of *N*-methylcoclaurine units to form compounds of the oxyacanthine–tetrandrine series was unsuccessful. Use of potassium hexacyanoferrate-(III) as oxidant or enzymatic oxidation in the presence of hydrogen peroxide converts coclaurine derivatives or their quaternary ammonium salts merely into the 7′,8-dehydro-derivatives

(LIX)

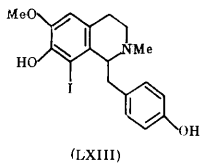


(LX)



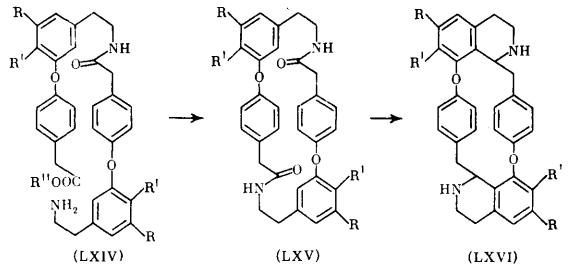
whose structures have been confirmed by synthesis[101–105].

2. Isochondrodendrine Alkaloids



Alkaloids of this type include isochondrodendrine, its methyl ether cycleanine, insularine, etc. The *RR*-configuration has been established for the first two (LXI: R = H, CH_3), which have an axis of symmetry, in contrast to alkaloids of the berbamine–oxyacanthine series. Although alkaloids of the present type were the first to attract the attention of chemists, progress in this field has been achieved only recently. Their synthesis presented certain difficulties, since methods developed for the preceding type of bases proved relatively unsuitable. Several unsuccessful attempts were made to effect a double Ullmann condensation of (LXII) with the aim of obtaining the macrocyclic system forming the basis of isochondrodendrine[106]. An attempt to synthesise 8-iodo-*N*-methyl-coclaurine (LXIII), an intermediate in the synthesis of isochondrodendrine, was also unsuccessful[107].

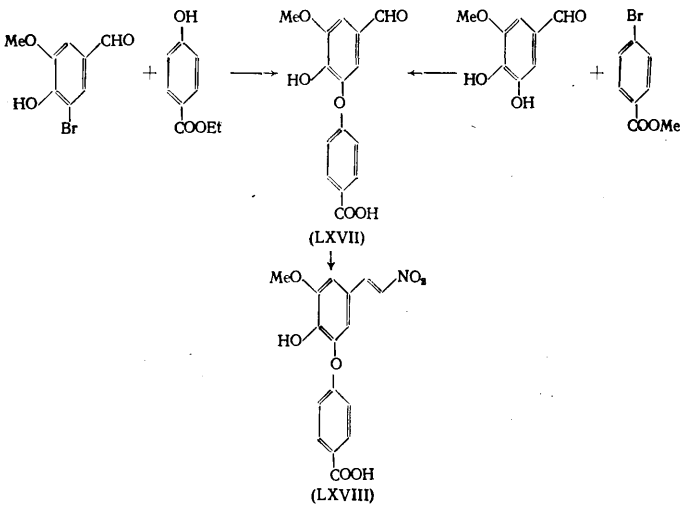
(LXI)



(LXII)

(LXIII)

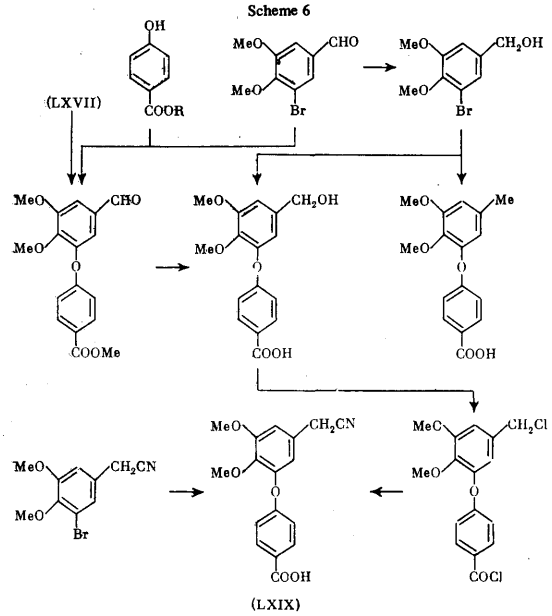
A theoretical synthesis of isochondrodendrine alkaloids was suggested by Preobrazhenskii et al.[108] and accomplished on a model compound. The main stage was intramolecular cyclisation of the monoamide (LXIV) to the macrocyclic diamide (LXV), which was converted by cyclisation followed by



reduction into (LXVI: R = R' = H):

(LXIV) (LXV) (LXVI)

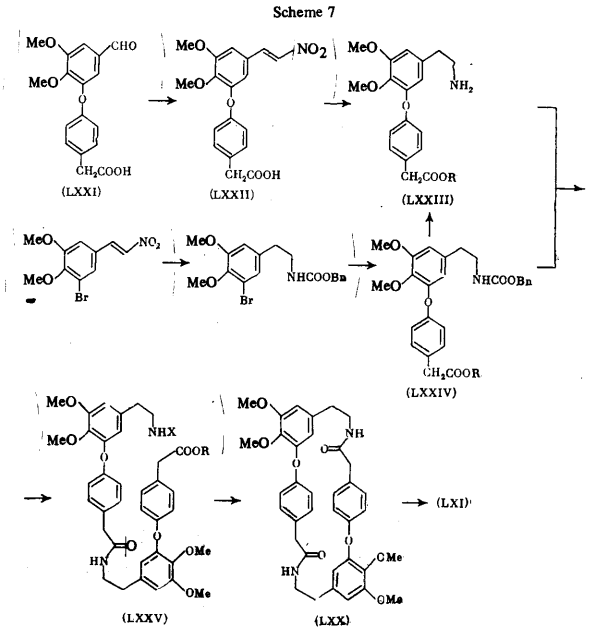
The initial diphenyl ethers were synthesised by condensing 5-bromovanillin with a *p*-hydroxybenzoic ester, or $O_{(3)}$-methylgallaldehyde with a *p*-bromobenzoic ester, to give *p*-5'-formyl-2'-hydroxy-3'-methoxyphenoxybenzoic acid (LXVII), which was converted by means of nitromethane into the corresponding nitrostyrene (LXVIII) (Scheme 5).[109] Alternatively, halogen activation was used to increase the yield of the products, by introducing a nitro-group into the halogenated component, and subsequently removing it. However, the additional operations required to eliminate the nitro-group from the nitrated diphenyl ether almost nullify the advantages of this method[109]. The nitrovinyl group can then be reduced over palladium black to an aminoethyl group[110].



Scheme 5

(LXVII) (LXVIII)

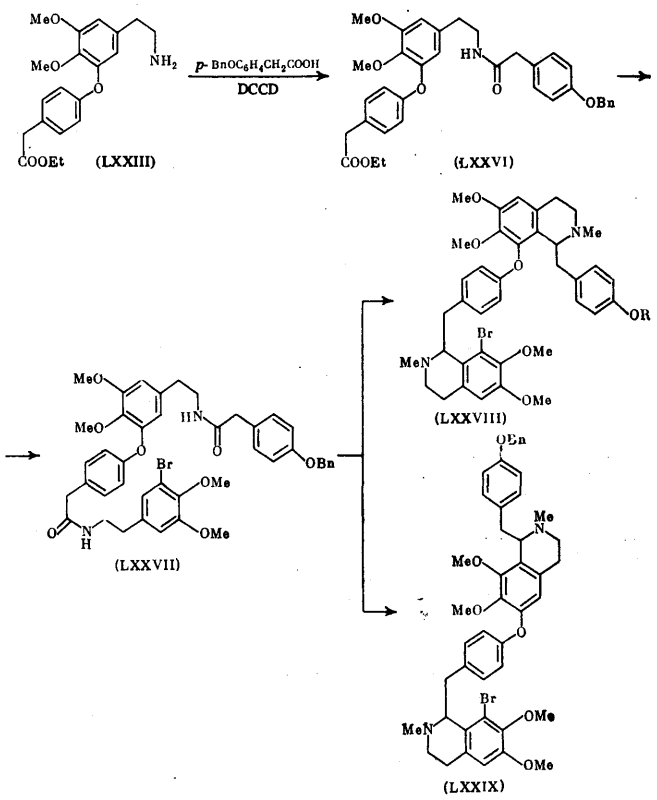
p-5'-Cyanomethyl-2',3'-dimethoxyphenoxybenzoic acid (LXIX), identical with the product of the condensation of 3'-bromo-4',5'-dimethoxyphenylacetonitrile with a *p*-hydroxybenzoic ester, was synthesised by methylating the phenolic hydroxyl in (LXVII), reducing the formyl group to a hydroxymethyl group, and then replacing the hydroxyl by a chlorine atom followed by a cyano-group (Scheme 6). Other intermediates in the synthesis have also been obtained independently, as outlined in Scheme 6.[111]



Scheme 6

(LXVII) (LXIX)

The two diphenyl ethers can be combined by Arndt–Eistert chain lengthening to give the cyclodiamide (LXV: R = R' = CH_3O). In view of the low overall yield, however, a search was made for more practicable methods of synthesis. In ticular, reduction of brominated nitrostyrenes with zinc amalgam was used to obtain 4-alkoxy-3-bromo-5-methoxyphenethylamines[13], which would yield 7-alkoxy-8-bromo-3,4-dihydro-1-*p*-hydroxybenzyl-6-methoxyisoquinolines[10], intermediates in the synthesis of these alkaloids. However, the cyclocondensation of (±)-8-bromoarmepavine was accompanied by debromination, so that only (±)-armepavine and (±)-*NOO'*-trimethylcoclaurine were isolated[112,113].

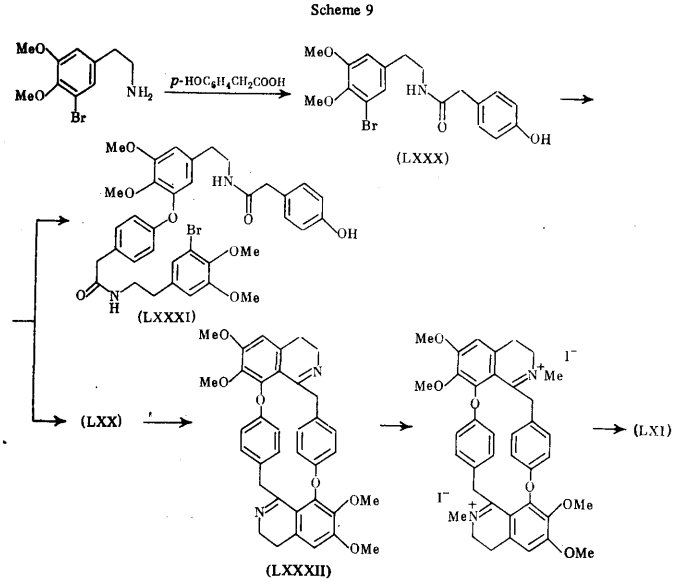


Scheme 7

(LXXI) (LXXII) (LXXIII) (LXXIV) (LXXV) (LXXVI) (LXI)

In the first of two independent syntheses of (±)-cycleanine (LXI: R = CH_3) via the cyclobisamide (LXX) the acetal of 5-bromoveratraldehyde was condensed with a *p*-hydroxyphenylacetic ester, and the resulting p-5'-formyl-2',3'-dimethoxyphenoxyphenylacetic acid (LXXI) was converted into the nitrostyrene (LXXII), which was reduced to the amino-acid (LXXIII) (Scheme 7). An ester of this acid was obtained by condensing benzyl *N*-5-bromohomoveratrylcarbamate with a *p*-hydroxyphenylacetic ester and then hydrogenolysing the carbamic ester (LXXIV). The two fragments (LXXIII) and (LXXIV) were condensed by means of dicyclohexylcarbodiimide in dichloromethane. The second amide link was formed by heating the *p*-nitrophenyl ester (LXXV) in the presence of pyridine and triethylamine[114–116].

Scheme 8

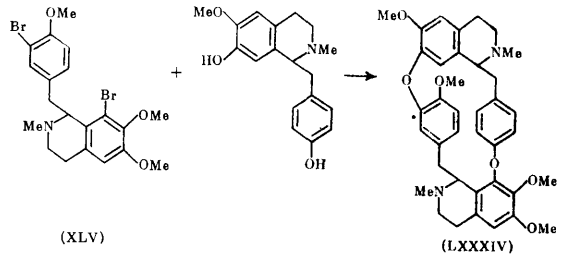


In another procedure[117] the initial amino-acid is condensed in the form of an ester [LXXIII] with *p*-benzyloxyphenylacetic acid, and the resulting amide (LXXVI) converted by reaction with 5-bromohomoveratrylamine into the diamide (LXXVII) which is cyclised, reduced, and methylated (Scheme 8). This yields a mixture of isomeric tetrahydroisoquinoline bases (LXXVIII) and (LXXIX), one of which was identified with the product of the condensation of (±)-8-bromoarmepavine with (±)-8-bromo-*NOO'*-trimethylcoclaurine in the presence of copper(II) oxide instead of metallic copper as catalyst. However, cyclocondensation of (LXXVIII: R = H) into cycleanine could not be achieved[112].

Scheme 9 outlines a successful double Ullmann cyclocondensation of the phenolic bromo-amide (LXXX), in which 5-bromohomoveratrylamine was condensed with *p*-hydroxyphenylacetic acid, and the potassium salt of the resulting bromo-amide (LXXX) was converted by an Ullmann reaction into a mixture of the cyclobisamide (LXX) and the open-chain diamide (LXXXI), which were easily separated by conversion of the latter into a salt[118]. The cyclic diamide was then subjected to Bischler–Napieralski cyclisation to give the bisdihydroisoquinoline derivative (LXXXII), whose methiodide was reduced to a mixture of tetrahydroisoquinoline bases that could be separated chromatographically. One of these showed the same chromatographic mobility as natural cycleanine.

Phenolic alkaloids—isochondrodendrine (LXI: R = H) and norcycleanine (7-*O*-demethylcycleanine)—have been obtained by the selective demethylation of cycleanine with hydrobromic acid[119].

Scheme 9



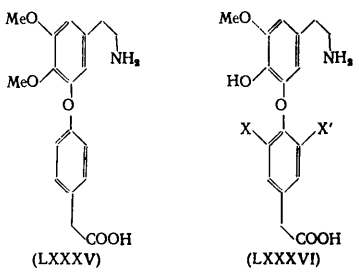
3. Curine–Tubocurarine Alkaloids

In contrast to the preceding group the present diether alkaloids are based on the unsymmetrical chondrodendrine (LXXXIII) skeleton. This group includes the alkaloids curine and the quaternary bases tubocurarine, chondrocurarine, etc. Tubocurarine chloride, the active principle of tubocurare, found application in surgical practice[120]. However, the relative inaccessability of this alkaloid and the great demand stimulated synthetic work on substitutes for curare, quaternary bisammonium salts, of which several thousands were obtained, most of them weaker than tubocurarine or having no advantages over the latter[121].

Two fundamentally different approaches have also been made to the synthesis of this group of alkaloids.

(*a*) Synthesis from benzylisoquinoline components

N-Methylcoclaurine (XI: R = H), obtained by the cleavage of isotetrandrine with sodium in liquid ammonia, was brominated at positions 3′ and 8 and then diazomethylated to give 3′,8-dibromo-*NOO*′-trimethylcoclaurine (XLV), which was condensed with the potassium salt of *N*-methylcoclaurine; *NOO*′-trimethylcoclaurine, isotetrandine, and dimethylcurine (LXXXIV) were found among the reaction products:

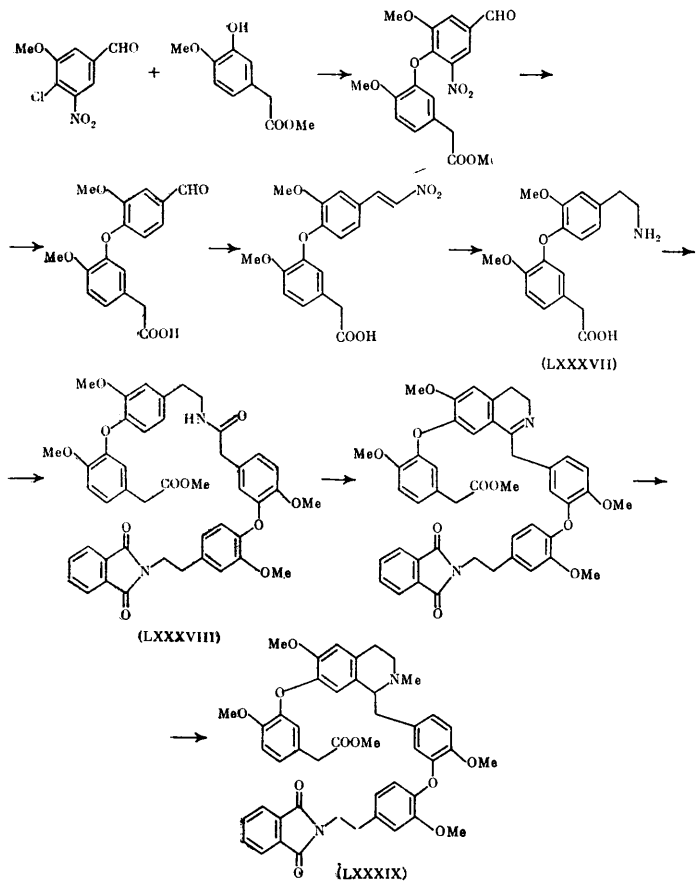


(XLV) (LXXXIV)

The use of laevorotatory components yielded (−,−)-*OO*′-dimethylcurine[122–124]. Phenolic components have also been employed for condensation, but the yield of the macroring is then very low. After methylation of the reaction products with diazomethane followed by chromatography diastereomeric racemates of *OO*′-dimethylcurine and of an acyclic base were isolated, the latter of which after debromination was identified with racemic *OO*′-dimethyl-liensinine.

(*b*) Synthesis from diphenyl ethers

The alternative synthesis of bisbenzylisoquinoline alkaloids from substituted diphenyl ethers has recently been applied to the oxyacanthine–berbamine series. However, the synthesis of amino-acid diphenyl ethers, of chondrodendrine and isochondrodendrine structural units, it made difficult by the inconvenience of obtaining them by the Ullmann reaction, because these alkaloids contain a hydroxyl next to the phenoxyphenyl link. It was shown experimentally that direct formation by the Ullmann reaction even of the simplest compounds of this type is devoid of preparative value owing to the very low yields[125]:

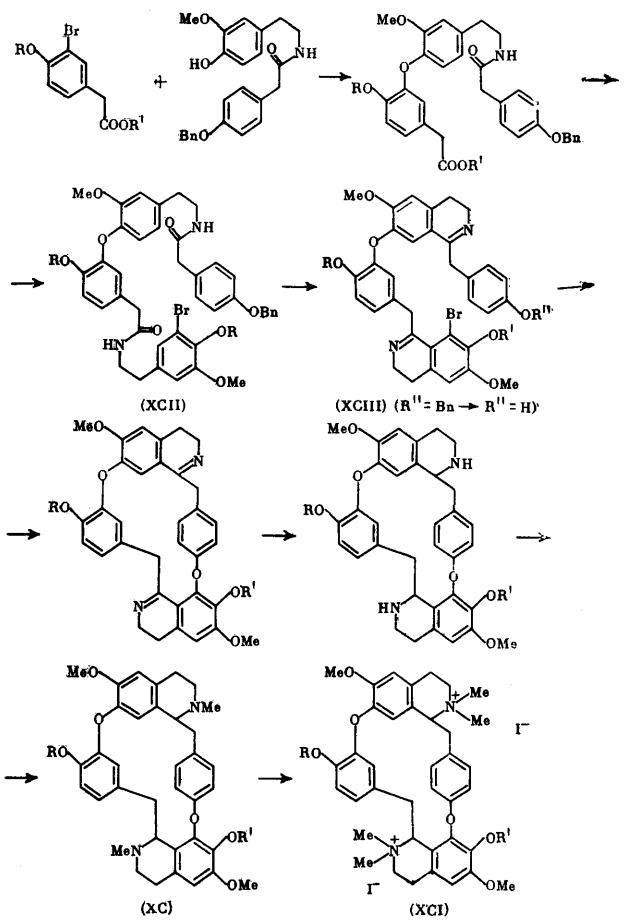


(LXXXV) (LXXXVI)

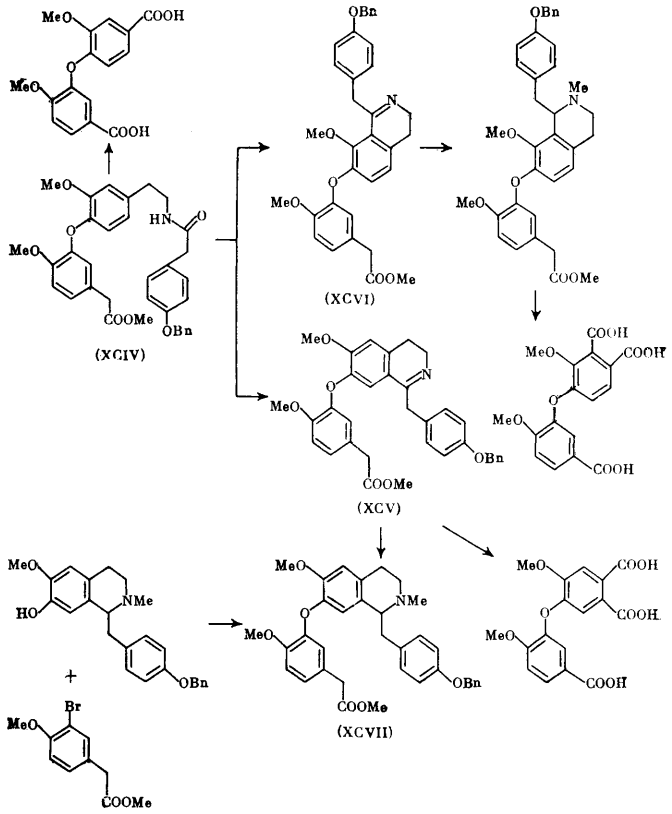
The structural formulae reveal that one diphenyl ether fragment is common to isochondrodendrine and curine, so that this moiety can be synthesised in the same way for the two alkaloids. Activation of aromatic halogen by means of groups such as nitro has been used to synthesise *p*-5′-aminoethyl-2′,3′-dimethoxyphenoxyphenylacetic acid (LXXXV) [126] and several of its phenolic analogues (LXXXVI),[127,128], as well as homologous acids (see above[109–111]).

The other component, *m*-*p*′-aminoethyl-*o*′-methoxyphenoxy-*p*-methoxyphenylacetic acid (LXXXVII), was also synthesised by the method of activated ethers from 4-chloro-3-methoxy-5-nitrobenzaldehyde and isohomovanillic acid (Scheme 10).[129,130] In all cases the activating group was removed by reduction to an amino-group, diazotisation, and subsequent treatment with hypophosphoric acid. The overall yield of the amino-acid (LXXXVII) was 12%. Further condensation of the corresponding ester with a phthalimide derivative gave the amide (LXXXVIII), which after cyclisation, reduction, and *N*-methylation was converted in low yield into the non-cyclised ether (LXXXIX).[130] It was also suggested that diphenyl ethers derived from phthalimidoamino-acids could be obtained via diaryliodonium salts, but the yield of a model compound was 6%.[131]

Scheme 10



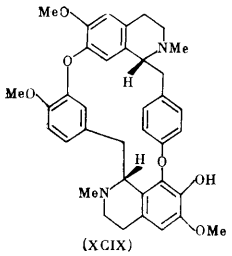
(LXXXVII) (LXXXVIII) (LXXXIX)



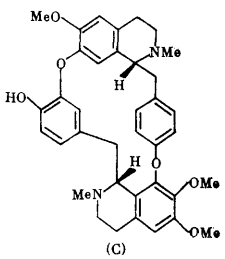
The total synthesis of racemic curine, i.e. (±)-chondrodendrine (XC: R = R′ = H), its ethers, and its quaternary salts (XCI: R = R′ = H, CH_3) is accomplished by successive chain extension followed by cyclisation of the diamide (XCII: R = R′ = CH_3, CH_3CO) to the bisdihydroisoquinoline base (XCIII: R = R′ = CH_3, CH_3CO), removal of the protecting groups, and formation of a second diphenyl ether bridge (Scheme 11).[132–137] It is noteworthy that the use of amides for Ullmann condensation enabled the required diphenyl

ethers to be obtained in good yield even when free phenolic hydroxyls were present in the compounds[138]. The amide protection of amino-groups in the Ullmann reaction later enabled Japanese workers to achieve the total synthesis of alkaloids of the oxyacanthine–tetrandrine group (see above). This scheme is simple to carry out, involves relatively few stages, and gives good yields at all stages. Diastereomeric compounds can be quite easily separated in the later stages by crystallisation of the salts. In the synthesis of (±)-chondrodendrine and its dimethiodide free hydroxy-groups must be protected by acetylation before Bischler–Napieralski cyclisation.

Scheme 11



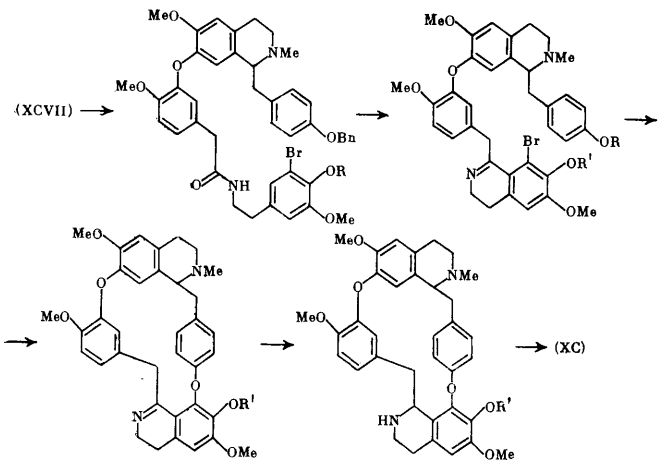
Scheme 12



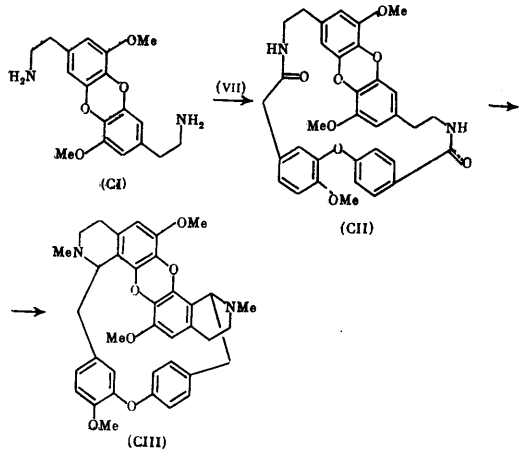
The acetamido-diphenyl ether (XCIV) was isolated in two forms, giving on cyclisation different dihydroisoquinoline derivatives (XCV) and (XCVI) (Scheme 12). The cyclisation products were identified by cross-synthesis of the compound (XCVII) and also of the oxidation products[139]. The same method was used to synthesise *NN'*-demethyl-4″-*O*-methyl chondrodendrine (*NN'*-demethylgaiatinine)[140]

The intermediate methyl *m*-l-*p'*-benzyloxybenzyl-1,2,3,4-tetrahydro-6-methoxy-2-methylisoquinolin-7-yloxy-*p*-methoxyphenylacetate (XCVII) has also been used in an alternative synthesis of *OO'*-dimethylchondrodendrine (XC: R = R' = CH_3) (Scheme 13).[141] *OO'*-Dimethyl-liensinine[70] and the non-cyclised analogue *OO'*-dimethyltubocurarine iodide[110] have been synthesised by the same route.

Demethylation of the methyl ether of curine with hydrobromic acid followed by separation of the demethylated products was reported[142], but the structures of the latter were not given. *RR*-12′-*O*-Methylcurine (4″-*O*-methylcurine) (XCIX) was obtained together with chondrofoline (C) by the partial methylation of (−)-curine with diazomethane[143].

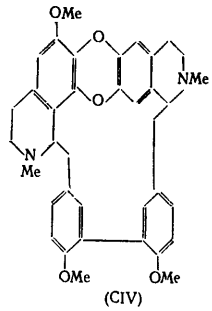


(XCIX)



(C)

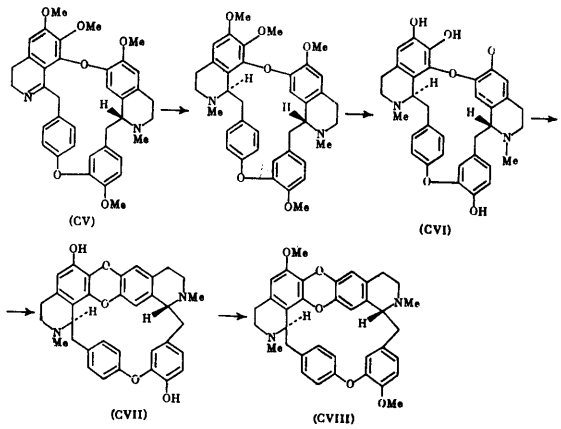
Scheme 13



V. SYNTHESIS OF BISBENZYLISOQUINOLINE ALKALOIDS CONTAINING THREE DIPHENYL ETHER LINKS

This group of alkaloids includes micranthine, menisarine, and normenisarine, as well as trilobine and isotrilobine. The structure of menisarine has been confirmed by synthesis of a derivative[144–147]. The condensation of 2,7-bis-2′-aminoethyl-4,9-dimethoxydibenzo-5,10-dioxin (CI) with 4-methoxy-3-phenoxybenzene-1,4′-bisacetic acid at high dilution gave a macrocyclic bisamide (CII), which on cyclisation, reduction, and *N*-methylation was converted into a ditertiary base, identified with dihydro-*N*-methylmenisarine (CIII) obtained from natural menisarine:

(CI) (CII) (CIII)



(±)-*O*-Methyltiliacorine

(CIV)

has been synthesised by an analogous scheme[148].

Scheme 14

(CV) (CVI) (CVII) (CVIII)

It is interesting to pass from the hydroxyacanthine to the trilobine group of alkaloids, which contains three diphenyl ether links. For example, (+)-epistephanine (CV), after reduction of the dihydroisoquinoline ring and *N*-methylation, was demethylated with hydrobromic acid at 100 °C to the tetraol (CVI), which when heated with this acid at 150 °C underwent dehydration to the prototrilobine derivative (CVII), diazomethylation of which gave (−)-isotrilobine (CVIII), the antipode of natural (+)-isotrilobine (Scheme 14)[149,150]. Repandine was similarly converted into isotrilobine[151,152], and dihydroepistephanine into the *N*-ethyl analogue of the antipode of trilobine[153].

---o0o---

During recent years synthetic schemes have been worked out for the chief bisbenzylisoquinoline alkaloids containing one, two, or three diphenyl ether links. The main criterion in the choice of method of synthesis is the biogenetic classification. At present most of these syntheses are merely of theoretical interest. However, the presence of high biological activity among bisbenzylisoquinoline alkaloids, e.g. antitumour and antitubercular in tetrandrine, etc., as well as their relative unavailability for practical use, makes further search desirable for practical methods of synthesis.

Organometallic Compounds with Heteroatomic Chains

M.N.Bochkarev

Studies on the synthesis and chemical properties of organometallic compounds containing a chain of σ-linked atoms of heteroelements are surveyed and problems of the stability of such compounds are examined.
The bibliography includes 176 references.

I. INTRODUCTION

In classifying the chemistry of organometallic compounds from the standpoint of composition, it is easy to identify the field in which compounds whose molecules contain a metal–metal group are studied. Such products are referred to as organobimetallic, organotrimetallic, etc. or the terminology adopted from inorganic chemistry is more frequently used nowadays, terms such as di-, tri-, ... poly-nuclear derivatives, in accordance with the number of heteroatoms in the molecule, being employed. The first representatives of this class were obtained in the 1920s but vigorous research has developed only in the last two decades. This took place in two main directions: (1) the search for and investigation of the properties of new combinations of heteroelements M–M′ in di- and tri-nuclear derivatives and (2) the synthesis and study of polynuclear compounds. The latter include typical clusters, i.e. substances whose molecules contain a three-dimensional or planar lattice of heteroatoms, as well as a variety of such compounds comprising substances with chains of σ-linked non-organogenic atoms, which can have a linear, branched, or cyclic form. It is noteworthy that, despite the significant difference between the kinds of M–M′ bonds in typical clusters and in σ-linked chains, these two types of substances are so close in their nature and structure that in some instances the assignment of a given compound to one class or the other is arbitrary.

The amount of literature information is by no means distributed uniformly between the above two fields of study. Whereas numerous original articles and reviews (see, for example, Vyazankin et al.[1] and Vahrenkamp[2]) have been devoted to the first area of the above studies, i.e. the investigation of di- and tri-nuclear compounds, data on polynuclear systems, particularly linear and cyclic compounds, are widely scattered and are incomplete; there is particularly little information about their reactivity. This can evidently be explained by serious technical difficulties of the synthesis of substances of this kind, their isolation in a pure state, and purification. At the same time, sufficient data exist on polynuclear compounds to make it necessary to survey them and arrange them systematically.

In the present review the first attempt is made to survey the available data on the synthesis and properties of organometallic compounds containing chains of four and more σ-linked atoms of heteroelements. The latter include all metals and metalloids with the exception of C, H, N, O and the halogens†. Sulphur-containing derivatives of the type $R_2\overset{\frown}{Sn}-S-SnR_2-\overset{\frown}{S}$, etc. are considered together with their scandium and tellurium analogues, despite the fact that sulphur belongs to organogenic elements. This approach is dictated by the similarity of the properties of all chalcogeno-derivatives and by the important role which organoelemental sulphides play in the chemistry of polynuclear compounds by virtue of the high stability of M–S compounds, their relative availability, and their likely practical usefulness.

In each section the data are arranged in accordance with the position of the heteroelements in Mendeleev's table. Initially data are presented on derivatives of non-transition elements in Groups ranging from I to VI, next mixed compounds are considered, i.e. compounds containing a non-transition element and a transition metal, and in the concluding part of the given section derivatives of transition metals are discussed.

For a more complete treatment of data on polynuclear linear and cyclic compounds, certain transition metal carbonyls and carbonyl halides are considered together with organometallic derivatives.

II. HOMOELEMENTAL COMPOUNDS

Organometallic oligomers containing chains of atoms of a single element were investigated before polyelemental compounds. This group of substances is related to inorganic crystalline polymers of the type $[K_2Pt(CN)_4Br_{0.3}.3H_2O]_x^3$ and $[Ir(CO)_3Cl]_x^4$, but they differ from them fundamentally by the absence of a crystalline columnar structure and also by the constant valence of the heteroatoms in the chain.

When diorganohalogenosilanes interact with alkali metals, cyclic polysilanes, $(R_2Si)_n$ are formed[5,6]. Together with low-molecular-weight products with $n \cong 6$, unstable polymers with $n \cong 55$ are obtained. The analogous reaction of diorganohalogenogermanes also leads to cyclic polygermanes but with a smaller number of heteroatoms in the chain ($n \leqslant 6$).[7,8] In the case of tin derivatives the first stage of the reaction of

† The terms "organoelements", "polyelemental", and similar ones imply that the atoms of any element other than those enumerated are present in the given compound.

R_2SnCl_2 with active metals (Li, Na) involves the formation of bivalent tin compounds R_2Sn. They polymerise in the course of several hours yielding 8–10-membered rings $(R_2Sn)_n$.[9–11] The formation of bivalent intermediates R_2M undoubtedly occurs also in the first two instances:

$$n\,R_2MX_2 + 2nM' \rightarrow 2n\,M'X + n\,[R_2M] \rightarrow (R_2M)_n\ ;$$
M=Si, Ge or Sn; M'=Li or Na; X=halogen .

In the reviews of Satge et al., devoted to germylenes[12], and Neumann[13], devoted to stannylenes, it was shown that polymerisation reactions and reactions involving insertion in metal–metal, metal–hydrogen, and metal–halogen bonds with formation of linear and cyclic oligomers and polymers are extremely characteristic of these highly reactive species.

The reactions of the monohalides R_3MX with alkali metals give rise to linear dimers. Thus the tetrasilane $R_3SiSiR_2SiR_2$. $.SiR_3$ was obtained from R_2SiSiR_2Cl.[14,15] Cyclic stannanes $(R_2Sn)_n$ containing between 4 and 9 tin atoms in the ring are formed when diorganotin dihydrides are heated in the presence of amines[16]. In order to obtain homonuclear linear oligomers, Neumann and coworkers used the ring opening reaction of iodine[17,18]:

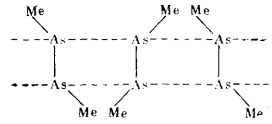
$$\begin{array}{l} Ph_2Ge{-}GePh_2 \\ \quad|\quad\ |\ \\ Ph_2Ge{-}GePh_2 \end{array} + I_2 \rightarrow I{-}GePh_2{-}[GePh_2]_2{-}GePh_2{-}I \xrightarrow{PhLi} Ph_3Ge{-}[GePh_2]_2{-}GePh_3$$

$$(Et_2Sn)_9 + I_2 \rightarrow I{-}SnEt_2{-}[SnEt_2]_7{-}SnEt_2{-}I\ .$$

A convenient method whereby one can sythesise Sn–Sn polymers as well as oligomers with a specified number of tin atoms has been developed[19,20]. The method consists in the hydrogenolysis of Sn–N bonds in amino- and amido-stannanes by organotin hydrides. This simple and convenient procedure for the formation of the metal–metal bond has come to be widely used also in the synthesis of two-element oligomers, examples of which are given in the next section.

An interesting Sn–Sn oligomer containing a cyclopentadienyltricarbonyltungsten substituent $\{Sn^{IV}[W(CO)_3Cp]_2\}_n$ have been obtained[21] by the reaction of $(CH_3C_5H_4)_2Sn^{II}$ with $HW(CO)_3Cp$. Unfortunately the value of n was not given for this compound, although it is apparently low:

$$(CH_3C_5H_4)_2\,Sn^{II} + 2HW(CO)_3\,Cp \xrightarrow{-CH_4C_5H_5}$$
$$\rightarrow \{Sn^{II}[W(CO)_3\,Cp]_2\} \rightarrow 1/n\,\{Sn^{IV}[W(CO)_3\,Cp]_2\}_n\ .$$



Silicon, germanium, and tin oligomers are viscous liquids, or, in rare cases, amorphous solids sparingly soluble in organic solvents. The solubility decreases with increase of molecular weight and the substances acquire a colour ranging from yellow to dark-red. Their thermal stability decreases on passing from silicon to germanium and tin and their reactivities increase in the same sequence.

Apart from Group IVB elements, homonuclear polymers are formed by phosphorus, arsenic, and antimony. Cyclic tetra-, penta-, and poly-phosphines are synthesised by the reaction of primary phosphines RPH_2 with dichlorophosphines[22,23]. The reaction of methylphosphine and methylarsine with dibenzylmercury results in the formation of the five-membered rings $(MeE)_5$ only[24]:

$$5MeEH_2 + 5\,(PhCH_2)_2Hg \rightarrow (MeE)_5 + 10PhMe + 5Hg$$
E = P or As.

The opening of rings of this type with the aid of RX leads to the formation of linear oligomers with the corresponding number of atoms of the heteroelement in the chain[25].

Penta- and hexa-nuclear formations are most typical for cyclic polyarsines, while in the linear oligomers the number of arsenic atoms can reach 50.[26,27] An X-ray diffraction study of the polymer $(MeAs)_n$, obtained by the reaction of $MeAsH_2$ with halogenoarsines or by the catalytic rearrangement of the cyclic pentomer $(MeAs)_5$, led to the conclusion that this compound has an unusual "ladder" structure[26]:

It was established that the length of the longitudinal As–As bonds (2.9 Å) appreciably exceeds the length of the transverse As–As bonds (2.4 Å) and the sum of the covalent radii (2.42 Å). On this basis, the authors[28] suggested that the aresenic atoms are linked to one another along the chain by "incomplete" bonds. In the determination of their physical properties it was found that the polymer is a semiconductor with a very low conductivity of 4.8×10^{13} cm Ω^{-1} (at 300 K).[28]

An analogous structure has been postulated for polymethylstibine $(MeSb)_n$, formed as a dark-red solid by the reaction of $MeSbH_2$ with dibenzylmercury[24]. The silylated polystibine $(Et_3SiSb)_n$ has been obtained together with ethylene and bromotriethylsilane by the reaction of $(Et_3Si)_3Sb$ with 1,2-dibromoethane[29].

III. TWO-ELEMENT COMPOUNDS

In the case of polynuclear compounds under consideration, the commonest are those whose molecules contain chains of atoms of two heteroelements. In the vast majority of cases the heteroatoms include those of silicon, germanium, or tin. The longest of the polynuclear derivatives whose existence has been demonstrated at the present time includes 11 heteroatoms: $Ph_3SiS{-}S_7{-}SSiPh_3$.[30] However, this nonasulphide should really be included among monoelemental compounds, since virtually the entire chain consists of sulphur atoms alone. The octanuclear cyclic cadmium ferrate $[-Fe(CO)_4-Cd-]_4$ should therefore be regarded as the two-element oligomer with the longest chain[31]. Several polymers are known whose molecular weights have not been determined owing to their poor solubility or low thermal stability, for example $[-Zr(SnPh_3)_2{-}SnPh_2-]_n$,[20] $[-Ge(C_6F_5)_2{-}Ge(C_6F_5)_2-Hg-]_n$,[32] and $(EtAlSe)_n$.[33,34] However, bearing in mind the considerable tendency of heteroatomic oligomers towards cyclisation, it is difficult to expect that n in these compounds exceeds 3–4. Furthermore, a more complex structure can be ruled out for the Zr–Sn polymer.

Derivatives of alkali metals with $M{-}(Si)_n{-}M$ chains (M = Li or Na; n = 4 or 5) have been obtained by the reaction of lithium or sodium and cyclic tetrasilane or pentasilane[35]. The products readily interact with organometallic halides[36,37] and are therefore suitable for the synthesis of other polynuclear compounds:

$$\begin{array}{l} Ph_2Si{-}SiPh_2 \\ \quad|\quad\ |\ \\ Ph_2Si{-}SiPh_2 \end{array} + M \xrightarrow{THF} M{-}SiPh_2SiPh_2SiPh_2SiPh_2{-}M\ ;$$

$$\xrightarrow[Cl_2BNMe_2]{Ph_2SnCl_2}$$

$$\begin{array}{ll} Ph_2Si{-}SiPh_2 & Ph_2Si{-}SiPh_2 \\ \quad|\quad\ |\ & \quad|\quad\ |\ \\ Ph_2Si\quad SiPh_2 & Ph_2Si\quad SiPh_2 \\ \quad\diagdown\quad\diagup & \quad\diagdown\quad\diagup \\ \quad\ SnPh_2 & \quad\ BNMe_2 \end{array}$$

M = Li or Na.

By allowing Ph_2GeH_2 to react with diethylmercury, Neumann and coworkers obtained the polymer $[-GePh_2-Hg-]_n$ in the form of a viscous yellowish resin[38,39]. However, this polymer cannot be regarded as an individaul compound, because its synthesis is accompanied by the liberation of metallic mercury and hence the formation of side products. It is impossible to

separate them from the polymer in view of the lability of the –Ge–Hg–Ge–Hg– chain. On heating or ultraviolet irradiation, the compound is readily demercurated with formation of polygermanes $[Ph_2Ge]_n$. The analogous silicon oligomer $[-SiMe_2-Hg-]_n$ has been synthesised by the reaction of dibromodimethylsilane with sodium amalgam[40].

The germylmercury chain becomes stable when the mercury atoms are in the γ-positions relative to one another. Thus the hexanuclear oligomer and the polymer have been obtained by the hydride method using 1,2-dihydro[tetrakis-(pentafluorophenyl)]digermane[32]:

$$(C_6F_5)_2Ge(H)-Ge(H)(C_6F_5)_2 \xrightarrow[-EtH]{EtHgGe(C_6F_5)_3} (C_6F_5)_5GeHgGe(C_6F_5)_2Ge(C_6F_5)_2HgGe(C_6F_5)_3$$

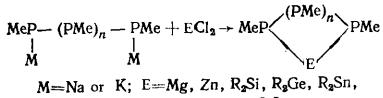
$$(C_6F_5)_2Ge(H)-Ge(H)(C_6F_5)_2 \xrightarrow[-(Me_3Si)_2NH]{[(Me_3Si)_2N]_2Hg} [-Ge(C_6F_5)_2-Ge(C_6F_5)_2-Hg-]_n .$$

Both products are thermally and hydrolytically stable and are not oxidised in air. In terms of its chemical properties and solubility, the former compound resembles $[(C_6F_5)_3Ge]_2Hg$.[41] The polymer $[-Ge(C_6F_5)_2Ge(C_6F_5)_2Hg^-]_n$ is virtually insoluble, as a result of which it exhibits a lower reactivity (for example, in oxidative addition reactions) than the above hexanuclear compound of bis[tris(pentafluorophenyl)germyl]-mercury.

Polynuclear substances having the general formula $[RMX]_n$, where M = Al, Ga, or In and X is a chalcogen, are formed in reactions of sulphur or hydrogen sulphide with R_3M [42,43] and also in the thermal decomposition of the unstable products of the interaction of hydrogen chalcogenides of the type Et_3GeSeH with triethylaluminium, triethylgallium, or triethylindium[33,34]. It has been suggested that the association of the M–X units in these substances,

$$(Et_3MX)_2M'Et \xrightarrow{\Delta} (Et_3M)_2E + 1/n\,(EtM'E)_n ;$$
M=Si or Ge; E=S, Se or Te; M'=Al, Ga or In

takes place via coordinate and not covalent bonds[34]. However, this hypothesis is based solely on a qualitative estimate of their solubility and requires additional confirmation. Analogous boron compounds (borasulphols) are known to exist as σ-heterocycles BR–S–RR–S–Br–S.[44]

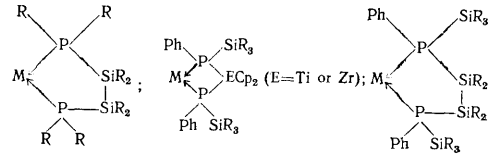


The method involving the hydrogenolysis of the Sn–N and Ge–N bonds by tin and germanium hydrides is extremely convenient for the formation of tin–germanium chains[19,20,45]:

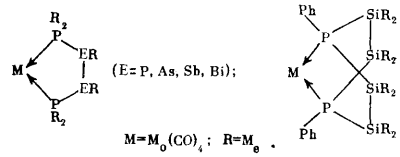
$$2R_3GeNR'_2 + 2R_2SnH_2 \rightarrow 2R_3Ge-SnR_2H \xrightarrow[R'_2NH]{\Delta} R_3Ge-SnR_2-SnR_2-GeR_3 + H_2 ;$$

$$n\,R_2Sn(NR'_2)_2 + n\,R_2GeH_2 \rightarrow [-SnR_2-GeR_2-]_n + 2n\,R'_2NH$$
R = alkyl, aryl .

Compounds with the linear groups $Ge-(Sn)_3-Ge$, $Ge-(Sn)_4-Ge$, and GeSnGeSnGe have also been obtained by this method. In terms of their physical properties, they differ little from polygermanes and polystannanes, while in terms of their reactivity, they occupy an intermediate position.

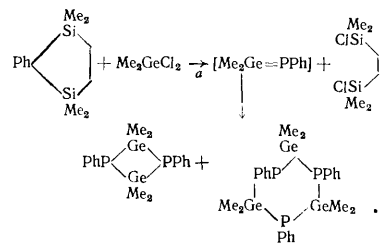


Group VB elements form a large series of polynuclear compounds. When phosphorus-containing rings $[RP]_n$ (n = 4 or 5) are opened under the influence of alkali metals, the products are linear polyphosphines containing Li, Na, and K atoms as the end-groups[46]. Their interaction with metal halides and organometallic halides yields penta- and hexanuclear heterocyclic products[46,47]:



M=Na or K; E=Mg, Zn, R_2Si, R_2Ge, R_2Sn, S or Cp_2Ti; n=2.3 .

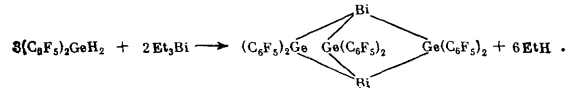
In certain cases the reactions under consideration are accompanied by the formation of polymers.



The high reactivity of alkali metal organophosphides is also used to synthesise linear silylpolyphosphines $R_3Si-(PR)_4-SiR_3$,[47] $Me_3Si-PPh-PPh-SiMe_3$,[48] $(Me_3Si)_2P-P(SiMe_3)_2$,[49,50] and $(Me_3Si)_2P-SiMe_2-P(SiMe_3)_2$.[51] The phosphorus atoms in these compounds, like those in the usual organophosphines, are capable of forming a coordinate bond with transition metal atoms. This made it possible to synthesise a series of unusual molybdenum complexes with phosphorus-containing heteroelemental polynuclear ligands[51–53]:

M=$M_0(CO)_4$; R=M_e .

The cyclic trimers $[-SiPh_2-PPh-]_3$ and $[-GePh_2-PPH-]_3$ have been obtained by the reaction of $PhPK_2$ with dichlorodiphenylsilane and $PhP(GeClPh_2)_2$ respectively[54]. Dimers and trimers with Ge–P units are also formed in reactions of dichlorodimethylgermane with phenylphosphine[55] and 2,5-disilaphospholan[56]. It has been shown[56] that in the latter case extremely active germaphosphimines $[R_2GePR']$, containing the Ge=P double bond, are formed at an intermediate stage:

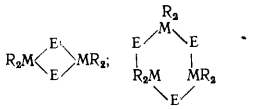


This reaction (stage *b*) is extremely characteristic of organometallic monomers. Resembling outwardly the polymerisation of olefins, it differs from the latter by the fact that it yields tetra-hexa-nuclear rings and not long linear chains.

The stannylphosphines $[-SnPh_2PPh-]_3$ and $[-SnPh_2-P(SnPh_3)-]_3$ are obtained by the reactions of triphenylstannyl-lithium with dichlorophenylphosphine[57].

Silyl-, germyl-, and particularly stannyl-phosphorus oligomers are readily hydrolysed and oxidised. In contrast to their phenyl analogues, the thermal stability of alkylstannylphosphines is low and they cannot be obtained by the above methods.

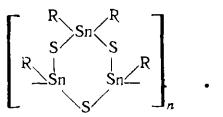
A surprisingly stable germylbismuth compound has been obtained recently by the reaction of $(C_6F_5)_2GeH_2$ with triethylbismuth[58]. An X-ray diffraction study failed to confirm the structure proposed initially for this product. It was established that its heteroelemental framework is made up of three germanium atoms and two bismuth atoms and has the form of a trigonal bipyramid[59]:



In contrast to $(C_6F_5)_3GeBiEt_2$ and $[(C_6F_5)_3.Ge]_2BiEt$, this product is not oxidised in air either in the crystalline state or in

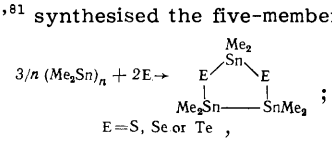
solution. At the same time, it exhibits a higher reactivity with respect to compounds such as, for example, $Pt(PPh_3)_3$.

The interaction of the silyl sulphide $(Me_2SiS)_3$ with dichlorophenylphosphine[60] and dichlorophenylarsine[61] leads to pentanuclear cyclic oligomers $(PhMS)_3$, where M = P or As. The reaction of $(PhPS)_3$ with $(PhP)_5$ gives rise to cyclotetraphosphine sulphide PPh–PPh–S–PPh–PPh. A further twelve methods of synthesis of this substance have been published[62].



A cyclic structure is also most characteristic of oligomers with chains made up of atoms of Group IVB and VIB elements:

R = alkyl or aryl; E = S or Se; M = Si[63,64] or Ge[65–70]; Sn[71–76] or Pb[68].

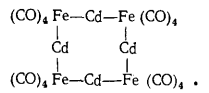


These compounds are usually obtained by the reaction of the dihalides R_2MHal_2 with a sodium chalcogenide or hydrogen sulphides in the presence of an amine. When sulphur or selenium is heated with tetra-alkyl(aryl)germanes and the corresponding stannanes, the dihydride $(C_6F_5)_2GeH_2$, or bis-(triphenylstannyl) sulphide to 100–150 °C, the same products are formed. In the majority of the reactions quoted compounds of the type of the germathione $[R_2Ge{=}S]$, whose polymerisation gives rise to tetra- or hexa-nuclear heterocycles, are apparently formed. This process has been established fairly reliably in relation to diethylgermathione in equilibrium with the cyclic trimer $(Et_2GeS)_3$.[77] The insertion of the stannathiones R_2SnS in the Sn–X bond in $R_{4-n}.SnX_n$ (X = Cl, Br, SCN, or OMe) yields a linear Sn–S oligomer[78].

The formation of linear intermediates of the type $R_3M-(Se)_n-SeR$ has been postulated in reactions of S or Se with R_4M.[68,72] In the presence of an excess of the chalcogen and for M = Sn this process leads to a product having the composition $R_4Sn_3S_4$, for which the authors postulate the polymeric cyclolinear structure[79]

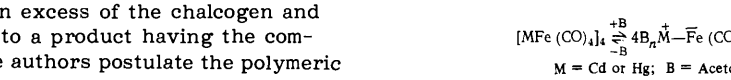
One should also note the formation of cyclic and linear germyl and stannyl chalcogenides by the reaction of the sulphide $Ph_2Ge(SNa)_2$ [65] or the selenides $R_3SnSeLi$ [74] with halogeno-derivatives of the type Ph_2GeBr_2. The formation of the polymer $ClR_2Ge-(Se-GeR_2)_n-Se-GeR_2Cl$ together with the cyclic trimer has been noted in the reaction of Me_2GeCl_2 with Na_2Se,[66] but the number of Se–Ge units in the chain was not determined.

Mathiasch[80,81] synthesised the five-membered heterocycles



E = S, Se or Te,

by the oxidation of polymeric dimethyltin with chalcogens. Their stability decreases appreciably in the sequence S > Se > Te.

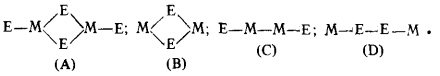


Chains having the composition Ge–S–S–Ge and $Si-S_n-Si$ (n = 5, 7, 9) are known. The former have been obtained by the interaction of triphenylgermanethiol or sodium triphenylgermyl sulphide with iodine[65,82] and the latter have been synthesised by the reaction of sodium triphenylsilyl sulphide with the dichloropolysulphides S_mCl_2 (m = 3, 5, 7).[30]

All compounds with chains consisting of Si(Ge, Sn) and sulphur atoms are colourless liquids (with R = alkyl) or crystalline solids (with R = aryl), which are stable in air. Selenium derivatives are less stable, decomposing rapidly in moist air with liberation of selenium. Both sulphur and selenium derivatives with a linear structure as a rule disproportionate on heating to 150–200 °C, forming four-membered hexanuclear heterocyles $(-MR_2-X-)_n$. X-Ray diffraction studies showed that the latter have the boat configuration and can exist in two crystalline modifications—tetragonal and monoclinic[83–85].

Compounds with chains comprising transition and non-transition metal atoms have been synthesised as some of the first polynuclear compounds. Thus cadmium and mercury carbonylferrates $[MFe(CO)_4]_4$ (M = Cd or Hg) have been obtained by the reactions of $Fe(CO)_5$ with cadmium and mercury salts[86,87]. An interesting method for the reversible degradation of such compounds under the influence of Lewis bases, which has been proposed recently, made it possible to obtain $[CdFe(CO)_4]_n$ in a crystalline form and to determine its structure[31]. It was found that the compound is a planar virtually square eight-membered heterocycle:

The reversible degradation method (involving the homolysis of M–M bonds) is important, because it makes it possible to solve one of the most difficult problems in the chemistry of polynuclear compounds—the purification of sparingly soluble and involatile substances with a high molecular weight. The crude polymer is depolymerised by simple dissolution in a basic organic solvent. The resulting solution of monomeric units solvated by solvent molecules, $[MFe(CO)_4].B_n$, is purified by the usual procedures and repolymerised by the gradual elimination of the solvent *in vacuo*[31,88,89].



M = Cd or Hg; B = Acetone, THF, amine, etc.

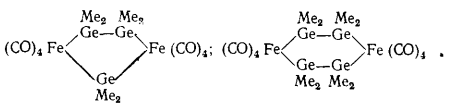
We may note that in the given case polymerisation leads to cyclic oligomers and not linear macromolecules.

Compounds with chains comprising aluminium (gallium, indium) and transition metal atoms have apparently not been obtained hitherto#. However, the extremely stable Ir–Tl bond in the complexes $[(RCO_2)_2Tl-Ir(O_2CR)ClPPh_3]$ (R = alkyl)[91] showed that such oligomers can be entirely stable.

Group IVB elements form linear, cyclic, and mixed linear-cyclic polynuclear compounds with Mn, Fe, Ru, Os, Co, and Pt. The (A),[92–98] (B),[89,99–115] (C),[116–124] and (D)[125–132] structures are commonest (E is a Group IVB element and M is a transition metal):

(A) (B) (C) (D)

Six-membered Co–Sn and Fe–Ge heterocycles[133] and the linear nonanuclear compound $[(Ph_3Sn)_3Zr]_2SnPh_2$ [20] are also known. X-Ray diffraction data and measurements of the magnetic susceptibility showed that in certain compounds with structures (A) and (B) there is a direct M–M bond[93–95]. It has been suggested that deformations of rings (B) can lead to the cleavage of the M–E bonds and the formation of linear structures of the type $R_2E \rightarrow M-M \leftarrow ER_2$.[134] However, this has not been confirmed[115].



The gallium (indium)–manganese carbonyl complexes, described by Preut and Haupt[90] belong to the series of typical clusters and are therefore outside the scope of this review.

The principal methods for the synthesis of oligomers (A) and (B) include the reactions of metal carbonyls with organogermanium and organotin hydrides and halides. There is an interesting reaction of dicyclopentadienyltin with $Fe_2(CO)_9$ leading to the formation of the ring $[Cp_2SnFe(CO)_4]_2$ containing the Cp–Sn σ-bond, while the initial stannane has a "sandwich" structure[89]. The interaction of the hydrides R_3EH (E = Si or Ge) with the carbonyls $M_3(CO)_{12}$ leads to linear compounds (B). One or several carbonyl groups in the latter can be substituted by other ligands, for example, cyclopentadiene[119-121]. Chains with structure (D) are formed on alkylation with a Grignard reagent of halogeno-derivatives of the type $Cp(CO)_2Fe–GeCl_3$ when dicyclopentadienyltin interacts with metal carbonyls and in reactions of the dihalides R_2GeBr_2 with an anion of the type $(CO)_5Mn^-$.

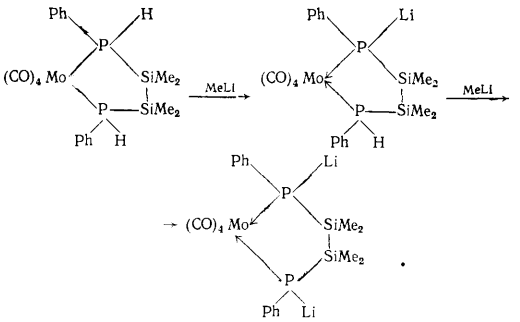
The reaction involving the insertion of the zero-valent triphenylphosphine complex of platinum in the Ge–H bond of 1,2-dihydrodigermane has been proposed for the synthesis of a germylplatinum chain[132]:

$$\begin{matrix}(C_6F_5)_2Ge—H\\ |\\ (C_6F_5)_2Ge—H\end{matrix} + Pt(PPh_3)_3 \rightarrow \begin{matrix}(C_6F_5)_2Ge—Pt(PPh_3)_2—H\\ |\\ (C_6F_5)_2Ge—Pt(PPh_3)_2—H\end{matrix} + 2PPh_3 .$$

The reaction of 1,2-dichlorogermane with disodium iron tetracarbonyl leads to penta- and hexa-nuclear heterocycles[135]:

It has been suggested[136] that the interaction of tin tetrachloride with $Ru_3(CO)_{12}$ leads to the formation of a compound with the $Cl–Ru(CO)_4–Ru(CO)_4–Ru(CO)_4–SnCl_3$ chain. In contrast to fairly stable compounds having the structures (A), (B), (C), and (D), this oligomer is rapidly converted into the dinuclear complex $(CO)_4Ru(Cl)SnCl_3$ on heating. $Os_3(CO)_{12}$ reacts analogously[137].

On interaction with NH_4S_5, dicyclopentadienyltitanium dichloride forms compounds containing a heterocycle made up of five sulphur atoms and a titanium atom: $Cp_2\overline{TiSSSSS}$.[138] The conformational transformations of this product have been investigated[139].



The complexes $[CpM(CO)_3M']_n$, where M = Mo or W and M′ = Cu or Ag, are examples of two-element polynuclear compounds whose skeleton is made up only of transition metal atoms[140]. They are obtained by the reaction of cyclopentadienyltricarbonyl-molybdenum or -tungsten anions with copper(I) and silver salts respectively. The complexes $[Co(CO)_4Ag]_n$, $[Co(CO)_4Cu(NH_3)_4]_n$, and $[(PhO)_3PFe(CO)_2.NOAg]_n$ have been synthesised similarly. On the basis of the stretching vibration frequencies of the CO groups in the infrared spectra, the authors postulate the presence of covalent M–M′ bonds in these compounds. The determination of n for the complex $[(Bu_3P)Co(CO)_3Ag]_n$ in various solvents showed that the degree of its polymerisation varies with the basicity of the solvent. Thus $n = 4$ in benzene and $n = 3$ in chloroform. Pyridine and other strong Lewis bases decompose these cyclic oligomers to monomeric units of the type $Co(CO)_4Ag.L$ (L is a solvent molecule). All the complexes decompose in the light and are oxidised in air.

The formation of an unstable intermediate with the linear Os–Os–Os–Au chain in the reaction of $Os_3(CO)_{12}$ with $ClAuPPh_3$ has been suggested[141].

IV. THREE-ELEMENT COMPOUNDS

The number of known compounds whose chains are made up of atoms of three different heteroelements is much smaller than that of two-element systems.

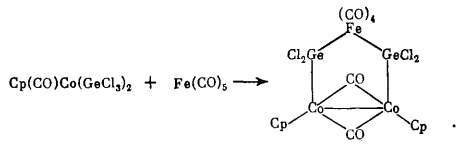
The only compound of this type, containing alkali metal atoms, has apparently been obtained by Johannsen and Stelzer[53], who metallated a bidentate phosphine ligand in a molybdenum complex:

A mercury derivative, with the Ge–Si–Hg–Si–Ge chain has been synthesised by the hydride method using the germylsilane $Et_3GeSiEt_2H$ as the starting material[142].

A large series of chalcogen-containing pentanuclear compounds have been obtained on the basis of the organoelemental hydride chalcogenides R_3MEH (M = Si, Ge, or Sn; E = S, Se, or Te). Their interaction with metals[143], metal alkyls[33,34,144,145], and organodielemental derivatives[146,147] proceeds readily and yields the required products with high yields as a rule

$$2(RO)_3SiSH + M \rightarrow (RO)_3SiSMSSi(OR)_3 + H_2 ;$$
$$M = Ca, Sr \text{ or } Ba$$
$$2Et_3SiSeH + Et_2M \rightarrow Et_3SiSeMSeSiEt_3 + 2EtH ;$$
$$M = Zn \text{ or } Cd$$
$$2Et_3SiSH + Et_3M \rightarrow (Et_3SiS)_2MEt + 2EtH ;$$
$$M = Al, Ga \text{ or } In$$
$$2Et_3SiTeH + (Et_3Ge)_2Hg \rightarrow Et_3SiTeHgTeSiEt_3 + 2Et_3GeH .$$

Zinc, cadmium, and mercury derivatives are stable under normal conditions and consist of colourless or pale-brown crystalline substances. The low solubilities and high melting points (decomposition temperatures) of the zinc and cadmium compounds apparently indicate their association. Chains based on Group IIIB metals have a very low thermal stability. In all cases, with the exception of $(Et_3SiS)_3AlEt$, they decompose fully in the course of the reaction. The reactions of triethylaluminium, triethylgallium, and triethylindium with an excess of the hydride chalcogenide lead to compounds of the $(Et_3SiTeAlTe)_n$ series[34], for which there is a possibility of both σ-linked Te–Al chains and associated coordination compounds with Te → Al bonds. These substances are evidently the products of the decomposition of unstable intermediates of the type $(Et_3GeSe)_3Al$. However, one should note that thermal decomposition of the analogous boron derivative $(Me_3SiS)_3B$ leads to products of another composition[148].

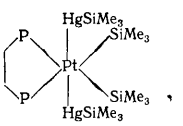


The tetranuclear organoelemental cadmium and mercury sulphides and selenides, for example, $(C_6F_5)_3GeSHgGe(C_6F_5)_3$, are obtained by the insertion of elemental chalcogens in the Ge–Hg, Ge–Cd, or Si–Hg bonds[70,149-151]:

$$(R_3Ge)_2Hg + 1/8\,E_8 \rightarrow R_3Ge—E—Hg—GeR_3 ;$$
$$E = S \text{ or } Se .$$

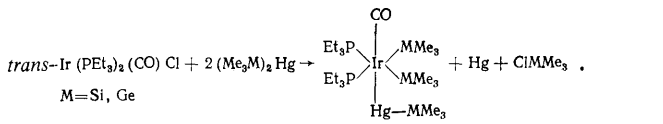
The insertion of a second chalcogen atom with formation of a pentanuclear chain of the type Ge–S–Hg–S–Ge is uncharacteristic of these reactions and is observed only on interaction of germylcadmium with sulphur. In contrast to the symmetrical pentanuclear compounds described above, all the tetranuclear chalcogen-containing substances decompose rapidly at room temperature (with the exception of the stable C_6F_5 derivative).

The condensation of $Cp_2Ti(SH)_2$ with dichlorodimethylsilane and similar compounds in the presence of an amine and also with dimethylsiloxane leads to cyclic products with the SiSTiSSi groups[152]. Ring closure takes place via the oxygen atom or siloxane groups.



A stable heterocyclic compound incorporating the atoms of two transition metals has been synthesised via the reaction[133]

Metal carbonyl anions are frequently used in the synthesis of three-element oligomers. For example, the reaction of the anion $Me_3SiOs(CO)_4^-$ with $Me_3SiRu(CO)I$ gives rise to a compound with the SiOsRuSi group[153]. An unexpected pentanuclear linear complex $[Me_3GeRu(CO)_4]_2Hg$ has been isolated in the reaction of $Me_3GeRu(CO)_4^-$ with the iodide $CpFe(CO)_2I$.[96] The authors explain the formation of the mercury derivative by the fact that sodium amalgam was used to synthesise the anion.



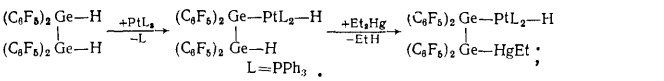
Frequent attempts have been made to employ carbonyl anions and dianions as well as carbonyl hydrides in polycondensation reactions with organometallic halides, for example, R_2SnCl_2, in order to form linear polymeric structures[118,154]. However, in most cases the reactions terminated by the formation of four-membered heterocycles. Collman and coworkers, who were the first to undertake an extensive search for methods of synthesis of organometallic polymers, were able to synthesise two linear pentanuclear complexes[154, 155]. The first of these $(CO)_5Re-SnBu_2-Os(CO)_4-SnBu_2-Re(CO)_5$, was obtained by the reaction of *trans*-$(ClBu_2Sn)_2.Os(CO)_4$ with rhenium pentacarbonyl hydride. The second, $(CO)_5Mn-GePh_2-Fe(CO)_4-GePh_2-Mn(CO)_5$ were synthesised by treating $Fe_2(CO)_9$ with two moles of $(CO)_5MnGePh_2H$. The iron derivative has the *trans*-configuration, which the authors believe gives grounds for the hope of obtaining longer chains.

Several methods, frequently used to synthesise three-element compounds, are based on the use of a series of compounds $(R_3M)_2Hg$, where M = Si, Ge or Sn, as the initial organoelemental mercury derivatives for the synthesis of three-element compounds. These methods include exchange reactions with halogen-containing transition metal complexes, oxidative addition reactions with zero-valent transition metal complexes, and a combination of these reactions. Thus the photochemical reactions of $Fe(CO)_5$ and $Fe_2(CO)_9$ with $(Me_3Si)_2Hg$, which lead to the pentanuclear compound $[cis\text{-}Fe(CO)_4SiMe_3]_2Hg$, are regarded as oxidative addition of the $Fe(CO)_4$ species to the Si–Hg bond[156]. By allowing bis(trimethylsilyl)mercury to react with $Cl_2Pt(Ph_2PCH_2)_2$, Glockling and Pollock[157] obtained a pale-red substance to which they attributed the following structure on the basis of spectroscopic data:

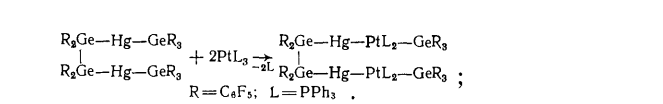
However, elemental analysis of this product was not carried out and, bearing in mind the very low stability of the analogous germanium groups $R_3Ge-Hg-Pt-GeR_3$, where R = alkyl[158], the proposed structure appears doubtful.

A similar combination of the exchange method and the method involving oxidative addition to a metal in a low-valence state obtains also in the reaction[159]

It is of interest to note that the Hg–Ir bond is chemically the most inert in the Si(Ge)–Hg–Ir–Si(Ge) chain formed.



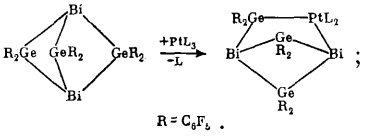
It was observed in 1976 that the triphenylphosphine complexes of zero-valent platinum and palladium are readily inserted in the M–M′ bond in compounds of the type $R_3Ge-Hg-GeR_3$.[160] The tetranuclear products formed proved to be entirely thermally stable in the case of $R = C_6F_5$:



This made it possible to obtain a series of compounds with a wide variety of chains: GeHgPdGe, SnHgPtSn, GeCdPtGe, and GeZnPtGe.[158,160] The reaction involving $Ni(PPh_3)_4$ apparently leads to the analogous nickel derivatives, but they could not be isolated in a pure state.

X-Ray diffraction and ^{31}P NMR data have shown that the Pt–Hg complexes have a square planar *cis*-structure probably with a small admixture of the *trans*-isomer. In the palladium analogue both isomers are present in approximately equal proportions. Qualitative comparison established that their thermal and chemical stabilities decrease in the sequences Hg > Cd > Zn, Pt > Pd > Ni, and Ge > Sn. When $(C_6F_5)_3Ge.HgPtL_2Ge(C_6F_3)_3$ reacts with reagents such as Br_2 and hydrogen chloride, the Ge–Hg and Hg–Pt bonds are the first to be cleaved. The complexes are colourless or pale-yellow crystalline substances readily soluble in benzene, acetone, and tetrahydrofuran (THF).

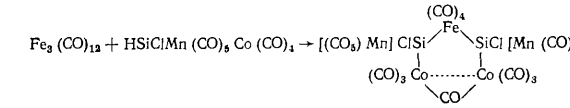
The complex $(Ph_3Ge)_2CdPd(PPh_3)_2$, which the authors also believe to contain the metal chain GeCdPdGe, has been obtained similarly[161]. It has been established that a second PtL_2 species is not inserted in the remaining Ge–Hg bond in chains of the type GeHgPtGe, which can be explained both by steric hindrance and by changes in the nature of the Ge–Hg bond after the addition of platinum to the Hg atom. 1,2-Dihydro-1,1,2,2-tetrakis(pentafluorophenyl)digermane and a mercury derivative based on it have therefore been used to synthesise compounds with a longer chain. The product of the insertion of PtL_2 in one of the Ge–H bonds in $HGe(C_6H_5)_2-Ge(C_6F_5)_2H$ was made to react with Et_2Hg. Despite the excess of hydride, this results in the evolution of only one equivalent of ethane and a tetranuclear compound is formed[132]:



In the oligomer $(C_6F_5)_3GeHgGe(C_6F_5)_2Ge(C_6F_5)_2HgGe(C_6F_5)_3$ the atoms are separated by the Ge–Ge group and the reaction of this compound with a platinum complex leads to the addition of two equivalents of $Pt(PPh_3)_2$, as was to be expected[162]:

The resulting diplatinum octanuclear compound is entirely stable. Its reactivity, solubility, and infrared and ultraviolet spectra are similar to those of the tetranuclear complex $(C_6F_5)_3GeHgPtL_2Ge(C_6F_5)_3$. The great length of the polymetallic chain is manifested only by the appearance of broadened low-intensity bands in the long-wavelength part of the electronic absorption spectrum. It is easy to show by calculation that not less than nine steric (*cis*-, *trans*-) and structural isomeric forms can exist for this product (PtL_2 is not inserted in the Ge–Ge bond under the conditions adopted)[158]. This finding clearly demonstrates the feature characteristic of all the polyelemental oligomers, which consist in the fact that the difficulties associated with the identification and study of the reactivities of these compounds increase sharply after even a slight increase of the length of the heteroelement chain.

The triphenylphosphine complexes of zero-valent platinum are also inserted in the Ge–Bi bond of the tricyclic compound $R_2GeBiGeR_2BiGeR_2$:[59]



$R = C_6F_5$.

It is of interest that the second equivalent of PtL_2 is not inserted despite the presence of several Ge–Bi bonds remote from the platinum involved in the addition process. The structure of the product isolated from benzene in the form of dark cherry-red crystals was established by X-ray diffraction. The molecule of the complex contains the non-planar heterocycle PtGeBiGeBi with the $(C_6F_5)_2Ge$ bridging group.

The Ge–S(Se) and Hg–Fe groups proved to be inactive with respect to $Pt(PPh_3)_3$. In reactions with $(C_6F_5)_3GeXH$ (X = S or Se) platinum adds to the X–H bond with the simultaneous formation of a small amount of the pentanuclear compounds $[(C_6F_5)_3GeX]_2Pt(PPh_3)_2$ as side products[132]. In the interaction of $(ClHg)_2Fe(C_5H_5N)$ with PtL_3 the Hg–Cl bond is attacked. The platinum derivatives formed in the intermediate stages are unstable and are rapidly demercurated[163].

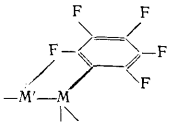
V. FOUR-ELEMENT COMPOUNDS

So far as we are aware, only five compounds whose chains contain the atoms of four heteroelements of different kinds have been synthesised at the present time. The first of these was obtained in the form of dark-green crystals by the reaction[164]

The labile compounds $Et_3SiXHgGeEt_3$ (X = S, Se, or Te) were synthesised by the protodegermylation of bis(triethylgermyl)mercury by the chalcogenide hydrides Et_3SiXH.[147]

In the interaction of tris(triphenylphosphine)platinum with $(C_6F_5)_3GeHgSn(C_6F_5)_3$ the PtL_2 species is evidently inserted in both Ge–Hg and Hg–Sn bonds with formation of the isomers GeHgPtSn and GePtHgSn, which cannot be separated[158]. There are virtually no data on the reactivities of these compounds.

Five-element chains have apparently not been obtained hitherto.



VI. THE STABILITY OF POLYMETALLIC GROUPS

One of the main conditions for the successful synthesis of organometallic compounds with chains comprising atoms of heteroelements is the stability of the resulting M–M bonds. The stability of the products is determined, like that of the usual mononuclear organometallic compounds[165], by quantum-chemical, thermodynamic, and kinetic factors. The first of these is manifested by the distinct dependence of the stability of polynuclear compounds on the positions in the Periodic Table of the heteroelements making up the chain. The stability of the oligomers incorporating atoms of *d* elements as a rule increases in each subgroup with increase of the atomic weight of the metal. The opposite variation of the stability of the M–M bond with the atomic weight of the element can be seen for *p* elements; the IIIB subgroup is intermediate in this respect.

The thermodynamic aspect is understood as the fulfilment of the condition $G_1 - G_2 > 0$ for stable compounds, where G_2 is the free energy of the oligomer system and G_1 the free energy of the system formed after the dissociation (spontaneous or under the influence of the attacking reagent) of the weakest or most reactive M–M bond. Presumably, in polymerisation and polycondensation reactions of organometallic compounds, the thermodynamic factor determines primarily the formation of small rings and not long linear molecules as in the case of *C*-derivatives. The possibility of the formation of conjugated groups as well as resonance effects lead to an appreciable energy gain for heterocycles compared with macrochains of the same elements.

The kinetic parameters constitute a no less important factor governing the stability of organopolymetallic compounds. The high activation energy for the initial decomposition reaction can lead to the stabilisation of thermodynamically unstable compounds or compounds with a low stability. Organic substituents at the heteroatoms play an important role in this respect. It is known that the presence of groups such as neopentyl-, t-butyl, trimethylsilylmethyl, etc. increases sharply the stability of the polymetallic compound[166-168]. For mononuclear compounds, the same effect has been explained[165] by the steric shielding of the metal atoms by bulky substituents from direct attack in collisions and also by the decrease of the efficiency of energy transfer to the M–C bond (which determines the stability of these compounds) in consequence of the distribution of energy among the vibrational levels of the substituents themselves. All these factors are equally applicable to compounds containing heteroelement chains§.

Evidently another cause leads to the stabilisation of pentafluorophenyl derivatives[158,169,170], because the bulk of the C_6F_5 ring is only slightly greater than that of the phenyl group. It has been suggested[59] that the stability of the compounds is achieved in this case by virtue of the intramolecular coordination of the unshared electron pairs of the *ortho*-fluorine atoms to the vacant orbitals of the heteroatom M′ in the β-position relative to the C_6F_5 substituent.

§ However, one cannot agree with the view[165] that polychloromethyl and the lower perfluoroalkyl groups are sterically hindered.

The spatial disposition of the o-F and M′ atoms favours such coordination[158,171]. We may note that, for this reason, i.e. by virtue of the molecular geometry, the coordination of o-F to the α-M atom, postulated for certain compounds $(C_6F_5)_n$ M (see. for example, Razuvaev et al.[172]), appears less probable. Evidently the coordination involving the β-heteroatom is impossible for compounds where M′ has no suitable vacant orbitals, for example, S, Se, Te, and Bi. In such cases the introduction of C_6F_5 substituents does not stabilise the polyelement groups[59,173]. On the other hand, if M′ is strongly electrophilic, then a rapid redistribution of bonds with liberation of the metal fluoride takes place in the five-membered coordination ring formed. Nor can one exclude the possibility of the dissociation of such compounds at the M–M′ bond with formation of highly reactive nucleophilic species of the type of $(C_6F_5)_3Ge^-$, which vigorously attack the C_6F_5 rings of the neighbouring molecules. For this reason, in the series of compounds with active M′ (Li, Pr, Nd) [174,175] the pentafluorophenyl derivatives are less stable than their H-analogues. On the other hand, in compounds with less active M′ (Zn, Cd, Hg, Pt) [158,169,170,176] intramolecular coordination increases the stability of the oligomer, formally increasing the energy of the M–M′ bonds in the M′–M–C_6F_5 fragments.

The chemistry of polynuclear organometallic compounds with linear and cyclic structures clearly exhibits the characteristic features of both the chemistry of the usual organometallic compounds and of carbochain polymers. At the same time oligomers and polymers with heteroelement chains have a number of specific properties, which require the development of fundamentally new methods of synthesis of such compounds and method for their investigation. These difficulties greatly inhibit studies on the field under consideration. However, virtually unlimited potential possibilities of varying the properties of organopolymetallic compounds (by selecting a wide variety of combinations of heteroatoms in the chains and their ligand environment) make substances of this class extremely attractive as convenient models for the solution of a number of theoretical problems in chemistry and physics. For the same reasons, the above compounds are extremely promising in the context of applied problems (high-temperature superconductivity, ferromagnetism, catalysis, etc.). There is no doubt that studies on organometallic polymers will develop vigorously in the immediate future.

The Formation of Inorganic Coatings in the Decomposition of Organometallic Compounds

G.A.Domrachev and O.N.Suvorova

The present status of the methods for producing inorganic coatings from the vapour phase by the decomposition of organometallic compounds (OMC) is considered critically and systematically. The methods are classified in terms of physicochemical features and the physical procedures involved. The efficiencies of various methods for the preparation of coatings from the vapour phase in the thermal decomposition of OMC and the possibilities of their employment for a specific alteration of the properties of the coatings obtained are compared. Patent data on various procedures and devices used in the formation of inorganic coatings from the vapour phase in the decomposition of OMC are widely used.
The bibliography includes 96 references.

I. INTRODUCTION

There exist numerous patents and other publications on the deposition of inorganic coatings from the vapour phase in the thermal decomposition of organometallic compounds (OMC) and metal carbonyls. In the USSR a group of investigators and technologists led by Academician G.A.Razuvaev is concerned with systematic studies and technological development of these processes.[1] Razuvaev showed an interest in the isolation of metals from organometallic compounds in thermal reactions as early as the 1920s.[2] These studies subsequently served as a basis for research by Razuvaev and his students into the thermal decomposition and photodecomposition of OMC in solution and then in the vapour phase; these studies have been surveyed in a monograph[1].

However, the literature contains no systematic review of the existing methods for the deposition of inorganic coatings from the vapour phase on decomposition of OMC; in the present review an attempt is made at such a systematic account.

II. CHEMICAL FEATURES OF THE USE OF ORGANOMETALLIC COMPOUNDS FOR THE PREPARATION OF COATINGS FROM THE VAPOUR PHASE

The use of OMC for processes where their intermediate formation transfers a metal to the substrate makes it possible to carry out the deposition at low temperatures and to increase the concentration of the working compound as a result of the lower decomposition temperature of the OMC and their higher vapour pressure at low temperatures[1]. The fundamental mechanism of the deposition of films from the vapour phase in the thermal decomposition of OMC can be formulated as follows:

$$R_nM\ (\text{solid or liq.}) \xrightarrow{t^\circ} R_nM\ (\text{gas}),$$
$$R_nM\ (\text{gas}) \xrightarrow[\text{support}]{t^\circ} R_nM\ (\text{ads.}),$$
$$R_nM\ (\text{ads.}) \xrightarrow{t^\circ} M\ (\text{solid})/\text{support} + nR\ (\text{ads.}),$$
$$nR\ (\text{ads.}) \xrightarrow{t^\circ} nR\ (\text{gas}).$$

These stages of the process determine its chemical nature and constitute the basis for the development of methods of deposition of coatings. In order to select the deposition procedure and to carry out the latter in a specific technological scheme, it is necessary to analyse in detail each stage of the process.

In the preparation of a multicomponent coating, for example a binary coating, a mixture of the necessary number of OMC of different metals, for example two, or a mixture of the OMC of one metal and the hydride of another element, is used[3-7]:

$$MR_n + M'R'_m \rightarrow M{-}M' + nR + mR',$$
$$Me_3Ga + AsH_3 \rightarrow GaAs + 3CH_4,$$
$$Me_4Pb + Me_2Te \rightarrow PbTe + x\,C_nH_m,$$
$$Me_3Ga + AsMe_3 \rightarrow GaAs + x\,C_nH_m.$$

It has been established that the intermediates in the joint decomposition of two OMC are, as in the case of Me_3Ga and Me_3As, oligomeric and polymeric fragments containing the $(R{-}Ga{-}As)_x$ group[6]; these fragments cannot catalyse the subsequent decomposition of the OMC mixture.

Hence it follows that, for the decomposition of binary compounds and OMC, one can employ the thermal decomposition of molecular complexes of OMC of the type $Me_3Ga.AsMe_3$ or organobimetallic compounds containing covalent M–M or M–E bonds[8]:

$$R_nM{-}M'R_m\ (\text{solid or liq.}) \xrightarrow{t^\circ} R_nM{-}M'R_m\ (\text{gas}) \xrightarrow[t^\circ]{\text{support}} \rightarrow (n+m)R\ (\text{gas}) + M{-}M'\ (\text{solid})/\text{support} + mR\ (\text{gas}).$$

Adsorption and desorption processes can also be involved in this scheme. In the general case the formation of a two-component system on the surface requires that the reaction between the metals liberated or the decomposition reaction must proceed via the formation of intermediate compounds containing the M–M′ bond[7].

Bearing in mind the high efficiency of the metal transfer to the support with the aid of OMC, one can also employ the metal transport reaction with the aid of organic radicals or ligands. The best known classical example of a transport

reaction with participation of free radicals is provided by the method of Paneth mirrors[9]:

$$R_nM\ (gas) \xrightarrow{t^\circ} M(solid) + n\,R\ (gas) \xrightarrow{+M'_l(solid)} R_mM\ (gas) \rightarrow \xrightarrow[t^\circ]{support} \rightarrow M'_l(solid)/support + m\,R\ (gas).$$

Free radicals, generated by the thermolysis of readily available OMC, for example Me_2Hg, behave as transporting agents for the transfer of solid metal through the gas phase to the region of higher temperatures; the support on which the metal film is formed by the thermal dissociation of the OMC formed is placed in this region. Such processes include the transport of nickel by carbon monoxide as a result of the reversibility of the reaction[10,11]:

$$Ni(solid) + 4CO \rightleftarrows Ni(CO)_4 \rightleftarrows Ni(solid)/support + 4CO.$$

Here carbon monoxide functions as the metal-transporting ligand. A metallic alloy, for example MM', can be transported similarly[12]:

$$MM'(solid) + (n + m)\,R\ (gas) \rightleftarrows \begin{cases} \rightarrow R_nM{-}M'R_m\ (gas) \\ \rightarrow R_nM\ (gas) + R_mM'\ (gas) \end{cases} \xrightarrow{t^\circ} MM'(solid) + (n+m)R\ (gas).$$

Combinations of these methods for the transport of metal are also possible.

However, a common feature of all these procedures is a high volatility of the OMC, a low decomposition temperature of the OMC with liberation of the metal, the obligatory presence of organic OMC decomposition products and sometimes their strong influence on the process, the possibility of the adsorption and secondary reactions of the OMC decomposition products, and a comparatively high vapour pressure of the organic OMC decomposition products at the deposition temperatures.

Although the first two factors are favourable from the standpoint of the use of OMC for the formation of coatings, the negative influence of the decomposition products can sometimes abolish altogether the positive effect. For the successful realisation of the OMC thermal decomposition processes, it is therefore necessary to employ special procedures for the deposition of coatings from the vapour phase in which the harmful effects of the decomposition products are diminished or eliminated with the aid of mass and heat transfer phenomena and mechanical and chemical methods.

The chemical features of the procedures for the deposition of coatings are determined by the composition and structure of the OMC and by the addition of various chemical reagents. In terms of the composition of the gas–vapour phase for the coating, the methods can be classified as follows:

(1) methods using an individual OMC;

(2) methods using a mixture of individual OMC;

(3) methods using an individual OMC mixed with the hydrides of other elements or with readily decomposed inorganic metal compounds;

(4) methods using individual OMC or their mixture in an atmosphere of a reactive gas [reducing to the metals (H_2),[13,14] oxidising (O_2),[13] etc.], which improves the elemental and phase compositions of the coatings;

(5) methods using OMC in mixtures with additives which serve as energy transferring agents or with "quenching agents" for the excited states (for example, iodine[15,16], amines[17–19], ammonia[15,20], diolefins[21,22], ferrocene[23], and other OMC[24–27]);

(6) methods using OMC in mixtures with added decomposition catalysts (halogen derivatives[28], sulphur derivatives[29] for the decomposition of bisarenechromium, transition metals for aluminium hydride complexes[30], and transition metal salts for metallocenes[31,32]);

(7) methods using OMC in a mixture with added active hydrogen atom donors in radical reactions (glycols for the decomposition of copper acetylacetonate[33,34], hydrogenated aromatic compounds of the type of dihydrobiphenyl, tetralin, cyclohexadiene, and cyclohexene[1], amines[35], etc.);

(8) methods using OMC in a mixture with added surfactants, which are adsorbed more strongly than the decomposition products, but less so than the OMC themselves and are displaced by the latter from the surface—for example, ferrocene in the decomposition of tri-isobutylaluminium[36];

(9) methods using OMC in the presence of added reactive gases (H_2S, H_2Te, NH_3, CO_2, etc.) and vapours (H_2O), which modify the elemental and phase compositions of the coating[1].

The above methods make it possible to obtain a wide variety of coatings whose composition corresponds to both pure metals, binary alloys, or semiconductor compounds and to pure oxides, carbides, nitrides, sulphides, etc. Furthermore it is possible to obtain mixed coatings of the type of carboxides[37], carbonitrides[38], etc.

The content of impurities in the phase composition of coatings can be regulated both by the chemical procedures enumerated above and by physicochemical and purely physical methods.

III. THE USE OF THE PHYSICOCHEMICAL CHARACTERISTICS OF THE DECOMPOSITION OF ORGANOMETALLIC COMPOUNDS FOR THE DEPOSITION OF COATINGS

There are many ways of depositing films and coatings from the vapour phase of OMC in their thermal decomposition; numerous devices and different types of apparatus have been developed, embodying various methods for deposition from the vapour phase.

The methods of deposition of coatings from the vapour phase can be classified in terms of the principal process parameters. The methods can differ in terms of (1) the procedure used to generate the vapour phase, (2) the pressure of the reaction mixture in the decomposition zone, (3) the state of the article being coated in the reactor, (4) the method used to heat the article being coated, and (5) the state of the principal units of the reactor.

1. Methods for the Generation of the Vapour Phase of the OMC

The methods for the deposition of coatings from the vapour phase in the decomposition of OMC differ in the procedure used to generate the vapour phase, which can be significantly non-equilibrium, or can be in equilibrium with the condensed OMC phase. Depending on this factor, when different procedures are used to generate the vapour phase, it is possible to attain markedly different maximum rates of deposition, which depend on the degree of supersaturation of the vapour phase by the metal, which is determined in its turn by the concentration of the OMC in the vapour.

Deposition from a non-equilibrium vapour phase can be carried out under both static and dynamic conditions. In the former case the process is usually performed with a deficiency

of OMC in a closed volume where the OMC vaporises completely and forms an unsaturated vapour, which is not in equilibrium with the condensed phase (since the latter is absent). The decomposition of the OMC under such conditions proceeds as a rule at low temperatures in the kinetic region, the aim being to obtain coatings with controllable physical properties (for example, the preparation of films for measuring devices).[39]

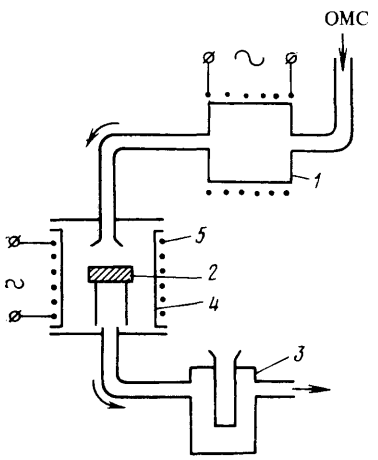

Figure 1. Deposition of coatings from a non-equilibrium vapour phase under dynamic conditions established in an autonomous evaporator: 1) evaporator; 2) support; 3) trap; 4) reactor; 5) heater.

The deposition of coatings from a non-equilibrium vapour phase under dynamic conditions is most frequently used. The equilibrium vapour phase generated by the evaporation of the condensed (liquid or solid) OMC phase is transported via pipes to the heated article to be coated, which is located in the reaction chamber. In the absence of a condensed phase in the pipes and under the conditions of high temperatures near the article to be coated and its dilution by the vapours of the decomposition products, the initially saturated OMC equilibrium vapour phase becomes unsaturated with respect to the OMC and is no longer in equilibrium with the OMC condensed phase. The state of this vapour phase, i.e. the degree of its deviation from the state of saturation with respect to the OMC and its state of equilibrium, is difficult to estimate and control. As a result of the decomposition of the OMC, the state of the vapour phase changes still further due to constant dilution by the decomposition products. For the practical employment of such a non-equilibrium vapour phase, one therefore creates dynamic conditions and uniform fluxes of the vapour phase near the surface of the article to be coated. Under such conditions, it is possible to attain reproducible rates of deposition of the coating.

However, owing to the unsaturation and the non-equilibrium nature of the OMC vapour phase, it is impossible to achieve high rates of deposition of coatings. The devices most frequently employed in this case are provided with autonomous evaporators located outside the limits of the reaction chamber used for the deposition[10,40-43] (Fig.1). The principles of the operation of the evaporator can be extremely varied, but usually one employs closed or flow compartments ("stills") and bubbling devices[44].

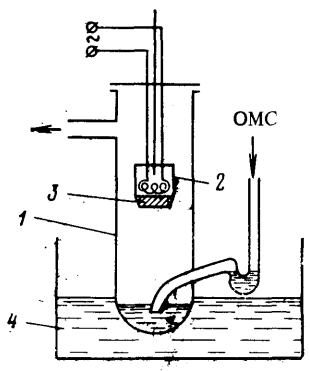

Figure 2. Deposition of coatings from an equilibrium vapour phase generated under static conditions: 1) reactor; 2) heater; 3) support; 4) thermostat.

The deposition of coatings from the vapour phase in equilibrium with the condensed (solid or liquid) OMC phase is a more effective process. Here it is possible to establish higher concentrations of the OMC in the vapour phase; since the vapour phase is in a state of dynamic equilibrium with the condensed phase, the vapour is enriched in the organometallic component when the latter is consumed in the deposition process. The process can be carried out under static or dynamic conditions such that the condensed (usually liquid) OMC phase in equilibrium with the vapour phase can exist. Under static conditions, the equilibrium OMC vapour phase is generated by the evaporation of the solid or liquid OMC within the reaction chamber. The location of the OMC condensed phase being evaporated can be below the article to be coated[45,46] or above it[47] (Figs.2 and 3). Furthermore, it has been suggested[46] that the condensed (solid) phase be placed around the article to be coated (Fig.4).

Under conditions where the condensed phase is located below the article to be coated, the deposition process takes place under least favourable conditions. This is because, in the course of the formation of the OMC decomposition products and the increase of their pressure, the partial pressure of the OMC diminishes and conditions for the supersaturation of the OMC vapour are frequently created, which is accompanied by the formation of aerosol particles of the condensed phase ("dew point"). These particles of the condensed OMC phase precipitate and the overall OMC concentration in the vapour phase diminishes. The additional vaporisation of this part of the OMC as a result of the heat radiated from the superheated (relative to the vapour temperature) support cannot occur owing to the negative temperature gradient in the direction of the fall of the particles. When this method is used, one usually observes a "peak" rate of deposition of the coating[48,49] at the initial instant of the coating process. In other words, the rate of formation of the coating initially increases to a maximum and then falls approximately by two orders of magnitude in consequence of

the decrease of the effective concentration of the OMC in the vapour phase[49].

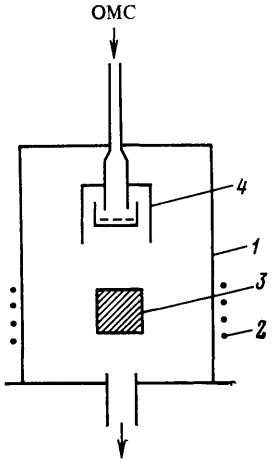

Figure 3. Deposition of coatings from a vapour phase in equilibrium with a static liquid OMC phase located below the article: 1) reactor; 2) heater; 3) support; 4) evaporator.

If the condensed OMC phase in equilibrium with the vapour phase is located on the particle to be coated and the outlet for the removal of the decomposition products ("evacuation") is placed below, then more favourable conditions are created for increasing the OMC concentration in the vapour phase[47]. Even under the "dew point" conditions, where part of the OMC condenses on increasing the pressure of the decomposition products and is precipitated in the form of liquid and solid particles, the OMC concentration in the vapour phase increases as a result of the re-evaporation of these particles as they fall freely downwards under the conditions of a positive temperature gradient towards the article to be coated, which is placed below the vaporisation zone.

We may note that the case under consideration, where the condensed OMC phase in equilibrium with the vapour phase is located above the article to be coated, cannot be classified as purely static: although the main bulk of the condensed phase is in a static state, the condensed OMC particles are in a state of dynamic equilibrium with the vapour. The use of a vertical temperature gradient (the temperature above the article is higher than under it) makes it possible to set up a pressure gradient which gives rise to a flux of particles and vapour along the surface of the article to be coated and this converts the procedure from one involving a static condensed phase in equilibrium with the vapour into a method with dynamic vapour and condensed phases in a flux[47]. Such conditions ensure higher rates of deposition of coatings than under static and dynamic conditions from a non-equilibrium vapour and under conditions of a static condensed phase located below the article to be coated and involved in equilibrium with the vapour phase.

The methods in which the condensed phase is placed around the article to be coated are a logical conclusion of the development of procedures for deposition from an equilibrium vapour phase in the presence of a static condensed OMC phase[46].

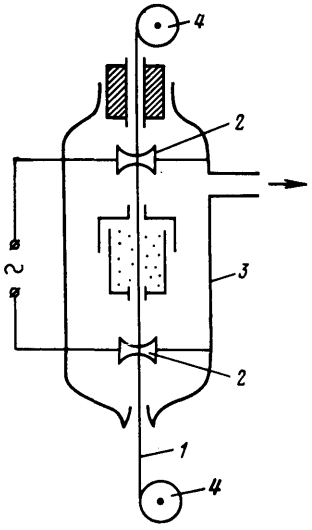

Figure 4. Deposition of coatings from an equilibrium vapour phase with a translational movement of the article: 1) filament (wire) to be coated; 2) electrical terminals; 3) reactor; 4) drums for rewinding the wire.

This method is usually applied when an article of small area is to be coated (for example, when a heated filament is drawn through a channel in a compressed substance undergoing decomposition[46]). The vaporisation of the substance being decomposed takes place as a result of its being heated by the heat emitted from the filament being coated. This method[46] makes it possible to generate a vapour phase in equilibrium with the static condensed phase.

However, in the presence of a quasi-closed reaction space bounded by the condensed OMC phase and when the area to be coated is large, the atmosphere may be supersaturated by the decomposition products, which leads to the appearance of stagnant zones, a decrease of the rate of deposition of the coating, and its contamination as a result of increased adsorption of secondary reaction products (carbon, oxides, carbides, resins, etc.). The method is then actually converted into a procedure in which coatings are deposited from a vapour phase in equilibrium with a static condensed phase under static (or quasi-static) conditions relative to the dynamics of the vapour phase. The first two instances ensure, in contrast to the last, the dynamics of the vapour phase in equilibrium with the condensed phase, although the mass fluxes established in the first case decrease the concentration of the OMC in the vapour near the substrate, while in the second the OMC concentration is actually increased in the descending vapour streams.

The use of methods involving the generation of a vapour phase in equilibrium with the condensed phase directly in the reactor for the deposition of coatings, in contrast to the procedures described above in which a non-equilibrium vapour phase is used, makes it possible to prepare coatings using involatile OMC with low vapour pressures and low decomposition temperatures. The introduction of the condensed OMC phase directly into the reactor creates conditions for the molecular distillation of involatile OMC[50] and significantly extends the scope of the deposition method under consideration compared with the previous procedures using a non-equilibrium vapour, the transport of which is relatively ineffective for involatile substances.

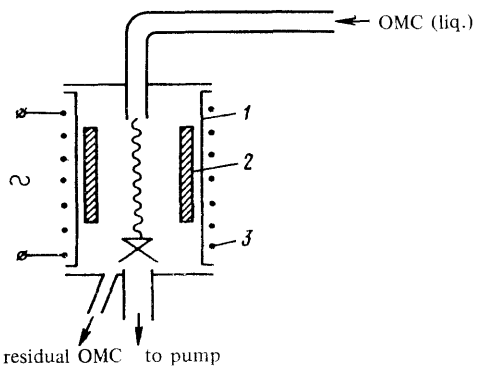

Figure 5. Deposition of coatings from an equilibrium vapour phase generated under dynamic conditions: 1) reactor; 2) support; 3) heater.

By analogy with this situation, which is observed in distillation processes, methods for the generation of a dynamic vapour phase in equilibrium with a moving liquid phase, are the most effective and have the greatest range of applications. One of the effective methods for the generation of the vapour phase in the deposition process which have been suggested[51–57] involves the use of a falling film of liquid OMC, its solution, or its suspension in a suitable solvent (Fig.5). The method permits a continuous and effective generation of the vapour phase in equilibrium with a moving spontaneous stream of the liquid phase (by analogy with all the advantages of film distillation—see Krel[50], p.301). The most important advantages of film vaporisation are that there is no need to heat thick layers of liquid for effective vaporisation[58], as happens in vaporisation from a still. This provides considerable possibilities for the employment of a wide range of involatile and readily decomposed OMC for the deposition of coatings.

The deposition of coatings by this procedure[51–57] on the surface of the heated article takes place with a continuous flow of liquid containing the OMC (liquid compound, solution, or suspension taken separately or in an appropriate combination) along the treated surface under the influence of gravitational force. As a result of the vaporisation of the liquid under the influence of the heat emitted from the article, the concentration of the vapour of the working OMC in equilibrium with its condensed phase is ensured. As the liquid moves along the surface of the article being coated, it is heated to higher temperatures, which promotes a more vigorous vaporisation of the substance being decomposed and leads to an increase of its concentration in the vapour phase and hence to an increase in the rate of deposition of the coating. An increased concentration of the vapour of the OMC being decomposed is also promoted by the fact that the particles of the condensed phase formed as a result of the condensation of the vapour, as the pressure of the decomposition products increases, migrate under the influence of gravitational force along the surface of the article being coated and are heated and revaporised as when deposition occurs from a static equilibrium vapour phase and the condensed OMC phase is located above the article to be coated.

Thus, over the entire pathway traversed by the liquid being decomposed, the saturated OMC vapour is in equilibrium with it. This leads to an appreciable increase of the steady-state OMC concentration in the vapour phase during the deposition of the coating and ensures high rates of formation of the latter; furthermore, this ensures the formation of more homogeneous coatings, with respect to thickness and chemical composition, owing to the smaller changes in the relative concentrations in the OMC vapour.

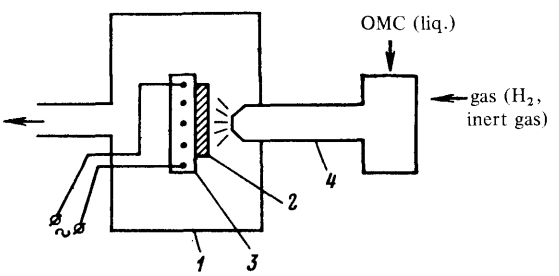

Figure 6. Deposition of coatings from an equilibrium vapour phase under dynamic atomisation conditions: 1) reactor; 2) support; 3) heater; 4) atomiser nozzle.

In this way it is possible to achieve rates of deposition of coatings of approximately 1–2 mm h^{-1} (or >10–20 μm min^{-1}), which is 10–100 times greater than the usual rates of deposition from the vapour phase by the methods already described. This procedure is most effective in the following cases: for the formation of thick coatings, particularly for the internal surfaces of hollow articles; when it is necessary to achieve a continuous process; when the rate of deposition of the coating is the rate-limiting stage of the process (when the process is automated). The method proposed in a number of patents[51–57] can be applied both for a freely falling liquid film (this is desirable for long articles and surfaces) and when the working liquid containing the OMC flows via the guiding surface under the influence of gravitational force and then along the surface to be coated starting from its upper section. The distance between the guiding surface and the

surface to be coated must ensure the heating and vaporisation of the moving liquid as a result of the thermal emission from the heated article. If heating (thermostatting) of the guiding surface is used to ensure uniform vaporisation of the liquid, then the minimum distance between the guiding and coated surfaces is determined by the distance over which there is no premature "ebullition" of the falling liquid film (before the attainment of the lower end of the article) due to heating of the liquid by the heat emitted from the article regardless of the thermostatting. The rate of vaporisation can be regulated either by altering the distance between the surfaces or by altering the rate of the free fall of the liquid along the guiding surface by changing the inclination, roughness, and relief of the latter.

The list of the available methods for the deposition of coatings from a vapour phase in equilibrium with a dynamic condensed phase is logically completed by the method involving the enforced movement of the condensed phase at the required rates. It consists in the atomisation or sputtering of the liquid phase onto the surface to be coated with thermal conditions in the heated article such that vaporisation of the condensed dispersed particles near the surface to be coated is ensured[59-61] (Fig.6). When nickel carbonyl is used, this method makes it possible to obtain coatings having a smooth surface with a thickness of several hundredths of a centimetre in the course of several seconds[59].

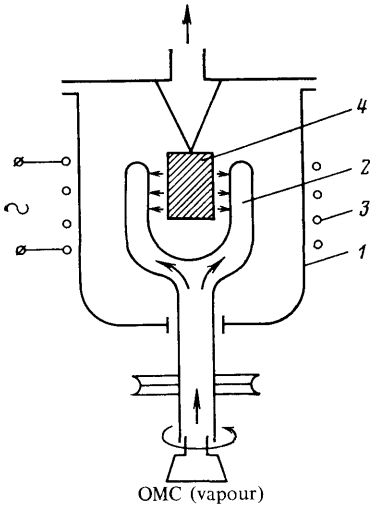

Figure 7. Deposition of coatings from a non-equilibrium vapour phase by the rotation of the vapour inlet: 1) reactor; 2) vapour inlet; 3) induction heating; 4) article.

However, despite the considerable gain in the rate of deposition of coatings compared with other methods, the atomisation procedure is relatively inapplicable to the preparation of coatings from the vapour phase using compounds having low vapour pressures. For such substances, it reduces to the preparation of coatings from the liquid phase and in many instances suffers from all the disadvantages of this procedure (contamination of the surface and bulk of the coating, difficulties when it is necessary to obtain crystalline coatings, and inhomogeneity of the coating with respect to thickness on articles of complex shape).

An interesting version of the method employing a non-equilibrium vapour phase transported along the surface of the article to be coated and gradually enriched in the decomposition products has been proposed in a patent[62]; in this method an increased rate of deposition from a vapour depleted in the working substance is achieved by establishing a temperature gradient throughout the entire extent of the article, which increases toward the end of the latter. However, this method is effective only in the kinetic region and for very large fluxes and is recommended for epitaxial processes.

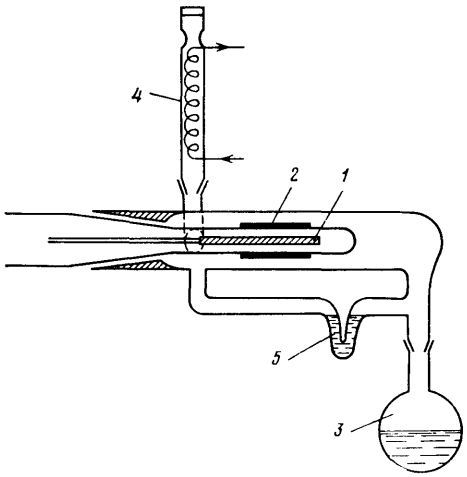

Figure 8. Method of deposition of coatings from the vapour phase in solvent vapour[1,44]: 1) support; 2) heater; 3) evaporator; 4) reflux condenser; 5) hydraulic seal.

One of the modifications of the method of deposition from a non-equilibrium vapour phase, which ensures the formation of a homogeneous coating, involves the establishment of a dynamic non-equilibrium vapour phase, proposed in a patent[63], around the article by mechanical means—by rotating a multichannel inlet supplying the vapour (Fig.7).

2. The Influence of Pressure on the Characteristics of the Deposition Process

It is possible to distinguish methods in which coatings are obtained (1) at atmospheric or elevated pressures of the test substance without a gaseous diluent, (2) at atmospheric or elevated overall pressures in the presence of a gaseous diluent, a carrier gas (usually nitrogen, inert gases, etc.), or the vapour of an inert solvent[64-66] (Fig.8), (3) at a

reduced pressure in the absence of a carrier gas, (4) at a reduced pressure in the presence of a carrier gas, a gaseous diluent, or the vapour of an inert solvent, and (5) in a high vacuum under molecular beam conditions in the absence of a gaseous diluent.

The methods used at atmospheric or elevated pressures have advantages over the remaining procedures in the sense that they make it possible to generate large mass fluxes of the test substance in the vicinity of the support to be coated, which leads to an increase in the diffusional limit to the rate of deposition of the coating and an expansion of the temperature range of the kinetic region.

However, together with this positive effect, a marked adsorption of the OMC decomposition product on the surface of the coating is observed at elevated and atmospheric pressures. For reactive coatings and decomposition products, such adsorption can promote secondary reactions leading to the formation of carbides, oxides, and similar compounds, which are in many instances undesirable. Furthermore, since the vapour pressure of the majority of OMC reaches 1 atm above their decomposition temperatures, the low thermal stability of the OMC restricts the upper limit of the OMC concentration in the gas phase and hence the rate of deposition of coatings at elevated and atmospheric pressures. On the other hand, high flow rates of the carrier gas in many cases preclude the formation of sufficiently homogeneous coatings (this is an advantage of the method of deposition of coatings from the vapour phase), leading to the appearance of a "shadow effect" due to the geometrical factors of the reactor and the support. The limiting case of this process is sputtering from an atomiser[67].

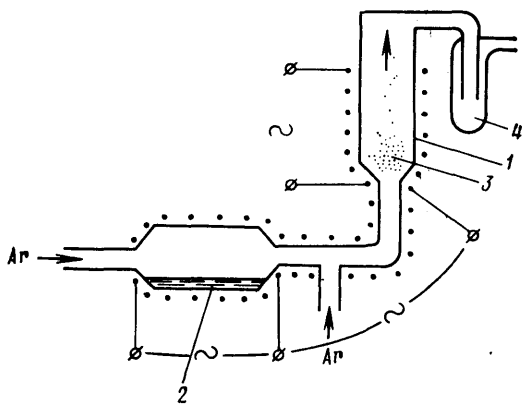

Figure 9. Deposition of coatings from a non-equilibrium vapour phase with an outside evaporator under the conditions of a fluidised bed consisting of the powdered specimen to be coated; 1) reactor; 2) evaporator; 3) specimen; 4) trap.

The use of reduced pressures makes it possible to obtain coatings with purer compositions owing to the decreased influence of adsorption by the products of decomposition and secondary reactions. However, the rates of deposition decrease owing to the decrease of the OMC concentration in the gas phase. In principle, similar rates of deposition can be attained in a stream of carrier gas at atmospheric pressure and in the absence of carrier gas at a reduced pressure. The difference between the rates of desorption of the decomposition products *in vacuo* and in an atmosphere of the carrier gas at elevated pressure may be altered. This sometimes leads to a significant difference between the impurity contents in the coatings (for example, 10% C in chromium deposited in a carrier gas and 2–3% C in chromium deposited *in vacuo* at the same temperatures[40]).

The homogeneity of the coatings obtained at reduced pressures is as a rule high. The deposition of coatings under molecular beam conditions[68] has the advantage that it makes it possible to increase the purity of the coating, but the rate of deposition is then reduced and a "shadow effect" appears when coatings are deposited onto articles of complex shape.

IV. PHYSICAL CHARACTERISTICS OF THE METHODS FOR THE DEPOSITION OF COATINGS FROM THE VAPOUR PHASE

1. Methods Differing in the State of the Article to be Coated in a Reactor

The state of the article to be coated can be determined both by its material and shape as well as its movement. The surface to be coated can be the outer or inner surface of the article or part of it, and the article can consist of a compact or porous solid body. For articles of small size, coatings can be obtained on a large number of the latter in a single cycle or with each article subjected consecutively to a single cycle. The formation of coatings on powders and friable materials requires specific deposition procedures.

Depending on the material of the substrate (the surface of the article), the methods of deposition of coatings differ mainly as regards the method and rates of heating of the surface and the employment of various chemical systems.

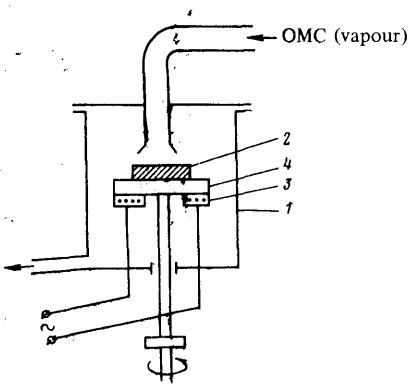

Figure 10. Deposition of coatings from a non-equilibrium vapour phase with rotation of the article: 1) reactor; 2) support; 3) heater; 4) rotating table.

A number of procedures for the deposition of coatings from the vapour phase differ by the type of movement of the article being coated in the reactor. The article to be coated may be stationary or have a wide variety of different types of movement: oscillatory movement—vibration or ultrasonic oscillations[69], a fluidised bed[10,44,70–72] (Fig.9) for the coating of powders, rotation of the article[73,74] (Fig.10), and translational movement of the article or a programmed movement[46,75–78]. A combination of different types of movement is frequently employed.

2. Methods of Heating of the Article to be Coated

The methods for the deposition of coatings from the vapour phase using OMC can differ by the method whereby energy is supplied to the article being coated. It has been suggested that different forms of energetic influences be used: thermal, light (ultraviolet and infrared irradiation[1]), laser beam[75,79-81], electron and ion impacts[82-85], and different forms of electric discharges and plasmas[84,86-88].

In methods with thermal heating of the articles to be coated, both direct heating (by an electric current[48], by a high frequency current[48], and by an electric heater built into the article[48]) and indirect heating (by the infrared irradiation of an external resistive heater[1] and by the absorption of visible and infrared radiation by the support[48]) are used.

There exist methods for the preliminary heating of the support and for carrying out the deposition process on a cooled support[89,90]. The latter is used to prepare thin films on articles with a low thermal conductivity. Despite the fact that the deposition takes place at a continuously decreasing temperature, these processes are used both in laboratory practice and in industry[77,91,92]. The possibility of employing such conditions arises partly from the fact that the process takes place at high temperatures in the diffusion region, where it depends only slightly on temperature. The coating process is highly technological and can be fully automated[92]; this being particularly suitable for the coating of dielectrics.

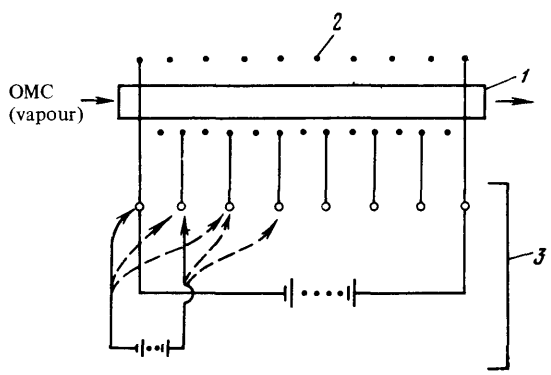

Figure 11. Zone coating of the inner surfaces of tubes from a non-equilibrium vapour phase: 1) reactor (tube); 2) electric heater; 3) switch for the maintenance of the temperature of the tube above the vaporisation temperature of the OMC and for the maintenance of the temperature of a narrow mobile zone equal to the deposition temperature of the coating.

The use of a laser beam for the local heating of the surface of the support[93,94] gives rise to extensive technological possibilities for the preparation of shaped coatings from the vapour phase[75,80,81]. The deposition process with local heating of the support by laser radiation is determined by a number of fundamental factors: the optical properties of the material of the support (high absorption coefficient and low reflection coefficient for the radiation at the wavelength of the laser emission); the thermophysical properties of the material of the support (low thermal conductivity and high melting point); the energy density of the laser beam and the duration of its action on a single site on the support (low energy density and short duration of pulses with a high repetition frequency); the rate of the chemical reaction and of mass transfer, which determine the rate of deposition.

For high local energy densities of the laser beam, a high thermal conductivity of the material of the support, a long duration of the local action, and an autocatalytic mechanism of the thermal decomposition of the OMC, the limits of the deposition of the coating undergo "temperature-dependent spreading". For high absorption coefficients of the radiation in the material of the support, there is a possibility of local fusion of parts of the support. The minimum "temperature-dependent spreading" of the limits of the coating will occur on supports with a low thermal conductivity and with a maximum absorption coefficient for the radiation. In this case the thinnest possible surface layer of the material of the support is heated and, owing to the low thermal conductivity, the energy relaxation along the surface is also minimal. The energy of the laser beam used for the local deposition of coatings from the vapour phase must therefore be optimal to avoid the breakdown of the surface of the support and to reduce the "temperature-dependent spreading" of the limits of the coating. To ensure the maximum possible rate of deposition, it is useful to employ the maximum possible concentration of the saturated OMC vapour by adjusting the temperature of the working chamber and the rate of evacuation. The temperature of the working chamber can be raised to values lower by 50–100 °C than the temperature of the coating deposition process to avoid the autocatalytic deposition of the coating over the entire surface of the support after the onset of deposition.

With a favourable combination of all four factors enumerated above, the local shaped coatings obtained possess the most satisfactory qualities.

3. Methods Differing by the State of the Fundamental Units of the Reactor

In order to obtain high-quality homogeneous coatings on articles made of different materials and of different complexity of shape and on long articles, particularly at sites which are relatively inaccessible (internal surfaces, cavities, etc.), and for the protection of friable, fibrous, and other materials, the technological features of the method and the device must be analysed.

Procedures have been developed for the deposition of coatings using different states of the fundamental units of the reactor (the evaporator, the heating of the decomposition zone, and the guiding devices for the supply of the given substance). It is possible to distinguish methods with a stationary arrangement of the units of the reactor[44], methods involving the rotation of the guiding devices for the introduction of the working substance[51-57,59,73] and the rotation of the heater together with the decomposition zone, and methods employing a translational movement of the heater or the heating zone[73,95] (Fig.11).

Depending on the purpose of the coating, a particular method of deposition and method of transferring the metal to the support (chemical transfer or a combination of several methods) are used. By virtue of the wide range of possibilities for the deposition of coatings from the vapour phase and the highly technological nature of the deposition process, coatings are extremely promising as regards their industrial applications. This is particularly important when it is possible to set up a waste-free manufacture of coatings where decomposition products such as aromatic hydrocarbons formed in the decomposition of bisarene derivatives of transition metals can be reused for the direct synthesis of OMC from

atomised metals by cocondensation[96]. This combination of "synthesis–decomposition" processes constitutes a virtually closed manufacturing cycle, which requires only the expenditure of energy and the metal and makes it possible to apply the given metal to articles of complex shape ("transfer" of the metal).

Spectroscopic Study of π-Acceptor Effects in Compounds of Silicon Subgroup Elements

A.N.Egorochkin and S.Ya.Khorshev

The general state of research into the π-acceptor properties of silicon subgroup elements (E) by spectroscopic methods is examined and the data obtained are surveyed. It is shown that the π-acceptor properties are weakened with increase of the atomic number of the element E, and the analogy between these properties and the conjugation effect in unsaturated carbon compounds is traced. The widespread interpretation of π-acceptor properties of these elements as a manifestation of the effect of the d_π-p_π interaction is justified.
The bibliography includes 167 references.

CONTENTS

I. Introduction 820
II. Characteristics of the manifestation of the π-acceptor effects 821
III. The nature of the π-acceptor effects in compounds of silicon subgroup elements 826

I. INTRODUCTION

The study of the nature of the chemical bond in compounds of silicon and the elements of its subgroup (E) is not only of great independent interest but is also of undoubted importance for the understanding of the characteristics of the chemical bond in organoelemental compounds of non-transition elements as a whole.

Despite the theoretical and practical importance of this problem (many of the compounds considered are used in the national economy), many of its aspects still remain controversial. These include primarily the problem of the mechanism of the π-acceptor effect of the atoms E, which is observed in M–X fragments, where X is an atom with unshared electron pairs (n-donor substituent) or an α,β-unsaturated hydrocarbon group (π-donor substituent) and is one of the causes of the sharp difference between the properties of compounds of carbon and the elements E.[1-6] The study of the intramolecular interaction between the E and X atoms not linked directly by chemical bonds has been studied vigorously in recent years[7]; it is evidently also a consequence of the manifestation of the acceptor properties of the atoms E.[8]

The traditional interpretation of the π-acceptor properties of the atoms E is based on the idea of the d_π–p_π interaction in E–X fragments caused by the presence of vacant nd orbitals in the atoms E.[9] The E–X bond then acquires a partial double bond character, the amount of double bond character depending on the ratio of the donor properties of X and the acceptor properties of E. The donor–acceptor properties depend on the nature of other substituents linked to the E and X atoms[3,6]. The hypothesis of vacant nd orbitals explains at least qualitatively all the properties of the compounds of silicon subgroup elements which significantly distinguish these derivatives from carbon compounds.

The possibility, in principle, of d_π–p_π binding has been demonstrated by a quantum-chemical method[10-12] and some of its aspects have been considered: the dependence of the overlap integrals of the p_π and d_π orbitals on the molecular geometry[3,11] and the enhancement of the double bond character with increase of the positive charge on the central element E.[11] The size of the d orbitals of the atom depends on the nature of the substituents linked to it[13]. For this reason, firstly, the atomic d orbitals can differ appreciably from molecular d orbitals[14] and, secondly, it is difficult to make an *a priori* estimate of the relative contribution of the d_π–p_π binding for compounds of different structure. At the same time critical analysis of the data obtained using various quantum-chemical computational methods showed that, in order to account for the nature of the bond in compounds of non-transition elements (particularly in silicon compounds), it is necessary to take into account the contribution of the 3d atomic orbitals of these elements[15]. We may note, however, that the opposite view has also been expressed[16].

The quantum-chemical data indicated above[10-16] and those quoted below in the present review should apparently be considered from two standpoints. On the one hand, the involvement of nd orbitals in the formation of bonds by the elements E is entirely possible. On the other hand, the actual degree of this involvement is in many cases so small that, although the effect produced by this can in fact be observed experimentally, their magnitude is comparable to the accuracy of the computational methods. For this reason, the application of modern quantum-chemical methods in many cases fails to yield an unambiguous result in the study of effects of this kind and, for reasons described above, the idea of the d_π–p_π interaction was partly in the nature of a working hypothesis from its very inception.

During the last decade other ideas have been invoked to account for the properties of compounds of silicon subgroup elements together with the nd-orbital hypothesis[17,18]. The more significant role of the hyperconjugation effects in organoelemental compounds compared with carbon derivatives, due to the greater polarisability of the bonds in the former compounds, has been known for a long time[19]. However, Pitt's attempt[17] to put forward the hyperconjugation effect as an alternative to the hypothesis of the decisive role of the d_π–p_π interaction in organosilicon compounds, maintained in some investigations (see, for example, Ponec and Chvalovsky[20,21]), was subsequently disproved by its author[22], who concluded that both effects are important: hyperconjugation and d_π–p_π interaction.

In 1969 Musher proposed the model of hypervalent bonds to account for the acceptor properties of Group V–VIII elements of the Periodic System in the highest valence states in compounds where the number of ligands is greater than four[18]; on the basis of this model, it was shown, in particular, that there is a transannular bond between the silicon and nitrogen atoms in silatranes[23]. With the exception of the study of Sidorkin et al.[23], there is no information about the applicability of this hypothesis to the study of compounds of silicon subgroup elements. This hypothesis cannot therefore be

recognised at present as an effective alternative to the idea of the d_{π}–p_{π} interaction[24,25].

Thus there are several points of view on the problem of the mechanism of the π-acceptor properties of the atoms E. While the possibility, in principle, of the involvement of the *d* orbitals of such atoms E in the formation of a bond is not to be denied, quantum-chemical methods do not yield unambiguous conclusions about the magnitude of the *d*-orbital contributions in specific compounds because of their approximate nature. At the same time, there are extensive literature data obtained in experimental studies of the π-acceptor effects of the E atoms by spectroscopic methods. A critical consideration of these data makes it possible to formulate the fundamental characteristics of the manifestation of these effects, which, as will be shown below, do not conflict with the hypothesis of the involvement of the *nd* orbitals of the E atoms in the formation of bonds of the d_{π}–p_{π} type. The present review deals only with those studies, among the large number described, in which the π-acceptor properties of the E atom have been studied by a correct method and which lead to generalisations and are of fundamental importance for the understanding of the subject of this review.

II. CHARACTERISTICS OF THE MANIFESTATION OF THE π-ACCEPTOR EFFECTS

We believe it to be most useful to arrange the literature data systematically on the basis of the type of E–X bonds. The π-acceptor effects of the elements of the silicon subgroup will be designated in the present review by the term d_{π}–p_{π} interaction (arguments justifying the legitimacy of this term are given in Section III).

1. The E-Group VII Element Bond

The E–X interatomic distances (X = halogen) in halogeno-derivatives of the E elements are in many cases shortened compared with the values calculated from the covalent radii of the E and X atoms after correction for their electronegativities. For example, the experimental[26] and calculated (given below in brackets) values are as follows for the compounds SiF_4, $SiCl_4$, $SiBr_4$, SiI_4, GeF_4, and SnF_4 respectively (in Å): 1.54 (1.69); 2.01 (2.05); 2.25 (2.22); 2.43 (2.44); 1.67 (1.75); 1.84 (1.94). These findings were used by Brockway and Wall[27] and also by Pauling[9] as a basis for the introduction of the concept of the d_{π}–p_{π} conjugation between the *d* orbitals of silicon and the unshared electron pairs of the halogens. A tendency has been observed towards a decrease of the discrepancy between the experimental and calculated E–X lengths in the series Si > Ge > Sn and F > Cl > Br > I; however, one should note that analysis of the discrepancies is complicated by the inadequate accuracy of the experimental E–X distances and some uncertainity in their calculated values.

The double bond character of the E–X fragments has been demonstrated more unambiguously by spectroscopic methods and by experiments designed to investigate the dipole moments. The occurrence of d_{π}–p_{π} binding between the E and X atoms is indicated by a whole series of facts.

1. The high valence force constants of the Si–X (X = halogen) indicating the partial double character of these linkages. A detailed examination of the dependence of the force constants on the electronic effects of the substituents led to the conclusion[2,28–32] that the force constants of the Si–X bonds cannot be described solely in terms of the inductive influence of X and other substituents.

2. The higher energies of the unshared electron pairs of the halogens in silicon compounds compared with the isostructural carbon compounds and the intermediate values of the germanium derivatives[33–36]. Thus the vertical ionisation potentials of the *np* orbitals of the halogens, determined by photoelectron spectroscopy, are 11.28, 11.61, and 11.34 eV for CH_3Cl, SiH_3Cl, and GeH_3Cl respectively and 10.70, 11.03, and 10.72 eV for CH_3Br, SiH_3Br, and GeH_3Br respectively[33]. It might have been expected that the replacement of a carbon atom by a less electronegative silicon or germanium atom would lead to an increase of the negative charge on the Cl and Br atoms and hence to a decrease of the ionisation potentials of the halogens. However, this is not observed experimentally owing to the manifestation of π-acceptor properties by the silicon atom (and to a lesser extent by the germanium atom).

3. The low-electron-donating capacity of chlorosilanes in the formation of a hydrogen bond[37]. In conformity with the ionisation potential data examined above, the compounds $(CH_3)_3MCl$ and $(CH_3)_2ECl_2$ (E = C, Si, Ge, or Sn), which are electron donors in the formation of a hydrogen bond with phenol, exhibit the lowest electron-donating capacity for E = Si. This also confirms the partial delocalisation of the unshared electron pairs of the chlorine atoms over the vacant 3*d* orbitals of the silicon atom.

4. The opposite signs of the conjugation contributions of the substituents R_i to the NQR frequencies of the halogens in the carbon derivatives $(R_i)_3CX$ and derivatives of the silicon subgroup elements $(R_i)_3EX$, where X = Cl or Br and E = Si, Ge, or Sn.[38] It has been observed that the NQR frequencies (characterising the state of the valence electrons and the type of chemical bond in which the halogens are involved) are correlated, within the limits of each of the above eight series of compounds, with the sums of the inductive Taft constant σ* of the substituents R_i. However, a more rigorous treatment leads to the conclusion that one must take into account not only the inductive but also the conjugation influence of R_i on the NQR frequency. Analysis of the correlation analysis data indicates an increased multiplicity of the E–X bonds and its dependence on the d_{π}–p_{π} interaction in the E–R_i fragments.

5. The reduced frequencies and increased intensities of the absorption bands associated with the stretching vibrations of the E–H bonds (E = Si or Ge) in the infrared spectra of halogenosilanes and halogenogermanes compared with the values expected on the hypothesis of a purely inductive influence of the halogens[39–42]. The transfer of electron density in the H–E–X fragment from the halogen atom to the E atom leads on the one hand, to a decrease of the acceptor properties of the halogen and a decrease of the force constant of the E–H bond and of its stretching vibration frequency and, on the other hand, it induces an increase of the negative charge on the hydrogen atom of the E–H bond and increases its polarity and the intensity of the E–H stretching vibration band in the infrared spectrum.

6. The increased shielding constants of the methyl and ethyl groups in the ^1H NMR spectra of alkylhalogeno-silanes and -germanes $R_{3-n}EX_n$ (R = CH_3 or C_2H_5; E = Si, or Ge; X = F, Cl, Br, or I).[43] Calculation taking into account the purely inductive influence of the substituents on the chemical shifts of the protons in the group R by the method of correlation analysis with corrections for magnetic anisotropy leads to a discrepancy between the calculated chemical shifts and their experimental values. The increased shielding of the groups R is a result of the weakening of the electron-accepting properties of the halogen atoms in consequence of the d_{π}–p_{π} interaction in the E–X fragments.

7. The smaller dipole moments of halogenosilanes compared with the corresponding halogenomethanes[3]. On the basis of

the lower electronegativity of silicon compared with that of carbon, a greater polarity of the Si–X bond compared with C–X might have been expected. However, experiment failed to confirm this. The example of the simplest silane derivatives shows that the polarity of the Si–X bonds[3] as well as the polarity of the E–X bonds in alkylhalogeno-derivatives of silicon, germanium, tin, and lead (see, for example, Sorriso et al.[44]) is reduced owing to the delocalisation of the unshared electron pairs of the halogen atoms over the *nd* orbitals of the E atoms.

2. The E–Group VI Element Bond

Among the compounds having this bond, the practically important derivatives containing the Si–O siloxane linkage and the Si–O–Si disiloxane linkages have been studied in greatest detail. Modern ideas about the nature of the siloxane linkage have been considered in a monograph[45]. The characteristic results of the manifestation of a strong d_π–p_π interaction in the Si–O bond are as follows[45]: the shorter length of the Si–O bond (~1.65 Å) compared with the sum of the covalent radii (1.83 Å) of the silicon and oxygen atoms; the greater Si–O–Si angle (105–180°); the high energy (100–120 kcal mol^{-1}) and high force constant[46] as well as the low polarity (dipole moment 1.2–1.6 D) of the Si–O bond; the weak-electron-donating properties of the oxygen atoms in alkoxysilanes, which are still further reduced in disiloxanes compared with the corresponding carbon analogues; the appreciably greater acidity of silanes compared with carbinols.

The strong d_π–p_π interaction in the Si–O bond is appreciably weakened on passing to the Ge–O fragment. The expected bond length in $(H_3Ge)_2O$ is therefore smaller by only 0.06 Å than the experimental value and the Ge–O–Ge angle (126°) is significantly smaller than the Si–O–Si angle in disilyl ether (144°).[47] The E–O–E angles in the $[(CH_3)_3Ge]_2O$ and $[(CH_3)_3Sn]_2O$ molecules, which are ~141°, indicate the important role of the effect of the d_π–p_π interaction also in the formation of the Sn–O bond[48].

Systematic studies of the dependence of the d_π–p_π interaction in the E–X fragment on the nature of the silicon sub-group elements E and the group VI elements X have been carreid out by infrared spectroscopy and ^{1}H NMR [40,43,46,49,50]. The use of correlation analysis methods showed that the frequency and intensity of the stretching vibrations of the E–H bond in the infrared spectra of compounds with the H–E–X (E = Si, or Ge; X = O, S, or Se) fragment are determined, apart from the inductive effect, also by the conjugation interactions in the E–X groups. The role of such interactions diminishes with increase of the atomic number of the elements E and X, i.e. in the sequences Si > Ge > Sn and O > S > Se > Te. The contribution of the d_π–p_π interaction to the Si–Te bond is extremely small if any.

A convincing confirmation of these conclusions was obtained by three independent methods: in the study of the relative electron-donating capacity of compounds with E–X–E groups in the formation of hydrogen bonds by them[51]; in the analysis of the chemical shifts in the ^{1}H NMR spectra of the protons of the CH_3E groups of the compounds $(CH_3)_3SiXCH_3$ (X = O or S) and $(CH_3)_3GeOCH_3$;[43] in the study of the variation of the stretching vibration frequency ν(E–C) as a function of the substituents X in organodielemental compounds of the type $[(C_2H_5)_3E]_nX$, where E = Si, Ge, or Sn and X is a Group I–VII element[52]. The following features of the spectroscopic parameters, which do not agree with the hypothesis of their dependence solely on the inductive influence of the various substituents, have been found using these three different methods: (1) the change in the electron-donating capacity of compounds with E–X–E groups, where E is a silicon subgroup element, as the Group VI elements X are varied is inconsistent with the sequence O > S > Se > Te known to hold[53] for carbon compounds. The differences diminish with increase of the atomic numbers of the elements E and X. The increase of the mobility of the hydrogen in the X–H group in structurally similar compounds with the E–X–H fragment corresponds to a decrease in the electron-donating capacity of the compounds with such a fragment[54,56]; (2) corrections for magnetic anisotropy and the inductive effect showed that the shielding constants of the protons of the CH_3E group in trimethylmethoxygermane and to an even greater extent in trimethylmethoxysilane are too high. The shielding constant of trimethylthiosilane has increased less than the constant of trimethylmethoxysilane[43]; (3) the points corresponding to compounds with E–Group VI element bonds deviate from the linear correlation between the ν(E–C) frequencies in the compounds $[(C_2H_5)_3E]_nX$ and the electronegativity of the elements X (where X is a Group I–III element); the deviations decrease in the sequence O > S > Se > Te.[52] However, they cease to be "anomalous" if one takes into account the effect of d_π–p_π interaction. In the E–X and E–X–E fragments this effect opposes the inductive effect of the atom X and therefore leads to the above deviations, which diminish with increase of the atomic numbers of the elements E and X

Specific aspects of the problem of the d_π–p_π interaction have been examined in a number of studies, in which details of the general relations discussed above were obtained. One of the most significant problems in this connection is competition between the effects of the d_π–p_π interaction and p,π conjugation in compounds containing groups of the type C_6H_5–X–Si< and R–C(=O)OE<. [49,57]. In $C_6H_5SiH_3$ both unshared electron pairs of the oxygen atom are involved in conjugation—one with the benzene ring and the other with the silicon atom[47][sic], [58]. In contrast to oxygen, the sulphur atom supplies only one electron pair for conjugation[59]. Therefore in $C_6H_5SSiH_3$ only the energetically more favourable conjugation with the benzene ring takes place, while there is no d_π–p_π interaction in phenylthiosilanes, in contrast to alkylthiosilanes[49]. The reduction of the electron density at the oxygen atom of the E–O–C fragment in benzoates and acetates in consequence of the R_3E–$\overset{\curvearrowright}{O}$–CR=$\overset{\curvearrowright}{O}$ conjugation is responsible for the small amount of the d_π–p_π character of the M–O bond in these compounds[57], compared with, for example, the alkoxy-derivatives of the elements E.

3. The E–Group V Element Bond

Fairly clear evidence in support of the operation of the effect of the d_π–p_π interaction in some of the E–Group V element bonds has been obtained in structural studies, selected results of which are presented in Table 1.

A classical example of the influence of the d_π–p_π interaction is the planar disposition of the heavy atoms in trisilylamine (with the Si_3N molecular skeleton), in contrast to the pyramidal structure of the C_3N fragment in trimethylamine. The delocalisation of the unshared electron pair of the nitrogen atom over the 3*d* orbitals of the silicon atoms leads to a sharp reduction of the basicity of trisilylamine compared with trimethylamine[3]. Solely on the basis of the smaller electronegativity of the silicon atom compared with the carbon atom, one would actually expect a greater basicity of trisilylamine compared with trimethylamine. The configuration of the bonds involving nitrogen atoms becomes nearly planar also in

the molecules of disilylmethylamine, silyldimethylamine, trigermylamine, and $Sn[N(CH_3)_2]_4$.[65] This shows that the effect of the d_π–p_π interaction contributes to the energy of not only the Si–N bond but also the Ge–N and Sn–N bonds. However, owing to the decrease of the contribution of the d_π–p_π interaction with increase of the atomic number of the elements E, the heavy atoms in trigermylamine are not entirely coplanar, unlike trisilylamine[63]. In contrast to derivatives with E–N bonds, the trisilylphosphine and trigermylphosphine molecules have a pyramidal configuration, while their E–P–E valence angles differ slightly from the C–P–C angle (~100°) in trimethylphosphine. The heavy atoms are also non-coplanar in trisilylarsine and trisilylstibine (Table 1).

Table 1. The bonds lengths and valence angles in derivatives of Group V elements.

Compound	E–X bond length, Å		E–X–E angle (°)	References
	experimental	calculated as the sum of covalent radii of E and X (Ref.60)		
$(H_3Si)_3N$	1.734	1.87	119.7	61

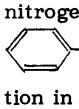
It follows from Table 1 that the Si–N and Ge–N interatomic distances deviate appreciably from the sum of the covalent radii of the E and N atoms. As in siloxanes, in silazanes the Si–N bond length is reduced (the bond length calculated from the covalent radii after introducing corrections for the amount of ionic character of the bond by the Schomaker–Stevenson method[66] is 1.80 Å) and the valence angles at the nitrogen atom are increased. These facts agree with the hypothesis of an increased order of the Si–N bond in silazanes due to the d_π–p_π interaction[67]. Thus structural data clearly indicate an increase of the E–N (E = Si, Ge, or Sn) bond orders. The amount of double bond character then decreases with increase of the atomic number of E.

On the other hand, the experimental E–X bond lengths (where E = Si or Ge and X = P, As, or Sb) virtually agree with the sum of the covalent radii of the E and X atoms. As stated above, compounds containing such bonds have a pyramidal structure like their carbon analogues (i.e. with E = C). Thus the structural data for derivatives containing elements of the phosphorus subgroup do not indicate an appreciable increase of the angles or a decrease of the interatomic distances which might be ascribed to the influence of the effect of the d_π–p_π interaction.

These facts, pointing to a significant weakening of the d_π–p_π interaction already on transiton from the E–N bond to the E–P bond were subsequently convincingly confirmed by infrared spectroscopy[68]. Analysis of the stretching vibration frequencies of the Si–H bond in the infrared spectra of compounds with the H–Si–N fragment showed that values of ν(Si–H) depend not only on the inductive influence of the three substituents at the silicon atom but are also determined by the influence of several mesomeric effects, the principal ones being those of the d_π–p_π interaction and the σ,p conjugation. In contrast to this, the frequencies ν(Si–H) in the infrared spectra of compounds containing the H–Si–P fragment depend solely on the inductive influence of the three substituents linked to the silicon atom[68].

The significant d_π–p_π character of the Si–N bond and the absence of double bond character in the Si–P group can be explained by assuming that the d_π–p_π interaction in the E–X bond has a profound analogy with conjugation effects in organic chemistry, for example, with the effect of ρ,π conjugation in the benzene derivatives C_6H_5–X (where X has the same substituents as in the organo-elemental compounds with the E–X bond). The possibility of drawing such an analogy is justified in detail in Section III of the present review.

The proposed approach makes it possible to regard d_π–p_π interaction as a process which depends on two factors: the electron-accepting properties of the atom E and the electron donating properties of the substituent X. It is well known[69] that, as a substituent in an aromatic ring, the dialkylamino-group exhibits an exceptionally high capacity for conjugation. This property of the dialkylamino-group is responsible for the considerable amount of the d_π–p_π character of the Si–N bond in fragments of the type $Si–N(CH_3)_2$.[68] The $P(CH_3)_2$ group has a low capacity for conjugation of the p,π type[70] due to the weak p character of the orbitals of the unshared electron pair of tervalent phosphorus[71]. This is the reason for the virtual absence of d_π–p_π character in the Si–P bond[68], which applies to an even greater extent, according to structural data, to other bonds of the type E–P and also to E–X bonds where X is a phosphorus subgroup element[52].



Important information about the π-acceptor properties of silicon subgroup elements E has been obtained in a systematic study of the electron-donating capacity of compounds containing E–N fragments[59,72–80]. The electron-donating capacity was estimated from the shift of the stretching vibration frequency of the C–D bond in deuterochloroform or the N–H bond of pyrrole in the infrared spectrum when the above compounds form a hydrogen bond with organoelemental compounds. The electron-donating capacity of organosilicon, organogermanium, and organotin amines depends significantly, like that of the usual organic amines, on the nature of the substituents linked to the Group IVb element; in the absence of appreciable steric hindrance, it decreases steadily with enhancement of the electron-accepting properties of the substituent. In isostructural series of compounds with a variable element E, the electron-donating capacity depends greatly on the nature of the atom E.[73–77,79].

In all cases, the electron-donating capacity of amines having one or several Si–N bonds is greatly reduced compared with that for the corresponding carbon compounds[59,72,75]. A typical example is provided by the extremely low electron-donating capacity of trisilylamine[3], while trimethylamine is a strong base. The electron-donating capacity of germanium-containing amines is also appreciably weakened compared with that of carbon compounds of analogous structure[75–77]. The relative electron-donating capacity of the nitrogen atoms in isostructural compounds is reduced to the sequence C–N–C > C–N–Ge > Ge–N–Ge > C–N–Si > Si–N–Si when the immediate environment of the nitrogen atom is altered[75]. This sequence is directly opposed to that expected on the basis of the electronegativities of the Group IV elements. The electronegativity varies in the sequence C > Ge > Si,[6] so that it might have been expected that carbon-based amines and silylamines would exhibit the minimum and maximum electron-donating capacities respectively. The experimentally observed opposite sequence of electron-donating capacities indicates the delocalisation of the unshared electron pairs of the nitrogen atoms over the vacant nd orbitals of the E atoms (i.e. d_π–p_π interaction occurs). This effect is enhanced on passing from germanium derivatives to silylamines and also with increase of the number of silicon atoms linked to the nitrogen atom[81].

The π-acceptor properties of the E atoms, which involve the transfer of electron density in the E–N fragments from the nitrogen atom to that of the silicon subgroup element, should lead to an increase of the mobility of the hydrogen atom in the E–N–H group compared with that expected on the basis of the inductive effect of the substituents linked to the nitrogen atom. The validity of this conclusion was demonstrated by comparing the relative acidities of amines and silylamines. It has been shown by infrared spectroscopy that, on formation of a hydrogen bond, silylamines exhibit much more pronounced electron-accepting properties than their carbon analogues in relation to electron donors to which they are linked by hydrogen bonds[74,75,82,83]. The effect of the d_π–p_π interaction in the Si–N bond leads to the appearance of electron-accepting properties in the R_3Si group, as a result of which the mobility of the hydrogen atom in compounds containing the R_3Si–N–H fragment increases sharply[83].

An extremely characteristic feature of compounds with an E–N fragment is the significant role of conjugation effects in the latter, which operate together with the d_π–p_π interaction. The specific features of the appearance of these effects are determined mainly by two factors: firstly, the exceptionally high capacity of the dialkylamino-group for conjugation, which has already been noted, and, secondly, the presence of only one electron pair at the nitrogen atom and the consequent possibility of competition between different conjugation effects involving this pair. If the conjugation effects are comparable in intensity, they do not appreciably weaken one another, acting independently. On the other hand, if one of the effects is energetically clearly preferable, its influence becomes dominant and that of the other effects is suppressed. The situation of the first type is characteristic of alkyl(dialkylamino)silanes and that of the second type is characteristic of *N*-trimethylsilyl, *N*-trimethylgermyl, and *N*-trimethylstannyl derivatives of aniline.

Analysis of the factors influencing the frequency and integral intensity of the stretching vibration of the Si–H bond in the infrared spectra of ethyl(diethylamino)silanes shows that, together with the d_π–p_π interaction, a second mesomeric effect—the σ, *p* conjugation $R_2\overset{\curvearrowright}{N}$–Si → H—plays a significant role in the Si–N bond in these compounds[84]. The manifestation of the σ, *p* conjugation is promoted by the small inductive effect ($\sigma_I \cong 0.1$) and the high capacity of conjugation ($\sigma_R = -0.8$) of the diethylamino-group. The introduction of second and third diethylamino-groups into the silane molecule is accompanied by the enhancement of the overall *-I* effect of the substituents, but the inductive effect is fully compensated by the electron-donating properties of the diethylamino-group via the d_π–p_π and σ, *p* conjugation mechanisms. Therefore, in contrast to any other silanes with functional groups, the frequencies ν(Si–H) decrease, and not increase, as the number of diethylamino-groups is increased. The dipole moment of the Si–H bond and the negative charge on the hydrogen atom in ethyl(diethylamino)silanes become greater than in trialkylsilanes as a result of the joint influence of the effects of the d_π–p_π interaction and the σ, *p* conjugation[84].

Typical systems in which the competition between the effects of the d_π–p_π interaction and the *p*, π conjugation induces a virtually complete suppression of the former effect are *N*-substituted anilines[85]. In the study of these compounds by infrared spectroscopic and NMR methods no stereochemical evidence for the occurrence of the d_π–p_π interaction in the E–N bonds was found. This is caused by the stronger *p*, π conjugation of the single unshared electron pair of the nitrogen atom with the aromatic ring in the fragment E–$\overset{\curvearrowright}{N}$–  (E = Si, Ge, or Sn) compared with the d_π–p_π interaction in the E–N bonds[68]. A similar phenomenon has been observed, as already mentioned above, in phenylthiosilanes[49] where the involvement of the sulphur atom in *p*, π conjugation with the aromatic ring Si–$\overset{\curvearrowright}{S}$i–  leads to the "switching off" of the d_π–p_π interaction between this atom and the 3*d* orbitals of silicon.

Thus, other conditions being equal, the d_π–p_π interaction is energetically less favourable than the *p*, π conjugation.

4. The E–Aromatic Ring Bond

The π-acceptor properties of silicon subgroup elements E in relation to an aromatic ring linked to them are indicated by numerous spectroscopic data. The principal data refer to the study of benzene derivatives; only a few have been concerned with aromatic heterocycles.

The electron-accepting properties of the E atoms linked to an aryl substituent are indicated by a series of data.

1. The higher energies of the first band in the photoelectron spectrum of phenylsilane compared with toluene, which indicate the stabilisation of the highest energy orbital in phenylsilane via d_π–p_π binding[86]. This has been confirmed by data for halogenotriphenyl derivatives of Group IV elements[87] and for the *p*-substituted derivatives of trimethylphenylsilane[88,89], which also indicate an appreciable transfer of electron density from the benzene ring to the silicon atom.

2. The enhanced electron-accepting properties of the substituents ER_3 compared with the corresponding carbon substituents (according to NMR data). ^1H NMR and particularly ^{19}F NMR of benzene derivatives constitute thoroughly developed methods for the estimation of the electronic effects of substituents linked to the benzene ring[90]. In particular, the secondary scale of Hammett constants is based on NMR data[90]. Derivatives of trimethylphenylsilanes containing different substituents in the *ortho*-, *meta*-, and *para*-positions have been studied by NMR [91]: compounds of the $(C_6H_5)_3EX$ series (E is a group IVB element and X are different substituents)[92]; the fluoro-derivatives *m*- and *p*-FC_6H_4E [93]; the pentafluorophenyl derivatives of Group IVB elements[94]; organotin compounds containing monofluorophenyl substituents[95–97]. The above investigations showed that, in the case of all the organoelemental substituents, including the organotin substituents, ideas based on the electronegativities of the silicon subgroup elements are insufficient for the description of the characteristic features of the variation of the chemical shifts and the spin–spin coupling constants. The electronic interactions between the organoelemental substituents and the aromatic ring proceed via a combined (inductive and resonance) mechanism (d_π–p_π interaction).

3. The increase, according to microwave spectroscopic data[98], of the potential barrier to the rotation of the silyl group in phenylsilane, compared with the analogous quantity for the methyl group in toluene, owing to the d_π–p_π binding between the silicon atom and the aromatic ring.

4. The smaller electron-donating capacity of silicon- and germanium-containing derivatives of benzene compared with their carbon analogues on formation by these compounds as π-donors of a hydrogen bond with electron acceptors[99,100]. This effect is caused by the reduced electron density in the benzene ring in organoelemental compounds in consequence of the d_π–p_π interaction in the E–C_6H_5 fragments.

5. The higher frequencies, ν_{CT}, of the charge-transfer bands in the electronic absorption spectra of charge-transfer complexes of phenylsilanes with tetracyanoethylene compared with their carbon analogues and the intermediate values of ν_{CT} in phenylgermane complexes[100–103]. Charge-transfer

complexes of the π,π type are formed between π-donors (aromatic compounds) and π-acceptors (for example, tetracyanoethylene). The absorption of a light quantum $h\nu_{CT}$ by such a complex causes the transition of the latter from the ground to an excited state. The energy $h\nu_{CT}$ is linearly related to the ionisation potential of the π-donor and the σ_n^+ constants of the substituents in the aromatic ring[100]. Analysis of the values of ν_{CT} in the spectra[100-103] and of the calculated Brown–Okamoto σ_n^+ constants shows unambiguously that the overall electronic effect of the substituents ER_3 in the ring (E is a silicon subgroup element) is the sum of two components—inductive and resonance (i.e. d_π–p_π interaction takes place). The d_π–p_π interaction is most pronounced in phenylsilanes.

6. The inadequacy of inductive ideas alone for the description of the nature of the changes in the frequencies and intensities of the stretching vibration bands of the E–H bond (E = Si or Ge) in the infrared spectra of silane and germane derivatives containing phenyl substituents[40-42,50,105]. This is caused by the effect of the d_π–p_π interaction in the E–C_6H_5 fragments. The dependence of the effectiveness of the d_π–p_π binding on the nature of the substituents in the aromatic ring will be specially considered in Section III of the present review in relation to arylsilanes[105].

7. Numerous data for the dipole moments of phenyl derivatives of Group IVB elements, which have been discussed in fair detail in a number of reviews[3,5,6] and surveys[106-110] have shown that the ER_3 fragments (E is a silicon subgroup element) manifest, together with a positive inductive effect, a negative mesomeric effect (d_π–p_π interaction), which diminishes on passing from organosilicon compounds to germanium and tin derivatives. The degree of d_π–p_π interaction depends on the nature of the substituents at the E atom and in the benzene ring. The presence of typically electron-donating substituents in the *para*-position in the ring leads to a direct polar conjugation effect in which the ER_3 fragment behaves as an acceptor centre.

As mentioned above, the d_π–p_π interaction between the E atoms and the aromatic ring has been studied mainly for benzene derivatives. However, it has been established in a number of studies[111-117] that significant π-binding is characteristic also of silylnaphthalenes.

Electronic spectroscopy of charge-transfer complexes has been used to investigate the π-acceptor effects of organoelemental substituents in thiophen[118] and furan[119] derivatives. Analysis of the frequencies of the charge-transfer bands in the spectra of charge-transfer complexes of these compounds (π-donors) with tetracyanoethylene (π-acceptor) and also comparison of these frequencies with proton chemical shifts in NMR spectra show convincingly that the electron-donating properties of the trimethylsilyl and trimethylgermyl groups are weaker than those of the t-butyl group owing to the d_π–p_π interaction. The decrease of the d_π–p_π character of the E–furyl bond as E is varied in the sequence Si > Ge > Sn [119] has been established in relation to furan derivatives and has been confirmed by NMR data[120].

Thus the sum total of the available spectroscopic data clearly indicates the d_π–p_π character of the E–aromatic ring bonds.

5. E–C = C and E–C ≡ C Systems

Numerous literature data have confirmed the involvement of the π electrons of an α,β-unsaturated hydrocarbon substituent linked to a silicon subgroup element (E) in d_π–p_π interaction with the vacant *nd* orbitals of the E atom. The most striking of these results are described below.

1. The smaller valence force constants of the C = C [112,121] and C ≡ C [122-124] bonds in organoelemental derivatives, compared with their carbon analogues, which is particularly pronounced for silicon derivatives. For example, the carbon–carbon bond orders in the compounds $H_3EC \equiv CH$ with E = C, Si, or Ge, are respectively 2.65, 2.47, and 2.53.[124] The maximum degree of delocalisation of the π electrons of the multiple bonds over the vacant *d* orbitals in the silicon compounds corresponds to the minimum order of the multiple bond in these compounds.

2. The lower electron-donating capacity of organoelemental compounds (as π-bases in the formation of hydrogen bonds with electron acceptors[122,125,126] and as π-donors in the formation of charge-transfer complexes of the π,π type[127,128]), linked indirectly to the lower force constant, as well as the greater mobility of the acetylenic hydrogen atom of the E–C = C–H fragment (E is a silicon subgroup element) compared with carbon analogues[129-132]. All these factors, caused by the π-acceptor properties of the E elements, are most strongly manifested in silicon compounds, while in lead derivatives they are virtually absent[129].

3. The inadequacy of inductive ideas alone for the description of the change in the frequency of the highly characteristic[133] out-of-plane deformation vibration of the $=CH_2$ group in the infrared spectra of ethylene derivatives $CH_2 = CH–ER_3$ containing organoelemental substituents ER_3 (E = Si, Ge, or Sn).[134] The frequency of this vibration is determined by the joint inductive and mesomeric (π,π and π,*p* conjugation as well as d_π–p_π interaction for organoelemental compounds) effects of the substituents.

4. The occurrence of a resonance interaction, together with the inductive effect, between the silicon atom and the C = C and C ≡ C fragments, which is manifested in the infrared spectra of silane derivatives containing such fragments[135]. The influence of the resonance effect (d_π–p_π interaction) is shown by the deviation of the stretching vibration frequencies of the Si–H bond from the values expected on the basis of allowance for the purely inductive effect of these fragments.

5. Analysis of the parameters of the NMR spectra[136-140] and the dipole moments[106,109,137] of organoelemental derivatives of ethylene and acetylene also demonstrate the necessity to take into account the π-acceptor properties of silicon subgroup elements in the interpretation of the experimental relations.

The experimental data considered in this section indicate unambiguously the presence of π-acceptor properties in silicon subgroup elements (E) with respect to the *n*- or *p*-donor type substituents linked to them (d_π–p_π interaction). In compounds having one E = X bond or one E–X–E fragment the capacity for d_π–p_π interaction is reduced with increase of the atomic numbers of the E and X atoms. The decrease of the capacity for d_π–p_π interaction with a constant E and a variable X is greater the smaller the number of the Group in the Periodic System to which X belongs. Other characteristics of the d_π–p_π interaction will be examined in Section III.

The results of the experimental study of the d_π–p_π interaction have been confirmed by quantum-chemical calculations by the molecular orbital method using various approximations. These calculations indicate an appreciable involvement of the vacant *d* orbitals in the formation Si–O,[141-143] Si–N,[144-146] Si–halogen[146-148], Si–aryl[143,149-155], Ge–C_6H_5,[152] and Si–C = C [155,156] bonds. However, as mentioned in the introduction, the conclusions reached in such calculations can depend on the accuracy of the method employed, which reduces sharply their value compared with experiment.

III. THE NATURE OF THE π-ACCEPTOR EFFECTS IN COMPOUNDS OF SILICON SUBGROUP ELEMENTS

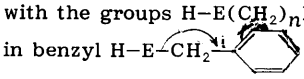
Numerous literature data have shown that spectroscopic methods make it possible to investigate the fine details of the π-acceptor properties of silicon subgroup elements. Without going into the details of the mechanism of the π-effects, we adopted for these effects, following the majority of published studies, the terms d_π–p_π interaction (interaction between an E atom and a substituent X which is an *n*- or π-donor in the E–X fragment) and (p–d) σ-interaction (interaction through space between atoms E and X not linked by a valence bond). The use of these terms is absolutely correct only when it is demonstrated unambiguously that the *nd* orbitals of the E atoms are responsible for the manifestation of π-acceptor properties by the latter. There is no direct evidence for this at the present time, but there exist no firmly demonstrated alternative to the hypothesis of vacant *nd* orbitals.

At the same time extensive experimental data have been accumulated on the relations obeyed by the π-acceptor properties of silicon subgroup elements. Under these conditions, it is important to analyse the extent to which the conclusions reached on the basis of these experimental data are consistent with the postulates of the *nd*-orbital hypothesis. In the fundamental study by Jaffé [11] and in other investigations[3,10,12–15], it was shown that the d_π–p_π bonds in the E–X fragment are formed when the following three necessary and sufficient conditions are fulfilled: (1) the substituent X must possess *n*- or π-donor properties; the involvement of *d* orbitals should lead to effects similar to those arising on conjugation of π-bonds; (2) there should be a positive charge on the atom E, an increase of which should entail an enhancement of the d_π–p_π interaction; (3) the effect of the d_π–p_π interaction arises only in the presence of high overlap integrals of the p_π and d_π orbitals of the interacting X and E atoms.

These conditions are inter-related. For example, the contraction of the *d* orbitals of the atom E and the decrease of the energy and electron affinity with increase of the positive charge on the E atom[13] create more favourable conditions for the interaction of the d_π orbitals of the E atom with the p_π orbitals of the X atoms, i.e. they increase the overlap integrals of the interacting orbitals of the E and X atoms[11]. Under these conditions, it is extremely significant that the molecular d_π orbitals are much less diffuse and have a much lower energy than the corresponding atomic orbitals[14] and their energy is therefore closer to that of the p_π orbitals of the X atom. In addition, the size of the molecular d_π orbitals, their energy, and the values of their overlap integrals with the p_π orbitals of the X atom depend also on the nature of the substituents at the E atom[13]. Electron-accepting substituents linked to E increase the positive charge of the latter and favour the d_π–p_π interaction[11]. Conditions (2) and (3) quoted above are therefore closely related.

At the same time condition (3) is of independent importance, particularly when not one but several X atoms involved in d_π–p_π interaction with tetrahedral E atoms are linked to the latter. Under these conditions, owing to the difference between the valence angles (~109.5°) and between the angles between the maximum intensity vectors of the d_π orbitals (90°), the interaction of E with several X proceeds when the orientation of the d_π orbitals is such that it does not lead to the maximum overlap integral in any of the E–X bonds[11]. In view of this, the overall effect of the d_π–p_π interaction in the molecule depends strongly and non-additively on the number of X atoms linked to E.[11,14].

The main task of the present section of the review is to examine to what extent the results of experimental studies of the d_π–p_π interaction are consistent with the above three conditions for the formation of d_π–p_π bonds and the conclusions arising therefrom.



1. Analogy Between the π-Acceptor Effects of the Elements E and the Conjugation Effects in Carbon Compounds

Systematic studies of the π-acceptor properties of silicon subgroup elements E, carried out in relation to organosilicon and organogermanium compounds by infrared spectroscopy and ^{1}H NMR, [39,40,49,50,157,158], have shown unambiguously that the elements E exhibit π-acceptor properties only when they are linked by direct chemical bonds to the group X in the E–X fragment, where X can be an atom with unshared electron pairs (*n*-donor) or an α,β-unsaturated hydrocarbon radical (π-donor). On the other hand, if E and X are separated by a fragment of the type $(CH_2)_n$, then the carbofunctional substituent $(CH_2)_nX$ in the group $E(CH_2)_nX$ exhibits only an inductive effect.

Generally speaking, the claim that the mutual influence of the atoms E and X in the fragment $E(CH_2)_nX$ occurs solely via an inductive mechanism is not entirely rigorous. In reality, there can be interactions of at least two types between these atoms. The first involves intramolecular coordination or the so-called α-effect (for $n = 1$):  [7]

The results of a number of studies have shown[6,8,160] that this type of interaction takes place through space, but its mechanism continues to be the subject of a lively discussion[159].

A detailed examination of this type of interaction is of independent interest and is outside the scope of the present review. We shall only mention that the majority of the spectroscopic features of the manifestation of intramolecular coordination in the fragment $E(CH_2)_nX$ can be given a non-contradictory explanation if the following view on the mechanism of the effect is adopted[6]. Intramolecular coordination takes place between the atoms E and X. The X atom behaves as an *n*-donor by virtue of the presence of unshared electron pairs; the E atom then behaves as an acceptor by employing the vacant *nd* orbitals with the formation of a new weak bond of the (p–d) σ-type with the atom X. The principal difference between the bond thus formed and the σ-bond between E and D in compounds of the type EX_4D and EX_4D_2 is that the former has a much smaller energy. Thus the enthalpy of formation of the (p–d) σ-bond in dimethylchloromethylsilane is ~1 kcal mole^{-1}.[160] The low energy of bonds of the (p–d) σ-type is apparently largely caused by the impossibility of the mutual approach of the atoms E and X in the fragment ECH_2X to a distance close to the sum of the covalent radii. Such mutual approach would require a significant alteration of the geometry of the fragment ECH_2X, which involves a considerable expenditure of energy. Intramolecular coordination has almost no effect on the chemical shifts of the protons of the group R in the fragments R–E (C = CH_3 or C_2H_5; E = Si or Ge) in the NMR spectra of compounds with the groups $E(CH_2)_nX$,[48] and its influence on the frequency and intensity of the stretching vibration of the E–H bond in the infrared spectra of compounds with the fragment $H–E(CH_2)_nX$ is manifested distinctly only for $n = 1$ [160] and can be taken into account by correlation analysis[160].

The second type of resonance interaction in the groups $E(CH_2)_nX$ is the effect of the σ,π conjugation manifested for $n = 1$. A detailed study of the frequency and intensity of the ν(E–H) vibration in the infrared spectra of compounds with the groups $H–E(CH_2)_nX$ showed that the σ,π conjugation in benzyl  and allyl ($H–E–CH_2–CH=CH_2$)

derivatives has almost no influence on the above spectroscopic parameters[39-43,49,50,158], although this effect does influence the change in electron density in the aromatic ring and in the double bond[99,125,161,162]. This is probably caused by the comparatively small effect of the σ,π conjugation in the ground electronic state, which intensifies appreciably only in the presence of a positive charge in the benzene ring or in the double bond, which follows from theoretical considerations[163,164] and from the electronic spectra of the charge-transfer complexes of benzyl and allyl derivatives of silicon subgroup elements[100,128].

Taking into account the foregoing it is possible to formulate the requirements which must be met by the correct empirical method for the estimation of the π-acceptor properties of the silicon and germanium atoms (E) in the fragment E–X.[6] In the first place, it is necessary to have a sufficiently representative series of compounds whose spectroscopic parameters depend exclusively on the electronic effects of the substituents (inductive and conjugation effects) and are sufficiently sensitive to the influence of substituents. In addition, it is extremely important that the research method employed should make it possible to separate the overall influence of the electronic effects of substituents into components due to the influence of the inductive and conjugation effects. The inductive and conjugation effects can be separated by methods of correlation analysis, which have been thoroughly developed for the study of problems of this kind in unsaturated carbon compounds[90]. The application of this approach leads to the possibility of a quantitative study of the characteristics of the manifestation of the π-acceptor properties of the elements E.

All the requirements enumerated above are satisfied by silane and germane derivatives. Important information has been obtained in the analysis of the frequencies and integral intensities of the Si–H and Ge–H stretching vibration bands in the infrared spectra of these derivatives[39-43,49,50,157,158]. The stretching vibration of the E–H bond (E = Si or Ge) takes place virtually only along the bond. The mass of the substituents linked to the atom E does not affect these vibrations. The mechanical interactions of the vibration with other vibrations in the molecule are very weak, so that the stretching vibrations of the E–H bond are highly characteristic as regards mode. At the same time, when other substituents at the atom E are varied, the frequency and intensity of the ν(E–H) band vibrations vary over a wide range owing to the electronic effects of the substituents which alter the force constant and the polarity of the E–H bond.

The ν(Si–H) frequencies were first investigated in the infrared spectra of compounds containing the $Si(CH_2)_nX$ fragments where resonance interactions between the atoms Si and X are ruled out[39,43,49,132]; the substituents in these compounds exhibit only an inductive effect. The ν(Si–H) frequencies in the infrared spectra of the above compounds are therefore linearly related to the sums of the inductive Taft constants $\sum \sigma^*$. For tri-, di-, and mono-derivatives of silane, individual correlation straight lines parallel to one another are observed+:

$$\nu_{ind} = 23 \sum \sigma^* + 2112 \ (R_3SiH), \quad (1)$$

$$\nu_{ind} = 23 \sum \sigma^* + 2121 \ (R_2SiH_2), \quad (2)$$

$$\nu_{ind} = 23 \sum \sigma^* + 2132 \ (RSiH_3). \quad (3)$$

The existence of three correlation straight lines has been explained by the hyperconjugation effect (σ,σ conjugation).[132] If the molecule contains even one *n*- or π-donor atom or a fragment X linked to a silicon atom, then the experimental stretching vibration frequency of the Si–H bond (ν_{exp}) in the infrared spectrum of such a compound becomes smaller than the value calculated from the corresponding equation in system (1)–(3). The differences $\Delta\nu = \nu_{ind} - \nu_{exp}$ are in all cases positive[39,43,49]. The difference Δν is caused by the manifestation of π-acceptor properties by the silicon atom. The inductive -*I* effect of the substituent X and the π-acceptor effect of the silicon atom in relation to the substituent X act in opposite directions. The resultant electronic effect can therefore be interpreted as a decrease of the inductive effect of the substituent X, which causes a decrease of the values of ν_{exp} relative to ν_{ind}.

The differences Δν depend strongly on the nature of the substituents X. Even a qualitative examination[157] shows that the series corresponding to increasing Δν is the same as the series based on the increase of the capacity of the substituents X for conjugation with the benzene ring when the latter is characterised by the quantity σ_R ($\sigma_R = \sigma_n - \sigma_I$, where σ_I is the inductive component of the Hammett constant σ_n of the *para*-substituent in the benzene ring). Next it was shown[157] that the quantities Δν and σ_R are linearly related:

$$\Delta\nu = -66 \sigma_R + 3. \quad (4)$$

The data examined above show, firstly, that the silicon atom exhibits an acceptor effect only when the substituent linked to it is an *n*- or π-donor and, secondly, that the π-acceptor effect of silicon exhibits the features which are observed in conjugation in unsaturated carbon compounds.

As mentioned at the beginning of this review, these features constitute one of the conditions whose fulfillment confirms that *nd* orbitals are responsible for the manifestation of acceptor properties by the atoms E. Taking into account data[134] for conjugation in ethylene derivatives, one may conclude that the mechanism of the d_π–p_π interaction is similar to that of conjugation with an aromatic ring and the vinyl group. Thus the well known[19] analogy in the behaviour of the π,π-, π,*p*-, π,σ-, and σ,σ-conjugated systems extends also to d_π–p_π interaction. When the molecule contains several groups X capable of involvement in resonance interaction with E, the degree of d_π–p_π interaction depends on the positive charge on the atom E and on the group overlap integral of the d_π and p_π orbitals of the atom E and the substituents X in the fragment EX. This will be examined in detail in the next section.

Features similar to those observed for silane derivatives are characteristic also of germane derivatives. Thus the following parallel correlation straight lines are observed for tri- and di-substituted germanes containing substituents which do not form d_π–p_π bonds with the germanium atom[40,158]:

$$\nu_{ind} = 23 \sum \sigma^* + 2015 \ (R_3GeH), \quad (5)$$

$$\nu_{ind} = 23 \sum \sigma^* + 2029 \ (R_2GeH). \quad (6)$$

The introduction into the molecule of a substituent capable of d_π–p_π interaction with the germanium atom leads, as for silane derivatives[39,43], to a decrease of the experimental stretching vibration frequency of the Ge–H bond (ν_{exp}) relative to the value calculated from the corresponding equation [(5) or (6)] on the basis of the inductive effect (ν_{ind}). The differences $\Delta\nu = \nu_{ind} - \nu_{exp}$, which constitute a quantitative

+ Here and henceforth in this review the frequencies ν, Δν, etc. are expressed in cm^{-1} and the intensities 10^{-4} *A* are expressed in $mole^{-1}\ cm^{-2}$.

measure of the effect of the d_π–p_π interaction for the compounds R_2XGeH and $RXGeH_2$, are linearly correlated with the constants σ_R of the substituents X [158]:

$$\Delta\nu = -53\,\sigma_R + 4. \quad (7)$$

Comparison of the parameters of the linear equations (4) and (7) demonstrates a smaller capacity of the germanium atom for d_π–p_π interaction compared with the silicon atom. The latter is not characteristic only of silane and germane derivatives, containing a single substituent in the molecule capable of d_π–p_π interaction with the silicon or germanium atom, but is a general property of organoelemental compounds of Group IVB elements. This problem will be examined in greater detail in the next Section; here we shall only mention that the values of $\Delta\nu$ in the infrared spectra of organosilicon and organogermanium compounds ($\Delta\nu_{Si}$ and $\Delta\nu_{Ge}$), incorporating from one to three substituents capable of d_π–p_π interaction, are linearly related[40]:

$$\Delta\nu_{Si} = 1.17\,\Delta\nu_{Ge} - 4. \quad (8)$$

It follows from Eqn.(8) that (a) the principal features of the d_π–p_π interaction in organosilicon and organogermanium compounds are identical and (b) the germanium atom exhibits a smaller capacity for d_π–p_π interaction than the silicon atom.

The results obtained in the analysis of the stretching vibration frequencies of the E–H bond in the infrared spectra of silane and germane derivatives have been confirmed by the intensities of these absorption bands (the intensity data are quoted below).

Thus the mechanism of the π-acceptor effect of the E atoms (E = Si or Ge) in compounds with the fragments E–X has a profound analogy with the effects of the conjugation of the substituent X with an aromatic ring or the vinyl group. In conformity with Jaffé's work[11], this conclusion constitutes the first argument in support of the involvement of the vacant *nd* orbitals of the atoms E in the manifestation of π-acceptor properties by these atoms.

Experimental data consistent with theoretical postulates (2) and (3) of the *nd* orbital hypothesis are examined below.

2. Dependence of the π-Acceptor Effects on the Charge on the Atoms E

As already mentioned at the beginning of this section, the strength of the d_π–p_π bonds E–X increases with increase of the positive charge on the central element E.[11] The increase of the positive charge on E (for example, as a result of the addition of electron-accepting substituents Y to the given E) while the substituent X in the molecule XEY_3 remains unchanged induces a decrease of the energy of the d_π orbitals of the atom E, since the energy of the latter approaches that of the p_π orbitals of the atom X.[13] This entails an increase of the overlap integrals of the p_π and d_π orbitals of the atoms X and E and an increase of the strength of the d_π–p_π bond E–X.

We shall consider how well these theoretical postulates [(2) and (3)] of the *nd*-orbital hypothesis are consistent with the results of the spectroscopic study and the characteristics of the π-acceptor effects of the silicon and germanium atoms in organoelemental compounds. Silane and germane derivatives are convenient objects for the investigation of the dependence of the π-acceptor properties of the element E (Si or Ge) on its charge. As shown above, the difference $\Delta\nu = \nu_{ind} - \nu_{exp}$ between the stretching vibration frequencies of the E–H bond (E = Si or Ge) in the infrared spectra calculated by Eqns.(1) to (3), (5), and (6), on the one hand, and the experimental values ν_{exp}, on the other, is a quantitative measure of the electron-accepting properties of the atoms E.

In the study of the dependence of the π-acceptor properties of the atoms E on their positive charge a number of difficulties are encountered. They are associated with the fact that an increase of the positive charge on E is usually achieved by the addition to E of substituents X having a negative inductive $-I$ effect. However, such substituents X are as a rule *n*- or π-donors and are involved in resonance interaction with the atom E, which increases the electron density on the latter. The magnitude and sign of the resultant charge on the atom E (particularly in the presence of several substituents X of the type under consideration) are therefore determined by the ratio of the electron-accepting and electron-donating properties of the substituents, i.e. depend on the relative roles of the inductive and mesomeric effects of these substituents[135].

For the reasons described, the dependence of the π-acceptor properties of the atoms E on their effective charge can be conveniently investigated by considering the values of $\Delta\nu$ for a series of compounds with an increasing number of substituents. Here the simplest case is provided by compounds with a single substituent X of the type R_2XEH or (more specifically) of the type $(C_2H_5)_2XEH$.[157] These compounds can be regarded as products of the substitution of one ethyl group in triethylsilane or triethylgermane by a substituent X. Since the silicon and germanium atoms in triethylsilane and triethylgermane have quite definite effective charges, the π-acceptor effects of these atoms are determined largely by the ability of the substituent X to transfer its unshared electron pairs to the atom E (d_π–p_π interaction). It is therefore natural to compare $\Delta\nu_1$, characterising the π-acceptor effect, with the parameter characterising the ability of unshared electron pairs of the substituent X to participate in conjugation phenomena. As shown above, such parameters are the constants σ_R. The linear correlation between $\Delta\nu_1$ and σ_R in compounds with a single substituent X [see Eqns.(4) and (7)] now becomes entirely understandable.

Consider a compound RX_2EH containing two substituents X.[135,158] The values of $\Delta\nu_2$ for these compounds, which represent the differences $\nu_{ind} - \nu_{exp}$ and are calculated by the method already examined, differ from the values of $\Delta\nu_{add}$, which are equal to twice the values of $\Delta\nu_1$ for the corresponding compounds R_2XEH (Table 2). The compounds RX_2EH can be regarded as products of the substitution of an alkyl group R in R_2XEH by the substituent X. The effective charge on the atom E in R_2XEH depends both on the inductive $-I$ effect of X and on the opposed π-acceptor effect of E in relation to X (or, in other words, the π-donor effect of X in relation to E). The magnitude and sign of this effect determine the strength of the second d_π–p_π bond between E and X and hence the overall π-acceptor effect of the atom E in X_2EH.[135,158]. This is the first cause of the discrepancy between $\Delta\nu_2$ and $\Delta\nu_{add}$ for RX_2EH (Table 2).

The charge on the atom E induced by the substituent X can be taken into account by the sum of two constants $\sigma_I + \sigma_R$, where σ_I characterises the inductive effect of X and σ_R characterises, as shown above, the π-donor effect of X in relation to E. The sum of the constants $\sigma_I + \sigma_R$ represents the Hammett σ_n constant of the substituent X. The Hammett constants are known[90] to be proportional to the charges induced by the substituent on the reaction centre. The σ_n constant of the substituent X is therefore the simplest parameter proportional to the effective charge on E. Following an enhancement of the electron-accepting properties of X, σ_n for the substituent X increases and so does the positive charge on the atom E.

According to theoretical ideas[11,12], the second cause of the discrepancy between $\Delta\nu_2$ and $\Delta\nu_{add}$ [i.e. the origin of the differences $\delta(\Delta\nu) = \Delta\nu_2 - \Delta\nu_{add}$; see Table 2] is a complex

but non-additive relation between the two- centre and group overlap integrals S. The group overlap integrals of EX_2 are related to two-centre integrals s of the E–X bonds by the expression $S = \sqrt{4/3}s$.[11] However, the values of $\Delta\nu_2$ for RX_2EH differ from the values of $\Delta\nu_{calc}$ calculated by the formula $\Delta\nu_{calc} = \sqrt{4/3}\Delta\nu_1$, where $\Delta\nu_1$ are the corresponding values for the compounds R_2XEH.

Table 2. The values of $\Delta\nu$ in the infrared spectra of the compounds $(C_2H_5)X_2SiH$.

X	$\Delta\nu_2$, cm^{-1}	ν_{add}, cm^{-1}	$\delta(\Delta\nu)$, cm^{-1}	$\Delta\nu_{calc}$, cm^{-1}	$\Delta(\Delta\nu)$, cm^{-1}	σ_n
C_6H_5	18	18	0	10	8	0.01
CH_2=CH	17	28	−11	16	1	−0.01
F	28	50	−22	29	−1	0.06
Cl	38	44	−6	25	13	0.22
Br	42	32	10	18	24	0.23
CH_3O	15	76	−61	44	−29	−0.27
CH_3S	26	44	18	25	1	−0.05

The differences $\Delta(\Delta\nu) = \Delta\nu_2 - \Delta\nu_{calc}$ are due to a single cause—the change in the effective charge on E as the substituents X are varied. The values of $\Delta(\Delta\nu)$ should therefore vary in parallel with the Hammett σ_n constants of the substituents X; experiment confirmed this. It follows from the relations

$$\Delta(\Delta\nu) = 92\,\sigma_n \quad (RX_2SiH), \tag{9}$$

$$\Delta(\Delta\nu) = 67\,\sigma_n \quad (RX_2GeH) \tag{10}$$

that an increase of the positive charge on the atom E (i.e. an increase of the values of σ_n) leads to an increase of $\Delta(\Delta\nu)$ and hence of $\Delta\nu_2$, i.e. to an enhancement of the π-acceptor properties of the atoms E. Such enhancement is more pronounced for silicon compounds[135,158].

These conclusions were confirmed by a theoretical estimate of the overlap integrals of the Si–X bonds (X = O, S, or Cl) in the SiX_n fragments (n = 1–4) and of the dependence of the overlap integrals on the effective charge on the silicon atom[135]. The dependence of the π-acceptor effects on the atomic charge of E is clearly manifested in the study of the stretching vibration frequencies of the Si–H bonds in the infrared spectra of arylsilanes[105] and of the intensity of the ν(E–H) bands in the spectra of silane and germane derivatives[41,42,50,165,166].

The electron-accepting nature of the group XC_6H_4 in arylsilanes $Alk_{3-n}(XC_6H_4)_nSiH$ becomes significantly more pronounced with enhancement of the electron-accepting properties of the *meta*- or *para*-substituents X. At the same time there is an increase of the positive charge on the silicon atom. The values of $\Delta\nu$ (examined in detail above), which characterise the π-acceptor effect of the silicon atom in relation to the aryl substituent, increase with enhancement of the electron-accepting properties of the aryl substituents, i.e. with increase of the positive charge on the silicon atom. Under these conditions, the following linear relation holds[105]:

$$\Delta\nu = 12\sum\sigma^* + 4, \tag{11}$$

since, according to the data of Fisera et al.,[167] the inductive constants σ^* of the aryl substituents are linearly related to their σ_n constants.

Systematic studies of the integral intensities of the bands associated with the highly characteristic vibrations of the Si–H [41,50] and Ge–H [42,165,166] bonds in the infrared spectra of silane and germane derivatives served as yet another source of information about the dependence of the π-acceptor properties of the atoms E on their charge. While analysis of the frequencies of the highly characteristic M–H vibrations (i.e. analysis of the force constants) yields information about the energies of the E–H bonds, the study of their intensities makes it possible to investigate the polarity (dipole moment) of the E–H bond and in particular the influence on polarity of the π-acceptor effects involving E.

The square roots $A^{1/2}$ of the ν(E–H) absorption band intensity in the infrared spectra are linearly related to the sums of the inductive Taft constants $\sum\sigma^*$ of the substituents, exhibiting only an inductive effect in trisubstituted silane and germane derivatives[166]:

$$A^{1/2}_{ind} = 1.20 - 0.21\sum\sigma^*(R_3SiH), \tag{12}$$

$$A^{1/2}_{ind} = 1.30 - 0.20\sum\sigma^*(R_3GeH). \tag{13}$$

The intensity ($A^{1/2}_{exp}$) of the ν(E–H) bands in compounds with substituents of the n- or π-donor type (X) is higher than the values calculated by Eqns.(12) and (13). The differences $\Delta A^{1/2}_{exp} = A^{1/2}_{ind} - [?]$ are characterised by the π-acceptor effect of the atom E and other conjugation effects. For compounds with E–X bonds in which the π-acceptor effect of the atom E is the dominant conjugation effect, the following linear relations hold[41,166]:

$$\Delta A^{1/2} = 1.47\Sigma\sigma_n + 0.12 \quad \text{(silane derivatives)}, \tag{14}$$

$$\Delta A^{1/2} = 1.09\Sigma\sigma_n + 0.36 \quad \text{(germane derivatives)}. \tag{15}$$

Thus it follows from the intensities of the infrared bands that the π-acceptor properties of the atoms E (characterised by the quantities $\Delta A^{1/2}$ and most pronounced for silicon compounds) increase with increase of the effective positive charge on E (characterised by the sums $\sum\sigma_n$ of the Hammett constants of the substituents linked to E).

Summarising the data presented in the third Section of this review, we may note that these conditions are regarded[3,10–15] as necessary and sufficient for the formation of d_π–p_π bonds. These were enumerated at the beginning of the Section and have been confirmed experimentally.

Thus the available experimental spectroscopic data for the π-acceptor effects of silicon subgroup elements do not require for their interpretation hypotheses other than that based on the d_π–p_π interaction and constitute an indirect confirmation of the widely held view that π-acceptor properties are a manifestation of the effect of the d_π–p_π interaction.

The Mechanisms of the Rearrangements of Peroxides

V.A.Yablokov

The results of studies on the mechanisms of the rearrangements of organic and organoelemental peroxides are surveyed and the similarity of the mechanisms regardless of the structure of the peroxides is emphasised. The rearrangements of peroxides are regarded as intramolecular processes involving a concerted redistribution of bonds in a polar or radical-ion activated complex.
The bibliography includes 151 references.

I. INTRODUCTION

The rearrangements of organic and organoelemental peroxides involve a change in the structure of the initial molecule to that of an isomeric compound without the peroxy-group. The peroxides undergoing the rearrangement do not induce the polymerisation of unsaturated compounds and are unaffected by inhibitors and initiators of radical reactions, but are extremely sensitive to the action of protic and Lewis acids. The rearrangement of organic peroxides was observed by Wieland and Maier[1] as early as the 1930's. The oxidation of aldehydes and ketones by hydrogen peroxide or peracids (the Baeyer–Villiger reaction) is also classified as a process involving an intramolecular rearrangement of intermediate peroxyesters[2]. In essence, it was not until the beginning of the 1950's that attention was drawn to reactions of this type; at that time the first factory in the work manufacturing phenol by the cumene method, based on the acid-catalysed rearrangement of peroxides, was set up in the USSR.[3,4] The possibility, in principle, of the catalytic rearrangement of cumenyl hydroperoxide was also demonstrated by Hock and Lang[5].

Since the determination of the principal products of the thermal decomposition of diacyl peroxides by Wieland and Razuvaev[6] and the introduction of Waters' concept of the homolysis of the peroxy-bond[7], a considerable time elapsed before practical applications of the reactions of peroxides were discovered. The urgent need for polymeric materials brought peroxides to the forefront as effective initiators of radical polymerisation and vulcanisation processes[8,9]. As knowledge of the reactions of peroxides deepened, investigators observed with increasing frequency simultaneous non-radical reactions.

The rearrangements of peroxides are encountered much more frequently than might have been supposed at the time when the chemistry of peroxides was established. They have been observed for all classes of peroxy-compounds (hydroperoxides, diacyl peroxides, peroxyesters, and organoelemental peroxides), in certain cases as the only possible reaction pathway.

There is not yet a unanimous view concerning the mechanism of the rearrangement. In some cases the rearrangement is regarded as a heterocytic process and in others as a homolytic process. The asymmetry of peroxyester and hydroperoxide molecules suggests the polarisation of the O–O bond already in the initial state. Even when the initial state is only weakly polar, for example, in symmetrical diacyl and silyl peroxides, the polarisation of the activated state has been postulated. The significant influence of the polar effects of substituents and the medium on the rate of reaction as well as the non-radical nature of the reaction products were regarded as the principal features of a heterolytic process[10]. However, an increasing amount of experimental data indicating that the above features are characteristic also of radical reactions has appeared. The radical formation reactions undergone by certain t-butylperoxesters constitute a homolytic fragmentation of a polar activated state[11].

The study of homolytic and heterolytic reactions led to the observation of an increasing number of facts which make it possible to treat these processes as inter-related. It is not fortuitous that evidence has been adduced in a number of studies for a radical-ion mechanism of the rearrangement of peroxides[12].

The aim of the present review was to analyse the mechanisms of the rearrangements of peroxides known at the present time and to determine how far they are consistent with the modern ideas of theoretical and experimental chemistry.

II. ACID-CATALYSED REARRANGEMENT OF HYDROPEROXIDES

The rearrangements of hydroperoxides of different structures involve their sensitivity to the action of electrophiles, which is common to all of them. Here the hydroperoxide behaves as a base in relation to protic or aprotic acids. The most effective electrophiles exhibiting catalytic activity are protic acids[13–15]. Acid anhydrides and chlorides as well as Lewis acids cannot be regarded as true catalysts of the rearrangement, because in the course of the reaction they interact irreversibly with the hydroperoxide[14].

The acid-catalysed rearrangement of the hydroperoxide takes place readily in polar and non-polar solvents. Depending on the direction of attack by the electrophile (HA), there is a possibility of either a rearrangement, if the oxygen atom O_β is attacked,

$$(R_f)_3 - C - O_\alpha - O_\beta - H,$$

or of a transformation of the hydroperoxide molecule into a carbinol and hydrogen peroxide if the oxygen atom O_α is attacked. The latter reaction occurs with triphenylmethyl hydroperoxide and its derivatives in water-containing media[16,17]: it is not characteristic of cumenyl hydroperoxide[16,17].

On the basis of general considerations concerning acid–base reactions, in early studies of catalytic reactions of hydroperoxides it was assumed[18,19] that the interaction of alkyl hydroperoxide with a strong acid leads to the formation of a peroxyester in which the O–O bond is ionic. The process was represented by two consecutive elementary reactions:

$$PhMe_2COOH + H_2SO_4 \rightarrow PhMe_2\overset{+}{C}O\overline{O}SO_2H + H_2O\ , \quad (1)$$

$$PhOH + Me_2CO + H_2SO_4 \xleftarrow{H_2O} (PhO)\,Me_2COSO_2H\ . \quad (2)$$

However, the attempts to demonstrate the existence of the cation $\geq C-O^{(+)}$ were unsuccessful. Even under the influence of superacids of the type FSO_3H/SbF_5, only the formation of alkoxycarbonium ions was detected (by NMR).[20]

The following objections were raised against the above mechanism[21]. First, it was shown that the peroxyesters of strong acids decompose via the reactions

$$PhMe_2COOSO_2R \rightarrow (PhO)\,Me_2COSO_2R\ , \quad (3)$$

$$(PhO)\,Me_2COSO_2R \rightarrow PhOC(Me)=CH_2 + RSO_3H \quad (4)$$

and cannot be intermediates in reactions (1) and (2). Secondly, when reactions (1) and (2) take place, the phenol and the ketone should contain the ^{18}O isotope on decomposition of the hydroperoxide in the presence of $H_2S^{18}O_4$ and $H_2{}^{18}O$.[22] Isotopic studies showed that the phenol did not contain an excess of ^{18}O compared with its natural abundance. In the ketone ^{18}O was detected in amounts corresponding to direct isotope exchange between $H_2{}^{18}O$ and the ketone[22]. The following mechanism is most plausible[21]:

$$(R_i)_3COOH + HA \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (R_i)_3COOH_2A\ ; \quad (5)$$

$$(R_i)_3COOH_2A \xrightarrow{k_2} \left[\begin{array}{c} R_i \quad R_i \\ \diagdown\ \ \diagup \\ C \\ R_i\,\delta+ \quad \delta-\,OH_2A \\ \diagdown\ \ \diagup \\ O \end{array}\right]^{\#} \rightarrow R_iO(R_i)_2COH + HA\ ; \quad (6)$$

(I)

$$R_iO(R_i)_2COH \xrightarrow{k_3} R_iOH + (R_i)_2C{=}O\ . \quad (7)$$

The protonation of the hydroperoxide is a rapid reversible reaction [reaction (5)]. In the rate-limiting stage [reaction (6)] the electron density is redistributed and the internal nucleophile migrates to one of the peroxide oxygens.

The linear dependence of the logarithm of the rate constant for the rearrangement of the hydroperoxide on the acidity function[23,24] as well as the positive kinetic isotope effect[25] support a rapid reversible interaction of hydroperoxides with the acid, leading to the formation of a hydroperoxide–acid complex. Simple calculations[26] lead to an expression for the experimental rate constant k for the rearrangement:

$$k = \frac{k_1}{k_{-1}} k_2 [HA]_0, \quad (8)$$

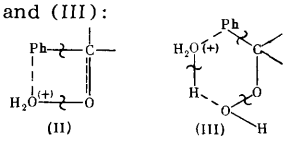
where $[HA]_0$ is the initial concentration of the acid.

Kinetic measurements[27–30] have shown that there is a linear relation between the apparent rate constant and the initial acid concentration. The order of the reaction with respect to the acid can be greater than unity if the acid is associated[31]. The experimental rate constants are effective quantities [see Eqn.(8)]. It is therefore difficult to expect the activation parameters to reflect fully the nature of the rate-determining stage of the process. Nevertheless one should turn attention to the fact that the pre-exponential factors correspond to a negative entropy of activation[26,32]. This agrees to some extent with the claim[26] that the rate-determining stage in the rearrangement of hydroperoxides involves a rigid cyclic complex.

Kinetic measurements have made it possible to elucidate a number of significant factors: firstly, the sequence in which the capacity for migration of the groups R_i varies has been established and, secondly, the nature of the interaction of the migrating group with the peroxide oxygen has been determined.

The aryl group in arylalkyl hydroperoxides is known to migrate in preference to the methyl group[23]. In substituted cumenyl hydroperoxides $Y_iC_6H_4C(Me)_2OOH$ the capacity of aryl groups for migration increases with enhancement of the electron-donating properties of the substituent Y.[23,26] The observed dependence of the logarithm of the reaction rate constant on the substituent constant σ^+ confirms the occurrence of a steric interaction between the migrating aryl group and the α-peroxide oxygen. The heterolysis of the peroxide linkage is accompanied by the simultaneous weakening of the Ar–C bond. This results in a transition from the sp^3-hybridisation of the tertiary carbon atom to the sp^2-hybridisation, which leads to an alteration of the valence angles in the activated state. The presence in the hydroperoxide molecule of a group acting as an internal nucleophile whose capacity for migration is comparable to that of the phenyl group, is the main condition for a high rate of the rearrangement.

In the acid-catalysed rearrangement of 2,2,4-trimethyl-2-pentyl hydroperoxide the neopentyl group migrates[33]:



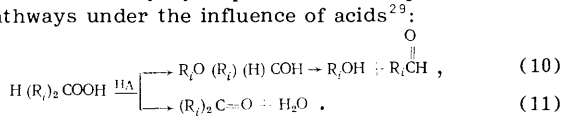
$$Me_3C{-}CH_2{-}CMe_2OOH \xrightarrow{HA} Me_3C{-}CH_2OH + Me_2CO\ . \quad (9)$$

9-Decalinyl hydroperoxide[34,35] rearranges with insertion of one of the peroxide oxygen atoms in the ring. A rearrangement with cleavage or expansion of the ring is characteristic of hydroperoxides derived from polynuclear hydrocarbons which have been partly or completely hydrogenated, as well 9-decalinyl hydroperoxide[36].

Competing reactions involving the migration of phenyl and cycloalkyl groups have been noted[37]. According to the proposed mechanism [reactions (5)–(7)], the rearrangement can be accounted for by the reaction of the hydroperoxide in a polar activated complex. Acid-catalysed rearrangements of tertiary hydroperoxides containing two or three hydroperoxy-groups are also known[38].

In tertiary arylalkyl hydroperoxides the methyl group cannot compete with the aryl group in the rearrangement. The consecutive replacement of the methyl group in cumenyl hydroperoxide by the ethyl, isopropyl, or t-butyl groups showed that the ethyl group, like the methyl group, does not migrate. The isopropyl group competes with the phenyl group as regards migration, while the t-butyl group has a much higher capacity for migration than the phenyl group[30].

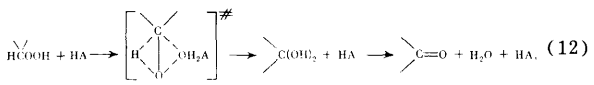
In discussing the structure of the activated complex [structure (I), reaction (6)], mention should be made of a study[39] in which the mechanisms of molecular and acid-base catalytic reactions were considered. The authors[39] suggested that the rearrangement of the hydroperoxide can take place in complexes (II) and (III):



(II) (III)

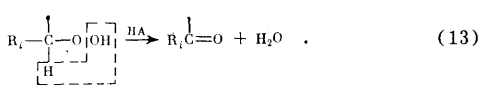
The formation of the above complexes is inconsistent with experimental data. According to reactions (5)–(7), the hydroperoxide rearranges in the rate-limiting stage to a hemiketal [reaction (6)]. Such hemiketals are not always stable, but in some cases it has been possible to isolate them[40]. Complex (II) is a closed structure in which the protonated hydroperoxide molecule is converted into a phenol and a ketone, by-passing the stage involving the formation of a hemiketal.

There is a well-founded objection also against the transformation of the hydroperoxide in complex (III). The structure of the complex presupposes the involvement of the H_3O^+ ion in the reaction. According to the ring structure, the reaction in $H_2{}^{18}O$ could lead to the formation of [^{18}O] phenol, while studies have shown[21,22] that the phenol does not contain an excess of ^{18}O.



Primary and secondary hydroperoxides decompose via two parallel pathways under the influence of acids[29]:

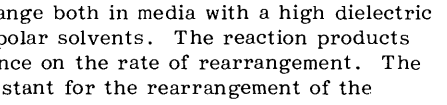
$$\mathrm{H(R_i)_2COOH} \xrightarrow{\mathrm{HA}} \begin{cases} \longrightarrow \mathrm{R_iO(R_i)(H)COH} \rightarrow \mathrm{R_iOH} + \mathrm{R_iCH}, & (10) \\ \longrightarrow \mathrm{(R_i)_2C{=}O} + \mathrm{H_2O}. & (11) \end{cases}$$



With enhancement of the electron-donating properties of the substituent R_i, the fraction of the products of the rearrangement involving the migration of the group R_i increases.

It is not at present clear which mechanism operates in the formation of water and carbonyl compounds from primary and secondary hydroperoxides. It may be that the acid-catalysed decomposition proceeds either via the reaction

$$\mathrm{HCOOH} + \mathrm{HA} \longrightarrow \left[\begin{array}{c} \mathrm{H} \\ \mathrm{C} \\ \mathrm{O} \end{array}\right]^{\#} \longrightarrow \mathrm{C(OH)_2} + \mathrm{HA} \longrightarrow \mathrm{C{=}O} + \mathrm{H_2O} + \mathrm{HA}, \quad (12)$$

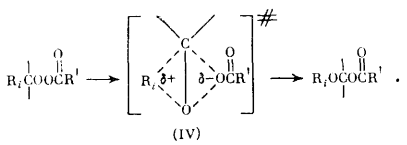


or constitutes a dehydration reaction:

$$\mathrm{R_i{-}C(H){-}O{-}OH} \xrightarrow{\mathrm{HA}} \mathrm{R_iC{=}O} + \mathrm{H_2O}. \quad (13)$$

III. THERMAL REARRANGEMENT OF PEROXYESTERS

Peroxyesters (PE) are the most convenient objects for the investigation of the mechanism of the rearrangement. These compounds can rearrange both in media with a high dielectric constant and in non-polar solvents. The reaction products have almost no influence on the rate of rearrangement. The experimental rate constant for the rearrangement of the peroxyester (k_{exp}) is formally a complex quantity. However, it can be regarded as equal to the rate constant for the elementary reaction of the rearrangement (k_2), provided that the equilibrium in the reaction between the peroxyester and an electrophile, which can be a solvent molecule (SH), is strongly displaced to the right [reaction (14)]:

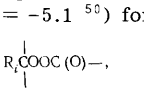


$$\mathrm{PE} + \mathrm{SH} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{PE.SH(fast)}, \quad (14)$$

$$[\mathrm{PE.SH}] \xrightarrow{k_2} \mathrm{P} + \mathrm{SH(slow)} \quad (15)$$

(P is the product of the rearrangement).

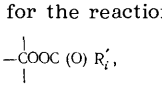
The activated state in reaction (15) is a highly structured polar complex. It was shown, first, that there is no transesterification during the rearrangement, because the peroxyester anion is not exchange for a salt anion[41,42] and, secondly, that the ^{18}O oxygen of the carbonyl group is fully retained in the isomeric product of the rearrangement[43,44]:



$$\mathrm{R_iCOOCR'} \longrightarrow \left[\begin{array}{c} \mathrm{C} \\ \mathrm{R_i}\delta+ \quad \delta-\mathrm{OCR'} \\ \mathrm{O} \end{array}\right]^{\#} \longrightarrow \mathrm{R_iOCOCR'}. \quad (16)$$

(IV)

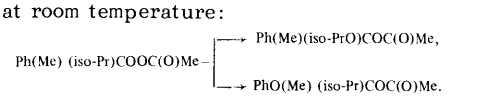
Peroxyesters containing the R_i aryl group rearrange on heating in polar and non-polar solvents regardless of the strength of the acid whose anion enters the peroxyester. The aryl group has a high capacity for migration, behaving as an internal nucleophile [activated complex (IV), reaction (16)]. An alkyl group R_i participates in the rearrangement only under severe conditions, where the medium consists of a superacid[45] or when the anion entering the peroxyester is a powerful electron acceptor[46].



The claim that the highly structured activated state is polar and exhibits the features of a heterolytic process is based on kinetic measurements published by different workers. The rate of rearrangement increases with enhancement of the electron-donating properties of the groups R_i [47,48] and of the electron-accepting properties of R_i'.[42,49]

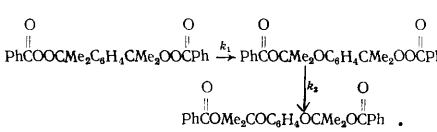
The reaction constant ($\rho = -5.1$ [50]) for the reaction series

$$\mathrm{R_iCOOC(O)}-,$$



in which R_i is varied, is much larger than the reaction constants ($\rho = 1.1$,[49] 1.21 [51]) for the reaction series

$$-\mathrm{COOC(O)R_i'},$$



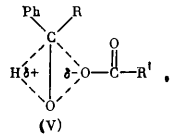
involving variable R_i'. The high sensitivity of the reaction to the electronic effects of R_i is probably caused by the involvement of the nucleophilic migrating group in direct interaction with the peroxide oxygen. Only this can explain the appreciable deviation of the reaction series of *para*-substituted cumenyl peroxybenzoates from the linear relation between $\lg k$ and σ.[52]

The role of the direct polar conjugation of the substituents with the reaction centre has been observed in the analysis of kinetic data[21] for the rearrangement of 2-propyl *p*-nitroperoxybenzoates in methanol, published by Hedaya and Winstein[47]. An increase in the size of the groups located in the alkyl fragment of the peroxyester should give rise to steric hindrance in the ground state and should remove it from the activated state. For peroxyesters containing alkyl or cycloalkyl groups R_i, such effects have an insignificant influence on the rate of rearrangement[47]. However, it was shown in a later study[51] that the rate of migration of the phenyl group increases with increase of the size of the adjacent alkyl group in the sequence methyl < ethyl < isopropyl. In the latter case the rate of rearrangement is so high that the peroxyester rearranges in the course of synthesis in toluene solution at room temperature:

$$\mathrm{Ph(Me)(iso\text{-}Pr)COOC(O)Me} \begin{cases} \longrightarrow \mathrm{Ph(Me)(iso\text{-}PrO)COC(O)Me}, & (17) \\ \longrightarrow \mathrm{PhO(Me)(iso\text{-}Pr)COC(O)Me}. & (18) \end{cases}$$

The successive transformation of the peroxy-groups in polyperoxyesters has been postulated[51]:

$$\mathrm{PhCOOCMe_2C_6H_4CMe_2OOCPh} \xrightarrow{k_1} \mathrm{PhCOCMe_2OC_6H_4CMe_2OOCPh}, \quad (19)$$



$$\mathrm{PhCOCMe_2OC_6H_4CMe_2OOCPh} \xrightarrow{k_2} \mathrm{PhCOMe_2COC_6H_4OCMe_2OCPh}. \quad (20)$$

Derivatives of secondary and primary alcohols occupy a special place among peroxyesters. These peroxyesters are extremely unstable and decompose to acids and carbonyl compounds[9]:

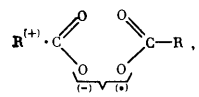
(21)

The simultaneous presence of a hydrogen atom and a phenyl group in the alkyl component of the peroxyester does not alter the nature of the decomposition. The thermal decomposition of peroxyesters having the structure PhRCHOOC(O)Me (R = Me or Ph) involves the quantitative formation of acetic acid and acetophenone or benzophenone; not even traces of phenol have been detected. Either the phenyl group is unable to compete with the proton in the rearrangement occurring in the cyclic complex[51]

(V)

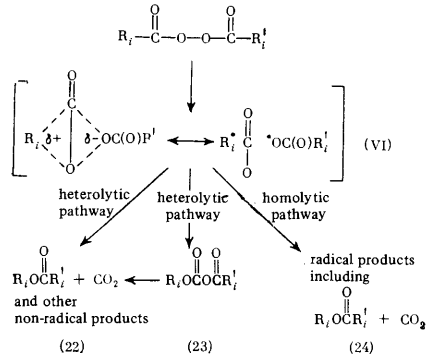
or the rearrangement proceeds via a many-centre mechanism [reaction (21)].

The study of the influence of solvent polarity on the rate of rearrangement of peroxyesters[44,52-57] showed that, with increase of solvent polarity, the rate of rearrangement also increases. For example, in nitromethane ($\varepsilon = 38.6$) the rate constant for the rearrangement of cumenyl peroxybenzoate is 20 times greater and in aqueous ethanol ($\varepsilon = 31.8$, mole fraction of water 0.35) 100 times greater than in benzene ($\varepsilon = 2.28$).



The choice of the Kirkwood parameter $(\varepsilon - 1)/(2\varepsilon + 1)$ as a measure of solvent polarity made it possible to observe a linear relation between $\lg k$ and $(\varepsilon - 1)/(2\varepsilon + 1)$ for the rearrangement of cumenyl peroxybenzoate. For each pair of the binary mixtures nitrobenzene–octane, methanol–water, and ethanol–water, the Kirkwood equation holds, but a general correlation could not be obtained for all the binary solvents[53].

The reason for the deviation from linearity and for the appearance of independent linear relations is the occurrence of specific interactions of the solvents with the peroxyester involving the formation of a hydrogen bond or coordination. Calculations have shown[53] that an increase of solvent polarity and specific solvation of the peroxyester favour the rearrangement of cumenyl peroxybenzoate involving the transition of the initial molecule to a more polar activated state. When the solvent polarity becomes sufficiently high, peroxyesters, which decompose via a radical mechanism in media with a low dielectric constant, undergo a rearrangement[58].



IV. THERMAL AND CATALYTIC REARRANGEMENTS OF DIACYL PEROXIDES

One of the possible pathways leading to the rearrangement of diacyl peroxides is carboxy-inversion, similar in type to the rearrangement of hydroxyperoxides and peroxyesters.

Several years ago studies were published[59-61] in which the thermal decomposition of diacyl peroxides, leading to the formation of radical and polar products, was regarded as a single process. Walling[59] believes that in the activated state a diacyl peroxide exists simultaneously as an ion pair and a biradical. Leffler and Moore[61] adhere to the same concept: they proposed the resonance hybrid intermediate

which is converted either into an ion pair or a radical pair, ensuring the development of a homolytic or a heterolytic reaction pathway. The most probable mechanism, which agrees with the available experimental literature data, can be represented by reactions (22)–(24):[62]

(VI)

The formation of a radical pair in the thermolysis of diacyl peroxides and the subsequent reactions of the radicals in the solvent cage or outside it are well known[62,63]. A quantitative transformation of a diacyl peroxide via the homolytic pathway can be achieved by altering its structure or by subjecting it to photochemical decomposition[64]:

(25)

The high polarity of the medium[65] as well as the electron-donating properties of the migrating group R_i or the electron-accepting properties of R_i' are factors favouring a heterolytic rearrangement.

The above mechanism (22)–(24) takes into account an important factor. It follows from the mechanism that the rearrangement need not necessarily lead initially to the intermediate carbonate $R_iOC(O)OC(O)R_i'$ and only then to the ester $R_iOC(O)R_i'$. There is also a possibility of another pathway, leading to the formation of the ester without the stage involving the formation of the rearrangement product [reaction (22)]. The main cause which makes it necessary to regard the process as one of the radical-ion type is that the majority of the factors (solvent polarity and the influence of substituents) are equally significant for the homolytic and heterolytic reaction pathways[65]. It is known[10], for example, that in certain thermal radical formation reactions the transition state in the homolytic fragmentation of peroxides is stabilised or destabilised by polar substituents or solvents, which have a significant effect on the rate of the process.

The attempts to separate competing homolytic and heterolytic processes with the aid of the ^{18}O oxygen isotope introduced into the carbonyl group of the diacyl peroxide proved unsuccessful[65-68]. In some cases isotope exchange of the oxygen atoms of the carbonyl and peroxy-groups in the rearrangement of a diacyl peroxide was observed[67], while in others the rearrangement took place with retention of ^{18}O in the carbonyl group of the isomeric product and did not entail

a change in the optical activity of the migrating group[68]. It has been shown[67] that carboxy-inversion, radical decomposition, and the isotope exchange between the [^{18}O]carbonyl group and the peroxide oxygen take place at comparable rates, which may be an argument in support of a radical-ion mechanism of the decomposition of diacyl peroxides [reactions (22)–(24)] if one rules out the possibility of a sigmatropic rearrangement[69,70].

The successive transformation of diacyl peroxides into alkyl cyclocarbonates and then into esters is catalysed by Lewis acids[71,72]. The optical properties and isotope composition of the carbonyl oxygen in the diacyl peroxide are fully retained in the rearrangement product when the reaction is catalysed by antimony pentachloride[73]. Together with the detection of the intermediate carboxyanhydride, this is evidence for the similarity of the mechanism of this reaction to the mechanism already discussed [reactions (22)–(24)].

Comparison of kintic data for diacyl peroxides of different structure makes it possible to observe the following feature. In the homolytic propagation of the process the reaction constants ρ have small negative values in the range between -0.2 and -0.9.[74–78] It is believed that the decrease of the dipole–dipole repulsion between the oxygen atoms in the molecule due to electron-accepting substituents reduces the rate of the homolytic decomposition[75]. In the thermal decomposition of substituted benzoyl isobutyryl peroxides a high yield of rearrangement products is observed, which increases after the introduction of electron-accepting substituents ($\rho > 0$); the rate of reaction also increases[70]. This is attributed to the heterolytic propagation of the process. The sign of the reaction constant can apparently serve as a criterion for differentiation between the homolytic and heterolytic reaction pathways in accordance with mechanisms (22)–(24).

Reutov and coworkers[79–81] have shown convincingly that the rearrangement of cyclobutanoyl, acetyl cyclobutyl, and acetyl cyclopropyl peroxides is neither a "purely" homolytic nor a "purely" heterolytic process. On formation of esters as a result of the rearrangement of diacyl peroxides, a radical pair is not produced, as shown by CINP data[80]. Carbonium ions were not formed either, as shown by studies of the thermolysis of acetyl cyclobutyl peroxide labelled with ^{13}C in the methylene group of the side chain[81,82]. Thus the rearrangement of diacyl peroxides must be regarded at the present time as a radical-ion process [reactions (22)–(24)].

V. REARRANGEMENT OF ALKYL(ARYL) PEROXIDES

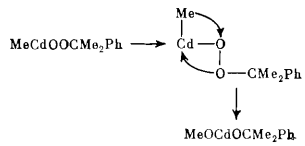
The rearrangement is not characteristic of symmetrical or asymmetric alkyl peroxides R_iOOR_i' (R_i and R_i' are primary, secondary, and tertiary alkyl groups). Cases are known where the migration of the aryl groups in alkyl aryl peroxides cannot be regarded as intramolecular processes. Kharasch et al.[83] showed that the conversion of triphenylmethyl peroxide into the diphenyl ether of benzopinacol on heating in xylene, described by Wieland[84], is a homolytic reaction:

$$(Ph_3CO)_2 \rightarrow 2Ph_3CO^{\cdot} \rightarrow 2Ph_2\dot{C}OPh \rightarrow Ph_2(PhO)C{-}C(PhO)Ph_2 \ . \qquad (26)$$

The same type of reaction is observed in the thermolysis of t-butyl triphenylmethyl and t-butyl diphenyl-*p*-tolylmethyl peroxides[83]:

$$YC_6H_4Ph_2COOCMe_3 \rightarrow YC_6H_4Ph_2CO^{\cdot} + {}^{\cdot}OCMe_3 \qquad (27)$$
$$\swarrow \quad \searrow$$
$$Ph_2\dot{C}OC_6H_4Y \qquad YC_6H_4(Ph)\dot{C}OPh \ .$$

Under the influence of protic acids, alkyl aryl peroxides decompose with formation of phenol[85,86]. The bimolecular reaction between the peroxide and the acid probably gives rise to a hydroperoxide, which then undergoes an acid-catalysed rearrangement. Thus organic peroxides R_3COOCR_3 constitute a class of peroxy-compounds for which the homolysis of the O–O bond is most typical[8,9].



VI. REARRANGEMENT OF ORGANOELEMENTAL PEROXIDES

The monographs and reviews published in recent years[87–92] characterise the field of organoelemental peroxides as one offering promise and developing rapidly. More than five hundred organoelemental peroxides, many of which are capable of rearranging, are now known.

Among organoelemental peroxides of Group II elements rearrangements are known for magnesium and cadmium compounds. When trimethylsilylmethylmagnesium chloride is oxidised by oxygen, the product is a peroxide, which rearranges under the conditions of the synthesis via the reaction[93]

$$Me_3Si{-}CH_2OOMgCl \rightarrow Me_3SiOCH_2OMgCl \ . \qquad (28)$$

Davies and Packer[94,95] pointed out that methylcumenylperoxycadmium, which is stable at room temperature, decomposes at 50 °C with formation of an isomeric compound:

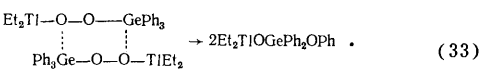
(29)

The reaction of diphenylcadmium with t-butyl hydroperoxide leads to the formation of an intermediate peroxide, which either participates in the disproportionation reaction or rearranges[96]:

$$PhCdOOCMe_3 \xrightarrow{Ph_2Cd} PhCdOCMe_3 + PhCdOPh \qquad (30)$$
$$PhCdOOCMe_3 \rightarrow PhOCdOCMe_3 \ . \qquad (31)$$

Among organoelemental peroxides of Group III elements, boron compounds have been studied in greatest detail and to a lesser extent aluminium, thallium, gallium, and indium compounds.

It has been established[97] that the reaction of phenylboronic acid with hydrogen peroxide results in the formation of phenol. The phenol isolated from the reaction mixture did not contain an excess of heavy oxygen[98] when phenylboronic acid $C_6H_5B(^{18}OH)_2$ was oxidised by the peroxide $H_2{}^{16}O_2$ in the presence of $H_2{}^{18}O$. An unstable hydroperoxide is probably formed and then rearranges like organic hydroperoxides.

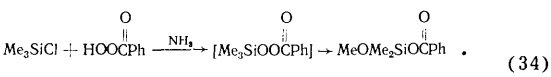


The rearrangement of certain organoboron peroxides take place quantitatively[99] or constitutes an appreciable proportion of the overall process[100–102]. Thus dimethylmethylperoxyboron is converted into a non-peroxide compound of the same molecular weight in the condensed and gas phases via the reaction[99]

$$Me_2BOOMe \rightarrow (MeO)_3BMe. \qquad (32)$$

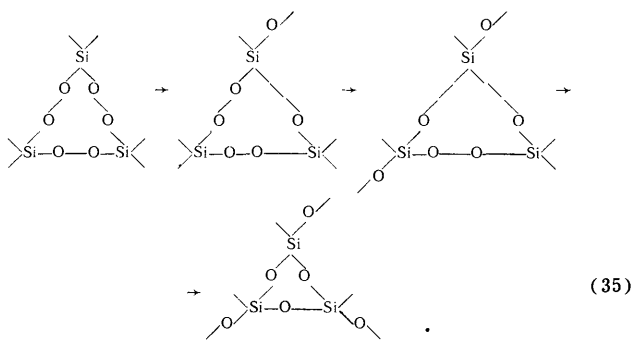
Organoaluminium peroxides are extremely unstable under normal conditions and readily decompose with formation of several products[103]. A rearrangement has been postulated as one of the possible reaction pathways[105,106].

A reliable demonstration of the rearrangement of organothallium peroxides has been achieved by Razuvaev et al.[106], who showed that, on heating diethylthalliumperoxy (triphenyl)



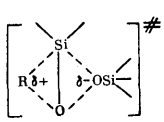
germane in an inert solvent at 80 °C, the rearrangement product is formed quantitatively via the second-order reaction

(33)



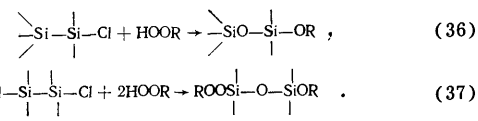
The syntheses of organogallium and organoindium peroxides have been achieved in recent years[107]. The products of the thermal decomposition reaction indicate that their rearrangement takes place simultaneously with homolytic decomposition[107].

The possibility of the rearrangement of peroxide compounds of Group IV elements was first pointed out by Buncel and Davies[108,109]. When an attempt was made to synthesise trimethylsilyl peroxybenzoate, the product isolated was dimethylmethoxysilyl benzoate, which the authors believe to be the product of the rearrangement of an intermediate peroxide:



(34)

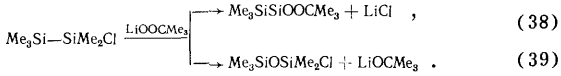
Approximately at the same time Jenkner[110] reported that dialkyldihalogenosilanes react with H_2O_2 to form cyclopolysiloxanes containing the Si–O–O–Si, Si–O–Si, and Si–O–C groups. The presence of the Si–O–C group was explained erroneously by the oxidation of the Si–C bond. It has been shown[111], that hexamethylcyclotrisilperoxane, which is the first representative of cyclic silyl peroxides, rearranges with contraction of the ring and migration of the methyl group:



(35)

X-Ray diffraction studies have shown that the average value of the Si–O–O–Si torsional angle is 135.6°, i.e. peroxide bridges have a nearly *trans*-conformation. The negative entropy $\Delta S^{\#} = -13.7$ e.u. and the spatial disposition of the atoms indicate a cyclic transition state:

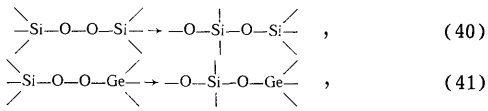
Kawazumi and Murai[112] observed that siloxanes are formed in the synthesis of t-butylperoxypentamethyldisilane and 1,2-di-t-butylperoxytetramethyldisilane:



(36)

(37)

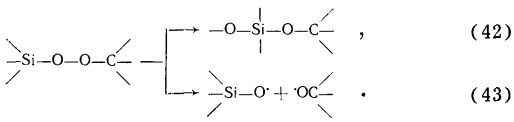
It has been suggested that an unstable intermediate silyl peroxide is formed:



which rearranges under the conditions of the synthesis. However, Razuvaev and coworkers[113–115] established that chlorine-containing di- and tri-silanes are oxidised at the Si–Si bond by the hydroperoxide or its lithium salt before the silyl peroxide is formed:

(38)

(39)



In the thermal and catalytic decomposition of the organoelemental peroxides R_3EOOH [116–120] a rearrangement is observed when E = Si or Ge.[116–118] Silicon and silicon-germanium peroxides rearrange quantitatively to the isomeric siloxanes[121–124]:

(40)

(41)

while organosilicon peroxides decompose via two parallel reactions[125]:

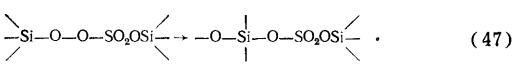
(42)

(43)

Peroxide compounds of Group V elements are capable of rearranging with migration of an alkyl or aryl group from a tertiary carbon atom[126–128]:

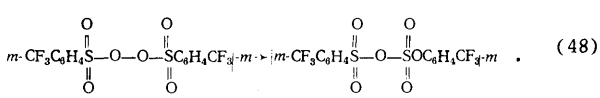
(44)

or from a phosphorus atom[129,130]:



(45)

Such reactions are also characteristic of antimony derivatives[131–134]:



(46)

Bressel and Blaschette[135] observed a rearrangement of bis-(trimethylsilyl) peroxomonosulphate in methylene chloride at a temperature below 0 °C:

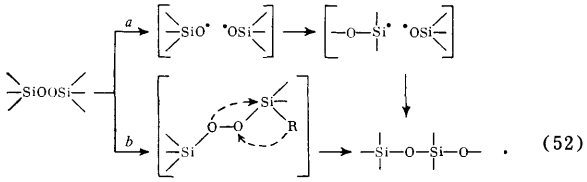
(47)

The decomposition of *m*-trifluoromethylbenzenesulphonyl peroxide in ethylbenzene and in cumene and also in the absence of a solvent is, according to the authors[136], an ionic reaction and involves the migration of the aryl group:

(48)

In essence, the consideration of the mechanism of the rearrangement of organoelemental peroxides involves the study of compounds of Group IV elements and in the first place silicon compounds. There is as yet no unanimous view concerning the mechanism of the rearrangement of organoelemental peroxide compounds. Some authors tend to regard the rearrangement as one occurring in a radical pair, while others treat it as a heterolytic process. The results of experimental studies do not provide an unambiguous answer. Investigators have frequently observed that the same factors, which had been believed earlier to be features of either heterolytic or homolytic processes, have the same influence on on both processes.

Dannley suggested that the rearrangement of organoelemental hydroperoxides has a free-radical mechanism[116,118,121]. The author believes that the radicals $\rangle EO^{\cdot}$ (E = Si or Ge), formed as a result of the homolysis of the peroxide linkage, rearrange in a solvent cage or are liberated into space and participate in radical reactions:



$$(R_i)_3EOOH \rightarrow (R_i)_3EO^{\cdot} + {}^{\cdot}OH\ ; \qquad (49)$$

$$(R_i)_3EO^{\cdot} \xrightarrow{SH} (R_i)_3EOH + S^{\cdot}\ , \qquad (50)$$

$$(R_i)_3EO^{\cdot} \rightarrow R_iO(R_i)_2E^{\cdot} \xrightarrow{{}^{\cdot}OH} R_iO(R_i)_2EOH \rightarrow R_iOH + [(R_i)_2EO]_x\ . \qquad (51)$$

A study of the decomposition of triphenylsilyl hydroperoxide[116] established that the reaction is insensitive to a change in the polarity of the solvent (nitrobenzene, methyl benzoate, anisole, *o*-dichlorobenzene), is accelerated on irradiation with ultraviolet light, and is not catalysed by acids (monochloro- and trichloro-acetic acids in *o*-dichlorobenzene).

In contrast to silyl hydroperoxide, the silyl peroxides $\rangle SiOOSi\langle$ rearrange quantitatively to isomerise siloxanes; the liberation of siloxy-radicals into space is not observed. In order to account for the mechanism of his process, Shubber and Dannley[121] were forced to assume that the rearrangement has a latent radical mechanism [reaction (52), pathway *a*], although they do not rule out the possibility of a concerted rearrangement of the bonds [reaction (52), pathway *b*] without the formation of free radicals:

(52)

The principal argument in support of the rearrangement in a radical pair reduces to the fact that in the silyl peroxides

a relatively slight increase of the capacity for the migration of the aryl groups is observed in the sequence phenyl (1.0) < *p*-tolyl (1.1) < anisyl (6.0), which is more likely to be a property of homolytic than heterolytic processes[121].

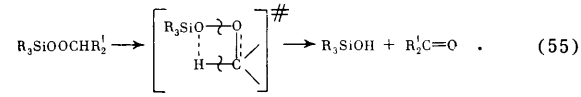
This finding can hardly be regarded as sufficient justification for a radical mechanism of the rearrangement. The sequence in which the capacity for migration of the aryl groups YC_6H_4 varies is different in radical reactions and in the rearrangements. It is known[83,137] that, following the rearrangement in an alkoxy-radical,

(53)

the capacity for migration of the YC_6H_4 group increases after the introduction of electron-accepting substituents Y. The same behaviour has been observed in isomerisation in an alkyl radical[138]:

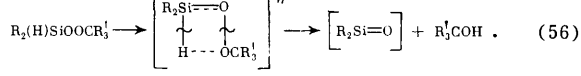
$$YC_6H_4CMe_2\dot{C}H_2 \rightarrow Me_2\dot{C}CH_2C_6H_4Y\ , \qquad (54)$$

while in rearrangements of silyl peroxides



the rate of reaction diminishes after the introduction of an electron-accepting substituent Y.[21] Furthermore, it has been shown that siloxy- and germyloxy-radicals do not isomerise[139,140].

Experimental data indicating a heterolytic mechanism of the rearrangement show that the reactions involved in the rearrangement of silyl peroxides are sensitive to changes in solvent polarity[141] and are accelerated under the influence of nucleophiles such as F^- and CN^-.[142] An increase of pressure to several thousand atmospheres increases the rate of rearrangement of silyl peroxides severalfold[143]. If the rearrangement occurred in a radical pair, the opposite relation would have been observed.



Silyl peroxides $R_3SiOOSiR_3$ do not rearrange quantitatively via reaction (40) in solution alone. For example, in the gas phase there is no solvent cage effect. However, even in this case it has been established that the rearrangement of $Me_3Si.OOSiMe_3$ takes place quantitatively, which indicates a non-radical mechanism of the process. The only difference between the gas-phase and liquid-phase reactions consists in the difference between the rates of the process[144].

Organosilicon peroxides containing an α-hydrogen atom at a silicon or carbon atom undergo thermolysis with migration of the hydrogen atom to one of the peroxide oxygen atoms. It has been shown that the migration of hyrogen constitutes an intramolecular rearrangement, which takes place simultaneously with the radical decomposition[145,146]:

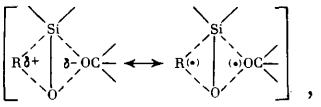
(55)

The rearrangement of silyl peroxides in which there is an α-hydrogen atom at the silicon atom is of special interest[145,146]:

(56)

Reaction (56) makes it possible to generate silanones in different solvents at 160–180 °C.

Since 1977 systematic studies have begun on the structure of organoelemental peroxides by electron diffraction[147] and X-ray diffraction[111,148–150]. The results of the studies on silyl peroxides agreed with the concept of rearrangement in a "rigid" cyclic complex.



In analysing the arguments for and against the homolytic and heterolytic mechanisms of the rearrangements of silyl peroxides one should probably not pose the question unduly categorically and one should postulate, for example, that "in the same reacting system some of the bonds undergo homolytic dissociation, while another fraction of the same bonds... are ruptured heterolytically".[151] It is quite probable that the elementary reaction in the rearrangement of the molecular skeleton is preceded by electron transfer. For example, two parallel reactions are observed in the thermolysis of cumenylperoxy(triphenyl)silane:

$$Ph_3SiOOCMe_2Ph \xrightarrow[\text{anisole}]{160^\circ} \begin{cases} \rightarrow PhOPh_2SiOCMe_2Ph \\ \quad (\Delta G^{\#} = 138\ \text{kJ mol}^{-1}; \end{cases} \qquad (57)$$

$$\begin{cases} Ph_3SiO^{\cdot} + {}^{\cdot}OCMe_2Ph \\ \rightarrow (\Delta G^{\#} = 142\ \text{kJ mol}^{-1}\ . \end{cases} \qquad (58)$$

The values of $\Delta G^{\#}$ calculated by Yablokov et al.[123] are the same, within the limits of the error of the measurement (±4 kJ), for the rearrangement and the homolytic reaction

and are consistent with the hypothesis of a radical-ion mechanism of thermolysis in an activated state:

which is analogous to that proposed by Leffler and More[61] for the rearrangement of diacyl peroxides.

α-Ketophosphonic Acid Esters—Synthesis, Structure, and Reactions

Yu.A.Zhdanov, L.A.Uzlova, and Z.I.Glebova

Studies on the synthesis and properties of α-ketophosphonic acid esters (KPE)—a class of highly reactive organophosphorus compounds—are surveyed. Data are presented concerning instances of the anomalous course of the process in the synthesis of KPE by the Arbuzov reaction. The reactions of KPE with nucleophiles, including those which lead to the rupture of the phosphorus-carbon bond, are examined in detail. The problems of the stereochemistry of KPE are dealt with briefly. The bibliography includes 162 references.

V. Carbohydrate-containing α-ketophosphonic acid esters 849

I. INTRODUCTION

For a long time, α-ketophosphonic acid esters (KPE) were comparatively little known and the chemistry of this unusual group of organophosphorus compounds began to be studied vigorously only in recent times. The experimental data for the properties of KPE obtained in the period 1962–71 have been partially surveyed in a short review[1]. Despite the lability of the phosphorus-carbon bond, KPE proved to be interesting key compounds in a number of syntheses based on the use of the increased reactivity of the carbonyl group, particularly in the preparation of α-aminophosphonic acids[2] and phosphorylcarbenes[3]. Even a superficial acquaintance with the chemical properties of KPE reveals an analogy with α-dicarbonyl compounds. On the other hand, the stereochemical aspects of the formation of the KPE molecule and its structure have been shown by the first studies[4,5] to be more varied compared with the same problems in the case of α-dicarbonyl compounds.

The synthesis of carbohydrate derivatives with a phosphorus–carbon bond using traditional methods for the formation of the latter is frequently accompanied by side reactions[6,7], one of the causes of which is the involvement in the reaction of the acetoxy-group of the protected monosaccharide. This feature was fully manifested also in the synthesis of carbohydrate-containing KPE, where the initial compounds were the chlorides of acetylated aldonic acids.

II. METHODS OF SYNTHESIS

The synthesis of KPE is based on the acylation of phosphite esters. Different versions of this reaction are distinguished by the nature of the acylating agent and the structure of the tervalent phosphorus acid derivative.

KPE (I) were first synthesised by Kabachnik et al.[8] from acyl chlorides and trialkyl phosphites:

$$\underset{}{RCOCl} + P(OR')_3 \rightarrow \underset{(I)}{RC(O)P(O)(OR')_2} + R'Cl \qquad [RC(O)OP(OR')_2] \text{ (II)}$$

In subsequent years a large number of a wide variety of KPE were synthesised by the interaction of the full esters of phosphorous acid with aliphatic[9–19] and aromatic[20–25] carboxylic acid chlorides. The method of synthesis has undergone certain changes compared with the initial procedure[8] (reaction in an inert gas atmosphere[10,13,20] and in a number of instances the reverse order of mixing of the reactants[13,16,21]).

KPE can be obtained by the reaction of acyl halides with other derivatives of tervalent phosphorus acids—tetraethyl pyrophosphite[26], hypodiphosphites[27,28], and phosphoramidite esters[29–32]. Attempts have been frequently made to employ dialkyl phosphites and their salts for the synthesis of KPE, but their reaction with halides does not proceed unambiguously and the yield of KPE is only 10–30%. This is because the KPE formed initially react further with dialkyl phosphites to form diphosphoryl compounds[15,33,34]; in other cases the enolic form of the α-ketophosphonate is acylated by the initial acyl halide[35]. The chlorides of halogeno-substituted acids give rise to high yields of KPE on interaction with dialkyl phosphites. The chlorides of trichloroacetic[36], trifluoroacetic[37], and other perfluorocarboxylic acids[38] have been used in this reaction.

Apart from acyl halides, carboxylic acid anhydrides can be used to acylate phosphite esters. The interaction of acetic anhydride with triethyl phosphite leads to a 10% yield of diethyl acetylphosphonate[39]. The main reaction product is a compound without an active carbonyl group. Referring to earlier studies, the authors[39] attributed the structure of tetraethyl 1-hydroxyethylidenediphosphonate (III) to this compound. However, it was shown later[34] that, under the conditons of the reaction described, the diphosphonate (III) rearranges to the phosphonophosphate (IV):

$$\underset{\text{OH}}{\underset{|}{CH_3C}}\text{—[P(O)(OC}_2\text{H}_5\text{)}_2\text{]}_2 \xrightarrow{t^\circ} \underset{\text{OP(O)(OC}_2\text{H}_5\text{)}_2}{\underset{|}{CH_3CHP(O)(OC_2H_5)_2}}$$

(III) (IV)

Trialkyl phosphite reacts anomalously with phthalic anhydride–biphthalyl was obtained in 70% yield instead of the expected α-ketophosphonate[40].

Mixed anhydrides of carboxylic and dialkylphosphorous acids (II) are converted into KPE under the influence of alkyl iodides, acyl iodides, and iodine, which function as catalysts in this reaction. The reaction has been carried out[41,42] with the anhydrides of a number of aliphatic acids, including those with the iso-structure. The anhydrides of carboxylic acids apparently interact analogously with dialkyl phosphorochloridites[43], whereupon the mixed anhydride (V) formed in the first stage isomerises to the ketophosphonate under the catalytic influence of the acyl chloride (VI):

$$(C_3H_7CO)_2O + (RO)_2PCl \rightarrow \underset{(V)}{C_3H_7C(O)OP(OR)_2} + \underset{(VI)}{C_3H_7COCl};$$

$$(V) + (VI) \rightarrow C_3H_7C(O)P(O)(OR)_2.$$

The formation of acetyl phosphonate $CH_3C(O)P(O)(OC_2H_5)_2$ (VII) by the reaction of acetyl acylals with diethyl phosphorochloridite can be explained satisfactorily[44] within the framework of the same mechanism.

KPE are frequently formed as intermediates in various reactions and their involvement in further chemical transformations has been confirmed by specific syntheses. The formation of the phosphonate (VII), which is then converted into the phosphonophosphate (IV), has been demonstrated[45,46] in the acetylation of dialkyl phosphite with vinyl acetate. The prototropic isomerisation of the esters of α-hydroxyallyl- and α-hydroxypropargyl-phosphonic acids to KPE has been observed recently[47,48]:

$$\underset{\text{(VIII)}}{CH_2{=}CHCH(OH)P(O)(OCH_3)_2} \xrightarrow{Na} \underset{\text{(IX)}}{CH_3CH_2C(O)P(O)(OCH_3)_2} .$$

The KPE (IX) formed in the intermediate stage acylates another molecule of the initial hydroxyacid ester (VIII).

The presence of halogen atoms in the α-position in the acyl halide frequently results in the reaction of the KPE (X) formed initially with the trialkyl phosphite via the mechanism of the Perkow reaction and the ultimate formation of unsaturated phosphonophosphates (XI):

$$\underset{\text{X=Cl or Br}}{RCH(X)COX} + P(OR')_3 \rightarrow \underset{\text{(X)}}{[RCH(X)C(O)P(O)(OR')_2]} \xrightarrow{P(OR')_3} \underset{\text{(XI)}}{RCH{=}\underset{\displaystyle OP(O)(OR')_2}{\underset{|}{C}}P(O)(OR')_2} ;$$

Such a complex course of the reaction of the halides of α-halogeno-derivatives of acids with trialkyl phosphites, observed in a few instances, can be explained[11,36,49-52] on the basis of the modern interpretation of the mechanism of the Perkow reaction[53,54]. However, α-ketophosphonates of type (X) can be obtained not only from the halides of perhalogenocarboxylic acids and dialkyl phosphites[36-38] (see above), but also as a result of the reaction of hexafluorodimethylketen with dialkyl phosphite[55] or of the chlorides of chloroacetic acids with acetyl dialkyl phosphite[52].

The latter reaction has been used to elucidate the mechanism of the formation of unsaturated phosphonophosphates from α-halogenoacyl halides and trialkyl phosphites[52]. In principle, the interaction of chloroacetyl chloride with trialkyl phosphite, which leads to the unsaturated phosphonophosphate (XIV), could proceed either via chloroacetyl phosphonate (XII) (pathway *1*) or via chlorovinyl phosphate (XIII) (pathway *2*):

$$ClCH_2COCl + P(OR)_3 \rightarrow \left[\begin{array}{l} \xrightarrow{(1)} \underset{\text{(XII)}}{ClCH_2C(O)P(O)(OR)_2} \\ \xrightarrow{(2)} \underset{\displaystyle Cl}{\underset{|}{CH_2{=}C}OP(O)(OR)_2} \text{ (XIII)} \end{array}\right] \rightarrow \underset{\displaystyle P(O)(OR)_2}{\underset{|}{CH_2{=}C}OP(O)(OR)_2} \text{ (XIV)} .$$

When the less reactive acetyl diethyl phosphite is used, it is possible to isolate the chloro-substituted KPE (XIIa) together with a small amount of high-boiling products formed as a result of further reactions:

$$ClCH_2COCl + (C_2H_5O)_2P(O)COCH_3 \rightarrow \underset{\text{(XIIa)}}{ClCH_2C(O)P(O)(OC_2H_5)_2} .$$

Thus pathway 1—the initial Arbuzov reaction with subsequent Perkow reaction—is more probable.

In the synthesis of KPE by the classical version of the Arbuzov reaction phosphites of different structures have been used[11,17,28-32,52]. The study of the kinetics of this reaction with phosphoramidite esters in benzene and acetonitrile solutions showed[31] that its direction depends on the structure of the phosphoramidite: cyclic phosphoramidites are less reactive and tend to react anomalously when acted upon by benzoyl chloride. An analogous phenomenon has been described in a number of other studies[29,30,32]. It has been noted[32] that the direction of the reaction of phosphoroamidite esters with acetyl chloride depends on the environment of the phosphorus and nitrogen atoms—the introduction of more electron-donating groups at the phosphorus atom promotes the preferential formation of acetyl phosphonate. The full amides of phosphorous acid react with acetyl and benzoyl chlorides at the nitrogen atom and, when benzoyl chloride was used, it was possible to isolate[32] intermediate benzoylphosphonium halides.

On interaction with acyl chlorides in diethyl ether, fully *O*-triorganosilylated phosphorous acids give rise to KPE in high yields[56]. When mixed alkyl triorganosilyl phosphites are used in this reaction, the most electrophilic triorganosilyl group is always split off[17,18,57]:

$$(R_3SiO)_nP(OR')_{3-n} + R''COCl \rightarrow R''C(O)P(O)(OR')_{3-n}(OSiR_3)_{n-1} + R_3SiCl .$$

Among the specific methods for the synthesis of bis(triethylsilyl)acetylphosphonates, mention should be made of procedures based on the reactions of acetoxytriethylsilane under the influence of halogeno-derivatives of tervalent phosphorus[57,58].

The reactions of sulphur analogues of carboxylic and phosphorous acids have been less investigated. While trimethyl phosphite reacts with thiobenzoyl chloride via the standard mechanism[59], the interaction of acyl chlorides with phosphorothioites does not lead to the synthesis of thioanalogues of KPE.

III. STRUCTURE

The products of the reaction of trialkyl phosphites with acyl halides can have the structure of ketophosphonates (I) or the isomeric structure of mixed phosphites with a tervalent phosphorus atom (II). The structure (I) has proved to be fully consistent with the pronounced carbonyl functions of these compounds and the usually easy hydrolysis, leading to the regeneration of phosphorous acid, was fully accounted for by the isomeric phosphite structure (II). However, the first investigators of this reaction[8] were forced to recognise on the basis of the chemical properties (and later infrared spectroscopic studies) that the reaction products are α-ketophosphonates (I) and that the interaction therefore proceeds via the mechanism of the Arbuzov reaction. If one assumes a reaction mechanism involving the formation of phosphonium salts as intermediates (there is also evidence[60,61] for the formation of intermediate pentacovalent derivatives in some reactions), then evidently adducts with a tetrahedral configuration are formed as intermediates in this case[62]:

$$RCOCl + P(OR')_3 \rightarrow \left[\begin{array}{c} R \\ | \\ (R'O)_3\overset{+}{P}CCl \\ | \\ O^- \end{array}\right] \rightarrow (R'O)_3\overset{+}{P}COR\ Cl^- \rightarrow \underset{\text{(I)}}{RC(O)\overset{O}{\overset{\|}{P}}(OR')_2} .$$

Summarising the result of earlier studies[8,9,22], Hudson[63] claims that the phosphonates (I) are thermodynamically more stable that the isomeric phosphites (II). The formation of thermodynamically stable isomers is consistent with the concept that the transition states resemble the intermediate addition products, so that the energy of bond formation plays a decisive role.

Spectroscopic studies of KPE and in recent years comprehensive investigation of their chemical reactions confirmed the phosphonate structure of these compounds. The low frequency of the carbonyl vibrations is a consequence of the

conjugation between the C=O and P→O bonds and demonstrates[22] the absence of an oxygen atom between the acyl group and the phosphorus atom.

In the KPE containing cycloalkane and aliphatic acyl groups the absorption by the C=O and P→O groups varies over a short range. The introduction of the phenyl group[16], alkoxy- and thioalkoxy-groups[14], and halogens[52] in the β-position in the KPE displaces the frequency of the carbonyl vibrations to the region 1715–1733 cm^{-1}, while in KPE with a β,γ-unsaturated bond the C=O vibrations appear[10] at 1645 to 1660 cm^{-1}. A low absorption frequency of the C=O group (1639–1672 cm^{-1}) compared with α-diketones and aliphatic KPE (1685–1695 cm^{-1}) is observed in the series of aroylphosphonates[20,22,23,64] and the extreme values correspond respectively to *o*-chlorobenzoyl- and *p*-anisoyl-phosphonates.

The study of the infrared spectra of *para*- and *ortho*-substituted bis(triorganosilyl)benzoylphosphonates showed that the shift of the frequencies of the C=O groups depends on the electronic effects of the substituents in the aromatic ring and a correlation between the frequency shifts of the stretching vibrations of the carbonyl group with the Hammett σ constants was clearly observed[64].

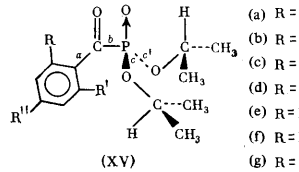
The structure of the acyl group in KPE has a slight influence on the position of the P→O absorption band: in thiobenzoylphosphonate[59] the P→O group absorbs at 1280 cm^{-1}, while in alkoxyacetylphosphonate[14] it absorbs at 1260 to 1270 cm^{-1}. The structure of the ester groups at the phosphorous atom has a more significant influence and the phosphoryl group in alkyleneacylphosphonates[28] can absorb at 1280–1290 cm^{-1}.

The infrared spectra of the phosphonates obtained from the chlorides of mono- and di-chloroacetic acids contain, apart from the frequencies characteristic of the C=O and P→O groups, absorption bands at 1605 and 3000–3400 cm^{-1}. These data suggested[52] the occurrence of keto–enol tautomerism, which was subsequently confirmed by ^1H NMR[65]:

$$\underset{(87\%)}{ClCH_2C(O)P(O)(OR)_2} \rightleftarrows \underset{(13\%)}{ClCH{=}C(OH)P(O)(OR)_2}\ .$$

The ratio of the tautomers of dichloroacetylphosphonate is the same, while the phenylacetylphosphonate molecule is 82% enolised. The keto–enol equilibrium is apparently based[65] on the free energy of the enol form and not on the acid properties of the CH protons.

Chemists soon ceased to be satisfied with spectroscopic data as an additional confirmation of the structure of KPE and the problem of the study of their steric structure was posed. It proved to be complex, primarily because of two factors—the uncertainty of the function performed by the vacant 3*d* orbitals of the phosphorus atom and the possibility of different steric configurations—different relative positions of the carbonyl and the neighbouring phosphoryl group, in which the phosphorus atom can be asymmetric depending on the structure of the other two substituents. Apart from the importance of the study of the steric structure of KPE from the theoretical point of view, investigation of the nature of the mutual influence of adjacent phosphoryl and carbonyl groups is necessary to elucidate many anomalous reactions of KPE.



Remarkably low absorption frequencies of the carbonyl group in KPE have been observed by Berlin and Taylor[22], who explained this phenomenon by the reaction of the non-bonding orbital of the oxygen atom in the phosphoryl group with the π orbital of the carbon atom in the C=O group. The overlap of the orbitals then reaches a maximum when the P→O bond is at right angles to the plane in which the aromatic ring, the carbonyl carbon, and phosphorus are located. Thus Berlin and Taylor not only interpreted the spectroscopic characteristics of KPE from the standpoint of conjugation between the C=O and P→O groups, but also proposed a possible version of their relative positions in space. The additional interaction between the carbonyl group and the phosphoryl centre, presupposing the involvement of the 3*d* orbitals of the phosphorus atom, can be investigated by spectroscopic methods in KPE. Laskorin and coworkers[37,66] investigated different spectroscopic characteristics of ketophosphoryl compounds, in particular a series of dimethyl esters of acylphosphonic acids, differing from one another in the structure of the acyl group. It was noted that the decrease of ν(C=O) and the appreciable bathochromic shift of the $n \rightarrow \pi^*$ transition in dimethylacylphosphonates compared with the corresponding ketones indicate the conjugation of the carbonyl group with the phosphorus atom. After comparing ultraviolet, infrared, and ^1H NMR spectroscopic data, the authors[66] concluded that the effective positive charge on the phosphorus atom increases with increasing electronegativity of the acyl residue in dimethylacylphosphonates and that the carbonyl group is involved in conjugation with the 3*d* orbitals of the phosphorus atom to a greater extent.

The same workers[5] made a detailed study of different spectroscopic characteristics of KPE in order to detect the conformers whose existence had been suggested[67]. Different sterically hindered KPE, containing bulky substituents at the carbonyl group and the phosphorus atom, were synthesised. Their infrared spectra showed that they do not exhibit the *cis-trans* isomerism involving the P(O)–C(O) bond, since the ν(C=O) frequency is not split. A detailed study of the ultraviolet and ^1H NMR spectra of KPE showed[5] that the dynamic equilibrium between the isomers cannot be observed by spectroscopic methods. The occurrence of $p_\pi - d_\pi$ conjugation in KPE was again confirmed; the adoption of this concept implies that the rotation about the C–P bond cannot be free.

The first investigators[68] of the electronic spectra of the acylphosphonates also expressed the view that there is a significant conjugation in the P(O)–C(O) system. Ultraviolet spectroscopic data have been frequently invoked to characterise KPE [4,37,66–70] (the bathochromic shift of the $n \rightarrow \pi^*$ transition relative to the corresponding methyl ketone reaches 68 nm). In the studies enumerated above correlations are presented between the bathochromic shift of the $n \rightarrow \pi^*$ transition, as a measure of the $p_\pi - d_\pi$ conjugation, and the structure of the acyl group.

The application of NMR to the conformational analysis of KPE is at present restricted to several investigations[4,5,67], although the ^{31}P NMR spectra of diethyl acetylphosphonate had been published in still earlier studies[33]. The ^1H NMR spectra published in various communications[4,5,10,13,15,32,37,65–67,71,72] are of interest from the standpoint of the study of the spin–spin coupling constants between the P and H nuclei. In the case of dialkyl acetylphosphonates J_{P-H} for the methyl group adjoining the carbonyl group is 5 Hz, which is significantly less than *J* for trimethyl phosphate (11.2 Hz), dimethyl methylphosphonate (CH_3, $J = 17.5$ Hz; OCH_3, $J = 11$ Hz), and trimethyl phosphite ($J = 11$ Hz).

Clark et al.[4] used NMR for the conformational analysis of KPE in relation to diisopropyl esters of aroylphosphonic acids (XV, a-i):

(XV)

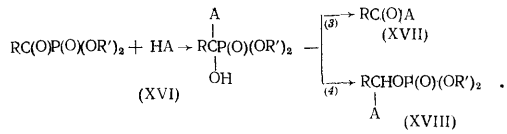
(a) R = R′ = R″ = H
(b) R = R″ = H, R′ = CH_3
(c) R = R′ = H, R″ = CH_3
(d) R = R′ = CH_3, R″ = H
(e) R = R″ = H, R′ = OCH_3
(f) R = R′ = H, R″ = OCH_3
(g) R = R′ = OCH_3, R″ = H
(h) R = R″ = H, R′ = Cl
(i) R = R′ = H, R″ = Cl

it was suggested[4] that the bulky isopropyl groups influence the preferred conformation of the system in which the angle between the C=O and P→O bonds can vary as a function of the nature of the substituents in the aromatic ring. A splitting, unusual for KPE, of the doublets due to the methyl group in the isopropyl group in consequence of their non-equivalence has been observed in the ^{1}H NMR spectra measured at temperatures from -50° to +100 °C. In compounds (XV, a, c, f, and i) the non-equivalence of the protons is observed between -50° and +20 °C, in the esters (XV, d, g, and h) between -50° and +100 °C, and in the compounds (XV, b and e) only at temperatures below -20 °C and at approximately +100 °C. Furthermore, the non-equivalence of the methylidyne protons of the isopropyl groups follows from the ^{31}P NMR spectra of the esters (XV, b and c). This fact suggests that, whatever the angle between the C=O and P→O bonds, the rotation about the P–O bond in these compounds (*c* and *c'*) must be restricted. On the basis of NMR data, the determination of dipole moments, infrared absorption, and theoretical calculations, the authors[4] concluded that the possibility of the existence of the system in a preferred conformation and of a restricted rotation about the C–P and possibly P–O bonds is ruled out. The authors[4] state that the earlier conclusion[73] that acylphosphonates exist as equilibrium systems of *s-cis*- and *s-trans*-isomers cannot be correct for the isopropyl esters (XV) according to their dipole moments. The C(O)–P(O) system does not need to be coplanar to achieve the overlap of the *d* and *p* orbitals of different sizes which ensure the d_π–p_π conjugation. The authors claim that the dihedral OPCO angle in the system can assume a series of values for which conjugation is achieved between the C=O and P→O bonds.

The study of the mass spectra of KPE showed[74] that, on electron impact, fragmentation evidently begins with ionisation of the oxygen of the carbonyl group and the dissociation of the P–C bond in consequence of the formation of the stable ion R–C ≡ O$^+$ (the latter is formed from the unstable KPE molecular ion). Among the fragments produced, other ions as well as keten and carbon monoxide were detected, but the formation of a fragment containing carbonyl and phosphoryl groups with simultaneous dissociation of other bonds at the phosphorus atom could never be observed. The P(O)–C(O) bond is least stable in KPE and this structural feature is reflected in a wide variety of chemical reactions of KPE.

IV. CHEMICAL PROPERTIES

The phosphorus–carbon bond, readily formed in the synthesis of α-ketophosphonates, is also readily ruptured under the influence of various nucleophiles. The decomposition of KPE under the influence of a weak nucleophile such as water is one of the chemical reactions observed for these compounds. The reactions of KPE with nucleophiles have been successfully classified by Pudovik and Gareev[75], who proposed a mechanism for the reactions of acetylphosphonate with compounds of type XH (or XNa) and diazoalkanes. The authors state that, when proton-containing compounds react with acetylphosphonate, the latter is cleaved at the P–C bond with formation of an acetic acid derivative and dialkyl phosphite. On the other hand, if the nucleophile is aprotic, the dissociation of the P–C bond is accompanied by the migration of the phosphorus-containing fragment. Numerous experimental facts confirm that the reactions take place generally via these pathways.

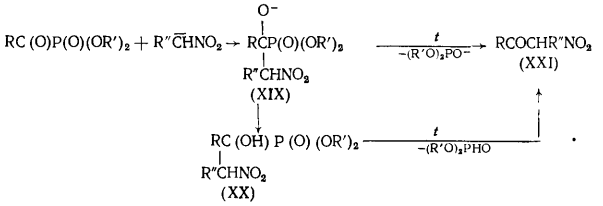


1. Interaction with Proton-Containing Compounds

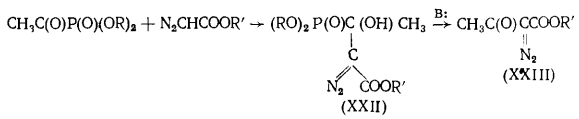
The hydrolysis of KPE, which leads to a carboxylic acid, can be carried out in a neutral medium[76], but it proceeds faster and reaches completion in the presence of acids[8,22] and alkalies[8,22]. Bertin and Taylor[22] made the first attempt to elucidate the mechanisms of the alkaline and acid hydrolyses by making a detailed study of the decomposition of *p*-anisoylphosphonate. The authors state that the alkaline hydrolysis proceeds more readily and explain this phenomenon by the fact that in the acid hydrolysis the protonation of the phosphoryl group is reversible and the positive charge on the phosphorus atom hinders attack on the carbonyl group. They do not rule out an alternative mechanism, i.e. the slow protonation of the carbonyl group with subsequent rapid attack by water on the carboxonium cation. The formation of an intermediate in the alkaline catalysis resembles the hydrolysis of carboxylic acid esters. However, the true mechanism of the hydrolysis of acylphosphonates is probably more complex[77].

Acylphosphonates and halogeno-substituted KPE react with alcohols in an acid medium[78] or in the presence of a tertiary amine[79], forming unstable adducts; the latter decompose into the corresponding carboxylic acid esters and dialkyl phosphites. Benzoylphosphonate behaves as a benzoylating agent in reactions with thiophenoxides[21]. The rupture of the phosphorus–carbon bond is observed when KPE are acted upon by various amines–aniline[79,80], dialkylamines in the presence of a catalyst (magnesium bromide),[24] and liquid ammonia[81].

In the above reactions with water, alcohols, and amines KPE play the role of acylating agents. It has been shown[24] for dimethylbenzoylphosphonate that these reactions (which the authors[24] called "direct benzoylation") are accelerated by magnesium chloride and bromide. A similar catalytic effect for magnesium salts had been observed earlier in a study of the interaction of Grignard reagents with phosphonates[82].



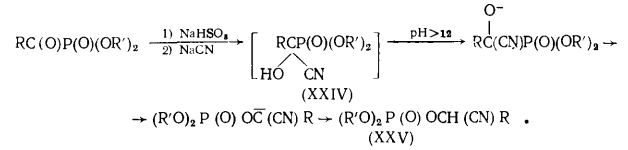
However, the reactions of KPE with proton-containing compounds can proceed also via different pathways, where the addition of the elements of HA to the carbonyl group leads to the formation of the α-hydroxyphosphonic acid ester (XVI). Under the conditions of alkaline catalysis, depending on the nature of A, the latter either decomposes with formation of the corresponding acylated compounds (XVII) or rearranges to a phosphoric acid derivative (XVIII):



Reactions via pathway *3* are known as "indirect acylation" and have been thoroughly investigated[24] in relation to the reaction of benzoylphosphonate with *N*-magnesium derivatives of amines. The adducts formed under these conditions, containing a hydroxy-group and a substituted amino-group attached to the same carbon atom, proved to be unexpectedly stable; they can be distilled without decomposition. Under the influence of sodium methoxide, the adduct decomposes with liberation of dialkyl phosphite and an acylated amine. It has been suggested[47,48] that the same mechanism is valid for the acylation of β,γ-unsaturated *d*-hydroxyphosphonic acid esters [for example (VIII)] by α-ketophosphonates (IX), which are formed as a result of protoropic isomerisation when esters of type (VIII) are acted upon by metallic sodium.

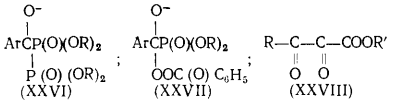
Apart from the reactions discussed above, in which KPE behave as *O*- and *N*-acylating agents, it has been shown in recent studies[75,83,84] that they can acylate the carbon atoms

in nitroalkanes, alkylmagnesium bromides, and diazoacetic ester. In these reactions the α-hydroxyacid ester formed initially decomposes in the presence of bases at the carbon–phosphorus bond with elimination of the phosphorus-containing group and the *C*-acylated nucleophile. The acylated nitroalkane[83] (XXI) can be formed from the corresponding α-hydroxy-β-nitroalkylphosphonates (XX) while from the intermediate anion (XIX):



When acetylphosphonate condenses with diazoacetic ester, the product is the ester (XXII),[85,86] stable under neutral conditions, which decomposes under the influence of basic compounds (sodium methoxide, amines, diazomethane) [75] with formation of the ester of 1-diazo-2-oxobutanoic acid (XXIII):

In their study of the stability of compounds containing the O=P–C–OH fragment in the molecule, Pudovik and Gareev[75] suggested that the decomposition of α-hydroxyphosphonates is due to the mobility of the hydrogen atom of the hydroxy-group and the highly nucleophilic properties of the oxygen atom of the phosphoryl-group. The reactions of α-hydroxyphosphonate derivatives, formed when benzoylphosphonate interacts with Grignard and Reformatskii reagents, can be assigned to the same group of reagents (pathway *3*)–the adducts are cleaved with formation of alkyl phenyl ketones and benzoylacetate esters respectively[24,84].

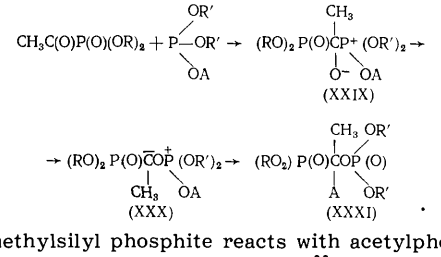


The conditions for the rearrangement[87,88] of α-hydroxyphosphonates to phosphoric acid derivatives (pathway *4*) have now been thoroughly investigated. The first reactions of this type were observed by Hall and Stephen when sodium cyanide was allowed to react with bisulphite compounds of KPE. Instead of the expected α-cyano-α-hydroxyphosphonic acid esters (XXIV), the isomeric phosphates (XXV) were obtained:

The pyrolysis of the phosphates (XXV) has been studied recently and the nitriles of α,β-unsaturated carboxylic acids were obtained in high yields[89]. The reactions of KPE with partially esterified phosphorus acids have been studied in fair detail. Such reactions sometimes accompany as side processes reactions involving the synthesis of α-ketophosphonate as the desired product. It was believed for a long time that the interaction of acetylphosphonate with sodium dialkyl phosphite and with dialkyl phosphite in the presence of amines leads to the hydroxydiphosphonate (III). The study of ^{31}P NMR spectra showed[33] that the products contain two non-equivalent phosphorus atoms. Under mild conditions (0 °C), it was possible to isolate diphosphonates of type (III), which are converted on distillation into the phosphonophosphates (IV). The conditions for the rearrangement were studied in greater detail by Pudovik and coworkers[34,45,46]. The phosphonophosphate (IV) has been obtained as a side product on heating acetylphosphonate with ethanol in the presence of triethylamine. The rearrangement to phosphates takes place readily[90] when dialkyl phosphites react with β-halogeno-substituted α-ketophosphonates without a catalyst.

In the case of asymmetric hydroxydiphosphonates (such diphosphonates have been obtained by the reaction of dialkyl acylphosphonates with derivates of ethylphosphinothioic[20] or dialkylphosphorothioic[91,92] acids as well as ethyl *N,N*-diethylphosphoramidite[93]) the structure of the isomerisation products (phosphates) was established by chemical and additional physicochemical methods[93].

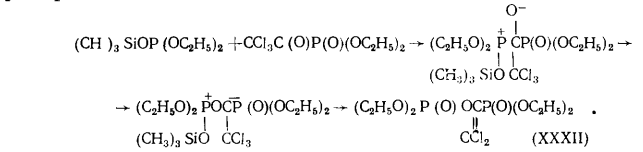
In the course of the phosphonate–phosphate rearrangement the dialkoxyphosphono-group migrates from carbon to oxygen. α-Hydroxydiphosphonates obtained from aroylphosphonates isomerise particularly readily; the unstable intermediate ion (XXVI), containing three electron-accepting groups, is then stabilised by conversion into a phosphate:



The preferred migration of the dialkoxyphosphono-group compared with the aryl group is observed in the oxidation of aroylphosphonates by perbenzoic acid[94]. The mixed anhydride of dialkylphosphorous and substituted benzoic acids is formed in high yield in this reaction from the intermediate addition product (XXVII).

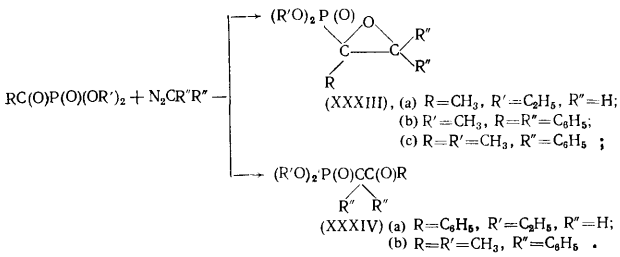
2. Reactions with Aprotic Nucleophiles

For the majority of reactions of KPE with aprotic reagents, the attack of the nucleophile is directed to the carbon atom of the carbonyl group. The dipolar ion formed can be stabilised in different ways; however, the migration of the electrophilic group (frequently the dialkoxyphosphono-group) is characteristic of all cases of stabilisation.



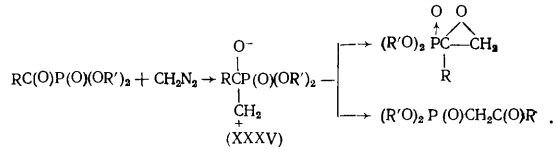
Part of the review of Konovalova and Pudovik[95] is devoted to the reactions of KPE and α-dicarbonyl compounds with trialkyl phosphites. They draw attention to the lower reactivity of KPE in the reaction with phosphites compared with α-ketocarboxylic acid esters (XXVIII) [96] and to a different course of the reaction. The interaction of trialkyl phosphites with the esters (XXVIII) usually leads to compounds having the 1,3,2-dioxophospholan structure, while KPE give rise to the phosphonophosphates (XXXI, A = alkyl). The reaction, occurring at 100–120 °C, probably begins with attack by the phosphite on the carbon atom of the carbonyl group and in the resulting zwitter-ion (XXX) the alkyl group migrates to the carbanionic centre of the molecule[97,98]:

When trimethylsilyl phosphite reacts with acetylphosphonate, the product is a diphosphonate[99]. Evidently[100] in this case the dipolar ion (XXIX, A = Si(CH$_3$)], which has



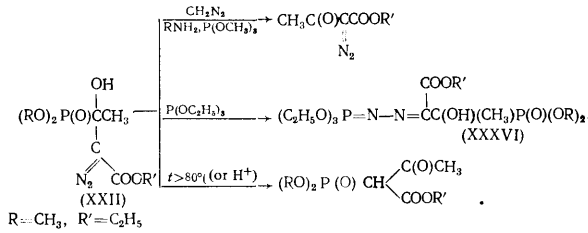
a harder electrophilic centre A, is rapidly stabilised as a result of the migration of the trimethylsilyl group and not the dialkoxyphosphono-group. The intermediate ion [XXIX, A = C(O)CH_3], formed by the interaction[101] of acetylphosphonate with acetyl phosphite, isomerises analogously.

The interaction of triethyl phosphite with β-halogeno-substituted KPE proceeds in a complex manner[36,52], discussed previously, with formation of a mixture of compounds including unsaturated phosphates. The reaction of trichloroacetyl phosphonate with mixed phosphites (trimethylsilyl and acetyl diethyl phosphite) is exothermic and leads to the same compound (XXXII). It has been suggested that, in the reaction with trimethylsilyl phosphite[102], the zwitter-ion is converted by the mechanism of the Perkow reaction into the phosphono-phosphate (XXXII):



Aldehydes, which have a potentially mobile hydrogen atom in the formyl group (trichloroacetaldehyde, benzaldehyde), react with KPE via a mechanism of the type of benzoin condensation at 80 °C in the presence of piperidine. At a higher temperature the resulting "benzoins" isomerise to phosphates[103,104]. When trichloroacetylphosphonate was allowed to react with chloral, the product was an unsaturated phosphate[105], formed evidently from the initial "benzoin" anion as a result of the elimination of the chloride ion.

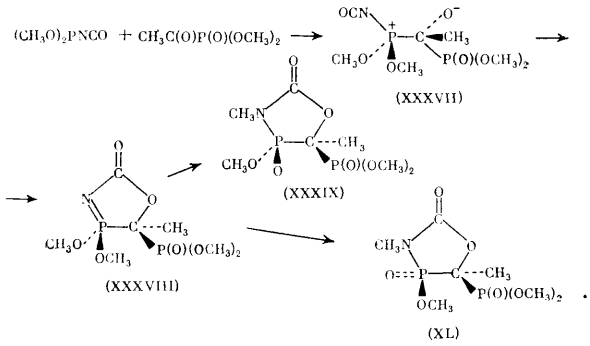
The reactions of KPE with diazoalkanes take place in different ways. Data have been published[106] on the interaction between certain KPE and diazomethane. The reaction of acetylphosphonate with diazomethane leads to the oxiran derivative (XXXIIIa) and benzoylphosphonate is converted into the β-ketophosphonate (XXXIVa). Acetyl- and benzoyl-phosphonates react with diphenyldiazomethane at 80 °C via one pathway with formation[107] of the epoxy-compounds (XXXIII, b and c). When the reaction of acetylphosphonate with diphenyldiazomethane was carried out at 0 °C, a mixture of products was obtained[108], consisting of derivatives of oxiran (XXXIIIc) and β-ketophosphonate (XXXIVb):



The authors[108] suggest that in the latter case both products are formed from the same intermediate ion. It was later shown[109] that, when benzoylphosphonate is acted upon by a threefold excess of diazomethane, the only reaction product is a compound to which the structure of the methyl ether of the enolic form of the β-ketophosphonate was attributed on the basis of spectroscopic data; evidently the carbonyl form enolises under the influence of diazomethane as a base. Under analogous conditions, diazoethane does not promote the enolisation of the corresponding ketophosphonate.

The mechanism of the reactions of KPE with diazoalkanes can be treated in different ways from the standpoint of the possible pathways leading to the formation of intermediates[109,110], but there is no doubt about the formation of a bond between the carbon atoms of the diazo-component and the carbonyl group of KPE [110]. The elimination of molecular nitrogen results subsequently in two pathways leading to the stabilisation of the ion (XXXV); for R = CH_3, both pathways operate, while for R = C_6H_5 only the second pathway is active:

In the transformation of the dipolar ion (XXXV, R = C_6H_5) to the stable β-ketophosphonate, the phosphorous-containing fragment migrates to the electron-deficient carbon atom. Contrary to expectation, the interaction of dimethyl acetylphosphonate with diazoethane leads to an oxiran derivative and not a β-ketophosphonate. On the basis of data obtained in the study of this reaction, it was concluded[111] that the nature of the final product of the reaction of KPE with diazoethane is independent of the type of substituent at the carbonyl group of the initial ketophosphonate.



As already mentioned previously, the condensation of diazoacetate ester with acetylphosphonate led unexpectedly to the formation of a product of the aldol type (XXII), [86] which undergoes interesting reactions. Under the influence of diazomethane[75] or trimethyl phosphite[112] as bases, the ester (XXII, R = CH_3, R′ = C_2H_5) is cleaved at the carbon–phosphorus bond with liberation of dimethyl phosphites. Under these conditions, the reaction with triethyl phosphite leads to the phosphazine system (XXXVI),[112] which is cleaved hydrolytically with elimination of triethyl phosphate. On heating above 80 °C or under the influence of acids, the ester (XXII) undergoes 1,2-fragmentation of a new type, which yields dialkoxyphosphonylacetoacetic ester. The mechanism of the formation and the structure of the latter have been studied in detail[113–115]:

A series of studies by Japanese workers were devoted to the investigation of KPE with thiazolium and benzimidazolium salts. A derivative of 2-substituted 1,4-thiazine was obtained from benzoylphosphonate and thiamine in the presence of bases[21,116,117]. Subsequently the reaction was extended to different *N*-substituted thiazolium salts[118–123] and 1,3,4-oxadiazolium salts[124], and in some cases intermediate isomerisation products were isolated[121]. It has been suggested that in all cases the nucleophilic thiazolium centre adds to the carbon atom of the carbonyl group in KPE. This is followed by isomerisation to a phosphate, which hydrolyses on treatment with alkali with formation of an enol. Ring expansion then takes place as a result of the insertion of a new carbon atom with formation of a 1,4-thiazine derivative. The reactions of KPE with benzimidazolium salts yielded adducts[125], which do not give rise to quinoxaline derivatives on alkaline hydrolysis.

The interaction of KPE with phosphoroisocyanatidites results in the formation of zwitter-ions [for example, (XXXVII)], the pathway leading to the stabilisation of which

is determined by the presence of several reaction centres. In the case of dialkyl phosphoroisocyanatidites, three structural isomers are formed[126,127] (demonstrated by infrared spectroscopy). A detailed study of the reaction[128] between dimethyl phosphoroisocyanatidite and acetylphosphonate at reduced temperatures made it possible to observe a new type of isomerisation of the zwitter-ion to the intermediate (XXXVIII) with subsequent conversion into a mixture of two configurational isomers of the substituted phosphaoxazolidinone, (XXXIX) and (XL), with a P–C bond in the ring:

The reaction of dialkyl phosphoroisocyanatidites with chloro-substituted acetylphosphonates does not proceed unambiguously. Whereas the only product of the interaction with trichloroacetylphosphonate is[129] a phosphonophosphate, resulting from the Perkow reaction, the interaction with mono- and di-chloroacetylphosphonate under analogous conditions leads[130] to a mixture of products. One of these is a phosphonophosphate and the other is a substituted phosphaoxazolidinone with a P–O–C linkage in the ring. A similar feature was noted in the behaviour of chloro-substituted acetylphosphonates in relation to alkyl phosphorodi-isocynatidites[65,131]. The migration of the alkyl group to the nitrogen atom is characteristic of the formation of cyclic products in the reactions indicated.

The C,O- and C,C-migration of the electrophilic dialkoxyphosphono-group in the intermediate dipolar ion, formed as a result of the nucleophilic addition of the carbonyl group of the ketophosphonate to carbon, is characteristic of the majority of the reactions of KPE with aprotic nucleophiles examined above. However, one can postulate also direct attack by phosphorus on the oxygen atom of the carbonyl group in the reaction of KPE with phosphoramidite[132]:

$$(C_2H_5O)_2PNHR + R'C(O)P(O)(OC_2H_5)_2 \rightarrow (C_2H_5O)_2\overset{+}{P}\overset{-}{O}CR'P(O)(OC_2H_5)_2 \rightarrow$$
$$\rightarrow (C_2H_5O)_2POCH(R')P(O)(OC_2H_5)_2 \rightarrow C_2H_5OP(O)OCH(R')P(O)(OC_2H_5)_2 .$$

The complex-forming properties of KPE have been studied inadequately. The formation of a complex on interaction of dimethyl benzoylphosphonate with aluminium chloride has been reported[24]. Molecular complexes[133] of aroylphosphonates with tin and titanium tetrahalides have been described; it has been established by infrared spectroscopy that the metal in the complex is coordinated to the carbonyl and phosphoryl groups. Diethyl acylphosphonates behave as bidentate ligands in the reaction[134,135] with 3*d* metal perchlorates. The reaction between aroylphosphonates and nickel complexes with cyclo-octa-1,5-diene proceeds via a different pathway: the arolyphosphonates are cleaved at the C–P bond[136].

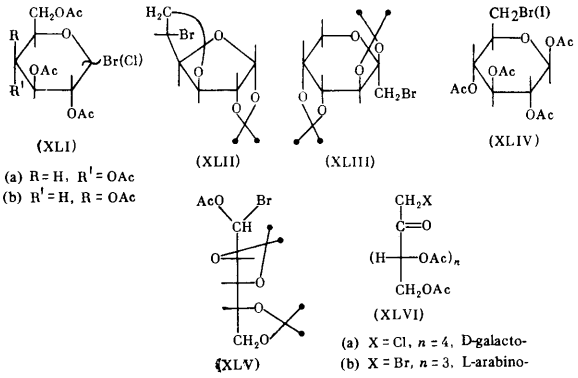
The synthesis of free α-ketophosphonic acids from the esters involves certain difficulties because of the hydrolytic instability of the phosphorus–carbon bond in the KPE molecule mentioned above. In a study of the use of aroylphosphonates as alkylating agents for the synthesis of *p*-toluenesulphonic acid esters, Golborn[137] isolated also acylphosphonic acids. Zygmunt et al.[138] reviewed briefly data on the dealkylation of acylphosphonates and suggested that the dealkylation can be carried out with the aid of trimethylsilyl iodide. KPE are silylated under mild conditions; the resulting trimethylsilyl α-ketophosphonate esters are readily hydrolysed by water under neutral conditions.

3. Reactions Involving the Substitution of the Carbonyl Oxygen

The traditional qualitative reactions of ketones are also undergone by KPE, which form phenylhydrazones and oximes. The methods for the preparation of arylhydrazones are various–heating with arylhydrazine in absolute alcohol, the addition of an ethereal solution of the KPE to solid *p*-nitrophenylhydrazine, and reactions in the presence of sulphuric acid. It is remarkable that β-halogeno-substituted KPE do not form[66,76] *p*-nitrophenylhydrazones and oximes. This fact has been explained[66] by the reduced amount of double bond character in the carbonyl group owing to the p_π-d_π conjugation with the phosphorus atom. KPE oximes (more rarely phenylhydrazones) have been used as the starting compounds in the synthesis of various α-aminophosphonic acids[2]. Apart from aluminium amalgam[23], diborane[139] and hydrogen over Raney nickel[16] have been used as reducing agents.

The conversion of acetylphosphonates into derivatives of α,β-unsaturated phosphonic acids has been described[140]. When acetylphosphonates react with cyanoacetic ester in the presence of amines, it is possible to obtain either the corresponding α-hydroxyphosphonates or their dehydration products, depending on the reaction temperature. α-Hydroxyphosphonates, obtained by the condensation of acetylphosphonate with malonodinitrile, are readily dehydrated[140].

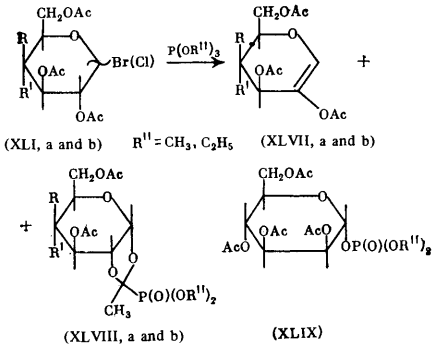
Dialkylphosphonodiazoalkanes have been synthesised by the decomposition of the tosylhydrazones of aliphatic KPE;[10,141,142] subsequently this method was extended[143] to aroylphosphonates. It has been suggested[71] that diazoalkylphosphonates be synthesised from the tosylhydrazones of KPE by treatment with sodium borohydride in methanol. A review has been devoted to the chemistry of aryldiazoalkylphosphonates[3].



The photochemical reactions of aroylphosphonates[70,144] are distinguished by a wide variety of reaction products. This behaviour is determined by the structure of the aroylphosphonate and the coreactant in the photochemical reaction. When diethyl benzoylphosphonate is irradiated with the light of a mercury lamp, a trioxan derivative is formed as a result of trimerisation; isopropyl and butyl esters undergo the pinacol rearrangement under these conditions. In methanol solution methyl benzoate is formed from these esters. Irradiation of substituted azirine in the presence of benzoylphosphonate leads to a satisfactory yield of a phosphonate-substituted oxazoline, whereupon the diatomic C–O bond is inserted in the ring[144].

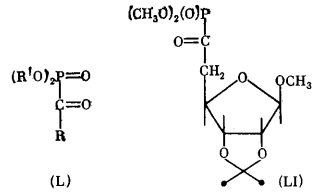
The conversion of KPE into alkylphosphonates can be achieved by reducing α-diazoalkylphosphonates with sodium borohydride in boiling tetrahydrofuran[71] or by electrochemical reduction[145].

V. CARBOHYDRATE-CONTAINING α-KETOPHOSPHONIC ACID ESTERS



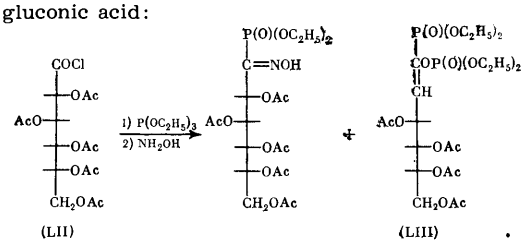
Numerous examples in which the usual organic reactions take place via non-standard pathways are known in carbohydrate chemistry. The Arbuzov reaction, applied to

halogen-containing monosaccharides in order to obtain carbohydrate derivatives with a phosphorus–carbon bond, is no exception in this sense. In the classical version of the Arbuzov reaction the principal types of halogeno-derivatives of monosaccharides (XLI)–(XLVI) have been used:



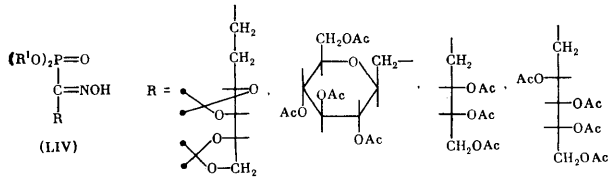
Among these compounds, only (XLIV) and (XLV) yield the "normal" products of the Arbuzov reaction–the corresponding carbohydrate-containing phosphonates[146–148]; compound (XLII) is reduced[149] by triethyl phosphite; acetohalogenoses (acetylated 1-halogeno-monosaccharides), for example, (XLI, a and b), react to form anomalous compounds, while compound (XLIII) does not react with trialkyl phosphites even under severe conditions. Acetylated non-cyclic halogenoketoses (XLVI) undergo the Perkow reaction on treatment with triethyl phosphite to form vinyl phosphates[150].

In the general case the interaction of acetohalogenoses with trialkyl phosphites results in a mixture of compounds[6,7,151], the ratios of which depend on the configuration of the initial halogenose:



Compounds (XLVIII, a and b) are formed from the acetohalogenoses (XLI, a and b) and trialkyl phosphites in 12–15% yield and by the Michaelis–Becker reaction (using the mercury and silver salts of dialkylphosphorous acids) in 20 to 80% yield. The glucal (XLVIIa) and the phosphate (XLIX) were isolated after the reaction of α-acetobromomannose with trialkyl phosphites. The probable mechanism of the formation of acetylphosphonates (XLVIII) under the conditions of the Arbuzov reaction is believed[151] to involve the formation of an intermediate acetoxonium ion, which combines with triethyl phosphite and then eliminates ethyl halide. It is remarkable that in the acetylphosphonates (XLVIII) the carbon–phosphorus bond is stable and the conversion of these phosphonates into the glycal (XLVII) has not been observed in any one instance. Compound (XLVIII) is a cyclic ketal of acetylphosphonate and exhibits a stability characteristic of KPE ketals[152] with respect to the action of alkaline agents. It has been suggested that α-ketophosphonates are formed in the oxidation of carbohydrate-containing α-hydroxyphosphonates by sodium periodate[153].

The synthesis of carbohydrate-containing α-ketophosphonate (L) (R is a polyol residue with protected hydroxy-groups) from the chlorides of acetylated aldonic acids was first reported by Zhdanov et al.[154]; the synthesis of compound (LI) from the chloride of uronic acid and trimethyl phosphite was described subsequently[72]:



The esters (L) have been isolated in low yields as hydroxyimino-derivatives. The principal reaction products are[155] diphosphoryl-containing compounds, the structure of which has been established with the aid of NMR and infrared specta; the alkyl esters of aldonic acids have also been obtained.

Diphosphorylcarbohydrate reaction products, with non-equivalent phosphorus atoms, an olefinic bond, and a smaller number of acetyl groups than in the initial acid halide, are formed via the Perkow reaction mechanism. α-Ketophosphonates with highly reactive carbonyl groups and an acetoxy-group activated by α-carbonyl and β-phosphoryl functional groups are obtained in the first stage and react with the excess phosphite. The α,β-unsaturated phosphonophosphates formed have been isolated as isomeric compounds. Thus compound (LIII) is formed from the chloride of acetylated D-gluconic acid:

Similarly compound (LII) reacts with tri-isopropyl phosphite and the chlorides of D-galactonic and D-arabonic acids react with triethyl phosphite[155]. It is of interest to note that the Perkow reaction observed for carbohydrate-containing α-ketophosphonates takes place under very mild conditions (at 25 to 30 °C), while in the case of the carbonyl forms of monosaccharides the enol phosphates are formed only on heating with triethyl phosphite to 85–140 °C.[156,157]

The interaction of trialkyl phosphites with the chlorides of desonoic acids gives high yields of carbohydrate-containing α-ketophosphonates, which have been identified as the oximes (LIV).[158] Such phosphonates are phosphorus analogues of 2-oxo-3-deoxyaldonic acids:

Carbohydrate-containing phosphonic acids, obtained from compounds of type (LIV) after removing the protecting groups at the phosphorus atom and in the carbohydrate residue, can apparently be used as substrates and inhibitors in the study of their interaction with a number of enzymes[159, 160]. This conclusion is based on convincing data[161] for the inhibition of pyruvate dehydrogenase by the phosphonate analogue of pyruvate and for the inhibition of acetyl-CoA synthetase when the substrate is acted upon by adenosine 5′-chloroacetylphosphonate[162].

Arylated Cyclopentadienes and Cyclopentadienylides

Ya.N.Kreitsberga and O.Ya.Neiland

Information on the synthesis of arylated cyclopentadienes and their ylide derivatives is systematically reviewed, and the chemical reactions of the compounds are discussed. A list of 110 references is included.

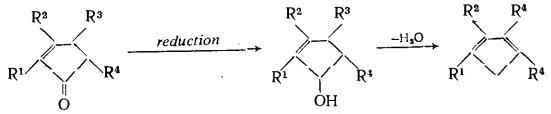
I. INTRODUCTION



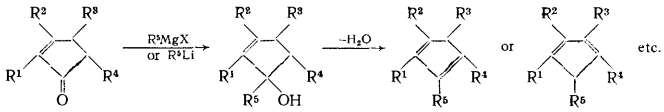
Several phenylated cyclopentadienes have found application as photosensitisers, but arylcyclopentadienes are of interest mainly as starting materials for the synthesis of cyclopentadienylides, fulvenes, ferrocenes, and other compounds.

The Review covers only those arylated cyclopentadienes in which the double bonds of the cyclopentadiene ring do not form part of an aromatic system (indenes are not covered).

II. METHODS FOR THE SYNTHESIS OF ARYLATED CYCLOPENTADIENES

1. Synthesis from Cyclopentenones

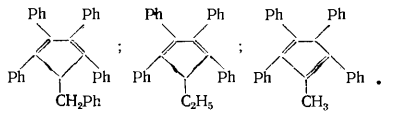
Cyclopentenones are used to obtain substituted cyclopentadienes because of the readiness with which the carbonyl group undergoes reduction and the Grignard reaction[1,2]. Cyclopent-2-enones are usually employed, for they are more stable and more readily available than cyclopent-3-enones[3]:



(*a*) $R^1=R^2=R^3=R^4=Ph$;
(*b*) $R^1=R^2=R^3=Ph$, $R^4=H$.

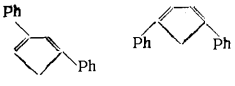
Selective reduction of the carbonyl group in the conjugated enone system is effected with lithium tetrahydroaluminate in ether at room temperature[1] or with sodium tetrahydroborate in aqueous dioxan[2]. The yields of cyclopentadienes reach 70–90% of theoretical, and the preparation can be accomplished in a single stage without isolation of the intermediate cyclopentenols. 1,2,3,4-Tetra- and 1,2,3-tri-phenylcyclopenta-1,3-dienes have been obtained in this way[1,2].

An attempt to use this method to obtain 1,2-diphenylcyclopenta-1,3-diene was unsuccessful[1,4], since 3,4-diphenylcyclopent-2-enol resinifies on acid dehydration, and the desired product is formed in small quantities, while the isomeric 3,4-diphenylcyclopent-3-enol does not eliminate water. 1,2-Diphenylcyclopenta-1,3-diene has been obtained in low yield by reducing 4-chloro-2,3-diphenylcyclopent-2-enone with lithium tetrahydroaluminate[5].



Substituted cyclopentadienes are most often obtained by treating cyclopentenones with organomagnesium and organolithium compounds and then dehydrating without isolating the intermediate carbinols[6-10]:

(*a*) $R^1=R^2=R^3=R^4=H$, $R^5=Ph$;
(*b*) $R^1=R^3=R^4=H$, $R^2=Ph$, $R^5=$ Ph or Alk; k;
(*c*) $R^1=R^2=R^3=R^4=Ph$, $R^5=$pH or Alk; ::
(*d*) $R^4=H$, $R^1=R^2=R^3=Ph$, $R^5=p$-Me–C_6H_4–;
(*e*) $R^1=R^2=Ph$, $R^3=R^4=H$, $R^5=Ph$

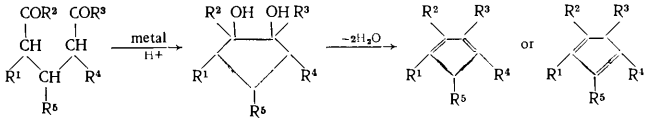


This method has been used to obtain the following cyclopenta-1,3-diene derivatives—1-phenyl[6], 1,4-diphenyl[7,8], 1,2,3,4,5-pentaphenyl[9], 1,2,3-triphenyl-4-*p*-tolyl, and 1,2,3-triphenyl[10].

The structure of the resulting cyclopentadienes cannot be predicted from that of the starting material, in the present case the cyclopentenone, since substituted cyclopentadienes that are isomeric with respect to the cyclic double bonds are in a state of thermodynamic equilibrium[3]. The potential barriers to interconversion of isomers are quite high, so that within certain temperature limits in effect only the thermodynamically more stable isomer can be isolated, but it is not so easy to predict which is the more stable form. Thus 5-benzyl- and 5-ethyl-1,2,3,4-tetraphenylcyclopenta-1,3-dienes are stable, but the methyl analogue has the structure 2-methyl-1,3,4,5-tetraphenylcyclopenta-1,3-diene[9]:

Therefore establishment of the structure of arylated cyclopentadienes requires careful examination of their proton magnetic resonance spectra.

Because of the complexity of determining the structure of the final product doubt attaches to the structure of several cyclopentadienes[7,8,11,12]. For example, it has not been established whether both isomers—1,3- and 1,4-diphenylcyclopenta-1,3-dienes

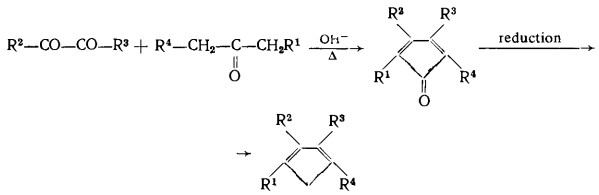


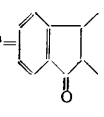
exist or only one of them. It appears more probable that only the 1,4-derivative can exist, since this structure is

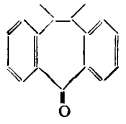
supported by the ^{1}H n.m.r. spectra[8] and ozonolysis products of the diene[11], as well as by the identity of its properties with those described much earlier[7] for 1,3-diphenylcyclopenta-1,3-diene. The authors of this last work ascribe to this compound the structure of 1,3-diphenylcyclopenta-1,3-diene, although its properties conform to those of 1,4-diphenylcyclopenta-1,3-diene. However, this is contradicted by a recent report[12] that two diphenylcyclopentadienes have been obtained, giving different fulvenes on reaction with benzaldehyde.

2. Preparation of Arylated Cyclopentadienes from 1,5-Diketones

Arylated cyclopentadienes were first obtained from 1,5-diketones, in two stages. The first stage involves reductive cyclisation to cyclopentanediols (by prolonged boiling with zinc in acetic acid[13-19] or by means of aluminium amalgam in aqueous ethanol[17]). In the second stage these diols are dehydrated by boiling with alcoholic hydrochloric acid[13,14] or by fusing with oxalic acid[13,14]. The yields vary, but do not exceed 50%. Many arylcyclopentadienes have been obtained in this way[13-19]:



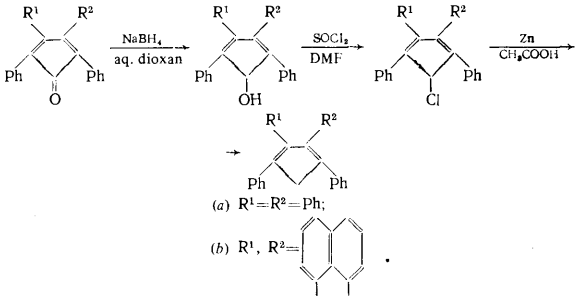




(*a*) $R^1=R^2=R^3=R^4=Ph$, $R^5=H$;
(*b*) R^1, R^2, R^3, $R^4=X-C_6H_4-$ (X=Cl, Me, OMe, NMe_2), $R^5=H$;
(*c*) $R^3=p$-MeO$-C_6H_4-$, $R^1=R^4=R^5=H$;
(*d*) $R^1=R^2=R^3=Ph$, $R^4=R^5=H$;
(*e*) $R^2=R^3=R^5=Ph$, $R^1=R^4=H$.

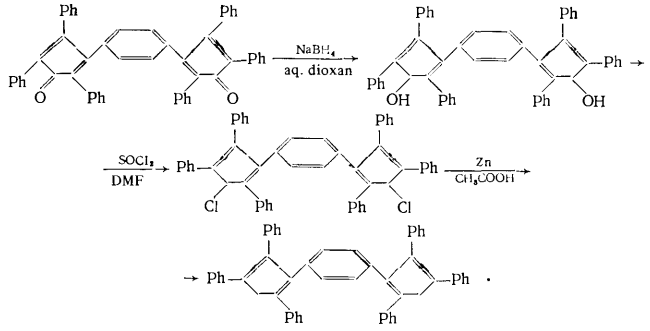
In acid media 1,2,3,4- and 1,2,3,5-tetraphenylcyclopentane-1,2-diols eliminate water to form the same 1,2,3,4-tetraphenylcyclopenta-1,3-diene[15], which apparently is thermodynamically the most stable isomer.

3. Preparation of Cyclopentadienes from Cyclopentadienones



Cyclopentadienones (cyclones) are very reactive, with a strong tendency to dimerise by diene synthesis, so that mono- and di-arylcyclones can exist only as dimers[20]. Therefore cyclopentadienes can be obtained from tri- and tetra-arylcyclones, which are readily formed by the condensation of diaryl-α-diketones with αα′-diarylacetones[21-27]:

(*a*) $R^1=R^2=R^3=R^4=Ph$;
(*b*) $R^1=R^4=Ph$, $R^2=R^3=p$-Ph$-C_6H_4$;
(*c*) $R^1=R^4=n$-Ph$-C_6H_4$, $R^2=R^3=Ph$;
(*d*) $R^1=R^2=R^3=R^4=p$-Ph$-C_6H_4$;
(*e*) $R^1=R^4=Ph$, R^2, R^3=  ;
(*f*) $R^1=R^4=Ph$, R^2, R^3=  or  .

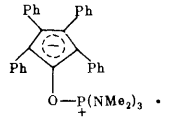


Selective reduction of the carbonyl group in tetraphenylcyclopentadienone (tetracyclone) was first attempted by Sonntag et al.[21], who obtained mixtures of various reduction products by the use of such reductants as zinc dust and lithium tetrahydroaluminate and by Clemmensen, Wolff–Kishner, or Meerwein–Pondorff reduction. Thus 5% and 12% yields of 1,2,3,4-tetraphenylcyclopenta-1,3-diene were obtained respectively on distillation with zinc dust at 270 °C and on reduction with lithium tetrahydroaluminate in dibutyl ether.

Recently, however, methods have been found for reducing tetra-arylcyclones to the corresponding cyclopentadienes. A fairly general scheme for obtaining tetra-arylcyclopentadienes is[22]

(*a*) $R^1=R^2=Ph$;
(*b*) R^1, R^2=.

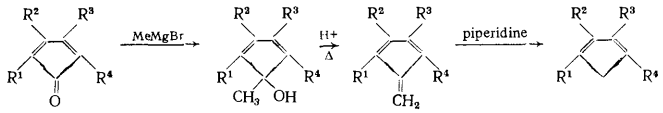
Sodium tetrahydroborate in aqueous dioxan converts tetra-arylcyclones quantitatively into tetra-arylcyclopentadienols, in which the hydroxy-group is then replaced by a chlorine atom by means of Vilsmeier's reagent. The resulting tetra-arylchlorocyclopentadienes are dechlorinated with zinc in acetic acid to form tetra-arylcyclopentadienes (in 60% yield based on the cyclones). This method can be used[22] to obtain a bistetraphenylcyclopentadiene:



A better yield (93%) of tetraphenylcyclopentadiene was obtained[23] by the reduction of tetracyclone with a mixture of lithium tetrahydroaluminate and aluminium chloride, and a 55% yield by the two-stage reduction to 2,3,4,5-tetraphenylcyclopent-2-enol with sodium tetrahydroborate followed by elimination of water. However, other workers have been unable to repeat these experiments[24,25]. Tetraphenylcyclopentadiene is formed only on prolonged boiling in the presence of a large excess of reductant[24], and isolation of a chromatographically pure product is possible only in an inert atmosphere in the dark and at low temperatures[26]. It has proved possible to reproduce the earlier experiments[23] in only one case[26]. Extending to other cyclones the method of reduction with a mixture of lithium tetrahydroaluminate and aluminium chloride has given mixtures of products, from

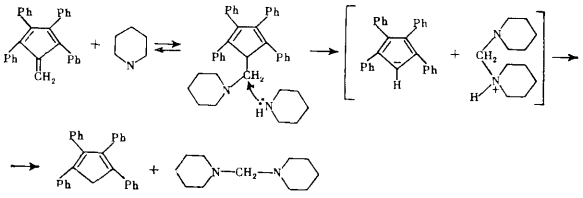
which corresponding cyclopentadienes have been isolated in yields of 10–20%[24,25,27].

Tetracyclone can be reduced also with hydrazine dihydrate and dihydrochloride in diethylene glycol[26], under which conditions 1,2,3,4-tetraphenylcyclopenta-1,3-diene is formed in 80% yield.



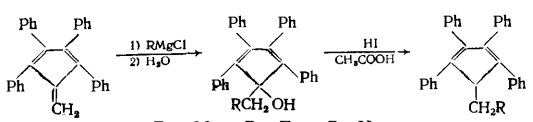
An interesting route from tetracyclone to tetraphenylcyclopentadiene was discovered[28] in an investigation of the action of tervalent phosphorus compounds on the former: with the hexamethyltriamide of phosphorous acid an unstable adduct is formed having the structure of an internal salt

This adduct is readily split by acids to form tetraphenylcyclopentadiene derivatives, but with hydrogen-donors it is reduced to 1,2,3,4-tetraphenylcyclopenta-1,3-diene in 87% yield. There have been no reports of the reactions of other cyclones with the triamide.



4. Fulvenes for the Preparation of Cyclopentadienes

Several tetra-arylcyclopentadienes can be obtained from tetra-arylfulvenes, which are formed by the action of methylmagnesium bromide on cyclones[29,30]:

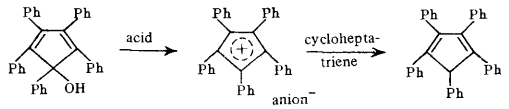


(*a*) $R^1=R^4=Ph$, $R^3=R^2=Ph$ or *p*-MeO—C_6H_4;
(*b*) $R^1=R^2=R^4=Ph$, $R^3=$ *p*-Me—C_6H_4—;
(*c*) $R^1=R^4=Ph$, $R^2=R^3=$ *p*-Me—C_6H_4— .

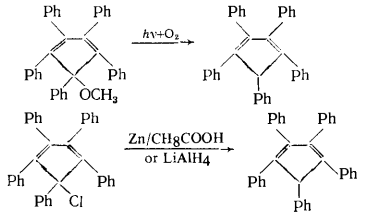
The mechanism

was suggested[29]. The ease of occurrence of this reaction (on boiling for a short time) is attributed to formation of the stable delocalised anion of tetraphenylcyclopentadiene. However, the reaction cannot be extended to other tetraarylcyclones ($R^2=p$-$X.C_6H_4$, where X = Cl, $(CH_3)_2N$, CH_3O), because the carbinols formed from cyclones and methylmagnesium bromide are unable to eliminate water[30].

Tetraphenylfulvene can be used to obtain alkyl- and arylalkyl-tetraphenylcyclopentadienes by the series of reactions[29,31,32]

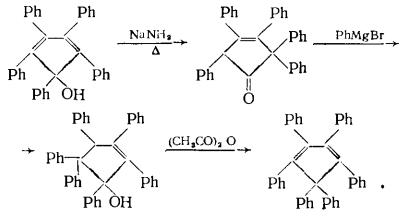


R = Me, t-Bu, Et, n-Pr, H

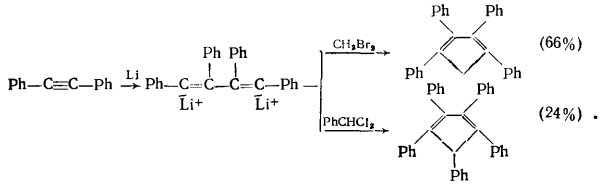


in which the yield is low. If $R=C_6H_5CH_2$ or t-C_4H_9, the carbinols are converted at high temperatures into the corresponding cyclopentadienes (without use of a reductant)[33].

5. Special Methods of Preparation of Arylated Cyclopentadienes



1,2,3,4,5-Pentaphenylcyclopentadiene can be obtained in two ways from 5-substituted derivatives. In the first method 1,2,3,4,5-pentaphenylcyclopenta-2,4-dienol is treated with a Lewis acid (boron trifluoride[34] or antimony pentachloride[35]) or with a strong acid, e.g. sulphuric acid[36,37], to form the pentaphenylcyclopentadienyl cation, stable only at low temperatures (−70 °C) which with a donor of a hydride ion gives 1,2,3,4,5-pentaphenylcyclopentadiene:

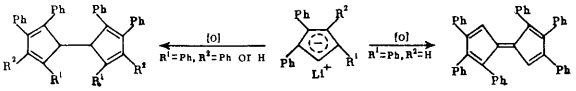


The second method may involve the photo-oxidation of 5-methoxylated[38,39] or the reduction with zinc dust or lithium tetrahydroaluminate of 5-chlorinated 1,2,3,4,5-pentaphenylcyclopenta-1,3-diene[14,38]:

Completely phenylated cyclopentadiene has been obtained by the isomerisation of 1,2,3,4,5-pentaphenylcyclopenta-2,4-dienol in the presence of sodamide into 2,2,3,4,5-pentaphenylcyclopent-3-enone, which reacts with phenylmagnesium bromide and then eliminates water to give a 30–40% yield of hexaphenylcyclopentadiene[40]:

The single-stage formation of 1,2,3,4-tetraphenylcyclopenta-1,3,diene from acetylenic compounds has still been little studied. In the presence of lithium, diphenylacetylene dimerises to form 1,4-dilithiotetraphenylbutadiene, which is alkylated by dibromomethane to give a 66% yield of tetraphenylcyclopentadiene[41]; when alkylation is effected with benzylidene dichloride, a 24% yield of 1,2,3,4,5-pentaphenylcyclopentadiene is obtained[42]:

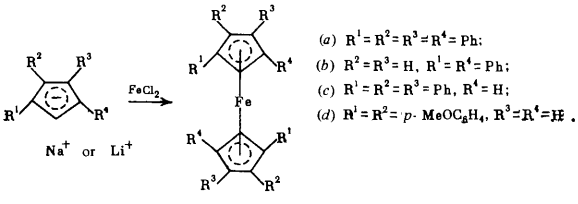
Yields of 1,2,3,4-tetraphenylcyclopenta-1,3-diene obtained by the action of diphenylacetylene on trimethylchromium[43] or on cyclopentadienylmethylmolybdenum tricarbonyl[44] are below 5%.



III. CHEMICAL REACTIONS OF ARYLATED CYCLOPENTADIENES

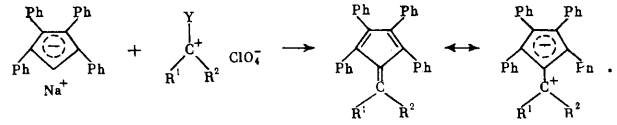
1. Acid-Base Reactions

Unsubstituted cyclopentadiene is a carbon–hydrogen acid, whose aqueous solution has $pK_a = 15.6$.[45] Such high acidity is attributed to stabilisation of the cyclopentadienyl anion by cyclic delocalisation of the six π electrons. The acidity is enhanced by the introduction of aryl substituents into the cyclopentadiene ring: thus for 8*H*-cyclopent[*a*]acenaphthylene in chloroform $pK_a = 14 \pm 0.5$.[46] For other arylated cyclopentadienes pK_a has not been determined, but their acidity is evident in reactions with bases and in many reactions involving condensation, in which they behave as containing an activated methylene group.



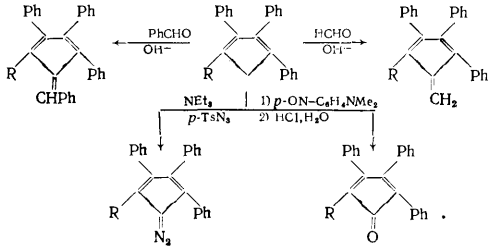
The sodium or lithium salt of 1,2,3,4-tetraphenylcyclopenta-1,3-diene is formed by the action of sodium in oxolan[47], sodamide[48,49], or sodium hydride in dimethyl sulphoxide (dimsylsodium)[47] or of phenyl-lithium or butyl-lithium[50,51]. Salts of 1,4-di- and 1,2,3,4,5-penta-phenylcyclopentadienes have been obtained by reaction of sodamide (or better dimsylsodium) with other substituted cyclopentadienes[49]. Phenyl-lithium has been used to obtain salts of 1,2,3-tri- and 1,2.3,4-tetra-phenylcyclopentadienes[49,2], and those of 1,2-di-*p*-methoxyphenylcyclopenta-1,3-diene by the action of methylmagnesium bromide[17].

Salts of arylated cyclopentadienes are readily oxidised by atmospheric oxygen and other oxidants, e.g. iodine, to form fulvalenes or, when this is prevented by steric hindrance, 1,1-dihydrofulvalenes[2]:



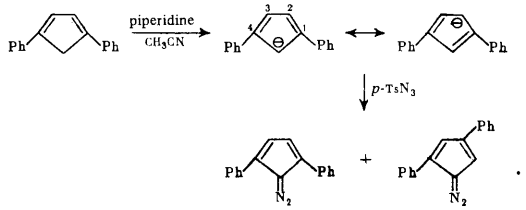
Salts of cyclopentadienes are therefore obtained in an inert atmosphere, and are immediately subjected to further reactions without isolation.

The reaction between salts of arylated cyclopentadienes and iron(II) chloride provides the only method for obtaining polyarylated ferrocenes[17,18,48,49]:



Almost all such compounds have been obtained in this way, with the exception of decaphenylferrocene, which was attributed[49] to steric hindrance.

The sodium and lithium salts of tetraphenylcyclopentadiene undergo nucleophilic substitution with 3,3-dichloro-1,2-diphenylcyclopropene[52], with methoxydiphenylcyclopropenylium[51], 4-chloro-2,6-dimethylthiopyrylium[53], and 2-methylthio-1,3-dithiolium[54] perchlorates, and with tropylium bromide[47] to form deeply coloured compounds of fulvene type, possessing large dipole moments:

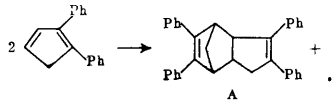


In the presence of bases arylated cyclopentadienes condense with aldehydes[12,55,56], *p*-nitrosodimethylaniline[16,56], and toluene-*p*-sulphonyl azide[3,24,50,56–59]:

The reactions with formaldehyde and benzaldehyde yield fulvenes, but that with *p*-nitrosodimethylaniline after hydrolysis gives cyclones. These reactions have been used repeatedly to characterise newly obtained cyclopentadienes[14,16,29].

The reaction with tosyl azide involves the formation of diazocyclopentadienes, which are starting materials for many cyclopentadiene derivatives, including ylides of arylated cyclopentadienes (Section IV). It is interesting that the reaction of 1,4-diphenylcyclopenta-1,3-diene with tosyl azide in the presence of piperidine gives a mixture of 1-diazo-2,4(and 2,5)-diphenylcyclopentadienes in yields of 30% and 58% respectively[59]. The explanation is that in an intermediate species—the anion of 1,4-diphenylcyclopenta-1,3-diene—the negative charge is delocalised to give an appreciable negative charge on the $C_{(2)}$ atom[59]:

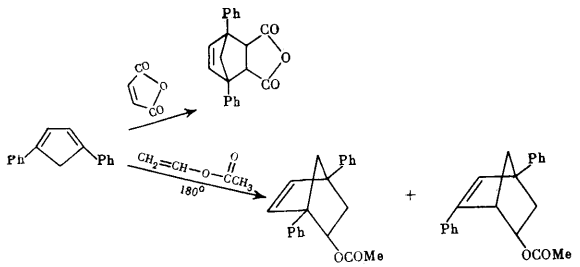
An analogous phenomenon was observed by Freeman and Lloyd[60], who obtained 2,4-diphenyl-1-triphenylarsoniopentadienylide in the reaction between 1,4-diphenylcyclopenta-1,3-diene and triphenylarsine oxide in triethylamine. The course of this reaction is also explained by formation of a conjugated anion of 1,4-diphenylcyclopentadiene. Hence it can reasonably be expected that conjugated anions of mono-, di-, and tri-arylcyclopentadienes will contain more than one nucleophilic centre, owing to delocalisation of the negative charge in the ring.



2. Arylated Cyclopentadienes in Diene Synthesis

Like other cyclopentadienes the arylated derivatives are able to undergo diene synthesis with various dienophiles, including cyclopentadienes, although the introduction of

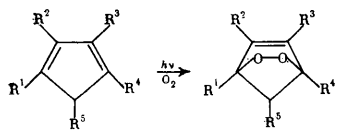
aryl substituents results in steric hindrance to the interaction of two cyclopentadiene molecules.



Crystalline phenylcyclopentadiene is monomeric, but its recrystallisation from ligroin leads to formation of a dimer (the structure of the latter has not been established, but dimerisation is supposed to occur by a mechanism of diene synthesis)[6].

On prolonged heating at 120 °C, 1,2-diphenylcyclopenta-1,3-diene dimerises to a mixture of products (with structure A predominating)[4,5,61]:

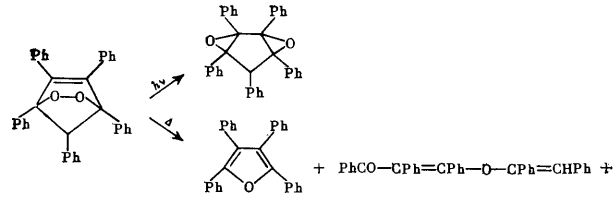
A



Dimerisation of the 1,4-diphenyl isomer has not been observed, although this compound readily undergoes diene synthesis with maleic anhydride[11,62] and with vinyl acetate[63]:

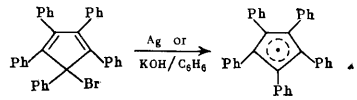
Dimerisation by a mechanism of diene synthesis does not take place in the presence of three or more aryl substituents. Perhaps interaction between the phenyl *ortho*-hydrogen atoms "twists" the phenyl groups out of the cyclopentadiene plane[18,64]. This impedes a frontal arrangement of two substituted cyclopentadiene molecules and formation of the transition state necessary for diene synthesis.

3. Photo-oxidation and Free Radicals of Pentaarylcyclopentadienes



1,4-Diphenylcyclopenta-1,3-diene has been recommended[65,66] for use as a photosensitiser, and is also an oxygen-acceptor (with formation of compounds of the type MO_2). Photo-oxidation has been studied on 1,2,3,4-tetraphenylcyclopenta-1,3-diene and its alkyl derivatives[9,67], and on the 1,2,3,4,5-pentaphenyl[68] and 1,2-diphenyl[5,61] compounds. Oxygen was found to undergo 1,4 addition to the diene system to form *endo*-peroxides:

(*a*) $R^1 = R^2 = R^3 = R^4 = Ph$, $R^5 = H$, Ph, Alk;
(*b*) $R^1 = R^2 = Ph$, $R^3 = R^4 = R^5 = H$;
(*c*) $R^1 = R^2 = R^4 = R^5 = Ph$, $R^3 = Me$.

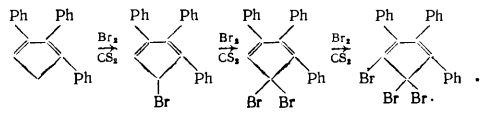


The structures of the latter have been confirmed by various chemical reactions. For example, reduction of the *endo*-peroxide of 1,2-diphenylcyclopentadiene with lithium tetrahydroaluminate gave 3,4-diphenylcyclopent-4-ene-*cis*-1,3-diol, but alkaline hydrolysis gave 4-hydroxy-3,4-diphenylcyclopent-2-enone[61].

When subjected to light or heat, *endo*-peroxides undergo further changes with fission not only of carbon–oxygen and oxygen–oxygen bonds but also of carbon–carbon bonds, so that the photo-oxidation of arylated cyclopentadienes usually gives a complicated mixture of products. For example, under the influence of light and of high temperatures the *endo*-peroxide of 1,2,3,4,5-pentaphenylcyclopentadiene undergoes the reactions[68]

The oxidation of cyclopentadienes in the dark or by means of other oxidants has not been investigated, with the exception of the oxidation of anions of tri- and tetra-phenylcyclopentadienes by iodine[2].

Many extremely stable, deeply coloured free radicals of 1,2,3,4,5-penta-arylcyclopentadienes are known. However, they have been obtained not by the direct oxidation of cyclopentadienes but by the action of silver or potassium hydroxide on penta-arylbromocyclopentadienes[14,69–76]:

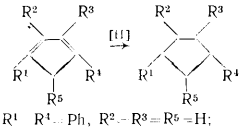


4. Halogenation of Cyclopentadienes

The action of halogens on arylated cyclopentadienes may involve either addition or substitution depending on the conditions and also on the halogenating agent used. Substitution occurs more readily.

Boiling 1,2,3-triphenylcyclopenta-1,3-diene with *N*-bromosuccinimide in tetrachloromethane for 1 h gives a mixture of the 1-bromo-2,3,4-triphenyl- and 5-bromo-1,2,3-triphenylcyclopentadienes[77]; boiling for 2 h yields 5,5-dibromo-1,2,3-triphenylcyclopenta-1,3-diene[2]. Under the same conditions 1,2,4-triphenylcyclopenta-1,3-diene forms the 5-bromo-1,2,4-triphenyl derivative[2,10].

With bromine in carbon disulphide all three hydrogen atoms in the 1,2,3-triphenylcyclopentadiene are successively replaced[2]:



The action of bromine on the 1,2,4-triphenylcyclopentadiene involves a mechanism of addition and elimination with the formation of 2,5-dibromo-1,3,4-triphenylcyclopenta-1,3-diene[19].

With bromine both methylene hydrogen atoms in 1,2,3,4-tetraphenylcyclopenta-1,3-diene are substituted at once to give the 5,5-dibromo-derivative[13]. To obtain the monobromo-compound it is necessary to use *N*-bromosuccinimide or bromopyridinium nitrate[78]. Similarly, iodopyridinium

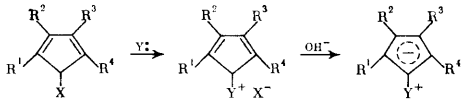
nitrate gives 5-iodo-1,2,3,4-tetraphenylcyclopenta-1,3-diene[78], and *S*-chloro-*S*-*p*-nitrophenyl-*N*-phenylsulphonylsulphidimine yields the corresponding 5-chloro-compound[79].

5. Hydrogenation of Arylated Cyclopentadienes

The hydrogenation of arylated cyclopentadienes to cyclopentane derivatives is used to establish and confirm the structure of cyclopentadienes obtained for the first time[11,13,19,80]:

(*a*) R^1 = R^4 = Ph, R^2 = R^3 = R^5 = H;
(*b*) R^1 = R^4 = *p*-Me—C_6H_4; R^2 = R^3 = R^5 = H;
(*c*) R^2 = R^3 = R^5 = Ph, R^1 = R^4 = H;
(*d*) R^1 = R^2 = R^3 = R^4 = Ph, R^5 = H.

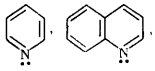
Hydrogenation is effected with hydrogen in the presence of a catalyst—Raney nickel[80] or palladium black[11]—or with hydriodic acid in the presence of red phosphorus[13,19].



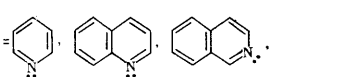
IV. PREPARATION OF ARYLATED CYCLOPENTADIENYLIDES

Much information has been published on the preparation and properties of tri- and tetra-arylcyclopentadienylides, but only in 1974 were the first diarylcyclopentadienylides—1-triphenylphosphonio- and 1-triphenylarsonio-2,4- and -2,5-diphenylcyclopentadienylides—described[60], since when 1-*N*-pyridinio-2,3- and -3,4-diphenylcyclopentadienylides have been obtained[22]. Ylides of monoarylcyclopentadienes are at present unknown.

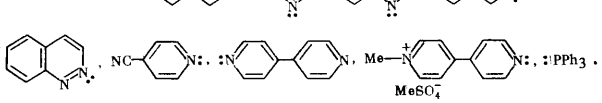
Two main methods—the salt method and the decomposition of diazocyclopentadienes—have been used to obtain arylated cyclopentadienylides. In addition, triphenylarsoniocyclopentadienylides have been obtained by condensing substituted cyclopentadienes with triphenylarine oxide in the presence of bases[60,77] or phosphorus pentoxide[81].



1. Salt Method

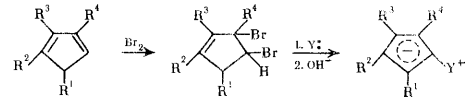


In the salt method onium salts of arylated cyclopentadienes are treated with bases to abstract the proton. Its limits of applicability depend on the accessibility of the onium salts[82]. These can be obtained in three ways, firstly from halogen derivatives of the substituted cyclopentadiene[60,77,83–85]:



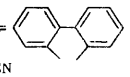
X = Cl or Br;

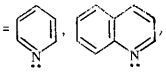
(a) R^1 = R^2 = R^3 = Ph, R^4 = H, Y: =  , :PPh_3, :$AsPh_3$, :SMe_2, :S=C(NR$_2$)(NR$_2$);

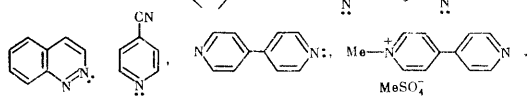


(b) R^1 = R^2 = R^3 = R^4 = Ph, Y: =  , :PPh_3, :S=C(NR$_2$)(NR$_2$);

(c) R^1 = R^4 = Ph, R^2, R^3 =  , Y: = 

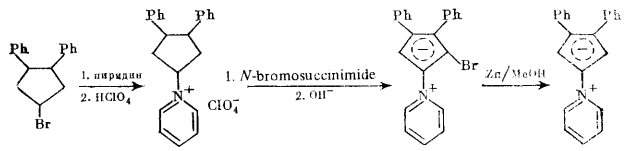






MeSO$_4^-$

In the second process an onium salt of an arylated cyclopentadiene is obtained by the action of a base on a dibromocyclopentene[24,87]:

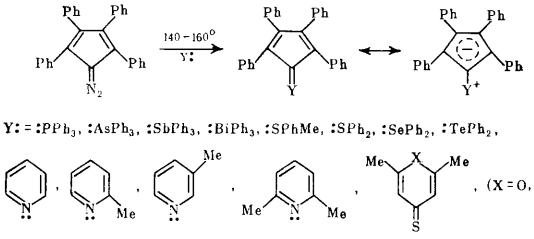


(*a*) R^1 = R^4 = H, R^2 = R^3 = Ph, Y: =  ;

(*b*) R^1 = R^4 = Ph, R^2, R^3 =  , Y: = 

MeSO$_4^-$

The starting compound in the third method is a halogenated cyclopentane, but in this case it is necessary also to dehydrogenate the onium salt[24]:



In all cases aqueous–ethanolic sodium hydroxide was used as the base.

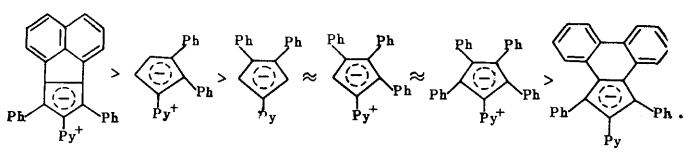
Two limitations have been found in obtaining onium salts of arylated cyclopentadienes, the first involving steric hindrance to nucleophilic substitution of the bromine atom. If the cyclopentadiene ring contains 2- and 5-phenyl substituents, the yield of onium salts in the reaction of the corresponding bromocyclopentadiene with 2-methyl- or 2,6-dimethyl-pyridine is 6%, but with quinoline reaction does not occur[84]. From the corresponding chlorocyclopentadiene and quinoline the onium bond is formed in low yield[85], but when the decomposition of diazocyclopentadienes is used, a method in which steric hindrance is absent from the reactant species (a carbene), onium salts are obtained in good yields[86]. The second limitation is due to dehalogenation in the reaction of halogenated cyclopentadienes with triphenylphosphine in acid solvents. This reaction involves the formation not of onium salts but of the original substituted cyclopentadienes[77,85], which is attributed to attack by triphenylphosphine on the bromine atom.

2. Decomposition of Diazocyclopentadienes

The thermal decomposition of arylated diazocyclopentadienes in the presence of nucleophilic species has been used to obtain a number of tetraphenylcyclopentadienylides[59,86,88,90–99], since diazotetraphenylcyclopentadiene itself is readily obtainable[88]:

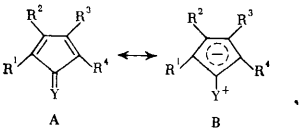
With copper bronze powder as catalyst the temperature can be lowered and the reaction conducted in such solvents as benzene, cyclohexane, and ethanol, when the yield of ylides is increased[60].

1-Triphenylphosphonio- and 1-triphenylarsonio-2,3,4-triphenylcyclopentadienylides have been obtained by the catalytic decomposition of 1-diazo-2,3,4-triphenylcyclopentadiene[60], although it had been reported earlier[77] that the decomposition of diazocyclopentadienes could not be used to obtain onium betaines of cyclopentadienes unsubstituted at position 2 or 5.



The decomposition of 1-diazo-2,5-diphenylcyclopentadiene in the presence of triphenylphosphine and triphenylarsine yields respectively 1-triphenylphosphonio- and 1-triphenylarsonio-2,4-diphenylcyclopentadienylides. The explanation proffered[60] is that positions 3 and 4 in the intermediate 1-carbene of 2,5-diphenylcyclopentadiene are sterically more favourable than position 1 to nucleophilic attack by triphenylphosphine or triphenylarsine.

Theoretically ylides can be formed from diazo-compounds in two ways. The nucleophile (triphenylphosphine, triphenylarsine, etc.) may add initially to the diazo-compound, and the resulting adduct breaks down to the ylide with the evolution of nitrogen. Alternatively the ylide may be formed via the carbene, which is partly supported by thermogravimetric investigation of these reactions[100].



V. PROPERTIES OF ARYLATED CYCLOPENTADIENYLIDES

1. Physical Properties and Structure

Arylated cyclopentadienylides are crystalline, sparingly soluble in water, ethanol, ether, and hexane, and soluble in benzene and chloroform. Phosphonium, arsonium, sulphonium, and selenonium ylides are stable, and decompose only when illuminated. Pyridinium, other *N*-heteronium, and stibonium ylides are stable in the solid state, but decompose in solution. Telluronium and bismuthonium ylides decompose slowly in the solid state, but rapidly in solution[86, 101]. The stability of ylides depends not only on the onium moiety but also on the aryl substituents in the cyclopentadiene ring. For example, known pyridium ylides of arylated cyclopentadienes can be arranged in the stability sequence

The stability of ylides is usually explained[86] by the nature of the bond between the heteroatom and the five-membered ring, which in turn depends on the charge distribution in the molecule (on the "contribution" by the dipolar structure B):

Increase in the volume of the heteroatom enhances the diffuse character of the *d*-orbital, while the efficiency of interaction between the 2*p*-electrons of the carbanion and the vacant *d*-orbitals of the heteroatom diminishes (the contribution by structure A decreases). The stability diminishes also as electrostatic interaction between carbanion and onium heteroatom becomes weaker (with decrease in the electronegativity of the heteroatom, with lengthening of the carbon–heteroatom bond).[86] Arylated cyclopentadienylides are less stable if aryl or onium substituents are "twisted" out of the cyclopentadiene plane owing to the steric hindrance in the molecule.

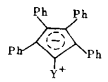


Table 1. Long-wavelength absorption by tetraphenylcyclopentadienylides[85,86].

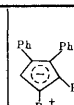
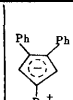
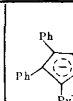
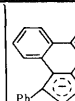






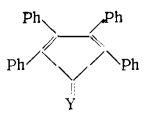


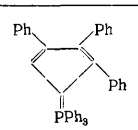
Y	PPh_3	$AsPh_3$	$SbPh_3$	$BiPh_3$	SPh_2
λ_{max}, nm (solvent)	288* (EtOH)	291* (EtOH)	349 ($CHCl_3$)	525 (EtOH); 596 (benzene)	292*; 328*(sh** (EtOH)

Y	$SePh_2$	$TePh_2$		
λ_{max}, nm (solvent	294*; 347* (sh**) (EtOH)	335 (MeOH) 347 (benzene)	538 (EtOH) 595 (benzene)	587 (EtOH) 645 (benzene)

*Absorption maximum independent of solvent (solvatochromism not observed).
**sh = shoulder.

Table 2. Long-wavelength absorption by pyridinium ylides of arylated cyclopentadienes[22].





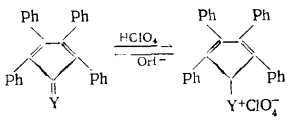
λ_{max} in						
Benzene	572	582	589	590	630	650
Ethanol	530	530	547	535	572	590

The structure of an ylide can best be characterised by X-ray examination, but only a few ylides of unsubstituted cyclopentadiene have been studied in this way[102–104].

All ylides are yellow with the exception of *N*-heteronium and bismuthonium ylides, which in the crystalline form are intensely coloured ($\lambda_{max} \cong 500-800$ nm) [85,87,101] (Table 1). With several ylides (Y = $(C_6H_5)_3P$, $(C_6H_5)_3As$, $(C_6H_5)_3Sb$, $(C_6H_5)_2S$, $(C_6H_5)_2Se$) the longer-wavelength absorption maximum is independent of the solvent, but negative solvatochromism is observed with bismuthonium and telluronium ylides of tetraphenylcyclopentadiene[86] and with all *N*-heteronium ylides of arylated cyclopentadienes[22,77,85,87] (Table 2). Slight solvatochromism has been found in 1-triphenylphosphonio-2,3,5-tri- and -2,4-di-phenylcyclopentadienylides[60]. It is assumed that betaines in which solvatochromism is observed have structure B in the ground state, or that the contribution by this structure is large, and that the longer-wavelength absorption is due to intramolecular charge transfer.

Table 3. Dipole moments of arylated cyclopentadienylides[105].

Y	μ, D	Y	μ, D
SPh_2	6.69		6.99
SPhMe	6.90		
PPh_3	7.75		
$AsPh_3$	8.32		
$SbPh_3$	2.2		



Dipole moments in benzene solution at 25 °C have been determined for several tetra- and 2,3,4-tri-phenylcyclopentadienylides (Table 3)[105]. The results indicate that the contribution by the ionic structure (B) increases in the series of betaines with sulphonio < phosphonio < arsonio. The low dipole moment of triphenylstiboniotetraphenylcyclopentadienylide is explained by association of the betaine with the solvent or with itself[105]. The dipole moment is larger in tetra- than in tri-phenylcyclopentadienylides and ylides of unsubstituted cyclopentadiene[106]; hence substitution by phenyl groups increases the contribution by the ionic structure in the ground state of the molecules.

Ionisation potentials have been determined for several ylides of 7,9-diphenyl-8*H*-cyclopent[*a*]acenaphthylene by spectrophotometric examination of intermolecular charge-transfer complexes[85]. These ylides are found to constitute a novel class of strong electron-donors with ionisation potentials of 6.7–6.75 eV.

2. Reactions of Arylated Cyclopentadienylides

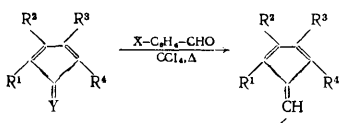
(*a*) Acid-base reactions

Arylated cyclopentadienylides are bases, forming with acids such as perchloric, hydrobromic, etc. salts that are readily hydrolysed to the original ylides:

Y=PPh_3, $AsPh_3$, $SbPh_3$, Py .

This procedure is the only method for purifying ylides that are unstable in solution[86]. However, several cyclopentadienylides of diphenylsulphonium[107], diphenyselenonium, and diphenyltelluronium are too weak bases to be protonated by mineral acids.

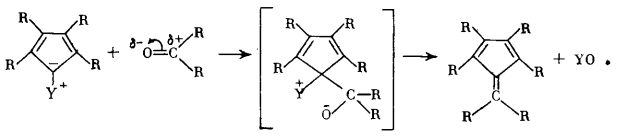
Table 4. Acidity constants pK_a of protonated forms of arylated cyclopentadienylides[101,107].



Tetraphenylcyclopentadienylides			2,3,4-Triphenylcyclopentadienylides	
Y=PPh_3	Y=$AsPh_3$	Y=$SbPh_3$	Y=PPh_3	Y=$AsPh_3$
5.3	7.6	7.6	4.2	5.6

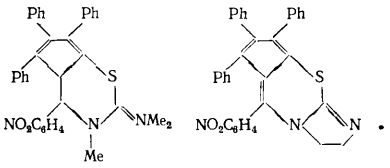
Acidity constants of the protonated forms in 95% ethanol have been determined for several tetra- and 2,3,4-triphenylcyclopentadienylides[101,107]. Table 4 shows that the basicity of the ylides is closely related to the polarity of the molecule. The basicity diminishes in the sequence stibonio > arsonio > phosphonio with decrease in the degree of interaction of the 2*p*-electrons of the anion with the vacant orbitals of the heteroatom. Values of pK_a are smaller for tri- than for tetra-phenylcyclopentadienylides, which indicates greater thermodynamic stability of the former[101].

The site of protonation depends on the structure of the ylide. Investigation of the proton magnetic resonance spectra of cyclopentadienylides in trifluoroacetic acid has established[60,101] that the unsubstituted carbon atom is protonated, for example positions 5 and 3 respectively in 2,3,4-tri- and 2,5-di-phenylcyclopentadienylides. On the other hand, 2,3,5-triphenylcyclopentadienylides are not protonated in the vacant position 4, as the n.m.r. spectra do not contain the signal of a methylene group.



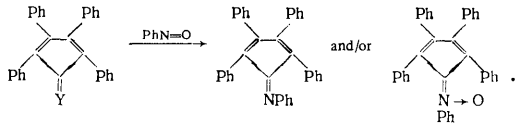
(*b*) Reaction with a polar double bond

Reactions with aldehydes and with *p*-nitrosobenzene have been studied for tri- and tetra-phenylcyclopentadienylides[60,83,86,101]. Only triphenylarsonium, triphenylstibonium, and thiouronium ylides react with benzaldehyde or *p*-nitrobenzaldehyde, forming fulvenes:



Y=$AsPh_3$, $SbPh_3$, S—CN $(HMe)_2$;
$R^1=R^2=R^3=$Ph, $R^4=$ Ph or H .

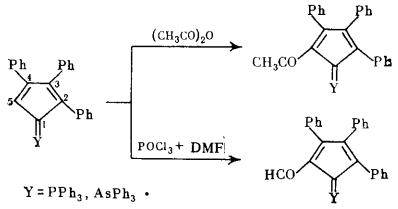
Formation of the latter is explained[86] by nucleophilic addition of the ylide to the carbonyl group with further change in the resulting adduct:



The reaction between 1-thiouronio-2,3,4-triphenylcyclopentadienylide and *p*-nitrobenzaldehyde yields mainly strongly coloured products having the structure[83]

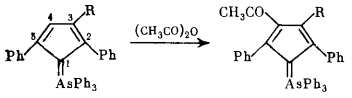
This is attributed[83] to attack by the aldehyde at the unsubstituted position 5 (not position 1) in the cyclopentadiene ring followed by attack on one of the nitrogen atoms. Ylides having Y = $(C_6H_5)_3P$, $(C_6H_5)_2S$, $(C_6H_5)_2Se$, $(C_6H_5)_2Te$ do not react with aldehydes.

Ylides of tetra-arylcyclopentadienes react with nitrosobenzene to form the tetra-arylcyclopentadienone anil, [its *N*-oxide], or a mixture of the two[83,86,101]:



Diphenysulphonio- and -selenonio-tetraphenylcyclopentadienylides, when boiled with nitrosobenzene in tetrachloromethane for 18 h, form the anil *N*-oxides of tetraphenylcyclopentadienone in 5% and 80% yields respectively. Under the same conditions triphenylarsoniotetraphenylcyclopentadienylide forms a mixture of the anil and the anil *N*-oxide (respective yields 35% and 48%), but the corresponding stibonio-ylide forms only the anil *N*-oxide (yield 80%) even with a shorter period of boiling[86].

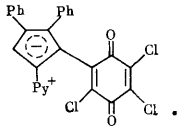
2,3,4-Triphenylcyclopentadienylides are more reactive than their tetraphenyl analogues towards polar double bonds, although the former are less basic: i.e. the nucleophilicity of the ylides (Sb > As > Se > S > P) does not parallel their basicity (Sb > As > P ≫ S ≅ Se) owing to the great sensitivity of nucleophilic reactions to steric factors[107].



(*c*) Electrophilic substitution

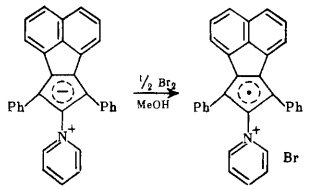
Electrophilic substitution in ylides of unsubstituted cyclopentadiene have been well studied[106,108–110], and arylated cyclopentadienylides are found to follow the same pattern. Substitution occurs more readily at position 2(5), but if this site is occupied, it occurs at position 3(4),[60] which is explained by the more favourable transition state with substitution in position 2(5).[108]

1-Triphenyl-phosphonio- and -arsonio-2,3,4-triphenylcyclopentadienylides are acylated by acetic anhydride[81] and undergo Vilsmeier formylation[101] to the corresponding 5-substituted ylides:



2,5-Di- and 2,3,5-tri-phenylcyclopentadienylides are acylated at position 4:[60]

1-Triphenylphosphonio-2,4-diphenylcyclopentadienylide forms a mixture of 3- and 5-acylated products in which the latter isomer predominates, but Vilsmeier formylation gives the disubstituted 3,5-diformyl-2,4-diphenyl-1-triphenylphosphoniocyclopentadienylide[60].



Azo-coupling has been investigated in 1-phosphonio- and 1-arsonio-2,4-di-, -2,5-di-, and -2,3,4-tri-phenylcyclopentadienylides. The products are quite stable red 2(5)-azo-compounds[60].

1-*N*-Pyridinio-3,4-diphenylcyclopentadienylide reacts with *p*-chloranil to form as electrophilic substitution product a stable betaine having two absorption bands in the visible (at 480–520 and 800 nm). The former absorption maximum exhibits negative solvatochromism, but the latter is independent of the solvent. Thus the interesting phenomenon is observed of simultaneous intramolecular charge transfer from the 3,4-diphenylcyclopentadiene anion to the onium substituent (~500 nm) and to the 2-substituent (~800 nm):[22]

(*d*) Oxidation

N-Heteronium, stibonium, telluronium, and bismuthonium ylides of arylated cyclopentadienes are relatively unstable[24,86,101]. Their instability is connected with their ready oxidisability by atmospheric oxygen, since they are more stable in an inert atmosphere. However, the decomposition (atmospheric oxidation) products of ylides have not yet been studied. It has been shown merely[22] that oxidation by bromine of 8-*N*-pyridinio-7,9-diphenyl-8*H*-cyclopent[*a*]-acenaphthylenylide gives a salt of a radical-cation:

In the crystalline state the yellowish-green product is extremely stable, but it decomposes readily in solution.

I. INTRODUCTION

A prop-2-ynyl (propargyl) ether (the methyl compound) was first obtained by Liebermann in 1865 from glycerol tribromohydrin[1]; its constants were determined by Henry[2]. The next homologue—ethyl prop-2-ynyl ether—was prepared a year later by Bayer[3]. Later the isopentyl[4], phenyl[5], propyl[6], and butyl[7] ethers were obtained. C_{sp}-Halogenated prop-2-ynyl ethers were described as early as 1894.[8] α-Halogeno-ethers of prop-2-ynol were first prepared in 1959.[9] A year later appeared the first paper on propargyl ethers of silanols[10]; those of silylalkanols have not yet been described.

A considerable quantity of information on methods of preparation and chemical behaviour has now accumulated, and indicates that prop-2-ynyl ethers are interesting subjects for investigation. Their peculiar chemical properties are due to the tendency to undergo rearrangements. The prospects for their use in experimental organic chemistry are demonstrated by their employment as starting materials in obtaining the relatively inaccessible allenyl ethers[11], allene hydrocarbons[12], cyclopropane derivatives[13], pyrazoles[14], etc. Prop-2-ynyl ethers are present in several natural materials. According to the patent literature[15] they possess high antibiotic activity.

Propargyl ethers have recently attracted attention in connection with their wide range of useful properties (they have biological activity, help to retard corrosion, aid the flotation of rare metals, and increase the energy content of complicated rocket fuels).

Hitherto, however, hardly any general reviews have appeared on methods of preparation, physical and chemical properties, and applications of this class of heteroatomic acetylenes[16]. The present Review attempts to survey and systematise the information on prop-2-ynyl ethers that has accumulated in the literature.

II. METHODS OF PREPARATION

General methods of preparation of prop-2-ynyl ethers are based on the dehydrohalogenation of halogenoalkyl or halogenoalkenyl ethers[6,17,18] and other elimination reactions[19,20], the action of α-chloroalkyl ethers on metal acetylides[21-24], the alkylation of alkoxides of prop-2-ynols[25-28], the interaction of alkoxides or phenoxides with prop-2-ynyl halides or sulphonates[27,29,30], and the isomerisation of prop-1-ynyl[31] or allenyl[32] ethers.

Alkyl, aryl, and halogenoalkyl prop-2-ynyl ethers have been obtained[17] by the dehydrobromination of 2,3-dibromopropyl ethers in the presence of ethanolic potassium hydroxide:

$$CH_2BrCHBrCH_2OR \xrightarrow[EtOH]{KOH} HC{\equiv}CCH_2OR + KBr \ .$$

This method has no preparative value because of the very low yield (≤10%). The ethyl ether cannot be obtained in this way owing to the difficulty of isolating it from the solvent. The aryl ethers can be obtained by the dehydrohalogenation of 1-aroxy-2,2-dihalogenopropanes in the presence of sodamide in liquid ammonia[33]:

$$\underset{X=Cl,\,Br}{ArOCH_2CX_2CH_3} \xrightarrow{NaNH_2/NH_3} ArOCH_2C{\equiv}CH \ .$$

The propyl ether has been obtained[18] by the dehydrochlorination of 3-chloroallyl propyl ether:

$$PrOCH_2CH{=}CHCl \rightarrow PrOCH_2C{\equiv}CH \ .$$

A method of preparation is provided by the alkylation of prop-2-ynols with alkyl arenesulphonates in alkaline media[25]. A convenient methylating agent is dimethyl sulphate, which is highly reactive and quite cheap:

$$HC{\equiv}CCH_2OH + Me_2SO_4 \rightarrow HC{\equiv}CCH_2OMe \ .$$

The ethyl ether is obtained similarly[34].

A simple and convenient procedure is alkylation with prop-2-ynyl halides. Thus the butyl and phenyl ethers have been obtained[7] by the action of prop-2-ynyl bromide on sodium butoxide and phenoxide respectively in ether, when acetylenic–allenic isomerisation is not observed:

$$HC{\equiv}CCH_2Br + RONa \rightarrow HC{\equiv}CCH_2OR \ .$$

A similar method has been used to obtain the tolyl ether[35], by the action of 3-bromopropyne on *p*-cresol in acetone in the presence of potassium carbonate, as well as the allyl[34] and vinyloxyalkyl[36] ethers. It has been recommended[37] to use metallic sodium in liquid ammonia in the alkylation of certain alkynols with benzyl bromide.

The selective alkylation[26-28] of acetylenic alcohols with alkyl halides, first applied to α-acetylenic alcohols, was extended to substituted α- and β-acetylenic alcohols[38]:

$$HC{\equiv}CCOH \xrightarrow[NH_3]{+MNH_2} HC{\equiv}CCOM \xrightarrow{RX} HC{\equiv}CCOR + MX$$
$$R=Bu,\ Cl(CH_2)_n;\ X=Br;\ M=Na,\ K \ .$$

The reaction is complicated by parallel dehydrohalogenation of the alkyl halide with formation of an alkene. The yield

of the prop-2-ynyl ether is 25–80%. The course of the reaction is affected by the nature of the alkyl halide, the alcohol, and the alkali metal; when lithamide is used, the acetylenic hydrogen atom—not the hydrogen atom of the hydroxy-group—is alkylated. The ethyl and butyl ethers (contaminated with allenic isomers) have been obtained by this method in 30% yield[39], and also the methyl ether in 10% yield[40]. The method has been used to obtain the aryl[37], halogenoalkyl, and higher alkyl[41,42] ethers, as well as prop-2-ynyl ethers of secondary and tertiary prop-2-ynyl alcohols[43].

A method of selective alkylation of acetylenic alcohols in the presence of organomagnesium compounds in Hexametapol has recently been worked out[44]. On reaction between ethylmagnesium bromide, an equivalent quantity of 1-bromobutane, and prop-2-ynol at 80–90 °C the hydroxy-group is 80–90% alkylated. With a molar excess of the organomagnesium bromide at 110 °C partial (15–20%) *C*-alkylation occurs. Under these conditions tertiary propargyl alcohols break down with the formation of ketones. The difference in acidity and reactivity between the hydroxyl and acetylenic hydrogen atoms permits successive alkylation of both functional groups or their simultaneous metallation followed by selective alkylation.

Propargyl ethers are obtained also by alkylating prop-2-ynol with alkyl halides in the presence of potassium hydroxide in dimethyl sulphoxide or cyclohexanone[45]. Benzene can be used as solvent in preparing the benzyl and furfuryl ethers[46,47]. Long-chain ethers have been obtained by alkylating prop-2-ynol in the presence of potassium t-butoxide in n-butanol[48]:

$$HC{\equiv}CCH_2OH + C_{18}H_{37}Br \rightarrow HC{\equiv}CCH_2OC_{18}H_{37} .$$

A patent[49] has described the production of ethers from propargyl alcohols and alkyl chlorides in alcoholic solution at 80–150 °C.

The use of propargyl arenesulphonates under mild conditions enables the prop-2-ynyl group to be introduced into various organic compounds (to give 80–95% yields)[50]. The initial sulphonates are obtained by reaction between the sulphonyl chloride and prop-2-ynol in the presence of powdered potassium hydroxide in absolute ether[51]. Interaction between prop-2-ynyl benzenesulphonate and alkoxides yields the corresponding alkyl ethers[52]:

$$PhSO_2OCH_2C{\equiv}CH + RONa \rightarrow ROCH_2C{\equiv}CH .$$

The reaction can be conducted by adding the alkoxide to an alcoholic solution of the sulphonate or by Claisen's method—addition of potassium hydroxide to a solution of the sulphonate and the alcohol—to give 59–60% yields of the ether[51].

The isomerisation of prop-1-ynyl ethers in several cases leads to prop-2-ynyl ethers[31]. Thus in the alkylation of phenol with 3-bromopropyne in the presence of sodamide the resulting ether isomerises into phenyl prop-2-ynyl ether[53]:

$$PhOC{\equiv}CMe \rightarrow PhOCH_2C{\equiv}CH$$

When allenyl ethers are metallated with lithamide in liquid ammonia, they isomerise into prop-2-ynyl ethers[32]:

$$CH_2{=}C{=}CHOR \rightarrow HC{\equiv}CCH_2OR .$$

Diazoalkynes can be used[19] to obtain prop-2-ynyl ethers. *N*-Nitroso-*N*-propargylureas on methanolysis in alkaline medium are converted into a mixture of allenyl methyl and methyl prop-2-ynyl ethers roughly in the proportions 1 : 10:

$$HC{\equiv}CCH(R)N(NO)CONH_2 \xrightarrow{MeOH} HC{\equiv}CCH(R)OMe + RCH{=}C{=}CHOMe$$

R = H, Alk .

The decomposition of 1,1,1-trichloro-3-ethoxy-2-trimethylsiloxypropane in the presence of butyl-lithium yields ethyl prop-2-ynyl ether[20]:

$$EtOCH_2CH(OSiMe_3)CCl_3 + 3BuLi \xrightarrow{Et_2O/oxolan} EtOCH_2C{\equiv}CH .$$

The phenyl ether can be obtained similarly (in 25% yield). An attempt to obtain this ether from its "structural components" (ethanol, paraform, and acetylene) in the presence of copper(I) chloride under pressure was unsuccessful[39]:

$$EtOH + CH_2O + CH{\equiv}CH \xrightarrow[25-28\ atm]{Cu_2Cl_2} \begin{cases} \rightarrow EtOCH_2OEt \\ \rightarrow EtOCH_2C{\equiv}CH . \end{cases}$$

At 80 °C reaction does not occur, and at 140 °C diethyl formal is produced.

According to patent claims[30] aromatic propargyl ethers are formed by the action of prop-2-ynyl arenesulphonates on phenols in the presence of bases. Prop-2-ynyl ethers of alkylphenols have been prepared[54] by Claisen's method; it was considered that the duration of the reaction greatly influences the yield, which reaches a maximum after 48 h.

A general method for preparing propargyl ethers is the action of alkyl-, aryl-, and aralkyl-magnesium halides on 1-chloroalkyl prop-2-ynyl ethers[55]. A series of studies[56–58] have shown the possibilities of this method for obtaining the ethers of arylalkanols.

C_{sp}-Silylated propargyl ethers of alkanols, phenols, and diols are obtained by the action of Iotsich reagents on trialkylchlorosilanes[55,56,59,60]:

$$ROCH_2C{\equiv}CMgBr + R'_3SiCl \xrightarrow{Et_3N} ROCH_2C{\equiv}CSiR'_3$$
$$R' = Me, Et .$$

4-Alkoxybut-2-ynyl ethers can be prepared from bisbromomagnesioacetylene and α-halogeno-ethers[21]:

$$BrMgC{\equiv}CMgBr + 2\,ClCH_2OR \rightarrow ROCH_2C{\equiv}CCH_2OR .$$

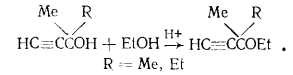
A promising method suitable for industrial application is the addition of prop-2-ynol to substituted alkenes in acid media:

$$HC{\equiv}CCH_2OH + R_2C{=}CR'_2 \rightarrow HC{\equiv}CCH_2OCR_2CHR'_2 .$$

Its possibilities have not yet been completely revealed because of the limited number of alkenes used in this reaction (fluoroalkenes[61], isobutene[62], norbornenes[63,64]).

Prop-2-ynyl ethers containing a halogen atom adjacent to the triple bond can be obtained by the use of hypohalites[65,66]:

$$HC{\equiv}CCH(R)OR' \xrightarrow{+KOCl} ClC{\equiv}CCH(R)OR' .$$



Prop-2-ynyloxyalkyl ethers (formals, acetals) are usually obtained from α-chloroalkyl ethers and prop-2-ynol in the presence of tertiary amines[67,68] or on the contrary from α-chloroalkyl prop-2-ynyl ethers and alcohols[69,70]:

$$\left.\begin{array}{l} HC{\equiv}CCH_2OH + ClCH(R')OR \\ HC{\equiv}CCH_2OCH(R')Cl + ROH \end{array}\right\} \xrightarrow{-HCl} HC{\equiv}CCH_2OCH(R')OR .$$

Prop-2-ynyl prop-2-ynyloxyalkyl ethers can also be obtained from prop-2-ynol and aldehydes in the presence of dehydrating agents[71]. Another widely used method for obtaining prop-2-ynyloxyalkyl ethers is the acid-catalysed addition of propargyl alcohols to vinyl ethers[72] and dihydropyran[73]. It is applicable also to the preparation of such ethers of organosilicon alcohols[60].

Tertiary prop-2-ynyl ethers are obtained by different methods from those for the primary ethers. When tertiary propargyl alcohols are heated (at 100 °C for 10 h) with ethanol in the presence of concentrated sulphuric acid, ethyl

tertiary propargyl ethers are obtained[74]:

This method can be used also to obtain tertiary homopropargyl ethers[75]. According to patent claims[76] tertiary propargyl ethers are formed by the action of alkoxides on acetylenic tertiary chlorides:

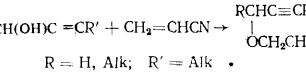
The reaction between acetylenic tertiary alkoxides and alkyl bromides in liquid ammonia gives significantly higher yields[77]. A tertiary benzyl propargyl ether has been obtained similarly; the reaction occurs also in the presence of sodium or sodamide in liquid ammonia[57,58]. Tertiary propargyl ethers are formed also by the alkaline fission of ethers of tetraalkylbutynediols[78] (Favorskii's reaction).

Hologenated ethers are obtained in various ways. Satisfactory yields of 1-chloroalkyl prop-2-ynyl ethers are given by the Henry–Litterscheidt method, by the action of hydrogen chloride or bromide on a mixture of an aldehyde and the alcohol[9]:

The method can be used to obtain C_{sp}-silylated[79-81] and C_{sp}-chloromethylated[82,83] propargyl ethers. When the chlorinating agent is boron trichloride the yield of 1-chloroethyl prop-2-ynyl ether rises[84] to 71%. Three modifications are proposed[85] for this method of obtaining α-halogenoalkyl ethers of primary and secondary propargyl alcohols. 2-Bromoalkyl prop-2-ynyl ethers can be prepared from Iotsich reagents and 1-chloroalkyl 2-bromoalkyl ethers[86]:

2-Halogenoethyl prop-2-ynyl ethers can be obtained from propargyloxyethanol and a halogenating agent (phosphorus tribromide, thionyl chloride)[87,88]:

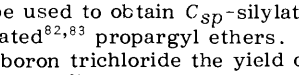
2,2,2-Trichloro-1-halogenoethanols are prepared similarly[89,90]. Prop-2-ynyl ethers containing halogen in the γ, δ, and more remote positions are obtained by alkylating prop-2-ynol with alkylene dihalides in the presence of alkali-metal amides in liquid ammonia[28], utilising the greater polarisability of the carbon–bromide than of the carbon–chlorine bond:



Homopropargyloxyalkyl ethers are formed[91,92] by the action of α-chloroalkyl ethers on terminal β-acetylenic alcohols in the presence of *NN*-dimethylaniline.

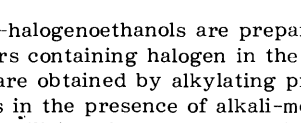
The action of aldehydes and secondary amines on prop-2-ynol forms aminoalkyl ethers[93]:

Since aminophenols contain two active centres (amino and hydroxy), their ethers cannot be obtained directly from prop-2-ynyl halides. Aminoaryl ethers are prepared from *N*-acylated aminophenols by the action of 3-bromopropyne in acetone in the presence of potassium carbonate, followed by alkaline hydrolysis[94]. The reaction of propargyl alcohols with acrylonitrile in the presence of sodium methoxide gives 2-cyanoethyl prop-2-ynyl ethers[95]:



Prop-2-ynyl ethers of silanols (prop-2-ynyloxysilanes) are most often obtained by reaction between trialkylchlorosilanes and propargyl alcohols in the presence of organic bases. The first report[96] that tertiary prop-2-ynyl ethers of trialkylsilanols had been obtained was not confirmed[97,98]. Compounds containing one prop-2-ynyloxy-group attached to the silicon atom were first prepared in 1960 by reaction between prop-2-ynol and monochlorosilanes in the presence of pyridine[10]. Diprop-2-ynyloxysilanes have been obtained from methyldichlorosilane and acetylenic alcohols in the presence of dimethylaniline[99] or triethylamine[100]:

Prop-2-ynyloxysilanes containing aromatic substituents attached to the silicon atom have been prepared similarly[101-103]. 4-Chlorobut-2-ynyloxysilanes have been obtained by reaction between 4-chlorobut-2-ynol and monochlorosilanes[104]:

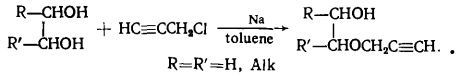


Si-Chloromethylated ethers are formed from chloromethyldimethylchlorosilane and propargyl alcohols[105]. Ethers of methylsilanols have been obtained[106] from the corresponding methylchlorosilanols and prop-2-ynol in the presence of urea (yield 70%):

Tetraprop-2-ynyloxysilane has been obtained by the transesterification of tetramethoxysilane with a considerable excess of prop-2-ynol in the presence of toluene-*p*-sulphonic acid, which enables formation of a difficultly separable mixture of methoxy-prop-2-ynyloxysilanes to be avoided[106]. The prop-2-ynyl ether of triethylsilanol can be obtained in 60–70% yield from triethylsilanethiol and prop-2-ynol[107]:

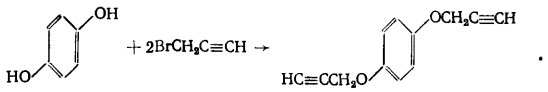
Tertiary propargyl ethers of silanols can be obtained also[108] by the uncatalysed reaction between prop-2-ynols and aminosilanes, which involves fission of the silicon–nitrogen bond, in contrast to the reaction with alkanols:

The dehydrocondensation of propargyl alcohols with alkyl(aryl)silanes also yields ethers of silanols[109]:



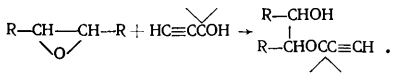
Ethers containing a siloxane group of the type

have been obtained by the dehydrocondensation of prop-2-ynol with tetra-alkyldisiloxanes in the presence of zinc chloride in benzene[110]:



Prop-2-ynyl ethers of glycols can be prepared in various ways. A general method for obtaining partial ethers involves reaction between 3-chloropropyne and monosodio-derivatives

of diols[111]:

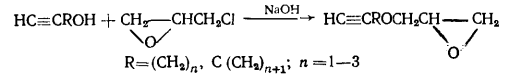


Ethers of polyhydric phenols are obtained by the action of 3-bromopropyne on the phenols[112]:

Mono- and di-ethers of quinol can be obtained by varying the quantities of alkaline component and aryl halide[112]. Prop-2-ynyl ethers containing a vinyl group have been prepared by the reaction[36]

$$CH_2{=}CHO(CH_2)_nONa + BrCH_2C{\equiv}CH \rightarrow CH_2{=}CHO(CH_2)_nOCH_2C{\equiv}CH \quad n=1{-}3 .$$

A convenient route to the monoethers of vicinal glycols is the reaction between propargyl alcohols and symmetrically substituted oxirans in the presence of catalytic quantities of Lewis acids[111,113–119]:



Boron trifluoride etherate[120], a trialkyl phosphite[121], or tin tetrachloride[122–124] can be used as catalyst. The method is restricted to symmetrical oxirans because fission of the epoxide ring is non-selective[125,126]. Furthermore, epichlorohydrin is almost quantitatively and selectively cleaved with the formation of primary monoprop-2-ynyl ethers[122–124,127]. The monoether of ethylene glycol is obtained from prop-2-ynol and 2-chloroethanol in the presence of potassium[120] or sodium[128] hydroxide:

$$ClCH_2CH_2OH + HC{\equiv}CCH_2OH \xrightarrow{-HCl} HOCH_2CH_2OCH_2C{\equiv}CH .$$

It can also be prepared from 3-bromopropyne and ethylene glycol[129]. Monoethers of 2,2,2-trihalogenoethanediols are readily obtained by the reaction of chloral or bromal hydrate with various propargyl alcohols in the presence of hydrochloric acid[89,130]:

$$CH(OH)_2 + HC{\equiv}CCRR'OH \rightarrow CX_3CH(OH)OCRR'C{\equiv}CH$$
$$X=Cl, Br;\ R=R'=H, Alk;\ R=Alk,\ R'=Ar .$$

The cleavage of 2,2-disubstituted 1,3-dioxolans by phenethynyl-, but-3-enynyl-,[131] and prop-2-ynyl-magnesium bromides[132] leads to the formation of γ-substituted tertiary propargyl ethers of ethylene glycol; the reaction of prop-2-ynylmagnesium bromide with 1,3-dioxolans is accompanied by transformation of the terminal triple bond into a disubstituted bond. Propargyl ethers of glycidol are obtained by the action of epichlorohydrin on acetylenic alcohols in the presence of alkali[133] or the ether complex of boron trifluoride[127]:

Phosphorus-containing propargyl ethers are usually obtained from the corresponding phosphorus acid chlorides in the presence of tertiary amines[134,135]:

$$n\,HC{\equiv}CCH_2OH + R_{3-n}PCl \xrightarrow[-n\,HCl]{Et_3N} R_{3-n}P(OCH_2C{\equiv}CH)_n \quad n=1,2 .$$

On standing the ethers are converted into the isomeric allenyl and prop-1-ynyl ethers[136].

C_{sp}-Substituted ethers are prepared by the action of Iotsich reagents obtained from propargyl ethers on alkyl[44], aryl, and hetaryl[137] halides, as well as by the alkylation of prop-2-ynyl ethers with alkyl halides in the presence of sodamide in liquid ammonia[138,139]. A general method for obtaining such substituted ethers is the reaction between acetals and Iotsich reagents based on monosubstituted alkynes[140]:

$$R'R''C(OEt)_2 + RC{\equiv}CMgBr \rightarrow EtOCR'R''C{\equiv}CR .$$

The γ-alkylated ethers can be obtained by the action of alcohols on 1-alkyl-1,3-dichloropropenes in dimethyl sulphoxide at 130–140 °C[141]:

$$ClCH_2CH{=}C(Cl)Me + ROH \xrightarrow[-2HCl]{} ROCH_2C{\equiv}CMe .$$

The action of alkylmagnesium halides on 4-bromobut-2-ynyl ethers also yields 3-alkylated propargyl ethers[142]. A high yield of 3-phenylprop-2-ynyl vinyl ether is formed on the vacuum distillation of bisphenylprop-2-ynyl acetal in the presence of ammonium dihydrogen phosphate[143]:

$$(PhC{\equiv}CCH_2O)_2CHMe \xrightarrow{\Delta} PhC{\equiv}CCH_2OCH{=}CH_2 .$$

1,3-Diphenylprop-2-ynyl ethers can be obtained in good yields[144,145] by heating acetals of aromatic or heterocyclic aldehydes with phenylacetylene in the presence of zinc chloride.

III. PHYSICOCHEMICAL AND SPECTROSCOPIC PROPERTIES

The boiling points of individual branched-chain homologous prop-2-ynyl ethers, in contrast to those of the corresponding alcohols, increase from the primary to the secondary and then to the tertiary ether.

The dipole moments of prop-2-ynyl ethers, unlike those of the corresponding halogeno-derivatives, exceed those of the allyl and propyl ethers, which is explained by a reversal in the direction of the dipole[146]. The inductive constant of the prop-2-ynyloxy-group $\sigma^*(CH{\equiv}CCH_2O) = 2.18$ is almost treble that for the prop-2-ynyl group[147]. Quantum-chemical models of prop-2-ynol and of the prop-2-ynyloxy-anion give a clear idea of the distribution of charges among the atoms and of the strengths of the bonds[148].

Prop-2-ynyl ethers are less basic than the corresponding allyl and propyl ethers because of the decrease in the $+I$ effect in the sequence propyl < allyl < prop-2-ynyl. The centre of maximum basicity in prop-2-ynyl ethers is the oxygen atom. In isostructural ethers $CH{\equiv}CEl(CH_3)_2OCH_3$ the oxygen atom is rather more basic when El = Si than C, which is attributed to $d_\pi-p_\pi$ interaction in the opposite direction to the inductive effect[149]. The oxygen atom is less basic in prop-2-ynyl ethers of silanols than in the saturated analogues, owing to the $-I$ effect of the prop-2-ynyl group and its π-electron-accepting power. 2,2-Dichlorovinyl prop-2-ynyl ether is more basic than the corresponding allyl compound[150].

The presence of intense characteristic absorption bands[151–155] makes it possible to use infrared spectroscopy for the reliable identification of prop-2-ynyl ethers or their detection in a mixture of unsaturated compounds. The spectra of these compounds contain bands characteristic of ≡C–H and C≡C bonds[156,157]. Stretching vibrations of the former bond produce a band in the range 3295–3320 cm^{-1}; the band in the region of 600 cm^{-1}, caused by deformation vibrations (overtone 1200 cm^{-1}), is unsuitable for analytical purposes, since other functional groups are able to absorb in these regions. For the same reasons caution is necessary in the interpretation of structure by means of the band at 1325–1336 cm^{-1},

which is ascribed[158] to angular vibrations of the methylene group in the prop-2-ynyl fragment. Greater importance attaches to the weak band due to the acetylenic bond, which usually appears in the frequency range 2110–2130 cm^{-1}.

A recent study of the infrared spectra of prop-2-ynyl ethers has provided direct evidence of the absence of conjugation through the methylene bridge between the lone electron pair of the oxygen atom and the π electrons of the triple bond[159]. Study of the Raman, ultraviolet, and nuclear magnetic resonance spectra also indicates absence of $p-\pi$ conjugation[160].

The signals from acetylenic protons in the ^1H n.m.r. spectra of alkyl prop-2-ynyl ethers appear down-field relative to those of α-alkoxyacetylenes. The ^1H n.m.r. spectra[161–163] of prop-2-ynyl ethers containing a $CH{:}CCH_2O$ fragment exhibit a triplet in the range $\delta = 1.4–2.2$ ppm (:CH protons) and a doublet at 4.05–4.25 ppm (protons of the $:CCH_2$ group). The characteristic spin–spin coupling constant is 2–3 Hz.[164]

In order to investigate the possibility of hydrogen bonding, chemical shifts of the signal from the acetylenic proton in the n.m.r. spectra of alkyl prop-2-ynyl ethers and their non-oxygen analogues have been measured in concentrated solutions and on dilution with inert or proton-donor solvents[165]. The presence of oxygen causes a considerable shift in the signal, as a consequence of formation of a hydrogen bond with the oxygen atom.

A study has been made of the dependence of the mass-spectrometric fragmentation of substituted phenyl prop-2-ynyl ethers on the nature of the cyclic substituents[166]. In several ethers (e.g. the phenyl ether itself) electron bombardment produces skeletal rearrangements with the loss of carbon monoxide and formation of the $[M-CO]^+$ ion, which has not yet found a theoretical interpretation[167]. In this respect it is interesting that the carbon monoxide molecule is among the stable neutral species most often eliminated in rearrangements of aromatic compounds. The mass spectra of tertiary propargyl ethers of ethanol have been examined[168].

IV. REACTIVITY

Prop-2-ynyl ethers undergo diverse reactions involving the acetylenic hydrogen atom, the triple bond, and also the ethereal oxygen atom. Their reactivity is due not only to the actual nature of the acetylenic bond but also to the presence of the electron-accepting ether group[169,170].

1. Rearrangement

Prop-2-ynyl ethers undergo various rearrangements with the formation of isomeric compounds. Thus the methyl ether isomerises into allenyl methyl ether when heated with solid caustic potash[171]; sodium methoxide in dimethyl sulphoxide has a similar effect[172]:

$$MeOCH_2C{\equiv}CH \rightarrow MeOCH{=}C{=}CH_2 .$$

The n.m.r. spectra show that the mixture does not contain even traces of methyl prop-1-ynyl ether. The latter does not form the allenyl ether under the influence of sodium methoxide in the presence of dimethyl sulphoxide, which implies that it is more stable than the prop-2-ynyl ether[172]. Rearrangement does not take place in the formation of ethers from the corresponding acetylenic chlorides and alcohols in the presence of alkalis[173,174], nor in the replacement of halogen in various prop-2-ynyl halides by means of alkoxides[7].

A method of preparing allenyl ethers[11] was based on the isomerisation of prop-2-ynyl ethers in the presence of potassium t-butoxide:

$$HC{\equiv}CCH_2OR \rightarrow CH_2{=}C{=}CHOR .$$

The allenyl ether is readily metallated by butyl-lithium:

$$CH_2{=}C{=}CHOR + BuLi \rightarrow CH_2{=}C{=}C(Li)OR .$$

When an ether is alkylated with an alkyl halide in liquid ammonia, a mixture of allenyl and prop-2-ynyl ethers is formed, whereas alkylation in an oxolan–ether mixture gives only α-alkylallenyl ethers. The action of organomagnesium compounds on prop-2-ynyl ethers in the presence of cuprous bromide yields allene hydrocarbons[12]:

$$MeOCRR'C{\equiv}CR'' + R'''MgBr \xrightarrow{Cu_2Br_2} RR'C{=}C{=}CR''R''' .$$

Under the influence of aldehydes or ketones in the presence of potassium hydroxide alkyl and aryl prop-2-ynyl ethers give mixtures of acetylenic ether–alcohols and allenyl ethers[172]:

$$PhOCH_2C{\equiv}CH + RCHO \xrightarrow[DMF]{KOH} \begin{cases} \rightarrow PhOCH_2C{\equiv}CCH(R)OH \\ \rightarrow PhOCH{=}C{=}CH_2 \end{cases} .$$

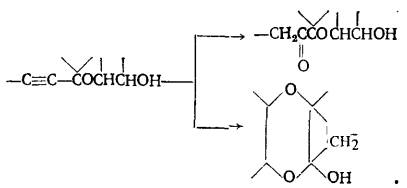
Similar isomerisation of prop-2-ynyl ethers in alkaline medium has been observed by several workers[175,176].

Alkynyl 2-bromoalkyl ethers, on dehydrobromination in the presence of sodamide in a liquid ammonia, undergo partial rearrangement into the corresponding prop-2-ynyl ethers. However, several workers[177] cast doubt on the isomerisation of terminal acetylenic compounds under the influence of this reagent. A tendency to prototropic isomerisation of aryl prop-2-ynyl ethers has been observed also under the influence of alcoholic alkali[33] or potassium t-butoxide[178]. For example, the preparation of prop-2-ynyl ethers from the bromides involves formation of a mixture of prop-2-ynyl, allenyl, and prop-1-ynyl ethers:

$$BrCHR''C{\equiv}CR' + ROM \longrightarrow \begin{cases} \rightarrow ROCHR''C{\equiv}CR' \\ \rightarrow ROCR''{=}C{=}CHR' \\ \rightarrow ROC{\equiv}CCH_2R' \end{cases}$$

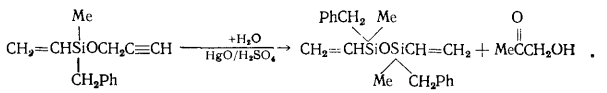
R=Alk, Ar; R'=H, Alk, Ar; R''=H, Alk .

Attempts to effect the rearrangement of phenyl and naphthyl prop-2-ynyl ethers under the conditions of the Claisen reaction were unsuccessful[179].



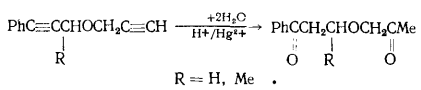
2. Addition

The most characteristic property of prop-2-ynyl ethers is their ready ability to undergo quantitative hydration to ether–ketones. Thus gentle heating of the methyl ether with water in the presence of mercury(II) sulphate forms methoxyacetone[25]:



$$HC{\equiv}CCH_2OMe + H_2O \xrightarrow{HgSO_4} MeCOCH_2OMe .$$

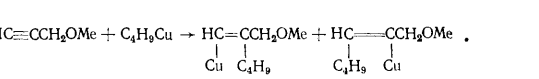
A rapid and convenient method has been developed[45] for the catalytic hydration of prop-2-ynyl ethers to the corresponding ethers of hydroxyacetone. Other alkyl prop-2-ynyl ethers have also been subjected to hydration, as well as those containing aromatic, alicyclic, and heterocyclic groups[17,37,139]. The monoethers of α-glycols undergo hydration in two ways determined by the polar and steric effects of substituents,



mainly in the prop-2-ynyl fragment[180-182]:

Hydration of the ethers of silanols in the presence of a mixture of mercuric oxide and sulphuric acid is accompanied by rupture of the silicon–oxygen bond, with formation of the corresponding disiloxane and hydroxyacetone[103]:

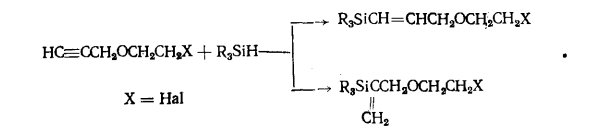
The hydration of prop-2-ynyl ethers of phenylprop-2-ynols gives phenacylalkyl ethers of hydroxyacetone[182]:



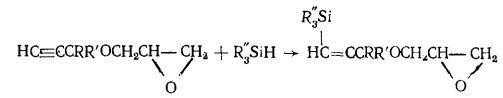
A monoadduct is obtained by the action of concentrated hydrochloric acid on methyl prop-2-ynyl ether in the presence of mercury(II) chloride[183]:

The catalytic effect is due to the formation of complexes with hydrogen chloride, not intermediate organomercury compounds. The kinetics of the addition of elementary bromine to the methyl ether

indicates a termolecular process[184]. A kinetic study has been made also of the addition of mercuric chloride to the methyl ether in the presence of lithium chloride[185]. Addition of a copper alkyl to a prop-2-ynyl ether[186] gives a mixture of isomers:



The organophosphorus esters smoothly add iodine[187]:



In the presence of a Speier catalyst prop-2-ynyl ethers readily undergo hydrosilylation[188]:

With hydroxylated ethers under these conditions the process is unaccompanied by dehydrocondensation: i.e. the hydroxy-group is unaffected[75]. Halogenated ethers give mixtures of isomeric adducts without involving the halogen atom[189]:

In the hydrosilylation of tertiary prop-2-ynyl ethers of chloral hydrate, however, products of addition at the multiple bond are accompanied by those in which chlorine atoms of the trichloromethyl group have been replaced by a trialkylsilyl radical[190]. The epoxide ring is preserved when prop-2-ynyl ethers of glycidol undergo hydrosilylation[124,127,191-193]:

Prop-2-ynyl ethers are readily hydrogenated in the presence of Raney nickel[137], palladium[139], and also platinum[57] catalysts, whose activity is the main factor determining the reaction velocity. For example, the rate of hydrogenation of the monoether of ethylene glycol on a nickel–molybdenum catalyst exceeds by a factor of 13 the rate when Raney nickel is used under the same conditions[194]. Platinum black can be used[57] for the exhaustive hydrogenation of a tertiary propargyl ether of benzyl alcohol. In the presence of a palladium catalyst deactivated with lead acetate the triple bond is hydrogenated to a double bond[195]:

3. Substitution

(a) Reactions with Metals

The tendency of prop-2-ynyl ethers to undergo substitution is evident primarily in their reactions with metals and organometallic compounds. The acetylenic hydrogen atom is readily replaced by a heavy metal. On treatment with ammoniacal silver nitrate white precipitates of silver salts separate. Cuprous chloride solution gives yellow precipitates of copper(I) salts.

Sodium derivatives of the ethers should be prepared by means of sodamide in liquid ammonia[196]. Lithium derivatives are obtained from butyl-lithium and the ether in diethyl ether[197]. Organocalcium derivatives have been obtained[198] in 90% yield by the reaction

Organomagnesium derivatives of prop-2-ynyl ethers (Iotsich reagents) are smoothly formed in ether or oxolan[199], and will react with almost all the reagents that undergo organomagnesium synthesis[137,197-201]. The reactions of the magnesium derivatives have been studied most thoroughly. Methyl prop-2-ynyl ether in its reactions with organomagnesium compounds is more active than hex-1-yne by a factor of almost 12,[169] which is explained by the ability of the oxygen atom to attract electrons and thereby to increase the mobility of the acetylenic hydrogen atom.

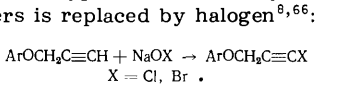
(b) Reactions with Carbonyl Compounds

Organomagnesium derivatives of prop-2-ynyl ethers are widely used for the synthesis of acetylenic ether–alcohols. When aldehydes and ketones are treated with Iotsich reagents obtained from these ethers, the corresponding secondary and tertiary ether–alcohols are formed. Iotsich reagents from alkyl prop-2-ynyl ethers give alcohols in 60–70% yields[199]. The methyl ether with aldehydes forms ether–alcohols in 60% yield[199,202]:

Similarly, 5-phenoxypent-3-yn-2-ol has been obtained (yield 50%) from phenyl prop-2-ynyl ether, iodoethane, and acetaldehyde[201].

Prop-2-ynyl ethers are able to react with aldehydes and ketones also under the conditions of the Favorskii reaction. The ethyl ether condenses with diphenyl ketone in the presence of potassium hydroxide in oxolan even at room temperature[203]:

The propyl and butyl ethers condense smoothly with various ketones[18,39,204,205] and alcoholic ketones[29,206].



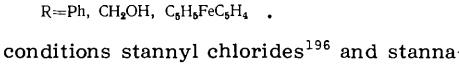
The condensation of prop-2-ynyl ethers with carbonyl compounds takes place also in liquid ammonia[207]. Thus the methyl ether reacts with benzaldehyde to give a 68% yield of 1-phenylbut-2-yne-1,4-diol.

Organomagnesium derivatives of alkyl prop-2-ynyl ethers are carboxylated by means of dialkyl carbonates[208,209] and oxalates[40] in ethereal solvents, being converted into the corresponding alkoxybutynoic esters. With α-chloroalkyl ethers the magnesium derivatives form γ-substituted alkoxyalkyl prop-2-ynyl ethers[197], and with orthoesters acetals are formed[73].

(c) Other Substitutions

In liquid ammonia the Iotsich reagents are readily alkylated by alkyl bromides[137,138].

On treatment with hypohalites the acetylenic hydrogen atom in the ethers is replaced by halogen[8,66]:



The halogen in the products can easily be substituted[66]:

The action of a copper(I) salt and ammonium chloride on the ethers yields diethers of "head to head" type[210]:

Dehydrodimerisation takes place also in the oxidative condensation of *p*-ferrocenylphenyl prop-2-ynyl ether[211] in a mixture of ether, pyridine, and methanol (2 : 2 : 1) in the presence of copper salts[212]:

Under certain conditions stannyl chlorides[196] and stannanols[213] react with alkyl prop-2-ynyl ethers with substitution of the acetylenic hydrogen atom by a trialkylstannyl group:

(d) Aminomethylation

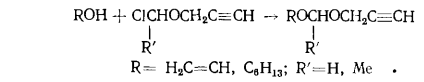
Prop-2-ynyl ethers react under the conditions of the Mannich reaction with formaldehyde and secondary amines to form the aminomethylated ethers[25,35,47,55,139,214–216]:

The reaction is usually conducted in the presence of copper(I) chloride in dioxan. Copper acetate has also been proposed as catalyst[139].

The uncatalysed aminomethylation of hydroxylated ethers involves the hydroxyl hydrogen atom[217]:

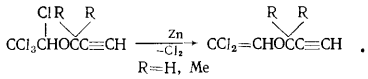
Preliminary chemical protection of the hydroxy-group enables this undesirable process to be suppressed and the desired products to be obtained[218]. Aminomethylation of the monoethers of ethylene glycol in the presence of cuprous chloride involves the ethynyl hydrogen atom without affecting the hydroxyl hydrogen[219].

Results have been published[101] indicating the possibility of obtaining C_{sp}-aminomethylated derivatives of prop-2-ynyl ethers of silanols:



The aminomethylation of the halogenated ethers does not involve the halogen atom[205]:

(e) Reactions of Halogenated Ethers Involving the Halogen Atoms



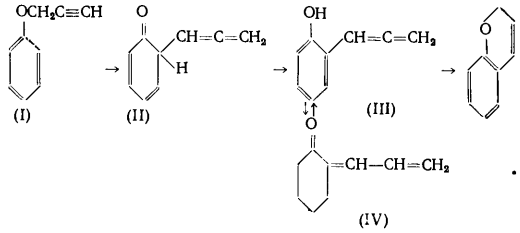
Under certain conditions halogen atoms present in prop-2-ynyl ethers can be replaced by various groups. Thus prop-2-ynyl acetals of aldehydes are formed by reaction of the chloroalkyl ethers with alcohols[220–222]:

1- and 2-Halogenoalkyl prop-2-ynyl ethers react readily with Iotsich reagents obtained from monosubstituted acetylenes[86] and also with alkali-metal alkoxides[223].

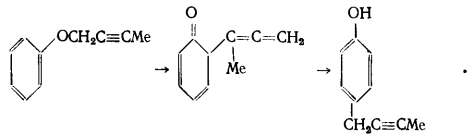
Investigation of the behaviour of mono- and di-halogenated prop-2-ynyl ethers towards various nucleophiles has provided an experimental basis for a suggested activity series of halogen atoms depending on polar and steric factors. This can be used in directed syntheses of technically valuable products[223].

Tertiary propargyl ethers of 1,2,2,2-tetrachloroethanol are dehalogenated in the presence of zinc with the formation of dichlorovinyl prop-2-ynyl ether[224]:

Subsequent addition of prop-2-ynol yields the diprop-2-ynyl acetal of 2,2-dichloroacetaldehyde:

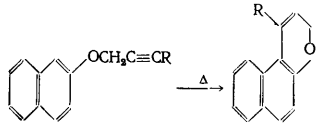


Organosilicon alkoxyalkenynes have been obtained[225] by the dehydrohalogenation of 3-silylated prop-2-ynyl ethers containing a 1-bromomethyl group:



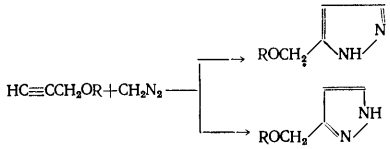
4. Cyclisation

The special synthetic value of prop-2-ynyl ethers consists in the possibility of transforming them into various difficultly accessible carbocyclic and heterocyclic compounds.

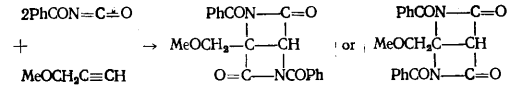


The unique scheme proposed[226] for the cylisation of the aryl ethers involves the formation, from the phenyl ether (I) as example, of the allenyl-dienone (II) (rate-determining stage) followed by rapid enolisation into allenylphenol (III), sigmatropic migration of hydrogen with conversion into (IV), and cyclisation to chromen:

In the case of but-2-ynyl phenyl ether the intermediate methylallenyl-dienone rearranges into but-2′-ynylphenol:



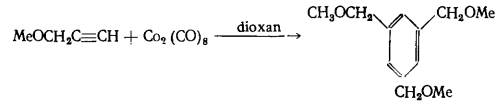
The thermal cyclisation of 4-phenoxybut-2-ynyl phenyl ether forms phenoxymethylbenzopyran[227]. The C_{sp}-substituted naphthyl ethers cyclise in the presence of diethylaniline into the corresponding naphthopyrans[228]:



The reaction involves a Claisen rearrangement. Phenyl prop-2-ynyl ethers when heated also undergo a sigmatropic rearrangement with formation of the corresponding chromens[229]. The cyclisation of aliphatic propargyl ethers has been described[230-233].

Examples are known of cyclisation in reactions with various types of dipoles. A method for obtaining alkoxylated pyrazoles is based on interaction with diazoalkanes[14]:

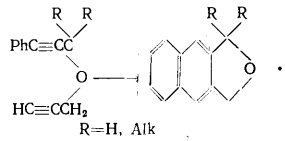
The reaction involves intermediate formation of the zwitterion $^{+}N_2CH_2CH{:}C^{-}R$, the uniform charge separation in which is confirmed by absence of a solvent effect on the proportions of isomers formed.



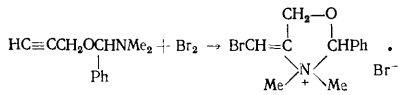
Prop-2-ynyl ethers have been subjected to intermolecular cyclisation with benzoyl and trichloroacetyl isocyanates[170]. The benzoyl compound and the methyl ether in diethyl ether at 0 °C give a product which was regarded as a diadduct:

Trichloroacetyl isocyanate reacts far more slowly; under severe conditions a mixture of isomers of cyclic and linear structure is obtained:

Methyl prop-2-ynyl ether undergoes cyclisation to an alkoxymethylquinol under the influence of iron carbonyls[234]. Similarly, trimerisation with formation of a mesitylene derivative occurs on heating in an organic solvent in the presence of a metal carbonyl[235]:



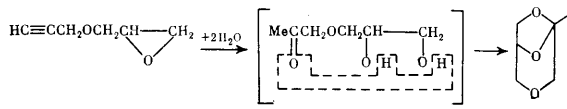
1,1-Diallylcyclopropane has been synthesised by the addition of allylzinc bromide to the methyl ether[13]:



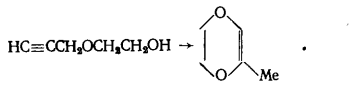
Replacement of methyl by phenyl facilitates cyclisation and increases the yield of the desired product.

Intramolecular cyclisation of phenylprop-2-ynyl prop-2-ynyl ethers in *p*-xylene yields naphtho-oxolans[236]:

The thermal cyclisation of C_{sp}-substituted prop-2-ynyl ethers forms 2*H*-chromens in 60% yield[237].



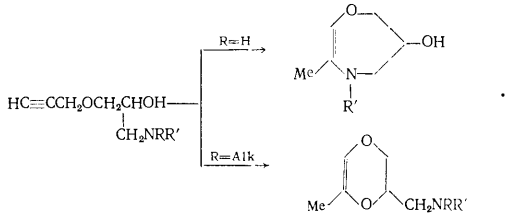
The bromocyclisation of α-dimethylaminobenzyl prop-2-ynyl ether yields 4-bromomethylene-3,3-dimethyl-2-phenyloxazolidinium bromide:



2-Halogenoalkylated prop-2-ynyl ethers are used in the synthesis of difficultly accessible prop-2-ynyated 1,4-dioxans[238].

A cyclobutene derivative is formed in the photochemical addition of methyl prop-2-ynyl ether to vinylene carbonate[239]. The catalytic oligomerisation of butadiene with alkynyl prop-2-ynyl ethers leads to the formation of 4,5-disubstituted cyclodeca-1,4,7-trienes[240].

Cyclisation of the prop-2-ynyl ether of glycidol gives trioxabicyclo-octane[241], presumably with intermediate formation of an acetonyl ether of glycerol, which cyclises by intramolecular acetalisation:



Cyclisation of the ethers of vicinal diols has been studied[111, 120,129]. Prop-2′-ynyloxyethanol in 2-ethoxyethanol in the presence of potassium hydroxide forms 2,3-dihydro-5-methyl-1,4-dioxin[120]:

Cyclisation of the ethers of alkylated ethylene glycols gives mixtures of alkylated dihydro-1,4-dioxins, isomeric heterocycles with an exocyclic double bond, and vinylated 1,3-dioxolans[111,129]. Under these conditions the cyclisation of

prop-2'-ynyloxycyclohexanol yields geometric isomers of dihydrocyclohexanodioxin.

The direction of the base-catalysed intramolecular cyclisation of monoprop-2-ynyl ethers of aminoalkylated α-glycols is determined by the degree of substitution at the nitrogen atom[242]. Cyclisation of the tertiary amines involves the hydroxy-group and gives dihydroaminoalkyl-1,4-dioxins, but that of the secondary amines involves the nitrogen–hydrogen bond and yields oxazepine derivatives:

V. PRACTICAL APPLICATION

Prop-2-ynyl ethers are continually finding new fields of practical application in addition to their use in organic synthesis. They can be applied as stabilisers for cellulose acetate and goods based thereon (acetate rayon, cinematograph film, plastic materials, etc.), which age under the influence of light, temperature, etc. during service, with a consequent deterioration in their physicochemical properties, premature failure, and wear[243]. Benzyl prop-2-ynyl ether has been proposed as stabiliser to increase the resistance of cellulose acetate to light[244]. Stability towards light is also acquired by lower chlorinated hydrocarbons on the addition of propyl, butyl, isobutyl, isopentyl, and phenyl prop-2-ynyl ethers together with a stabiliser[243].

The ethers with aryl and diaryl groups can serve as monomers for the synthesis of heat-resistant polymers[112]. Oligomers of the type $HO[CH_2C{:}CCH_2OCR(OH)]_nR'$ (R, R' = H, Alk) are used as power-consuming additives for rocket fuels, improving the ballistic properties of the compositions[245].

Several hydroxylated prop-2-ynyl ethers have found application in the synthesis of auxiliary agents for the textile and paper industries[246]. Products of the hydrosilylation of prop-2-ynyl ethers of silanols are used as finishes for textile materials[247]. Monoprop-2-ynyl ethers of ethylene and propylene glycols may find application in electroplating as brightening agents[248]. Dibenzocycloheptatrienes obtained from prop-2-ynyl ethers are employed in the pharmaceutical industry with inert carriers[249].

1. Biological Properties

Many prop-2-ynyl ethers possess biological activity and can be used in agriculture both as toxic chemicals and in veterinary practice to destroy parasites and in the fight against gastric diseases in farm animals[250–252].

The use has been proposed of preparations based on these ethers that destroy arachnoid mites, leaf aphids[253], beetles and rats[252], house-flies[254], nematodes and other parasitic worms in the soil[250]. The compound $I_2C{:}CClCH_2OR$, obtained by the interaction of a prop-2-ynyl ether, chloroform, and iodine, stimulates the growth of poultry[255]. The same preparation has been recommended for use in veterinary practice for the treatment of diarrhoea, and its isologue for the treatment of gastric diseases in pigs[252].

Prop-2-ynyl ethers also possess strong bactericidal and herbicidal properties[256]: the ether of 2',4',6'-tri-iodo-2,4-dinitroazophenol is a more active bactericide than is chloramphenicol[257]. 4-Chlorobut-2-ynyl *m*-chlorophenylcarbamate (Barban) is a herbicide for the post-germination treatment of fine-grained cereals against wild oats[258]. Chlorine-containing C_{sp}-silylated prop-2-ynyl ethers of general formula $ClCH_2Si(CH_3)_2C{:}CCH_2OCHRCH_3$ surpass known standard preparations (chloramine, Rivanol, Nitrofungin) in antibacterial activity[259].

There are indications[256] that prop-2-ynyl ethers may serve as starting materials for the synthesis of diverse bifunctional acetylenes and amino-ethers developing fungicidal activity. Several derivatives are pharmacologically active compounds[260]. A tertiary prop-2-ynyl carbamate (Oblivon C) is used as a mild hypno-sedative agent and has an antispasmodic effect[261]. In contrast to prop-2-ynyl ethers[262] homopropargyl aminoacetates possess a strong soporific–anticonvulsant type of psychotropic activity[263–265].

The C_{sp}-iodinated prop-2-ynyl ether of 2,4,5-trichlorophenol is used therapeutically as an antimycotic and antiseptic[266]. The muscarinic action of the prop-2-ynyl ether of choline is double those of the allyl and propyl analogues[266]. C_{sp}-Aminomethylated derivatives of the monoprop-2-ynyl ether of ethylene glycol[264] and diprop-2-ynyl acetal[265] have a mild hypno-sedative action combined with a muscle-relaxant effect and slight antispasmodic properties. Substances having a general hypno-sedative profile include also prop-2-ynyl ethers of silanols[267,268]. The ethers of glycerol possess spasmolytic properties[260], and those of oxan hypnotic properties[266].

1-Alkylprop-2-ynyl ethers of long-chain alcohols $ROCHR'C{:}CH$ ($R = C_6H_{13}$, C_8H_{17}, etc.) have a beneficial effect on blood formation[269]. Prop-2-ynyl ethers of arylated pyranols have been claimed[270] as pesticides. The tertiary prop-2-ynyl ether of the monochlorohydrin of glycerol $HC{:}CC(CH_3)_2OCH_2CH(OH)CH_2Cl$ (an analogue of Mephenesine) is able to relax muscles[122]. The hypothesis that structures having both propargyl and oxiran groups would probably possess antitumour activity was not supported by an investigation of C_{sp}-substituted prop-2-ynyl ethers of glycidol[123]. However, C_{sp}-aminomethylated tertiary ethers of general formula $ROCR'R''C{:}CCH_2N(CH_2CH_2Cl)_2$ do exhibit such activity[271]. Several hydroxylated prop-2-ynyl ethers are perfumes[272].

2. Protection of Metals from Corrosion

The problem of inhibitors of acid corrosion merits close attention, since the rate of corrosion breakdown and the associated material damage are especially large for most metals particularly in contact with acid media[273–280]. In connection with the increasing demand for inhibitors of the high-temperature corrosion of steel in hydrochloric acid recent years have been the concentration of attention on acetylenic compounds, and the preparation of novel functionally substituted compounds of this class has again occupied a primary position in work on fine organic synthesis.

Even mechanical mixtures of known nitrogen-containing inhibitors with certain acetylenic compounds are found to be quite reliable corrosion inhibitors at high temperatures[281,282]. The position of the triple bond has a very strong influence on the protective effect, which is greatest when the bond is terminal[283]. The protective effects of acetylenic compounds fall in the sequence[284] secondary alcohols > primary alcohols > ethers > sulphides > tertiary alcohols > hydrocarbons. Diacetylenic compounds are more promising than vinylacetylene derivatives[285].

Prolonged tests on acetylenic inhibitors in technical 28% hydrochloric acid have demonstrated the stability of prop-2-ynol and its ethers[286,287]. Alkylcycloalkylphosphonic esters of the type $AlkC_6H_{10}PO(OCH_2C{:}CH)_2$ have proved to be effective inhibitors, protecting metals at temperatures up to 100 °C and above[288-290], with the protective effect depending on the size and structure of the radical[284]. Diprop-2-ynyl sulphide, which is comparatively readily available, also has a strong anticorrosive effect[291]. Diprop-2-ynyl ether is a corrosion inhibitor for ferrous metals and nickel in non-oxidising acids[276].

Prop-2-ynyl ethers of phenols also have a protective effect: for example, that of *m*-cresol inhibits the corrosion of steel in hydrochloric acid more effectively than does prop-2-ynol. The protective effect of the *m*-tolyl ether is weakened when the ethynyl hydrogen is replaced by alkyl[292,293]. In the aromatic series the most effective inhibitors of the corrosion of steel and its absorption of hydrogen in hydrochloric acid have been the prop-2-ynyl ethers of 1- and 2-phenylalkanols and of 3-phenylprop-2-ynol[294-296]; the inhibition coefficient increases steadily with temperature. Introduction of a sulpho-group into the benzene (naphthalene) ring weakens the inhibiting properties of the derived ethers[297].

The protective effect of prop-2-ynyl ethers of silanols is determined mainly by the action of products of acid hydrolysis[295]. Among complete and partial prop-2-ynyl and prop-2'-ynyloxyalkyl ethers of glycols the most effective and stable properties are exhibited by diprop-2-ynyl ethers, in particular by that of ethylene glycol[298,299]. Prop-2-ynyl esters of aliphatic acids are less effective corrosion inhibitors than are the corresponding ethers of alcohols and phenols[300]. The introduction of amino-radicals into the ethers considerably diminishes the inhibiting effect[299,300].

Many investigators have been concerned to elucidate the mechanism of the inhibiting effect of acetylenic compounds on acid corrosion[301-306]. An adsorption–polymerisation mechanism is consistent with established laws. Most research workers have shown that the protective action of terminal acetylenes is due to polymerisation by opening of the triple bond, leading to formation of a protective polymer film on the metal surface[301,304]. However, Japanese workers consider[305] that the protective effect of acetylenic compounds is due rather to adsorption than to formation of a polymer film. Acetylenic compounds are adsorbed on iron by means of the triple bonds[278], forming π complexes with the metal, with a consequent positive displacement of the potential on the *I* scale.

Since the mechanism of the protective action of acetylenic compounds in the acid corrosion of metals still remains an open question, further study is required of the influence of their structure on their inhibiting effect.

α,β-Unsaturated Heteroatomic Compounds in 1,3-Dipolar Addition Reactions

V.A.Galishev, V.N.Chistokletov, and A.A.Petrov

The reactions of α,β-unsaturated heteroatomic compounds with an unshared electron pair in the heteroatom, proceeding via the 1,3-dipolar addition mechanism, are examined. The ideas about 1,3-dipolar compounds developed by Huisgen are extended to compounds with elements in the Long Periods (phosphorus and sulphur).
The bibliography includes 231 references.

I. INTRODUCTION

Among the methods for the synthesis of alicyclic and heterocyclic compounds, which play an exceptional role in modern organic chemistry and industry (mainly in the synthesis of polymers, dyes, pesticides, medicinal preparations, etc.), reactions in which ring formation involves the dissociation of π-bonds only, without the scission of any other fragments, occupy a notable place. Such processes include the reactions of carbenes with unsaturated compounds, the dimerisation of allenes, syntheses involving alkadienes (of the 4 + 1 = 5 type), the diene synthesis (4 + 2 = 6), and 1,3-dipolar cycloaddition (3 + 2 = 5 or 3 + 3 = 6).

The term 1,3-dipolar cycloaddition was proposed by Smith in 1938.[1] The complete classification of 1,3-dipolar systems (1,3-DS) was given by Huisgen[2,3]. According to Huisgen's definition, a 1,3-dipolar system can be any compound a–b–c, in which the atom a has an electron sextet and constitutes a positive centre, the atom c has a free electron pair and carries a negative charge, and the atom b has an unshared electron pair. According to Huisgen, six octet-stabilised 1,3-DS with a double bond and twelve octet-stabilised dipoles without a double bond can be constructed with elements in the Second Period. All the 1,3-DS with a double bond are known. Typical 1,3-DS are nitrile imines, nitrile ylids, nitrile *N*-oxides, diazo-compounds, and azides. Reactions involving addition to double bonds via a 3 + 2 = 5 mechanism and dimerisation reactions proceeding by both 3 + 2 = 5 and 3 + 3 = 6 mechanisms are most characteristic of 1,3-DS.

Huisgen's school investigated widely only the reactions of 1,3-DS incorporating the elements of the Second Period. The authors of the present review attempted to analyse on the basis of literature data the possibility of constructing 1,3-DS with participation of the elements of the Long Periods, in particular phosphorus and sulphur. Attention was turned to α,β-unsaturated compounds of the above elements, which correspond to Huisgen's limiting carbenoid structure of the 1,3-DS.

The reactivity of unsaturated compounds containing a heteroatom with an unshared electron pair ($\ddot{Z}$–X=Y, $\ddot{Z}$–X≡Y) in the α-position is determined by the degree of localisation of the unshared electron pair of the element $\ddot{Z}$ and the presence of vacant *d* orbitals in the latter. According to modern ideas, a heteroatom with an unshared electron pair exhibits as a rule an electron-donating effect in relation to the multiple bond: the unshared electron pair of the heteroatom is delocalised (p,π conjugation)[4]. The capacity of heteroatoms with an unshared electron pair for p,π conjugation is determined, according to Tsvetkov and Kabachnik[5], mainly by the nature of the hybridisation of this pair. Since the capacity of heteroatoms for p,π conjugation increases with increasing *p* character of the unshared electron pair, atoms can be arranged in the following sequence in terms of their capacity for p,π conjugation: N > O > S > P. The validity of this sequence has been confirmed by quantitative data for the ability of aromatic phosphines, sulphides, and amines to form polar complexes with strong acceptors (for example Group III metal halides).[6-10]

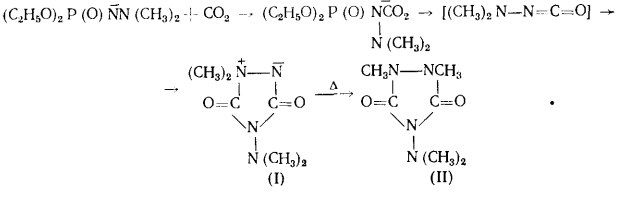
Whereas in the case of elements in the Second Period (O, N) the distribution of electron density in the ground state of the molecule gives rise only to a π-donor effect[11,12], for elements of the Third Period (S, P) the effect caused by the involvement in the conjugation of low-lying 3*d* orbitals ($d-p$) π-conjugation can also be manifested. The interaction of 3*d* orbitals with the electrons of the multiple bonds is responsible for the mesomeric electron-accepting properties of the heteroatoms of the elements of the Third Period: the electron density at the heteroatom increases and that in the multiple bond decreases. It has been shown[13] that the symmetry of the 3*d* orbitals permits overlap with a *p* orbital of the type of (p,p)π-bond. The possibility of ($d-p$)π-conjugation has also been confirmed for arylphosphines[14-16]. The degree of conjugation depends on the electronegativity of the substituents: a more electronegative substituent decreases the electron density at the phosphorus atom, promoting the contraction of the 3*d* orbitals and a stronger ($d-p$)π-interaction[13,17,18]. For example, in this connection, the degree of π-binding in acetylenic compounds of phosphorus(III) is greater than in the ethylenic compounds owing to the greater electronegativity of carbon in the *sp*-hybridised state that in the sp^2-state[19,20].

Thus in the Z–X=Y or Z–X≡Y systems, where X is a heteroatom with unshared electron pairs but without vacant *d* orbitals (Z = O or N), the electron density is markedly displaced from the heteroatom towards the multiple bond. By virtue of the delocalisation of the unshared electron pair, the nitrogen and oxygen atoms manifest π-donor properties[21].

If the heteroatom Z = S or P, then, apart from the electron pairs, low-lying vacant *d* orbitals can participate in the distribution of electron density. The negative inductive and weak π-donor effects of the sulphur atom as well as the involvement of the 3*d* orbitals in conjugation lead to the appearance of opposed shifts[21]. In the phosphorus atom the

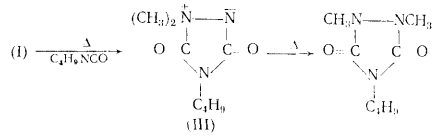
effect due to p,π-conjugation is either absent or is overlapped by the $(d-p)\pi$-conjugation. As stated above, this is associated with the diminution of the p character of the unshared electron pair at the phosphorus atom and therefore, despite the presence of the electron pair, tervalent phosphorus in α,β-unsaturated compounds exhibits π-acceptor properties in relation to the multiple bonds.

The distribution of electron density in π-systems containing heteroatoms with unshared electron pairs has been studied by various physical methods: with the aid of NMR,[12,21-30] ultraviolet spectroscopy[31-36], infrared spectroscopy[37,38], and the determination of dipole moments[39]. The results of these studies indicate different roles of the effects of the p,π- and $(d-p)\pi$-conjugations in the distribution of electron density and hence a difference in the chemical properties of the compounds investigated.



α,β-Unsaturated heteroatomic compounds can enter into 1,3-dipolar addition reactions in two ways. If the unshared electron pair is delocalised over the entire system, then the latter is a dipolarophile and interacts with the 1,3-DS via its multiple bond in accordance with the usual 3 + 2 = 5 cyclisation mechanism with formation of five-membered cyclic compounds. On the other hand, if conditions are created in the initial π-system for the localisation of the unshared electron pair of the heteroatom, two reaction centres are produced (the multiple bond and the heteroatom). Such α,β-unsaturated heteroatomic compounds can undergo cyclisation reactions with participation of the heteroatom both via 3 + 3 = 6 mechanism, i.e. via a mechanism involving the "mixed dimerisation" of the 1,3-DS, and via the 3 + 2 = 5 mechanism, behaving as a 1,3-DS. In the latter case only the electrophilic multiple bonds can behave as dipolarophiles.

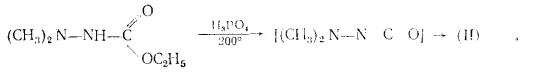
II. OXYGEN- AND NITROGEN-CONTAINING π-SYSTEMS



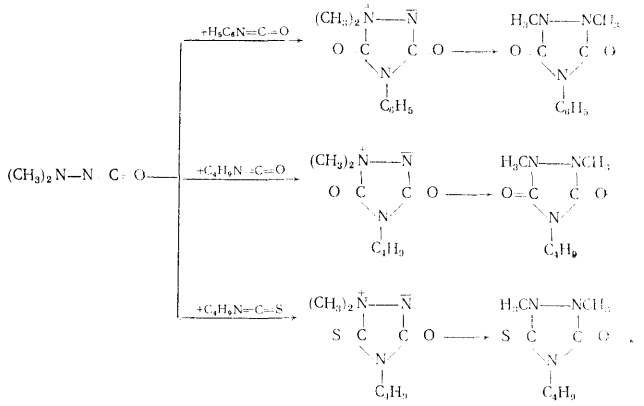
As a rule oxygen- and nitrogen-containing π-systems behave as dipolarophiles in 1,3-dipolar addition reactions. The mode of the reactions of such systems with 1,3-DS does not differ from that of the reactions of unsubstituted olefins and acetylenes: ynamines[40,41], enamines[42-50], and acetylenic [51-59] and vinyl ethers[60-62] form under these conditions five-membered cyclic compounds without the inclusion of the heteroatom in the ring.

The reactions of α,β-unsaturated oxygen-containing compounds, proceeding via a mechanism of the 1,3-dipolar addition type with inclusion of the oxygen atom in the reaction, have not so far been observed.

α,β-Unsaturated nitrogen-containing compounds can react via a 1,3-dipolar cyclisation mechanism with participation of the nitrogen atom only when the system is highly polarised. Thus it has been established[64] that the carboxylation of a phosphoramidate ion[63] (derivative of *N,N*-dimethylhydrazine) leads to the formation of a dimethylaminoisocyanate dimer (I), having the ylid structure. Its pyrolysis leads to the stable 1-dimethylamino-3,4-dimethyl-1,3,4-triazolidine-2,5-dione (II):

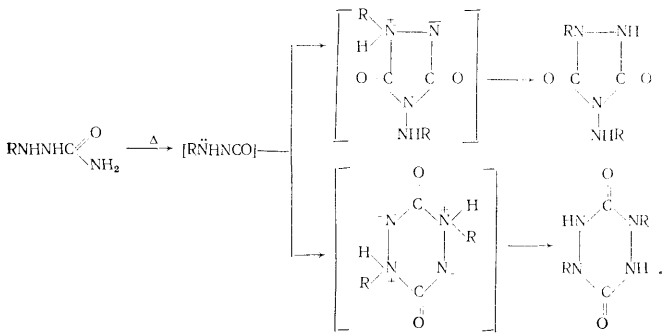


The interaction of the dimer (I) with an excess of butyl isocyanate leads to the formation of a new ylid (III), in which there is also a possibility of the migration of the methyl group:



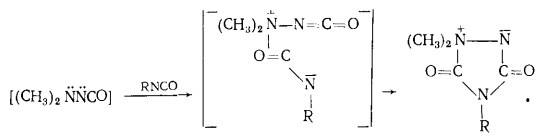
In the case of the t-octyl isocyanate, this type of reaction is reversible and at 90 °C the equilibrium is fully displaced towards the initial reactants, probably owing to steric hindrance.

The ylid structure of compound (I) and its analogues has been demonstrated by the reaction with HCl in benzene and subsequent elimination of methyl chloride. The authors[64] used also another method for synthesising dimethylaminoisocyanate using *N*-dimethylaminourethane:

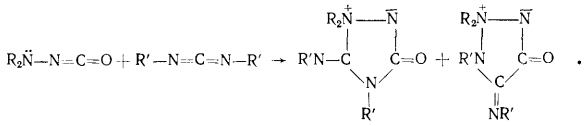


If the reaction is carried out in the presence of isocyanates or isothiocyanates, it is possible to "intercept" the intermediate monomeric dimethylaminoisocyanate:

The stable triazolidine derivatives are formed as a result of the migration of the methyl groups. Pyrolysis of *N*-dimethylaminourethane in the presence of isocyanate or isothiocyanate constitutes a convenient method for the synthesis of various methyl-substituted triazolidines.

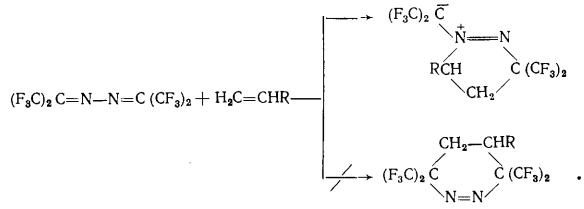


The pyrolysis of methylaminourea likewise leads to the formation of a triazolidinedione[65] and there is also a possibility of dimerisation via a 3 + 3 = 6 mechanism, leading to triazine derivatives:

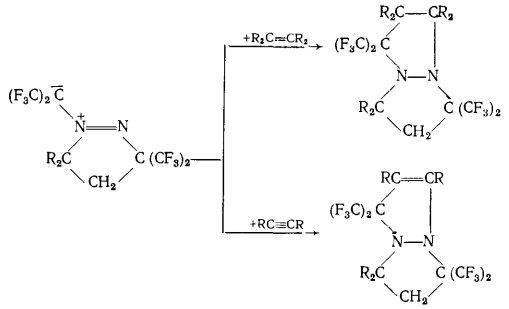


All the reactions described above may be regarded as 1,3-dipolar cycloadditions via the 3 + 2 = 5 mechanism. One molecule of dimethylaminoisocyanate behaves as a 1,3-DS, while another molecule of the same compound or a molecule of iso- or isothio-cyanate behaves as a dipolarophile. The stability of the product is determined by the stability of the ylid linkage. Dimethylaminoisocyanates can be classified as rare nitrogen-containing π-systems in which an electron pair is localised at the nitrogen atom adjoining the multiple bond. The localisation is probably caused by the presence of the adjacent nitrogen atom, which also has an unshared electron pair and this prevents the delocalisation of the charge over the system and enhances sharply the nucleophilic properties of the amino-nitrogen:

The extremely reactive 1,3-DS adds to the multiple bond of the initial molecule or alkyl isocyanate as a result of attack by the nucleophilic nitrogen atom of the dimethyl amino-group on the *sp*-hybridised carbon atom of the isocyanate group. Ring closure occurs when the nitrogen atom of the NCO group interacts with the carbon atom of the aminoisocyanate[64,66]:

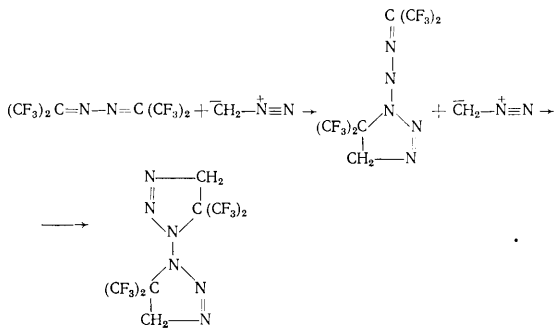


The reactions of dimethylaminoisocyanates with carbodiimides are also known. One of the two reaction products is a structural analogue of compound (I) and the other contains a bond between the amino-nitrogen of the dimethylaminoisocyanate and one of the nitrogen atoms (and not the *sp*-hybridised carbon atom) of the carbodi-imide:



This probably involves nucleophilic attack on the carbodiimide nitrogen with transfer of the negative charge to the *sp*-hybridised carbon atom[67,68].

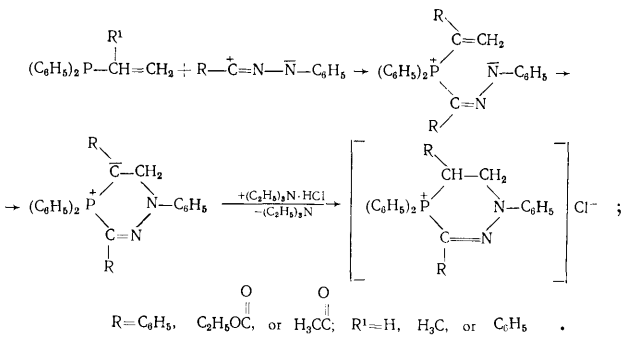
The interaction of hexafluoroacetone azine[69,70] with terminal olefins or dienes can also serve as an example of the 1,3-dipolar activity of a nitrogen-containing π-system[71-83]. The localisation of the unshared electron pair at the nitrogen atom converts such compounds into 1,3-DS. Hexafluoroacetone azine reacts with olefins of the type $H_2C{=}CHR$ and $H_2C{=}C(CH_3)R$ and with dienes to form, in the first stage, the product of 1,3-dipolar cycloaddition via the 3 + 2 = 5 mechanism and not via the mechanism of diene synthesis (4 + 2 = 6):[74]



The product is a stable azomethine imine[2,76,81,83-88], If R is a bulky group, subsequent intramolecular deprotonation and reprotonation take place with formation of 3-pyrazolines[74-76,81,89].

The stable azomethine imine is capable of reacting further with systems containing multiple bonds via the usual 1,3-dipolar cycloaddition mechanism[74,75,80,81] to form a bicyclic heterocycle. This product can also be formed immediately if an excess of the olefin relative to the azine is taken:

Such mixed cycloaddition of two differently substituted systems with double bonds (or one system with a double bond and another system with a triple bond) in the 1,3 : 2,4-positions relative to hexafluoroacetone azine with intermediate formation of a stable azomethine imine leads to a new pathway to bicyclic heterocycles of the type of 1,5-diazobicyclo-octenes and 1,5-diazobicyclo-octanes and their heteroanalogues. One should note that the cycloaddition cross-reactions of azines with olefins had also been described earlier[92-97], but due importance had not been attached to them.



Hexafluoroacetone azine behaves as a dipolarophile in reactions with classical 1,3-DS. Thus the reaction with diazomethane involves one or both C=N bonds of the initial compound[98]:

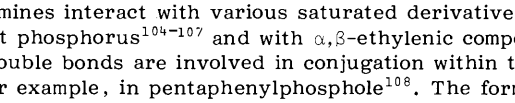
III. PHOSPHORUS(III)-CONTAINING π-SYSTEMS

The interaction of α,β-unsaturated compounds of tervalent phosphorus and 1,3-DS can proceed via two reaction centres: the heteroatom and the multiple bond. In the general case phosphorus-containing π-systems can be regarded as reactive 1,3-DS with a negative charge on the phosphorus atom and a positive charge on the extreme carbon atom of the multiple bond. The first such reaction of α,β-unsaturated phosphorus(III) compounds with 1,3-DS via the mechanism involving mixed dimerisation of 1,3-DS (3 + 3 = 6) with participation of the phosphorus atom and the multiple bond in the reaction

and the formation of six-membered heterocycles has been described[99]. In this study the interaction of diphenylvinylphosphine with *C,N*-diphenylnitrile imine in the presence of triethylamine hydrochloride yielded a phosphonium salt—a derivative of 1,4,5,6-tetrahydrophosphoniapyridazine:

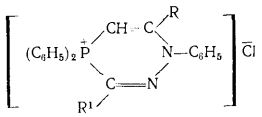
R=C_6H_5, C_2H_5OC, or H_3CC; R^1=H, H_3C, or C_6H_5 .

Alkenylphosphines having a substituent in the α-position relative to the multiple bond or one methyl group in the β-position react with nitrile imines in this way[100-103] regardless of their structure.



Nucleophilic attack by a tricoordinate phosphorus atom on the carbon atom of the nitrile imine leads apparently to the initial formation of a dipole ion, which, by virtue of the strong polarisation of the multiple bond and the influence of the tetracoordinate phosphorus atom, cyclises to a phosphorane. The cyclic phosphorane, being a stronger base than triethylamine, reacts with triethylamine hydrochloride to form a stable phosphonium salt. The stepwise course of the reaction can probably be regarded as a possible extreme case; one cannot rule out the possibility that such reactions can also proceed synchronously via a cyclic transition state. Different aspects of the mechanism of the 1,3-dipolar cycloaddition reaction are considered in reviews published previously[90,91].

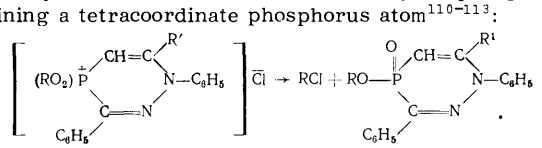
When there are two methyl or phenyl groups in the β-position in alkenylphosphines, the reaction stops in some cases at the stage involving the formation of dipolar ions, the stabilisation of which is promoted by electron-accepting groups at the carbon atom of the nitrile amine. Account should also be taken of the steric hindrance caused by the substituents at the β-carbon atom of the multiple bond[101]:



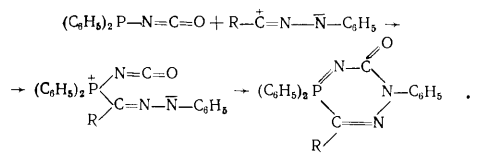
R=C_2H_5OCO, or H_3CCO .

The same azomethylenephosphoranes are formed when nitrile amines interact with various saturated derivatives of tervalent phosphorus[104-107] and with α,β-ethylenic compounds whose double bonds are involved in conjugation within the ring, for example, in pentaphenylphosphole[108]. The formation of these compounds confirms the proposed mechanism of the interaction of α,β-unsaturated derivatives of phosphorus(III) with nitrile amines:

R=Ar, $(Alk)_2N$, or AlkO; R^1=C_2H_5OCO, or H_3CCO; R^2=Ar .

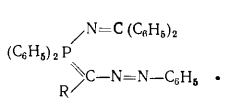


In contrast to alkenylphosphines, alkynylphosphines react with nitrile imines to form cyclic quasi-phosphonium compounds regardless of the degree of substitution at the β-carbon atom of the multiple bond[103,109,110], which indicates a lower sensitivity of acetylenic derivatives of phosphorus(III) to steric hindrance than that of the ethylenic derivatives:



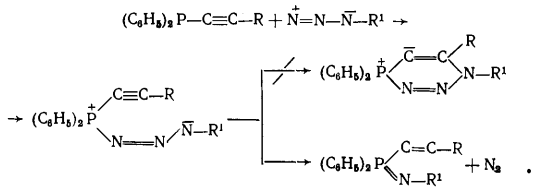
R=H, CH_3, $C(CH_3)_3$, or C_6H_5 .

The degree of conjugation of the 3*d* orbitals of the phosphorus atom with a triple bond is greater than with a double bond[19,20], so that the β-carbon atom should be more activated in the former case. Account should also be taken of the fact that the *sp*-hybridised carbon atom is more reactive in reactions with nucleophiles.



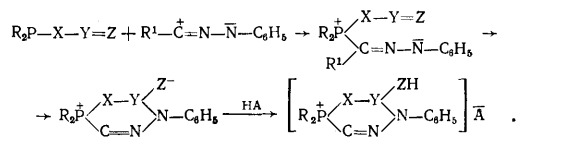
α,β-Unsaturated ethylenic and acetylenic phosphonites react with nitrile amines regardless of the nature of the substitution in the β-position of the multiple bond via the 1,3-DS mixed dimerisation mechanism. The quasi-phosphonium salts obtained undergo the Arbuzov rearrangement with elimination of the alkyl halide and the formation of a cyclic phosphinate containing a tetracoordinate phosphorus atom[110-113]:

The amides of alkenyl- and alkynyl-phosphonous acids form cyclic compounds only with nitrile amines without electron-accepting substituents at the carbon atom. In all the remaining cases the reaction stops at the stage involving the formation of open-chain azomethylenephosphoranes[101,114]. Heteroatomic α,β-unsaturated compounds of tervalent phosphorus such isocyanates of phosphorus acids and methyleneaminophosphines can also enter into Huisgen's 1,3-dipolar addition reactions with 1,3-DS. The reaction with diphenylphosphinyl isocyanate also proceeds via the 1,3-DS "mixed dimerisation" mechanism and stops at the stage involving the formation of a cyclic ketoiminophosphorane[115,116]. The isolation of this product can be regarded as confirmation of the possibility of the formation of cyclic methylenephosphoranes as intermediates also in the other cases described above:



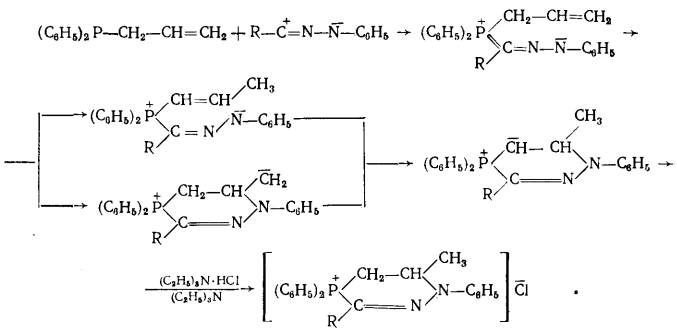
Acyclic azomethylenephosphoranes are products of the interaction of diphenylmethyleneaminophosphines with nitrile imines:

Cyclisation does not take place, apparently owing to the steric hindrance in ring closure caused by the phenyl groups[117].

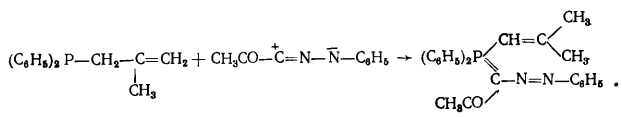


The choice of a 1,3-DS for reactions with α,β-unsaturated phosphorus(III) compounds is limited by the high reducing capacity of the latter. This factor rules out the possibility of using oxygen-containing 1,3-DS such as nitrile oxides, nitrones, etc. Together with nitrile imines, organic azides can serve as 1,3-DS. The interaction of α,β-unsaturated acetylenic phosphines with organic azides does not lead to cyclic products. The initial dipolar ion (phosphatriazene) is unstable and decomposes with liberation of nitrogen and the formation of a phosphine imine with an unsaturated group at

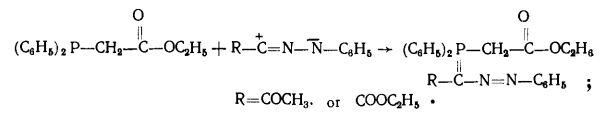
the phosphorus atom[118]:



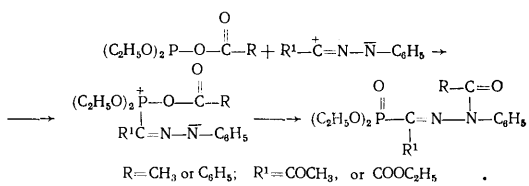
The nucleophilic mechanism of the reaction of unsaturated phosphorus(III) compounds with nitrile imines is also indicated by the relative rate constants for the reactions of different phosphorus-containing compounds with diphenylnitrile imine. For example, $(k_2)_{rel} = 0.56$, 1.00, and 2.72 for $(C_2H_5O)_2P{-}C{\equiv}C{-}C_6H_5$, $(C_6H_5)_2P{-}C{\equiv}CH$, and $[(CH_3)_2N]_2P{-}C{\equiv}C{-}C(CH_3)_3$ respectively[114]. The study of the dipole moments and ^1H NMR spectra of unsaturated phosphorus(III) derivatives is also important for the understanding of the mechanism of this reaction[119,120].



In the case of β,γ-unsaturated phosphorus(III) compounds the manifestation of 1,3-dipolar activity may be expected when an active electrophile is present in the β-position:

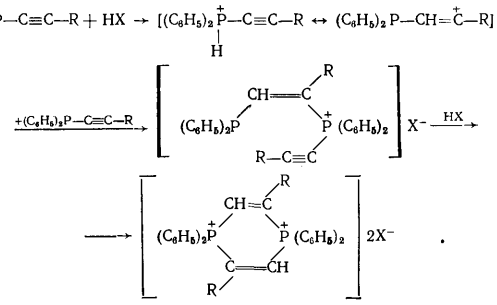


β,γ-Unsaturated phosphines (studied in relation to allyldiphenylphosphine)[102] isomerise in the reaction and the resulting phosphoniapyridazine is identical with the products of the reaction of diphenylpropenylphosphine (an α,β-unsaturated compound of tervalent phosphorus) with nitrile imines:

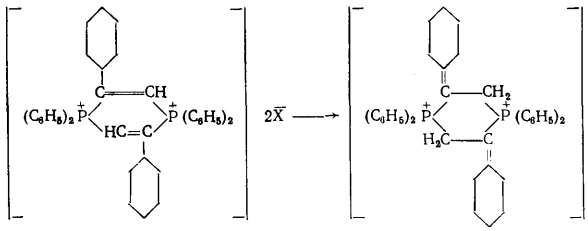


The isomerisation can occur either in the stage involving the formation of the intermediate dipolar ion or in the intermediate formed as a result of the attack by the nitrogen atom on the β-position of the multiple bond; this is followed by the transfer of a proton from the methylene group. The first pathway is apparently preferred, since the positively charged phosphorus atom facilitates the isomerisation of the allyl group[121]. In addition, it has been established that methylallyldiphenylphosphine reacts with *C*-acetyl-*N*-phenylnitrile imine to form azomethylenephosphorane as the product of the isomerisation of the phosphorane formed in the first stage[102]:

When nitrile imines react with ethoxycarbonylmethyldiphenylphosphine, the ethoxycarbonyl group is not involved in the reaction. Evidently the abstraction of a methylene proton and the substitution of the ethoxy-group, without which a stable product cannot be formed, is impossible in this case. The reaction stops at the stage involving the formation of azomethylenephosphorane[122]:



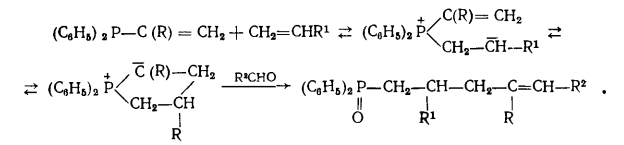
Only mixed anhydrides of dialkylphosphorus and carboxylic acids (diethyl acetyl phosphite and diethyl benzoyl phosphite) react with nitrile imines, where the carbon atom of the carbonyl group is involved in the reaction in addition to the phosphorus atom. As a result of the rearrangement, the final reaction products are acyclic phosphonates



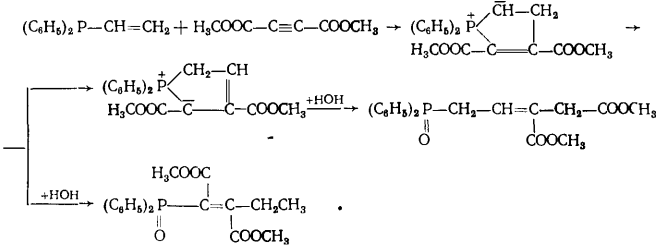
Mixed anhydrides of dialkylphosphorous and carboxylic acids react via a similar mechanism with methyl iodide[123], aldehydes, and ketones[124-126].

α,β-Acetylenic phosphines can also participate in simple dimerisation reactions via the 3 + 3 = 6 mechanism. Derivatives of 1,1,4,4-tetraphenyl-1,4-diphosphiniacyclohexa-2,5-diene are formed from alkynyldiphenylphosphines in glacial acetic acid in the presence of HBr.[127,129] According to the authors, the initial phosphine is protonated at the phosphorus atom in the first stage of the reaction, as a result of which the β-carbon atom of the multiple bond becomes more electrophilic owing to the strong conjugation of the 3*d* orbitals of phosphorus with the π-electrons of the triple bond. A second phosphine molecule with a localised unshared electron pair attacks the β-carbon atom of the first phosphine molecule with subsequent cyclisation and formation of a diphosphonium salt[130,131]:

The mode of this reaction, which proceeds in a protic solvent, can depend on the nature of the halide involved in it. The strongest nucleophile (the iodide ion) prevents cyclisation and the competing reaction involving the formation of β-iodovinylphosphine takes place; in the presence of the bromide ion, which is less nucleophilic than the iodide ion, cyclisation proceeds more readily. It is facilitated still further in the presence of the chloride ion. If the substituents in the β-position of the multiple bond are alkyl, cyclopentyl,

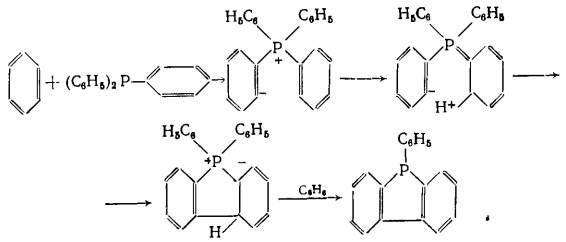


or cyclohexyl, then heating of the cyclic salts can lead to irreversible isomerisation, showing that the degree of stabilisation of the system as a result of the π-electronic interaction with the phosphorus atom is low[129,131]. For example, with R = cyclohexyl, the isomerisation proceeds as follows:

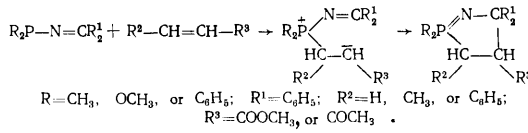


It is noteworthy that the study of the electrochemistry of derivatives of 1,4-diphosphophoniacyclohexa-2,5-diene led to the discovery of a new class of radical-cations[132,133].

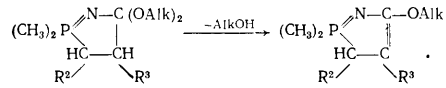
Phosphorus-containing π-systems, like the classical 1,3-DS, can react with compounds containing activated multiple bonds (dipolarophiles) via the 3 + 2 = 5 mechanism. The five-membered heterocycles formed in these reactions are unstable. in some cases. For this reason, the products of their interaction with other substances have been isolated.



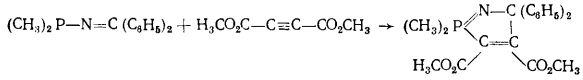
The interaction of vinylphosphines with activated olefins leads to the formation of five-membered ylids, apparently with the intermediate formation of dipolar ions[134]. When the reaction is carried out in the presence of aldehydes, the five-membered ylid undergoes the Wittig reaction with formation of the corresponding phosphine oxide[135]:



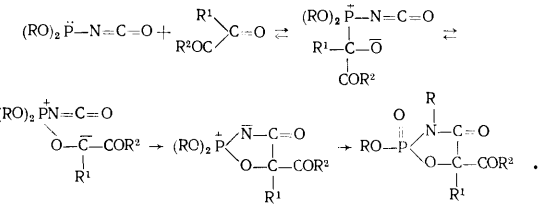
Diphenylphosphine reacts with the dimethyl ester of acetylenedicarboxylic acid to form a cyclic compound which can rearrange to a tautomer having the ylid structure: on interaction with water, both ylids decompose with formation of phosphine oxides[136]:



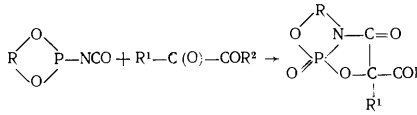
When triphenylphosphine interacts with dehydrobenzene, biphenylenephenylphosphine is formed as one of the products. A betaine is apparently formed as an intermediate with subsequent cyclisation and elimination of benzene[137]:



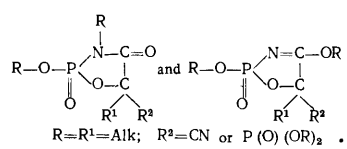
Phosphorus-containing dipolar π-systems with multiple heterobonds can also undergo the 3 + 2 = 5 cycloaddition reactions. Methyleneaminophosphines[138] react with derivatives of acrylic, crotonic, and cinnamic acids and α,β-unsaturated ketones to form five-membered addition products via the 2 + 3 = 5 mechanism[139,140] and the intermediate formation of the betaine is also postulated:



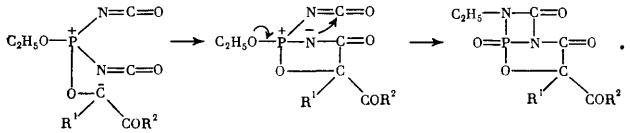
If R^1 = OAlk, then the cyclic product is converted with elimination of the alcohol, forming a more stable product[140]:



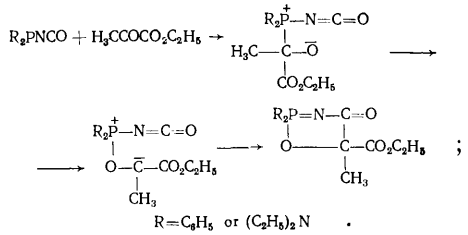
The dimethyl ester of acetylenedicarboxylic acid reacts with methyleneaminophosphines to form a cyclic iminophosphorane:



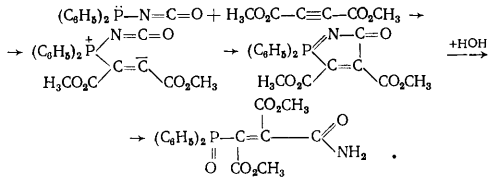
Dialkyl and alkylene phosphoromonoisocyanatidites also react via the 3 + 2 = 5 1,3-dipolar cycloaddition mechanism with carbonyl compounds activated by electron-accepting substituents α,β-unsaturated phosphorus(III) compounds with an unshared electron pair at the phosphorus atom functioning as the 1,3-DS. In cases where the dipolarophiles are the esters of α-ketocarboxylic acids and α,β-diketocarboxylic acids or α-diketones, the reaction begins with nucleophilic attack by the phosphorus atom on the carbon atom of the carbonyl group with formation of a dipolar ion, which rapidly isomerises to the thermodynamically more stable ion with P–O–C bonds. The latter is stabilised with formation of a five-membered ring as a result of the attack by the carbanion on the carbon atom of the isocyanate group. The final reaction product is obtained after subsequent *N*-alkylation[141–143]:



Alkylene phosphoroisocyanatidites form bicyclic addition products[143,144]:

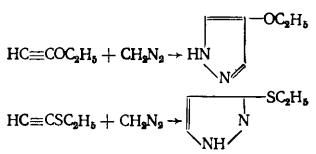


If the dipolarophiles are the nitriles of α-ketocarboxylic acids, the final stage of the reaction is not only *N*-alkylation, but also *O*-alkylation and a mixture of two products is formed[145,146]:



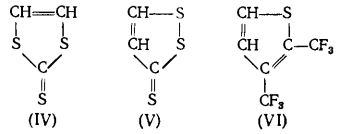
The ethyl ester of a phosphorodi-isocyanatidic acid reacts with carbonyl-containing compounds via a mechanism common to such reactions, but the second isocyanate group also participates in the stabilisation process[147]:

The intermediate dipolar ions can be stabilised not only via transalkylation but also via a pathway involving the formation of cyclic phosphine imines. The reaction between diethyl phosphoroisocyanatidite and aldehydes[148] and between isocyanatodiphenylphosphine and the bis-(*N*,*N*-diethylamide)-of phosphoroisocyanatidic acid, on the one hand, and ethyl pyruvate, on the other, also proceeds via this pathway[149]:



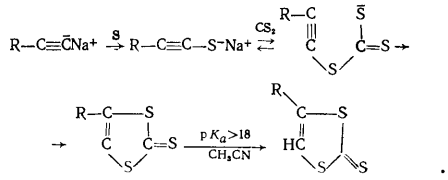
Isocyanatodiphenylphosphine reacts as a 1,3-DS with a dipolarophile such as dimethyl acetylenedicarboxylate with formation of a five-membered heterocycle, which being unstable, decomposes with formation of phosphine oxide. The reaction apparently proceeds via a stage involving the formation of a dipolar ion[150]:

The data presented show that formally α,β-unsaturated compounds of phosphorus(III) do not differ in type of reactivity from classical 1,3-DS.

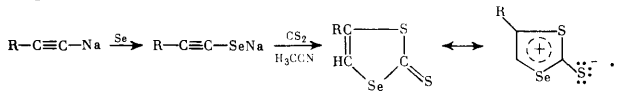


IV. SULPHUR-CONTAINING π-SYSTEMS

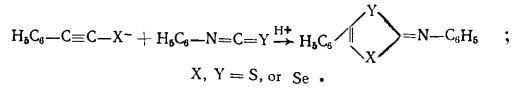
In many cases ethylenic and acetylenic compounds of sulphur and its analogues (selenium and tellurium) combine with 1,3-DS as dipolarophiles via the multiple bond[151], although the presence of vacant 3*d* orbitals in the sulphur atom influences the mode of the 1,3-dipolar cycloaddition[59]. For example, the interaction of diazomethane with ethoxyacetylene and ethylthioacetylene leads to products of different structure, which makes it possible to postulate the possibility of the stabilisation of the carbanion formed initially by (*d*-*p*) π-conjugation, which determines the mode of addition in the case of a sulphur-containing compound:



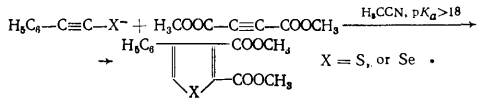
However, the multiple bond nevertheless remains the reaction centre.



The reactions of compounds containing sulphur next to a multiple bond, which proceed via the 1,3-dipolar addition mechanism, have been described in recent years. The reaction of acetylene with sulphur and carbon disulphides, yields, together with other compounds, the isomeric 1,3-dithiole-2-thione (IV) and 1,2-dithiole-3-thione (V).[152] The analogous reaction in the presence of perfluoro-2-yne yields 1,3-bis-(trifluoromethyl)thiophen (VI):[153,154]

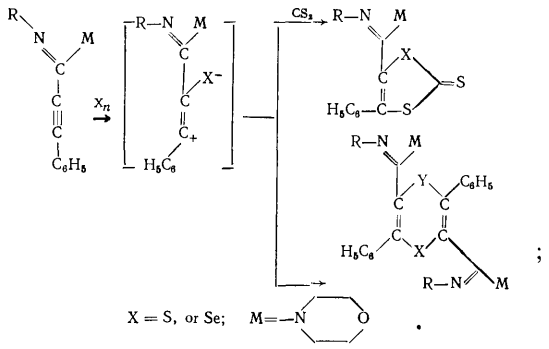


The reaction apparently proceeds with formation of a primary thiolation product. The interaction of acetylenes with sulphur and carbon disulphide in polar solvents probably proceeds via the same mechanism with formation of 1,3-dithiole-2-thiones[155-157]. If one begins with sodium acetylide, sulphur, and carbon disulphide, then derivatives of 1,3-dithiole-2-thiones are formed in the presence of a proton-donating solvent even at room temperature[156-158]. The formation of the product of the thiolation of sodium acetylide is most probably an intermediate stage[159]:

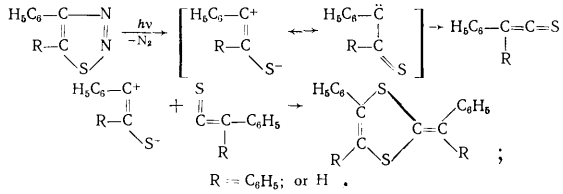


Products of analogous structure are formed also by selenium and tellurium which are sulphur analogues[160-162]. In the presence of carbon disulphide in a proton-donating solvent, when the product obtained by treating sodium acetylide with selenium is acted upon by carbon disulphide in a proton-donating solvent, 1-thia-3-selenole-2-thione is formed[163] and is stabilised by resonance, like its sulphur analogue:

The use of phenyl isothiocyanate and phenyl isoselenocyanate as heterocumulenes in this type of reaction does not alter its mechanism[164]:

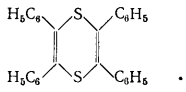


Acetylenic thiolates and selenolates also react with dimethylacetylenedicarboxylate via the 1,3-dipolar cycloaddition mechanism with formation of derivatives of thiophen- or selenophen-dicarboxylic acids[165-166]:



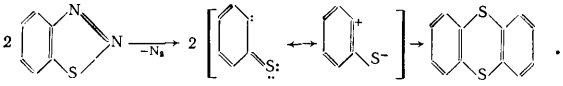
1,3-Dithiole-2-thiones have been obtained not only from terminal acetylenes with intermediate formation of thiolates but also from compounds having a doubly substituted triple bond. When the amidines of phenylpropiolic acid interact with sulphur or selenium in the presence of a tertiary amine, derivatives of 1,3-dithiole-2-thiones are produced[167]. A

sulphur-containing 1,3-DS is apparently formed in the first stage and then reacts with the dipolarophile (carbon disulphide):

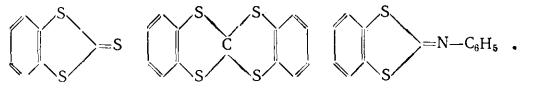


If phenyl isocyanate or phenyl isothiocyanate is introduced into the reaction mixture instead of carbon disulphide, the sulphur-containing 1,3-DS dimerises, apparently owing to the lower reactivity of the multiple bond of the heterocumulene.

Extremely reactive compounds are formed on decomposition of 1,2,3-thiadiazoles. Photolysis of derivatives of 1,2,3-thiadiazoles proceeds with evolution of nitrogen and the formation of dithiafulvenes[168]. It has been suggested[169] that, when a nitrogen molecule is split off, a thioketocarbene is formed as an intermediate and can then be converted into a thioketen as a result of a rearrangement analogous to the Wolff rearrangement. The reaction probably proceeds subsequently via the 1,3-dipolar cycloaddition mechanism: the thioketocarbene (1,3-DS) reacts with the thioketen (dipolarophile) via the 3 + 2 = 5 mechanism:

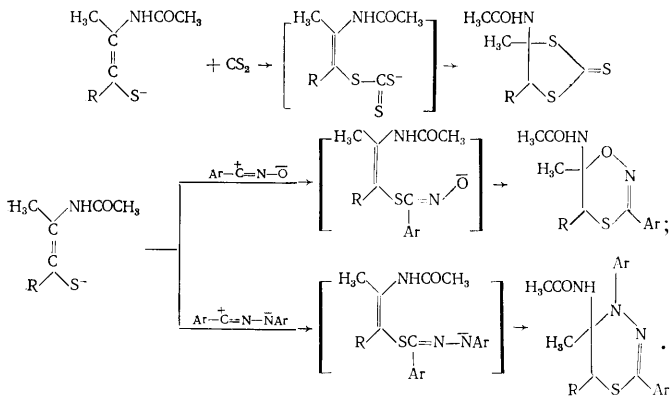


If R = C_6H_5, the competing dimerisation reaction of the 1,3-DS (thioketocarbene) can proceed via the 3 + 3 = 6 mechanism with formation of dithiacyclohexadiene[168]:

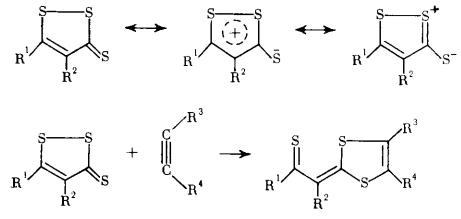


It is noteworthy that the products of cycloaddition via the 3 + 2 = 5 mechanism (the dithiafulvenes) are also obtained from acetylenic thiolates and selenolates[157,165,166] and the lower the pK_a of the solvent the higher the yield of the dithiafulvenes.

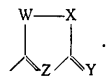
The aromatic thioketocarbenes formed on thermolysis of benzothiazoles dimerise with formation of thianthrene[170]:



Thioketocarbenes dimerise so readily that, even when the reaction is carried out in dipolarophiles (used as solvents) such as diethyl fumarate, α-naphthyl isocyanate, or benzonitrile, the products of addition via the 2 + 3 = 5 mechanism are not obtained; the product of the 3 + 3 = 6 reaction is formed exclusively[2,171]. Only certain compounds containing the C=S double bond combine with thioketocarbene relatively smoothly. Carbon disulphide reacts via both one and two multiple bonds, while phenyl isothiocyanate forms 2-phenylimino-1,3-benzodithiole[171]:

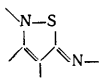


The decomposition of unsubstituted 1,2,3-thiadiazole in carbon disulphide at 200 °C yields only 0.2% of 1,3-dithiole-2-thione[171], while the reaction with perfluorobut-2-yne leads to the formation of 2,3-bis(trifluoromethyl)thiophen; the reaction involving 5-methyl-1,2,3-thiadiazole proceeds analogously[153].

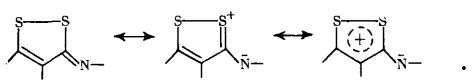


It has been shown recently that alkenethiolates[172,173] are also capable of behaving as 1,3-DS and of reacting with dipolarophiles (carbon disulphide) via the 3 + 2 = 5 cyclisation mechanism[174] and with other 1,3-DS (nitrile oxides, nitrile imines) via the 3 + 3 = 6 cyclisation mechanism[175]:

Numerous studies published recently have been devoted to yet another form of sulphur-containing π-systems capable of undergoing 1,3-dipolar cycloaddition reactions. It has been shown[176,177] that 1,2-dithiole-3-thiones react with activated acetylenes via the 3 + 2 = 5 cyclisation mechanism[176,177]. The nucleophilic properties of the exocyclic sulphur atom in such compounds are based on the stability of the quasi-aromatic dithiole ring system, by virtue of which the unshared electron pair is localised at the thione sulphur atom and the system as a whole is a kind of 1,3-DS:



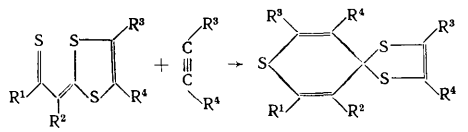
Apart from 1,2-dithiole-3-thiones, their isoelectronic analogues can enter into similar reactions and all these compounds can be represented by the general formula



The examples investigated are summarised in Table 1.

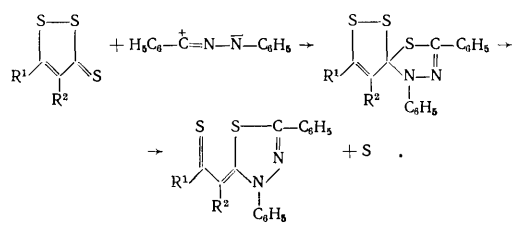
Table 1 shows that the ring system can include both sulphur and nitrogen and in the latter case the electron density in the ring increases, which enhances the nucleophilic properties of the exocyclic atom and hence the 1,3-dipolar activity. 1,2,4-Dithiazole-3-thiones react more vigorously with activated acetylenes than 1,2-dithiole-3-thiones.

Table 1. Sulphur-containing 1,3-DS.



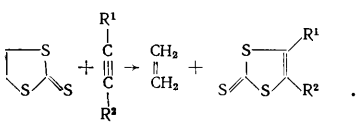
Compound	References	Compound	References
 1,2-Diothiole-3-thione	176—200	 3-Imino-1,2-dithiole	184, 189
 1,2,4-Dithiazole-3-thione	180; 184—186, 189, 195, 199, 201—205	 3-Imino-1,2,4-dithiazole	180, 209
 Isothiazole-5-thione	206—208	 5-Iminoisothiazole	206
 Isothiazole-3-thione	208		

The reaction proceeds in some cases with dissociation of the S–S bond and in others with rupture of the S–N bond, which, incidentally, does not alter its essential features. Instead of the exocyclic sulphur atom, the system may contain an exocyclic nitrogen atom; such a system is also a 1,3-DS and a partly ionised structure can be formulated for it as well:



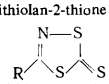
Such systems could be considered in the section devoted to nitrogen-containing π-systems, but, relative to the thiolethione systems, the 1,3-dipolar activity of iminothioles is particularly clear-cut.

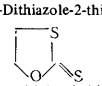
The initial 1 : 1 product of the 1,3-dipolar cycloaddition can react in many instances with yet another molecule of the dipolarophile with formation of spirans (1,4-addition):

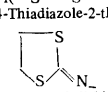


Such spirans can be obtained with almost all the systems investigated[177,184,185,187,191,204], but in some cases the 1,3-dipolar cycloaddition products could not be isolated, since the subsequent reaction was rapid[184,208].

1,2-Dithiole-3-thiones and their analogues participate only via their C=S double bond in reactions with classical 1,3-DS (benzonitrile oxide and diphenylnitrile imines); in other words, sulphur-containing heterocycles behave in this reaction as dipolarophiles[203,210–213]. The products formed initially react subsequently in a way which depends on the nature of the initial substances. For example, the reaction involving 1,2-dithiole-3-thione and diphenylnitrile imine proceeds via the following mechanism[212,213]:

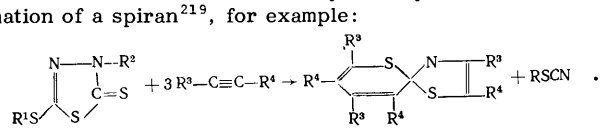






Sometimes the reaction involving addition to the C=S bond (1,2-addition) takes place also with substituted acetylenes[178–181,204], tetracyanoethylene[214], and diphenylketen[215]; likewise one should note that, under the influence of certain reagents, the 1,3-cycloaddition products can rearrange to 1,2-addition products[178,193,220].

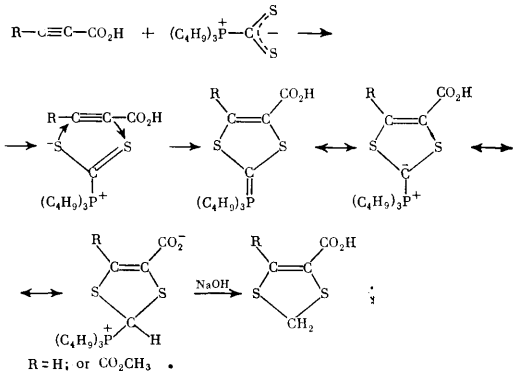
Apart from 1,2-dithiole-3-thiones and their analogues, 1,3-dithiolan-2-thione systems and other compounds isoelectronic with them can undergo reactions via the 1,3-dipolar cycloaddition mechanism. During the reaction, ethylenic hydrocarbons or other unsaturated compounds are split off. For example, the reaction of 1,3-dithiolan-2-thiones proceeds as follows:



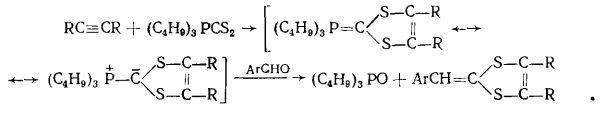
The compounds investigated are listed in Table 2.

Table 2. Nitrogen- and sulphur-containing 1,3-DS.

Compound	Compounds split off	References
 1,3-Dithiolan-2-thione		177, 180, 191, 201, 217, 218
 1,3,4-Dithiazole-2-thione		181, 201, 203
 1,3-Oxathiolan-2-thione		217
 1,3,4-Thiadiazole-2-thione		199, 219
 2-Imino-1,3-dithiolan		199, 219

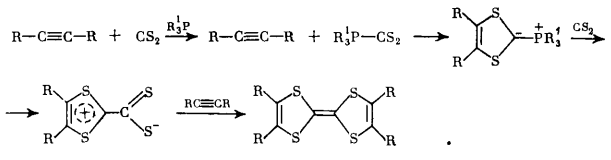


In some cases the product formed initially can combine with a further two molecules of the acetylenic hydrocarbon with formation of a spiran[219], for example:

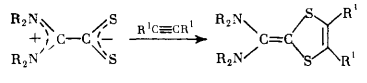


There exist also other examples of the 1,3-dipolar activity of sulphur-contaning π-systems. Complexes of phosphines with carbon disulphide, which have been known for a very long time, can react with acetylenic hydrocarbons via a mechanism which can be regarded as 1,3-dipolar cycloaddition.

Propiolic and acetylenedicarboxylic acids react with the complex $(C_4H_9)_3 \rightarrow CS_2$ to form a dipolar ion[221,222]. The authors suggest that the reaction proceeds via a concerted single-stage addition and that a dipolar complex with a positive charge on the phosphorus atom and a negative charge on the CS_2 group can be regarded as the 1,3-DS in the given reaction; in the limiting case one can postulate the presence of the C=S double bond and a negative charge on the second sulphur atom.



The reaction between $(C_4H_9)_3P \rightarrow CS_2$ and substituted acetylenes in the presence of aldehydes[223,224], leading to the formation of dithiafulvene derivatives, proceeds via an analogous mechanism:



The authors suggest that the intermediate reacts with the aldehyde to form the product of the Wittig reaction:

It is known that acetylenic hydrocarbons react with carbon disulphide to form tetrathiafulvenes[222,223,225-230]. As a rule, this type of reaction takes place in the presence of tertiary phosphines. The formation of fulvenes can be accounted for if one postulates the existence of an intermediate phosphorane, which reacts with carbon disulphide to form a 1,3-dipolar compound[226,229]. The subsequent interaction with a second acetylene molecule gives rise to the final product:

The following reaction probably proceeds via a similar mechanism[193,220]:

The study of reactions in which unsaturated systems containing a heteroatom with an unshared electron pair in the α-position, which are capable of reacting as 1,3-DS, made it possible to formulate new principles for the structure of 1,3-DS.[231] Apparently any system $\ddot{Z}-X=Y$ and $\ddot{Z}-X\equiv Y$, where $\ddot{Z}$ is an element having an unshared electron pair and X and Y are elements capable of forming π-bonds, can behave as a 1,3-DS.[231] The 1,3-dipolar activity of compounds of this type is determined in each individual case by the nature of the elements Z, X, and Y.

Anions of the type $\bar{Z}-X=Y$ or $\bar{Z}-X\equiv Y$ should be more active 1,3-DS, although it is then necessary to add a proton donor to the reaction mass in order to stabilise the anion formed as a result of cyclisation.

The proposed principle for the construction of 1,3-DS can be extended also to the usual Huisgen 1,3-DS. The analogy is particularly clear when the formulae of these 1,3-DS are written as those of carbenoid structures[231].

Organometallic (Non-transition Metals) Free Radicals

A.G.Milaev and O.Yu.Okhlobystin

The available information about the free radicals and radical-ions formed by "true" organometallic compounds of non-transition metals is surveyed and described systematically. The methods of synthesis and the properties of radicals with the free valence located at the metal or in a ligand and the synthesis and structure of organometallic radical-ions are considered.
The bibliography includes 185 references.

I. INTRODUCTION

The study of organoelemental free radicals and radical-ions constitutes a new branch of physical organic chemistry, which has arisen at the boundary between classical organoelemental chemistry and the physical chemistry of free radicals. For a long time, the intermediate formation of species of this kind was merely postulated in the study of various organometallic reactions and only in recent years they became the object of direct investigation. The first advances in this field led to a flood of hypotheses and postulates, many of which lack experimental justification and are purely speculative. However, progress in outwardly varied fields, such as reaction mechanisms, biochemical electron transport, catalysis, and organic synthesis, depends significantly on the prospects for the development of the chemistry of organoelemental radicals. The aim of the present study was to select and describe systematically the reliable relevant information and to outline the most fruitful pathways to be followed in future research.

The field under consideration can be clearly divided into three main branches: organoelemental radical-ions; element-centred free radicals; organometallic compounds with the unpaired electron localised preferentially in the ligand†.

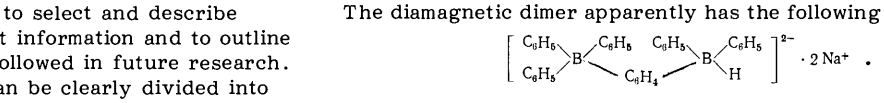
II. ORGANOMETALLIC RADICAL-IONS

Many organometallic reactions can be usefully regarded as a consequence of electron transfer[1-3]. In this approach one postulates two main types of dissociation of the metal–carbon bond, which are in general unrelated to its homolytic or heterolytic dissociation under the influence of a reactant or the solvent[4]. Electron capture by the organometallic molecule leads to the splitting off of a carbanion with formation of a reduced form of the metal:

$$R{-}m \underset{-e}{\overset{+e}{\rightleftarrows}} [R{-}m]^{\cdot-} \rightarrow R^- + m^{\cdot} \quad .$$

In the one-electron oxidation of the substrate a free radical is produced:

$$R{-}m \underset{+e}{\overset{-e}{\rightleftarrows}} [R{-}m]^{\cdot+} \rightarrow R^{\cdot} + m^+ \quad .$$



†The free radicals of phosphorus compounds, information about which can be found in a recent review by V.V.Pen'kovskii in Uspekhi Khimii, **44**, **969 (1975)**, **have been** excluded from consideration.

The radical-ion states $R{-}m^{\cdot-}$ and $R{-}m^{\cdot+}$ are then formed either as elements of the activated complex or as more or less stable intermediates whose energy corresponds to dips in the energy curve; in the latter case they can be identified directly and investigated. There are as yet few examples of this kind, but it is already evident that the stability of organoelemental radical-ions varies within very wide limits.

Organoboron radical-anions were discovered first. As early as the 1930's, the formation of coloured adducts of alkali metals with triarylboron derivatives was noted[5,6]. Subsequent studies showed that solutions of these compounds contain equilibrium mixtures of the triarylboron radical-anion $Ar_3B^{\cdot-}M^+$ (M is an alkali metal) and the diamagnetic dimeric form[7,8]:

$$2\,Ar_3B^{\cdot-}M^+ \rightleftarrows (Ar_6B_2)^{2-} \cdot 2\,M^+ \quad .$$

The diamagnetic dimer apparently has the following structure[9]:

The ratio of the two forms depends on the nature of the aryl group and the solvent. Thus, whereas the trimesitylboron radical-anion is monomeric in ether, the triphenylboron radical-anion is fully dimerised in this solvent; tri-α-naphthylboron-sodium exists as a dimer in ether but in tetrahydrofuran (THF) it is fully monomeric and paramagnetic[10].

It follows from the EPR spectra of triarylboron radical-anions that the unpaired electron is delocalised over all the aryl groups; in other words, the boron atom does not behave as an isolating bridge. The form of the spectra is determined by the interaction of the unpaired electron with the ^{11}B nucleus ($I = 3/2$), which is responsible for the appearance of the four main lines, each being split owing to the interaction with the protons of the aryl groups[11-13]. The following hyperfine interaction (HFI) constants have been obtained for the triphenylboron radical-anion in dimethoxyethane: $a_B = 7.84$ G, $a_H^{para} = 2.73$ G, $a_H^{ortho} = 1.99$ G, and $a_H^{meta} = 0.67$ G. The assignments were made on the basis of a study of the EPR spectra of deuterated triphenylboron radical-anions[11]. The reduction of alkyl derivatives of boron does not lead to stable radical-anions; only in the case of tribenzylboron is the solution coloured dark-green and the EPR spectrum shows a single line with a width of 30 G.[11]

Being powerful reductants, triarylboron radical-anions are instantly decolorised by iodine and reduce the triphenylmethyl radical to the anion:

$$2\,Ar_3B^{\cdot-} + I_2 \rightarrow 2\,Ar_3B + 2\,I^- \quad ,$$
$$Ar_3B^{\cdot-} + Ph_3C^{\cdot} \rightarrow Ar_3B + Ph_3C^- \quad .$$

An interesting reaction of triphenylboron-sodium with methanol leads to the formation of sodium triphenylborohydride[14]:

$$2\,(C_6H_5)_3\,B^{\cdot-}Na^+ + CH_3OH \rightarrow Na\,[(C_6H_5)_3\,BOCH_3] + Na\,[(C_6H_5)_3\,BH]\ .$$

Triarylboron radical-anions are capable of combining with a further electron to form a diamagnetic dianion[7,8,15]:

$$Ar_3B^{\cdot-} \underset{-e}{\overset{+e}{\rightleftarrows}} Ar_3B^{2-}\ .$$

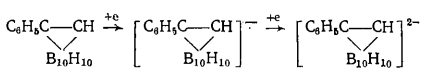
The triarylboron radical-anions are fully stable in solution in dimethoxyethane (DME), but, after prolonged contact with the metal, the EPR spectrum of the radical-anion disappears and is replaced by that of the decomposition products. Depending on the nature of the aryl group, the following processes are observed:

$$Ar_3B^{\cdot-} \xrightarrow{K,DME} ArH^{\cdot-}\ , \qquad (1)$$

$$Ar_3B^{\cdot-} \xrightarrow{K,DME} (Ar{-}Ar)^{\cdot-}\ . \qquad (2)$$

If Ar = 2,4,6-trimethyl-3,5-dinitrophenyl, the decomposition takes place in accordance with Eqn.(1), while in the case of Ar = Ph or MeC_6H_4, it follows Eqn.(2). When Ar = 2,4,6-Me_3.C_6H_2 or 2,4-$Me_2C_6H_3$, the corresponding organoboron radical-anions do not decompose at all. It is important to note that reaction (2) is an intramolecular process, which has been demonstrated by the formation of only symmetrical biphenyls from an equimolar mixture of their radical-anions $(p\text{-}DC_6H_4)_3B^{\cdot-}$ and $(3,5\text{-}D_2C_6H_3)_3B^{\cdot-}$. The elimination of biaryl is accompanied by the formation of the arylboron[11]:

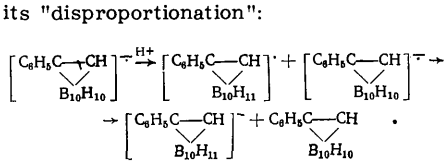
$$n\,Ar_3B^{\cdot-} \xrightarrow{K,DME} n/2\,(Ar{-}Ar)^{\cdot-} + (ArB)_n\ .$$



The latter is obtained also in the reduction of phenylboron dichloride by sodium in toluene[16]:

$$n\,C_6H_5BCl_2 \xrightarrow{Na} (C_6H_5B)_n\ .$$

Its hydrolysis leads to phenylboronic acid:

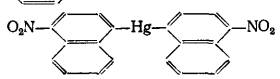


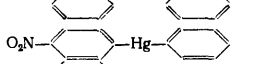
$$(C_6H_5B)_n \xrightarrow{H_2O} n\,C_6H_5B\,(OH)_2 + H_2\ .$$

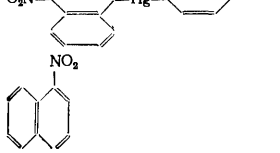
When phenyl-*o*-carbaborane is acted upon by alkali metals in THF or dimethylformamide (DMF), a coloured paramagnetic solution, whose EPR spectrum shows a single broad signal (11 G) without a hyperfine structure, is readily formed[17,18]. When it is acted upon further by the reductant, a diamagnetic dianion, obtained previously[19–21] in liquid ammonia, is formed:

The absence of a hyperfine structure in the spectrum of the radical-anion indicates a high degree of delocalisation of the unpaired electron over the entire carbaborane system. It is of interest to note that, despite the presence of acidic hydrogen atoms in the phenylcarbaborane molecule, the reaction with alkali metals is not accompanied by the evolution of hydrogen and the formation of a carbanion. On formation of the radical-anion no changes in the skeleton take place, since oxidation of the radical-anion with mercury(II) chloride results in a quantitative regeneration of the initial phenylcarbaborane[18].

The acid hydrolysis of the phenylcarbaborane radical-anion results in its "disproportionation":

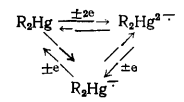






Organoaluminium radical-anions have been generated in the low-temperature γ-radiolysis (^{60}Co) of trialkylaluminium compounds[22]. Analysis of the EPR spectra indicates a pyramidal structure of such radical-anions in which the angle of deviation from the plane is ~21°. This agreed well with the large splitting constants for the ^{27}Al nuclei (324–390 G) due to the appreciable s character of the unpaired electron orbital[28]. The reduction of triphenylaluminium with sodium in ether leads to a dimeric product whose structure is apparently similar to that of its boron analogue[23].

Organogallium radical-anions have not been detected by EPR. It is only known that, when trimethylgallium is reduced with alkali metals in dimethoxyethane, a dimer is formed[24]:



$$2\,K^+\,[(CH_3)_3\,Ga{-}Ga\,(CH_3)_3]^{2-}\ .$$

The existence of organomercury radical-anions of the type $R_2Hg^{\cdot-}$ has been demonstrated in relation to nitroaryl derivatives obtained both in electrochemical reduction[25] and on treatment with sodionaphthalene[26]. Analysis of the HFI constants shows that the mercury atom has hardly any influence on the spin density distribution (cf. the constants for $R_2Hg^{\cdot-}$ and $RH^{\cdot-}$ in Table 1).

Table 1. The nature of the EPR spectra of the radical-anions of certain organomercury compounds R_2Hg and the corresponding hydrocarbons[25,26].

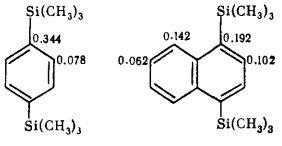
Compound	a_H^{ortho}, G	a_H^{meta}, G	a_H^{para}, G	a_N, G	a_{Hg}, G
	3.25	1.00	—	9.29	42.3
	3.25	1.10	—	9.29	39.2
	3.20	—	4.00	9.50	—
	5.20	—	—	7.35	58.0
	5.08	—	—	7.30	52.3
	5.24	—	5.24	7.43	—

The stepwise nature of the electrochemical reduction of diarylmercury is noteworthy. Thus di-(*p*-nitrophenylmercury) is reduced in DME at a potential of −1.58 V to the radical-anion $R_2Hg^{\cdot-}$, which is also formed on oxidation of the corresponding triplet dianion $R_2Hg^{2\cdot-}$. The latter is a result of the two-electron reduction of di-(*p*-nitrophenyl)mercury at −1.84 V:

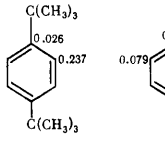
The fact that the ultraviolet spectra of $R_2Hg^{\cdot-}$ and $R_2Hg^{2\cdot-}$ are entirely identical indicates the lack of interaction between the unpaired electrons of the two nitrophenyl groups separated by the mercury atom (i.e. mercury behaves as a non-conducting bridge). The relatively high stability of the radical-anions of the nitrophenyl derivatives of mercury is due to the electron-accepting effect of the nitro-groups,

which prevents the accumulation of excess spin density in the mercury–carbon bond. In the general case radical-anions of the type $R_2Hg^{\cdot-}$ (R = phenyl, benzyl, or phenyl-*o*-carbaboranyl), formed on reduction of substrates with sodionaphthalene or lithium in DME, are unstable and decompose with liberation of metallic mercury and the formation of reactive carbanions, which undergo various transformations[26,27]:

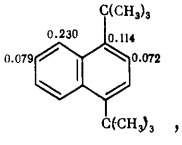
$$R_2Hg + C_{10}H_8^{\cdot-} \rightarrow R_2Hg^{\cdot-} + C_{10}H_8 \rightarrow R^- + {}^1/_2R_2Hg + {}^1/_2Hg \quad .$$



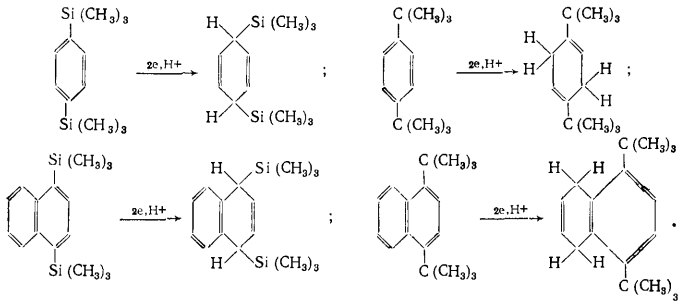
Numerous studies have been devoted to the radical-anions of Group IVA elements. It was of interest to elucidate the possibility of the involvement of the vacant *d* orbitals of these elements in the delocalisation of the unpaired electron. The radical-anions of trimethylsilyl- or trimethylgermyl-substituted benzenes and naphthalenes have EPR spectra with a hyperfine structure due to the methyl protons of the Me_3M groups[28–33]. The splitting of the signal by the methyl protons of the trimethylsilyl and trimethylgermyl groups is observed also in the radical-anions obtained by the reduction of phenylethynyltrimethylsilane and phenylethynyltrimethylgermane by alkali metals THF ($a_H^{SiMe_3} = 0.28$ G, $a_{Si} = 4.4$ G, $a_H^{GeMe_3} = 0.15$ G, and $a_{Ge} = 1.67$ G).[34,35] The chemical and electrochemical reduction of cyclic permethylpolysilane $(Me_2Si)_n$ ($n = 5$, 6, or 7) leads to the corresponding radical-anions, in which the unpaired electron interacts with all the methyl protons[37,38]. The spectrum of the radical-anion of di-(t-butyl)diacetylene is a singlet, while that of the radical-anion of di(trimethylsilyl)diacetylene consists of 19 lines due to the interaction of the unpaired electron with the 18 methyl protons ($a_H^{SiMe_3} = 0.15$ G and $a_{Si} = 5.25$ G).[36]



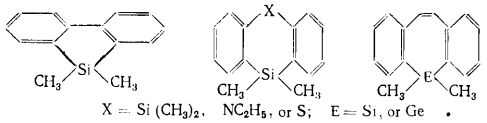
It is noteworthy that the radical-anions containing the trimethylsilyl and trimethylgermyl groups are more stable than their carbon analogues. With increase of the number of these groups, the stability of the radical-anion increases. Thus the *p*-bis-(t-butyl)benzene radical-anion is stable only at −70 °C, the *p*-bis(trimethylsilyl)benzene radical-anion is stable at 0 °C, and the radical-anion derived from 1,3,5-tris-(trimethylsilyl)benzene does not decompose for a long time at 20 °C.[30,39,40] The Hammett constants of the trimethylsilyl and trimethylgermyl groups in radical-anions of the type



$(CH_3)_3E$, E = Si or Ge,



are positive, which shows that they have electron-accepting properties[41,42]. This also follows from a comparison of the HFI constants for the radical-anions containing the trimethylsilyl and t-butyl groups and from the calculation of the spin densities by the MacConnell method[39,43]:



The above difference between the silicon and carbon analogues agrees well with the finding that the reduction of these compounds with sodium in liquid ammonia leads to products of different structure[43]:

In the radical-anions of phenylethyl derivatives of silicon and germanium the hyperfine interaction constants for the *meta*-protons of the benzene rings are higher than those for the *ortho*-protons, which confirms yet again the electron-accepting nature of these groups; the opposite relative values of the constants obtain for the t-butyl group[34,35]. The introduction of the trimethylsilyl group into the *N,N*-dimethylaniline molecule increases its electron affinity to such an extent that, despite the influence of the electron-donating dimethylamino-group, it is possible to obtain the radical-anion[44,45]. In the radical-anion of *p*-trimethylsilyl-*N,N*-dimethylaniline[44] the distribution of spin density is analogous to that for the benzene radical-anion, i.e. the influence of the two substituents cancels out.

The radical-anions formed in the reduction of different cyclic silicon and germanium compounds have been detected[46–49]:

X = $Si(CH_3)_2$, NC_2H_5, or S; E = Si, or Ge .

Their stability varies within fairly wide limits, but in this case the heteroatom has a stabilising influence and exhibits the properties of a π-acceptor[48].

The possibility of the delocalisation of the unpaired electron via the silicon in the radical-anions obtained on reduction (with potassium in DME) of dimethyldiphenylsilane, methyltriphenylsilane, and tetraphenylsilane has been studied[46,50,51]. The EPR spectra of the resulting radical-anions were characterised by the main doublet splitting ($a_H^{para} = 8$ G), which initially led to the conclusion that the unpaired electron is localised solely in the benzene ring. The lack of conductivity of the silicon atom was also noted for the radical-anions in which biphenyl groups are separated by a dimethylsilyl bridge[52,53]. Subsequently it was found that the primary radical-anions are extremely unstable even at a low temperature and decompose as a result of the following rapid reactions[54]:

$$(C_6H_5)_4Si \xrightarrow{e} [(C_6H_5)_4Si]^{\cdot-} \xrightarrow{e} (C_6H_5)_3Si^- + C_6H_5^-$$

$$(C_6H_5)_3Si^- \xrightarrow{CH_3OCH_2CH_2OCH_3} (C_6H_5)_3SiCH_3 \xrightarrow{e} [(C_6H_5)_3SiCH_3]^{\cdot-} \rightarrow$$

$$\xrightarrow{e} (C_6H_5)_2SiCH_3^- + C_6H_5^- \xrightarrow{CH_3OCH_2CH_2OCH_3} \ldots . [C_6H_5Si(CH_3)_3]^{\cdot-} \quad .$$

The trimethylphenylsilyl radical-anion is most stable in this series of radical-anions; its spectrum had apparently been detected in all previous instances.

The radical-anions derived from phenylsilanes are more stable in THF and give rise to resolved EPR spectra, which are identical regardless of whether they are produced chemically or electrochemically. The unpaired electron is delocalised over the entire phenyl groups and the form of the spectra is determined by the principal splitting by the *para*-protons

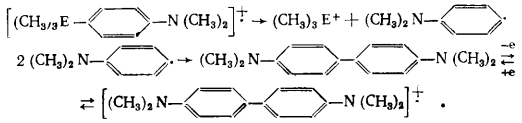
of the benzene rings with additional splitting of each component by the ring protons and the methyl protons of the silyl groups[54–57] (Table 2). For the dimethyldiphenylsilane radical-anion, the dependence of the distribution of spin density on temperature was demonstrated. In THF at temperatures below −70 °C the unpaired electron is localised in only one benzene ring, while on raising the temperature to −40 °C both phenyl groups are involved in the formation of a single conjugated system incorporating the silicon atom[58].

Table 2. EPR spectroscopic parameters for radical-anions of certain silicon-containing compounds (multiplicity in brakets)[54].

Compound	a_H^{ortho}, G	a_H^{ortho}, G	a_H^{meta}, G	$a_H^{CH_3}$, G
$C_6H_5Si(CH_3)_3$	8.06 (2)	2.61 (3)	1.03 (3)	0.26 (10)
$(C_6H_5)_2Si(CH_3)_2$	4.15 (3)	1.44 (5)	0.34 (5)	0.17 (7)
$(C_6H_5)_3SiCH_3$	2.76 (4)	1.01 (7)	0.19 (7)	0.10 (4)
$(C_6H_5)_4Si$	2.12 (5)	0.80 (9)	0.10 (9)	—

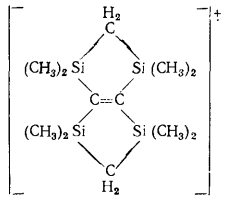
Thus analysis of the EPR data indicates the inclusion of the silicon and germanium atoms in the overall molecular orbital in which the unpaired electron is located. The transfer of spin density apparently takes place via a d_π–p_π interaction, which has been confirmed by the hyperfine structure due to the methyl protons of the trimethylsilyl and trimethylgermyl groups, the π-electron-accepting properties of these groups, and the conductivity of the silicon in the phenylsilane radical-anions.

Organotin and organolead radical-anions are almost unknown. There are data indicating the formation of radical-anions at 77 K by γ-radiolysis (^{60}Co) from tetramethyltin, trimethyltin chloride, and hexaphenyldistannane; the constants for the interaction of the unpaired electron with the $^{117/119}$Sn nuclei and the spin densities in the 5*s* orbitals of these isotopes have been determined. The hexaphenyldistannane radial-anion decomposes in accordance with the equation[59]

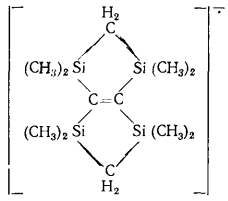


$$[(C_6H_5)_3Sn{-}Sn(C_6H_5)_3]^{\cdot-} \rightarrow (C_6H_5)_3Sn^- + (C_6H_5)_3Sn^{\cdot}\ .$$

Lead-containing radical-anions of the type $R_3PbX^{\cdot-}$ ($R = CH_3$ or C_6H_5; X = Cl or Br),[60,61] characterised by a marked splitting of the EPR signal by the ^{207}Pb nuclei ($a_{Pb} = 2108$–2366 G) and a hyperfine structure due to ^{35}Cl and ^{81}Br, have been generated by the same method.

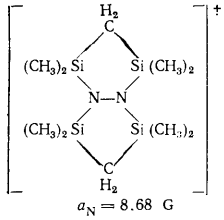


Organoelemental radical-cations were discovered only recently. An unstable radical-cation is formed on electrochemical oxidation of *p*-trimethylsilyl- and *p*-trimethylgermyl-*N*,*N*-dimethylanilines[62,63]:

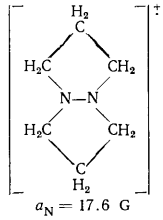


The negligibly small methyl proton hyperfine interaction constants of the organoelemental groups ($a_H < 0.1$ G) indicate only a slight interaction of the silicon and germanium atoms with the π-system of the radical-cation. In the presence of nucleophiles the radical-cations decompose rapidly:

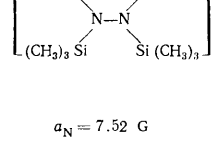
One-electron oxidation of tetrasilylethylenes and tetrasilylhydrazines (by $AlCl_3$, $AgBF_4$, and $SbCl_5$) in CH_2Cl_2 yielded stable silicon-containing radical-cations[64,65]. The splitting constants for the nuclei in the corresponding radical-anions of tetrasilylethylene were much smaller than for the radical-cation[64]:



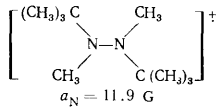
$a_{Si} = 22.716$ G, $a_H^{CH_3} = 0.62$ G, $a_H^{CH_2} = 2.48$ G



$a_{Si} = 6.72$ G, $a_H^{CH_3} = a_H^{CH_2} = 0.48$ G.

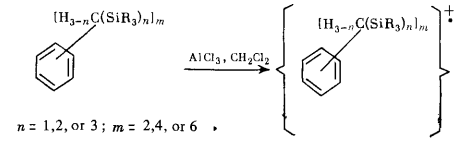


In tetrasilylhydrazine radical-cations the spin density at the >N–N< fragment is reduced compared with the carbon analogues[65,66]:

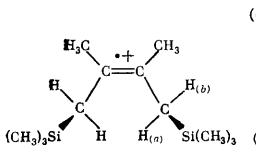


$a_N = 8.68$ G

$a_N = 17.6$ G

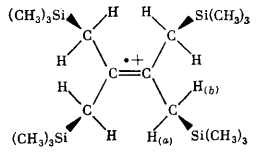


$a_N = 7.52$ G



$a_N = 11.9$ G

In the tetrakis(trimethylsilyl)hydrazine radical-cation the trimethylsilyl group has the same influence as the phenyl group in the tetraphenylhydrazine radical-cation ($a_N = 7.52$ G).[67] All this reflects the electron-donating properties of the trimethylsilyl group, which is capable of delocalising the positive charge in the radical-cation[68]. This conclusion was confirmed in a study of a series of radical-cations obtained from derivatives of poly(trimethylsilylalkyl)-substituted benzenes[69]:



$n = 1,2,$ or 3; $m = 2,4,$ or 6.

Here too a decrease of spin density in the benzene ring was observed with increase of the number of trimethylsilyl substituents. It is noteworthy that the methylene protons in the radical-cations containing trimethylsilylmethyl groups are non-equivalent:

$a_H^a = 1.07$ G, $a_H^b = 0.76$ G

$a_H^a = 0.85$ G, $a_H^b = 0.73$ G.

The difference between the splitting constants ($a_H^a \neq a_H^b$) indicates the absence of free rotation of the $CH_2Si(CH_3)_3$ groups and the conformational stability of these radicals[70,71].

Thus, whereas the trimethylsilyl group in the radical-anions described above behaves as a π-acceptor, in the radical-cations the same group is a powerful electron donor. The transfer of spin density apparently takes place via a mechanism involving hyperconjugation between the silicon–carbon bond and the *p* orbital of the unpaired electron[72].

III. ELEMENT-CENTRED RADICALS

This class of free radicals includes organoelemental radicals in which the unpaired electron is localised preferentially at the atom of the element. The formation of such radicals is frequently an intermediate stage in a whole series of reactions, but there is comparatively little reliable information about them. This is due to the lack of convenient methods for their generation unaccompanied by their rapid subsequent reactions. Being essentially derivatives of elements which do not exhibit their full valence element-centred radicals should behave as active electron donors; in this respect they differ significantly from the majority of "purely" organic free radicals.

The chemistry of organomercury free radicals RHg· has been continuously discussed for more than forty years, but so far it has not been possible to detect them by any of the physical methods. The formation of the free radicals RHg· has been postulated in the classical studies by Razuvaev and coworkers[73–76] on the thermal and photochemical decomposition of organomercury compounds:

$$R_2Hg \rightarrow RHg^{\cdot} + R^{\cdot}; \quad RHgOH \rightarrow RHg^{\cdot} + {}^{\cdot}OH \quad .$$

In halogen-containing media reactions of this kind lead to organomercury halides (formally, this entails the abstraction of the halogen atom):

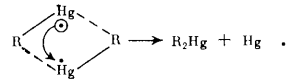
$$RHg^{\cdot} + R'Cl \rightarrow RHgCl + R'^{\cdot} \quad .$$

However, it is perhaps more correct to treat the last reaction as a one-electron transfer process:

$$RHg^{\cdot} + R'Cl \rightarrow RHg^{+} + R'^{\cdot} + Cl^{-} \quad .$$

The radicals RHg· are clearly incapable of abstracting a hydrogen atom and in solvents without a halogen they decompose, according to Razuvaev, in one of two ways:

$$RHg^{\cdot} \rightarrow R^{\cdot} + Hg, \quad 2\,RHg^{\cdot} \rightarrow R_2Hg + Hg \quad .$$



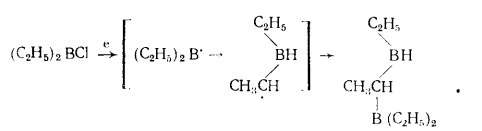
Radicals of the type RHg· are undoubtedly formed in the electrochemical reduction of organomercury solvents[77–79]:

$$RHg^{+} + e \rightleftarrows RHg \quad .$$

However, the electrode reaction, which is in principle reversible, in the present instance becomes in fact irreversible owing to the rapid subsequent reactions of the radical RHg·. The final products are dialkylmercury and mercury[79,80]; the majority of investigators are at present inclined to the idea that an "organic calomel" RHgHgR is formed as an intermediate, but not a single compound of this type has so far been isolated[77–79]. The electrochemical symmetrisation of the stereoisomeric β-chlorovinylmercury chlorides takes place with complete retention of the configuration of the organic group[81], which means that the β-chlorovinyl free radicals are not involved in such symmetrisation and the reaction

$$ClCH{=}CHHg^{\cdot} \rightarrow ClCH{=}CH^{\cdot} + Hg$$

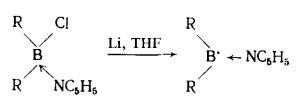
can occur only as a side process (liberation of the radical from the "cage"). The intermediate formation of "organic calomel" is at present only a hypothesis; the available data can be accounted for no less successfully by the disproportionation of two RHg· radicals occurring as a one-electron transfer process in the transition complex:



Substances readily conducting electric current and decomposing on heating with formation of dialkylmercury and mercury have been isolated in the electrolysis of solutions of alkylmercury chlorides in liquid ammonia at the cathode[82–84]. However, EPR study of these substances showed that they are diamagnetic[85]. Evidently the compounds obtained have a metallic lattice formed by ions and all the conduction electrons belong to it as a single whole. The view that the homolysis of fully substituted organomercury compounds takes place, like their electrochemical reduction, with the simultaneous abstraction of both organic groups, has been established recently. However, one should bear in mind the meaning attributed to the concept of simultaneity. In their discussion of the mechanism of one-electron transport, Basolo and Pearson correctly note that the "concept of simultaneity is unsatisfactory"[86]. True simultaneity is kinetically indistinguishable from a sequence of two reactions the first of which is rate-limiting:

$$R_2Hg \xrightarrow{\text{slow}} RHg^{\cdot} + R^{\cdot}; \quad RHg^{\cdot} \xrightarrow{\text{fast}} R^{\cdot} + Hg \quad .$$

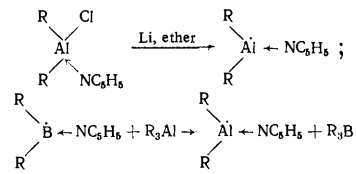
There is at present no reason to abandon Razuvaev's initial treatment and the reduction of organic halides in the course of photolysis of dialkylmercury can be regarded as important evidence in support of the actual existence of RHg· radicals. The possibility, in principle, of the stepwise electrochemical reduction of diarylmercury also clearly follows from the study of Dessy et al.[25] already quoted.



Attempts have been made in a number of investigations to obtain organic derivatives of Group IIIA elements not in their maximum valence state. The reduction of dialkylboron chlorides by alkali metals did not lead to organoboron radicals which could be detected by EPR, owing to their rapid dimerisation[87,88]:

On treatment with potassium in benzene, diphenylboron chloride gives rise to a dimeric product, which is reduced in DME to a radical-anion; the EPR spectrum consists of 7 lines due to the interaction of the unpaired electron with two boron atoms ($a_B = 2.9$ G):[11]

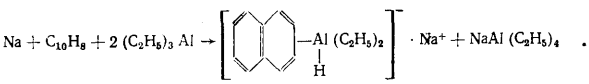
$$(C_6D_5)_2BCl \xrightarrow{\text{K, benzene}} (C_6D_5)_2B{-}B(C_6D_5)_2 \xrightarrow{\text{K, DME}} [(C_6D_5)_2B{-}B(C_6D_5)_2]^{-} \quad .$$



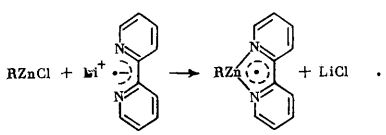
Data apparently indicating the formation of the dimesitylboron radical on reduction of dimesitylboron fluoride proved to be erroneous[89]. The spectrum of the radical obtained proved to be identical with the spectrum of the trimesitylboron radical-anion[11]. However, dialkylboron radicals stabilised by bases (pyridine, quinoline) are fairly stable[87,88]:

(R = C_2H_5 or C_6H_5).

Depending on the base, boron-centred radicals are associated



to different extents in solution. Thus the diethylboron radical stabilised with 4-methylquinoline is monomeric. In the case of 4-methylpyridine the analogous radical exists as the trimer; the EPR spectrum exhibits 10 lines due to the splitting of the unpaired electron signal by three boron nuclei ($a_B = 3.83$ G). Aluminium-centred radicals have been obtained similarly[87]:

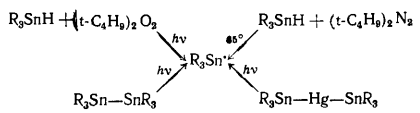


They are also formed on electrochemical reduction or on treatment of trialkylaluminium compounds with sodionaphthalene[90,91]. It is believed that the dialkylaluminium cation, obtained by the reaction[92]

$$[(C_2H_5)_3\,Al]_2 \rightleftarrows (C_2H_5)_2\,Al^+ + (C_2H_5)_4\,Al^-$$

is then reduced. The radicals formed in the reduction process are stabilised in the presence of bases. The following adduct has been obtained with sodionaphthalene[91]:

One must note that the true structure of the boron- and aluminium-centred radicals involves an appreciable transfer of spin density to the stabilised ligand. In the organozinc radicals having a similar structure the unpaired electron is fully localised in the ligand:



This is indicated by the absence of a hyperfine coupling with ^{67}Zn and the protons of the alkyl substituents[93]. These radicals have in fact the structure of an ion pair.

The greatest successes in the field of element-centred free radicals have been achieved for derivatives of Group IVA elements. A convenient method for the generation of radicals of the type $R_3E^\cdot$ involves the interaction of the hydrides of these elements with t-butyl peroxide under irradiation[94,99]:

$$R_3EH + t\text{-}C_4H_9O^\cdot \rightarrow R_3E^\cdot + t\text{-}C_4H_9OH\ .$$

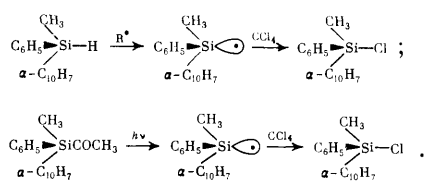
The tris-(2-phenyl-2-methylpropyl)stannyl radical has been obtained by several methods[100]:

Unusually stable radicals of this type are formed when the dihalides ECl_2 (E = Sn or Ge) interact with bis(trimethylsilyl)methyl-lithium and this is followed by ultraviolet irradiation[101–103]:

$$ECl_2 + RLi \rightarrow R_2E \xrightarrow{h\nu} R_3E^\cdot$$

$$Si_2Cl_6 + RLi \rightarrow (RSiCl_2)_2 + [R_2SiCl{-}SiCl_3] \xrightarrow{-SiCl_4} [R_2Si] \xrightarrow{h\nu} R_2Si\ .$$

The corresponding bivalent derivatives R_2E have been isolated for tin and germanium[104]; therefore the photochemically initiated decomposition actually leads to the formation of stable element-centred radicals. The same radicals can be obtained on ultraviolet irradiation of the trialkyl derivatives of the halides of the elements in the presence of electron-donating olefins[105]:



$$2\,R_3ECl + (Me_2N)_2C{=}C(NMe_2)_2 \xrightarrow{h\nu} [R_3ECl]^{\tau} \rightarrow R_3E^\cdot + [(Me_2N)_2C{=}C(NMe_2)_2]^{2+} \cdot 2\,Cl^-\ .$$

The multiplet EPR spectra of element-centred radicals with satellite lines due to the magnetic isotopes ^{29}Si, ^{73}Ge, and $^{117/119}$Sn have been recorded (Table 3).

Table 3. EPR spectroscopic parameters for certain element-centred radicals[100–105].

Radical	a_H, G	a_E, G	g-Factor
$(CH_3)_3Si^\cdot$	6.28	181	2.0032
$(CH_3)_3Ge^\cdot$	5.28	84.7	2.0101
$(CH_3)_3Sn^\cdot$	2.76	1899 and 1986	2.0154
$[(Me_3Si)_2CH]_3Si^\cdot$	4.8	198	2.0027
$[(Me_3Si)_2CH]_3Ge^\cdot$	3.8	92	2.0078
$[(Me_3Si)_2CH]_3Sn^\cdot$	2.1	1698 and 1776	2.0094

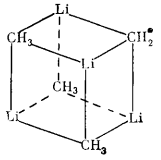
The high values of the splitting constants for the nuclei of the central elements indicate significant *s* character of the unpaired electron orbital, as a result of which 80% of the spin density corresponds to the heteroatom[106–109]. This also indicates a pyramidal structure of the radicals, in which the metal–carbon bonds deviate from the plane by 12–14°. This structure has been confirmed by a chemical study of the radicals derived from asymmetric silicon compounds, which react with retention of configuration[110,111]:

The latter factor shows that the large series of old studies on the mechanism of substitution at the silicon atom, where the reaction mechanism was inferred from the retention of optical activity, are evidently incorrect[112].

Element-centred radicals are very reactive and their lifetime is therefore extremely short. However, there exists a group of radicals which are unusually stable: the half-lives of $R_3E^\cdot$ [E = Si, Ge, or Sn; R = bis(trimethylsilyl)methyl] at 30 °C are respectively 10 min, 4 months, and 1 year[102]. This is caused by the steric hindrance due to the bulky alkyl groups, as a result of which the central metal atom cannot assume the tetrahedral configuration and hence the recombination or abstraction of a hydrogen atom from the solvent becomes impossible.

Measurements of the magnetic susceptibilities of solutions of compounds of the type $R_3E{-}ER_3$ ($R = C_6H_5$; E = Ge, Sn, or Pb) showed that they are incapable of dissociating into free radicals[113–115]. Small amounts of trimesityl-lead radicals, detected by EPR, are formed only in highly dilute solutions of hexamesityldiplumbane[116].

Thus the stability of organoelemental radicals R_3E is determined mainly by the size of the organic groups linked to the central metal atom. The radicals are most stable in the presence of bulky substituents.



Information about the principal reactions of element-centred radicals can be found in recent monographs[117,118].

IV. ORGANOELEMENTAL COMPOUNDS WITH PARAMAGNETIC LIGANDS

This group of compounds is most varied among those considered. Naturally the classification adopted in the present study is conventional and there are no absolutely clear-cut boundaries between the three groups of paramagnetic species which we have distinguished. Thus in many compounds of the last group a definite proportion of spin density corresponds also to the metal.

Organoelemental free radicals in which the unpaired electron is localised mainly in the ligand include, in particular, α-substituted alkyl radicals of the type $^{\cdot}CR_2ER'_n$, where ER'_n is an organometallic group.

The reaction of methyl-lithium with photochemically generated t-butoxy-radicals in ether yielded a radical containing the CH_2Li fragment[119]. The well-resolved EPR spectrum of this radical consists of a triplet of decets due to the interaction of the unpaired electron with two equivalent protons ($a_H = 18.23$ G) and three equivalent ^7Li nuclei ($a_{Li} = 1.67$ G), which corresponds to the following structure of the radical:

Consequently the structure of tetrameric methyl-lithium[120,121] is not significantly distorted following the abstraction of a hydrogen atom and the system comprising three lithium atoms is non-conducting.

The interaction of t-butoxy-radicals with organomagnesium compounds proceeds in two ways[122]:

$$RCH_2MgX + t\text{-}C_4H_9O^{\cdot} \begin{cases} \longrightarrow R_2\dot{C}H_2 + t\text{-}C_4H_9OMgX \\ \longrightarrow R\dot{C}HMgX + t\text{-}C_4H_9OH \end{cases}$$

The hyperfine interaction constants for the α-protons are almost independent of R for magnesium-containing radicals and are in all cases 18.5 G. The absence of hyperfine structure due to the ^{35}Cl and ^{19}F nuclei in the radicals $^{\cdot}CH_2MgCl$ and $^{\cdot}CH_2MgF$ and the methyl protons in $^{\cdot}CH_2MgCH_3$ shows that the magnesium atom is non-conducting in radicals of this type. Low-temperature γ-radiolysis of trialkylaluminium compounds[123] and methylmercury chloride[124] leads to the corresponding alkyl radicals containing the organometallic group in the α-position. The negative sign of the hyperfine interaction constants for ^{27}Al is evidence for the transfer of spin density via a spin polarisation mechanism.

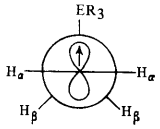
Analogous radicals of Group IVA elements have been obtained via the same general mechanism[125,126]:

$$R_3ECH_3 + t\text{-}C_4H_9O^{\cdot} \rightarrow R_3E\dot{C}H_2 + t\text{-}C_4H_9OH$$

In view of the independence of $a_H^{CH_2}$ and the *g*-factor of the type of element, it was concluded that there is no direct delocalisation of the unpaired electron over the vacant *d* orbitals of these elements[127,128].

Thus the nature of the substituent in the radicals of the type $^{\cdot}CR_2ER'_n$ has little influence on the spin density distribution (the $a_H^{CH_2}$ constant changes only slightly) and the observed splittings by the nuclei of the elements are caused by spin polarisation.

The addition of element-centred radicals to carbon–carbon double bonds leads to radicals in which the organoelemental group is in a β-position with respect to the radical centre[126, 129–132]:



E = Si, Ge, or Sn.

The EPR spectra of these radicals are characterised by an anomalously small splitting by β-protons (Table 4).

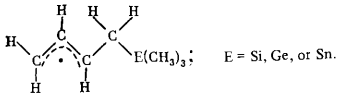


Table 4. EPR spectroscopic parameters for β-substituted ethyl radicals $^{\cdot}CH_2–CH_2–E(CH_3)_3$.[126,129–132]

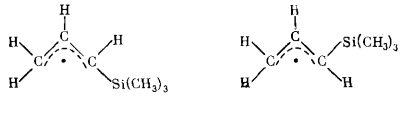
E	a_H^{α}, G	a_H^{β}, G	$a_H^{CH_3}$, G	a_E, G	*g*-Factor
C	22.06	24.71	0.1	—	2.00268
Si	21.05	17.68	0.10	37.4	2.00265
Ge	20.70	16.57	0.14	488.9	2.00255
Sn	19.69	15.84	0.15	467	2.00255

The temperature dependence of the constant a_H^{β} indicates the presence of a barrier to rotation about the $C_\alpha–C_\beta$ bond. In the most stable configuration the organoelemental group is eclipsed by the *p* orbital, in which the unpaired electron is located:



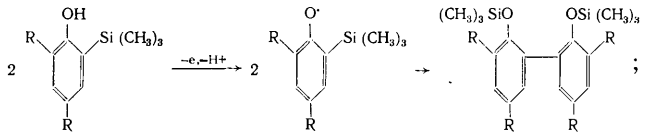
Allyl radicals also exhibit conformational stability[133,134]:

E = Si, Ge, or Sn.

This is confirmed by the non-equivalence of the methylene protons attached to the carbon atom linked to the organoelemental group; here too the organoelemental group is eclipsed by the *p* orbital of the unpaired electron. It is of interest to note the significant difference between the hyperfine interaction constants of the methyl protons in *cis*- and *trans*-trimethylsilylallyl radicals[136]:

$a_H^{CH_3} < 0.05$ G $\qquad$ $a_H^{CH_3} = 0.27$ G

These radicals proved incapable of isomeric interconversion.

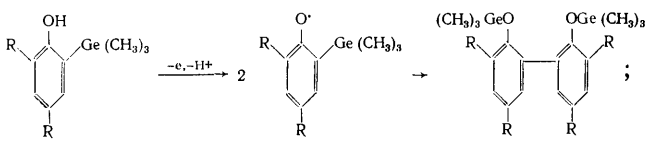


In trimethylsilyl-substituted cyclopentadienyl radicals the trimethylsilyl group in the α-position with respect to the radical centre behaves as an electron acceptor, while the same group in the β-position with respect to the π-system exhibits electron-donating properties. This follows from a comparison of the spin densities in the following radicals[136]:

Thus the conformational stability of β-substituted ethyl radicals $\cdot CH_2CH_2ER_3$ is due to the interaction of the unpaired electron with the organoelemental group, which exhibits the properties of an electron-donating substituent. This interaction apparently takes place via the hyperconjugation of the metal–carbon bond with the *p* orbital of the unpaired electron[137–139].

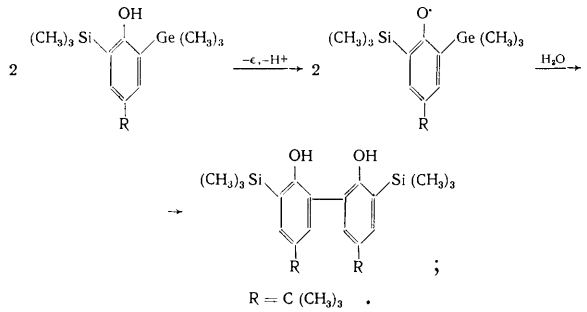
The radicals obtained by the oxidation of organoelemental derivatives of sterically hindered phenols are convenient objects for the study of the structure and properties of radicals in which the metal atom is involved in conjugation with a paramagnetic fragment. The phenoxy-radicals known hitherto, containing the substituents R_nE (E = Si, Ge, Sn, P, or As), differ sharply in their stability and reactions from their carbon analogues.

When 4,6-di-t-butyl-2-trimethylsilylphenol is oxidised by PbO_2 or an alkaline solution of $K_3Fe(CN)_6$, the phenoxy-radical formed dimerises rapidly with simultaneous migration of the *o*-trimethylsilyl group to the oxygen atom[140,141]:



R = C $(CH_3)_3$.

The EPR spectrum of this radical contains four lines due to the interaction of the unpaired electron with the two non-equivalent *meta*-protons (a_H = 1.7 G, a_H = 2.2 G).[142,143] The migration of the *o*-trimethylsilyl group and the formation of a dimer are also possible on oxidation of 4-t-butyl-2,6-bis-(trimethylsilyl)phenol. The spectrum of the intermediate phenoxy-radical consists of a triplet (a_H = 1.8 G) with additional splitting of each component by the protons of the trimethylsilyl group ($a_H^{SiMe_3}$ = 0.4 G).[142]



o-Phenyldimethylsilyl and *o*-triphenylsilyl groups are also able to migrate to the oxygen atom of the aryloxy-radical[144,145]. The introduction of the *o*-triphenylsilyl group reduces the capacity of the *o*-trimethylsilyl group for migration, increasing at the same time the stability of the corresponding phenoxy-radical. In the radical formed on oxidation of 4-cyclohexyl-2-trimethylsilyl-6-triphenylsilylphenol the "inhibiting" effect of the triphenylsilyl group makes the trimethylsilyl group altogether incapable of migration, while the 4-t-butyl-2-trimethylsilyl-6-triphenylsilylphenoxy-radical is the most stable silicon-containing phenoxy-radical; its EPR spectrum consists of a triplet (1:2:1) with additional splitting of each component by the protons of the $(CH_3)_3Si$ and $(C_6H_5)_3Si$ groups (a_H^{meta} = 1.8 G, $a_H^{Si(CH_3)_3}$ = 1.5 G).[145] The hyperfine interaction constants for the protons of the t-butyl groups in the *ortho*-positions in the 2,4,6-tri-t-butylphenoxy-radical (a_H = 0.072 G)[146] and the trimethylsilyl groups in the 4-t-butyl-2,6-bis(trimethylsilyl)phenoxy-radical (a_H = 0.4 G) differ by a factor of approximately 6. This shows that the spin conductivity of silicon is much higher than that of carbon[147].

The trimethylgermyl group is also capable of migrating to the oxygen atom of the aryloxy-radical[148–150]:

R = C $(CH_3)_3$.

In order to compare the migratory capacities of R_3Si and R_3Ge, mixed silicon-germanium-containing phenoxy-radicals have been synthesised. The oxidation of 4-t-butyl-6-trimethylgermyl-2-trimethylsilylphenol leads to 5,5′-di-t-butyl-2,2′-dihydroxy-3,3′-bis(trimethylsilyl)biphenyl[149,150]:

R = C $(CH_3)_3$.

This indicates a greater capacity of the trimethylgermyl group for migration. The replacement of the trimethylsilyl group by the triphenylsilyl group increases the stability of the radical[149]. Thus the capacity for migration of the group in the *ortho*-position diminishes in the sequence $(CH_3)_3Ge > (CH_3)_3Si > (C_6H_5)_3Si$.

2,6-Di-t-butylphenoxy-radicals containing an organometallic group in the *para*-position are more common. The EPR spectra contain, apart from the main signal due to the interaction of the unpaired electron with the *meta*-protons, additional lines due to coupling with the magnetic nuclei of the substituents (Table 5).

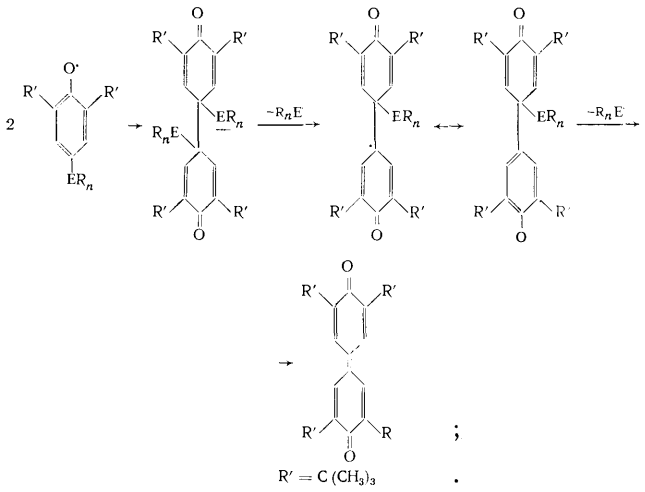


Table 5. EPR spectroscopic parameters for 2,6-di-t-butylphenoxy-radicals containing an organoelemental group R in the *para*-position.

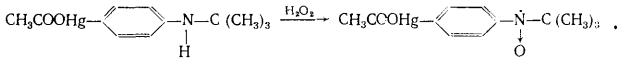
R	a_H^{meta}, G	a_E, G	References
$(CH_3)_3Si$—	1.8	12.4	148
$(CH_3)_3Ge$—	1.7	2.9	148
$(C_6H_5)_3Sn$—	1.82	58.13 и 61.0	151
$(C_6H_5)_2P$—	1.6	6.8	152–154
$(C_6H_5)_2P$ (O)—	2.0	14.7	152–154
$(C_6H_5)_2P$ (S)—	2.0	15.4	152–154
$(C_6H_5)_2As$—	1.83	24.7	153–155
$(C_6H_5)_2As$ (O)—	2.0	14.1	153–155
$(C_6H_5)_2As$ (S)—	2.0	14.5	153–155

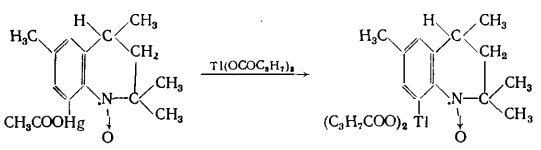
It follows from a comparison of a_H^{meta} for the 2,4,6-tri-t-butylphenoxy-radical (a_H = 1.80 G)[157] and the data in Table 5 that the organometallic group has only a weak influence on the spin density distribution in the radical. The splitting constants for Ge and Si in the *para*-position are greater than those for Ge and Si in the *ortho*-position, which shows that, as regards the distribution of spin density, such radicals are analogous to the 2,4,6-tri-t-butylphenoxy-radical[158].

In contrast to the *ortho*-analogues, in *para*-substituted organoelemental phenoxy-radicals the organometallic group proved to be incapable of migrating to the oxygen atom of

the aryloxy-radical. The most common property is elimination of the organometallic group with formation of 3,3',5,5'-tetra-t-butyldiphenoquinone as the final product[152,153]:



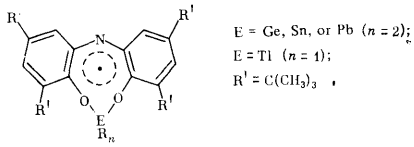
$R' = C(CH_3)_3$.



A qualitatively new spin density distribution has been observed for phenoxy-radicals containing electron-accepting carbaboranyl substituents[159]. Analysis of the hyperfine structure of the EPR spectra showed that the unpaired electron hardly interacts with the protons located in the *meta*-positions in the ring. The observed spectra can be interpreted as a result of the splitting of the signal by six boron nuclei ($a_B = 0.9$ G) closest to the carbon–carbon bond in the carbaborane ring. These radicals are distinguished by high stability in solution; in particular, they persist for several hours in acetic acid and hardly interact with atmospheric oxygen. It has been observed[160] that the 2,6-di-t-butyl-4-(2-carbaboranyl)phenoxy-radical readily rearranges to the *ortho*-isomer.

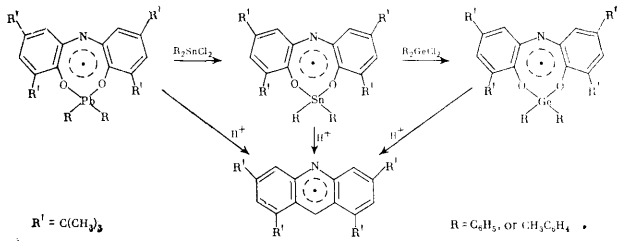
Thus the presence of the unpaired electron in the *m*-carbaborane ring significantly distorts the system of many-centre orbitals linking the boron–carbon skeleton, as a result of which the *meta–ortho* rearrangement, noted previously for the diamagnetic *m*-carbaborane dianions[161,162], is considerably facilitated.

Stable organomercury radicals have been obtained by the oxidation of mercurated phenylamines by hydrogen peroxide in dioxan in the presence of sodium tungstate[163]:



The EPR spectra of these radicals show the main triplet splitting by the ^{14}N nucleus and the additional groups of lines, due to splitting by the magnetic mercury isotopes, reproduce exactly the structure of the "nitrogen" component. A common feature of mercury-containing nitroxy-radicals is increased splitting by nitrogen and the phenyl protons compared with the unsubstituted radicals. An interesting fact was observed in the study of the reaction of 8-acetoxymercuri-2,2,4,6-tetramethyl-1,2,3,4-tetrahydroquinoline nitroxy-radical with thallium tri-isobutyrate[164]:

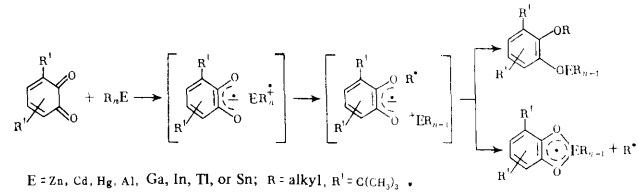
The exchange of mercury for thallium gives rise to a new thallium-containing radical. The hyperfine structure of its EPR spectrum indicates the interaction of the unpaired electron with two thallium isotopes—^{203}Tl ($I = 1/2$) and ^{205}Tl ($I = 1/2$) ($a_{Tl} \approx 240$ G).



The reduced nitrogen splitting constant ($a_N = 6.5$ G) for the bis(trimethylsilyl)nitroxy-radical $(Me_3Si)_2NO^{\cdot}$ indicates an intense d_π–p_π interaction between the silicon and nitrogen atoms. The trimethylgermyl group is a weaker acceptor; thus the hyperfine interaction constant for nitrogen in $(Me_3Ge)_2NO^{\cdot}$ is 8.8 G.[165]

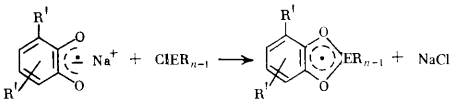
The interaction of the 2-amino-4,6-t-butylphenoxy-radical with the diaryl derivatives of the halides of Group IVA elements[166–168] and thallium[169] leads to radicals having the following structure:

E = Ge, Sn, or Pb ($n = 2$);
E = Tl ($n = 1$);
$R' = C(CH_3)_3$.



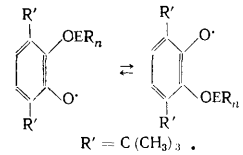
They are stable with respect to the action of atmospheric oxygen and can be isolated in a solid state. Their EPR spectra exhibit lines due to the interaction of the unpaired electron with the nuclei of the elements ^{73}Ge ($a = 3.02$ G), ^{119}Sn ($a = 46.5$ G), ^{117}Sn ($a = 44.5$ G), and ^{207}Pb ($a = 41.68$ G). The hyperfine interaction constants for the protons and the nitrogen atom are virtually the same for all the radicals and are independent of the nature of the substituent R attached to the element. In the series Pb, Sn, Ge each succeeding element can substitute the preceding element in the radical via the mechanism

$R' = C(CH_3)_3$ $R = C_6H_5$, or $CH_3C_6H_4$.



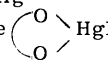
On treatment with acid, the 2,4,6,8-tetra-t-butylphenoxazinyl radical is formed[170].

o-Quinones are effective oxidants for metals capable of one-electron oxidation[171–173]; the reactions of organometallic compounds with substituted *o*-quinones also involve a one-electron transfer stage and lead to the formation of relatively stable intermediates[174–178]:

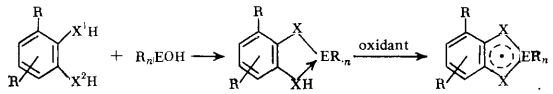


E = Zn, Cd, Hg, Al, Ga, In, Tl, or Sn; R = alkyl, $R' = C(CH_3)_3$.

Paramagnetic semiquinolates containing the organoelemental groups ER_{n-1} have been detected by EPR. The same radicals can be obtained by an exchange reaction:



The nature of the metal–carbon bond has a strong influence on the spin density distribution in *o*-semiquinolates and on the hyperfine interaction with the paramagnetic nuclei of the central atom. In the *o*-semiquinolates obtained from 3,6-di-t-butyl-*o*-quinone and organometallic compounds of zinc, cadmium, or tin an intramolecular migration of the organometallic residue between the oxygen atoms at a rate measurable by EPR was observed[175,176]:



R′ = C(CH$_3$)$_3$.

Thus, owing to the temperature variation of the frequency of the intramolecular migration of the chlorodimethylstannyl group, the EPR spectrum of the radical is transformed from a doublet of doublets with splitting by the ring protons ($a_H = 5.2$ G and $a_H = 2.6$ G) at a low temperature into a triplet ($a_H = 3.6$ G) at a high temperature. The splitting constants for tin change little under these conditions ($a_{^{117}Sn} = 21.5$ G, $a_{^{119}Sn} = 22.5$ G).[176] In paramagnetic chelates formed with central atoms of other elements this effect was not observed, which can be explained either by the rapid migration of the organometallic group or by its localisation on the C_2 symmetry axis or in the symmetry plane of the benzene ring.

A sharp decrease of the *g*-factor has been noted for mercury derivatives compared with other derivatives as well as a dependence of a_{Hg} on the nature of the substituent at the mercury atom[175,177]. With increase of the bulk of the alkyl substituent, a_{Hg} increases from 5.3 G for the methyl group to 10.4 G for the t-butyl group. The nature of the influence of the group at the mercury atom on a_{Hg} has been explained by a change in the configuration of the  fragment as the bulk of the substituent is altered. It is believed that in the complex the mercury atom has a pyramidal structure, but, with increase of the substituent bulk, the fragment is flattened, which leads to an increase of the amount of *s* character of the bonding orbitals of the Hg–O bond. For the most bulky substituent, pure sp^2-hybridisation occurs at the mercury atom, which corresponds to the maximum value of a_{Hg} and this is due to the spin polarisation of the σ-bonds by the unpaired electron in the *p* orbital of the oxygen atom[175]. The increase of splitting by the Al, Ga, Tl, and In nuclei in the alkyl derivatives of the corresponding elements relative to their halides[179,180] has also been attributed to a change in the geometry of the chelate on passing to the more bulky alkyl substituents[174].

Paramagnetic nitrogen-containing thallium and tin chelates have been obtained via the mechanism[181–184]

R = phenyl; E = Sn or Tl; $X^1 = O$, $X^2 = NH$ or $X^1 = X^2 = NH$.

An increase in the splitting constants for the nuclei or the elements on passing to nitrogen-containing chelates has been noted. Whereas $a_{Tl} = 10$ G for the *o*-semiquinolates of diphenylthallium, the constants for the chelates formed by *o*-aminophenol and *o*-phenylenediamine are 40 and 90 G respectively. The dependence of a_{Tl} on the solvating capacity of the solvent increases in the same sequence, which has been explained by the increasing covalence of the metal–ligand bonds for complexes of the latter type[182,183].

The influence of the solvent on the splitting constants due to the interaction with the nuclei of the central elements is apparently associated with a change in the geometry of the chelate under the influence of the solvating solvent, as a result of which the contributions of the *s* and *p* orbitals of the elements to the atomic orbital responsible for the hyperfine structure is changed and the direct appearance of the spin density is caused by the polarisation of these orbitals[185].

Thus there are good prospects for the further development of the chemistry of paramagnetic organic derivatives of non-transition elements established at the present time. The relatively stable radical-ions of the type $R{-}m^{\cdot-}$ and $R{-}m^{\cdot+}$ are convenient models for the determination of the detailed features of the mechanism of the dissociation of the element–carbon bonds. The study of the properties and reactions of element-centred radicals creates the necessary basis for the development of fundamentally new synthetic methods in the field of organoelemental chemistry. Both these fields make it possible in many instances to solve problems of the electronic structure of organoelemental compounds, in particular the problem of the resonance conductivity of the heteroatom. The extensive field of the chemistry of stable radicals will be undoubtedly enriched by data for organoelemental species of this class.

Oxidation-reduction Measurements and Their Applications in the Study of Interactions in Solutions

V.V.Pal'chevskii and Kh.M.Yakubov

The theoretical principles of oxidation-reduction measurements and their applications in the study of chemical processes accompanied by electron transfer are considered. These include complex formation, protolytic reactions, and association in homogeneous and heterogeneous oxidation-reduction systems.
The bibliography includes 168 references.

I. INTRODUCTION

The oxidation potential, which is a thermodynamic characteristic of a reversible oxidation-reduction system or an oxidation-reduction reaction, is used in many studies among which one can distinguish three main fields.

1. Quantitative determination of the content in solution of one or several components. These must react fairly completely and rapidly with the oxidant or reductant introduced into the solution. This field, established for a long time, constitutes a branch of analytical chemistry[1]. The measurement of the oxidation potential in analytical determinations is carried out either potentiometrically or with the aid of oxidation-reduction indicators[2].

2. Determination of the composition and equilibrium constants for the formation of molecular and ionic forms of substances constituting an oxidation-reduction system.

3. The study of the nature of the chemical bond and of the charge distribution in polyatomic compounds capable of oxidation or reduction. The difference between the oxidation potentials of related compounds, in which the nature of the oxidising (reducing) centre remains unchanged, is interpreted quantitatively. The theoretical methods employed (correlations, quantum-chemical methods) are varied and differ significantly in their validity[3,4]. It is noteworthy that the conversion of the oxidation potential to the molecular orbital energy requires assumptions whose justification is difficult to estimate.

The requirements which must be met by the accuracy of the determination of the oxidation potential in each field differ significantly. They are greatest in the second field, whose establishment and development are associated with the studies of Clark and Michaelis[5,6]. Measurements of the oxidation potential in order to discover the nature of the chemical interaction have been made and are being made on a very wide scale. An appreciable development of the second field has been achieved in the studies of Academician B.P.Nikol'skii. This review deals mainly with the studies carried out by Nikol'skii's school.

II. THE OXIDATION POTENTIAL

Oxidation-reduction measurements constitute a branch of physical chemistry which deals with the study of chemical reactions accompanied by electron transfer[7]. This transfer can take place between the components of two oxidation-reduction systems, where the oxidised form of one system removes electrons from the reduced form of the other, oxidising it and being itself reduced. As a result of such oxidation–reduction reaction, new substances are formed. The transfer of n electrons e also occurs between the components of a single oxidation–reduction system:

$$\mathrm{Ox} + ne \rightleftharpoons \mathrm{Red} \ . \qquad (1)$$

Chemical analysis demonstrates the constancy of the concentrations of Ox and Red subject to the condition that the composition of the solution remains unaltered and the influence of any oxidant or reductant is excluded. In order to characterise the oxidation–reduction system (1), it is necessary to introduce another oxidation–reduction system, the role of which is fulfilled by a plate of an indifferent metal. After the attainment of equilibrium, the plate acquires the equilibrium electrical potential, which ensures the equality of the electrochemical potentials of the electrons in the solution and in the metal in the absence of a potential shift of the equilibrium of reaction (1). Hence it follows that

$$\varphi = \psi^{\mathrm{M}} - \psi = \mathrm{const} - \lg a_e = \overline{\varphi}^0 + \frac{\vartheta}{n} \lg \frac{a_o}{a_r} \ , \qquad (2)$$

where ψ^{M} and ψ are the Galvani potentials of the metal and solution, a_e, a_o, and a_r are the activities of the electrons and the oxidised and reduced forms respectively, and $\vartheta = 2.3RT/F$.

The oxidation potential ϕ, which is equal to the difference between the Galvani potentials of the metals and the solution, includes a constant component $\overline{\phi^0}$—the standard oxidation potential. This constant defines the level of the oxidising capacity of the Ox–Red system and depends on the electron affinity of the species constituting the oxidation–reduction

system as well as their free energies of formation and solvation. Since the absolute value of the standard oxidation potential is unknown, it is assumed that $\overline{\phi^0} = 0$ for the standard hydrogen system, where the activity of hydrogen ions $h = 1$ and the partial pressure of hydrogen is 1 atm (1×10^5 Pa). The oxidation potential of the reversible Ox–Red system is then numerically equal to the e.m.f. of the galvanic cell made up of the oxidation–reduction and hydrogen half-cells.

The oxidation potential, referred to the conventional hydrogen zero, is an electrical measure of the free energy of the oxidation–reduction reaction of the Ox–Red system with the standard hydrogen system[8]:

$$\varphi = -\frac{\Delta G}{nF}, \qquad (3)$$

where F is the Faraday.

The oxidation potentials can vary in a specific manner also under conditions where the effect of the oxidant or reductant is excluded, but the concentrations of the other components of the solution vary. Changes in the oxidation potential are induced by the interaction of the substances constituting the reversible oxidation–reduction system with the solvent and other components of the solution. The appearance of a new species as a result of protolytic, complex formation, and association reactions, as well as other processes leads to an alteration of the activity of the electrons in solution and hence to a change of the oxidation potential. Thus the oxidation potential is not only an electrical measure of the free energy of the oxidation–reduction reaction between the given system and the standard hydrogen system, but is also an electrical measure of the free energies $\Delta G'$ of the chemical reactions between the substances in the oxidised and reduced states, on the one hand, and other components of the solution, on the other, i.e.[9]

$$\varphi = -\Delta G/nF - \Delta G'/nF. \qquad (4)$$

If the first term of Eqn.(4) is kept constant (by protecting the system from oxidation or reduction), the oxidation potential will follow the change in the free energy $\Delta G'$ induced by the chemical reactions occurring in solution.

III. THEORY OF OXIDATION–REDUCTION MEASUREMENTS

All the interactions accompanied by the transfer of n electrons between p kinds of species in the reduced state and q kinds of species in the oxidised state can be described by a single equation for the oxidation potential:

$$\varphi = \varphi(P, T, c_0, c_r, x_1, \ldots, x_m) = \overline{\varphi}^0 + \frac{\vartheta}{n}\lg\frac{c_0}{c_r} + \frac{\vartheta}{n}\lg\sum_1 \cdots \sum_q K_i^{(o)} \prod_i x_i^{\nu_i} + \frac{\vartheta}{n}\lg\sum_1 \cdots \sum_p K_j^{(r)} \prod_j x_j^{\nu_j}, \qquad (5)$$

where $\overline{\phi^0}$ is the standard oxidation potential, P the pressure, c_0 and c_r are the overall concentrations of the substances in the oxidised and reduced states respectively, x_1, x_2, ..., x_m are the concentrations of substances of m kinds involved in the reaction, $K_i^{(o)}$ and $K_j^{(r)}$ are the equilibrium constants of these reactions, ν_i and ν_j are stoichiometric coefficients, and the subscripts and superscripts o and r show that the given quantities refer to the oxidised and reduced states.

The first sum in the logarithmic term of Eqn.(5) takes into account the formation of species of any composition in the reactions where the system components in the oxidised state are involved and the second takes into account the corresponding interaction of the components in the reduced state.

It is assumed that the following equation should hold for the chemical potential of species of each ith and jth kind:

$$\mu_k = M_k + RT\ln c_k. \qquad (6)$$

The quantity

$$M_k = \mu_k^0 + RT\ln y_k,$$

where μ_k^0 is the standard chemical potential and y_k the activity coefficient, can be regarded as constant under certain conditions. The number of concentration variables in Eqn.(5) is equal to the sum of the concentrations of all the substances present in solution, i.e. $m + p + q + 2$, while the number of independent variables is $m + 2$.

Eqn.(5) can be regarded as a complete mathematical model of all the interactions associated with the given oxidation–reduction system. Interactions of this kind include the stepwise complex formation reactions, comprising mixed, polynuclear, and heteropolynuclear complex formation, hydrolysis (solvolysis), stepwise protolytic dissociation reactions, and the association of the ions and molecules forming part of the oxidation–reduction system investigated or interacting with the latter.

Eqn.(5) makes it possible to obtain any form of the ϕ surface in the space of states (P, T, c_0, c_r, x_1, ..., x_m) by varying the quantities $K_i^{(o)}$ and $K_i^{(r)}$ from 0 to $+\infty$. The determination of the set of the quantities $\{K_i^{(o)}, K_j^{(r)}\}$ compatible with experimental data constitutes the solution of the problem of the quantitative description of reversible reactions in reversible oxidation–reduction systems. The method involving successive sections through the surface in the $\{c_0, c_r, x_1, \ldots, x_m\}$ space with respect to one of the independent concentration variables while all others are kept constant is widely used. This makes it possible to obtain curves representing the partial relations between the oxidation potential and each independent variable. These curves consist as a rule of linear sections joined by smooth bends. The linear sections correspond to the states of the solution in which compounds with specific stoichiometric coefficients predominate. The compositions of the compounds formed can be found from the slopes of the linear sections, which are proportional to the stoichiometric coefficients. The sets of constants $\{K_i^{(o)}, K_j^{(r)}\}$ are determined in simple cases by graphical or computational methods. In the case of chemical interactions leading to the formation of several compounds of complex composition, which are frequently present simultaneously, the above quantities are found with the aid of computers.

In specific cases Eqn.(5) is simplified, because the number of independent concentration variables is reduced and limitations are imposed on the permissible stoichiometric coefficients.

IV. MEASUREMENT OF THE OXIDATION POTENTIAL

The description of interactions in solutions of oxidation–reduction systems is based on the experimental values of the oxidation potential under the conditions of equilibrium at the indicator electrode–solution interface. The correct formulation of the potentiometric experiment involves the establishment of this equilibrium.

The solution of specific problems may be complicated by the low rates of homogeneous and heterogeneous electron transfer reactions, by the breakdown of the condition of the indifference of the electrode owing to the catalytic effect of the material on the processes in solution, including the decomposition of its components, and other causes[7,10–12].

Thus platinum electrodes cease to be indifferent at low oxidation potentials. On the other hand, certain oxidation–reduction systems, for example Ce(IV)–Ce(III), Ti(IV)–Ti(III), V(III)–V(II), and Eu(III)–Eu(II), which should decompose water on the basis of their standard oxidation potentials, actually form stable aqueous solutions. Their stability is associated with the low rates of the reactions of the components of the above oxidation–reduction systems with water. The possibility of the measurement of the oxidation potential depends on the availability of an electrode material with a high oxygen overvoltage (in the region of low potentials) or a high hydrogen overvoltage (in the region of high potentials). Noble metal electrodes are heterogeneous catalysts of reactions involving the decomposition of water and cannot serve as materials for the indicator electrode[13]. On the other hand, when the rate of the homogeneous electron transfer reaction is low, the electrode must catalyse the electron transfer between the oxidised and reduced forms of the system or must catalyse one of the stages of the overall oxidation–reduction reaction.

By virtue of the above complications, the range of systems susceptible to experimental study and the quality of the information obtained depend largely on the extent to which the material of the indicator electrode and the state of its surface satisfy the requirements arising from specific conditions. These requirements can be justified, because, together with the thermodynamic characteristics of oxidation–reduction systems, there are data on the rates of homogeneous[14] and electrode[15] oxidation–reduction reactions. The following postulates have been formulated concerning oxidation–reduction measurements[7,8,10,11]: (1) there can be no universal electrode in oxidation–reduction measurements; a set of electrodes with a wide range of properties is required; (2) in the absence of equilibrium between the components of the solution which are capable of participating in oxidation–reduction interaction, one chooses an electrode whose material ensures reversible electron exchange with one of the oxidation–reduction systems; (3) the agreement between the oxidation potentials measured by different electrodes constitutes an adequate criterion of the attainment of equilibrium in the electrode–solution system.

The choice of the electrode material is based on information concerning the characteristics of the chemical interactions in solution and also on the results of studies designed to determine the limits of the indifference of the electrode materials and the kinetic parameters of electrode processes[8,16–18].

Together with traditional smooth platinum and gold electrodes, iridium and rhodium[7,19–22] as well as mercury[10,23] electrodes are used in oxidation–reduction measurements. The search for new electrode materials and new types of electrodes has led to the development of thin-layer platinum electrodes[8,24,25], electrodes made of semiconducting tin dioxide[26–28], glass electrodes for oxidation–reduction measurements[29,30], electrodes based on polymeric organic semiconductors[31,32], and modified graphite electrodes[33].

Thin-layer platinum electrodes are catalytically active in relation to many oxidation–reduction interactions[8], which permits measurements of the oxidation potential in those cases where homogeneous electron exchange is highly inhibited. However, the high catalytic activity of thin-layer platinum electrodes hinders their use when the stability of individual solution components breaks down and in kinetic studies.

Glass electrodes with an electron response have been developed on the basis of results of systematic studies of the dependence of the electrode properties of glasses on their chemical composition[29,30,34–37]. The possibility of using these electrodes in oxidation–reduction measurements is determined by the chemical indifference of glasses and the high electronic conductivity associated with the introduction of iron or titanium oxides into the composition of the glasses. It has been shown[10,11,38,39] that glass electrodes possess important characteristics such as insensitivity to oxygen and hydrogen, and that they are suitable for the measurement of the oxidation potential beyond the limits of the thermodynamic stability of water. The semiconducting properties of glasses determine their specificity in relation to systems with low oxidation potentials, which provides a basis for further studies on these lines. A semiconductor electrode, reversible in alkaline media, has been developed for the oxygen–hydrogen peroxide system, which is of both theoretical and practical interest[10,39].

The improvement of the experimental formulation of potentiometric measurements is of great importance. Special hermetically sealed apparatus, which eliminate the access of air, have been constructed for the determination of the oxidation potential under the conditions of varying concentrations of individual solution components[7,19,21,40,41].

V. PROTOLYTIC EQUILIBRIA

Clark[6,42] showed that the oxidation potentials of organic reversible oxidation–reduction systems are involved in a complex relation with oxidation–reduction and protolytic equilibria in solutions. In relation to individual examples, Clark formulated the fundamental postulates of the thermodynamic theory of the phenomenon and proposed a graphical method for the determination of the protolytic dissociation constants. During the subsequent development of this research, the study of the protolytic processes occurring in oxidation–reduction systems in a general form was undertaken[7,40,43,44]. Two types of systems were investigated. The first includes systems where the oxidised form is a q-basic acid and the reduced form is a p-basic acid. Regardless of the nature of the protogenic (proton-accepting) groups, their protolytic dissociation takes place as a result of isotypical reactions of the following type:

$$RH_j + H_2O \rightleftarrows RH_{j-1} + H_3O^+ \ . \qquad (7)$$

For systems of the second type, the concluding $(q+1)$th stage of the successive reactions of type (7) consists of the formation of the free base of the oxidised form:

$$R^+ \cdot H_2O + H_2O \rightleftarrows ROH + H_3O^+ \ . \qquad (8)$$

The regions where individual protolytic forms exist in the oxidised and reduced states are determined by the ratios of the protolytic dissociation constants and the pH values. The relation linking the electron transfer processes between protolytic forms and processes involving proton exchange with solvent molecules is reflected in the equations for the oxidation potential ϕ

(a) type I systems:

$$\varphi = \varphi^0 + \frac{\vartheta}{n}\lg\frac{c_o}{c_r} + \frac{\vartheta}{n}\lg\sum_{i=1}^{p} h^{p-i}B_i^{(r)} - \frac{\vartheta}{n}\lg\sum_{j=0}^{q} h^{q-j}B_j^{(o)}; \qquad (9)$$

(b) type II systems:

$$\varphi = \varphi^0 + \frac{\vartheta}{n}\lg\frac{c_o}{c_r} + \frac{\vartheta}{n}\lg\sum_{i=1}^{p} h^{p-i}B_i^{(r)} - \frac{\vartheta}{n}\lg\sum_{j=0}^{q} h^{q+1-j}B_j^{(o)} + \frac{\vartheta}{n}\lg h, \qquad (10)$$

where c_o and c_r are the overall concentrations of all the protolytic forms in the oxidised and reduced states respectively, $B_j^{(o)}$ and $B_i^{(r)}$ are the overall apparent jth and ith dissociation constants, and h is the activity of hydrogen ions. Eqns.(9) and (10) make it possible to predict the properties

of the oxidation–reduction system in the form of its dependence on the oxidation potential and the pH.

The experimental data are thermodynamically highly rigorous and can be very readily interpreted with a consequent high accuracy of the determination of the protolytic dissociation constants when the following oxidation voltage is introduced[7,40,44]:

$$\mathscr{E} = \varphi - \vartheta \lg h. \qquad (11)$$

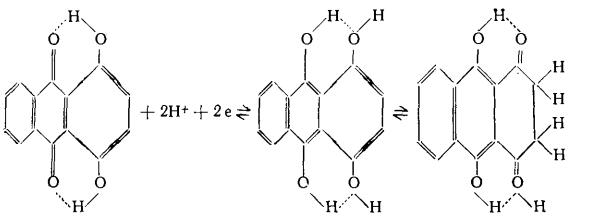
The oxidation voltage is numerically equal to the e.m.f. of the galvanic cell comprising the hydrogen (glass) and oxidation–reduction half-cells. The properties of the oxidation voltage have been formulated in the following postulates[7,44].

(a) The $\mathscr{E} = \mathscr{E}$ (pH) curve consists of linear sections joined by smooth bends; the number of these sections is equal to the number of all the protolytic forms in the oxidised and reduced states plus one.

(b) The slopes, equal to the partial derivative $(\partial\mathscr{E}/\partial\,\mathrm{pH})_{pc_o pc_r}$, depend on the predominance of one of the protolytic forms in the oxidised state and one form in the reduced state and can be predicted with the aid of Eqns.(9)–(11).

(c) Each bend in the curve and the establishment of a linear section with another slope correspond to a specific stage of the protolytic dissociation; an increase in the slope of the linear section with increase of pH is a sign of the dissociation of the oxidised form and its decrease is a sign of the dissociation of the reduced form.

(d) Each dissociation stage alters the slope of the subsequent linear section of the $\mathscr{E} = \mathscr{E}$ (pH) curve by an amount ϑ/n.



(e) The similarity of two dissociation constants of one of the forms leads to the disappearance of the corresponding linear section; the dissociation of the same protogenic group involved in both the oxidised and reduced forms induces the appearance of an inflection in the $\mathscr{E} = \mathscr{E}$ (pH) curve and a shift of the subsequent linear section parallel to the preceding one; the identity of the dissociation constants should cancel out their influence on the shape of the curve.

(f) The pK for protolytic dissociation is numerically equal to the pH at the point of intersection of the lines obtained by producing two neighbouring sections.

In a consecutive two-stage dissociation of the reduced form the $\mathscr{E} = \mathscr{E}$ (pH) curve becomes concave relative to the abscissa axis, while in the case of the corresponding dissociation of the oxidised form it becomes convex. If the dissociation constants corresponding to these two-stage processes are similar, then the curves pass through an extremum, The appearance of the latter makes it possible to determine stepwise dissociation constants with similar values; the graphical determination with the aid of the $\phi = \phi$ (pH) curve makes it possible to find only their product.

The study of type I systems in relation to the Alizarin C–leuco-Alizarin C system[7,45,46] and of type II systems in relation to the Toluidine Blue–leuco-Toluidine Blue and Methylene Blue systems[7,40,47–49] demonstrated the complete agreement between the theory and experiment. A quantitative characteristic of the oxidation–reduction and protolytic properties, which includes the dependence of the oxidation potential and the oxidation voltage on the pH, the stepwise protolytic dissociation constants, and the distribution of the relative contents of the protolytic forms as a function of pH, has been obtained for the systems investigated.

Since systems formed by quinone or quinone imine and their reduced forms served as prototypes of reversible organic systems, the number of proton-donating (proton-accepting) groups in the reduced state is two greater than in the oxidised state. The study of systems formed by anthraquinone derivatives and their leuco-forms, which contain nucleophilic substituents (OH or NH_2) in the *para*-positions of their aromatic side rings, showed that, on reduction, the number of protogenic groups in these systems does not change or increases by unity[50–56]. The manifestation of these anomalous properties is due to the retention of the quinonoid structure in the leuco-form, which has been shown experimentally[53] to be a consequence of a desmotropic transition; for example, the following transition occurs for quinizarin:

The second stage can be regarded as a result of the partial intramolecular oxidation of the extreme ring by the central ring, which is promoted by strong intramolecular hydrogen bonds.

By comparing the $\mathscr{E} = \mathscr{E}$(pH) relations and the electronic absorption spectra of the six anthraquinone dues investigated and their leuco-forms in CCl_4 and aqueous alcoholic solutions, the sequence of the dissociations of the protogenic groups was established[55]. The OH groups in the β-position are the first to dissociate. Their acid properties are enhanced on conversion into the leuco-form. As a result of the formation of strong intramolecular hydrogen bonds, the acid properties of the OH groups in the β-position are appreciably weakened.

Together with protolytic dissociation, other processes, in the first place association, can occur in organic systems. The study of the Neutral Red–leuco-Neutral Red system[57–59] showed that, in consequence of association, its oxidation potential becomes a function not only of the activity of hydrogen ions but also of the concentration of form RH^+ of Neutral Red, which is capable of association:

$$\varphi = \varphi^0 + \frac{\vartheta}{2}\lg\frac{c_o}{c_r} + \frac{\vartheta}{2}\lg(h^2 + hK_1^{(r)} + B_2^{(r)}) + \vartheta\lg h - \frac{\vartheta}{2}\lg(K_1^{(o)} + Ah), \qquad (12)$$

where

$$A = 1 + 2K_2^{(o)}[RH^+] + 4(K_2^{(o)}K_4^{(o)})^2[RH^+]^3,$$

and $K_2^{(o)}$ and $K_4^{(o)}$ are the formation constants of the dimer and tetramer.

The formation of the associated species was demonstrated and its identification with a specific protolytic form was achieved by analysing the partial relations $\phi = \phi(\lg c_o)$, $\phi = \phi(\lg c_r)$, and $\phi = \phi(\lg c)$, where $c = c_o + c_r$, obtained for the pH ranges corresponding to the conditions where particular protolytic forms predominate. These relations are used to find the compositions and the formation constants of the associated species. Association, taken into account in Eqn.(12) by the quantity A, influences only the protolytic dissociation constant of the associable species RH^+ and does not influence the protolytic equilibria of other forms. Association does not affect the numerical dissociation constants of the forms determined graphically from $\phi = \phi$ (pH) relations.

The oxidation of Neutral Red yielded a hitherto unknown compound, which is apparently a charge-transfer complex of the quinhydrone type[60]. It is stable in the crystalline state but in solution it is slowly oxidised by atmospheric oxygen. Its protolytic properties differ from those of the dye and its leuco-form.

VI. COMPLEX FORMATION

In oxidation-reduction systems formed by ions of the same metal in two oxidation states the appearance of complexes of these ions is reflected in the oxidation potential. Two fields differing in their interpretation of the experimental relations are being established[61,62]. In studies on one of them the compositions of the complexes and their stability constants are found with the aid of secondary concentration variables—the formation functions and degrees of formation and complexation (Rossotti and Rossotti[63], chapters 4 and 7). The second field arose and is being developed in the studies of Nikol'skii and his school. In view of the analogy between protolytic process and complex formation, Nikol'skii[64] suggested that complex formation be studied by methods developed for the investigation of protolytic equilibria in oxidation–reduction systems. The experimental study of the iron(III)–iron(II)–acetic acid–water system[65] confirmed the likely usefulness of this approach and initiated the theoretical and experimental studies on complex formation in reversible oxidation–reduction systems consisting of the aquo-complexes of the metal in two oxidation states.

In the course of the development of the thermodynamic theory[7,8,61,62,66], the entire set of reversible reactions leading to the formation of the complexes $M_qH_kA_x(OH)_y \cdot (H_2O)_z^{(qm+k-bx-y)+}$ (oxidised state) and $M_pH_lA_u(OH)_v \cdot (H_2O)_w^{[p(m-n)+l-bu-v]+}$ (reduced state) was taken into account. It is assumed that complexes are formed in aqueous solution of an acid H_bA, with a constant ionic strength, as a result of the substitution by the acido-ligand $H_{b-s}A^{s-}$ of the water molecules coordinated in the aquo-complexes of M^{m+} and $M^{(m-n)+}$, polymerisation, and protolytic reactions including the hydrolysis and protolytic dissociation of the acid and the protonated complexes. The state of the system is described by the equation for the oxidation potential of the type[7]:

$$\varphi = \varphi^0 + \frac{\vartheta}{n}\lg\frac{c_o}{c_r} + \frac{\vartheta}{n}\lg\sum_{p=1}^{P}\sum_{u=0}^{U}\sum_{s=b}^{Bu}\sum_{v=0}^{V} p\,(\beta_{puvl}^{(r)})^{1/p}\,\rho_{puvl}^{(p-1)/p}\,(B_b^{(a)})^{u/p}\times$$
$$\times\, c_a^{u/p} h^{(l-v)/p}\mathcal{H}^{u/p} - \frac{\vartheta}{n}\lg\sum_{q=1}^{Q}\sum_{x=0}^{X}\sum_{s=b}^{Bx}\sum_{y=0}^{Y} q\times \qquad (13)$$
$$\times\,(\beta_{qxyk}^{(o)})^{1/q}\,\omega_{qxyk}^{(q-1)/q}\,(B_b^{(a)})^{x/q}\,c_a^{x/q}h^{(k-y)/q}\mathcal{H}^{-x/q},$$

where β are the overall stability constants of the complexes, $B_s^{(a)}$ and $B_b^{(a)}$ are the overall sth and bth protolytic dissociation constants of the acid, c_a is the overall concentration of the acid, c_o and c_r are the overall concentrations of the complexes including the aquo-complexes, in the oxidised and reduced states respectively, ω and ρ are the concentrations of the complexes, the superscripts o and r show that the given quantities refer to the oxidised and reduced states, while the subscripts $qxyk$ and $puvl$ indicate the compositions of the complexes. The influence of the protolytic dissociation of the acid on the oxidation potential is taken into account by the multiplier

$$\mathcal{H} = \sum_{s=0}^{b} h^{b-s}B_s^{(a)}.$$

It follows from Eqn.(13) that the oxidation potential is a function of four independent variables: h, c_a, c_o, and c_r. In the study of complex formation in mixed solvents and concentrated aqueous solutions, where the activity of water can vary appreciably, this quantity must be introduced into the equation for the oxidation potential.

The partial relations of the oxidation potential, i.e. its dependence on each independent concentration variable while the others are kept constant, are described by curves consisting of linear sections connected by smooth bends. The establishment of a linear section is possible only when complexes of a specific composition, in the oxidised and the reduced states, predominate.

The composition of the complexes, i.e. the sets of values of q, k, x, y and p, l, u, v, are determined by the successive inspection of the curves for all the partial relations of the oxidation potential, starting with the initial linear section of zero slope for each curve, indicating the presence in the system of aquo-complexes alone, or with the section for which the composition of the complexes is known. The slopes of the linear sections and the changes in them serve as a source of the required information.

The nuclearity of the complexes is determined from the slopes of the linear sections of the partial relations $\phi = \phi(pc_o)$ and $\phi = \phi(pc_r)$, since

$$\left(\frac{\partial\varphi}{\partial\, p\, c_o}\right)_{p\, c_r,\, p\, c_a,\, pH} = -\frac{\vartheta}{nq}, \qquad (14)$$

$$\left(\frac{\partial\varphi}{\partial\, p\, c_r}\right)_{p\, c_o, p\, c_a,\, pH} = \frac{\vartheta}{np}. \qquad (15)$$

The number of groups A^{b-} in the complexes can be found from the slope of the curve for the partial relation $\phi = \phi(pc_a)$, because

$$\left(\frac{\partial\varphi}{\partial\, p\, c_a}\right)_{p\, c_o,\, p\, c_r,\, pH} = \frac{\vartheta}{n}\left(\frac{x}{q} - \frac{u}{p}\right). \qquad (16)$$

The nuclearity (the numbers q and p) and the number of the groups A^{b-} in the complexes (the numbers x and u) can be determined fairly reliably and simply.

The $\phi = \phi$ (pH) curve depends in the general case on the activity of hydrogen ions in a complex manner. Owing to the protolytic dissociation of the acid, linear sections may not appear, or their slopes can be distorted, since

$$\left(\frac{\partial\varphi}{\partial\, pH}\right)_{p\, c_o,\, p\, c_r,\, p\, c_a} = -\frac{\vartheta}{n}\left[\frac{l-v}{p} - \frac{k-y}{q} + \left(\frac{u}{p} - \frac{x}{q}\right)\sum_{s=0}^{b}(b-s)\,h^{b-s}B_s^{(a)}/\mathcal{H}\right]. \qquad (17)$$

The differences k–y and l–v in such systems can be determined with the aid of Eqns.(17) by substituting in the latter the values of the derivative found graphically at selected points. In the analysis of the $\phi = \phi$ (pH) curves one must take into account the intramolecular neutralisation reactions[7], because the differences $k-y$ and $l-v$ indicate either the basicity of the complex, when $k > y$, and $l > v$, or the number of its OH groups, when $y > k$ and $v > l$. Intramolecular neutralisation reactions apparently involve proton transfer from the protonated ligand to the OH group with conversion of the latter into a water molecule. The proton transfer is facilitated by the presence of intramolecular hydrogen bonds in the complex.

Complex formation in oxidation–reduction systems containing metal ions in two oxidation states and two different ligands—the anions of the acids H_bA and $H_\beta L$, includes competitive and mixed complex formation and hydrolysis. The oxidation potential becomes a function of five independent concentration variables, including the overall concentrations of the two acids c_a and c_α:[67]

$$\varphi = \varphi^0(c_o,\, c_r,\, c_a,\, c_\alpha,\, h). \qquad (18)$$

Analysis of Eqn.(18) together with the study of the characteristics of the mixed complex formation made it possible to determine the conditions under which a quantitative investigation of the formation of simple and mixed complexes becomes possible.

The formation of heteropolynuclear complexes containing the ions of two metals is no less complex. A thermodynamic description of heteropolynuclear complex formation has been

achieved in relation to the Fe(III)–F(II)–M(III) system in an aqueous solution of an acid HA, where M(III) is not involved in oxidation–reduction interactions with bivalent and tervalent iron[7,68].

The equation of the oxidation potential expresses the dependence of the latter on five independent variables, namely the overall concentrations of tervalent and bivalent iron, the ions of the metal M(III) and the acid HA, as well as the activity of hydrogen ions. The slopes of the linear sections of the partial relations $\phi = \phi(pc_O)$ and $\phi = \phi(pM)$ make it possible to determine the nuclearity of the heteropolynuclear complex with respect to Fe(III) and M(III) respectively. Information about the number of anions A and hydroxy-groups in the heteropolynuclear complex can be obtained with the aid of partial relations between the oxidation potential and pc_a and pH subject to the condition that the composition of the coexisting complex of the M(III) ion is known.

The reactions involving the formation of complexes in heterogeneous oxidation–reduction systems metal ion (solution)–metal[7,69] and complex formation with ligands constituting an oxidation–reduction system[7,70] have also been examined theoretically.

In oxidation–reduction measurements the necessary condition for the determination of the composition and stability constants of ionic and molecular forms of the oxidation–reduction system is the validity of Eqn.(6) for all the types of species whose concentrations vary in the solution composition ranges investigated. This is usually achieved either by employing fairly dilute solutions with respect to electrolytes at a constant ionic strength or by using a constant and high concentration of a supporting salt, which is an indifferent and strong electrolyte, for example, sodium or lithium perchlorates, etc.

In the latter case the compositions of the complexes are determined without taking into account their association with the cation or anion of the supporting salt. The study of the association of the components of an oxidation–reduction system with the ions of the supporting salt therefore constitutes an independent problem, the solution of which must be obtained at a variable ionic strength. A method has been developed for the investigation of complex formation (ionic association) between ferrocenium cations and Cl^- and ClO_4^- anions, under conditions where the concentration of the main electrolyte (HCl, $HClO_4$) varies within wide limits (0.01–3 M).[71]

A characteristic feature of the method is that the concentration variable employed is a function of the concentration of the acid and the mean activity coefficient of the main electrolyte ($\lg c_a$, $\lg c_a y_\pm$, or $\lg c_a y_\pm^2$) such that the effects of the "non-ideality" of the test system are compensated to the maximum extent in the partial derivative of the oxidation potential. The study of the complex-forming capacity of the ferrocenium nucleus in relation to the Cl^-, SCN^-, ClO_4^-, SO_4^{2-}, NO_3^-, and Br^- ions by various methods[7,72–74] confirmed the reliability of the proposed procedure.

By analogy with the oxidation voltage [Eqn.(11)], the following quantity was introduced[7]:

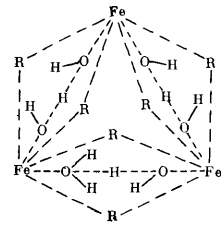
$$\mathscr{E}_A = \varphi + \vartheta \lg[A]. \qquad (19)$$

The quantity $\mathscr{E}_A$, called the oxidation voltage on the ligand scale, is numerically equal to the e.m.f. of a galvanic cell consisting of an oxidation–reduction half-cell and a half-cell reversible with respect to the anion A. The properties of the partial relation $\mathscr{E}_A = \mathscr{E}_A(pH)$ resemble those of the oxidation voltage. The use of the oxidation voltage on the ligand scale is limited by the restricted set of reversible electrodes. The complex formation reactions in the Fe(III)–Fe(II)–HCl–water system have been investigated with the aid of the function $\mathscr{E}_A$.[75–77]

The stability and hydrolysis constants in relatively simple systems are determined graphically or by simple computational methods[7]. A quantitative description of the chemical interactions, leading to the formation of complex compounds having an involved composition and frequently present simultaneously, is achieved with the aid of computers[7,72–82]. In this case the stability constants of the complexes are regarded as parameters of a regression relation, which is expressed by the equation of the oxidation potential [Eqn.(13)]. The above parameters are found by the method of least squares using a program for the direct minimisation of the sum of squares of deviations of the experimental oxidation potentials from the theoretical values. A combination of random search and coordinate-by-coordinate procedures is useful as a minimisation method.

The set of complexes which is sufficient for the description of all the partial relations between the oxidation potential and independent concentration variables, i.e. the entire set of experimental data, can be refined by comparing the content of a particular complex and the overall error referred to as the limit of sensitivity[7,78]:

$$\delta = |10^{\pm n\tau/\vartheta} - 1| \cdot 100\%, \qquad (20)$$



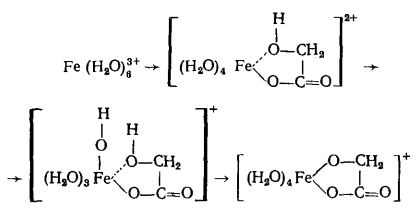
where τ is the accuracy of the potentiometric measurements. If the maximum content of the complex is less than δ, then its presence is undetectable and it can be disregarded. In general, one should bear in mind that the set of the stability constants of complexes obtained with the aid of the most sophisticated programs can be regarded as compatible with the available experimental data.

The experimental study of complex formation in systems formed by metals in two oxidation states and various ligands promoted the development of a theory of oxidation–reduction measurements and the elucidation of the fundamental characteristics of the reactions occurring in inorganic–reduction systems.

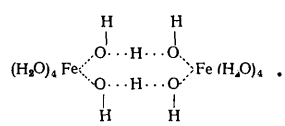
The complex formation reactions have been studied in particular detail in the Fe(III)–Fe(II) system in aqueous solutions of aliphatic acids (in the formic acid–valeric acid series), chloroacetic, aminoacetic, and hydroxyacetic acids, acrylic acid[7,19,21,65,83–106], dibasic aliphatic acids[107–110], aromatic acids[111–115], and strong inorganic acids (hydrochloric and sulphuric)[75–77,116]. The iron complexes were studied in aqueous solutions containing the anions of two acids (acetate ions and those of salicylic and sulphosalicylic acids or thiocyanate ions, ethylenediaminetetraacetate anions, and thiocyanate ions)[72,73,117–121]. The hydrolysis of tervalent iron has been studied in detail[122–128]. The formation of heteropolynuclear hydroxoacetato-complexes of tervalent iron and chromium has been investigated in aqueous acetic acid solutions[129–134].

Appropriate treatment of the experimental data made it possible to obtain the quantitative characteristics of the reversible complex formation reactions which include information about the compositions of the complexes, their stability constants, and the regions where they exist. The influence of temperature and ionic strength on the above characteristics was investigated for the Fe(III)–Fe(II) system in aqueous solutions of acids in the formic acid–valeric acid series[89,90,92] and in perchloric acid (hydrolytic reactions)[124,128]. The thermodynamic formation functions of the complexes of bivalent and tervalent iron were found from the results of these investigations by the temperature coefficient method. Direct calorimetric determinations of the enthalpy of formation were carried out for a number of complexes[85] by thermodynamic titration[135].

The quantitative study of the reversible formation of complexes of bivalent and tervalent iron in aqueous solutions has led to the following conclusions. The stability of the complexes increases with increase of temperature, ionic strength, and acid concentration. These factors are manifested particularly clearly in the case of the trinuclear complex having the composition $Fe_3A_6(OH)_2^+$, which predominates over a wide range of compositions; this has been explained by the conversion of the complex into a cyclic structure as a result of ring closure by linkages between coordinated aliphatic acid anions via iron atoms[7]:



(21)



The cyclic structure is supported by the thermodynamic functions for the formation of the above complex and the ease with which it is converted into mono- and di-nuclear complex species and is formed from them. On crystallisation, structure (21) is apparently converted into an Orgel structure[136], according to which three metal atoms are combined via a single oxide ion and the formula $M_3OA_6(H_2O)_3^+$ must therefore be attributed to the complex.

Protolytic processes determine the characteristics of the complex formation in solutions of acids containing two and more protogenic groups. The deprotonation of the alcoholic group in the coordinated ligands (hydroxyacid anions) is due to the weakening of the O–H bond as a result of the polarising effect of the metal atom and, what is most important, as a result of the intramolecular neutralisation reaction. Here one takes into account the fact that the hydroxy-group is coordinated via the oxygen in the deprotonated state and its dissociation strengthens the corresponding chelate. In conformity with the hypothesis of the intramolecular neutralisation reaction, the formation of the deprotonated iron(III) glycolate complex FeA^+ can be represented by the following scheme[106]:

(22)

The formation of hydroxo-complexes of tervalent iron is promoted by the increase of the concentration of metal ions, temperature, and the concentration of the supporting electrolyte. It is suggested that iron(III) ions in the complex are linked via OH groups and water molecules[128]:

(23)

Hydrolysis and complex formation are in general competing processes. In solutions of weak monobasic organic acids, mixed di- and tri-nuclear complexes incorporating the OH group are formed.

New results have been obtained in a study designed to discover chemical interactions by oxidation–reduction measurements in Ce(IV)–Ce(III) systems[137,138] and in the heterogeneous cadmium ion–cadmium amalgam[69,78,81,139] and indium ion–indium amalgam[140] systems. The influence of the relatively unstable species on the nature of the partial relations of the oxidation potential has been demonstrated for these systems and those mentioned above. The study of the cadmium ion–cadmium system is of fundamental importance, since it confirmed experimentally the applicability of oxidation–reduction measurements in the study of chemical interactions in heterogeneous oxidation–reduction systems and hence greatly extended the scope of such measurements.

Complex formation with ligands constituting an oxidation–reduction system was first investigated for the Alizarin C–leuco-Alizarin C–M(III) systems (M = Al, Ga, or In).[141–143] Joint consideration of the partial relations between the oxidation potential and the concentration parameters together with the results of a spectrophotometric study made it possible to establish the sequence of reversible processes occurring in the system and to determine the compositions of the Alizarinate and leuco-Alizarinate complexes, their stability constants, and the protolytic dissociation constants of the ligands in the coordinated state. The acid properties of the latter are enhanced owing to the polarising influence of the metal atom.

VII. REDOXITES

By a redoxite we understand a homogeneous variable-composition phase whose components form a reversible oxidation–reduction system and can be involved in reversible oxidation–reduction interaction with aqueous solutions and oxidation–reduction systems[7]. It is necessary that, when the redoxite comes into contact with aqueous electrolyte solutions, its oxidised and reduced forms should not dissolve appreciably in the aqueous phase.

It is possible to distinguish three classes of redoxites: redox polymers[144,145]; ion exchangers saturated by variable-valence metals[146,147]; solutions of hydrophobic oxidation–reduction systems in solvents immiscible with water–liquid redoxites[7]. The properties of liquid redoxites have been studied mainly by Nikol'skii's school.

A characteristic feature of liquid redoxites is that the equilibrium between the redoxite and the aqueous solution is established rapidly, the measurement of the oxidation potential does not require the introduction of a mediator into the equilibrium aqueous solution[148], and the measurements of the potentials themselves are carried out using an indifferent electrode in the redoxite phase[149]. Under the conditions of the redoxite–aquoues solution phase equilibrium and when fairly dilute aqueous solutions are used, the chemical potentials of water and the non-aqueous solvent hardly change under isothermal-isobaric conditions. Therefore, in the determination of the state of the components of the oxidation–reduction system in the redoxite phase the involvement of the solvent species and water in the corresponding processes is not observed. The relation between the composition of the phases of the heterogeneous redoxite–aqueous solution system and the oxidation potential of the redoxite has been studied theoretically using as the independent variables the concentrations of the substances in the phase where they are largely concentrated[150–153]. This choice of

variables makes it possible to characterise the phase compositions solely in terms of the macrocomponents, which significantly facilitates the experimental study and the oxidation–reduction reaction consequently involves extraction of substances from one phase to the other.

It has been shown experimentally[154,155] and proved theoretically[7,156] that a fundamental characteristic of liquid redoxites is that it is always possible to specify a region in the aqueous solution where an indifferent electrode combined with the redoxite phase constitutes an ion-selective electrode for one of the ions of the aqueous solution. Borate[157], perchlorate[158], bromide, and iodide[159] ion-selective electrodes have been proposed on the basis of redoxites.

The oxidation–reduction and other properties of redoxites have been studied in greatest detail on the basis of the following reversible oxidation–reduction systems: (a) alkylferrocene–alkylferrocenium[7,149]; (b) quinone–hydroquinone and their derivatives[160]; (c) Alizarin–leuco-Alizarin[154,161]; (d) Nile Blue–leuco-Nile Blue[162]. In the determination of the state of the components of the oxidation–reduction system in the redoxite phase, it was found that 1:1 and 1:2 ionic association reactions between the ferrocenium cation and anions develop in system (a) and that protolytic dissociation coupled with the formation of ionic associated species with the cations of quaternary ammonium bases takes place in systems (b) and (c).

The study of solid redoxites is complicated by the low rate of the oxidation–reduction reaction between the redoxite and aqueous solution[144]. It has been found that protolytic and ion-exchange processes involving the redoxite are fairly rapid and their study is therefore not difficult, provided that electron exchange equilibrium has been established beforehand in the redoxite–solution system[163]. This permitted extensive experimental studies on redoxites of the phenothiazine type on the basis of polyene fibres[163–168]. The representation of the experimental data by the dependence of the oxidation potential of the redoxite on the pH makes it possible to find separately the number of protogenic groups due to the dye- and leuco-dye in the redoxite and to determine their dissociation constants. On the basis of the proton-donating groups manifested, it is possible to discover whether the bond formed by the dye and the leuco-dye is chemical or covalent[154]. The relation between the oxidation–reduction and protolytic properties of redoxites has been proved theoretically[150].

Dynamics of the Potential and the Mechanism of Action of Ion-selective Glass Electrodes

A.A.Belyustin

Studies on the dynamics of the potential of glass electrodes with hydrogen and metal ion functions are considered. The transient processes occurring in the concentration jump in the region of response to one cation and with partial or complete transition to response to another cation are classified. The transition phenomena are described on the basis of the thermodynamics of ion exchange and diffusion kinetics in the liquid and solid phases. The influence of ion-exchange processes in the surface layers of glasses and at the interface with the solution on the dynamics of the glass electrode potential is considered. The bibliography includes 90 references.

IV. Conclusion 930

I. INTRODUCTION

Ionometry—potentiometry using ion-selective membrane electrodes (ISE) of different types and designed for different purposes—has been developing vigorously during the last decade. Numerous monographs, collections of papers, and reviews dealing with the development, principles of operation, and applications of ISE have been published; a specialist journal began publication in 1979.[1] However, in this stream of information there has been a surprisingly small proportion of studies devoted to the dynamic properties of ion-selective electrodes. This was already noted in the first theoretical review of the dynamics of the ISE potential[2]. Since then the position has altered somewhat; at any rate, among the characteristics of ISE mention is now always made of the time when they attain a stationary potential.

The study of the dynamics of the potential of ISE is important primarily for their practical applications as devices whereby processes can be monitored potentiometrically and regulated. In industrial apparatus and in research carried out using ISE it is necessary that the response time of the ISE to a change in the concentration of the relevant substance is shorter than the time taken to complete the given process with participation of this substance. The response time of ISE is influenced by a multiplicity of factors: the nature of the membrane of the ISE, their design, the hydrodynamic and temperature conditions of the experiment, the concentration and qualitative composition of the solution, etc. The knowledge of the quantitative relation between these factors and the ISE response time determines the correct employment of such electrodes.

The present review deals mainly with theoretical aspects of the problem. A thermodynamic theory of the membrane potential of ISE with membranes of glass or other ion-exchange materials has now been established. According to this theory, the stationary membrane potential consists of interfacial (Donnan) potential jumps on either side of the membrane and the diffusion potential within the membrane phase, determined by the opposed streams of ions involved in the exchange and by the difference between their mobilities ($\bar{u}$). The equilibrium mobilities, more precisely their functions such as the transport numbers $\bar{t}_i$ and their ratios, enter into important characteristics of the electrode function such as the slope[3] of the relation between E and the logarithm of the ionic activity:

$$dE/d\ln a_i = \bar{t}_i RT/F, \quad (1)$$

the potential coefficient of the selectivity of the function in the system of ions I^+ and J^+:

$$K_{ij}^{pot} = K_{ij}\bar{u}_j/\bar{u}_i, \quad (2)$$

and Nikol'skii's fundamental equation of the thermodynamic ion-exchange theory of ISE[4]:

$$\varphi = \varphi^0 + \frac{RT}{F}\ln(a_i + K_{ij}^{pot}a_j). \quad (3)$$

Here ϕ is the electrode potential, ϕ^0 the standard potential, E the e.m.f. of the galvanic cell, a_i and a_j are the activities of the ions I^+ and J^+ in solution, $\bar{u}_i$ and $\bar{u}_j$ their mobilities in the glass, K_{ij} is the ion exchange constant (the energy factor), $\bar{u}_j/\bar{u}_i$ the migration factor, R the gas constant, T the absolute temperature, and F the Faraday.

Information about the migration factor cannot be obtained from the potentiometric experiments alone. For this purpose, additional experiments are required, particularly the study of the fluxes of ions entering and leaving, the kinetics of the attainment of a steady potential, etc. It is not clear *a priori* whether the ionic mobilities in the surface layers of the glass, altered by the interaction with solutions, are the same as for the unchanged glass. In kinetic experiments components of the potential which disappear in the stationary state may be manifested.

For various reasons, the present review will be confined to glass electrodes (GE) of different kinds and designed for different purposes. Firstly, GE, particularly those for potentiometric pH titrations, are the most widely used ISE in both laboratory practice and for industrial monitoring and regulation. Secondly, the equilibrium (stationary) properties of GE have been most thoroughly investigated. Thirdly, the theory of the stationary electrode behaviour of Ge has been most thoroughly developed and in this respect GE can serve as a kind of model for other ISE, at least those with an ion-exchange membrane. It has been suggested that the kinetic concepts developed for GE can also be partly extended to other ISE and conversely.

The results of the study of the dynamic properties of GE will be considered mainly from the standpoint of the mechanism of their action under particular experimental conditions. Attention has been concentrated on the electrochemical method of concentration jumps[5] as one which is most consistent with, on the one hand, the high-resistance system investigated and, on the other hand, with the usual conditions under which GE

are employed. If necessary, results (hitherto few but nevertheless significant) obtained by other electrochemical methods, involving the passage of a current through a GE from an external source, are invoked for the purpose of explanation.

The term transient processes will be given to the variation with time of the potential on passing from one stationary potential level to another. In the literature the term transient phenomena is sometimes understood as the non-monotonic variation of the potential during this period, but we shall employ it in its wider significance. As regards the classification of transient processes, the following can be distinguished for GE: (1) when the concentration of the solution is altered in the region of a stationary electrode function with respect to the given cation; (2) in the region of transition from the response with respect to one cation to the response with respect to another; (3) in the region of "acid deviations" associated with the influence of the anion on the cationic function; (4) when the solvent is altered and in non-aqueous solvents.

With few exceptions, the last two cases will not be considered in the present review. The consideration of the third case would require too much space; the available data are very contradictory, although there is no doubt that the potential varies rapidly with time in the region of the acid error (see, for example, Bates[6]). In the fourth case there is also a possibility of the observation of transient phenomena (see, for example, Ivanovskaya[7]), but, so far as the present author is aware, specific kinetic studies on the influence of the change of the solvent have not been carried out.

The principal aim of the present review is to survey the available data on the dynamics of the attainment of a steady potential of GE under various conditions and the results of attempts at a quantitative description of the transient phenomena and their theoretical treatment.

II. DYNAMICS OF THE POTENTIAL IN THE REGION OF RESPONSE TO ONE CATION

1. Experimental Results

Table 1 presents the results referring to the H^+ function of GE for potentiometric pH titrations and Table 2 deals with the dynamics of GE in the region of response to different metal ions. By virtue of specific features, the causes of which will become clear subsequently, the initial columns in Tables 1 and 2 differ somewhat. In Table 1 only H^+ is the potential-determining ion and it is not indicated. The preparation of GE, i.e. preliminary soaking in any one solution whose composition is in the region of the H^+ function, is important only for experimental, but not industrial, pH titration glasses and, if necessary, this will be mentioned in the text. The metal ion function of GE made of any glass and their dynamic properties are influenced significantly by the preliminary treatment and a separate column is provided for its characteristics in Table 2.

All the results for the H^+ function have been obtained under the conditions of special dynamic experiments with the fastest possible concentration jump. The authors of earlier

			~1		extrema, see text	
8	HHT, Na-20	pH 2.1 ⇌ 3.05	~1	$\tau_3=0.3$ (87%); $\tau_2=6$ (13%); $\tau_3<0.3$ (>70%); $\tau_2\cong7$ (≅20%); $\tau_1\cong100$ (~10%)	exact compositions of solutions at pH 2.1 and 3.05 respectively: 0.009 N HCl + 0.001 N NaCl and 0.001 N HCl + 0.009 N NaCl	17–20
	NaAl-2010; NaAl-2704	HCl 0.1 ⇌ 0.01 N		$\tau_3=1.3$ (~50%); $\tau_2=7.1$ (~30%); $\tau_1=33$ (~20%); $\tau_3\sim1.4$ (~75%); $\tau_2\sim8$ (~15%); $\tau_1\sim45$ (~15%)	treatment of data in terms of Eqn. (13), see below. The average values of τ_i are presented for direct and reverse experiments together with approximate values of $\Delta E_i^0/\Delta E$(%)	

* The designations of the compositions of the glasses, when they are known, are based on a system which can be understood from the following examples: NaCa-21$_4$06$_2$ is a glass containing (mole %) 21.4 Na_2O, 6.2 CaO, and the rest, i.e. 72.4, SiO_2; NaAl-2704—27 Na_2O 4 Al_2O_3 and 69 SiO_2. If the quantitative composition is unknown, the known qualitative characteristics of the composition are indicated, the symbols of the elements indicating the oxides; SiO_2 is not indicated: LiAl(Li_2O–Al_2O_3–SiO_2); LiCsLa (Li_2O–Cs_2O–La_2O_3–SiO_2), etc. Sometimes commercial designations of the electrodes and glasses are given: HHT, Beckman 39 046, etc. The same designations are used in Table 2 and in the text.

** The values of τ at 300 K; the corresponding activation energies are 7, 4.3 and 2.2 kcal mol^{-1}.

studies, where metal ion functions were investigated, were interested in the GE dynamics only incidentally and attention was concentrated on the stationary potentials. Nevertheless useful kinetic observations, summarised in Table 2, were made in such studies.

The principal factor for subsequent analysis is the relation between the time of the concentration jump and the time of the electrode response. The latter is expressed either by the degree of completion of the transient process between one stationary potential level and another ($t_{0.5}$, $t_{0.8}$, $t_{0.95}$) or simply by the time t when the process is believed to have been completed.

The majority of the potential–time curves in the region of variable concentrations under consideration are characterised by a monotonic exponential relation for which the following empirical expression will be adopted[2]:

$$E_t = E_1 + (E_2 - E_1)[1 - \exp(-Kt)], \quad (4)$$

where E_t is the e.m.f. at time t, E_1 and E_2 are the stationary e.m.f.'s in solutions *1* and *2*, and K is a constant. Henceforth, we shall use also the abbreviated formulation

$$\Delta E_t = \Delta E^0[1 - \exp(-t/\tau)], \quad (5)$$

where $\Delta E_t = E_t - E_1$, $\Delta E^0 = E_2 - E_1$, and $\tau = 1/K$.

The quantity τ is a convenient characteristic of an exponential transient process: $\tau \cong t_{0.63}$; $2\tau \cong t_{0.83}$; $3\tau \cong t_{0.95}$; $5\tau \cong t_{0.99}$. In certain cases the exponential approximation is satisfactory, while in others it is too inexact. Sometimes the process is described by the sum of several exponential relations[2,17–20] or other functions of time[2]. If the response times in Tables 1 and 2 are characterised by the quantity τ without further comment, the implication is that the exponential approximation is regarded as satisfactory.

Consideration of the "time of jump" and "response time" columns in Tables 1 and 2 leads to the conclusion that, in response to the concentration jump occurring over a period of

approximately 1 s, the transient process in the region of the H^+ and M^+ functions is completed during a period less than 10 s; when the solution is changed (over a period of the order of milliseconds with the aid of special devices) the response time is also of the order of milliseconds. The latter result is of fundamental importance both for the characterisation of the electrode and for the understanding of the essential features of the processes controlling the dynamics of the attainment of a steady potential. We shall consider this in greater detail.

It is highly likely that the arrest of the establishment of a steady potential after the concentration jump achieved[8,28] over a period of several milliseconds is caused by the charging of a capacitance C through an ohmic resistance R: $\tau = RC$. It has been shown in at least one study[28] that, after an "instantaneous" change in the Na^+ concentration from 0.05 to 0.01 M, the $\Delta E_t - t$ curves for Beckman 39 047 and 39 046 glass electrodes (NaAl-2704 and LiAl respectively) resemble the curves after the "instantaneous" application of an $(RT/F) \ln (0.05/0.01) = 38$ mV potential pulse. The $\Delta E_t - t$ curves are different for each electrode (in conformity with the difference between the ohmic resistances).

For the same types of glasses (but for larger GE), $\tau = 1.8$ and 4.3 ms at 25 °C have been measured[29] (see also Lakshminarayanaiah[13]); hence the capacitances for the corresponding R were found to be 40 and 32 nF cm^{-2} respectively. For a tenfold difference between the values of R the values of τ were found to differ[28,29] approximately by a factor of two (12.2 and 27 ms—see Table 2). It may be that the values of τ include a contribution from an electrochemical transient process.

It has been found[30] that after a stepwise (after a period of approximately 10 μs) change in the potential of a GE of NaAl-2704 glass in NaCl solutions the relaxation process is completed in approximately 10 ms, which led to the conclusion that the standard exchange current density for the transient process $Na^+(glass) \rightleftharpoons Na^+(soln)$ is greater than 2×10^{-6} A cm^{-2}. All these facts permit the conclusion that the relaxation time for the transient processes $H^+(glass) \rightleftharpoons H^+(soln)$ and $Na^+(glass) \rightleftharpoons Na^+(soln)$ for GE subjected to an appropriate preliminary treatment is of the order of milliseconds or less.

It is seen from the data in Tables 1 and 2 that, for a slower change of solution, over a period of approximately 1 s, the GE response time is also approximately 1 s or (frequently) longer. One should note that in those cases where it was possible to observe processes completed in milliseconds after the change of solution, investigators did not follow the subsequent variation of the potential. Conversely, in observations on processes lasting seconds and minutes, we find that the millisecond process has already been completed and one can only conclude that the two groups of processes may have different mechanisms. Two groups of theories, devoted to the kinetics of glass and in general ion-selective electrodes, correspond to the two groups of processes and their characteristics.

2. Theoretical Treatment

The theories of the first group are based on the hypothesis of an energy barrier which must be overcome by ions in order to pass from solution to the glass and conversely[12,31] (for a description of the results of Johansson and Norberg[12], see Lakshminarayanaiah[13]). The theories of the transient overvoltage are analogous to this approach in electrochemical kinetics[32]. In theories of the second group the diffusion processes in the solution and in the glass (diffusion kinetics) are considered to be the cause of the slow attainment of the GE potential. Both groups of theories have been considered by Shatkay[2] and we shall confine ourselves to a brief description of the conclusions of earlier studies and a more detailed consideration of later investigations, which have not been included in the earlier review[2].

It may be expected, in confirmity with experimental data (Tables 1 and 2), that the efforts of theoreticians should be directed to the explanation of the exponential $\Delta E_t - t$ relation. Indeed, when a number of more or less well-founded assumptions are made, both groups of theories lead to equations of type (4) or (5). Judging from Shatkay's review[2], a particularly large number of assumptions, simplifications, and simple errors have been made by Rechnitz and Hameka[31]; fewer were made in Johansson and Norberg's study[12]. The physical significance of the parameter K in Eqn.(4) is difficult to interpret in this approach and its numerical value is difficult to predict.

As a result, in order to confirm the relation of type (4) which they obtained, Rechnitz and Hameka[31], for example, used the results of a study[26] of the dynamics of the attainment of the K^+ function of GE made from glasses based on the $Na_2O-Al_2O_3-SiO_2$ systems not subjected to an adequate preliminary treatment, as a result of which the attainment of a steady potential took tens of minutes. The same data have been used[2] for the correlation analysis of the applicability of Eqn.(4) and others. Johansson and Norberg[12] used their own data, obtained in aqueous and non-aqueous solutions (Table 1), to test this equation. They used $t_{0.5}$ as a characteristic of the time; this quantity proved to be three times greater for non-aqueous solutions than for aqueous solutions. The time $t_{0.5}$ which they found[12] for the GE response in aqueous solutions is closer to that found by Disteche and Dubuisson[8] and Rechnitz and Kugler[28] and also by Buck and Krull[29] and Kiprianov et al.[30] for the relaxation of electrical impulses. According to Buck's classification[33-35], this is the relaxation time of the space charge in the conducting system.

The second group of theories is based on the ideas of diffusion kinetics. It is assumed that the diffusion of ions to the exchange site in the glass takes place slowly with a coefficient D, via a diffusion layer of the solution with a thickness δ, which retards the attainment of a steady potential, while the attainment of ion-exchange equilibrium at the glass-solution interface (including the exchange of identical ions) is much faster. The Nernst equation holds at any instant t in the following form:

$$\varphi_t = \varphi^0 + \frac{RT}{F} \ln \frac{c_{k,t}}{\bar{c}_k}, \qquad (6)$$

where ϕ_t is the potential at the interface, ϕ^0 its standard value, $c_{k,t}$ the concentration of the potential-determining k^{th} ion in solution in the immediate vicinity of the exchange site, and $\bar{c}_k$ its concentration in the solid phase, which is constant under the conditions of the k^{th} function of the GE. Thus the determination of the $\phi_{k,t} - t$ or the $\Delta E_t - t$ relation reduces to determining the $c_{k,t} - t$ relation.

The latter is obtained as a solution of the differential equation of Fick's Second Law in the following form, for example [15]:

$$c_t = c_1 + (c_2 - c_1) \left\{ 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \exp \left[-\frac{\pi^2}{4} \frac{D}{\delta^2} (2n+1)^2 t \right] \right., \qquad (7)$$

where c_1 and c_2 are the concentrations in solutions *1* and *2* and the subscript k has been omitted.

The expansion is usually restricted to the first term of the series ($n = 0$), whereupon we obtain for the potential:

$$\varphi_t \approx \varphi_1 + \frac{RT}{F} \ln \left\{ 1 + \frac{c_2 - c_1}{c_1} \left[1 - \frac{4}{\pi} \exp (-t/\tau) \right] \right\}, \qquad (8)$$

where

$$\tau = \frac{4}{\pi^2}\frac{\delta^2}{D} \simeq \frac{\delta^2}{2.5D} \quad (8a)$$

Morf et al.[36] obtained the equation for ϕ_t in a somewhat different form:

$$\varphi_t = \varphi_2 + \frac{RT}{F}\ln\left[1 - \frac{c_2 - c_1}{c_2}\exp(-t/\tau)\right], \quad (9)$$

where

$$\tau = \delta^2/2D. \quad (9a)$$

Buck[35] formulated both equations [(8) and (9)] in the form usually employed in electrochemical literature:

$$\varphi_t = \varphi_1 + \frac{1}{f}\ln\left\{\exp(f\Delta\varphi) - \frac{4}{\pi}[\exp(f\Delta\varphi) - 1]\exp(-t/\tau)\right\} = \varphi_2 + \frac{1}{f}\ln\left\{1 - \frac{4}{\pi}[1 - \exp(-f\Delta\varphi)]\exp(-t/\tau)\right\}, \quad (10)$$

where $f = F/RT$, τ is defined by Eqn.(8a), and $\Delta\phi = \phi_2 - \phi_1$. In further simplifications of Eqns.(8) and (9) it is assumed that the concentration jump $\Delta c = c_2 - c_1$ and the corresponding potential jump $\Delta\phi$ are small, whereupon exponential equations are obtained, for example:

$$\varphi_t = \varphi_1 + \frac{RT}{F}\frac{\Delta c}{c_1}\left[1 - \frac{4}{\pi}\exp\left(-\frac{t}{\tau}\right)\right], \quad (11)$$

which can be reduced to equations of type (4) and (5) describing the $\Delta E_t - t$ relation for very short t.

The present author's calculation[20] by Eqns.(8) and (11) for specified $\tau = 1$ s and $\Delta c/c_1$ varying in the range $1 \leq |\Delta c/c_1| \leq 9$ demonstrated the following features. Firstly, the curves corresponding to an increase ($c_2 > c_1$) or decrease ($c_2 < c_1$) of concentration are markedly asymmetric, particularly for large Δc. With increase of the concentration of the ion, the curves are steeper than with its decrease. Secondly, the converse representation of Eqns.(8) and (11) on a semilogarithmic scale ($\lg \Delta E - t$) leads to linear plots passing through calculated points in the region where $t > 0.5$ s. For $t < 0.5$ s, the points deviate from the straight line; this is always the case for Eqn.(8) and for Eqn.(11) only when $|\Delta c/c_1| > 2$. Consequently extrapolation of the straight line from $t > 0.5$ s to $t = 0$ leads to a value of ϕ_1 which deviates more or less significantly from a specified value. However, it is important to note that the values of τ calculated on this basis are 1 ± 0.1 s, i.e. the "specified" value of τ is approximately maintained. From this it follows that in Eqn.(5), which we adopted previously as entirely empirical, the quantity τ can now be regarded as theoretically justified and can be calculated from Eqns.(8a) and (9a) for diffusion kinetics in the layers near the electrode.

The concept of diffusion through the electrode layer of solution (unstirred, Nernst, adhering, stagnant) as the stage which determines the retardation of the attainment of the steady potential of the GE has been used in many studies, including those quoted in Table 1.[9,15,16] The order of magnitude of the quantity τ corresponding to this process can be readily estimated using the known (for electrolyte solutions) thickness of the diffusion layer δ and the diffusion coefficient D of the binary electrolyte or the diffusion coefficient of the ion in the supporting electrolyte with the aid of the criteria defined by Eqns.(8a) or (9a). For $\delta \leq 10^{-2}$ cm and $D \cong 10^{-5}$ cm^2 s^{-1}, it is found that $\tau = 0.5$–5 s. The values of τ or τ_3 in Tables 1 and 2, for experiments where the change of solution was achieved over a period of approximately 1 s, are of the same order of magnitude, as already mentioned.

The study of Hershkovitch et al.[16], not included in Shatkay's review[2], constitutes a significant development of the above concepts. The authors regard the process as the reciprocal diffusion of ions and not as the diffusion of the electrolyte as a whole, as in the majority of previous instances. Account was also taken of the possibility of the generation or disappearance of active ions as a consequence of the reaction in the layer near the electrode. The fundamental differential equation has the following form:

$$\frac{\partial c_j}{\partial t} = D_j\frac{\partial^2 c_j}{\partial x^2} + R_j - \sum_k \frac{z_k}{z_j}(D_k - D_n)\frac{\partial}{\partial x}\left(t_j\frac{\partial c_k}{dx}\right), \quad (12)$$

where subscripts j, k, and n correspond to ions (cations and anions), z are the charges, x is the distance in the range $0 \leq x \leq \delta$, D are the diffusion coefficients, t_j is the transport number of the ion, and R_j is the rate of generation of the ion Jz_j.

For a solution of a strong binary electrolyte (acid or base), the first term is significant and the case discussed above obtains [equations of type (7) and (8)]. For solution flow rates of 27–42 cm s^{-1} in acid solutions at pH 3, the values of δ are in the range 0.014–0.016 cm and $t_{0.8}$ is up to 4 s. A satisfactory agreement has been achieved between the calculated and experimental curves. For a solution of a weak electrolyte (CH_3COOH), account is taken of R_j—in the present instance, the rate of dissociation. The experimental process is completed faster than predicted by the calculation, possibly owing to the obstacle-free penetration of electrolyte molecules through the charged component of the double layer. This can explain, in particular, the faster attainment of a steady potential in buffer solutions compared with unbuffered solutions. Finally, yet another special case was examined by Hershkovitch et al.[16]—mixed solutions of the type HCl + NaCl and HCl + $MgCl_2$. Experimental $\Delta E_t - t$ curves with extrema, due to the different mobilities of the two cations and the common anion in solution, were predicted and obtained for this case. Such extrema in the region of the H^+ function of the GE have been observed[14] in buffer solutions under unfavourable hydrodynamic conditions and in the region of metal ion functions by Friedman[22,37], Rechnitz[28,38], and Eisenman[21]. The above extrema, except that described by Mokhov and Leikvishvili[14], were usually attributed to the time-dependent sensitivity of the GE surface to one of the cations and will be considered in the next section. However, mention should be made of their possible "purely solution" origin.

Both in the study of Hershkovitch et al.[16] and in the studies quoted previously[9,15], as well as many others, the diffusion through the liquid "stagnant" layer is believed to be the main if not the only cause of the retardation of the attainment of a steady potential; for example, Hershkovitch et al.[16] did not even indicate the kind of glass used in the experiments. However, it has been noted[9] that, when an attempt is made to describe the attainment of a steady potential in later stages (for $t > 6$ s), it is found that this cannot be achieved with the aid of the exponential function (characterised by $\tau \cong 1$ s) used in the early stages and another exponential function (with $\tau \cong 15$ s) must be introduced. Markovic and Osburn[15] did not arrive at such conclusions, but in the case of one of the glasses they obtained an activation energy $E_a \cong 7$ kcal mole^{-1} for τ, which is greater than for "purely solution" diffusion. These facts necessitate the hypothesis of yet another process in the glass or at its interface with the solution. As already mentioned, the electrochemical exchange reaction is very rapid (over a period of milliseconds). It is natural to suppose that, for $\tau \cong 10$ s, we are dealing with diffusion in the solid phase.

Tables 1 and 2 present the results of a number of studies[17-20] in terms of the values of τ_i corresponding to the equation

$$\Delta E_t = \sum_{i=1}^{3} \Delta E_i^0 [1 - \exp(-t/\tau_i)], \quad (13)$$

where

$$\Delta E_i^0 = |E_{i\,t\to\infty} - E_{i,t=0}| \quad (13a)$$

is the jump in e.m.f. corresponding to the completion of the ith process;

$$\Delta E^0 = \sum_{i=1}^{3} \Delta E_i^0 \quad (13b)$$

is the overall jump in e.m.f. after the completion of all the processes. Thus $\Delta E_i^0/\Delta E^0$ is the contribution of the given process to the overall jump.

In the above studies not more than three exponential components were required to describe the dynamic GE curves with an average error of ±20% for identical GE subject to an error in the measurement of e.m.f. of 1 mV. The numbering of the exponential functions, starting from the "slowest", corresponds to the order in which the experimental curves are represented on the semilogarithmic scale. The "fastest" exponential function, characterised by $\tau_3 \leqslant 1$ s and $\Delta E_3^0/\Delta E > 50\%$ (frequently >75%) has been attributed[20] to processes involving the slow replacement of the stagnant layer of liquid near the electrode. The next exponential function ($2\text{ s} < \tau_2 < 20$ s; $10\% \leqslant \Delta E_2^0/\Delta E^0 \leqslant 30\%$) was attributed to the diffusion of acid within the pores of a thin (approximately 10^{-5} cm) surface layer of glass (see also Buck[39]). For glass Na-20, the activation energy for this process is approximately 7 kcal mole^{-1}. The quantities τ_3 and τ_2 "sense" the difference in the roughness and porosity of the GE surfaces, for example a flame-polished surface and a surface subjected to etching with an HF solution, the difference in the acid anion (HCl and H_2SO_4), and the direction of the change in the concentration of the solution.

The last exponential function ($\tau_1 \cong 100$ s with $\Delta E_1^0/\Delta E^0 \leqslant 10\%$) can be attributed, if it is manifested at all, to the mutual diffusion of the cations in the glass pores, i.e. in the solid phase; $D \leqslant 10^{-12}$ cm^{-2} s^{-1}. In many cases there are two exponential functions. For the Na^+ ion and GE made from sodium–aluminosilicate glasses, there is a single exponential function with the $\tau_3 \cong 1$ s and $\Delta E_3^0/\Delta E^0 = 100\%$. When the comments on the results of Rechnitz and Kugler[28] are considered (see Table 2), the only cause of the retardation of the GE response in this case is the diffusional change in the composition of the layer of liquid near the electrode.

As already stated in connection with Eqn.(5), the approach resulting in Eqn.(13) can be used as a purely empirical procedure[2,17-20]. The present author now believes that at least τ_3 has a theoretical justification [criteria defined by Eqns. (8a) and (9a)]; τ_2 and τ_1 can be treated by analogy. The quantities ΔE_i^0 are still empirical, although it is evident that $(RT/F)\ln(\Delta c/c_1)$ makes a large contribution to ΔE_3^0.

Attempts to derive Eqn.(13) theoretically have been described in the literature. For example, in relation to the F^--selective electrode with an LaF_3 membrane (which is sometimes regarded as an anionic analogue of GE), an equation has been derived[40] with two exponential components; however, one of these was attributed to diffusion and the other to a surface reaction. The corresponding experiment was carried out over the range 1–44 min.

Among empirical and semiempirical equations describing experimental data with a high degree of accuracy, there is a hyperbolic expression for the time variation[2,40]; in some time intervals it is more convenient to employ the dependence on $t^{1/2}$. These equations have been compiled by Buck[35].

III. TRANSITION FROM RESPONSE TO ONE CATION TO THE RESPONSE TO ANOTHER

1. Classification of Phenomena and Experimental Results

In the given case it is necessary to take into account the involvement of at least two and frequently three potential-determining cations in the electrode reaction and one of the cations can have a multiple charge.

In the previous section the response to only one cation I^+ was as a rule considered. The presence of an "interfering" ion for a specified ratio of the concentration of I^+ and J^+ did not affect the equilibrium potential of the GE in the region of its I^+ function. This section deals with the dynamics of the GE potential and with the form of the kinetic curves in cases where the presence of the cation J^+ (or J^{2+}) has the following effects: (1) does not affect the equilibrium potential in the region of the I^+ function but does affect the dynamics of its attainment[14,16,22,28,37,38,41-43]; (2) causes a deviation from the I^+ function and a transition to the "mixed" $I^+ + J^+$ function[28,38,41,43-48]; (3) causes a transition to the full J^+ function[19,21,47,49-61].

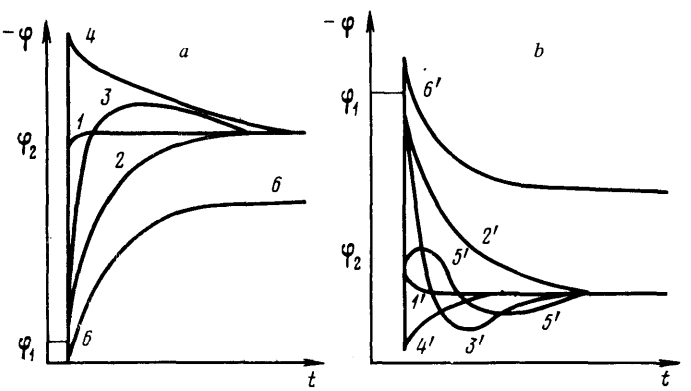

Figure 1. Schematic representation of dynamic curves for two cases: for transient processes in the region of I^+ function in the presence of J^+ or on transition to (from) the mixed $I^+ + J^+$ function: *a*) dilution with respect to I^+; *b*) concentration with respect to I^+; for transient processes with almost complete replacement of I^+ by J^+ in solution: *a*) when the stationary selectivity of the GE with respect to I^+ is higher than with respect to J^+; *b*) when the selectivity is lower. Curves 5′, 6, and 6′ refer solely to the second case—see Bobrov and Rudenko[54] and Belyustin et al,[19] respectively.

The first two cases are frequently encountered in practical applications of GE and the last is of great theoretical interest. The phenomena associated with the first two cases have been studied using pH titration GE made from lithium and sodium glasses for the pairs of ions H^+–Na^+,[14,16,41,44-48] H^+–Mg^{2+},[16] and H^+–Li^+;[45,47] series based on the increasing influence of M^+ and M^{2+}, determined from the height of the extremum on the ϕ–t curve (see Fig.1 above) have been published for GE

with metal ion functions made from NaAl-1118 [23,37,42,43,49] and NaAl-2704 [28,38] glasses for the pairs of ions Na^+–K^+, [22,37,42,49] Na^+–M^+ ($NH_4^+ < Cs^+ < Rb^+$, K^+), and Na^+–M^{2+} ($Mg^{2+} \leq Co^{2+}$, Ni^{2+}, $Zn^{2+} < Ca^{2+} < Mn^{2+} < Sr^{2+} < Cd^{2+} < Cu^{2+} < Ba^{2+} < Pb^{2+}$).

The third case—transition from the full H^+ function to the postulated M^+ function in an alkaline solution ($M^+ = Li^+$, Na^+, or K^+)—obtains in the study of GE made from glasses based on the Na_2O–CaO–SiO_2 system[47], pH titration lithium glasses[47], and the model lithium and sodium silicate glasses Li-27, LiB,[50] Na-16, Na-25,[51] and Na-20 [52–54] (the numerous studies by Bobrov and coworkers on the dynamics of the potential of GE made from non-silicate glasses are not considered here; they have been surveyed elsewhere[57,58]). For GE with a predominant response to metal ions, the transiton

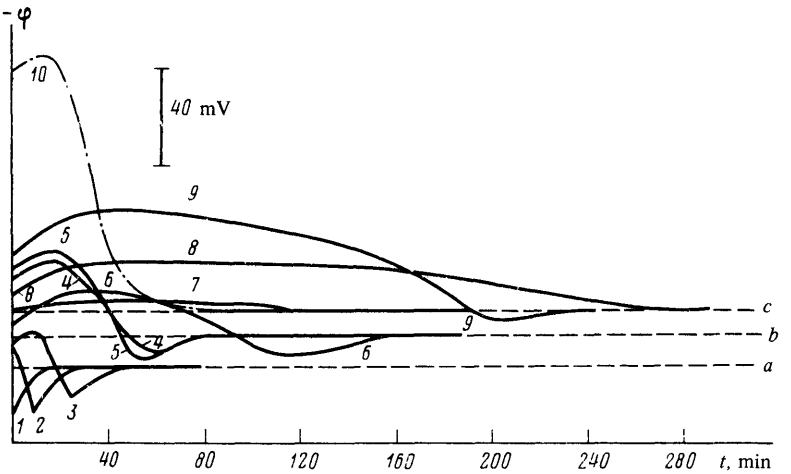

Figure 2. Dynamics of the potential of a GE of Na-20 glass in a buffer solution at pH 6,86 after treatment in a solution of the same pH and then in 1 *N* NaOH; GE subjected to a preliminary treatment for 3–4 min in a 1 : 1 HF + HCl solution at pH −0,6 *a*)–*c*) stationary potential levels corresponding to soaking for 1,2–3, and 7 days in a solution at pH 6.86 at 17–20 °C; duration of treatment (in days) in solution at pH 6,86: *1*) 0; *2*) 2/24; *3*) 5/24; *4*) and *5*) 2; *6*) 3; *7*) 10–7; duration of treatment (in days) in 1 *N* NaOH solution: *1*)–*4*), *6*), and *8*) 1; *5*) 9; *7*) 3/24; *9*) 7; *10*) 1/24 (90 °C) and 1 (17 °C). The figure has been constructed on the basis of the data of Bobrov and Rudenko[54] with the authors' permission.

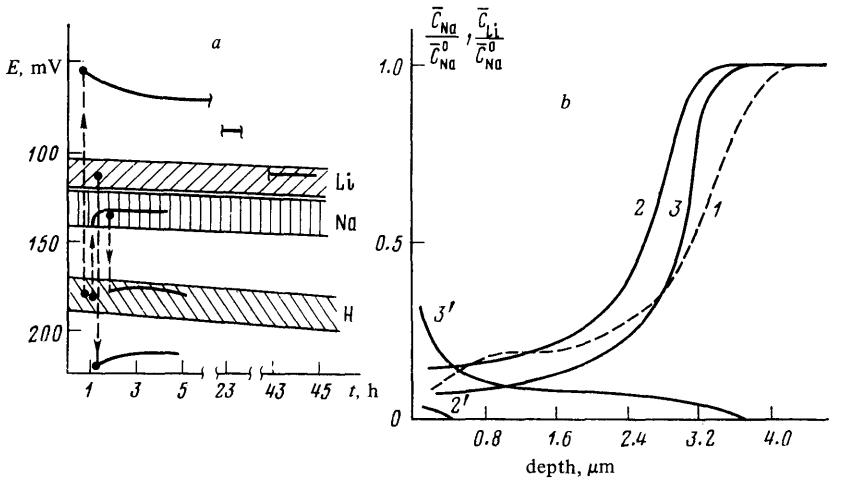

Figure 3. Dynamics of the potential of a GE of NaAl-2704 glass soaked for eight days in 0.1 *N* HCl, NaCl, or LiCl with replacement of one solution by another (*a*) and the corresponding distribution of the concentrations of Na (curves *1*–*3*) and Li (curves *2'* and *3'*) in the surface layers of the glass (*b*) after soaking the latter for 8 days in 0.1 *N* HCl and subsequent treatment in 0.1 *N* LiCl for different periods (days): *1*) 0; *2*) and *2'*) 1; *3*) and *3'*) 3. The shaded bands (representing the experimental scatter of data for a series of electrodes) correspond to stationary levels of potential obtained after prolonged soaking in 0.1 *N* HCl (H), NaCl (Na), or LiCl (Li).[59]

from the region of the H^+ function to that of the M^+ function has been studied using LiAl,[19,55] LiAlGe,[56] NaBAl, NaAl–2704, and NaAl-1118 [29] glasses. For GE of this type in neutral and alkaline solutions containing Na^+ or K^+, the transient phenomena, in which the involvement of the H^+ ion is not postulated, were studied using glasses with low (NaBAl) and high (NaAl–1118, LiAl) Na^+-specificities[19,21,59–61], and also NaAl-2704 [19,21] glass. Transitions of the type $(tris)^+ \rightleftharpoons M^+$ ($M^+ = Na^+$, Li^+, Ag^+, NH_4^+, Rb^+, Cs^+, or K^+) and $(tris)^+ \rightleftharpoons M^{2+}$, where $(tris)^+$ is the cation of the base tris(hydroxymethyl)-aminomethane and M^{2+} has the significance indicated above, have been studied using the NaAl-1118 glass.

The most characteristic observed feature of the kinetic curves considered in this section is their non-monotonic variation: there are extrema on the $\phi-t$ curves (although this is not obligatory). Fig.1 illustrates schematically the types of curves obtained experimentally in the studies mentioned above. Examples of real curves are presented in Figs.2 and 3 (see opposite).

The absolute height of the extrema reaches 60 mV in individual cases[43], although it is usually smaller. The duration of the transient processes in mixed solutions is between several seconds (in this case they can have a "solution" origin as in studies[16,28,38,43] dealing with M^{2+}, except Ba^{2+} and Pb^{2+} in Ref.43) and 30–60 s.[41–49] In the complete transition from one function to another the duration of the processes is between several minutes and tens of minutes and hours[19,21,50–56,61]. A drift continuing for days is frequently noted[31,50–58].

The principal components of the above processes are the exchange reactions

$$Li^+(glass) + I^+(soln) \rightleftharpoons I^+(glass) + L^+(soln) \qquad (14a)$$

or

$$I^+(glass) + J^+(soln) \rightleftharpoons J^+(glass) + I^+(soln) \qquad (14b)$$

(where L^+ is the "intrinsic" mobile cation of the glass), which lead to the breakdown of the constancy of the activity of the L^+ or I^+ cations in the glass ($\bar{a}_l$ or $\bar{a}_i$) which is a necessary condition for the Nernst equation to hold for the L^+ or I^+ function.

The ion-exchange process can be complicated by non-ion-exchange processes involving the hydration of the glass, its corrosion, etc., which lead to the formation of layers with a structure different from that of the bulk of the glass. Diffusion through such layers or their very formation are believed[41,43–48,50–58] to be a factor which determines the dynamics of the potential both for a response to a single ion and in the cases considered here.

2. Theoretical Treatment

The kinetic relations described for the potential can be explained in terms of the modern theory of the membrane GE potential, mentioned in the introduction[4,21] and modified by the hypothesis of surface layers differing in their structure from the bulk of the glass membrane[62].

The unmodified theory dealt with an ion-exchange membrane separating solutions, designated by single and double primes, containing cations I^+ and J^+ having the activities a_i', a_j', a_i'', and a_j'', the concentrations $\bar{c}_i$ and $\bar{c}_j$ within the membrane, and the mobilities $\bar{u}_j$ and $\bar{u}_i$. If the ratio of the ionic activity coefficients within the membrane $\bar{\gamma}_j/\bar{\gamma}_i$, the ratio of the mobilities $\bar{u}_j/\bar{u}_i$, and the activities of the ions in the solution of one side of the membrane (for example, that designated by a double prime) are assumed to be constant, then the overall membrane potential is described by an equation of type (3) [taking into account Eqn.(2)].

The possible dependence of ϕ on t subject to these limitations has been discussed[63,66] and it has been concluded that, for two ions involved in exchange and reciprocal diffusion, the relation will cease to hold after the attainment of equilibrium at the interfaces between the membrane and the solutions designated by single and double primes even when the variation of the concentration profiles within the membrane is a continuous process. The point is that for two ions, the values of $\bar{u}_j/\bar{u}_i$ and the transport numbers $\bar{t}_i$ and $\bar{t}_j$ are single-valued functions of the limiting concentrations and the independence of ϕ of t after the attainment of equilibrium is observed even for $\bar{u}_j/\bar{u}_i \neq$ const.[62,64], while the membrane phase can be non-ideal under these conditions ($\gamma_j/\gamma_i \neq$ const.). For more than two exchanging ions bearing charges of the same sign, the independence of ϕ of t can be observed only for an ideal membrane ($\bar{\gamma}_i, \bar{\gamma}_j = 1$) and subject to the conditions $\bar{u}_k/\bar{u}_1 =$ const.[64,65] (here k denotes any ion and 1 denotes the first cation).

The theory, derived for any ion-exchange membrane, has been extended to a glass membrane with modified surface layers and a fixed thickness in which current is transported by a single cation L^+. All the changes in the surface layers were reduced to ion exchange despite the fact that the occurrence of stresses[64] and hydration (solvation), hydrolytic, silanol group condensation, etc. reactions in such membranes have been known for a long time. Furthermore, all these reactions can lead to the breakdown of the above conditions ensuring the independence of ϕ from t as a result of a change in the structure of the membrane as a function of time and space.

Savage and Isard[26] pointed to hydration as a possible cause of the time variation of the GE potential. Shul'ts and Ivanovskaya[7,67] considered the influence of non-aqueous solvents on the GE potential and its dynamics. Isard[62] took into account the available experimental data for the structure and properties of the surface layers of glasses[68–72] (the present author could add to these the data in Refs.18, 46 to 48, 73–83, etc.), and linked them to the observations made on the dynamics of the GE potential (a number of studies of are quoted[21,26,41]). He arrived at an important conclusion: if the surface hydrated (leached) layer of glass is homogeneous and there are no concentration gradients (there is no diffusion potential), then equilibrium is established between the surface layer, the solution, and the bulk of the glass and the final potential has the value that it would have if there were no surface layer. The same conclusion was arrived at by Shul'ts[84] as early as 1960, which served as a basis for a number of studies in which a relation was found between the chemical composition of the initial glass and its electrode properties[85–87].

When the solution is changed rapidly, concentration gradients may arise in the outer part of the surface layer of the glass and an "external diffusion" potential can be established (the same diffusion potential for the outer layer has also been reported by Baucke[83]). These gradients are gradually "dissipated" and new concentration levels are established throughout the leached layer up to the inner gradient layer, where the "internal" potential acquires a new value. A similar explanation has been given by Hozumi and Akimoto[43].

The above considerations are largely qualitative. A quantitative treatment of the dynamics of the GE potential on transiton from one function to another has been given by Morf[66] on the basis of the Doremus[64] two-layer model of the glass membrane. Doremus considered a glass membrane consisting of two homogeneous components I and II with different ratios $(\bar{u}_j/\bar{u}_i)^I$ and $(\bar{u}_j/\bar{u}_i)^{II}$ and exchange constants K_{ij}^I and K_{ij}^{II} at the interfaces with the solutions designated by

single and double primes respectively in equilibrium with this membrane. He obtained the following expression for the overall membrane potential:

$$\varphi = \frac{RT}{F}\left[\ln\frac{a_i' + K_{ij}^{I}(\bar{u}_j/\bar{u}_i)^{I}a_j'}{a_i'' + K_{ij}^{II}(\bar{u}_j/\bar{u}_i)^{II}a_j''} + \ln\frac{\bar{c}_i^{I,II} + \frac{K_{ij}^{II}}{K_{ij}^{I}}\left(\frac{\bar{u}_j}{\bar{u}_i}\right)^{II}\bar{c}_j^{I,II}}{\bar{c}_i^{I,II} + \left(\frac{\bar{u}_j}{\bar{u}_i}\right)^{I}\bar{c}_j^{I,II}}\right], \quad (15)$$

where $\bar{c}_i^{I,II}$ and $\bar{c}_j^{I,II}$ are the concentrations of ions in the immediate vicinity of the inner interface between components I and II on the side of I. The ratio K_{ij}^{II}/K_{ij}^{I} reflects the difference between the standard chemical potentials of the ions in I and II. At this interface there is an interfacial potential jump. In the derivation of Eqn.(15) the same assumptions were made as in the derivation of Eqn.(3) but separately for each component I and II.

If $(\bar{u}_j/\bar{u}_i)^{I}K_{ij}^{I} = (\bar{u}_j/\bar{u}_i)^{II}K_{ij}^{II}$ and phases I and II are ideal, then, for an initially homogeneous membrane, we obtain $\phi \neq \phi(t)$ following the attainment of equilibrium at the interfaces. If the phases are non-ideal, then the maintenance of such independence requires that the activity coefficients in different phases should be identical functions of concentration [identical values of the "thermodynamic factor" n in the equality $(\bar{u}_j/\bar{u}_i)^{I}(K_{ij}^{I})^{1/n} = (\bar{u}_j/\bar{u}_i)^{II}(K_{ij}^{II})^{1/n}$]. If this is not so, then $\phi = \phi(t)$ when the concentration changes at the inner interface.

Suppose that component I is a hydrated surface layer of the glass in the I^+-form and component II is the bulk of the glass. When the membrane is immersed in a solution designated by a single prime, containing J^+, the J^+ ions will begin to diffuse through I to II, but $\phi = \text{const.}$ as long as the diffusion occurs within I. When J^+ reaches the inner interface between I and II at a sufficient concentration, the potential will begin to change and will vary with time until the attainment of equilibrium at this interface.

Morf[66] adopted Eqn.(15) as the initial expression. The inner solution (designated by a double prime) is constant; then, omitting the single prime, we obtain from Eqn.(15):

$$\varphi = \varphi^0 + \frac{RT}{F}\ln\left[a_i + K_{ij}^{I}\left(\frac{\bar{u}_j}{\bar{u}_i}\right)^{I}a_j\right] + \frac{RT}{F}\ln\left\{\left[\bar{c}_i^{I,II} + \frac{K_{ij}^{II}}{K_{ij}^{I}}\left(\frac{\bar{u}_j}{\bar{u}_i}\right)^{II}\bar{c}_j^{I,II}\right]\Big/\left[\bar{c}_i^{I,II} + \left(\frac{\bar{u}_j}{\bar{u}_i}\right)^{I}\bar{c}_j^{I,II}\right]\right\}. \quad (16)$$

Morf retained the assumptions adopted by Doremus and added the following ones: (a) the diffusion of ions through I is slower than the attainment of equilibrium on the outer interface but faster than the diffusion in II; (b) the overall concentration of cations in the surface layer I is constant: $\bar{c}_i^{I} + \bar{c}_j^{I} = c^{OI} = \text{const.}$; (c) $\bar{u}_i^{I} = \bar{u}_j^{I} = \bar{u}^{I}$. The latter assumption greatly reduces the generality of the derivation, but cannot be avoided. It implies in fact that the diffusion potential in the surface layer is assumed to be zero and all the changes in the potential as a function of time are attributed to the change of the interfacial potential at the inner interface—a procedure used in a number of studies[2,15,39].

The solution of the diffusional equation for the concentration at this interface $\bar{c}_i^{I}$ at any instant is found in the form

$$\bar{c}_i^{I} = \bar{c}_{1,i}^{I} + (\bar{c}_{2,i}^{I} - \bar{c}_{1,i}^{I})\,f(t), \quad (17)$$

where $f(t) = 0$ when $t = 0$ and $f(t) = 1$ when $t \to \infty$. Here $\bar{c}_{1,i}$ and $\bar{c}_{2,i}$ are the initial and final concentratons corresponding to equilibrium with solutions *1* and *2*, where the ionic activities are $a_{1,i}$, $a_{1,j}$ and $a_{2,i}$, $a_{2,j}$. The form of $f(t)$ is determined by an equation of type (7) containing a parameter τ defined by an equation of type (8a).

For the case under consideration, the general equation of the ϕ–t relation is as follows [we now go over to Morf's notation for I and II: I = s (surface) and II = m (membrane)]:

$$\varphi = \varphi^0 + \frac{RT}{F}\ln[a_{1,i} + K_{ij}^{pot}(m)\,a_{1,i}] + \frac{RT}{F}\ln\left[\frac{a_{2,i} + K_{ij}^{pot}(m)\,a_{2,i}}{a_{1,i} + K_{ij}^{pot}(m)\,a_{1,i}}f(t) + \frac{a_{2,i} + K_{ij}(s)\,a_{2,i}}{a_{1,i} + K_{ij}(s)\,a_{1,i}}[1 - f(t)]\right]. \quad (18)$$

Here K_{ij}^{pot} and K_{ij} have the same signficance as in Eqn.(2). Analysis of Eqn.(18) shows that, for $t < 0$, the equilibrium potential is specified by the initial solution ($a_{1,i}$, $a_{1,j}$) and by the properties of the bulk of the membrane; for $t = 0$ (the instant of the completion of the change of solution), the response of the surface itself to the change in activities is added to this; when $t \to \infty$, a potential determined by the properties of the final solution and the bulk of the membrane is established.

For intermediate values of t, Eqn.(18) predict curves of the following type when $a_j = a_{1,j} = \text{const.}$ and a_i is variable (Fig.1):

(a) Curves *1* and *1'* when the surface and the bulk of the glass are selective with respect to I:

$$K_{ij}^{pot}(m) \ll 1,\ K_{ij}(s) \ll 1;$$

(b) Curves *2* and *2'* when the surface is selective with respect to J^+ and the bulk of the glass is selective with respect to I^+:

$$K_{ij}^{pot}(m) \ll 1,\ K_{ij}(s) \gg 1;$$

(c) Curves *3* and *3'* or *4* and *4'* when the surface is selective with respect to I^+ and the bulk of the glass is selective with respect to J^+:

$$K_{ij}^{pot}(m) \gg 1,\ K_{ij}(s) \ll 1^{66}.$$

Eqn.(15) also has a number of corollaries which are important for the understanding of properties of GE such as the asymmetric potential, the specific solvent effect, and other phenomena associated with the variation of the standard potential ϕ^0 and its drift (without affecting the Nernst function). To make the system concrete, we shall put $I^+ = H^+$ and $J^+ = Na^+$ in Eqn.(15); suppose that the existence of regions I and II reflects the asymmetry of the properties of the glass membrane arising either in the preparation of the GE or as a result of the action of solutions designated by single and double primes on each side. The asymmetry is manifested in the potential, as long as one of the components (I and II) has not been "worked through" and as long as equilibrium is not established at the inner interface between I and II. We shall assume that phase I consists of the entire modified surface layer of glass in contact with the solution designated by a single prime and phase II is the bulk of the membrane and the modified surface layer on the other side. Then $\bar{c}_H^{I,II} = 0$ and we have from Eqn.(15)

$$\varphi = \frac{RT}{F}\ln\frac{a_H' + K_{HNa}^{I}(\bar{u}_{Na}/\bar{u}_H)^{I}a_{Na}'}{a_H'' + K_{HNa}^{II}(\bar{u}_{Na}/\bar{u}_H)^{II}a_{Na}''} + \frac{RT}{F}\ln\frac{K_{HNa}^{II}(\bar{u}_{Na}/\bar{u}_H)^{II}}{K_{HNa}^{I}(\bar{u}_{Na}/\bar{u}_H)^{I}}. \quad (19)$$

This equation was first derived[7,67] to account for the specific influence of the non-aqueous solvent on the GE potential and has been used[88,89] to describe the asymmetric GE potential (ϕ_{as}). Indeed, in the region of the H^+ function, when $a'_H \gg K_{HNa}^{I}(\bar{u}_{Na}/\bar{u}_H)^{I}a'_{Na}$, $a''_H \gg K_{HNa}^{II}(\bar{u}_{Na}/\bar{u}_H)^{II}a''_{Na}$, and $a'_H = a''_H$, we have

$$\varphi_{as,H} = \frac{RT}{F}\ln\frac{K_{HNa}^{II}(\bar{u}_{Na}/\bar{u}_H)^{II}}{K_{HNa}^{I}(\bar{u}_{Na}/\bar{u}_H)^{I}}. \quad (19a)$$

In the region of the Na^+ function, the opposite inequalities hold, and when $a'_{Na} = a''_{Na}$, we have

$$\varphi_{as,\,Na} = 0. \qquad (19b)$$

We shall extend the approach developed in relation to a one-sided leached layer in a number of studies[62,64,66] and others, to a real leached layer having for a number of reasons an inhomogeneous structure (we assume, as before, that $I^+ = H^+$ and $J^+ = Na^+$). This inhomogeneity is modelled by a sequence of n layers differing in the values of $(\bar{u}_{Na}/\bar{u}_H)^{(k)}$ and in the standard chemical potentials of the ions (and hence in the values of $K^{(k)}_{HNa}$ and the interfacial potential jumps; here k is the number of the layer).

If all the surface layers have been equilibrated with one another and with the solution with respect to the H^+ and Na^+ ions, then, according to Eqns.(15) and (18), the potential is determined by the equilibrium between the solution and the nth layer adjoining the bulk of the membrane and tentatively retaining its structure and properties. When the situation in solution is altered, a new equilibrium is established slowly as the reciprocal diffusion front passes the interfaces between the layers and equilibria are established at the latter. Suppose that equilibrium has been established at $k-1$ interfaces and that the concentration profile changes in the kth layer without reaching its interface with the $(k+1)$th layer. We then have an expression for the overall potential of the type of Eqns.(15) and (16):

$$\varphi^{(k)} = \varphi^0 + \frac{RT}{F}\ln\left[a_H + K^{(k)}_{HNa}(\bar{u}_{Na}/\bar{u}_H)^{(k)}a_{Na} + \frac{\bar{c}^{(k)}_H + \frac{K^{(k+1)}_{HNa}}{K^{(k)}_{HNa}}\left(\frac{\bar{u}_{Na}}{\bar{u}_H}\right)^{(k+1)}\bar{c}^{(k)}_{Na}}{\bar{c}^{(k)}_H + (\bar{u}_{Na}/\bar{u}_H)^{(k)}\bar{c}^{(k)}_{Na}}\right]. \qquad (20)$$

Suppose that for some reason [the condensation of ≡SiOH (see below) groups, the interaction with OH^-, etc.] we have $c^{(k)}_H \to 0$. We then obtain in the region of the H^+ function

$$\varphi^{(k)}_H = \varphi^0 + \frac{RT}{F}\ln\frac{K^{(k+1)}_{HNa}(\bar{u}_{Na}/\bar{u}_H)^{(k+1)}}{K^{(k)}_{HNa}(\bar{u}_{Na}/\bar{u}_H)^{(k)}} + \frac{RT}{F}\ln a_H. \qquad (20a)$$

In the region of the Na^+ function subject to the same condition, we have

$$\varphi^{(k)}_{Na} = \varphi^0 + \frac{RT}{F}\ln\left[K^{(k+1)}_{HNa}(\bar{u}_{Na}/\bar{u}_H)^{(k+1)}\right] + \frac{RT}{F}\ln a_{Na}. \qquad (20b)$$

We may note that, when there is a rapid alteration of the H^+ or Na^+ concentration in solution, the extent of the corresponding response is determined by the closeness to unity of the H^+ or Na^+ transport number in the first layer of the glass in equilibrium with the solution [see Eqn.(1)].

In Eqns.(20a) and (20b) terms which are constant under the conditions where the reciprocal diffusion front passes the kth layer are added to the potential ϕ^0. The time during which constant values of the potential are retained at the intermediate "quasi-stationary" level depends on the thickness of the layer $\delta^{(k)}$ and the reciprocal diffusion coefficient $D^{(k)}_{HNa}$. The $(k+1)$th layer is then in equilibrium with the subsequent layers and the parameters K_{HNa} and $(\bar{u}_{Na}/\bar{u}_H)$ characterising it can be replaced by the parameters of the nth layer and can be introduced into the expression for ϕ^0. We then obtain from Eqn.(20a)

$$\varphi^{(k)}_H = (\varphi^0)' - \frac{RT}{F}\ln\left[K^{(k)}_{HNa}(\bar{u}_{Na}/\bar{u}_H)^{(k)}\right] + \frac{RT}{F}\ln a_H. \qquad (21)$$

When the reciprocal diffusion front reaches the nth layer, the potential reaches a stationary level and no longer changes, provided that no structural changes take place within this layer.

Differences between the structure and properties of the layers can arise when the GE is soaked in solution, as a result of ion-exchange processes such as hydration, corrosion, hydrolysis ⇋ condensation (hydroxylation ⇋ dehydroxylation) by the reaction

$$\equiv Si{-}O{-}Si\equiv + H_2O \rightleftarrows 2 \equiv Si{-}OH, \qquad (22)$$

the sorption of acid by the outer layer from a concentrated solution, etc.

Presumably the low-temperature condensation of the ≡Si–OH groups, observed by infrared spectroscopy[74,75,77] for the surface layers of many silicate glasses after leaching with acid and leading to an increase of their chemical stability towards a number of reagents, including HF solutions[78], results simultaneously in an increase of the selectivity of the H^+ function of the GE, i.e. in a decrease of $K^{pot}_{HNa} = K_{HNa}\cdot(\bar{u}_{Na}/\bar{u}_H)$. Hydrolysis has the opposite effect. It then follows from Eqn.(22) that, on condensation in the kth layer, a $\phi^{(k)}$ potential in the region of the H^+ function should shift towards positive values and on hydrolysis the shift should be towards negative values. We shall now quote several examples.

In Wikby's study[46] glass electrodes made from $NaCa\text{-}21_4O6_2$ glass were hydrated for a long time in a 10^{-4} M NH_4HCO_3 solution at pH 7. The electrodes were then transferred to an etching solution (0.1 M HCl + 0.3% HF). A potential of approximately 340 mV was established initially and was then maintained for several tens of minutes, whereupon it changed abruptly to approximately 250 mV and then remained constant. The first, quasi-stationary level corresponds to equilibrium with the leached layer, in which considerable condensation was observed for this glass[74,75,77], and the second, stationary level corresponds to equilibrium with the internal ion-exchange layer adjoining the bulk phase.

Bobrov and coworkers[52,54] noted a shift of the stationary potential of GE made from Na-20 glass in a negative direction when the electrodes were soaked in an acid or neutral solution, which was regarded as the result of an internal increase of the alkalinity of the liquid within the pores. Consequently, under these experimental conditions, it was possible to postulate the maintenance of equilibrium with respect to H^+ ions between the solution and the internal ion-exchange layer adjoining the bulk phase. In this layer there is a possibility of the hydrolysis of the ≡Si–O–Si≡ bonds, leading to an increase of K^{pot}_{HNa}.

Even more striking negative shifts of ϕ were observed after treating the glasses in alkaline solutions (Fig.2), which leads not only to a partial dissolution of the outer layer but also to its loosening and an increase of the overall concentration of ionogenic groups in the residual layer. Then $\phi_{quasi\text{-}st} < \phi_{st}$ when the GE is transferred from alkali to an acid solution. As H^+ diffuses into the bulk phase, the change of potential is described by curve 5′ (Fig.1). The entire multiplicity of curves with extrema can be accounted for similarly (Figs.1 and 2).

We shall note separately the initial sharp extrema on curves of type 4 and 4′ (Fig.1) and also curves of type 6 and 6′. The latter were observed experimentally[19] after a rapid replacement of dilute (10^{-2}–10^{-3} M) $Na^+ \rightleftarrows K^+$ solutions for GE made of NaAl-1118, NaBAl, and LiAl-1608 glasses. Judging from the time required for their manifestation (several seconds for curves 6 and 6′ and several minutes for curves

4 and *4'*), these phenomena are associated with non-stationary processes involving the reciprocal diffusion of ions of different mobilities in the stagnant liquid layer and the adjoining porous surface layer of glass as well as the kinetics of the attainment of the interfacial concentration.

In order to describe such phenomena, it is convenient to solve beforehand Eqn.(12) for mixed solutions. It is also possible that the general causes of the type described above in relation to a porous layer of glass, differing markedly in structure and properties from deeper layers, can also operate in this instance.

For GE made of glasses with a predominately metal ion function, which do not tend to form deep leached layers[79,81], the duration of the transient processes is also small, particularly when two ions are involved, one of which is the "intrinsic" ion of the glass. Thus in GE made of NaBAl glass, soaked in NaCl solutions, the transient process after the replacement of NaCl by HCl in 1 s is completed in approximately 30 s (curves of type *2'* and *3'* in Fig.1), while in the opposite replacement the transient process lasts 2–3 min (curves of type *3* and *4*).[19] For GE made of NaAl-2704 glass, soaked in 0.1M HCl for 1,3, and 8 days, there is a transition to the Na^+ function in 0.1M NaCl in less than 1 h (curves of type *2* in Fig.1; see also Fig.3*a*). The opposite transition is faster (curves of type *2'* in Fig.1 after 1 and 3 days and of type *3'* after 8 days) and is sharper (Fig.3*a*).

Specific features have been noted in the transiton from the H^+ function to the response to an alkali metal ion which is not the intrinsic (L^+) ion of the glass: $H^+ \to Na^+$ for the LiAl glass[19]; $H^+ \to K^+$ [59] and $H^+ \to Li^+$ for the NaAl-2704 glass (Fig.3*a*). As a rule, curves of type *4* are obtained with a rapid attainment of a certain level of potential. However, in subsequent observations (after hours and days)[59] it was found that this level is quasi-stationary. After 24 h in the case of $H^+ \to K^+$ there is a transition to another layer which no longer changes; for $H^+ \to Li^+$, another quasi-stationary layer is established after 24 h and after a further 24 h a final (stationary) level is reached, which is also attained when the GE is soaked in the LiCl solution alone. At each level the K^+ or Li^+ function of the GE is manifested approximately. In both cases the potential at the stationary level is more positive than at the quasi-stationary level.

The attainment of the stationary level of potential coincides in time (approximately 40 h) with the attainment by the Li^+ ions of the internal interface between the leached layer and the bulk phase at a depth of 3 μm (Fig.3*b*). The use of these parameters for the calculation of D_{LiNa} by Eqn.(8a) leads to reasonable values $D_{LiNa} = 2.5 \times 10^{-13}$ cm^2 s^{-1}, which agree well with the values calculated from concentration profiles after treating the NaAl-2704 glass with LiCl solutions[90]. The reverse transition from the K^+ or Li^+ function to the H^+ function is also accompanied by the attainment by the potential of a more positive quasi-stationary level than the stationary level (curves of type *4'* for $Li^+ \to H^+$ in Fig.1 and of type *3'* for $K^+ \to H^+$).[59]

The relative positions of the stationary levels correspond to the series of equilibrium specifities[21] after prolonged soaking of the GE in solutions of the corresponding ions. The distribution of the quasi-stationary levels depends on the time of the observation and, for the same time, on the solution concentration[19].

When an attempt is made to explain theoretically the phenomena described, complications arise due to the involvement of three ions in the process. In this case there is no unambiguous relation between the mobility ratio or the ionic transport numbers in the glass, on the one hand, and the ionic concentrations at the interface, on the other. However, we suggest that this case can be reduced in most instances to the previous one, i.e. it is possible to neglect the contribution of the third potential-determining ion to the sum of the transport numbers at the given interface between the layers. Thus, when the mutual diffusion of metal cations in a glass with an increased Al_2O_3 content, in equilibrium with neutral or alkaline salt solutions, is considered, it is possible to neglect the contribution of H^+.[79]

On being soaked in HCl, a glass with a low Al_2O_3 content, for example, NaAl-2704, tends to form a leached layer. When the GE soaked in HCl is transferred to an LiCl solution, at the beginning of the process one can neglect the contribution of Na^+ and the quasi-stationary potential levels may be assumed to correspond to the reciprocal diffusion $H^+ \rightleftharpoons L^+$. As already mentioned, the establishment of a stationary level of potential at the end of the process corresponds to the attainment by Li^+ ions of the ion-exchange layer adjoining the bulk of the glass, where the reciprocal diffusion $Li^+ \rightleftharpoons Na^+$ is of decisive importance (Fig.3*b*).[59]

IV. CONCLUSION

On the basis of the experimental data examined and the theoretical studies, it is possible to formulate the following picture of the dynamics of the attainment of the potentials of glass electrodes after a stepwise alteration of the concentration of the potential-determining cation in aqueous solution.

1. In the region of the response by the electrode to the "intrinsic" cation of the glass or the exchange function with respect to a given cation I^+ of a "prepared" GE, it is possible to assume that the activity of this cation in the surface layer of the glass is constant and the response time is limited not by the transfer of the charge through the glass/solution interface but by both the diffusion of the electrolyte through the liquid diffusion layer arising near the GE surface and by the mutual diffusion of the ions within the pores and the walls in the outer loosened (hydrated) layer of glass (or by one of the processes indicated). The potential–time curves for the case under consideration have a complex exponential form and consist (when the accuracy of the measurements is to within 1 mV) of not more than three components with characteristic relaxation times $\tau_3 \leq 1$, $\tau_2 \cong 10$, and $\tau_1 \cong 100$ s when the duration of the concentration jump is ≤ 1 s. The contribution of the fastest process, corresponding to diffusion in the liquid layer near the electrode, to the overall change in the potential is usually greater than 50% and frequently 85–100%.

The values of τ_i are resonably predicted by the formula $\tau_i = m\delta_i^2/D_i$, where δ_i is the thickness of the diffusion layer, D_i the reciprocal diffusion coefficient, and m a multiplier ($m = 1$, 0.5, or $4/\pi^2$ in different models of the diffusion layer).

2. In the concentration jump in a mixed solution containing, apart from I^+, an "interfering" cation J^+ in the range of the ratios of the I^+ and J^+ concentrations where the constancy of the activity of I^+ ($\bar{a}_i$) in the surface layer of the glass is virtually unaffected in the stationary state, i.e. the I^+ function is retained, there is a possibility of the retardation of the attainment of a steady potential or of the presence of an extremum on the potential–time curve caused either by the reciprocal diffusion of the electrolyte ions in the diffusion layer of the liquid or by the time-dependent breakdown of the condition $\bar{a}_i = \text{const}$. in the outer surface layer of the glass (the time-dependent sensitivity of this layer to the cation J^{z+}).

3. In the concentration jump in the region of the transition from the I^+ function to the J^+ function of the GE in a mixed solution of I^+ and J^+ or in a pure solution of J^+ the dynamics of the attainment of a steady potential is determined by the low rate of the attainment of the boundary conditions in the ion-exchange reciprocal diffusion of cations in the surface layers of the glass differing in their structure from the bulk of the glass membrane. This structure is established during the preliminary preparation of the GE in a I^+ solution and is the result of non-ion-exchange corrosion, hydration, the hydrolysis of $\equiv Si-O-Si\equiv$ linkages, the condensation of $\equiv SiOH$ groups, the sorption of acid molecules in acid solutions, etc.

Against this background, the main result of the process is a decrease of $\bar{a}_i$ due to the substitution of I^+ ions by J^+ ions and an increase of $\bar{a}_j$ to a constant value. This is accompanied by a change in the phase and diffusion potentials in the glass.

When the boundary conditions are established, the overall GE potential reaches a definite level—in minutes if the native surface interacts with the new solution and a layer with the structure of the bulk phase is formed and in tens of minutes if an altered surface layer exists beforehand. In the latter case this layer can persist for a long time—hours and days (quasi-stationary potential) until the migration of the reciprocal diffusion front into the bulk of the glass results in the attainment of a layer with a different structure and properties, such as K_{ij} and $\bar{u}_j/\bar{u}_i$, i.e. until the boundary conditions change again. The potential can then change more until the attainment of another quasi-stationary level. This continues until the I^+ ions reach the internal ion-exchange diffusion layer having the structure of the bulk phase. A stationary potential level is then established. This level can vary over a very long time (days and weeks) owing to secondary corrosion, condensation, hydration, etc. processes.

At each quasi-stationary level and at the stationary level a I^+ function of the GE, close to the theoretical Nernst function, can obtain, provided that the transport number t_i in the layer in equilibrium with the solution is close to unity.

At the beginning of the process, immediately after the concentration jump, a non-monotonic variation of the potential—time (seconds, minutes) curve is frequently observed owing to the difference between the mobilities and the exchange current of the mutually diffusing ions in the boundary layer of the electrode and in the glass pores, and also as a consequence of the possible large difference between the properties of the surface layer of the glass itself, established by the preliminary treatment, and the properties of the deeper layers.

The semiquantitative theoretical description of the transient curves for the transition from one electrode function to another has been based on the hypothesis of interfaces between the glass layers mentioned above, differing in structure, the exchange constants, and ionic mobilities, and hence of potential jumps at such interfaces and of diffusion-dependent limitations within the layers. The explanation given in the literature for two homogeneous layers has been extended in this review to a large number of layers.

Inorganic Ion-exchange Materials Based on Insoluble Antimony(V) Compounds

F.A.Belinskaya and E.A.Militsina

Studies of inorganic ion exchangers based on insoluble compounds of antimony(V) are reviewed [polymeric antimonic acid and its numerous derivatives containing one or two multivalent elements (P, Zr, Nb, Ti, Te, etc.)]. Different approaches to the discussion of their composition, structure, and ion-exchange properties are analysed. Examples of the preparation and of the characteristics of different types of exchanger are given, and their possible practical applications are outlined.

I. INTRODUCTION

The scientific and technological need for selective ion-exchange materials with a high stability towards heat and radiation was responsible for the interest shown in the 1950's in inorganic ion exchangers and for the extensive studies which began at that time of the ion-exchange properties of various sparingly soluble inorganic compounds. Among the most important of the modern inorganic ion exchangers are the insoluble oxygen compounds of quinquevalent antimony: polymeric antimonic acid and its derivatives, including (in addition to antimony) one or two multivalent elements such as P, Zr, Nb, Ti, Te, etc.

Many papers have been published on the synthesis, properties, and applications of these cation exchangers, because of their unusually high selectivity (which allows many important practical problems to be solved by ion exchange methods). Previously published reviews of inorganic ion exchangers[1-5], including Sb(V) compounds, do not mention the advances made in the last few years. Furthermore, none of the foreign reviews deals adequately with the work done in the Soviet Union.

The aim of this review was to fill this gap by generalising the results of research on ion exchangers based on Sb(V) compounds, both published and still in progress in the ion exchange laboratory of the physical chemistry department of Leningrad State University. Thus we aim to bring to the reader's attention not only problems which have been solved but also controversial questions on the synthesis of these materials and on different approaches to studies of their composition, structure, and ion-exchange properties. When discussing the characteristics of different types of ion exchanger we shall specially emphasise their advantages, their shortcomings, and their possible practical applications.

II. POLYMERIC ANTIMONIC ACIDS

The study of the ion-exchange properties of polymeric antimonic acids (hydrated Sb(V) oxides, Sb(V) hydroxide, hydrated antimony pentoxide, hydrates of antimony pentoxide) began almost simultaneously in several countries. The earliest widely available publications appeared in 1965–1969. These include the work of Lefebvre[6], Lefebvre and Gaymard[7], Abe and Ito[8,9], Baetsle and Huys[10], and Girardi and Sabbioni[11]. In the Soviet Union the ion-exchange properties and the structure of antimonic acids began to be studied in 1965, and the first publications appeared in 1967–1969.[12,13]

This work made clear the high exchange capacity of antimonic acid (up to 5 mg-equiv g^{-1} or 20 mg-equiv cm^{-3}), its ability to undergo ion exchange in acid solutions, and its selectivity towards Sr^{2+}, Ba^{2+}, Cd^{2+}, Pb^{2+}, Ag^{+}, Na^{+}, and K^{+} ions. However, even at that early stage different points of view on the origin of the ion-exchange properties of these materials and on the composition and structure of polymeric antimonic acid began to emerge: in particular, it was shown that the selectivity is very sensitive to the method of preparation.

The fundamental aspects of the preparation of sparingly soluble ("precipitated") antimonic acids and antimonates were first examined during the previous century. Since then there have been many changes in our understanding of the nature of these compounds. It is now generally accepted[14-21] that monomeric antimonic(V) acid—the starting material for the preparation of the insoluble forms—is a strong monobasic complex acid (hexahydroxoantimonic acid $H[Sb(OH)_6]$), which can exist in solution for a short time but is converted by condensation (in 2 or 3 days) into a precipitate of polymeric antimonic acid[18,19-22]. The salts of $H[Sb(OH)_6]$ (the hexahydroxoantimonates) also show a tendency towards polymerisation[23-25].

The state of antimony(V) in solution and the mechanism of the ageing processes of antimonic acid and antimonate solutions have been studied in detail[26-35]. Some substances were found to be a "stabilising" effect on solutions of antimonic acid (H_2O_2, oxo-compounds[19,36,37], and arsenious acid[38]), whereas other substances (such as KCl[19,36]) accelerate the precipitation.

It is therefore essential in the synthesis of insoluble antimonic acids (and especially in the preparation of mixed sorbents) to fix a large number of parameters in order adequately to characterise the initial solution: its concentration and pH, method of preparation, conditions and time of storage, presence of other substances, etc.

1. Preparation of Amorphous Antimonic Acid

Amorphous antimonic acid (AAA) can be prepared by the following methods:

a) by adding solutions of mineral acids (HCl, HNO_3) to solutions of the so-called "acid potassium or sodium pyroantimonates"†[10,13,23,39,40–43];

b) by hydrolysing $SbCl_5$ with water, chlorine water, or a dilute solution of NH_4OH;[13,23,42–44,47];

c) by treating $SbCl_3$ with oxidising agents such as HNO_3 or HNO_3 + HCl,[44,48–50] or H_2O_2,[24,45,51] and diluting the solution with a large volume of water;

d) by dissolving metallic antimony in *aqua regia* and evaporating the solution with repeated additions of nitric acid[43,52,53];

e) by dissolution of Sb_2O_3 in *aqua regia*[54] followed by hydrolysis;

f) by dissolving freshly precipitated antimonic acid and removing the solvent by freezing[44];

g) by a recently developed ion exchange method[55]. A solution of $K[Sb(OH)_6]$ is passed through the hydrogen form of a strongly acid cation exchanger in order to give a solution of $H[Sb(OH)_6]$,[18,19] which is then frozen or slowly evaporated, and the residue is dried over P_2O_5[13,42] or $CaCl_2$.[57,58]

Production of the amorphous acid is assisted by a low hydrolysis temperature, short time of contact between the precipitate and the mother liquor (4 h,[43] or 1 day[42]), and a low drying temperature[44,56]. These same factors favour the production of an amorphous product with a high solubility[44].

Washing AAA precipitates with water causes dispersion of the solid, increasing as the electrolyte is removed by the wash liquid. In order to minimise the loss of antimonic acid and to obtain a more stable product Abe and Ito[43,59] recommend washing the precipitate with cold water and separating it from the wash liquid by centrifuging. Colin and Lefebvre[56] froze the solution of antimonic acid prepared by ion exchange and treated the residue with alcohol at −4 °C. The granular material thus obtained was rapidly filtered and dried at 25 °C. Loss of antimony during washing of the AAA can be reduced still further[13] by introducing an additional drying stage (after partial removal of the chloride ions).

The composition of the AAA can vary over a wide range. Immediately after precipitation the value of n in the empirical formula $Sb_2O_5.nH_2O$ (which defines the composition of the samples) can be as high as 29–30,[43,47] but the water is rapidly lost. Relatively stable AAA samples, amorphous to X-rays, may contain between 3 and 8 molecules of water per molecule of Sb_2O_5 (reported values include $n = 5–8$,[13,42] $n = 4–5$,[43] and $n = 3$[57,58]).

Amorphous antimonic acid is not a stable product. It is spontaneously converted into crystalline antimonic acid on storage. When dry samples are kept at room temperature the first indications of crystallinity are observed after 3 months, and crystallisation is complete after 1.5–2 years[13,42].

† The term "pyroantimonate", which reflects the early, erroneous belief that antimony (like phosphorus) can form meta-, ortho-, and pyroantimonic acids and salts, is still used in textbooks as well as in research publications. Doubts concerning the validity of this analogy were expressed even in the last century (see, for example, Ref.44). More recent work has shown that the "pyroantimonates" are really hexahydroxoantimonates of the type of $M(I)[Sb(OH)_6]$,[15,16,20,21] or their partial condensation products[45,46].

2. Preparation of Crystalline Antimonic Acid

Crystalline antimonic acid (CAA) can be prepared by the methods used in the preparation of AAA. Crystallisation of the antimonic acid can be induced either in the mother liquor (by allowing very long ageing times, by increasing the temperature of the mother liquor, or by increasing the concentration of mineral acid[32,43,54,59,60,61]), or it can be induced by heat treatment of the precipitate (separated from the solution).

For example, Abe and Ito[43,59] prepared samples showing a high degree of crystallinity by hydrolysing $SbCl_5$ in a large volume of water and allowing the precipitate to stand in the mother liquor at 30 °C for 20 days. The time could be shortened to 4 h by raising the temperature to 60 °C and increasing the concentration of mineral acid present during the hydrolysis.

The preparation conditions of CAA by thermal dehydration of the amorphous acid and the optimum drying conditions for the crystalline acid are more complex. The usually recommended procedure[13,42,62] involves drying the amorphous phase for 2–3 days at 110–180 °C, i.e. in the temperature range corresponding to reversible sorption of water according to thermal analysis data[13,42,59,61]. The CAA samples obtained in this way are white powders or free-flowing granules of composition $Sb_2O_5.nH_2O$ (where $n = 3–4$), showing no tendency to peptisation; under the electron microscope they appear as cubic crystals ~0.1 μm in size[13]. At lower temperatures the crystallisation is slower, and at higher temperatures structural changes are possible (reduction of Sb(V) to Sb(III)), leading to changes in the ion-exchange properties of the material.

We should note that in many laboratories the CAA samples (including the hydrated antimony pentoxide marketed by the Italian Carlo Erba firm) are prepared by heat treating the amorphous material at 270 °C.[11,54,61] These samples have good mechanical properties[54], but they appear to have undergone some thermal changes (yellow colour[54,61], lower intensity of the odd-index X-ray reflections[13,61,69], weight losses at 900–1000 °C smaller than those of samples which have not been heat treated[54,61]).

In addition to AAA and CAA, we can prepare glassy antimonic acid by dissolving freshly precipitated antimonic acid in hot water and rapidly evaporating and cooling the solution[43,57–59].

The choice of crystallisation conditions and temperature for the preparation of CAA is determined mainly by the views of individual workers on the composition, structure, and mode of operation of the ion-exchange groups and on the processes which accompany thermal decomposition. We shall therefore discuss some of the most important results obtained in physicochemical studies of antimonic acid.

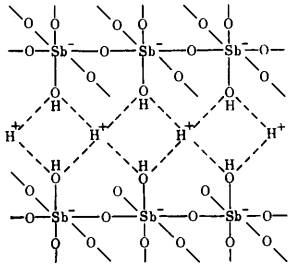
3. Results of Physicochemical Studies of the Structure of Antimonic Acids

Physicochemical studies of the oxygen compounds of Sb(V) can be arbitrarily divided into two periods. The first was concerned mainly with the composition of Sb(V) oxides, and it included some early applications of X-ray diffraction methods. The second period has been concerned with the ion exchange and catalytic properties of the Sb(V) oxides. It has coincided with the extensive introduction of new methods of analysis (differential thermal analysis, high-temperature X-ray diffraction, i.r. spectroscopy, etc.).

Work done during the first period could not establish whether the hydrates formed by Sb_2O_5 have a fixed or an indeterminate composition. The reported dehydration and thermal decomposition products included the hydrates $Sb_2O_5.nH_2O$ with $n = 3$, 2, and 1 (by analogy with the phosphoric acids), and also $n = 6$, 5, $4\frac{1}{2}$, 4 (see Ref.47), or $n = 6$, 4, 3, 2, 1.5,[63] or anhydrous Sb_2O_5, Sb_3O_6OH, Sb_6O_{13}, Sb_2O_4, and Sb_2O_3.

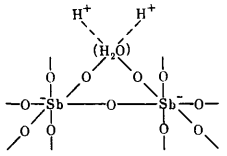
The initial oxide $Sb_2O_5.nH_2O$ and the products obtained by baking it at 800 °C (with formation of Sb_2O_4) have similar crystal structures (pyrochlore type, *Fd3m* space group[64-67]). X-ray data for the hydrates ($n = 3$, 1) and for the heat treatment products are given in the ASTM tables, although the existence of definite hydrates and of some of the heat treatment products is still being debated.

Thus, Sb_3O_6OH[64] was not detected by some workers[43,68], and was categorically excluded by others[69]. In place of Sb_6O_{13},[70] the compound $Sb_2O_{4.35}$ (of almost identical composition) has been suggested[69]. Doubts on the existence of anhydrous Sb_2O_5 have been expressed[64,71].



Natta and Baccareda[66,67], when reporting their X-ray diffraction results for $Sb_2O_5.3H_2O$, $Sb_2O_5.H_2O$, Sb_2O_5, and Sb_2O_4, pointed out that the compound which they had denoted Sb_2O_5 contained not less than one mole of water per mole of Sb_2O_5. However, this reservation was ignored by later workers and the original results[66,67] are still referred to anhydrous Sb_2O_5 [43,57,58,68,71].

A more recent comparison of the diffraction patterns and microwave resonance spectra of commercial samples of "anhydrous" Sb_2O_5[69] has shown that all these materials either contain water or show evidence of thermal decomposition (since all the samples dried at high temperatures contain Sb(III), including the Sb_2O_5 discussed in Ref.72). Only in the initial CAA of composition $Sb_2O_5.4H_2O$ (which had not been dried at high temperature) was the whole of the antimony in the Sb(V) form. Heating the CAA to 700 °C does not alter the crystal lattice type (pyrochlore, *Fd3m* space group), but the relative intensity of the reflections with odd indices is decreased by the treatment, suggesting structural rearrangements involving the cations. A decrease in the intensity of the odd reflections has been observed even in CAA held at 150 °C for 2 h.[69] It is thought that materials of reproducible composition cannot be produced by heat treatment up to 700 °C, and the breaks observed on the TG curves are ascribed to changes in the rate of dehydration and decomposition processes.



Other workers, however, interpret[73-76] the breaks in the TG curves (and the corresponding extrema on the DTG curves) as evidence for the formation at these temperatures of stable pyrochlore phases of composition $H_xSb(III)_tSb(V)_{16}.O_{56}$ (the composition of the elementary cell). Transitions between the phases are accompanied by the loss of O_2 and H_2O, and by reduction of some of the Sb(V) to Sb(III), the Sb(III) being transferred from a B position to an A position of the $A_2B_2X_7$ pyrochlore structure. The latter effect accounts for the decreased intensity of the odd reflections in the diffraction patterns. The number of pyrochlore phases stable up to 820–840 °C corresponds to the number t of Sb(III) cations which can be accommodated in the first coordination sphere of the $Sb(V)O_{6/2}$ octahedra without infringing the electrical neutrality of the pyrochlore structure as a whole. These views on the thermal decomposition processes deserve to be taken seriously and to be developed further.

Even the first studies of the ion-exchange properties of CAA led to rejection of the formula $Sb_2O_5.nH_2O$ and showed the need to establish a correlation between the exchange capacity of the ions and the structure of the CAA. Thus, in 1965 Lefebvre[6] examined the ion-exchange properties of crystalline CAA (in particular, the equivalent exchange of H^+ and Ag^+), and they compared the composition of the Ag^+ form ($AgSbO_3.0.5H_2O$) with that of the original CAA ($Sb_2O_5.4H_2O$) by using the formula $HSbO_3.yH_2O$ for the CAA. In 1972 Jolivet and Lefebvre[77] arrived at the formula $H(H_2O)SbO_3.0.5H_2O$, which reflects the non-equivalence of the water molecules, by studying exchange on CAA and antimonates.

Abe and Ito[43,59,78] proposed the following formulae for CAA and AAA:

CAA: $H_2Sb_2O_5(OH)_2$

AAA: $Sb_2O_5 \cdot nH_2O$

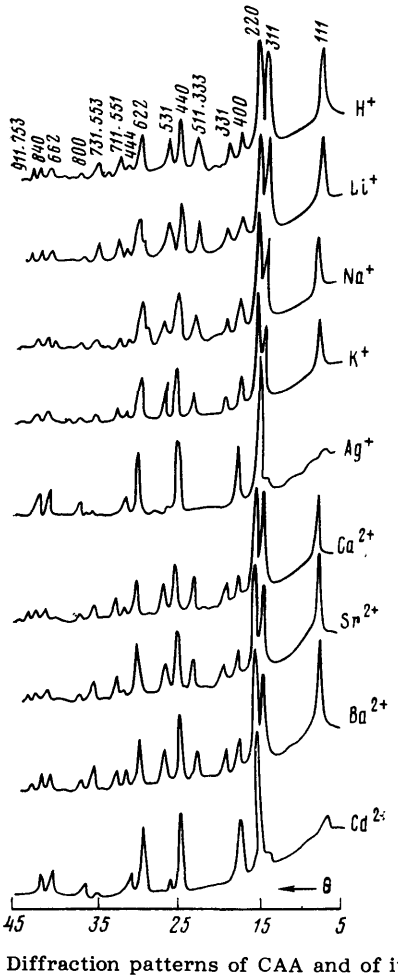


Figure 1. Diffraction patterns of CAA and of its salt forms[13,62].

They showed[59] that the exchangeable H^+ ions (like the Na^+ ions in the $Na[Sb(OH)_6]$ structure) are surrounded by six oxygen atoms. The H^+ ions in this structure can attach

themselves to H_2O, forming H_3O^+ ions. SbOH groups are postulated only in the CAA, following an i.r. spectral study[59] in which absorption bands assigned to Sb—O vibrations (750 cm^{-1}) and to sorbed water (1630 and 3350 cm^{-1}) were observed in all the samples, whereas bands at 1280 and 2430 cm^{-1} (assigned to vibrations of the SbOH group) were found only in the CAA. This conclusion is surprising, since SbOH groups would be expected to appear first in the AAA (the partial condensation product of $H[Sb(OH)_6]$).

The first attempt to correlate the ion-exchange properties and the structural features of CAA was reported in 1968 by Baetsle and Huys[10], who studied partly crystallised samples of CAA. Starting from the composition $Sb_2O_5.4H_2O$ and the experimentally determined density (4.27 g cm^{-3}), and assuming a lattice constant $a = 10.3$ Å, they concluded that the elementary cell contains 14 antimony atoms. They proposed an elementary cell structure of composition $[H_3Sb_3O_5.(OH)_8]_3.H_5Sb_5O_6(OH)_{18}$. This CAA structure accounts for the equality of the maximum exchange capacity to the concentration of Sb, and for the *S*-shaped isotherms (the nine strongly acidic exchange points of the trimers are assumed to be non-equivalent to the five weakly acidic points of the pentamer).

One weakness of the model[10] is its reliance on the measured densities of finely divided materials to calculate the number of Sb atoms in the elementary cell. Experimentally measured densities in these materials are usually lower than the true value (see, for example, Ref.79): this should lead to an erroneously low value of the number of Sb atoms in the elementary cell (14 instead of 16). We note that the CAA structure proposed by Baetsle and Huys[10] is still accepted by many workers[5,80].

In 1969 Novikov and coworkers[13] demonstrated that all the following materials had identical Debye diffraction patterns: the initial CAA, its sodium form, a synthetic sample of $NaSbO_3$ (prepared by heating $Na[Sb(OH)_6]$ at 480 °C), and the product obtained by treating $NaSbO_3$ with acid (i.e. antimonic acid prepared independently from $NaSbO_3$). Diffraction patterns for the hydrogen form and some salt forms of CAA, confirming the conclusions from the Debye patterns, are shown in Fig.1[62,81–83]. We note the regular decrease in the relative intensity of the odd-order reflections as the scattering power of the counter-ion is increased, and the almost complete disappearance of these reflections for the heaviest counter-ions (Ag^+ and Cd^{2+})#.

All these compounds belong to the pyrochlore structure type ($Fd3m$ space group). According to published data, the Sb(V) atoms in this structure can occupy only the 16(*c*) positions of the elementary cell, and the Sb(III) atoms must be partly or fully accommodated in the 16(*d*) positions[64–67]. Since the maximum exchange capacity for Ag^+ (in mg-atom g^{-1}) is equal to the Sb content (in mg-equiv g^{-1}) we may conclude that the whole of the antimony in CAA is in the Sb(V) form. Using the coordinates of the Sb(V) [16(*c*)] and O atoms (48*f*)[85,86] we constructed a model of the CAA anion skeleton[83]§ consisting of corner-sharing $[SbO_{6/2}]^-$ octahedra

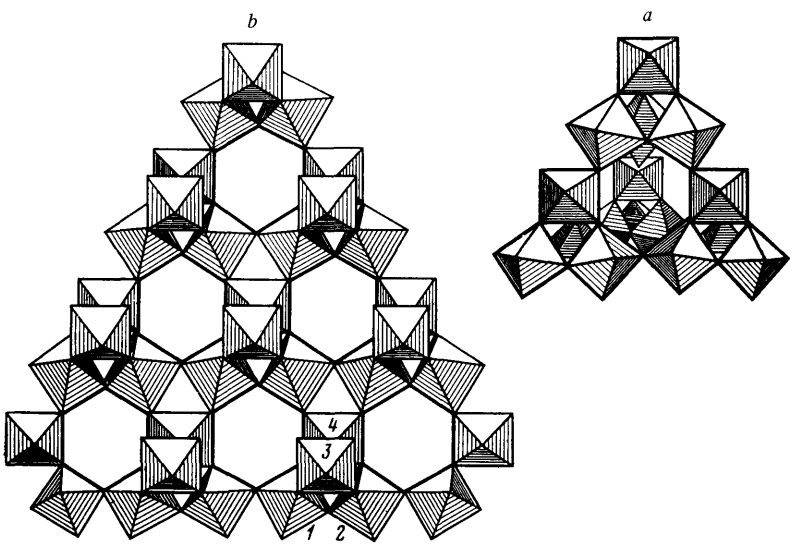

Figure 2. Structure of the anion skeleton of CAA: (*a*) elementary cell, (*b*) schematic representation of two types of (111) plane formed by $[SbO_{6/2}]^-$ octahedra.

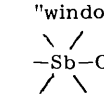
The effect of the difference in scattering power between A and B ions in compounds with the pyrochlore structure and in CAA is discussed in Refs.61 and 84. The similarity between the losses of reflections by ion exchange and by heat treatment[13,69,73,75,76] confirms that the counter-ions and Sb(III) occupy identical positions in the CAA structure.



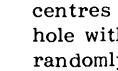
§ The pyrochlore structure was described by Belov[87] as a derivative of the fluorite structure. Interest in compounds with the pyrochlore structure has increased in recent years (see, for example, Refs.88 and 89). A detailed description of the structure is given in Ref.90.

carrying an excess of negative charge. This charge is compensated by the exchangeable cations (counter-ions) H^+ (or H_3O^+), Na^+, Sr^{2+}, Ag^+, etc.

The elementary cell of the anion skeleton is shown in Fig.2, with two types of (111) plane. The CAA structure can be built up in different ways. One is to arrange in layers the two types of (111) plane shown in Fig.2*b*. The lower plane forms a system of hexagonal "windows", the upper plane is more open. The next plane is similar to the first, but its "windows" are in a staggered configuration with respect to the lower plane, and so on. The CAA structure can also be built up from layers of parallel columns of octahedra: octahedra *1* and *2* in Fig.2*b* belong to one of these columns, *3* and *4* belong to a column of the next layer. In each layer the columns are perpendicular to those of the next layer. We can choose as the building block the group of four octahedra (*1*, *2*, *3*, and *4* in Fig.2*b*) joined to form an empty octahedron.

As Fig.2 shows, the anion skeleton of CAA has an open-lattice structure. At the centre of the elementary cell we find a hole connected to the neighbouring holes by four hexagonal rings ~3 Å in diameter. Six of the faces of each $[SbO_{6/2}]$ octahedron are in contact with six different holes, the other two with an empty octahedron. The counter-ions and the water can be accommodated at the centre of the hexagonal windows [16(*d*)] or at the centre of the holes [8(*b*)].

By assuming the simplest, uniform distribution of the Sb^{5+} and O^{2-} charges over all the bonds[91] we can calculate the excess of negative charge at the centre of the hexagonal "windows" or at the centre of the holes. Each oxygen bridge



$-Sb-O-Sb-$ contributes an excess charge of $\delta = z_O + n_O\, z_{Sb}/n_{Sb} = -2 + 2(5/6) = -1/3$, where z_O, n_O and z_{Sb}, n_{Sb} are the valence and the coordination number of O and Sb respectively in the anion skeleton. Since each window is formed by six bridges and each bridge contributes to the formation of two windows, each hexagonal ring will carry a charge of -1. On the other hand if we assume that the counter-ions are located at the centre of holes formed by four hexagonal windows (each contributing to two holes) the same calculation gives a charge of -2 for the hole. It follows that singly-charged cations are easily accommodated at the centre of the windows [16(*c*)], as in typical pyrochlores. This leaves room at the centre of the hole [8(*b*)] for the sorbed water. The compositions $NaSbO_3.0.5H_2O$ and $H_3O.SbO_3.0.5H_2O$ are exactly consistent with this distribution of counter-ions on the assumption that H_3O^+ plays the role of a counter-ion. When the skeleton contains doubly charged counter-ions the most suitable locations for these ions are the centres of the holes (as in $RbNbTeO_6$,[90] in which Rb occupies a hole with a charge of -1), or alternatively the M^{2+} ions are randomly distributed at the centres of hexagonal windows, filling alternate windows as in normal pyrochlore structures.

The assumption that H_3O^+ can be treated as a counter-ion in CAA is confirmed by i.r. spectral results[92].

In addition to the strong ν_{Sb-O} absorption band (770 cm^{-1}) the CAA samples give two absorption bands in the region of the OH_n bending vibrations: a wide band with a maximum at 1640 cm^{-1}, assigned to bending vibrations of adsorbed water, and a stronger, narrow band at 1705 cm^{-1}, assigned to H_3O bending vibrations[93]. Deuteration of the CAA shifts both these bands towards lower frequencies (the isotopic shift of the 1705 cm^{-1} band is $\delta(OH)/\delta(OD) = 1.34$). The absorption band at 1705 cm^{-1} is absent in the Na^+ form of CAA, but it reappears when this is converted into the H^+ form. From these results, and from the absence of the absorption bands at 1030–1300 cm^{-1} (assigned to δ_{Sb-OH} vibrations[20,21]), we may conclude that the SbOH group does not exist in CAA and the counter-ions are H_3O^+.[92] Data on the thermal decomposition of antimonic acid are consistent with this conclusion[13].

However, other workers[58,59] failed to observe an absorption band at 1704 cm^{-1} in the i.r. spectra of CAA, and at the same time they found two absorption bands at 1030–1300 cm^{-1} which they assigned to vibrations of the OH group in bridging

Sb–O–Sb groups (1290 cm^{-1}) and to SbOH end-groups (1140 cm^{-1}). Conversion into the Ag^+ form suppresses the 1290 cm^{-1} band, and treatment of the initial CAA sample with hydrofluoric acid suppresses the 1140 cm^{-1} band. From these results the authors conclude[58,59] that the protons of the SbOH bridging groups are responsible for the exchange, and that the SbOH end-groups do not take part in exchange.

Lukina and coworkers[94,95] concluded, from an analysis of i.r. spectra, that both SbOH and H_3O^+ are present in CAA. We must assume that the CAA samples used in that work had an unusual degree of condensation and crystal size, and hence an atypical ratio of surface $[Sb(OH)_{6-x}O_{x/2}]^-$ to bulk $[SbO_{6/2}]^-$ complex groups: this is suggested by the observed i.r. spectra.

The fact that the maximum exchange capacity of AAA and CAA is equal to the Sb content (whatever the degree of condensation or the crystallinity[42]) provides additional evidence that the surface and the bulk complex groups carry a charge of -1, and that the SbOH end-groups do not take part in the exchange: the traditional dissociation of these groups, often invoked to explain the ion-exchange properties of hydroxides, does not apply in this case[42,96].

4. Ion-exchange Properties of Antimonic Acid

The ion-exchange properties of CAA have been fairly fully characterised. Even in acid solutions the exchange capacity for Ag^+, Na^+, Sr^{2+}, Pb^{2+}, and Cd^{2+} ions is already quite high. Thus, the absorption (in mg-equiv g^{-1}) from 0.01 and 0.1 *N* solutions under static conditions (with a 1 : 100 ratio of weight of exchanger to volume of solution) is found to be[13,97]

$$\left.\begin{array}{c} Ag^+ > Na^+ > K^+ > Li^+ > Cs^+ \\ 5.06 \quad 2.22 \quad 1.28 \quad 0.26 \quad 0.04 \\ Pb^{2+} > Cd^{2+} > Sr^{2+} \geqslant Ba^{2+} > Ca^{2+} > Mg^{2+} \geqslant Ni^{2+} \\ 5.10 \quad 3.72 \quad 2.52 \quad 2.42 \quad 1.14 \quad 0.16 \quad 0.10 \end{array}\right\} \text{0.1 } N \text{ solutions},$$

$$\left.\begin{array}{c} Cd^{2+} > Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+} > Ni^{2+} \\ 3.37 \quad 2.76 \quad 2.05 \quad 0.97 \quad 0.09 \quad 0.07 \end{array}\right\} \text{0.01 } N \text{ solutions}.$$

The absorption of Ag^+ and Pb^{2+} ions under these conditions reaches its maximum value, equal to the exchange capacity (and therefore to the Sb content) of the material.

Since the distribution coefficient (K_d) for the sorption of many cations from dilute solutions can be as high as 10^4, detailed studies of the dependence of K_d on the concentration and nature of the background electrolyte have been carried out (HNO_3, HCl, $HClO_4$, CH_3COOH, NH_4OH, HF, etc.)[10,11,97–99,61].

Exchange isotherms and titration curves give complementary information and offer the fullest description of the ion-exchange properties of CAA. Titration curves for CAA have been obtained with the following solutions: NaOH[6,7,9,13]; KOH, LiOH, $(CH_3)_4NOH$, and CsOH[82]; $Ba(OH)_2$, $Ca(OH)_2$, and $(CH_3)_4NOH$ in the presence of $MgCl_2$ and $NiCl_2$.[83] Isotherms for the exchange of H^+ ions by Na^+,[7,97,100] K^+,[97,100] Li^+,[10,97] Rb^+,[100] Cs^+,[101] Ag^+,[77,97,100] Mg^{2+}, Ni^{2+}, Cd^{2+}, Ca^{2+},[83,97] Sr^{2+},[10,50,101] Ba^{2+},[10,83,97] and La^{3+}[10] have been reported. Isotherms for exchange on CAA in H^+–M^{z+} systems (where $M^{z+} = Ag^+$, Na^+, Li^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Cd^{2+}, and Ni^{2+})[97] are compared in Fig.3 for a total concentration of

exchanging ions of 0.1 *N*. Almost all the isotherms are *S*-shaped, intersecting the diagonal of the square at different values of $\gamma_{M^{z+}}$ (the equivalent fraction in the solid phase). Various workers have pointed out that isotherms measured at different total concentrations of exchanging counter-ions are identical[10,101].

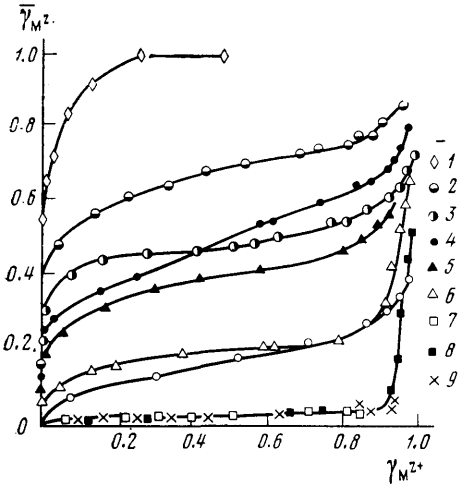


Figure 3. Isotherms for the H^+–M^{z+} exchange on CAA[83,97]: *1*) Ag^+, *2*) Cd^{2+}, *3*) Ba^{2+}, *4*) Sr^{2+}, *5*) Na^+, *6*) K^+, *7*) Ni^{2+}, *8*) Li^+, *9*) Mg^{2+}.

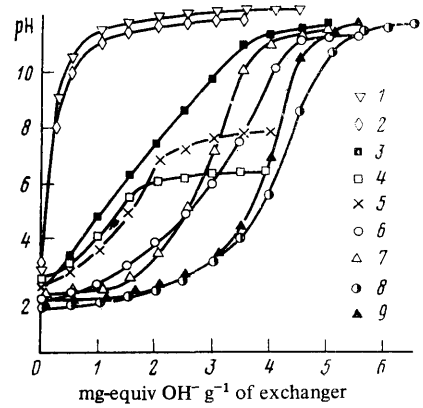

Figure 4. Titration curves of CAA for different solutions[13,82,97]: *1*) CsOH, *2*) $(CH_3)_4NOH$, *3*) LiOH, *4*) $(CH_3)_4NOH$ with Ni^{2+}, *5*) $(CH_3)_4NOH$ with Mg^{2+}, *6*) $(CH_3)_4NOH$ with Ca^{2+}, *7*) KOH, *8*) $Ba(OH)_2$, *9*) NaOH.

Fig.4 shows the titration curves of crystalline antimonic acid with 0.1 *N* solutions of LiOH, NaOH, KOH, CsOH, $Ba(OH)_2$, and $(CH_3)_4NOH$ in the presence of a 1 *N* background of the chloride of the corresponding metal. Since the $(CH_3)_4N^+$ cation is not sorbed (the titration curve for the $(CH_3)_4NOH$ solution being almost identical to the blank titration) we can use this solution for titrations in the presence of 1 *N* $CaCl_2$, $MgCl_2$, and $NiCl_2$, and characterise the sorption of the Ca^{2+}, Mg^{2+}, and Ni^{2+} ions at high pH values (up to the precipitation of the corresponding hydroxide). The titration curves which characterise the ion exchange in the region $2 < pH < 12$ (the non-buffering range of the alkali chosen for the titration and of the acid produced by the exchange) also differ according to the nature of the cation being exchanged. Thus, the titration curve of LiOH suggests that CAA is a polyfunctional cation exchanger, that of NaOH is consistent with a monofunctional cation exchanger, and the *S*-shaped isotherm for the H^+–Na^+ exchange again indicates polyfunctionality of the exchanger.

At first sight polyfunctionality appears inconsistent with the uniform structure of the CAA and with the location of all the counter-ions in identical positions. However, the high charge density of the polymer skeleton¶ and the interconnection between neighbouring holes and six-membered rings through the antimony–oxygen octahedra (see preceding section, p.937, left column) ensure that the replacement of one counter-ion by any other ion affects the bond energy of the other counter-ions. The number of these energetically non-equivalent exchange steps can be estimated by examining the CAA structure (Fig.2). Since each $[SbO_{6/2}]^-$ octahedron of the polymer skeleton contributes to the formation of six windows, at the centre of which the counter-ions are located, the replacement of all the singly charged cations of one kind by singly charged cations of another kind can occur in six energetically non-equivalent stages (each stage having a capacity of $\Gamma^0/6$). If the singly charged cations are replaced by doubly charged cations the number of these non-equivalent stages is three (each corresponding to a capacity of $\Gamma^0/3$). Hence the exchange isotherms (and titration curves) should be interpreted as sums of isotherms (or titration curves) whose shape is determined by the partial exchange constants. The number of these partial exchange constants varies by discrete amounts and depends on the charge of the exchanging cations.

An important aspect of the practical use of CAA is the reversibility and equivalence of the exchange of ions on this material. Contradictory views are held on this problem. Thus, some workers[6,82,83,100,102] find that the exchange is reversible, and that equivalence is preserved. On the other hand complete elution of selectively sorbed ions (Na^+, Sr^{2+}) is difficult or impossible[54,76,103,104]. This problem can be solved by correctly choosing the eluent[98,102]. Thus, Na^+ ions can be eluted by 2 *M* NH_4OH (but not by 10 *N* HNO_3);[98] 1 *M* HNO_3 is recommended for the desorption of Mg^{2+} and Ba^{2+}, and 3 *M* HNO_3 for the desorption of Sr^{2+} and Ca^{2+}.[102] Ag^+ and Pb^{2+} ions are recommended as universal displacers[10], though it is difficult subsequently to remove them from the exchanger (for example, Ag^+ ions can only be removed by converting them into an ammine complex[81]).

No less important is the dependence of the selectivity of CAA and AAA on the preparative conditions and on the degree of crystallinity of the samples[13,42,43,54,60,61,105]. An increase in selectivity and a decrease in the absorption of salts from solutions is observed as the crystallinity is increased from AAA to CAA[43,60,105]. The titration curves of AAA and of its crystallisation products (Fig.5) show a gradual shift from the curve for the monomeric $H[Sb(OH)_6]$ to that for the fully crystallised acid. The maximum exchange capacity (achieved in alkaline solutions) is the same for all the samples, and

¶ In contrast to the aluminosilicates, in which the charge of the anion skeleton is carried by $[AlO_{4/2}]^-$ groups alternating with neutral $[SiO_{4/2}]^0$ groups, in CAA the lattice is composed entirely of charged $[SbO_{6/2}]^-$.

equal to the amount of antimony present, but at lower pH values the capacity for Na^+ of the crystalline samples may be lower than that of the amorphous samples.

Systematic studies of the effect of crystal size on the ion-exchange properties of CAA have not yet been reported. It is stated[68] that the size of the primary crystalline blocks in CAA can vary over wide limits (from 150 to 3200 Å) depending on the preparative conditions. We can expect the sorption properties of small CAA crystals to be more similar to those of the monomeric acid $H[Sb(OH)_6]$ than to those of fully developed crystals. Neglect of the surface groups $[Sb(OH)_{6-x}O_{x/2}]^-$ is justified only when the crystal size is not less than 5×10^2 Å (the size of a cubic crystal containing five elementary cells of the CAA structure along each cube edge).

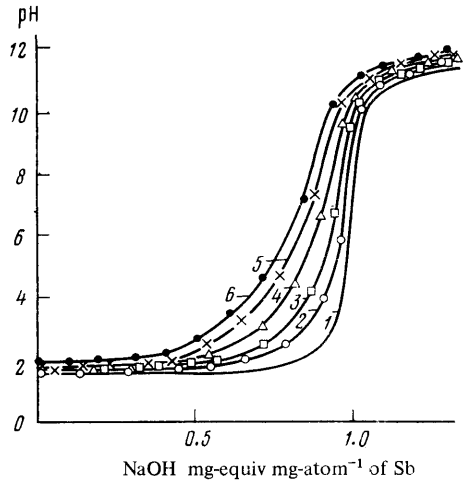

Figure 5. Titration curves of different samples with NaOH solutions: *1*) $H[Sb(OH)_6]$,[18] *2*) freshly prepared AAA and its crystallisation products, *3*) after 5 months, *4*) after 10 months, *5*) after 1.5 year, *6*) after 2 years[42].

Heat treatment of the H^+ form of CAA above 200 °C causes reduction of the Sb(V): as a result, some of the counter-ion sites are occupied by Sb(III), and the exchange capacity decreases. The thermal stability of AAA is lower than that of CAA,[13,105] and therefore samples which have been heat treated (for example, those dried at 270 °C) cannot be said to be identical to samples which have not been heat treated in comparisons of the ion-exchange properties and of the selectivity of these materials. The observed differences in properties suggests useful methods of thermally modifying CAA as an ion exchanger.

III. SYNTHESIS AND PROPERTIES OF MIXED CATION EXCHANGERS DERIVED FROM ANTIMONIC ACID

Ion-exchange properties are found not only in antimonic acid but also in various insoluble oxygen compounds of antimony(V) whose structure includes one or two multivalent elements (P, Si, Zr, Ti, etc.). There is no unique terminology for these materials, but they are often called antimonates. By analogy with the salts of heteropolyacids we shall call them phosphoantimonate, silicoantimonate, titanoantimonate (etc.) cation exchangers, stressing the ability of both constituents (Sb(V) on the one hand and P, Si, Zr, Ti, etc. on the other hand) to form a polymeric skeleton. The role of the second element in the structure of the antimonic acid is not always clear, but there can be no doubt of its influence on the selectivity of the material. At the time of writing, 17 types of these mixed cation exchangers are known.

1. Phosphoantimonate Cation Exchanger (PSb, Phosphoantimonic Acid, Antimony Phosphate)

This cation exchanger was prepared by Abe and Ito by mixing solutions of antimony pentachloride (or pentafluoride) and of phosphoric acid and heating the mixture for 16 h at 80 °C.[106,107] The $\overline{Sb}/\overline{P}$ atomic ratio in the solid phase decreases sharply as the concentration of H_3PO_4 is increased (which also lowers the rate of formation of the precipitate). At H_3PO_4 concentrations of 0.3–0.4 *M* the $\overline{Sb}/\overline{P}$ ratio is approximately 2, and a glassy product is obtained[108]. Glassy materials with different $\overline{Sb}/\overline{P}$ ratios can be prepared also by adding NH_4OH to a mixed solution of $SbCl_5$ and H_3PO_4 in hydrochloric acid[109–112]. Changes in the Sb/P ratio in solution from 0.5 to 8 give samples with $\overline{Sb}/\overline{P}$ ratios between 1.31 and 9.3.[112] Increasing the amount of phosphorus in solution during the synthesis does not yield an even greater concentration of phosphorus in the solid phase. Instead of NH_4OH, we can use NaOH, NH_4Cl, or HNO_3 as precipitants[113,114]. Phosphoantimonate cation exchangers have been prepared with reagents of various concentrations: 8 *M* $SbCl_5$,[113,114] 1 *M* and 10 *M* H_3PO_4,[109] 1 *M* and 0.01 *M* H_3PO_4,[114] and 0.25–4.0 *M* H_3PO_4.[113]

A granular product is obtained either by drying the precipitate in a thermostat[106–113] or by freezing it (at −10 °C[114] or at −6 °C[115]). When the dried material is mixed with water the larger granules disintegrate into smaller granules[108,109], but if the sample is first stored for 1 week in air at room temperature and then in a desiccator it can be mixed with water without change in granule size[108].

A series of papers by Lefebvre and coworkers[116–121] describes a detailed study of the products of the interaction of $SbCl_5$ and H_3PO_4, and of the properties of the resulting compounds.

The phosphoantimonate cation exchanger consists of transparent, heavy (density 2.66–3.22 g cm^{-3} for samples with an atomic ratio $\overline{Sb}/\overline{P} = 1.3–9.3$[112]), glassy granules[108,109] which can be amorphous to X-rays[111,112] or show a crystalline structure[115] (for $\overline{Sb}/\overline{P} \geq 2$).

The ion-exchange properties of phosphoantimonate cation exchangers have been characterised by potentiometric titration curves[106,109–115,122,124], by measurements of the absorption of cations bearing different charges[97,111,112], by isotherms for the exchange of hydrogen ions by alkali metal[97,112,125,126], alkaline-earth[97,112,125], and cadmium ions[127], and by the distribution coefficients of alkali metal ions[114,128] and of barium and lanthanum[97]. Studies of the rate of ion-exchange processes are described in Refs. 112, 114, and 122.

The high chemical stability of PSb cation exchangers in solutions of acids and salts has been stressed[97,108]. Partial dissolution of the samples occurs in hot water[108] and at pH > 8;[97] it is pointed out[108] that the materials are more stable in NH_4OH solutions than in NaOH solutions. The chemical stability depends markedly on the drying temperature of the sample: samples dried at 60 °C are more soluble than those dried at 100 °C.[108]

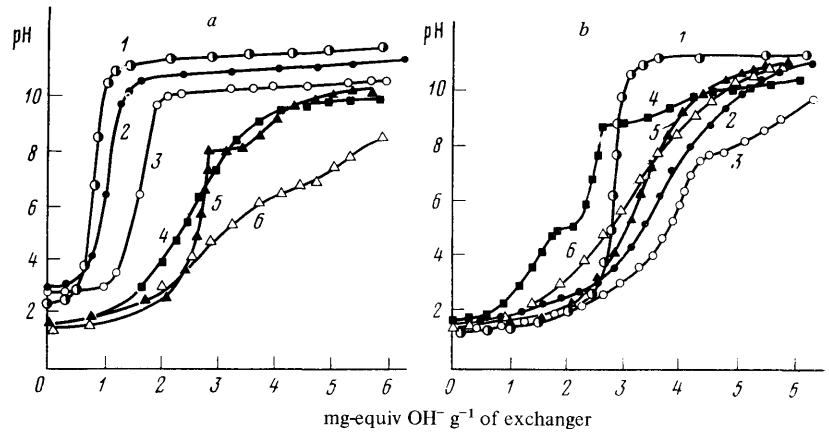

Figure 6. Titration curves of PSb for different solutions: *1*) $Ba(OH)_2$, *2*) $Sr(OH)_2$, *3*) $Ca(OH)_2$, *4*) LiOH, *5*) NaOH, *6*) KOH; (*a*) sample of composition $\overline{Sb}/\overline{P} = 1.35$, (*b*) sample of composition $\overline{Sb}/\overline{P} = 6.8$.

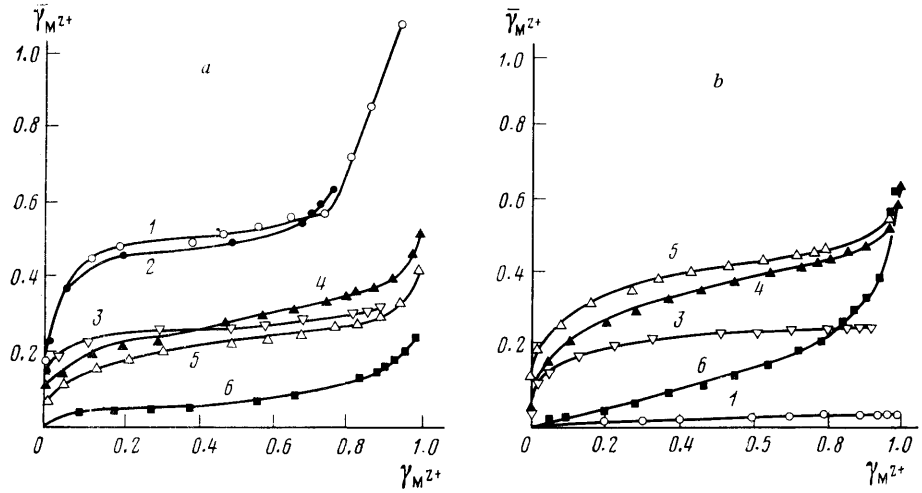

Figure 7. Isotherms for the H^+–M^{z+} exchange on PSb:[97,125] (*a*) sample with $\overline{Sb}/\overline{P} = 6.73$, (*b*) sample with $\overline{Sb}/\overline{P} = 1.64$; *1*) Ca^{2+}, *2*) Sr^{2+}, *3*) Cs^+, *4*) Na^+, *5*) K^+, *6*) Li^+.

Drying the gels at 100 and 200 °C shortens the time needed to prepare these materials without significantly affecting their ion-exchange properties[122]. Increasing the drying temperature of the granules lowers the ion exchange capacity, by a negligible amount for temperatures up to 140 °C[108] but more markedly in the range 100–260 °C (depending on the $\overline{Sb}/\overline{P}$ ratio in the sample), with complete loss of exchange capacity at 800 °C.[122] Hence there must be some doubt about the claim[123] that PSb samples with good exchange capacity can be prepared by drying the gel at 300–700 °C.

The most detailed study of the ion-exchange properties of PSb samples as a function of the $\overline{Sb}/\overline{P}$ ratio is described in Refs.112, 124, and 125. The titration curves of PSb samples with different alkalis and a constant 1 *N* salt background are shown in Fig.6 (for LiOH, NaOH, KOH, $Ca(OH)_2$, $Ba(OH)_2$, and $Sr(OH)_2$). We see that the shape of the curve and its distance from the pH axis depend not only on the nature of the exchanging cation (as in the case of CAA) but also on the $\overline{Sb}/\overline{P}$ ratio of the sample.[112,124] For each sample we can distinguish a number of pH regions of different selectivity. As a result, statements of the functionality of PSb cation exchangers (monofunctional or multifunctional) may be contradictory[106,115]. The type and shape of the exchange isotherms (Fig.7) also depend on the nature of the cation and on the $\overline{Sb}/\overline{P}$ ratio. The titration curves and the exchange isotherms (as well as the absorptions of different ions from 0.1 *N* solutions of their chlorides or of $AgNO_3$) can be used to demonstrate the effect of the phosphorus content on the selectivity of PSb.[97,111,112] Samples in which the P content is relatively small ($\overline{Sb}/\overline{P} = 9.3$) are like CAA in absorbing Ca^{2+} and Sr^{2+} more selectively than Mg^{2+}, Ni^{2+}, Co^{2+}, and triply charged or singly charged ions. High phosphorus contents ($\overline{Sb}/\overline{P} = 1.3$) favour selectivity towards singly charged cations, and the absorption of doubly or triply charged cations becomes negligible[111,112].

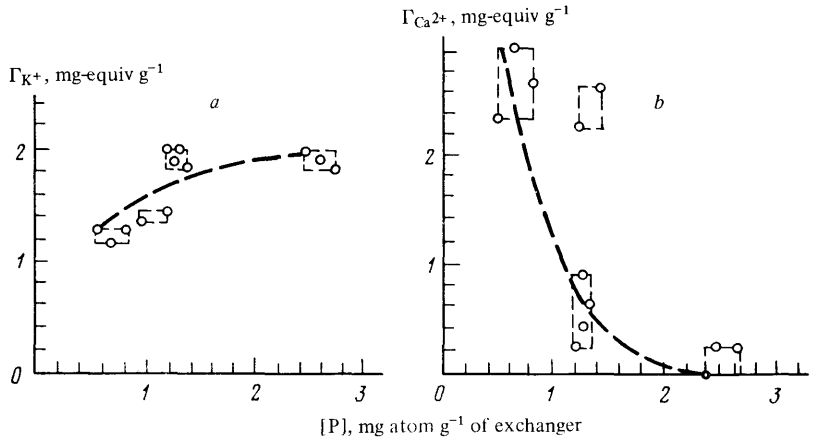

Figure 8. Plots of the absorption Γ_{K^+} (*a*) and $\Gamma_{Ca^{2+}}$ (*b*) against the phosphorus content of PSb samples[112]. Sorption from 0.1 *N* solutions of the chlorides. Data for PSb samples synthesised from nominally identical solutions are indicated by the rectangles.

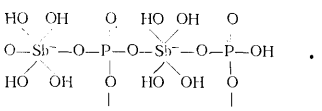
A closer study of the dependence of the absorption (ΓM^{z+}) on the phosphorus content (Fig.8) shows that this is the predominant (but not the only) effect on the selectivity of the material. Other factors tending to influence ΓM^{z+} include the number of functional groups in the sample (which is equal to the concentration of antimony), and their accessibility to the counter-ions. This structural characteristic of the PSb samples can be evaluated qualitatively from differential thermal analysis results[112]. This method can be used to calculate the amount of free water and of structural water in the PSb sample and to highlight differences between samples of similar composition ($\overline{Sb}/\overline{P}$) prepared under identical conditions[112]. The combined effect of all three factors determines the position of the sample within the rectangles arbitrarily drawn in Fig.8 as well as the relative positions of the rectangles.



The highest affinity of the phosphoantimonate cation exchangers is for silver ions[97,108,110–112,118,126]. The selectivity of the PSb increases as the loading of the exchanger phase with metal ions decreases[112,125] and as the concentration of the solution decreases[97,112,114]. Several workers report high values of the distribution coefficients of alkali metal ions[114,128] and of Ba[97].

A study[108] of the reversibility of ion exchange in a PSb sample ($\overline{Sb}/\overline{P} = 2$) showed that both sorption and displacement go to completion in the H^+–NH_4^+, K^+–NH_4^+, and Ag^+–NH_4^+ systems. The hydrogen ions are quantitatively replaced by potassium ions; the sorbed K^+ ions are not washed out by 3 *N* solutions of HCl or HNO_3, but they are easily eluted by 1 *M* NH_4NO_3.[108]

Oxidation–reduction processes can take place on PSb cation exchangers. Treatment of PSb samples with a 0.2 *N* solution of $SnCl_2$ in 1 *N* HCl produces sorption of Sn^{2+}, accompanied by conversion of some of the Sb(V) in the solid phase into Sb(III) with formation of Sn(IV).[129] A Mössbauer study[129] of the Sn forms revealed the presence of two types of Sn(II), differing in the ionicity of their bond with the ionogenic group (52% and 26% respectively). The appearance of Sb(III) in the cation exchanger causes a decrease in the total exchange capacity for Na^+ ions and in the absorption of doubly and triply charged cations[129].

Abe and Ito believe[106] that antimony-containing, strongly acidic groups analogous to $H[Sb(OH)_6]$ are responsible for the ion-exchange properties of PSb.

Studies of phosphoantimonate cation exchangers by ion exchange, differential analysis, and i.r. spectroscopy[111,112,130] have led to the following structure, in which the polymer chains consist of interconnected antimony–oxygen octahedra (the building blocks of CAA) and phosphorus–oxygen tetrahedra:

The hydrogen ions which compensate the charge on the $[SbO_{x/2}(OH)_{6-x}]^-$ octahedra and the hydrogen ions of the phosphate groups are involved in the ion exchange process[112,130]. The dependence of the selectivity of the phosphoantimonate cation exchangers on the phosphorus content stems from the decrease in the density of fixed charges produced by the phosphorus, which enters the structure as the non-exchanging $\equiv PO_4$ group[111,112].

More recently, Lefebvre and coworkers[119,120] proposed a PSb structure in which the basic elements are groups of three $[SbO_{6/2}]^-$ octahedra associated with one $\equiv PO_4$ (or $=HPO_4$) tetrahedron and which is consistent with all the above considerations.

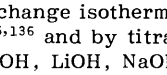
In contrast, Tikavyi and Bratennikova[115] suggest that the phosphorus in the PSb structure is present as HPO_4^{2-} and $H_2PO_4^-$ groups, but Astaf'eva and coworkers[113] support the $=HPO_4$ structure.

2. Silicoantimonate Cation Exchanger (SiSb, Silicoantimonic Acid, Antimonosilicic Acid, Antimonosilicic Cation Exchanger)

The SiSb cation exchanger is prepared by joint polycondensation of the hydrolysis products of $SbCl_5$ and Na_2SiO_3[62,131–133]. The resulting gel is allowed to remain in the mother liquor for 1–2 days before being washed and dried. In contrast to PSb, in SiSb the $\overline{Sb}/\overline{Si}$ ratio can be varied over wide limits (0.29–17.67).[133] The diffraction patterns of SiSb are similar to those of CAA, but the peaks are more diffuse in the case of SiSb. Raising the temperature (to 150 °C) and increasing the drying time (to 200 h) has no effect on

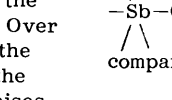
the degree of crystallinity. The similarity between the diffraction patterns of SiSb and CAA suggests that the structure of SiSb is determined by the antimony[62,133].

Unlike the normal CAA material, SiSb does not form a powder but consists of mechanically strong white granules of irregular shape. Its chemical stability is very high, as shown by the absence of any indication of dissolution during the measurement of titration curves or of exchange isotherms. SiSb is decomposed only by concentrated HCl at the boiling point.



Samples of SiSb can be characterised by the absorption from 0.1 *N* or 0.01 *N* solutions of various salts[97,134], by their exchange isotherms (H^+–Li^+, Na^+, K^+, Ba^{2+}, Sr^{2+}, Cd^{2+}),[97, 135,136] and by titration curves obtained with different alkalis (KOH, LiOH, NaOH, $Ba(OH)_2$)[135]: the equivalence and the reversibility of the exchange have been demonstrated. Over a wide range of pH values and of solution compositions the exchange capacity (as in CAA) is correlated only with the antimony content of the samples. Increasing the pH raises the exchange capacity to its maximum value, corresponding to the amount of Sb in the sample. At pH 9–10 the SiSb titration curves show a second horizontal section, corresponding to weakly acid groups[135,136].

The exchange isotherms for samples with low concentrations of silicon ($\overline{Sb}/\overline{Si} = 13.8$) are almost indistinguishable from those for CAA[97,135,136]. On the other hand in samples with $\overline{Sb}/\overline{Si} = 2.34$ and 0.51 (Fig.9*a* and 9*b*) the isotherms are shifted within the $\bar{\gamma}_M = f(\gamma_M)$ square. The selectivity towards Ca^{2+}, Sr^{2+}, and Ba^{2+} is improved, especially at low concentrations, and there is a small increase in the absorption of Li^+, Mg^{2+}, and Ni^{2+} ions (whose absorption is very slight on CAA), but the shape of the H^+–Cd^{2+} exchange isotherms is almost unaffected.



By comparing the diffraction patterns, exchange isotherms, and titration curves of CAA and SiSb we conclude that the silicon may be present as $[SiO_{4/2}]^0$ or $[SiO_{6/2}]^{2-}$ groups. In the former case the silicon should not contribute to the exchange capacity, but in the second case the exchange capacity of the sample should be greater than the antimony content. By using Pauling's electrostatic valency rule we can show[134–136] that in the first case the bond between the proton and the oxygen bridges in the SiSb structure should be weaker (i.e. the acidic properties should be enhanced), and in the second case the bond should be stronger (the strength of the residual O^{2-} bond in the

and

groups should be 1/6 and 1/2 respectively, as compared with 1/3 for the

group in CAA).

Since the ion-exchange properties of SiSb also indicate a slight weakening of the bond between the polymer skeleton and the H^+ counter-ion, and a small increase in capacity in the alkaline region, it has been suggested[133,135] that the $[SiO_{4/2}]^0$ and $[SiO_{6/2}]^{2-}$ groups can exist together in SiSb.

Further studies of SiSb cation exchangers are reported in Refs.99, 137, and 138. Super-equivalent sorption on SiSb was observed in a study of the sorption of Na^+ (using radioactive tracers) in the pH range 0–1.5, and of the sorption of Na^+, Sr^{2+}, Cd^{2+}, and Hg^{2+} from nitric acid solutions at pH 3.5.[99,137,138]. There is a report of irreversible sorption of the Sr^{2+} ion[99], which cannot be eluted from SiSb either by 7–10 *N* HNO_3 or by concentrated salt solutions. The protonogenic groups in SiSb are thought to be[138] "the hydroxyl

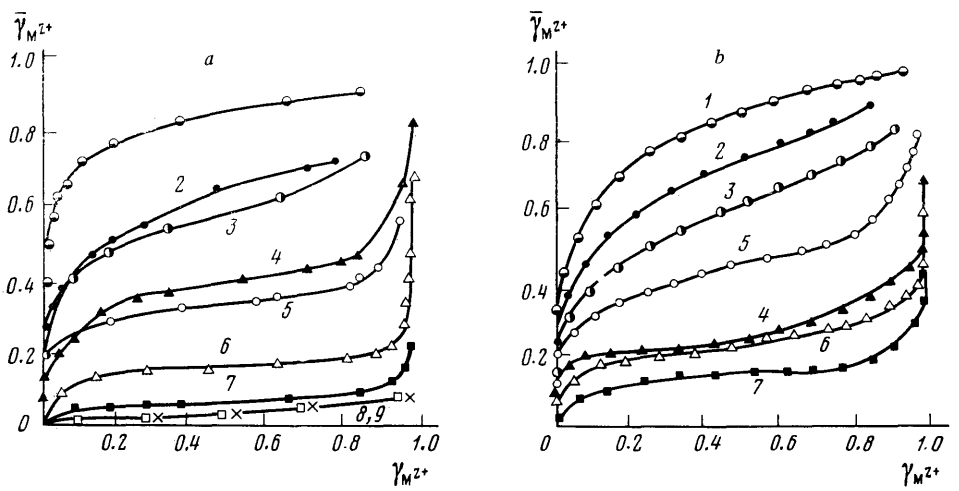


Figure 9. Isotherms for the H^+–M^{z+} exchange on SiSb[97,135,136]: (*a*) sample with $\overline{Sb}/\overline{Si} = 2.43$, (*b*) sample with $\overline{Sb}/\overline{Si} = 0.51$; *1*) Cd^{2+}, *2*) Sr^{2+}, *3*) Ba^{2+}, *4*) Na^+, *5*) Ca^{2+}, *6*) K^+, *7*) Li^+, *8*) Ni^{2+}, *9*) Mg^{2+}.

groups in –SbOH and –SiOH, and also H_2O molecules attached by coordination bonds to neighbouring SbO_6 octahedra".

Since many of the published papers[99,137,138] fail to state exactly the conditions under which the samples were prepared, and to describe the methods of analysis and the methods of measuring exchangeable and non-exchangeable sorption, it is not easy to discuss the discrepancies between their results and ours.

3. Silicophosphoantimonates (SiPSb, Phosphoantimonosilicate (PASC) Cation Exchangers)

The samples are prepared by mixing solutions of $SbCl_5$, Na_2SiO_3, and H_3PO_4; the precipitate is washed with water to pH 4–6 or with acetone, dried in a thermostat at 60 °C, converted into the hydrogen form by treating it with 1 *N* HCl, washed with water until free from Cl^- ions, and air-dried[139–143]. Approximately 50 samples were prepared in our laboratory[143], and used to investigate the relationship between the composition of the solid phase and that of the solutions used for the synthesis. In each sample the combined phosphorus and silicon contents were found to be strictly determined, and directly proportional to the concentration of antimony in the sample[143] (Fig. 10*a*). The concentrations of silicon and phosphorus vary in opposite senses (Fig. 10*b*).

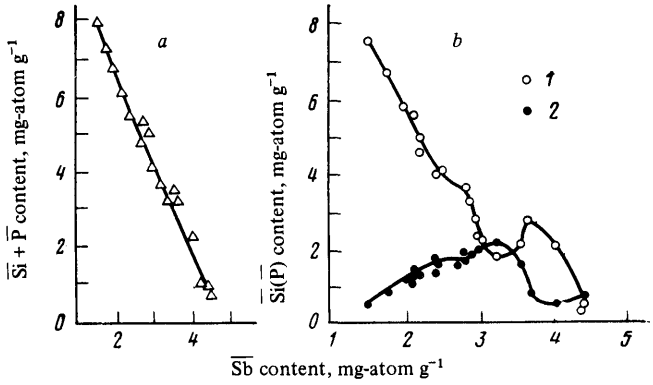

Figure 10. Variation of the $\overline{Si}(\overline{P})$ and $(\overline{Si} + \overline{P})$ content with amount of $\overline{Sb}$ in SiPSb samples[143]: (*a*) $\overline{Si} + \overline{P}$; (*b*), *1*) $\overline{Si}$, *2*) $\overline{P}$.

The compositions of the SiPSb samples and those of the samples in the binary systems (SiSb and PSb) were plotted in a composition triangle[143] (see Fig. 11). We can see that the concentration of silicon in the SiPSb samples can vary over wide limits, but the phosphorus concentration can vary only over a narrow range, and both these ranges apply to the binary systems as well. The SiPSb samples consist of mechanically strong granules of irregular shape and density between 2.0 and 3.2 g cm^{-3} (measured pyknometrically in CCl_4 at 20 °C).[143]

The SiPSb cation exchangers are chemically very stable[143]. According to the potentiometric titration curves obtained with different alkalis, these exchangers are polyfunctional[144].

The variation of the absorption of M^{z+} (at different pH values) with composition suggests that in the acid and the neutral region the H^+–M^{z+} exchange takes place at the antimony–oxygen ionogenic groups, whereas in the alkaline region (pH ≥ 9) phosphorus-containing groups are involved (as well as the antimony–oxygen groups) in the exchange of singly-charged ions. The silicon–oxygen groups take part in the exchange of doubly charged cations[144].

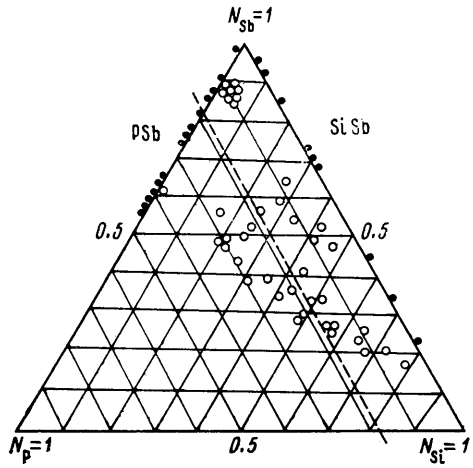

Figure 11. Composition triangle for SiPSb, SiSb, and PSb samples[143]. *N* is the atom fraction of the element in the solid phase (the ratio of the concentration in mg-atom g^{-1} of one of the components $\overline{Sb}$, $\overline{Si}$, or $\overline{P}$ to the sum of the concentrations).

Like the other types of antimony-containing cation exchanger the SiPSb samples are most selective towards Ag^+ ions, and the Γ_{Ag^+} value corresponds to the antimony content. Addition of silicon favours the sorption of doubly and triply charged cations, whereas an increase in the concentration of phosphorus has the opposite effect. Above a critical phosphorus concentration (1.5–2.0 mg-atom g^{-1}, shown in Fig. 11 as a broken line) the sorption of multiple-charged cations decreases, and below this concentration multiple-charged cations can be sorbed (but Γ_M depends on the concentration of antimony and silicon: an increase in the concentration of antimony favours the sorption of Sr^{2+} and Cd^{2+}, and an increase in the concentration of silicon favours the sorption of La^{3+}).[145,146]

The sorption of ions on SiPSb samples takes place by an ion exchange mechanism in which equivalence is preserved[145,146]. The shape of the exchange isotherms (as in the case of the related SiSb and PSb samples) depends on the composition of the material and on the nature and charge of the counter-ion[127,146] (Figs. 12*a* and 12*b*).

Non-equivalent sorption of singly charged and doubly charged cations has been observed[47,94,99,147,148] in a study of SiPSb (Sb : P = 8 : 1; 4.5 wt.% Si).

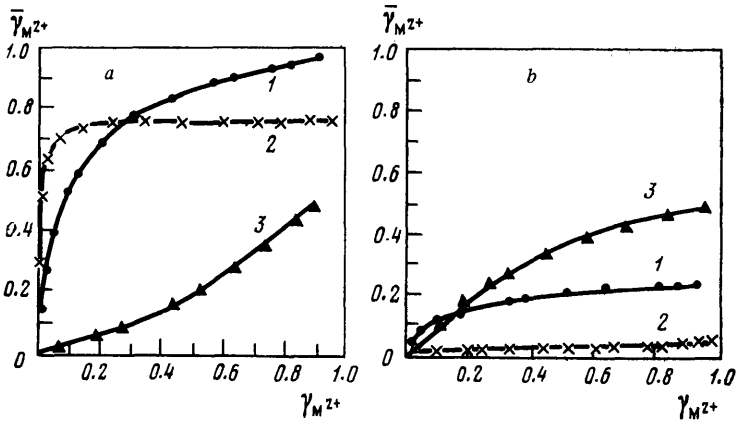

Figure 12. Isotherms for the H^+–M^{z+} exchange on SiPSb samples[127,146]: (*a*) sample with $\bar{Sb} : \bar{Si} : \bar{P} = 2.18 : 4.49 : 1.24$, (*b*) sample with $\bar{Sb} : \bar{Si} : \bar{P} = 3.52 : 2.17 : 1.71$; *1*) Sr^{2+}, *2*) La^{3+}, *3*) Na^+.

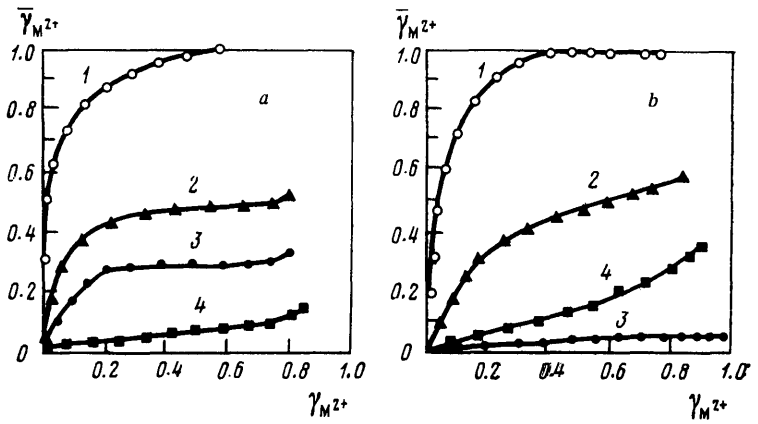

Figure 13. Isotherms for the H^+–M^{z+} exchange on TeSb[151]: (*a*) sample with $\bar{Sb}/\bar{Te} = 5.76$, (*b*) sample with $\bar{Sb}/\bar{Te} = 1.93$; *1*) Ag^+, *2*) Na^+, *3*) Sr^{2+}, *4*) Li^+.

4. Telluroantimonate Cation Exchanger (TeSb)

The exchanger was prepared by mixing solutions of 1 *M* $SbCl_5$ (in 3 *M* HCl) and 0.5 *M* H_2TeO_4.[149–151] Varying the Sb/Te ratio in solution during the synthesis allows the ratio in the solid samples to be varied in the range $\bar{Sb}/\bar{Te} = 1.93$–6.23, but the total concentration of tellurium and antimony is almost constant in all the samples (4.98–5.19 mg-atom g^{-1})[151]. The selectivity is again greatest towards Ag^+ ions, and the sorption of Ag^+ is practically equal to the concentration of antimony in the sample. As the tellurium concentration increases the absorption values for alkali metal ions (Li,Na, K) increase somewhat, but those for the alkaline earth metals (Mg, Sr, Ba) and for Cd fall off sharply, reaching zero at tellurium concentrations Te ≥ 1 mg-atom g^{-1}. Triply charged ions are not sorbed on the majority of these samples[127,150,151]. Thus the effect of tellurium on the selectivity is similar to that of phosphorus, but it can be observed at much lower concentrations[151].

Measurements of the exchange isotherms in the H^+–Ag^+, H^+–Li^+, H^+–Na^+, and H^+–Sr^{2+} systems revealed that—depending on the composition of the sample (i.e. on $\bar{Sb}/\bar{Te}$) and on the nature of the exchanging counter-ion—the sorption of M^{z+} can be predominant over the whole range of solution compositions (in the H^+–Ag^+ system), or the sorption of H^+ can be predominant (in the H^+–Li^+ system, and also in the H^+–Sr^{2+} system for the $\bar{Sb}/\bar{Te} = 1.93$ sample), or a selectivity reversal can take place, with an *S*-shaped exchange isotherm (H^+–Na^+ on both samples and H^+–Sr^{2+} on the sample with $\bar{Sb}/\bar{Te} = 5.73$, see Figs. 13*a* and 13*b*).[151]

The potentiometric titration curves obtained with 0.1 *N* solutions of NaOH and KOH showed that as the pH increases from 2 to 12 the capacity of the samples (Γ, mg-equiv M^+ g^{-1}) varies from 2.3 to 4.6 for the H^+–Na^+ exchange and from 2 to 4.5 for the H^+–K^+ exchange: $\Gamma_{K^+} < \Gamma_{Na^+}$ for all samples[151]. At high pH values (>10) the capacity for Na^+ of all samples exceeds the antimony content, the difference increasing with the tellurium content[151].

This work led to the conclusion that both the antimony and the tellurium are accommodated in the cation exchanger structure with six oxygen atoms as nearest neighbours. The tellurium replaces antimony isomorphously, and the structure is similar to that of polymeric antimonic acid. The protons which compensate the charge on the antimony–oxygen

octahedra and those of the tellurium-containing groups are both involved in the ion exchange process[150,151].

5. Zirconium Antimonate (ZrSb)

The ZrSb samples were prepared by adding an NH_4OH solution to a mixed solution of $ZrOCl_2$ and $SbCl_5$ in hydrochloric acid[152-155], or by mixing solutions of zirconium oxide chloride and of potassium pyroantimonate[156,157] or of antimonic acid prepared by ion exchange[156]. Samples with the following $\overline{Sb}/\overline{Zr}$ ratios were obtained: 2,[152] 0.53–4.1,[154] and 0.99–1.14.[157]

The most detailed studies of the preparation, structure, and of the physicochemical and ion-exchange properties of the ZrSb cation exchanger were reported by Lapitskii and Tikavyi[154,155,158-161]. The ZrSb samples consist either of white, glassy granules, suitable for operation in a column[154,157], or of friable, chalky particles[154]. The chemical stability of ZrSb was studied in several laboratories[152,154,157]. Raising the drying temperature of the samples lowers their ion-exchange capacity[153,157], and when ZrSb is heated to 300 °C its selectivity towards singly charged cations increases[155,159].

The cation exchange capacity of ZrSb increases with the antimony content[154,157,161]. Samples with $\overline{Sb}/\overline{Zr}$ ratios of 0.53 and 0.55 showed anion exchange properties: their capacity towards chlorine, determined from the potentiometric titration curves, was 0.75 and 0.95 mg-equiv g^{-1} respectively.[154]

The kinetics of the exchange of H^+ ions by Cs^+ and Rb^+ ions have been studied in detail[162] on a sample with an $\overline{Sb}/\overline{Zr}$ ratio of 1.03. The rate-determining step in the exchange of these ions was found to be diffusion in solution (in the case of 0.02 *M* and 0.05 *M* solutions) and diffusion in the grains for solution concentrations ≥ 0.1 *M*.[162] The kinetics of ion exchange on ZrSb are discussed also in Refs. 154 and 157.

The unusual alkali metal selectivity sequence ($Na^+ > Rb^+ > K^+$) of a sample with $\overline{Sb}/\overline{Zr} = 2$ was first noted by Phillips and Kraus[152]. Abe and Ito point out[156] that a more conventional selectivity sequence is obtained with samples in which the ratio is $\overline{Sb}/\overline{Zr} < 1$, whereas samples with $\overline{Sb}/\overline{Zr} > 1$ contain enough antimonic acid to display an abnormally high selectivity towards Na^+ ions. Similar explanations are given in Refs. 155 and 158. The following selectivity sequence is given[157] for a ZrSb sample with $\overline{Sb}/\overline{Zr} = 1.03$:

	Ba^{2+}	$>Ca^{2+}\geqslant Mg^{2+}\simeq Na^+$		$>K^+>NH_4^+\simeq Li^+$			
Γ, mg-equiv g^{-1}	1.85	1.24	1.21	1.20	1.09	0.74	0.73

Exchange isotherms have been measured in H^+–M^+ systems ($M^+ = Li^+$, Na^+, K^+, Rb^+, Cs^+, NH_4^+, Ag^+, Tl^+) with three ZrSb samples ($\overline{Sb}/\overline{Zr} = 0.55$, 3.05, and 4.1).[155,158] The selectivity of the cation exchanger towards these ions was found to increase as the antimony content increases and as the equivalent fraction of the ions in the exchanger decreases. The sample with the ratio $\overline{Sb}/\overline{Zr} = 4.1$ had the highest affinity for the Ag^+ and Tl^+ ions.

Contrasting views have been expressed on the structure and on the functional groups of ZrSb.[155,163] Mathews and Tandon[163] describe zirconium antimonate as the polymeric condensation product of antimony and zirconium hydroxides. On the basis of DTA and TGA data they assign to the $\overline{Sb}/\overline{Zr} = 1.03$ sample the formula $ZrO_2.0.5Sb_2O_5.5.1H_2O$. The number of water molecules shown in this formula describes the total content of water of crystallisation and water of constitution. The formula weight contains only one exchangeable proton (in the Sb–OH hydroxyl group[163]). Singly charged ions (Rb^+ and Cs^+) are sorbed by an ion exchange mechanism, unlike the doubly and triply charged ions (whose sorption is thought[157,163] to involve a more complicated mechanism).

From these results, and using the criteria for the monofunctionality of the cation exchanger discussed above, the authors conclude[162,163] that ZrSb is polyfunctional, either because it contains more than one type of functional group or because the single functional group $[Sb(OH)_6]^-$ is connected to the exchanger skeleton in different ways. However, no data on the structure of the ZrSb exchanger or on the constitution of the $[Sb(OH)_6]^-$ group are given in these papers.

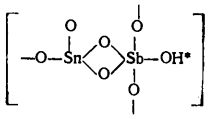
Lapitskii and Tikavyi[155,160,161] treat zirconium antimonate as a polymeric compound of variable composition, consisting of $[SbO_6]^-$ antimony–oxygen octahedra attached to zirconium atoms. By comparing the i.r. spectra of antimony and zirconium hydroxides with those of the hydrogen and the sodium form of ZrSb (whose absorption bands are assigned according to Balicheva and Roi[57,58]) these workers conclude that the cation exchanger structure includes bridging hydroxyl groups

(Sb–O–Zr) whose proton can be exchanged reversibly for different counter-ions[155,161]. It is suggested[155] that, in addition to the proton from the bridging hydroxyl groups, oxonium ions H_3O^+ are also involved in ion exchange on ZrSb, but their absorption band (1710 cm^{-1} according to Yukhnevich[93]) does not appear in the spectra reported by these workers[155,160].

6. Tin Antimonate (Sn(II)Sb, Sn(IV)Sb)

An ion exchanger containing Sb(V) and Sn(II) was synthesised by Abe and Ito[164] by mixing solutions of stannous chloride and potassium pyroantimonate. Increasing the Sb/Sn(II) ratio in the solution increases the $\overline{Sb}/\overline{Sn}$(II) ratio in the samples from 0.25 to 5. All the samples are stable towards water and mineral acids, but only the samples with a high $\overline{Sb}/\overline{Sn}$ ratio are stable in alkaline solutions. The potentiometric titration curves suggest weakly acidic properties. As we have shown[129], reduction of Sb(V) to Sb(III) with formation of Sn(IV) can be expected in the Sn(II)–Sb(V) system.

Several papers on the preparation and ion-exchange properties of tin(IV) antimonate have been published[156,165,166,167]. The Sn(IV)Sb samples were prepared by mixing $SnCl_4$ solutions with solutions of $SbCl_5$[165] or of potassium pyroantimonate[166], or of antimonic acid[166]. The samples obtained by precipitation with antimonic acid are found to have a higher exchange capacity and greater mechanical strength than those prepared by precipitation with potassium pyroantimonate[166].



The exchanger is stable in water and in mineral acids (less so in hydrochloric than in nitric and in sulphuric acid), and its stability in these media is higher than that of TiSb.[165] When these samples are heated their capacity decreases: by 21.6% at 100 °C and by 50% at 500 °C.[165] Studies of the chemical and thermal stability of these materials are reported also in Ref. 166.

The capacity of an Sn(IV)Sb sample with $\overline{Sb}/\overline{Sn}$(IV) = 5.10 towards NH_4, alkali metal, and alkaline earth metal ions decreases in the sequence[166]

NH_4^+	$>Ba^{2+}>Na^+\geqslant Ca^{2+}>Mg^{2+}>K^+>Li^+>Rb^+>Cs^+$								
1.94	1.76	1.60	1.55	1.18	1.09	0.88	0.72	0.56	

Measurements of the distribution coefficient have shown that this exchanger has a high affinity for the Hg^{2+}, Pb^{2+}, and Ag^+ ions[166]; the cations Zr^{4+}, Hf^{4+}, Th^{4+}, La^{3+}, Ce^{3+}, Y^{3+}, Sm^{3+}, Nd^{3+}, and Pr^{3+} are fully sorbed at pH 0–6.[165]

Qureshi and coworkers[165] treat Sn(IV) antimonate as an individual compound for which they propose the formula

The hydrogen ion of the Sb–OH group, indicated by an asterisk, takes part in ion exchange.

On the other hand, Mathew and Tandon[166] consider their cation exchanger as a mixture of oxides in which Sb–OH groups only can take part in exchange. They point out that only Rb^+ and Cs^+ are sorbed by an ion exchange mechanism: other ions (Tl^+, Ca^{2+}, Zn^{2+}, Tl^{3+}) are sorbed by a different mechanism[166].

7. Titanoantimonate Cation Exchanger (TiSb, Titanium Antimonate)

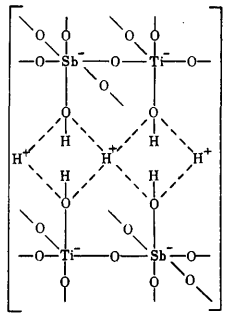
This exchanger is prepared by adding a solution of NH_4OH to a solution of $TiCl_4$ and $SbCl_5$ in hydrochloric acid[168–170], or by mixing solutions of titanium tetrachloride and of potassium pyroantimonate (or of hexahydroxoantimonic acid).[171] Samples with different $\overline{Sb}/\overline{Ti}$ ratios have been obtained (0.3–3.6,[168,169] 1.0–1.10,[171] and 0.16–4.7[170]), some of which showed weak crystallinity while others were amorphous to X-rays.

The material consists of mechanically strong, semi-transparent granules suitable for packing in columns[168–171]; however, the TiSb samples obtained from solutions of potassium pyroantimonate are less suitable for column operation and have a lower capacity than the samples prepared from antimonic acid solutions[171].

The TiSb cation exchanger is chemically stable in solutions of mineral acids and alkalis[97,168–172]. Its stability is higher than that of TiAs, TiMo, and TiSe, and it is also more thermally stable than these compounds[4,172], retaining its exchange capacity up to 300 °C.[171] The properties of TiSb (with $\overline{Sb}/\overline{Ti} = 1.04$) are unaffected by a dose of 4×10^7 Rad of γ-radiation[171]. The exchange of ions bearing different charges (Cs^+, Hg^{2+}, Tl^+) on TiSb obeys the law of mass action[173].

Fairly large differences in exchange capacity are reported by different workers for samples of similar composition: for $\overline{Sb}/\overline{Ti} = 1$, $\Gamma_{Na^+} = 0.73$,[169] for $\overline{Sb}/\overline{Ti} = 1.04$, $\Gamma_{Na^+} = 1.71$,[171] and for $\overline{Sb}/\overline{Ti} = 1.4$, $\Gamma_{Na^+} = 1.5$ mg-equiv g^{-1}.[170]

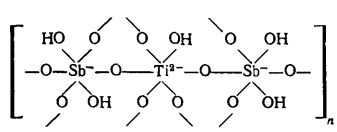
The selectivity of TiSb varies between samples of the same material[168–171]. Qureshi and Kumar[168] ascribe this variation to holes of different size, whose relative numbers are determined by the precipitation conditions rather than by the composition ($\overline{Sb}/\overline{Ti}$) of the sample.



According to some workers[168–171] the potentiometric titration curves of TiSb samples are typical of a monofunctional cation exchanger. On the other hand, other workers[97,124,170] consider TiSb to be a bifunctional exchanger, its potentiometric titration curves (for a 0.1 *N* NaOH solution and samples of different $\overline{Sb}/\overline{Ti}$ composition) lying between those of CAA and titanium hydroxide[124].

The ion-exchange capacity of TiSb samples towards ions with different charges increases with pH.[170] The sorption of silver ions is good on all the TiSb samples. However, unlike other cation exchangers containing antimony (such as PSb,[97,111] SiPSb,[144] TeSb[151]), this material has a capacity for Ag^+ ions not equal to its antimony content[170].

The selectivity towards cations carrying multiple charges increases with the titanium content of the samples[170]:

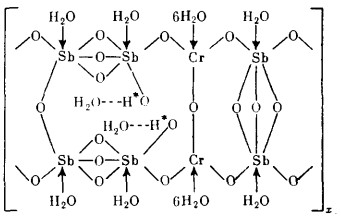


$\overline{Sb}/\overline{Ti} = 2.4$, $Ag^+ > Ba^{2+} > Na^+ > La^{3+}$;
$\overline{Sb}/\overline{Ti} = 1.4$, $Ag^+ > Na^+ > Ba^{2+} > La^{3+}$;
$\overline{Sb}/\overline{Ti} = 0.16$, $Ag^+ > La^{3+} > Na^+ > Ba^{2+}$.

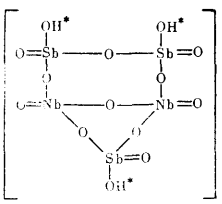
Contradictory results have been published on the structure and on the functional groups of the titanoantimonate cation exchanger. Qureshi and Kumar[168] treat the material as the product of simultaneous condensation of titanium and antimony hydroxides, and they propose a structural formula in which Sb and Ti have oxygen coordination numbers of 5 and 4 respectively. However, in their next paper[169] they assign to the Sb atom its characteristic coordination of 6, but the Ti atom has a coordination of 5:

Gill and Tandon[174] propose the formula $TiO_2 \cdot \frac{1}{2}Sb_2O_5 \cdot 4H_2O$, and they conclude from the i.r. spectra of as-prepared and of baked samples that OH^- groups are responsible for the ion-exchange properties of the material (without specifying whether those groups are attached to Sb or Ti atoms).

Using the concepts on the structure of inorganic cation exchangers developed in Ref. 96 we can describe TiSb as a polymer consisting of alternate $[SbO_{x/2}(OH)_{6-x}]^-$ and $[TiO_{y/2}(OH)_{6-y}]^{2-}$ [124,170] (or $[TiO_{y/3}(OH)_{6-y}]^{-(2-y/3)}$) octahedra:



The hydrogen ions which compensate the charge on these octahedra take part in the exchange of counter-ions.



8. Other Mixed Cation Exchangers

Other mixed ion exchangers based on oxygen compounds of antimony have been prepared, mainly by Qureshi and coworkers: NiSb and CoSb,[175] AlSb,[176] FeSb,[165,177,178] CrSb,[179,180] CeSb,[173,174,181] ThSb,[165,182,183] TaSb,[184] NbSb,[185,186] AsSb,[187] and WSb[188]. However, these compounds (described as antimonates of the stated metals) have not been studied as fully as the sorbents discussed above. By mixing solutions of M^{z+} salts and of $SbCl_5$, or potassium pyroantimonate, orantimonic acid, samples with different $\overline{Sb}/\overline{M^{z+}}$ ratios have been prepared. Like the other sparingly soluble antimony compounds, these are found to be chemically very stable. Their capacity decreases as the drying temperature is increased, and increases with the pH of the solution. Each sorbent has a characteristic selectivity towards certain ions: for example, CeSb[181] has a high affinity for Hg^{2+} ions, and NbSb[185] for Mg^{2+} ions.

When the structure of these compounds and the functional groups responsible for their exchange properties are mentioned it is usually assumed that the exchangeable ions are the protons of hydroxyl groups, without specifying whether these groups are attached to Sb or to M atoms[174,184]; alternatively, Qureshi and his coworkers rely on the analogy between antimony and phosphorus compounds, and they suggest the following formulae: for NiSb and CoSb,[185] $M(OH)_2M_3(HSb_2O_7)$; for FeSb,[165] $FeSbO_4.\frac{3}{4}H_2O$; for CrSb,[179] $Cr_2O_3.3Sb_2O_5.22H_2O$, i.e.

and for NbSb[185]

The protons of the SbOH groups (labelled with an asterisk) take part in ion exchange on NbSb and CrSb.

These formulae are unacceptable, since it is well known that antimony differs from phosphorus in not forming tetrahedral oxygen groupings either in solid compounds or in solutions (see, for example, the recent work on the stereochemistry of antimony compounds[86], on the state of antimony in solutions[18,28-35,38], and on the i.r. spectra of antimony compounds[20,21,57,58,130,155,160,162,163]).

9. Modified Sorbents

The term "modified" refers to sorbents supported or precipitated on an inert carrier. The preparation and ion-exchange properties of phosphoantimonic acid (PSb) supported on silica gel have been described[189], and also those of the same exchanger supported on SKT and BAU active carbons[190-192]. The silica gel (or carbon) is steeped in a hydrochloric acid solution of $SbCl_5$ (or a mixed solution of $SbCl_5$ and H_3PO_4), and the resulting material is hydrolysed with water or NH_4OH solution. By baking the finely ground inorganic sorbent (for example, CAA, SiSb, or SiPSb) with polytetrafluoroethylene at 375 °C porous blocks are obtained: these are very convenient for use in columns[193,194]. The capacity (referred to antimony content) is somewhat decreased by this treatment, and the selectivity is slightly affected, but the kinetic characteristics of the material are greatly improved.

A method for preparing heterogeneous compositions from a suspension in acetone of finely divided cation exchanger and the F-26 soluble fluorine-containing polymer has been developed[110,124,195]. By varying the geometric shape of the composition (membranes, tubes, filaments, gauzes, etc.) it is possible to vary the conditions of the sorption process over wide limits, to achieve high flow rates, to control the free volume of the column, to apply an electric field, etc.

Modification of the exchangers yield granulated materials, convenient for column operation, with improved kinetic characteristics and enhanced dynamic exchange capacity, without (as a rule) significant loss of selectivity.

IV. APPLICATIONS OF CATION EXCHANGERS

The high selectivity of sorbents based on oxygen compounds of Sb(V) defines the practical applications of these materials. The most widely used so far is "hydrated antimony pentoxide", marketed by the Italian firm Carlo Erba; the use of the silicoantimonate cation exchanger as a medicinal preparation has also been described. The application of the other sorbents described in this review is still at the stage of practical recommendations by the authors, based on laboratory tests. These recommendations include the possible applications listed below.

CAA: to purify highly radioactive acid solutions from decay products, and to separate ^{137}Cs and ^{90}Sr;[10] to remove Sr^{2+} from dilute nitric acid solutions[50]; to separate alkali[98,196] and alkaline-earth metal ions[197]; to purify lithium chloride solutions from sodium and potassium[198]; to separate Cd^{2+} (or Sr^{2+}, Ba^{2+}) from Ca^{2+} (or Mg^{2+}, Ni^{2+}), and Ca^{2+} from Mg^{2+} (or Ni^{2+}), and for the selective concentration of elements to be sorbed (Cd^{2+}, Sr^{2+}, Ba^{2+}, Ag^+)[13,63,97]; to extract Na radioisotopes from biological samples during neutron activation analysis[11,103,199-203]. The use of antimonic acid activated at 150 and 500 °C in gas chromatography (for the separation of n-butane, n-pentane, n-hexane, n-heptane, and n-octane) has been described[204]. Antimonic acid supported on silica gel or active carbon[104,191,192] is recommended for the removal of Na^+ from solutions of mineral acids[104], and for purifying Li^+, K^+, and Cs^+ salts from Na^+ impurities[190].

SiSb: for the extraction of Cd^{2+}, Sr^{2+}, and Ba^{2+} ions from mixed solutions[134], and for the separation of Cd^{2+} (or Sr^{2+}, Ba^{2+}) ions from Ca^{2+} (or Mg^{2+}, Ni^{2+}), and of Ca^{2+} ions from Mg^{2+} (or Ni^{2+})[134]; SiSb is known as the medicinal preparation "Polisur'min", used in cases of contamination with radiostrontium[205-207].

PSb: for the chromatographic separation of alkali metal ions[128]; to separate the short-lived sodium isotope from large quantities of magnesium and aluminium[208]; to extract strontium from natural waters[209]. Membranes made of PSb have a high electrical conductivity[110,124], and have been used to partition the cathode space in the electrolytic refining of metals[210]; filaments made from PSb have been used for sorbing potassium from biological fluids[195,211].

Because of their high specificity towards Cd^{2+} the cation exchangers SiSb, PSb, and SiPSb have been recommended[127] for the medical treatment of poisoning by cadmium salts. A method of using modified sorbents (CAA, SiSb, SiPSb) for the rapid extraction of sodium from the condensate of boiling water reactors[194] and in the analysis of effluent waters from atomic power stations[193] has been developed.

ZrSb: for the separation of alkali metal ions[152,156]; for the separation of Hg^{2+} from Zn^{2+}, Cd^{2+}, Pb^{2+}, and Bi^{3+}; of Ca^{2+} from Mg^{2+}; of Sr^{2+} from Rb^+, Cs^+, and Ba^{2+}; of Ba^{2+} from La^{3+}; of In^{3+} from Fe^{3+}, Ga^{3+}, and La^{3+}; of Ag^+ from Tl^+.[157]

SnSb: for the following separations. Mg^{2+}–Sr^{2+}, Cd^{2+}, Cu^{2+}, Al^{3+}, La^{3+};[165] Zn^{2+}–Cd^{2+}, Hg^{2+}–Bi^{3+}, Cs^+–UO_2^{2+}, UO_2^{2+}–ZrO_2^{2+}; Th^{4+}–La^{3+}; Th^{4+}–ZrO_2^{2+}; Mn^{2+}–Fe^{3+}; Mg^{2+}–Ca^{2+}; Zn^{2+}–Hg^{2+}–Cd; Al^{3+}–Fe^{3+}–UO_2^{2+}.

TiSb: for the separation of various cations[168,169]. The material can be used to fabricate ion-exchange membranes[124]; filaments made from TiSb compositions are recommended for

the sorption of calcium from complex solutions including biological fluids[212].

Separations of various ions on the following sorbents have been reported:

$NbSb^{186}$: Mg^{2+} — Sr^{2+}, Ba^{2+}, Hg^{2+}, Al^{3+}, Ga^{3+}, Fe^{3+}, La^{3+}, Th^{4+}.
$FeSb^{177}$: Mg^{2+} — Sr^{2+}, Al^{3+} — Ga^{3+}, Y^{3+} — La^{3+}, Th^{4+} — Sm^{3+}, Mg^{2+} — Cd^{2+} — Sm^{3+}.
$AlSb^{176}$: Th^{4+} — UO_2^{2+}, Mg^{2+} — Ca^{2+}, Mg^{2+} — Sr^{2+}, Ni^{2+}—Cu^{2+}—Ag^{+}, Mo^{6+}—Ti^{4+}—W^{6+}.
$CeSb^{181}$: Hg^{2+}—Cd^{2+}, Zn^{2+}, Pb^{2+}, Tl^{+}; Cu^{2+}—Mn^{2+}, Fe^{3+}—Al^{3+}, Zr^{4+}—Th^{4+}.
$ThSb^{183}$: Mg^{2+}—Zn^{2+}, Mg^{2+}—Cd^{2+}, Mg^{2+}—Cu^{2+}, Zn^{2+}—Cd^{2+}, Ni^{2+}—Cu^{2+}, Co^{2+}—Cu, Mn^{2+}—Cu^{2+}.
$TaSb^{184}$: VO^{2+}—Fe^{3+}—Ti^{4+}, VO^{2+}—Al^{3+}—Ti^{4+}, UO_2^{2+} — Ti^{4+}.
$NiSb^{176}$: Bi^{3+}—Cu^{2+}, Cd^{2+}, Al^{3+}, Fe^{3+}, Hg^{2+}, Zn^{2+}, Mn^{2+}, VO^{2+}, Mg^{2+}, Ba^{2+}, Ca^{2+}, Sr^{2+}, Co^{2+}, Pb^{2+}, Y^{3+}.

The high affinity of CrSb for the following ions has been stressed[180]: Ag^{+}, Tl^{+}, Hg^{2+}, Co^{2+}, Pb^{2+}, Ca^{2+}, Sr^{2+}, Fe^{3+}, Bi^{3+}, Al^{3+}, La^{3+}, and Zr^{4+}.

---o0o---

To conclude this review we should point out that cation exchangers based on antimony(V) compounds are scientifically important as well as having great practical value. Crystalline antimonic acid is one of the few "hydrated oxides" for which a simple correlation between composition, structure, and ion-exchange properties has been demonstrated.

Antimony also plays a structure-determining role in many mixed cation exchangers: when symptoms of crystallinity are detected in these materials the X-ray reflections are usually those of CAA. However, the structure of mixed cation exchangers and the role of the second element (added to the antimonic acid polymeric skeleton during the synthesis) are still the subject of debate. The structures proposed by some workers for the mixed sorbents are incompatible with modern views on the crystal chemistry of the oxygen compounds of antimony(V). For example, the coordination number of Sb(V), which is almost invariably 6, is taken[168] to be 5, and by analogy with phosphorus the group $-\mathrm{Sb}(=\mathrm{O})-$ is postulated[175,186]; the soluble form of antimonic acid is written[175] $H_4Sb_2O_7$, and so on. Differences in the coordination number of Sb(V) lead to different interpretations of the nature of the active groups: either in terms of the dissociation of the SbOH groups[168,180,186], which is not typical of the chemistry of antimony, or in terms of exchange with the outer-sphere ligands of the $[SbO_{6/2}]^-$ complex groups[96]. Hence, structural studies of Sb-containing compounds (including those of variable composition) are still needed.

Because of the discrepancies between the ion-exchange characteristics of sorbents of the same type studied in different laboratories, greater attention must be paid to the state of the starting materials in the solutions from which the sorbent is synthesised, especially in the preparation of mixed sorbents, for which it is not always clear whether the product is a single-phased or a multi-phased (micro-heterogeneous) system.

Ion-selective Electrodes in the Study of Cholinesterases

E.A.Materova and E.B.Nikol'skaya

This review is devoted to the application of various types of ion-selective electrodes in the study of the activities and catalytic properties of cholinesterases and also in chemical analysis with participation of these enzymes. Studies using a membrane "substrate" electrode, a glass pH electrode, an oxidation-reduction platinum electrode, and a polycrystalline electrode based on silver sulphide are considered. Investigations using enzyme electrodes based on immobilised cholinesterases are also described. The advantages and disadvantages of individual methods employing different types of ion-selective electrodes are discussed.
The bibliography includes 66 references.

CONTENTS

I. Introduction 953
II. The "substrate" electrode 953
III. The use of the glass pH electrode 954
IV. Other ion-selective electrodes 954
V. Enzyme electrodes using cholinesterases 955
VI. Conclusion 955

I. INTRODUCTION

The special attention devoted to the study of cholinesterases (CE) can be explained not only by the physiological importance of this enzyme, which plays a significant role in the transmission of the nerve pulse, but also by its considerable practical importance in medicine, toxicology, pharmacology, specific syntheses of certain pesticides, and analytical chemistry. Certain diseases are diagnosed on the basis of the level of activity of this enzyme and the degrees of poisoning by certain organophosphorus compounds and carbamates are determined. Cholinesterase is the target of the action of certain insectoacaricides and specific synthesis of the latter therefore requires the knowledge of the specific features of the properties of cholinesterases of different animals. In analytical chemistry enzymatic analysis of organophosphorus compounds and carbamates based on cholinesterase activity is unique in its sensitivity and selectivity.

Cholinesterase is a highly specific catalyst of the hydrolysis of choline esters and their thio-derivatives and of the hydrolysis of certain aromatic and aliphatic carboxylate esters[1]. Cholinesterases which hydrolyse acetylcholine at the highest rate have been called true cholinesterases or acetylcholinesterases (ACE) (E.C.3.1.1.7), while cholinesterases which hydrolyse other choline esters (butyrylcholine, propionylcholine, benzoylcholine, etc.) at the highest rate are called pseudocholinesterases or cholinesterases (E.C.3.1.1.8). The natural substrate of cholinesterases is acetylcholine, in the enzymatic hydrolysis of which the products are an alcohol (choline) and acetic acid:

$$[CH_3CO{-}O{-}CH_2{-}CH_2{-}N(CH_3)_3]^+ + H_2O \overset{CE}{\rightleftarrows} CH_3COOH + [HO{-}CH_2{-}CH_2{-}N(CH_3)_3]^+.$$

All studies on cholinesterases associated with their catalytic properties are bound to include the determination of the enzyme activity or of the rate of enzymatic hydrolysis. Ion-selective electrodes have found extensive applications, among other metals, in the solution of these problems[2,3]. The high selectivity and fairly high sensitivity of the method and the possibility of automation combined with a comparative simplicity of the analysis and of the relevant apparatus have made ionometry an extremely attractive and sometimes irreplaceable procedure for the investigation of the properties and activities of cholinesterases as well as the analysis of their substrates, inhibitors, and activators[4,5].

Ion-selective electrodes sensitive either to the substrate, for example, to choline esters, or to the hydrolysis products (the alcohol or acid) can be used in studies on cholinesterases.

II. THE "SUBSTRATE" ELECTRODE

Only one ion-selective membrane electrode sensitive to choline esters, which has come to be called the substrate electrode, is used nowadays[6]. The electrode is based on a liquid membrane [5% solution of acetylcholine tetra-(*p*-chlorophenyl)borate in *o*-nitroxylene] and is the first ion-selective electrode sensitive to organic cations. This electrode was first proposed by Baum for the investigation of choline esters and was subsequently used by the same worker to determine the cholinesterase activities[7] and kinetic characteristics of ACE and CE [8,9] as well as their substrate specificities[9].

The study of the selectivity of this electrode with respect to different choline esters[9] showed that it increases from choline to benzoylcholine by a factor of 10^5 in the following sequence: choline < acetylcholine < propionylcholine and acetylmethylcholine < butyrylcholine < valerylcholine < benzoylcholine. The sensitivity of the electrode to alkali metal ions[7] proved to be very low compared with acetylcholine: thus the sensitivity to potassium and ammonium ions is smaller by a factor of 10^3 and that with respect to sodium ions by a factor as large as 10^4. The kinetic characteristics of the enzymatic hydrolysis (the Michaelis constant and maximum velocity) determined with the aid of the substrate electrode for the ACE of the electric organ of the eel and the CE of horse blood serum agree satisfactorily with the available literature values of these quantities[10]. Baum and Ward[9] also used the electrode successfully for the analysis of biological media—for the determination of the cholinesterase activity in blood.

A disadvantage of the "substrate electrode" method in kinetic research is the decrease of its sensitivity with increase of the concentration of choline esters, which virtually restricts the region of its applicability to a substrate concentration limit of a little more than 10^{-3} M, because the optimum version of the enzymatic hydrolysis and the determination of its rate from the change in the substrate concentration involves conditions in which 5% hydrolysis takes place during a time interval suitable for the experiment;

this cannot be expected for a substrate concentration greater than 10^{-3} M. The substrate electrode apparently cannot be used in the study of the action of irreversible inhibitors in inhibitor analysis either, because a large substrate concentration (approximately 10^{-2} M) is required to suppress the effect of the inhibitor[11-13]. Furthermore, one should note that a large group of reversible and some irreversible inhibitors of cholinesterases contain in their structure a quaternary nitrogen group[1] and can therefore have an appreciable influence on the readings of the substrate electrode.

III. THE USE OF THE GLASS pH ELECTRODE

Historically the first ion-selective electrode used to determine the activity of cholinesterases was the glass pH electrode[14,15]. A method based on measurements of the rate of the change of pH of the reaction medium owing to the accumulation of acetic acid in the latter during the enzymatic hydrolysis of acetylcholine in an unbuffered or weakly buffered medium has been proposed[16]. The author[16] used this method to investigate the cholinesterase activity of erythrocytes and plasma. It has been called the "ΔpH" method.

The exceptional simplicity of the "ΔpH" method and its high sensitivity attracted the attention of many investigators, who modified it by introducing a number of improvements[4,17-35]. The "ΔpH" method has been applied in clinical studies on cholinesterases[16,20-22,24,25,28], in toxicology[18,19,23,26], in pharmacology[26], in the study of inhibitors and insecticides[17,18,23], and in analytical chemistry for rapid mass analyses[5,36] (up to 50 analyses per hour). It is noteworthy that the cholinesterase enzyme electrodes available at present[5,37-40], which have been described above, are also based on the "ΔpH" method.

However, together with many useful qualities, the "ΔpH" method also suffers from a series of disadvantages. Firstly, the method requires additional calibration in order to obtain the absolute activities of cholinesterases[31-34]. Secondly, the sensitivity of the method depends markedly on the buffer capacity of the system, so that it can be used only for unbuffered and weakly buffered media. Thirdly, considerable errors are associated with the influence of atmospheric CO_2, which necessitates an effective protection from CO_2.

Some of these disadvantages can be avoided in the method of potentiometric titration at constant pH, where the acid accumulated during hydrolysis is titrated with alkali[14,15,41-49]. The titration can be carried out automatically[50-52].

In Yakovlev's modification[49] involving the use of a capillary burette the potentiometric titration method proved to be very convenient for kinetic research; it is difficult to point to a field of study of cholinesterases where it has not been used. Grigor'eva[53] proposed yet another improvement to the method—additional titration with the substrate simultaneously with the titration of the liberated acid with alkali, which made it possible to carry out studies at very low constant substrate concentrations (1×10^{-5} M). Such low substrate concentration can be used only in the substrate electrode method.

The potentiometric titration method has become a kind of standard for tests on other new methods for the investigation of the activity of cholinesterases. However, one should note the limitations of this method: its application is interfered with by atmospheric CO_2 and a high buffer capacity of the medium; comparatively large volumes of solutions of the reactants are required, since a decrease in the volume of the reaction medium entails an appreciable decrease in the accuracy of the method.

IV. OTHER ION-SELECTIVE ELECTRODES

As already mentioned, the hydrogen ion is the first product of cholinesterase hydrolysis which became the object of ionometric measurements. At the present time ionometry has advanced so much both qualitatively and quantitatively that it has become possible to use also other ions produced by the enzymatic hydrolysis in the study of cholinesterases. Ion-selective electrodes based on perfluoroacyl groups, sensitive to acetate, propionate, and butyrate ions, have been developed in the Ionometric Laboratory of Leningrad State University[54] and have been used to determine the activities of cholinesterases in the Laboratory of the Chemistry of Biologically Active Substances of the Institute of Evolutionary Physiology and Biochemistry. Experiments showed that the activity of cholinesterases can be determined in this way; however, the electrodes investigated proved to be insufficiently selective with respect to carboxylate anions in the presence of chloride and bromide anions in 100–1000-fold excess compared with the pyranil determined. The interfering ions cannot be eliminated or their elimination is fairly difficult. The successful application of this method therefore requires other anion-sensitive ion-selective electrodes with a high selectivity with respect to the test anion in the presence of Br^- and Cl^-.

The activity of cholinesterases can be studied in relation to another hydrolysis product—the alcohol, for example, choline, which contains a quaternary nitrogen cationic group. The choline electrode exists, but so far there has been no information about its applications in the analysis of cholinesterase hydrolysis.

Thiocholine has been more convenient for the application of ionometry. The point is that, owing to its SH group, thiocholine is a comparatively powerful reductant, being oxidised by many oxidants, including atmospheric oxygen, to the disulphide (the oxidation-reduction potential of this system is approximately 300 mV), which permits the use of oxidation-reduction electrodes for the determination of thiocholine. Apart from potentiometric methods amperometric and polarographic methods have been used for the determination of thiocholine[3,56]. This review deals only with potentiometric methods.

In 1962 Guilbault et al.[57] used platinum electrodes to determine the activity of cholinesterases with respect to thiol ethers on the basis of the amount of thiocholine. Two platinum electrodes and a reference electrode (a silver|silver chloride electrode) were placed in a buffer solution of the enzyme to which a solution of potassium iodide was added. A small constant current (5–25 μA) was passed through the solution; free iodine was then evolved at the anode in a small and constant amount. The platinum anode and the reference electrode were connected to a potentiometer. When a current was passed, a constant potential difference (approximately 400 mV) arose at the anode. After the addition of the thiocholine ether as the substrate to the reaction mixture, enzymatic hydrolysis began, which resulted in the appearance in the system of thiocholine, a more active reductant than I^-, which caused the depolarisation of the electrode and reduced the potential difference. The rate of decrease of potential in the same range, for example, between 300 and 100 mV, then proved to be directly proportional to the activity of cholinesterase and the final potential depended on the concentration of the thiocholine ether[4,58]. The method is satisfactorily sensitive and highly accurate (to within approximately 1.5%); it is possible to automate the analysis[59]. The inventors of the method have used it successfully to analyse organophosphorus compounds and carbamates[60]. It is noteworthy that the involvement of

platinum electrodes made it necessary to use the method with caution in the study of media with a large amount of protein, since platinum can be "poisoned" under these conditions.

In order to determine the amount of thiol obtained in the hydrolysis of thiocholine esters, an HS-sensitive ion-selective electrode with a polycrystalline membrane based on Ag_2S has also been used[5,61,62]. The method exhibits a high sensitivity combined with an adequate accuracy. However, the readings of the HS^- electrode are unstable in time, probably owing to the erosion of the surface, which appreciably restricts its use for the determination of the activity of cholinesterases[5]. More reliable results are obtained by potentiometric titration with a silver electrode[63].

V. ENZYME ELECTRODES USING CHOLINESTERASES

In the application of cholinesterases for analytical purposes, the device developed in Ref.64, which combines the immobilised enzyme with the corresponding ion-selective electrode, is convenient; it has been called the enzyme electrode. Enzyme electrodes exhibit a high selectivity and permit the analysis not only of ions, but also of non-ionic organic substances[65].

In Guilbault's review[5], devoted to the use of enzyme electrodes in analytical chemistry, a cholinesterase enzyme electrode is described, where cholinesterase solutions are immobilised on the surface of a glass pH electrode with a thin membrane†. Apart from the CE solution, Crochet and Montalvo[37] immobilised in this way a substrate solution, which enabled them not only to determine the concentration of inhibitors in the reaction medium, but also to estimate the activity of CE in biological samples. However, the method has not been used widely in practical applications owing to the technical difficulty of the preparation of the electrode and its short lifetime, which is largely due to the method of immobilisation of the enzyme.

The method of covalent binding of the enzyme to an inert protein has a considerable advantage in this respect. This method of immobilisation has been developed for acetylcholinesterase by a group of French investigators[66], which enabled them to prepare an acetylcholinesterase electrode[38,39] for the determination of the concentrations of acetylcholine and cholinesterase inhibitors—proserine and eserine. After 2 months, the activity of the immobilised enzyme decreased by 90%, while the sensitivity of the electrode to acetylcholine was 1×10^{-4} M. The dependence of the electrode potential on the logarithm of the acetylcholine (AC) concentration in the range 10^{-4}–10^{-2} M at pH 8.5 remained linear ($\Delta E/\lg [AX] \cong 35$ mV). With increase of acetylcholine concentration above 10^{-2} M, the electrode potential remained almost unchanged. Thus the acetylcholinesterase enzyme electrode for the measurement of the acetylcholine concentration is very inferior to the substrate electrode described above. However, in the measurement of the concentrations of certain ACE inhibitors, for example nicotine and particularly proserine (neostigmine) and eserine (physostigmine), the enzyme electrode proved to be extremely sensitive. Thus a linear dependence of this potential on the logarithm of the inhibitor concentration was observed up to 5×10^{-8} M in eserine solutions and up to 5×10^{-7} M in proserine solutions, which makes it possible to regard the enzyme electrode method as extremely promising for analysis.

VI. CONCLUSION

Comparison of the possibilities of a wide variety of methods—"ΔpH", potentiometric titration with a pH electrode, the substrate electrode, and Guilbault's oxidation-reduction method for thiocholine esters (see Table)—shows that, despite the large number of methods (including their modifications), none is universal. In each specific study it is

Brief characteristics of the principal potentiometric methods for the determination of the activity of cholinesterases (under optimum conditions).

Method	Ion-selective electrode	Ion being determined	Sensitivity of method			Accuracy of method	Limitations of method
			w.r.t. enzyme activity, mg^{-1}	w.r.t. substrate concn., M	w.r.t. concn. of hydrolysis product		
"ΔpH"	pH electrode (glass)	hydrogen ion	0.02	$(1-2) \times 10^{-4}$	1×10^{-5}	~10%	unbuffered and weakly buffered media; the presence of CO_2 interferes; special calibration is required
Potentiometric titration with alkali at constant pH	pH electrode (glass)	hydrogen ion	0.01–0.02	1×10^{-5}	1×10^{-5}	~4%	weakly buffered medium; the presence of CO_2 interferes; a large volume of reaction mixture (~10 ml) is required
Substrate electrode method	membrane ion-selective electrode sensitive to choline esters	organic cations: AC, PrC, BuC, and other choline esters	0.01–0.02	1×10^{-5}	—	~8%	high substrate concentrations ($> 10^{-3}$ M) cannot be used; the presence of other quaternary hydrogen compounds interferes
Oxidation-reduction potentiometry	oxidation-reduction electrodes	thiocholine ion	0.005	1×10^{-4}	1×10^{-5}	~1.5%	a protein medium interferes; additional apparatus for electrolysis is needed; the method requires calibration; only thiocholine esters can be used

†This electrode was made by Crochet and Montalvo in 1973.[37]

necessary to select carefully a suitable method which nevertheless introduces errors into the results, frequently exceeding the random errors of the measurements.

All this makes it necessary to seek and design new ion-selective electrodes whose application would improve the method for the investigation of cholinesterases. From our point of view, such research should be carried out by designing new, more sensitive "substrate" electrodes, anion-sensitive electrodes with a response to carboxylate ions and a high selectivity in the presence of halide ions, and a choline electrode with a high selectivity in the presence of choline esters.

A second approach involves the creation of new enzyme electrodes based on cholinesterase preparations. For its successful development, it is necessary to manufacture industrially highly active and stabilised cholinesterase preparations and to develop new methods for their immobilisation.

Rhenium Fluorides

E.G.Rakov, A.S.Dudin, and A.A.Opalovskii

The properties of simple and complex fluorides of rhenium have been reviewed, and the most important directions of study in the field of rhenium fluorides have been formulated.
The bibliography contains 152 references.

I. INTRODUCTION

The electronic configuration of the rhenium atom (d^5s^2) and its position in the periodic system make it unusual among transition metals. It can form compounds in which it has oxidation numbers from −1 to +7 (including zero in the carbonyls), many of which are thermally stable. Rhenium compounds have coordination numbers from 4 to 9. Rhenium is the only metal forming a stable heptafluoride. The relative similarity in the affinities of rhenium for oxygen and fluorine leads to the formation of a large number of oxide fluorides and oxofluoro-anions.

The melting point of rhenium (3190°) [1] is exceeded only by those of tungsten (3420°) [1] and carbon, and this opens up extensive possibilities for its practical application. Because of the extremely low concentration of rhenium in ores and concentrates[2,3], a special place in the technology of this metal is occupied by processes for obtaining alloys and coatings; one of the most progressive methods for producing the latter is considered to be the reduction of gaseous fluorides by hydrogen[4-7]. Dozens of papers have been devoted to the development of this method, and their examination represents an independent problem.

Thus rhenium fluorides are of interest from the viewpoints of both chemistry and technology. However, the only review summarising the properties of rhenium fluorides[8] requires supplementing and correcting.

The aim of the present review is to systematise the methods of preparation and properties of rhenium fluorides, and to outline the principal directions of study in this field.

II. SIMPLE RHENIUM FLUORIDES

Rhenium hepta-, hexa-, penta-, and tetrafluorides are known. The highest fluoride, ReF_7, was first obtained from the elements[9,10]. To isolate pure rhenium heptafluoride, the mixture of ReF_6 and ReF_7 formed by fluorinating the metal was heated at 400 °C and a fluorine pressure of ~3 atm. For this purpose, Slivnik and coworkers[11] recommended more rigorous conditions—a fluorine pressure of ~50–60 atm and a temperature of 150–500°. ReF_7 has been successfully synthesised using a solution of KrF_2 in anhydrous HF.[12] Small quantities of the heptafluoride having a low concentration of ReF_6 (~1%) can be obtained by exploding rhenium wire in an atmosphere of fluorinating reagents[13].

The physical properties of the heptafluoride are similar to those of ReF_6 and other metal hexafluorides (Table 1).[14] The high-temperature modification of ReF_7 is cubic, with lattice parameters 6.26 Å at 25° and 6.14 Å at −90°.[14,17] There is no published information on the low-temperature modification. The vapour pressure of ReF_7 is given by the equations[10,14]:

$$\lg p, [\text{atm}] = 10.1624 - 1.4703 \lg T - 2205.8/T \quad (258.68 \leqslant T \leqslant 321.45\ \text{K})$$
$$\lg p, [\text{atm}] = -24.4643 + 9.90825 \lg T - 244.28/T \quad (321.45 \leqslant T \leqslant 347.76\ \text{K}).$$

Table 1. Physical properties of ReF_7 and ReF_6.[10,14]

Parameter	Value	
	ReF_7	ReF_6
Melting point, °C	48.3±0.1	18.5±0.1
Boiling point, °C	73.7±0.2	33.7±0.1
Temperature of phase transformation, °C	−110	−3.45±0.10
Heat of formation in the gaseous state at 298.2 K, kcal mole^{-1}	−337±3[16]	−324±3[16]
Heat of the phase transformation, kcal mole^{-1}	—	2.02±0.01
Heat of fusion, kcal mole^{-1}	1.3±0.2	1.09±0.01
Heat of volatilisation, kcal mole^{-1}	7.6±0.2	6.76±0.05
Heat capacity of the gas at 298.2 K, cal mole^{-1} K^{-1}	31.6±0.3	28.6±0.3
Entropy of the gas at 298.2 K, cal mole^{-1} K^{-1}	84.7*	86.9±0.5
Density of the crystal, g cm^{-3}	4.32 (cubic)	4.06 (cubic) 4.68 (orthorh.)
Density of the liquid, g cm^{-3}	3.65 (52° C)	3.58±0.02 (22° C)

*This value is apparently too low.

The vibrational spectra of ReF_7 (Table 2) have been interpreted with the assumption that the molecule has the pentagonal bipyramidal configuration[18]; this has been confirmed by the ^{19}F NMR spectra[19].

Vapour-phase electron diffraction has confirmed that the ReF_7 molecule belongs to the symmetry point group D_{5h},[24] and the average internuclear distance Re–F has been calculated (1.835 Å). It was also shown that this model is not completely adequate, and that the axial distances are greater than the equatorial distances, by 0.062 Å. The ReF_7 molecule has a non-zero dipole moment[25,26], which is not compatible with simple D_{5h} symmetry. Nevertheless, it is usually assumed that the distortions are small, and this

symmetry has been assumed in calculations of the force constants[22,23,27] and thermodynamic properties[14,22,23].

The photoelectron spectra of ReF_7 have been characterised[28,29], and the ionisation potentials determined. The range 14.1–17.0 eV contains bands assumed to be due to a contribution from molecular orbitals of the p_π-type; the most intense band lies at 14.6 eV.

Table 2. Vibrational wavenumbers in the spectra of ReF_7 (cm^{-1}).

—	299	—	—	ν_7
—	217	—	—	ν_6

*Symbols: v.s. = very strong, s. = strong, med. = medium, w. = weak.
The wavenumbers ν_3 and ν_{11} were estimated as 800 cm^{-1} and 241 cm^{-1}.[23]

The chemical properties of ReF_7 have been little studied. It is hydrolysed rapidly by water to HF and $HReO_4$. ReF_7 does not react with oxygen up to 500°.[10] In the opinion of some authors[30], the reactivity of ReF_7 in redox reactions is similar to that of ReF_6. Thermodynamic calculations[31] show, however, that ReF_7 is a much stronger oxidising agent than ReF_6. This is confirmed, for example, by the fact that, at the same temperatures, ReF_7 reacts with metallic rhenium, and ReF_6 does not[10].

Attempts to obtain Re^{VII} complexes by bringing ReF_7 into contact with alkali metal fluorides under pressure were unsuccessful[10], but ReF_7 reacts with nitryl and nitrosyl fluorides to form $NOReF_8$ and NO_2ReF_8.[32] The compounds $[ReF_6]^+[SbF_6]^-$ and $[ReF_6]^+[Sb_2F_{11}]^-$ have been isolated by heating ReF_7 with antimony pentafluoride[33]. The force constants of the bond in the $[ReF_6]^+$ cation were found to be much greater than those for ReF_6 and WF_6, indicating the high electronegativity of Re^{VII}.

The solubility of ReF_7 in anhydrous HF at 25° is 0.26 mole in 1000 g HF.[21] The solutions are weakly ionised.

Rhenium hexafluoride has been much more fully characterised. It was first obtained from the elements at 120 to 125°.[34–36] It is usually formed in a mixture with ReF_7,[9] and can be purified by reducing the latter by metallic rhenium at 400°,[10] or by distilling in a stream of dry hydrogen.[37] ReF_6 can also be obtained by treating the metal with ClF_3 [38] or O_2F_2.[39]

The kinetics of the reaction of rhenium and a W–Re alloy with fluorine have been studied[40,41]. An interesting feature is that the fluorination of the metal has a much lower activation energy than the fluorination of transition metal oxides, the activation energy of which is close to 25 kcal $mole^{-1}$.[42] The thermodynamic parameters of the fluorination (from out-of-date original data) have been published[43].

The chief physical properties of ReF_6 are given in Table 1. The low-temperature orthorhombic modification of ReF_6 (VF_3 structure, space group *Pnma*) at −22° has the following lattice parameters: $a = 9.61$; $b = 8.76$; $c = 5.06$ Å; $Z = 4$. The low-temperature modification is isostructural with the cubic phase MoF_6 ($Z = 2$), and at 10 °C has lattice parameters 6.26 ± 0.02 Å.[17] The cubic crystals are glassy. The magnetic moment of ReF_6 is only 0.25 B.M. [8]

The vapour pressure of ReF_6 is given by the equations[10,14]:

$$\lg p, \text{ [atm]} = 9.8264 - 2303.6/T - 0.8327 \lg T \ (262.68 \leqslant T \leqslant 269.70 \text{ K})$$

$$\lg p, \text{ [atm]} = 6.2421 - 1765.4/T - 0.1790 \lg T \ (269.7 \leqslant T \leqslant 291.65 \text{ K})$$

$$\lg p, \text{ [atm]} = 16.3273 - 1956.7/T - 3.599 \lg T \ (291.65 \leqslant T \leqslant 321.21 \text{ K}).$$

These results[10,14] agree with earlier measurements[44]. The wavenumbers in the vibrational spectrum of ReF_6 are given in Table 3. All authors agree that ReF_6 has a regular octahedral configuration. The anomalies in the wavenumbers are attributed to the Jahn–Teller effect[50–52]. Electron diffraction measurements[53] show that the interatomic distances in the octahedron are 1.832 ± 0.004 Å. The force constants of ReF_6 have been published[54].

Table 3. Vibrational frequencies in the spectra of ReF_6 (cm^{-1}).

Infrared (gas) (Refs. 45–48)	Raman (gas) (Refs. 46–48)	Raman (soln. in HF) (Ref. 49)	Assignment	Infrared (gas) (Refs. 45–48)	Raman (gas) (Refs. 46–48)	Raman (soln. in HF) (Ref. 49)	Assignment

715	715	—	ν_3	246	246	249	ν_5
596	596	578	ν_2	193	193	—	ν_6

The electronic structure of ReF_6 has been described[28,29,55–59]. The photoelectron spectra have been recorded[28,29], and the ionisation potentials of WF_6 and ReF_6 correlated; the bands in the range 15.1–17.2 eV correspond to p_π-orbitals, those in the range 18.0–20.1 eV to p_σ-orbitals, and the band having a maximum at 11.43 eV is due to the additional electron of ReF_6, situated in a $2t_{2g}$-orbital.

The chemical properties of ReF_6 resemble those of other metal hexafluorides[60,61]. It is hydrolysed extremely readily, and on contact with atmospheric moisture it disproportionates to give flocculent black rhenium dioxide[62]. Traces of moisture convert ReF_6 into $ReOF_4$.[63] Hydrolysis by water is sometimes accompanied by the formation of an unstable green solution, which rapidly becomes dark and non-transparent. The green colour of the solution has been attributed to the formation of the unstable anion $ReOF_5^-$.[64]

ReF_6 is coordinatively unsaturated, and forms complexes with alkali metal fluorides[65]; it gives ionic compounds with NOF and NO_2F.[66] In the hexafluoride series, ReF_6 is intermediate between the most reactive PtF_6 and the kinetically most stable SF_6; its properties are similar to those of MoF_6.[30,61]. Like MoF_6 [67,68] and WF_6,[4,69] ReF_6 is reduced to the metal by hydrogen[4,7]. At 200°, the reaction stops when ReF_4 is formed[70,71], but at 250° in a large excess of hydrogen it gives up to 75% yield of the metal[7].

The Gibbs free energies for the reduction of ReF_6 by hydrogen and for the simultaneous reduction of ReF_6 and the higher fluorides of a series of elements of groups III–VI have been calculated[31]. The simultaneous reduction of ReF_6 with

BF_3, NbF_5, MoF_6, and WF_6 by hydrogen is probable at room temperature, and that with SiF_4, TiF_4, and TaF_5 at a temperature above 500–650 K. SO_2 reduces ReF_6; at 400° it converts ReF_6 into ReF_4.[71] Thermodynamic calculations show that many elements can reduce ReF_6 to the metal; the strongest reducing agents include Zr, Ti, and Si.[31]

ReF_6 reacts with the carbonyls of rhenium, tungsten, and molybdenum to give $ReOF_4$, and also ReF_5 in an excess of tungsten carbonyl[72]. A detailed study of the reaction of ReF_6 with $Re_2(CO)_{10}$ in liquid HF made it possible to identify two compounds, for which X-ray diffraction indicated the formulae $Re(CO)_5F.ReF_5$ and $[Re(CO)_6]^+[Re_2F_{11}]^-$.[73] The fluorination of a solution of $Re_2(CO)_{10}$ in 1,1,2-trichlorofluoroethane by xenon difluoride also gives the first of these salts[74].

In HF solution, rhenium hexafluoride is reduced by $N_2H_6F_2$ to $N_2H_6ReF_6$ and $N_2H_6(ReF_6)_2$,[75] and in solution in SO_2 and IF_5 it is reduced by alkali metal iodides to M_2ReF_6 and $MReF_6$ respectively (M = Na, K, Rb, Cs).[76,77] ReF_6 is also reduced by NO ($NOReF_6$ is formed),[66] BCl_3 ($ReCl_5$ is formed),[16] etc.[30] In IF_5 solution, elemental iodine is oxidised to I_2^+ by rhenium hexafluoride.

ReF_6 is readily soluble in anhydrous HF (1.75 mole in 1000 g HF).[49] The molar conductance of this solution is 0.70 Ω·cm·mole, and the degree of ionisation of ReF_6 in solution is ~0.2%.

Rhenium pentafluoride can be obtained together with ReF_4 and $ReOF_4$ by the reaction of tungsten carbonyl with an excess of ReF_6.[72] ReF_5 is also obtained by reducing ReF_6 by hydrogen, silicon[78], metallic tungsten or rhenium[79,80], and PF_3.[30]

Various physical properties of ReF_5 are given in Table 4. ReF_5 crystallises in the orthohombic system, with lattice parameters: $a = 5.70$; $b = 17.23$; $c = 7.67$ Å.[81]

Table 4. Physical properties of ReF_5.[14,72]

Parameter	Value
Melting point, °C	48.0
Boiling point, °C	221.3*
Heat of volatilisation, kcal mole^{-1}	12.0 (221.3 °C)
Heat capacity of the gas at 298.2 K, cal mole^{-1} K^{-1}	25
Entropy of the gas at 298.2 K, cal mole^{-1} K^{-1}	80.7
Entropy of volatilisation, cal mole^{-1} K^{-1}	24.2 (221.3 °C)
Curie–Weiss temperature, K	580

*The boiling point was determined by extrapolation, since above 180 °C ReF_5 disproportionates irreversibly to ReF_4 and ReF_6.[72]

The vapour pressure of ReF_5 is given by the equation[44]:

$$\lg p, [\text{atm}] = 9.024 - 3037/T \quad (321.15 \leqslant T \leqslant 413.15\ \text{K}) .$$

The vibrational wavenumbers of the two possible structural forms of ReF_5, and the thermodynamic properties in the temperature range 298–3200 K, have been calculated[82]. Reference works[14,83] give estimated values of S^0_{298} and C^0_p (298.2) for gaseous ReF_5 (cal mole^{-1} K^{-1}): 81 and 25, and 84.1 and 28.55 [83] respectively.

The mass spectrum of ReF_5 [84–86] has shown that it is associated in the gaseous phase, and exists as dimers and trimers at temperatures close to room temperature.

The chemical properties of ReF_5 have been little studied. It reacts with CCl_4 [72] and is hydrolysed instantly by water to give $ReO_2.2H_2O$ and the ions F^-, ReO_4^-, and ReF_6^{2-}.[8] Like ReF_6, ReF_5 is coordinatively unsaturated, but only a few fluoro-complexes of Re^V are known[8].

Rhenium tetrafluoride is obtained by reducing ReF_6 by metallic rhenium, hydrogen, or SO_2, or by the disproportionation of ReF_5.[72,79] Crystalline ReF_4 sublimes above 300°.[72]

The X-ray diffraction pattern of ReF_4 has been indexed[8] on the basis of a tetragonal cell having the parameters $a = 10.12$ Å and $c = 15.95$ Å.

Estimated values of the thermodynamic functions of gaseous ReF_4 have been published[14,82].

Rhenium tetrafluoride is readily hydrolysed by water according to the equation[8]:

$$ReF_4 + 4\,H_2O \rightarrow ReO_2 \cdot 2H_2O + 4H^+ + 4F^- .$$

The existence of fluorides of rhenium having an oxidation number less than +4 has been doubted by many workers, but Malm and Selig[10] have reported the preparation of the fluoride $ReF_{3.5}$. Other authors[13] considered that they isolated $ReF_{2.99 \pm 0.17}$ and $ReF_{2.05 \pm 0.16}$ by exploding rhenium wire in at atmosphere of SF_6 and PF_5. There are apparently no grounds for regarding these products as individual compounds.

III. RHENIUM OXIDE FLUORIDES

Possible simple oxide fluorides of rhenium(V–VII) are given in Table 5. ReO_3F, ReO_2F_3, $ReOF_5$, and $ReOF_4$ have been most reliably characterised[8]. $ReOF_3$ has also been isolated and described[72].

Table 5. Rhenium oxide fluorides.

Oxidation state of rhenium		
V	VI	VII
$ReOF_3$ (ReO_2F)	$ReOF_4$ (ReO_2F_2)	$ReOF_5$ ReO_2F_3 ReO_3F

Rhenium trioxide fluoride was first obtained by the reaction of ReO_3Cl with anhydrous HF.[87] It can also be synthesised by the reaction of $KReO_4$ with IF_5,[88] of Re_2O_7 with ReF_7,[89] and of Re_2O_7 or $KReO_4$ with an excess of anhydrous HF.[90] ReO_3F melts at 147° and boils at 164° with slight decomposition[87]. At the same time, it has been reported[89] that ReO_3F has the highest thermal stability among rhenium oxide fluorides.

The microwave spectrum of gaseous ReO_3F showed that the bond lengths are Re–O 1.692 Å and Re–F 1.859 Å, and the angle F–Re–O is 109.5°.[91] The calculated dipole moment is 0.85.

The infrared and electronic spectra of gaseous ReO_3F [92] and the Raman and NMR spectra of its solutions in anhydrous HF [90] show that the ReO_3F molecule belongs to the symmetry group C_{3v}. Thus the infrared and Raman spectra show all six vibrational wavenumbers expected for this structure[93,94]; the force constants of the ReO_3F molecule isolated in an argon matrix have been calculated. The photoelectron spectra of

gaseous ReO_3F have been recorded[28,29], and the ionisation potentials determined; the first ionisation potential is 12.37 eV. The calculated thermodynamic functions of gaseous rhenium trioxide fluoride have been published[14,95].

All that is known of the chemical properties of ReO_3F is that it is readily hydrolysed in a moist atmosphere to give HF and $HReO_4$.

Rhenium dioxide trifluoride ReO_2F_3 has been obtained (with small quantities of $ReOF_5$) by fluorinating rhenium oxides or $KReO_4$ in flow[96] and static[89] systems. It is also obtained by the action of a mixture of O_2 and F_2 on metallic rhenium[44]. Pure ReO_2F_3 can be isolated by the reaction of a mixture of Re_2O_7 and KBr (1:1) with bromine trifluoride[94]. Various physical properties of ReO_2F_3 are given in Table 6.

Table 6. Physical properties of ReO_2F_3.[8]

Parameter	Value
Melting point, °C	90
Boiling point, °C	185.4
Heat of volatilisation, kcal mole^{-1}	15.7
Entropy of volatilisation, cal mole^{-1} K^{-1}	34.3

The vapour pressure of ReO_2F_3 is given by the equation[14,44]

$$\lg p,[\text{atm}]=7.48-3437/T \quad (363\leqslant T\leqslant 443\ \text{K}) .$$

Falconer and coworkers[97] found that the ReO_2F_3 molecule is non-polar and apparently belongs to the symmetry point group D_{3h}, with the oxygen atoms in the *trans*-position. Later studies[94] showed that in the gaseous phase, ReO_2F_3 is chiefly monomeric and has a trigonal bipyramidal structure, but with the oxygen atoms in the *cis*-position (symmetry C_{2v}). A study of the dimer $(ReO_2F_3)_2$ in the gaseous phase[26] established the relatively high stability of the system, formed by two oxygen bridges. The high viscosity of ReO_2F_3 indicates association in the liquid phase[8].

The chemical properties of rhenium dioxide trifluoride have been little studied. It is stable in the glass up to the boiling point. Like other Re^{VII} oxide fluorides, it is rapidly hydrolysed to HF and $HReO_4$.

Rhenium oxide pentafluoride $ReOF_5$ is formed by the same reactions as ReO_2F_3, but is obtained in smaller yields[96]. The difference in the volatilities of ReO_2F_3 and $ReOF_5$ makes it possible to separate these substances easily by sublimation. The physical properties of $ReOF_5$ resemble those of ReF_6 and ReF_7 (Table 7).[8,14,44]

The vapour pressure is given by the equations[14,44]:

$$\lg p,[\text{atm}]=6.700-2250/T \quad (273\leqslant T\leqslant 303\ \text{K})$$
$$\lg p,[\text{atm}]=5.739-1958.9/T \quad (303\leqslant T\leqslant 314\ \text{K})$$
$$\lg p,[\text{atm}]=4.846-1678.6/T \quad (314\leqslant T\leqslant 346\ \text{K}) .$$

Analysis of the NMR,[19] infrared, and Raman spectra[98,99] indicates that the $ReOF_5$ molecule belongs to the symmetry group C_{4v}. Thus for gaseous $ReOF_5$, all eleven wavenumbers required for this configuration were detected: 989.8, 738.6, 643, 309, 652, 234, 334, 713, 260, 365, and 125 cm^{-1}.

The calculated thermodynamic functions of gaseous $ReOF_5$ have been published[14]; these have been used[31] to calculate the parameters of the reduction of $ReOF_5$ by hydrogen, and it was shown that it is possible to obtain the metal at room temperature. The first ionisation potential of gaseous $ReOF_5$, determined from the photoelectronic spectrum, is 13.53 eV.[28,29]

Table 7. Physical properties of $ReOF_5$ and $ReOF_4$.[8,14]

Parameter	Value	
	$ReOF_5$	$ReOF_4$
Melting point, °C	40.8	108
Boiling point, °C	73.0	171
Temperature of phase transformation, °C	30	—
Heat of formation in the crystalline state at 298.2 K, kcal mole^{-1}	−294*	—
Heat of the phase transformation, kcal mole^{-1}	1.339	—
Heat of fusion, kcal mole^{-1}	1.220	—
Heat of volatilisation, kcal mole^{-1}	7.720	14.59
Heat of sublimation, kcal mole^{-1}	10.280**	17.82
Heat capacity of the gas at 298.2 K, cal mole^{-1} K^{-1}	28.0	21.7

*From published data[100].
**Value at temperatures below 30 °C; above 30 °C, the heat of sublimation is 8.940 kcal mole^{-1}.

The chemical properties of $ReOF_5$ resemble those of ReF_6;[101] at the same time, it is more readily reduced to rhenium(VI) by organic compounds, compared with ReO_2F_3, and on hydrolysis it gives HF and $HReO_4$. The reaction of $ReOF_5$ with NOF and NO_2F gives the ionic salts $NOReOF_6$ and NO_2ReOF_6.[32]

Rhenium oxide tetrafluoride can be obtained by the reactions of $W(CO)_6$ with ReF_6,[72] of ReF_6 with SiO_2,[102] of ReF_6 with ReO_3,[29] of ReF_6 with aqueous HF solution[89,102], and also by fluorinating metallic rhenium or ReO_3 at fluorine : oxygen ratios of 4:1 and 2:1 respectively[89]. Various physical properties of $ReOF_4$ are given in Table 7.

$ReOF_4$ crystals have a monoclinic lattice, space group $C2/c$.[103,104] The values of a, b, and c are 19.01, 5.57, and 14.72 Å; $\beta = 114°$, $Z = 16$; the bond lengths are Re–O 1.65 Å, Re–F(terminal) 1.86 Å, and Re–F(bridging) 1.99 Å and 2.30 Å. The calculated density is 5.28 g cm^{-3}. The magnetic moment of $ReOF_4$ agrees with that expected for Re^{VI}.[8]

The vapour pressure of $ReOF_4$ is given by the equations[44]:

$$\lg p_i[\text{atm}]=8.92-3888/T \quad (323\leqslant T\leqslant 380\ \text{K})$$
$$\lg p_i[\text{atm}]=7.21-3206/T \quad (381\leqslant T\leqslant 445\ \text{K}) .$$

The structural and spectroscopic characteristics of gaseous $ReOF_4$ have been estimated[105]; it has been assigned to the symmetry group C_{2v}, and the thermodynamic functions at 298–2000 K have been calculated on this basis[106]. Later studies[107,108] of the infrared spectra of $ReOF_4$ isolated in an argon matrix indicate that the rhenium oxide tetrafluoride molecule has C_{4v} symmetry. The corrected thermodynamic functions of $ReOF_4$ have been published[95].

Mass-spectrometric studies[89,102] showed that $ReOF_4$ is monomeric in the gaseous phase. The ionisation potentials of gaseous $ReOF_4$ have been published[29]; the first ionisation potential is 10.98 eV. Like $ReOF_5$, $ReOF_4$ can be reduced by hydrogen to the metal[31].

The chemical properties of $ReOF_4$ have been little studied. It reacts vigorously with water to give HF, $ReO_2.2H_2O$, and $HReO_4$; it reacts with CCl_4 to give $ReCl_5$.[72] In HF solution, rhenium oxide tetrafluoride is weakly ionised according to the scheme[102]:

$$ReOF_4 + 2HF \rightleftarrows H_2F^+ + ReOF_5^- .$$

At 250°, $ReOF_4$ vapour reacts slowly with Pyrex, forming black non-volatile $ReOF_3$.[72]

Rhenium oxide trifluoride is extremely hygroscopic; it crystallises in the tetragonal system with unit cell parameters $a = 8.54$ Å and $b = 8.21$ Å.[72] $ReOF_3$ dissolves in water to give a pale-blue solution. The mechanism of the process has not been established.

No reports of the existence of other oxide fluorides have been published, particularly containing rhenium having an oxidation number below +5. This is probably due to the fact that this class of compound has been little studied. At the same time it has been reported[89] that the non-volatile residues formed by the reactions of ReO_2F_3 with Si and of $ReOF_4$ with Si consist of mixtures of lower oxide fluorides of rhenium, which when heated to 500° disproportionate to give ReO_3F, which is more stable at this temperature.

IV. COMPLEX FLUORIDES AND OXIDE FLUORIDES OF RHENIUM

Fluoro-complexes of rhenium are known only for rhenium having oxidation numbers from +4 to +7. The properties of the Re^{IV} salts have been most fully studied, firstly because of their stability and relative ease of handling, and secondly because of the interest in the electronic configuration of the rhenium ion in a d^3-octahedral environment. Complex oxide fluorides are known only for rhenium(V–VII).

Hexafluororhenates(IV) can be obtained either by reducing ReF_6 by alkali metal iodides in liquid SO_2 [109] or by ion exchange from K_2ReF_6, which is formed by the hydrofluorination of hexachloro-, hexabromo-, or hexa-iodorhenates(V),[63,110] and also by treating molten KHF_2 with a $KReO_4 + KI$ mixture or K_2ReBr_6.[79]

The fluororhenates of Na^+, NH_4^+, K^+, Rb^+, and Cs^+ have the K_2GeF_6 structure; the Re–F distance in the almost regular octahedron is ~2 Å.[111,112] The magnetic moment of the crystalline salts (3.3 B.M. at 300 K) and the aqueous solutions (3.47 B.M.) is lower than the spin-only value for a regular d^3-octahedron[113].

The vibrational spectra of a number of salts show that the ReF_6^{2-} ion has D_{4h} symmetry (the force constants and mean amplitudes of the vibrations of the Re–F bond have been published[114,117]). The electronic, infrared, and Raman spectra of a single crystal of Cs_2ReF_6 [118,119] confirmed these conclusions. The ionic character and energy of the Re–X bond in ReX_6^{2-} anions (X = F, Cl, Br, I) decrease from fluorine to iodine[120,121].

Hexafluororhenates(IV) are stable to hydrolysis, and can be recrystallised from aqueous solutions. The solubility decreases from the Na^+ to the Cs^+ salts. The enthalpy of solutions of crystalline K_2ReF_6 in water, determined calorimetrically, is 15.05 kcal mole^{-1}; the calculated enthalpy of hydration of the gaseous ReF_6^{2-} anion is 239 kcal mole^{-1}.[122] Alkalies slowly decompose the ion ReF_6^{2-}, giving ReO_2; decomposition is complete in molten alkali[63]. The thermal decomposition of $(NH_4)_2ReF_6$ in air is accompanied by hydrolysis and oxidation. One of the decomposition products is NH_4ReO_4,[123] taken as ReNF by other workers[79].

Hexafluororhenates(V) are formed by reducing ReF_6 by alkali metal iodides in SO_2 or IF_5 solution[76,109]; $NOReF_6$ is obtained by bringing ReF_6 into contact with nitric oxide[66]. The reaction of Cd, Cu, and Tl with a solution of ReF_6 in acetonitrile gives the solvates $Cd(ReF_6)_2.5CH_3CN$, $CuReF_6.4CH_3CN$, and $TlReF_6.2CH_3CN$.[124] The structure of salts of the ReF_6^- anion is similar to that of the compounds MoF_6^- and WF_6^-.[125]

The anomalies in the temperature dependence of the magnetic properties of the number of hexafluororhenates(V) were attributed to antiferromagnetic interaction[76]. The infrared, Raman, and electronic spectra of the salts $M^+ReF_6^-$ indicate that the ReF_6^- anion belongs to the symmetry group O_h; the force constants of the Re–F bond have been calculated[109,126,127].

Salts of the type $M^+ReF_6^-$ react vigorously with water to give hydrated rhenium dioxide, F^-, ReO_4^-, and ReF_8^{2-};[76] like salts of the type $M_2^+ReF_8^{2-}$, however, decomposition is complete only when fused with alkali.

Fluororhenates(VI) are obtained by the reaction of ReF_6 with alkali metal fluorides. Depending on the conditions, the reactions give salts of the type $M^+ReF_7^-$ or $M_2^+ReF_8^{2-}$,[65] which differ sharply in colour, crystal form, and other properties. The salt K_2ReF_8 crystallises in the orthorhombic system, space group *Pnma*, lattice parameters $a = 8.70 \pm 0.02$ Å, $b = 5.91 \pm 0.02$ Å, $c = 12.53 \pm 0.03$ Å, pyknometric density 4.33 ± 0.03 g cm^{-3}.[128] The basic structural unit of K_2ReF_8 is the $[ReF_8]^{2-}$ anion, having the form of a twisted cube with angle of rotation 45°.[129] The Re–F distance is 1.90 ± 0.03 Å. The magnetic moment of the K^+, Rb^+, and Cl^+ salts lies in the range 1.6–1.7 B.M., and differs considerably from the low moment of ReF_6.[65] The alkali metal octafluororhenates are thermally stable[130].

The action of ReF_6 on M_2ReF_8 gives yellow salts having the composition $MReF_7$ ($M = K^+$, Rb^+, Cs^+).[65] The thermal stability of the hexafluororhenates decreases in the order $Cs^+ > Rb^+ > K^+$. Magnetic measurements[65] showed that these salts are weakly paramagnetic (0.6–0.7 B.M.).

The vibrational spectra of hepta- and octafluoro-complexes of rhenium(VI) [131] show that the MF_8^{n-} ion is a square antiprism, whereas the spectra of $RbReF_7$ and $CsReF_7$ are similar to the spectra of ReF_7 and IF_7, and the ReF_7^- anion can be assigned D_{5h} symmetry.

Hepta- and octafluororhenates(VI) are hydrolysed, with the intermediate formation of $MReOF_5$.[132] The stability to hydrolysis decreases in the order $Na^+ > K^+ > Rb^+ > Cs^+$. K_2ReF_8 dissolves in anhydrous HF with decomposition according to the equation[133]:

$$K_2ReF_8 + n\,HF \rightarrow ReF_6 + 2KF \cdot n\,HF .$$

When this solution is evaporated in a stream of dry nitrogen, ReF_6 volatilises, with the partial entrainment of HF.

As already noted, ReF_7 reacts with nitrosyl and nitryl fluorides to give the adducts $NOReF_8$ and NO_2ReF_8. The Raman spectra of the solid salts and the ^{19}F NMR spectra of their solutions in anhydrous HF show that these complexes are ionic, and that the ReF_8^- anion has D_{4d} symmetry[32].

The complex oxide fluoride of Re^V, $NH_4ReO_{1.5}F_3.H_2O$, has been obtained by the reaction of NH_4ReO_4, NH_4HF_2, and Re at 400 °C and high pressure[134]. The product crystallises in the cubic system (space group *Fm*3*m*) with parameter $a = 16.563$ Å. The calculated density (for $Z = 32$) is 3.55 g cm^{-3}, and the measured density 3.57 g cm^{-3}. The magnetic properties showed the presence of unpaired electrons, possibly due to the existence of isolated $Re_8O_{12}F_{24}$ molecules, joined by NH_4^+ bridges.

Complex oxide fluorides of Re^{VI} can be isolated by the careful hydrolysis of complex fluorides of Re^{VI}.[109,130] The hydrolysis products—salts of the type $M^+ReOF_5^-$—are soluble in methyl ethyl ketone. The oxidation number of rhenium in the caesium salt is +6, and the magnetic moment 1.40 B.M. [132] The vibrational spectra of a series of salts containing the $ReOF_5^-$ anion showed that it has C_{4v} symmetry; the force constants were also calculated[109].

Complex oxide fluorides of Re^{VII}, which can be regarded as derivatives of ReO_3F, ReO_2F_3, and $ReOF_5$, are also known. The first of these ($M_2ReO_3F_3$ and $MReO_2F_4$) are obtained by the action of IF_5 and BrF_3 [135,136] on alkali and alkaline earth metal perrhenates. In addition, ReO_3F complexes of the type $ReO_3F.2DMF$ and $[(CH_3)_4N]ReO_3F_3$ [137] have been isolated, and their infrared spectra studied. The vibrational spectra of $K_2ReO_3F_3$ and $KReO_2F_4$ have been studied[109], and the force constants of both anions have been calculated assuming C_{2v} symmetry.

The only known derivatives of $ReOF_5$ are the ionic complexes $NOReOF_6$ and NO_2ReOF_6, formed by the reaction of $ReOF_5$ with NOF and NO_2F. The $ReOF_6^-$ anion has C_{5v} symmetry[32].

Conductometric titration of $KReO_4$ solutions in hydrofluoric acid[138] showed the formation of the ionic complex $[ReO_4F]^{2-}$. Attempts to isolate the fluoro-complexes of K^+, $Co(NH_3)_6^{3+}$, and $[Co(en)_3]^{3+}$ were unsuccessful. A later study of the ReO_4^-–HF–H_2O system[139] showed the formation of the anionic complexes $[ReO_3(OH)F_2]^{2-}$ at an F^- ion concentration of 0.05–0.26 M, and $[ReO_2(OH)(HF_2^-)_3]^-$ at 0.5–5.3 M, with stability constants $\lg\beta_2 = 4.8 \pm 0.4$ and $\lg\beta_3 = 2.8 \pm 0.4$ respectively.

The synthesis of $H_2[ReOF_5]$ in HF solution has been reported[140]. The electronic spectra of the systems $ReOF_5^{2-}$–H_2SO_4–HF and Re^{VII}–H_2SO_4–HF showed that $[ReOF_5]^-$ ions are formed in solution in the first case, and rhenium(VII) complexes in the second.

V. CONCLUSION

As expected, the physicochemical properties of rhenium fluorides to a large extent resemble those of molybdenum fluorides. The hexafluorides of the two elements show extremely similar chemical and thermodynamic properties[30]. The oxide tetrafluorides have similar melting points and boiling points (108° and 171° for $ReOF_4$, and 97.2° and 186° for $MoOF_4$).[14] The oxide tetrafluorides are polymerised in the crystalline state[104,141] and partly in the vapour. The properties of rhenium dioxide difluoride, which has not yet been obtained, are probably similar to those of molybdenum dioxide difluoride. The pentafluorides also have similar melting points and boiling points (48.0° and 221° for ReF_5, and 67° and 214° for MoF_5),[14] and also tend to polymerise in the liquid and even in the vapour[93].

The extremely limited amount of experimental data for rhenium tetrafluoride and more particularly rhenium trifluoride makes a reliable comparison difficult, but there are grounds for assuming that in this case, analogies with the corresponding molybdenum fluorides will be observed.

Definite similarities are observed in the methods of synthesis and chemical and physicochemical properties of the fluoro- and oxofluoro-complexes of rhenium and molybdenum[61], although in this case also it is difficult to make an exhaustive comparison, because of the limited amount of data for fluoroderivatives of rhenium.

The main difference between rhenium fluorides and oxide fluorides and the analogous molybdenum compounds is the higher reactivity of the rhenium derivatives. Rhenium fluorides are much more sensitive to hydrolysis, and are more readily reduced by hydrogen, organic compounds, and many metals.

Moreover, rhenium, unlike molybdenum, forms compounds in which it has an oxidation number of +7, and this extends considerably the range of fluorides and oxide fluorides formed.

An important problem in the chemistry of rhenium fluorides is the development of reliable methods of synthesis giving sufficiently pure products.

Table 8. Methods of preparing higher fluorides and oxide fluorides of rhenium.

Rhenium fluoride	Starting material	Reagent	Conditions of reaction	Side products	Refs.
ReF_7	Re	F_2	400 °C, 2–3 atm	—	9, 10

*Here and subsequently, the molar ratio is given.
**Heating from 20 °C to 140 °C.

An analysis of methods for obtaining higher fluorides and oxide fluorides of rhenium (Table 8) shows that these methods require improvement. Thus the preparation of ReF_7 requires the use of fluorine under pressure, and the only reagent which makes it possible to carry out the synthesis at low temperature and atmospheric pressure is KrF_2. Available published data indicate that even more effective methods of obtaining rhenium heptafluoride may be developed by fluorination using atomic fluorine and by using catalysts[142,143].

Existing methods for synthesising ReF_6 from the elements are simple and satisfactory. Here, however, the main problem of the purification of the starting materials and products is still unsolved; even traces of oxygen in the metal or fluorine lead to the contamination of ReF_6 by oxide fluorides.

Of the methods for synthesising ReO_3F, the best yield with a low concentration of impurities is given by the reaction between ReF_7 and Re_2O_7 (1:3.6).[89]

ReO_2F_3 and $ReOF_5$ are most simply obtained in a mixture by the reactions of oxides of rhenium[89,96] or the metal[96] with a mixture of fluorine and oxygen. The improvement of the synthesis of these individual oxide fluorides will involve the development of effective methods of separation.

The synthesis of $ReOF_4$ using metal carbonyls[72] is complicated, and gives a low yield of the main product, which is difficult to purify. Methods for preparing $ReOF_4$ by fluorinating the metal and ReO_3 are simpler[89], but in this case the product contains impurities which are difficult to remove. The purest oxide tetrafluoride can be obtained by the careful hydrolysis of ReF_6.[89,102] Here, the complexity of the method is associated with the need to observe carefully the reagent ratio and the reaction conditions. The optimum method may be the reaction of B_2O_3 with a slight excess of ReF_6.[152]

The synthesis of lower fluorides and oxide fluorides of rhenium (Table 9) involves the reduction of the higher fluorides by carbonyls, metals, and hydrogen, and also by sulphur dioxide and phosphorus trifluoride. Many transition metals (for example Zr, Ti, etc.) can also be used as reducing agents. Thermodynamic calculations[31] show, however, that many of these reagents can reduce the higher fluorides and oxide fluorides of rhenium to the metal, and this may give mixtures difficult to separate.

Table 9. Methods of preparing lower fluorides and oxide fluorides of rhenium.

Rhenium fluoride	Starting material	Reagent	Conditions of reaction	Side products	Refs.
ReF_5	ReF_6	$W(CO)_6$	small excess of ReF_6, 20 °C, 1 atm	$ReOF_4$, WF_6, ReF_4	72
ReF_5	ReF_6 in WF_6	$W(CO)_6$	small excess of ReF_6, large excess of WF_6, 20 °C, 1 atm	ReF_4, lower fluorides	72

ReF_4	ReF_6 in HF	Si	20 °C, 1 atm	SiF_4	77
ReF_4	ReF_6	H_2	200 °C, 1 atm	HF	70, 71
ReF_4	ReF_5 in HF	H_2	20 °C, 3.5 atm	HF	77
ReF_4	ReF_6 in HF	H_2	20 °C, 3.5 atm	ReF_5	77
ReF_4	ReF_5	—	240 °C, 1 atm	ReF_6	72
$ReOF_3$	$ReOF_4$	SiO_2	250 °C, 1 atm	SiF_4, O_2	72

In general, the lower fluorides of rhenium have been much less extensively studied than the analogous compounds of molybdenum and tungsten. Thus molybdenum fluorides have been studied by Opalovskii and Khaldoyanidi[61], and the lower fluorides of molybdenum and tungsten by Pervov[144–150], whereas rhenium fluorides have not been studied.

The data in Table 10 indicate that methods for the synthesis of fluoro-complexes of rhenium are insufficiently developed. The synthesis of rhenium complexes is based on reactions of three types—the combination of a rhenium fluoride with the fluoride ion, oxidation–reduction, and partial replacement of oxygen by fluorine in the starting material. There is only one example of the partial hydrolysis of a fluoro-complex to give an oxofluoro-complex (Table 10). Even this group of methods, however, does not exhaust all possible ways of obtaining fluoro- and oxofluoro-derivatives of rhenium. For example, the possible hydrolysis of oxofluoro-complexes has not been carried out, although new methods of synthesis and the preparation of new substances can be expected here; the reactions of $ReOF_5$, ReO_2F_3, and ReO_3F with alkali metal fluorides in the absence of solvent and in non-aqueous solutions have not been studied.

Table 10. Methods of preparing complex fluorides and oxide fluorides of rhenium.

Complex fluoride of rhenium	Starting material	Reagent	Conditions of reaction	Side products	Refs.
$NOReF_8$	ReF_7	NOF	20° C, 1 atm	—	32
NO_2ReF_8	ReF_7	NO_2F	20° C, 1 atm	—	32

** X=Cl, Br, I.

Rhenium should form a larger number of fluoro-complexes than are known at present. The known crystalline compounds containing the anions ReF_8^-, $ReOF_6^-$, $ReO_2F_4^-$, $ReO_3F_3^{2-}$, ReF_8^{2-}, ReF_7^-, $ReOF_5^-$, ReF_6^-, $ReO_{1.5}F_3.H_2O^-$, and ReF_6^{2-} [32,65,76,109,132,134,135,136] apparently do not exhaust the possible complex compounds of rhenium. Their theoretical and practical importance is potentially very high, since complex fluorides might be used to separate rhenium fluorides and oxide fluorides, and to purify them and remove them from gas streams.

The detailed study of fluoro-complexes of rhenium containing organic ligands would reveal the regular features of the change in the structure of transition metal compounds.

The thermochemistry and thermodynamics of rhenium fluorides are among the unsolved problems in this field. Their solution would make possible a deeper understanding of the regular features of the change in the strength of the bonds formed by metals with fluorine with change in the position of the metals in the periodic system. The first studies in the thermochemistry of rhenium fluorides were carried out only recently[15,16,100], however, and unfortunately do not extend to complex fluorides.

Simple rhenium fluorides deserve more extensive study. Thus ReF_6 is still the only rhenium fluoride whose electronic structure has been described.

Preliminary calculations by the present authors have shown that ReF_7 can decompose with the liberation of fluorine at 500 °C. The liberation of fluorine or oxygen may be expected when rhenium(VII) oxide fluorides are heated. This is of interest, since at present, PuF_6 is the only known volatile metal fluoride decomposing with the liberation of fluorine[151].

The problems in the field of the chemistry and technology of rhenium fluorides are wider than those listed, but the latter appear to be the most important.

The Isotope Effect for Diffusion in Solids

A.N.Murin, I.V.Murin, and V.I.Portnyagin

The theory of the isotope effect and its application to studies of migration in metals, ionic crystals, oxides, and other solids are discussed. Methods of measuring the isotope effect are briefly described. 96 references.

I. INTRODUCTION

The study of diffusion processes in solids began several decades ago, and the results obtained have been presented in thousands of original papers and discussed in excellent textbooks and reviews[1-4]. We must nevertheless agree with the reviewer[1] who stated, when discussing diffusion in crystals of alkali metal halides, that "in spite of a large volume of careful work we still lack a detailed understanding of diffusion processes, even in materials as familiar as NaCl". Further developments in our theoretical models and in our experimental techniques are needed to provide a deeper understanding of the nature of migration processes in solids.

The migration of structural units in transport processes (diffusion, ionic conduction, thermo-diffusion, etc.) occurs by a series of jumps from one equilibrium position to the next. Many different models have been proposed to describe these elementary diffusion acts, but most of these models rely on the motion of two types of defect: vacancies (unoccupied crystal lattice sites) and interstitial atoms or ions, or combinations of these defects (divacancies, interstitial configurations, etc.).

We shall confine our discussion (except in the case of electrical conduction) to the direct methods of determining diffusion coefficients by monitoring the redistribution of the diffusing "impurity" atoms in the solid. In this context the term impurity includes labelled atoms, i.e. isotopic indicators (such as ^{22}Na or ^{24}Na) which are chemically almost indistinguishable from the atoms of the matrix (^{23}Na). In some cases (e.g. when nuclear isomers are used) the indicator atoms and the matrix atom have the same weight as well as being chemically identical. The macroscopic significance of the diffusion coefficient D follows directly from Fick's familiar laws, and its microscopic significance (in the simplest case of an isotropic medium) from the Einstein relationship $D = \langle R^2\rangle/6t$, where $\langle R^2\rangle$ is the mean square displacement in time t. For the displacement of a diffusing atom in a simple cubic lattice we can write

$$\langle \mathbf{R}^2\rangle = \omega a^2 t + \left\langle 2 \sum_{j,k} (\mathbf{a}_j \mathbf{a}_k) \right\rangle, \qquad (1)$$

where $\mathbf{a}_i$ is the elementary jump, $(\mathbf{a}_j\mathbf{a}_k)$ is the scalar product of vectors, $a = |\mathbf{a}_i|$, and ω is the jump "frequency" of the diffusing atom in unit time.

In the diffusion of a labelled atom each jump is correlated with the previous jump, and only a fraction of the jumps contributes to random diffusion. It is easy to see that in the vacancy mechanism the probability of a diffusion jump in any direction depends on the direction of the previous jump, since each jump of a diffusing labelled atom leaves behind a vacancy and thus increases the probability of a jump in the reverse direction. Clearly, if an atom carries out a "forward" jump followed by its correlated "backward" jump (to the initial position) the two jumps are mutually compensating. Thus the term $2 \sum_{j,k} (\mathbf{a}_j\mathbf{a}_k)$ in the right-hand side of Eqn.(1), which vanishes in the case of random motion, is not zero in the general case.

We shall introduce the concept of the correlation coefficient f, equal to the fractional number of jumps which make an effective contribution to the random diffusion: $\omega_{\text{eff}} = f\omega$. Hence Eqn.(1) can be re-written

$$D_T = \omega_{\text{eff}} a^2 t = f\omega a^2 t. \qquad (2)$$

The correlation factor f also appears in the expression [equivalent to Eqn.(2)]

$$D_T = D_{\text{real}} = f D_{\text{rand}},$$

where D_{rand} is the diffusion coefficient of the atom for fully random (spatially independent) successive diffusion jumps. Throughout this review we shall use the term self-diffusion coefficient to refer to the "real" diffusion coefficient of isotopically labelled atoms or ions (D_T). In most cases this quantity is independent (to a first approximation) of the difference in mass between the indicator atoms (for example, ^{22}Na or ^{24}Na) and the matrix atoms (^{23}Na), though of course diffusion isotope effects are the subject of this review.

In the case of self-diffusion in cubic crystals the correlation factor (to this approximation) is a purely geometric coefficient, depending only on the diffusion mechanism and on the crystal structure. As an example, the calculated correlation factors for self-diffusion in a face-centred cubic lattice (f.c.c.) are listed in Table 1.

Experimental measurement of the correlation factor should at least help to identify the elementary mechanism of the diffusion process. For the isotropic self-diffusion of particles having a single jump frequency ω the diffusion coefficient can be written $D = A\omega f$, where A includes geometric and other factors independent of the jump frequency.

Table 1. Calculated correlation factors for self-diffusion by different mechanisms in a b.c.c. lattice.

Diffusion mechanism	f_0
Vacancy	0.781
Divacancy	0.475
Interstitial	1.000
Relay:	
collinear jumps	0.667
non-collinear jumps	0.969

We shall now compare the diffusion coefficients for the atoms of two isotopes of mass m_α and m_β. We shall express their ratio as

$$D_\alpha/D_\beta = f_\alpha\omega_\alpha/f_\beta\omega_\beta. \quad (3)$$

The difference in mass between the isotopes leads to differences in the jump frequencies ω_α and ω_β, and hence in the correlation factors f_α and f_β (which depend on ω_α and ω_β). This statement is true both for self-diffusion and for the diffusion of impurities, since in self-diffusion the labelled atom (having a different mass) acts as an impurity atom with respect to the atoms of the host lattice. Hence f_α and f_β are true correlation coefficients for the impurity atoms. The correlation factor for "true" self-diffusion ($f = f_0$, see Table 1) is, strictly speaking, meaningful only in the ideal case when the diffusing atom and the matrix atom have identical jump frequencies. The approximate equality $f_\alpha \cong f_\beta \cong f_0$ is obeyed satisfactorily in most cases.

For the systems considered the correlation factor of the impurity can be expressed as $f = (u/\omega + u)$, where u is the jump frequency of the matrix atoms only. Assuming that this expression is valid for any labelled atom, i.e. that u is independent of the mass of the labelled atom, we can express f_α and f_β as

$$f_\alpha = u/(\omega_\alpha + u);\ f_\beta = u/(\omega_\beta + u). \quad (4)$$

Eliminating u and one of the correlation factors from (3) and (4) we obtain the following expression for the fractional difference between D_α and D_β:

$$\Delta D/D_\beta = f_\alpha\ \Delta\omega/\omega_\beta, \quad (5)$$

where $\Delta D = D_\alpha - D_\beta$, and $\Delta\omega = \omega_\alpha - \omega_\beta$.

Since the absolute value of the jump frequency cannot be determined in a diffusion experiment, for practical purposes the ratio $\Delta\omega/\omega$ in expressions such as (5) must be written as a function of the isotopic masses m_α and m_β. Treating the diffusional jump as the motion of an atom through a potential barrier, we write

$$\omega = \nu \exp(-Q/kT),$$

where Q is the energy (enthalpy) of activation of the jump, and ν is the mean vibrational frequency of the migrating atom.

Since Q denotes the height of the potential barrier, its value should be the same for chemically identical isotopes. Atomic vibration frequencies vary with the mass of the atom as $\nu \propto m^{-1/2}$. Hence

$$\Delta\omega/\omega_\beta = [(m_\alpha/m_\beta)^{-1/2} - 1]. \quad (6)$$

Combining (5) and (6) gives the following expression for the diffusion isotope effect:

$$E_\beta^\alpha = \frac{\Delta D/D_\beta}{(m_\beta/m_\alpha)^{1/2} - 1} = f_\alpha \simeq f_0. \quad (7)$$

Expressions like (6) and (7) were derived for conditions in which only the migrating atom is able to jump, and no allowance was made for changes in the state of the lattice. Obviously, allowing for the part played by the neighbours of the diffusing atom in the migration act must modify Eqn.(6) in the sense of decreasing the magnitude of the isotope effect. Introducing the correction coefficient

$$\Delta K = \Delta\omega/\omega_\beta \left[\left(\frac{m_\beta}{m_\alpha}\right)^{1/2} - 1\right]^{-1},$$

we convert Eqn.(7) into

$$E_\beta^\alpha = \frac{\Delta D/D_\beta}{(m_\beta/m_\alpha)^{1/2} - 1} \simeq f_0\Delta K. \quad (8)$$

An expression for the diffusion isotope effect in the form of Eqn.(8) was first proposed by Mullen[4]. Using the classical theory of reaction rates ΔK can be interpreted as the fraction of the kinetic energy of the diffusing atom at the saddle point associated with motion in the direction of the jump. Thus, ΔK can vary between zero and unity. It follows from Eqn.(8) that by measuring the isotope effect E_β^α it should be possible to evaluate the product $f\Delta K$: hence, in order to obtain the coefficient f (and thus to identify the diffusion mechanism) we must introduce additional information. We shall examine first of all the possibility of measuring (and interpreting) quantities such as the electrical conductivity σ (in the case of ionic conductors) and the activation volumes of diffusion or ionic conduction processes.

The well known Einstein–Nernst expression related the mobility μ and the diffusion coefficient D of a charged particle:

$$\mu/D = q/kT \quad (9)$$

where q is the charge of the particle, k is Boltzmann's constant, and T is the absolute temperature.

The electrical conductivity (resulting from the migration of charged particles in an electric field) is $\sigma = \mu qN$, where N is the number of current-carrying particles per unit volume. To simplify the discussion we shall consider the case of unipolar ionic conduction, for which we can write

$$D/\sigma = kT/q^2N. \quad (10)$$

In Eqns.(9) and (10) the quantity D is the "random" or "chaotic" diffusion coefficient, wheras the real diffusion coefficient D_T (measured experimentally with radioactive indicators) is related to σ by the generalised expression $D_T/\sigma = (kT/q^2N)f$.

Comparative measurements of the real self-diffusion coefficient D_T and of the ionic conductivity coefficient σ allow (in some cases) the coefficient f to be determined. Measurements of the quantity called the "activation volume" can also help to identify diffusion mechanisms. The diffusion coefficient D_T can be described with adequate generality by the expression[2]

$$D_T = \gamma a^2 f\nu \exp(-\Delta g/kT) = \gamma a^2 f\nu \exp\left(\frac{\Delta S}{k}\right)\exp\left(-\frac{\Delta H}{kT}\right),$$

where γ depends on the geometry of the crystal lattice, ν is

the frequency, and Δg, ΔS, and ΔH are the changes in thermodynamic potential, entropy, and enthalpy which accompany each diffusional jump. Using the standard thermodynamic relation $(\partial g/\partial p)_T = V$ (where p is pressure and V is volume) we can write to a good approximation

$$\left(\frac{\partial \ln D}{\partial p}\right)_T \simeq \left(\frac{\partial \Delta g}{\partial p}\right)_T = \Delta V,$$

where ΔV is called the activation volume. Using the Einstein–Nernst relation, the activation volume for ionic salts can be determined also from electrical conductivity data. The quantities Δg, ΔH, and ΔS can be expressed as sums of the free energy (enthalpy, entropy) of formation of the lattice defect responsible for the diffusion (i.e. Δg_f, ΔH_f, ΔS_f) and of the corresponding quantities for the migration process itself (Δg_m, ΔH_m, ΔS_m). In exactly the same way ΔV can be separated into its components ΔV_f (the activation volume of formation) and ΔV_m (the activation volume of migration).

Theoretical models of the effect of high pressures on migration processes in solids allow some of these quantities to be calculated. For example, in the case of self-diffusion in metals the quantity $\Delta V^1\nu$ for diffusion by single vacancies is approximately $^1/_2$–$^3/_4$ of the atomic volume, and $\Delta V^2\nu$ for the divacancy mechanism is slightly less than $2\Delta V^1\nu$; the corresponding quantities for interstitial diffusion are very much smaller[2].

There are many other physical parameters whose measurement can help to establish the nature of the point in solids and hence to identify the diffusion mechanism. For example, useful measurements include anomalous thermal expansion, specific heat anomalies, high-precision density and lattice parameter measurements, relaxation studies, measurements of optical properties, etc. We shall refer to the results of these (and other) methods in our discussion of isotopic experiments.

II. THEORY OF THE ISOTOPE EFFECT

The general theory of diffusion in solids (and, in particular, the basic elements of the theory of isotope effects in diffusion) are discussed in many theoretical publications both by Eyring's theory of absolute reaction rates and by the dynamic variants of the theory, in both the harmonic and the anharmonic approximation. Eyring and Bigeleisen's general theory of the kinetic isotope effect predicts that the effect will be most marked when the isotopic atoms are loosely bound in the activated complex.

Zener[5] and others developed Eyring's theory of rate processes by treating the diffusion process as the motion of an atom through a potential barrier. They showed that the average jump frequency of the atom is related to its mass by the expression $\omega \propto m^{-1/2}$. In this model the elementary diffusion act is carried out by a single particle: the contribution from the crystal lattice is not considered. Other assumptions made in the model include: 1) an activated state can exist at the top of the potential barrier, and its life time is long enough to determine it thermodynamic properties; 2) irreversibility of the diffusion is produced by an unexplained mechanism which causes the migrating atom to lose so much energy that it is unable to re-cross the barrier in the backward direction.

Prigogine and Bak[6] proposed a theory in which irreversibility of the diffusion follows from the anharmonicity of the interactions between the normal modes of the matrix and those of the moving particle. Their model ignores the participation of the lattice atoms in the formation of the activated complex in the saddle-point configuration; a consequence of this model is that the diffusion coefficient is inversely proportional to the square of the mass of the migrating atom.

The contribution to the formation of the activated complex by the nearest neighbours of the diffusing atom can be allowed for by making the frequency of the jumps into a vacancy proportional to $(m^*)^{-1/2}$, where m^* is an effective mass whose value is determined by the highest and the lowest mass of the whole configuration. Rice and Frisch[7] allowed for the participation of the lattice in the saddle configuration and used a dynamic model free from the assumptions of the classical theory. According to their model the jump of a diffusing atom is the result of the fluctuations in its energy and momentum (quantity of motion) produced by the thermal vibrations. In order to calculate the amplitude of these fluctuations they introduce a definition of the reaction co-ordinate which allows for the displacement of both the migrating atom and the barrier atoms. This quantity can be treated as a measure of the extent to which the thermal motion has been able to overcome the resistance of the neighbouring atoms to the passage of the migrating particle. A jump is assumed to take place each time the reaction co-ordinate exceeds some critical distance. Thus, the basic feature of the dynamic theory is the assumption that a jump can occur only as a result of a specified type of fluctuation of the reacton co-ordinate, determined by the lattice geometry. However, the energy of this fluctuation cannot be calculated in the present state of the theory. The dynamic theory of diffusion has been developed also by other workers[8–12].

Discussion of the diffusion isotope effect from the standpoint of the dynamic theory produces results similar to those of the classical model. Hence, both theories can be used for practical purposes. The classical model has the advantage of being simpler, as well as offering the possibility of calculating the thermodynamic characteristics of the diffusion jump. Our discussion of the isotope effect will therefore be confined to this variant of the theory.

A problem still not fully solved is the mechanism by which the energy of the activated atom is dissipated when this atom has gone beyond the saddle point. Unless the energy is dissipated very rapidly the atom may retain enough energy to undergo the backward jump. Clearly, the diffusion problem is closely bound up with our interpretation of the isotope effect, i.e. with the physical significance of the term ΔK which appears in Eqn.(8).

The jump frequency of an atom in the saddle configuration (at the top of the potential barrier) should be given by an expression including the frequencies of the normal lattice modes for the initial configuration (ν_j) and for the activated complex (ν_j'). Le Claire[13] showed that one of the normal modes corresponding to the saddle configuration (of frequency ν_1') is unstable, and leads to the breakdown of that configuration and to completion of the jump. Changes in the mass of the migrating atom affect the frequency of this unstable mode only. By treating the jump as the motion of an atom at the saddle point through the potential barrier we demonstrate (in accordance with the above discussion) that ΔK is the fraction of the total kinetic energy of the system (at the saddle point) which is assigned to the migrating atom only. Thus the quantity ΔK provides information on the energetics of an individual act of diffusion, which is not obtainable by any other method.

Eqns.(7) and (8) apply only if the mechanism of the migration act involves only one particle (vacancy mechanism, direct interstitial mechanism, etc.). If the elementary displacement

requires the simultaneous motion of n atoms (as in the indirect interstitial or in the ring mechanism) Eqns.(7) and (8) become

$$E_{\beta}^{\alpha}=\frac{\Delta D}{D_{\beta}}\left[\left(\frac{m_{\beta}+(n-1)m_0}{m_{\alpha}+(n-1)m_0}\right)^{1/2}-1\right]^{-1}=f_{\alpha}\Delta K, \qquad (11)$$

where m_0 is the average mass of the matrix atoms.

Since ΔK allows for the contribution of the lattice atoms to the elementary diffusion act we can establish the relationship between this quantity and the relaxation of the atoms adjacent to the defect. This correlation was first investigated by Barr and Mundy[14], who expressed the activation volume for diffusion ΔV in units of the atomic volume and found that ΔK was numerically very similar to $\Delta V/V$. Le Claire[13] looked for a correlation between the kinetic energy of an atom at the saddle point and vibrating with the frequency ν_1', on the one hand, and the jump distance of this atom, on the other hand, and he obtained the following expression for ΔK:

$$\Delta K=\left[1+\frac{n}{3}\left|1-\Delta V_f\right|\right]^{-1}, \qquad (12)$$

where n is the number of relaxed atoms taking part in the saddle configuration. For the self-diffusion of Na atoms in metallic sodium we have $\Delta K = 0.50$ [15] and $\Delta V_f = 0.52$.[16] This gives, from Eqn.(12), $n = 6$, which is the same as the number of neighbours of a migrating atom in a body-centred cubic (b.c.c.) crystal. However, this agreement must be treated with some caution: very probably the number of relaxing atoms is greater than six, but their contribution to ΔK is not uniform. In the case of self-diffusion in metallic silver $\Delta K = 0.86$ [17] and $\Delta V_f = 0.70$. These values lead to $n = 1.6$, which is not surprising, since the number of relaxing atoms in the more closely packed f.c.c. structure must be smaller than in the b.c.c. lattice.

It is interesting to establish whether n is a constant, characteristic of a given type of crystal structure. If so, Eqn. (12) can be used to calculate ΔK values appropriate to the isotope effect in impurity diffusion. Most workers assume that ΔK_S for self-diffusion is equal to ΔK_{imp} for impurity diffusion: this assumption is consistent with the experimental fact that the activation volumes for impurtiy diffusion and for self-diffusion do not differ very markedly (for example, $\Delta V_{In/Ag}$ and $\Delta V_{Ag/Ag}$ differ by 5%; $\Delta V_{Sb/Ag}$ and $\Delta V_{Ag/Ag}$ differ by 10%).[2] Theoretical calculations for structures in which ΔK_S is not very different from 1 lead to the same conclusion: in the case of an f.c.c. lattice, for which $\Delta K_S = 0.9$,[17] substitutional impurities should have ΔK values differing from ΔK_S by not more than 8%.[9-11] However, the same is not true of crystals in which $\Delta K_S \ll 1$.

Theoretical calculations of ΔK have been reported for various crystal structures. Brown and coworkers[18] obtained $\Delta K = 0.998$ for NaCl, in excellent agreement (within experimental error) with the experimental value[19] $\Delta K = 0.93 \pm 0.09$. They also calculated ΔK for copper[20]. A comparison of ΔV and ΔK values is shown in Table 2.

Achar[12] used the dynamic theory of diffusion to calculate ΔK for several f.c.c. and b.c.c. metals. The results are consistent with experiment.

Eqn.(8) was obtained by classical statistical mechanics, without allowance for quantum effects. Experiment shows that this expression adequately describes the diffusion isotope effect in most systems. The only exception is the diffusion of the hydrogen isotopes, for which Eqn.(8) gives unacceptably low values of E. It has been clearly shown[13,21,22] that quantum effects cannot be ignored in the diffusion of such light isotopes. The contribution of quantum corrections to the hydrogen diffusion isotope effect has been discussed for Pt [23] and Nb [24] matrices. A study[25] of the diffusion of hydrogen, deuterium, and tritium in Ni and Cu has shown the need to allow for the anharmonicity of the lattice vibrations in addition to the quantum corrections.

Table 2. Calculated and experimental values[2] of ΔK and $\Delta V/V$.

Matrix	Isotope pair	ΔK_{calc}	ΔK_{exper}	$\Delta V/V$
Ag	^{105,111}Ag	0.80[12]	0.86±0.05[17]	0.90[34]
γ-Fe	^{55,59}Fe	—	0.74±0.08[29]	0.77[35]
Cu	^{64,67}Cu	0.82[12]	0.87±0.02[30]	0.90[36]
			0.92[20]	
Na *	^{22,24}Na	0.54[12]	0.50±0.05[15]	0.52[16]
α-Fe *	^{52,59}Fe	0.51[12]	0.56±0.05[31]	—
Zn **	^{65,69}Zn	—	0.93±0.08[32]	0.43[37]
NaCl	^{22,24}Na	0.99[18]	0.93±0.09[19]	1.20[38]
AgBr	^{105,111}Ag	—	0.66±0.02[33]	0.69[33]

*b.c.c. structure; ** close-packed hexagonal structure; in every other case f.c.c. structure.

The experimental value of E has been found to be temperature-dependent in several studies of the isotope effect in self-diffusion (for example, in the self-diffusion of ^{105,110}Ag in metallic silver[17] and in the self-diffusion of ^{22,24}Na in NaCl).[26] Since $E = f\Delta K$, the temperature dependence of the isotope effect may be due to a variation with temperature of either f, or ΔK, or both. The correlation factor in self-diffusion is a purely geometrical parameter, depending only on the type of lattice and on the diffusion mechanism; on the other hand, as was shown theoretically for Ag and Al,[12] the quantity ΔK should also be independent of temperature. Thus, in order to explain the temperature dependence of the isotope effect we must postulate the simultaneous operation of several diffusion mechanisms. Changes in the contribution of each mechanism to the overall diffusion process may account for the observed dependence of E on temperature.

Bakker[27] derived an expression for the isotope effect in the case of two simultaneous mechanisms (vacancy and divacancy diffusion) in an f.c.c. lattice:

$$E=\frac{D_1}{D_1+D_2}f_1\Delta K_1+\frac{D_2}{D_1+D_2}f_2\Delta K_2; \qquad (13)$$

where D_i, f_i, and ΔK_i are the diffusion coefficients and the isotope effects for each mechanism. The most general expression for the diffusion isotope effect in the case of diffusion by several simultaneous mechanisms is

$$\frac{\Delta D}{D_{\beta}}=\sum p_i\Delta K_i f_i \delta_{m_i}, \qquad (14)$$

where p_i is the fractional amount of diffusion by the stated mechanism, and δ_{m_i} is the mass term (for the vacancy and the direct interstitial mechanism $\delta_{m_i} = [(m_{\beta}/m_{\alpha})^{1/2}-1]$).[27] Eqns.(13) and (14) can be used to calculate the contribution of each mechanism to the overall diffusion process.

We shall now consider the limits of the validity of expressions of the type of (8), (11), and (14). Both the derivation and the practical use of these and similar expressions involve the following assumptions:

a) $\Delta f/f_{\beta}$ is small compared with unity, i.e. $f_{\alpha} = f_{\beta} = f_0$;

b) changes in mass affect only ω in Eqn.(2), and they have no effect on u;

c) the number of labelled atoms introduced into the crystal by diffusion is much smaller than the number of matrix atoms, and therefore the probability of finding an impurity atom among the nearest neighbours of a diffusing atom is negligibly small.

LeClaire has shown[13] that the measured diffusion isotope effect is only slightly affected by these assumptions, since the necessary corrections are less than 2% and therefore beyond the precision of the experiment (5–10%).

III. SELF-DIFFUSION IN PURE METALS

1. Face-centred Cubic Metals

Diffusion isotope effects have been studied in a large number of metals with a face-centred cubic lattice. In most cases the conclusion is that self-diffusion in f.c.c. metals is mainly by the single vacancy mechanism. A contribution from the divacancy mechanism is observed near the melting point.

Self-diffusion in copper has been studied in several laboratories[30,36]. We shall dwell mainly on Rothman and Peterson's results[30], obtained in an investigation of the effect of temperature on diffusion isotope effects. At relatively high temperatures (698–1061 °C) the diffusion is described by the following parameters: $D_0 = 0.78$ cm^2 s^{-1}, $Q = 2.18$ eV. From the diffusion of ^{64}Cu and ^{67}Cu in copper single crystals the ratio $D_{64}/D_{67} = 0.0155 \pm 0.0003$ was obtained, and found to be independent of temperature. These results led to the value $\Delta K = 0.87 \pm 0.02$, and to the conclusion that self-diffusion by the single vacancy mechanism is predominant in copper. The variation of E_{67}^{64} with temperature is negligibly small, showing that the contribution of divacancies to the diffusion process is slight.

The pressure dependence of the diffusion coefficient for self-diffusion in Cu [36,39] gives an activation volume of 0.9 of the atomic volume, corresponding to diffusion by the single vacancy mechanism or by a combination of the single vacancy and the divacancy mechanism. Mehrer and Seeger[40] arrived at the following series of optimum parameters for the defects in Cu by combining data on the temperature dependence of D and on the isotope effect with data[41] on high-temperature defect equilibria: $H_f^{1V} = 1.03$ eV, $\Delta S_f^{1V} = 0.3\ k$, $H_m^{1V} = 1.06$ eV, $\nu^{1V}\exp(\Delta S_m^{1V}/k) = 1.4 \times 10^{14}$ s^{-1}, $H_m^{2V} - H_b^{2V} = 0.54$ eV, $\Delta S_f^{2V} = 2k$, $\nu^{2V}\exp(\Delta S_f^{2V}/k) = 1.6 \times 10^{14}$ s^{-1}. Electron-microscopic studies by Bowden[42] have confirmed Mehrer and Seeger's interpretation (which allows for divacancy migration).

Self-diffusion in Ag has been studied by several workers. Rothman's results[17] show a small, systematic deviation from an Arrhenius dependence of ln D on $1/T$, which he ascribes to the presence of a second diffusion mechanism. The temperature dependence of the isotope effect for self-diffusion in Ag (Fig. 1) gives additional evidence for the presence of two diffusion mechanisms[17]. At low temperatures the E value corresponds to diffusion by the single vacancy mechanism ($\Delta K^{1V} = 0.92$), decreasing at higher temperatures to a level which suggests an increasing contribution from divacancies. Reimers and Bartdorff[43] also measured the temperature dependence of E: their results are less accurate than Rothman's but consistent with them.

Two extreme cases of the contribution of divacancies to self-diffusion in silver can be defined. On the one hand, the difference between E and f^{1V} can be ascribed wholly to the contribution from divacancies (i.e. $\Delta K^{1V} = 1$). Assuming $\Delta K^{1V} - \Delta K^{2V} = 1$, and $f^{2V} = 0.475$, we find that the divacancy contribution is a maximum ($D^{2V}/D^{1V} = 0.872$) at high temperatures ($E = 0.639$), falling to 0.263 at low temperatures ($E_{111}^{105} = 0.718$). Since only the single vacancy mechanism operates at low temperatures, i.e. $\Delta K^{1V} = 0.918$, and divacancy effects on E appear only at high temperatures, we can obtain $D^{2V}/D^{1V} = 0.12$ by assuming that ΔK is independent of temperature and that the contribution of divacancies at the melting point is a minimum for $\Delta K^{2V} = 0$. A critical analysis of all the experiment data[44] leads to the following set of thermodynamic parameters for the defects and for their mobility in metallic silver: $H_f^{1V} = 0.99$ eV, $H_m^{1V} = 0.86$ eV, $\Delta S_f^{1V} = 0.5\ k$, $H_m^{2V} - H_b^{2V} = 0.34$ eV, $H_m^{2V} = 0.58$ eV, $\Delta S_f^{2V} = 2.6\ k$.

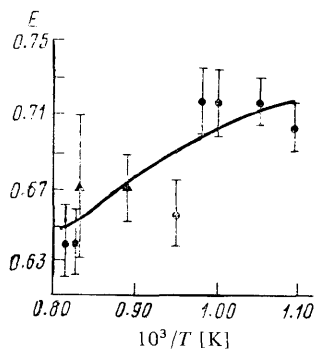

Figure 1. Isotope effect for self-diffusion in Ag:[17,33] the curve is taken from Mehrer's analysis[44] of these results.

Isotope effects for self-diffusion in Pd and γ-Fe have been measured accurately enough to identify the diffusion mechanism, but the temperature dependence of E was not measured to an accuracy sufficient to justify the calculation of the thermodynamic properties of the defects. Peterson[45] investigated the isotope effect for self-diffusion in Pd, and found $E = 0.79 \pm 0.04$ in a narrow region of temperature near the melting point. Since ΔK cannot be greater than unity, self-diffusion in Pd must take place by the single vacancy mechanism, with $(1 - \Delta K) \leq 0.02$. The experimental temperature range was too narrow to allow the contribution of divacancies to be detected, but the numerical value of the isotope effect suggests that this contribution is very small.

Published studies[29,46] of the isotope effect for self-diffusion in γ-Fe are consistent ($E_{59}^{55} = 0.53$–0.57), and suggest that the single vacancy diffusion mechanism predominates. The observed temperature dependence of E allows for some contribution from divacancies to the transport processes in γ-Fe.[29]

2. Body-centred Cubic Metals

Studies of self-diffusion in b.c.c. metals have yielded inconsistent results, and the diffusion parameters in these systems cannot yet be interpreted unambiguously. For most b.c.c. metals the diffusion coefficient near the melting point is ~10^{-7} cm^2 s^{-1}, as compared with ~10^{-8} cm^2 s^{-1} for f.c.c. metals. Interesting results were obtained for the self-diffusion effects in sodium. The model of self-diffusion in Na is more complicated than the model for f.c.c. metals, and is probably typical of the majority of metals which crystallise in a body-centred cubic lattice. The anomalously low value

of the ratio $\Delta D/D_{24} = 0.016$ was pointed out early on[14]: such a value of the mass effect may be due to an indirect interstitial mechanism, diffusion occurring along split interstitials. However, since the predominant defect in Na has been shown independently[16] to be a lattice vacancy, a diffusion model involving relaxed vacancies is proposed: this gives a lower value of f and explains the low value of E.

Later work in the same laboratory showed a decrease in the magnitude of the isotope effect near the melting point of sodium[15]: $\Delta D/D_{24} = 0.016$ at 40–84 °C, and $\Delta D/D_{24} = 0.013$ at $t > 84$ °C. Evidently, diffusion occurs by more than one mechanism at temperatures near the melting point, but the nature of these mechanisms has not been established. On the other hand, two models of the relaxed vacancy have been proposed for the region of constant E: $f_1 = 0.5$ and $\Delta K_1 = 0.72$, or $f_2 = 1$ and $\Delta K_2 = 0.36$. However, the authors are unable to choose between these models.

The isotope effect in Na has been calculated theoretically[18] for different types of defect. Agreement with experiment is best for the interstitial diffusion mechanism.

Mundy[28] attempted to explain unambiguously the mechanism of self-diffusion in sodium by carrying out a complex investigation over a range of hydrostatic pressures. His results, and in particular the irregularities in the plot of $\ln D = f(1/T)$, suggest that at least two diffusion mechanisms are operative: a high-temperature and a low-temperature mechanism. Within the high-temperature region two separate mechanisms can be distinguished. Thus, the total number of mechanisms involved is three. The dependence of self-diffusion on pressure at 14.8 and 91.4 °C indicates that at 14.8 °C approximately 2/3 of the diffusion takes place by the low-temperature mechanism, whereas at 91.4 °C this mechanism accounts for only 40% of the diffusion. When several mechanisms are possible an increase in pressure causes an increased contribution from the low-temperature processes. Therefore the decrease in the isotope effect at 91.4 °C becomes less marked when the pressure is raised to 7 kbar, though this effect may be due to the increase in the melting point of sodium at high pressures (145 °C at 7 kbar).

Thus the experimental results show that self-diffusion in sodium involves at least two mechanisms. The following pairs of mechanisms have been proposed for the two-process model: 1) a vacancy and an interstitial, and 2) a vacancy and a divacancy. By associating (in the first variant) the interstitial mechanism with the low-temperature region and the vacancy mechanism with the high-temperature region we can explain many experimental results. However, this model does not allow us to explain the variation of E with temperature. On the other hand, the temperature dependence of the isotope effect is easily explained by postulating two types of divacancy whose relative contribution to the transport of matter varies with temperature. Evidence for this model is provided by the similarity of the activation volumes for the two high-temperature processes ($\Delta V_2/V = 0.68 \pm 0.21$, and $\Delta V_3/V = 0.68 \pm 0.25$ at 91.3 °C).[28]

For the model which includes three self-diffusion mechanisms Mundy[28] suggests the following processes: a low-temperature (interstitial) process with $\Delta D/D = 0.018$ and two high-temperature processes with $\Delta D/D = 0.014$ and 0.003 respectively. The latter value is surprisingly small, and we have to use Eqn. (11) to calculate the number of atoms taking part in the elementary act: the result is $n = 20$. This is not too surprising, since neutron diffusion experiments in liquid sodium have shown that at temperatures slightly above the melting point ~30 atoms are involved in each diffusion jump. We may assume that the concentration of vacancies increases steeply near the melting point, and therefore the relaxation around one vacancy may affect other vacancies. This type of interaction may lead the formation of regions within the crystal in which diffusion is a polyatomic process.

Studies of isotope effects in self-diffusion in α-Fe [31,46] and δ-Fe [47] have been reported. The results are mutually consistent, the E values in α-Fe and δ-Fe being similar to those in Na at the same reduced temperatures (i.e. at temperatures referred to the melting point of the appropriate metal, T/T_f). The complex temperature dependence of the isotope effect in α-Fe, δ-Fe, and Na suggests that the migration of atoms in these b.c.c. metals occurs by the same mechanism. In order to test this hypothesis with a higher-melting b.c.c. metal, Mundy and coworkers[48] studied the isotope effect of chromium, and they again observed a decrease in the E_{51}^{48} value for the effect with increase of temperature (0.52–0.31 at 1440–1810 °C). The high values of the Arrhenius parameters (as in the case of self-diffusion on vanadium) are consistent with a predominantly divacancy migration mechanism in chromium, with a negligibly small contribution from single vacancies. The temperature dependence of the isotope effect is explained (as in the case of sodium) by the participation of two types of divacancy in the transport process.

Evidently, further work on diffusion isotope effects in other b.c.c. metals is needed to solve the problem of anomalous diffusion in these materials, which are industrially important.

3. Close-packed Hexagonal Metals

Isotope effects in the self-diffusion in zinc, which has an anisotropic lattice, have been reported[32,49]. At 289–418 °C the self-diffusion coefficients parallel (∥) and perpendicular (⊥) to the sixth-order symmetry axis are different, but the isotope effects are identical (within experimental error) in the two directions, and do not depend on temperature. The numerical values of the diffusion isotope effect suggest transport by a single vacancy mechanism in both directions, without a significant contribution from divacancies, i.e. $f_\parallel = f_\perp$ and $\Delta K_\parallel = \Delta K_\perp$. Different configurations of barrier atoms for these two cases can be proposed from geometrical considerations. However, the experimental values of ΔV are identical for both directions[37].

Stein and coworkers[50] proposed a method of calculating the correlation factor for self-diffusion in close-packed hexagonal metals by the single vacancy and divacancy mechanism. The results have been compared with experimental data[49] on the isotope effect for self-diffusion in zinc. The calculated correlation factor was shown to be the upper limit of the diffusion isotope effect.

IV. ISOTOPE EFFECTS IN HETERO-DIFFUSION IN METALS

Mundy and McFall[51] studied the diffusion of copper in metallic lithium, and observed deviations from linearity in the $\ln D = f(1/T)$ plots, which they ascribed to the presence of two diffusion mechanisms. The numerical value of the diffusion isotope effect ($E_{Cu/Li} = 0.11 \pm 0.03$) is incompatible with both the vacancy and the direct interstitial mechanism. For the vacancy mechanism the E value should be ≅0 (i.e. $f_{Cu/Li} \to 0$), whereas for interstitial diffusion E should be close to unity. Assuming a dissociative mechanism for the dissolution of Cu in Li, involving an equilibrium between the numbers of copper atoms in normal lattice sites and in interstitials respectively, the authors[51] conclude that diffusion takes place by a direct interstitial and a vacancy mechanism simultaneously. The two mechanisms are thought to contribute to a similar extent

to the transport process, since they involve comparable activation energies for diffusion. These considerations led the authors to the values $E = 0.17$ and $E = 0.05$ for the two mechanisms respectively. By measuring the diffusion isotope effects of $^{105,110}Ag$ and $^{22,24}Na$ in lithium Mundy and McFall[52] were able to compare experimental results with conclusions from the dynamic theory of diffusion.

An interesting example of the use of the isotope effect in identifying the diffusion mechanism of an impurity is provided by the fast diffusion of $^{105,110}Ag$ in lead[53]. An interstitial diffusion mechanism is almost invariably assumed to account for the abnormally fast diffusion of an impurity. The vacancy mechanism is excluded by the very small effect of the added impurity on the rate of self-diffusion. However, the effect cannot be explained on the assumption that the diffusion occurs wholly by an interstitial mechanism. To resolve this problem, the diffusion isotope effect of Ag in Pb was measured. The result[53] was $E_{Ag/Pb} = 0.25 \pm 0.05$, and the effect of the Ag impurity of $E_{Ag/Pb}$ was undetectable (addition of 0.08 at.% of Ag giving $E = 0.26 \pm 0.02$). The effect of temperature on $E_{Ag/Pb}$ was also negligibly small. These experimental observations were explained by postulating that the diffusion of Ag in Pb involves two mechanisms, though the contribution of the interstitial mechanism is predominant (80%). The remaining 20% is ascribed to any mechanism in which the diffusion of the impurity is directly linked to the diffusion of the solvent. Typical of these mechanisms is diffusion by impurity–vacancy pairs, with the silver atoms in interstitial sites. The relatively small contribution from the pair diffusion mechanism (20%) explains the failure of Ag additions to accelerate the self-diffusion in Pb. On the other hand, this small contribution from impurity–vacancy pairs to the overall diffusion process tends to obscure the influence of this mechanism on the isotope effect and to make the isotope effect temperature-independent.

Thus it is firmly established that most of the transport of Ag in Pb occurs by the interstitial mechanism. We also know that in this case $E \cong 1$, whereas the experimental value is $E = 0.25$. Since there is no reason to assume that either ΔK or f is very different from unity in this case, we must conclude that according to Eqn.(11) $n \neq 1$, i.e. several particles are involved in the elementary migration act. The most important defect in solutions of silver in lead is the split interstitial. If this defect consists (as in the present case) of two Ag atoms the presence of the impurity should accelerate the diffusion much more substantially than is found in practice. If on the other hand the split interstitial is composed of one Ag atom and one Pb atom, the Ag atom can perform one migration act by jumping from this defect into a normal site of the lead lattice. In this case $n = 3$, and if $f = 1$ and $\Delta K = 1$ the E value calculated from Eqn.(11) is 0.20, which agrees with the experimental value[53].

The isotope effects in the diffusion of cadmium (E_{115}^{109}) [54] and copper (E_{67}^{64}) [55] in lead were studied for the same purpose, i.e. in order to identify the hetero-diffusion mechanism. In the latter case the isotope effect ($E_{67}^{64} = 0.23 \pm 0.08$) was found to be close to the corresponding value for the diffusion of $^{105,110}Ag$ in Pb,[53] suggesting a similarity between the migration mechanisms of the impurities in the two systems. We should note that because of the low solubility of copper in lead the concentration dependence of the rate of diffusion could not be studied over a significantly wide range. Thus, the measurement of the isotope effect is the only method available for identifying the hetero-diffusion mechanism.

It should be remembered that in a pure metal the correlation factor f_0 is a constant, and depends only on the type of crystal structure and on the diffusion mechanism, whereas in impurity diffusion the correlation factor depends on the jump frequencies of the impurity atoms and of the solvent atoms. Therefore the quantity f_{imp} obtained from measurements of the diffusion isotope effect can be combined with other data (such as the dependence of the self-diffusion coefficient on the impurity concentration) to give the ratio of the jump frequencies of impurity and matrix atoms. For example, data on the isotope effect for the diffusion of zinc in silver[2] and data on the effect of zinc impurities on the rate of self-diffusion in Ag have allowed this ratio to be calculated for different temperatures. Results from studies of isotope effects accompanying the diffusion of Fe in Ag and Cu,[4] of cadmium in zinc[49], etc. have been interpreted in a similar way.

V. DIFFUSION IN ALKALI METAL HALIDE CRYSTALS AND IN SILVER HALIDES

Work on diffusion isotope effects in alkali metal halide crystals and in silver halides has been confined mainly to determining the contribution of vacancy pairs to the overall diffusion, and to evaluating the parameter n in Eqn.(11) for the case of simultaneous motion of two (or more) ions, since the indirect interstitial mechanism appears to operate in silver halides. From the results, thermodynamic parameters describing the migration under hetero-diffusion conditions have been calculated. The experimental data are summarised in Table 3.

Table 3. Experimental values of the diffusion isotope effect in single crystals of alkali metal halides and silver halides.

* In the case of $^{105,111}Ag$ the $\Delta D/D_\beta$ values are given

1. Contribution of the Divacancy Mechanism

As was stated above, the concentration of vacancy pairs increases steeply in many crystal structures at temperatures close to the melting point, and the contribution of vacancy pairs to the diffusion process increases correspondingly. The presence of a second diffusion mechanism will be reflected also by the magnitude of the isotope effect.

Attempts have been made in recent years to calculate the contribution of vacancy pairs to the diffusion of Na^+ ions in

sodium chloride. Nelson and Friauf[56] measured the self-diffusion coefficients of Na^+ in NaCl and also monitored (at the same time) the migration of this ion in an electric field, and concluded that the contribution from vacancy pairs was ~40%. Though the contacts to the crystal during the measurements in an electric field were far from ideal, the results obtained in this way are more accurate than those of independent measurements of D and σ.

Beniere and coworkers[57] calculated the contribution of vacancy pairs to the diffusion of the sodium ion in sodium chloride (~10%) from measurements of D_{Cl} in NaCl samples containing small amounts of bivalent cation impurities. The addition of bivalent cations is known to lower the concentration of single anion vacancies, and therefore at sufficiently high concentrations of M^{2+} the anions should migrate almost exclusively along vacancy pairs. However, these workers[57] based their calculations on the assumed equivalence[58] of cation and anion diffusion by the divacancy mechanism. By combining this (to say the least) arguable assumption with their experimental results on D_{Cl}, D_{Na}, and σ they obtained[57] $f^{1V} = 1$.

Rothman and coworkers[26] studied the isotope effect in the self-diffusion of Na in NaCl. Measurements of E_{24}^{22} in NaCl had been carried out even earlier[19], but the effect of temperature on this parameter had not been observed, and it had been concluded[57] that correlation is absent in the diffusion of Na in NaCl (i.e. $f=1$). Rothman[26] observed a change in E_{24}^{22} in NaCl: from 0.484 at 796.6 °C to 0.624 at 589.3 °C. By ascribing the lack of constancy of the isotope effect to an increasing contribution from divacancies to the diffusion process they evaluated[26] this contribution at different temperatures. This calculation is more complex for an ionic crystal than for a metal, since f becomes a function of the ratio of the jump frequencies of the anion (ω_a) and of the cation (ω_c) into the divacancy, and it can vary from zero to 0.782. The value of ΔK^{2V} for divacancy diffusion is also unknown.

Rothman and coworkers[26] define two limiting cases for the participation of divacancies in the transport process: 1) assuming that $E^{2V} = 0$ at the melting point, and noting that $E^{1V} = 0.624$, they estimate the minimum contribution from vacancy pairs at the melting point to be 22%; 2) assuming that at 796.6 °C the diffusion is wholly along divacancies they find $E^{2V} = 0.484$. Then, if $\Delta K_2 \leq 0.8$, we have $f^{2V} \leq 0.6$ and $\omega_a/\omega_c < 0.5$. Using these values they obtain[26] the maximum value of $D_2/(D_1 + D_2) = 53\%$ at 589 °C. A more critical analysis of the experimental results suggests that the most reasonable of all the possible values of E^{2V} is <0.2: in this case $f^{2V} \leq 0.25$ and $\omega_a/\omega_c \leq 0.1$. Adopting these values we find that the difference in activation energy between the two diffusion mechanisms is $\Delta Q = Q^{2V} - Q^{1V} = 0.82-0.9$ eV, and the contribution of vacancy pairs to diffusion near the melting point is 30–45%.

Using the ratio $\omega_a/\omega_c \leq 0.1$ to interpret the results of Beniere and coworkers[57] we find that the contribution of vacancy pairs at 800 °C is 50%, i.e. not very different from Rothman's value[26]. Also, with this value of $D_2/(D_1 + D_2)$ Beniere's results[57] give an f_{1V} value nearer to 0.78 than to 1, in good agreement with Nelson and Friauf's value[56].

Self-diffusion isotope effects have been studied also in single crystals of LiF [59] and CsI.[60] In both cases the migration mechanism was found to be by single vacancies.

2. Self-diffusion Istope Effect in Systems with Frenkel' Defects

In all the systems discussed so far the predominant defects are vacancies. As an example of the application of the isotope effect to structures containing Frenkel' defects we shall consider the diffusion of $^{105,111}Ag$ in AgCl.[33]

Studies[61-63] of ionic conduction in AgCl and AgBr single crystals (both pure and doped with divalent cations) have shown that most of the Ag ions migrate by the direct interstitial mechanism in pure AgCl and AgBr. The variation of the quantity $\Phi = \mu_i/\mu_V$ with temperature and pressure (where μ_i and μ_V are the mobilities of the interstitial ions and of the vacancies) has also been studied[61,62]. Self-diffusion can take place by indirect interstitial mechanisms involving collinear (frequency ν_1) or non-collinear jumps. Non-collinear jumps of two types are possible (frequencies ν_2 and ν_3). Peterson and coworkers[33] consider only the ν_1 and ν_2 jumps, pointing out that the ν_3 jump is energetically unfavourable, and they arrive at the following expression for the effect of mass on self-diffusion in silver halides:

$$\frac{D_\alpha}{D_\beta} - 1 = \frac{\Delta D_{tot}}{D_{\beta,\,tot}} = \frac{\Delta D_v}{D_v}\left(\frac{D_v}{D_{tot}}\right) + \frac{\Delta D_i}{D_i}\left(1 - \frac{D_v}{D_{tot}}\right);$$

where $\Delta D_V/D_V$ and $\Delta D_i/D_i$ are the relative differences between the self-diffusion coefficients of the two isotopes for the vacancy and the interstitial mechanism, and $\Delta D_{tot}/D_{tot}$ is the experimentally observed mass effect.

Introducing the functions $F_1(\chi)$ and $F_2(\chi)$, relating the frequencies of the collinear and the non-collinear jump ($\chi = \nu_1/\nu_2$), Peterson and coworkers obtain[33]

$$\Delta D_{tot}/D_{tot} = \alpha_1 \Delta K_1 + \alpha_2 \Delta K_2 + \alpha_v \Delta K_v, \qquad (15)$$

where

$$\alpha_1 = [1-(M_\alpha/M_\beta)^{1/2}]F_1(\chi)[1-D_v/D_{tot}],$$
$$\alpha_2 = [1(M_\alpha/M_\beta)^{1/2}]F_2(\chi)[1-D_v/D_{tot}],$$
$$\alpha_v = [1-(M_\alpha/M_\beta)^{1/2}]f_v D_v/D_{tot},$$

and $M_\alpha = [m_\alpha + (n-1)m_0]$, $M_\beta = [m_\beta + (n-1)m_0]$ for $n = 2$. The ratio D_V/D_{tot} can be obtained from the expression

$$\frac{D_v}{D_{tot}} = \frac{f_v}{(D_{tot}/D_v)(1-\Phi)},$$

where f_V is the correlation factor for the vacancy mechanism. Thus, by using Eqn.(15), the quantities α_1, α_2, and α_V can be calculated for different temperatures.

In order to determine ΔK_V Peterson and coworkers[33] measured the isotope effect for the self-diffusion of $^{105,111}Ag$ in AgBr doped with $CdBr_2$, because diffusion in this system is entirely (100%) by the vacancy mechanism. The best agreement between experiment and calculation was obtained by putting $\Delta K_1 = 1$ and $\Delta K_2 = 0.1$ (note that ΔK_V is constant in very case, $\Delta K_V = 0.66$). This result suggests that the interaction between the migrating atom and the lattice is weak during a collinear jump, whereas during a non-collinear jump the interaction is substantial. This conclusion is confirmed by other experimental results, showing that the activation energy is much lower for the collinear than for the non-collinear jump ($Q_1 = 0.058$ eV, $Q_2 = 0.274$ eV). The difference between the pre-exponential factors is even more striking ($D_{01} = 6.1$ cm^2 s^{-1}, $D_{02} = 1090$ cm^2 s^{-1}), indicating a large entropy of activation for the ν_2 jumps (due to the large number of particles taking part in this process).

3. The Isotope Effect in Hetero-diffusion

Tosi and Doyama[64] calculated the energy of formation (Hf) and the energy of migration (Hm) of cation vacancies in NaCl, KCl, and RbCl, the energy of migration of Na^+, K^+, and Rb^+ impurities in these chlorides, and the impurity–vacancy bond energy (Hb) for these impurities. They obtained[64] a very small value for the energy of migration of Na in RbCl (0.22 eV) in comparison with the Hm value for the migration of Rb^+.

The activation energy for the hetero-diffusion in the "intrinsic" (high-temperature) region is given by the expression

$$Q_{\text{intr}} = \frac{1}{2}H_f + H_m - k\left(\partial \ln f/\partial \frac{1}{T}\right)_{\text{intr}} + H_b.$$

In the "extrinsic" (low-temperature) region, in which no new defects are formed and therefore the term $\frac{1}{2}Hf$ can be ignored, we have

$$Q_{\text{extr}} = H_m - k\left(\partial \ln f/\partial \frac{1}{T}\right)_{\text{extr}} + H_b.$$

Experimental measurements of the temperature dependence of f in both regions give $\frac{1}{2}Hf$ and $(Hm + Hb)$, which can be compared with the calculated values[64]. Peterson and Rothman[65] measured the diffusion coefficients of Na in RbCl and the diffusion isotope effect of $^{22,24}Na$ at different temperatures. Plots for evaluating the ratio $[\partial \ln f/\partial (1/T)]_{\text{extr}}$ are shown in Fig. 2. The experimental results give $Q_{\text{intr}} = 2.06 \pm 0.02$ eV, $Q_{\text{extr}} = 0.59 \pm 0.01$ eV, $[\partial \ln f/\partial (1/T)]_{\text{intr}} = -0.19 \pm 0.02$ eV, $[\partial \ln f/\partial (1/T)]_{\text{extr}} = 0.05 \pm 0.03$ eV. They also obtained[65] $(H_m + H_b) = 0.65$ eV, and $\frac{1}{2}Hf = 1.22$ eV. According to Tosi and Doyama's calculations[64] the interaction energy of the Na^+ ion with a vacancy in RbCl is 0.1 eV. Taking $H_b = 0.1$ eV, we find $H_m = 0.55$ eV, in contrast to the calculated value[64] $H_m = 0.22$ eV. As expected from the theory, the energy of migration of the Na^+ ion is experimentally found to be higher than the energy of migration of the native rubidium ions. The experimental value $\frac{1}{2}Hf = 1.22$ eV also differs significantly from the calculated values (1.05 eV;[64] 1.12 eV),[66] but the migration energy calculated by the conventional ionic model is usually lower than the experimental value in all the alkali metal halide crystals. This discrepancy can be ascribed[66] to an excessive allowance for the polarisation energy of the ions surrounding the vacancy.

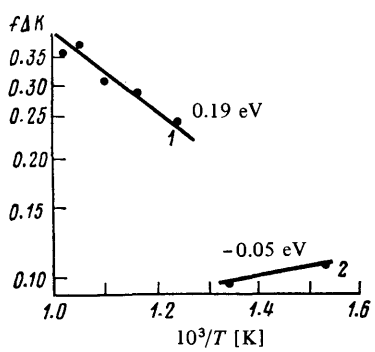

Figure 2. Isotope effect for the diffusion of Na in RbCl in (*1*) the intrinsic region and (*2*) the impurity region[65].

In order to determine $\frac{1}{2}Hf$ Peterson and coworkers[65] assumed that $(H_m + H_b)$ is the same in the intrinsic and the extrinsic state, i.e. that the energy needed to exchange a Na^+ ion with a vacancy and the bond energy are independent of whether the vacancy is free or attached to a multivalent impurity. This assumption was not tested experimentally.

The changed sign of $[\partial \ln f/\partial (1/T)]$ observed on going from the intrinsic to the extrinsic region has been explained qualitatively as follows[65]. In the intrinsic region the Na^+ ion can exchange places with a vacancy very much faster than any of the neighbouring Rb^+ ions. At 575 °C the rate of the Na^+–vacancy exchange (ω_2) is 10 times greater than the rate of the Rb^+–vacancy exchange (ω_0) if all the other jump frequencies are assumed to be equal. On raising the temperature ω_2 increases more slowly than ω_0, i.e. $Hm(Na^+) < Hm(Rb^+)$. This leads to low values of the correlation factor for the diffusion of the impurity, increasing with temperature. On the other hand, in the extrinsic region some of the vacancies may be bound to multivalent impurity ions. If these ions exchange places with vacancies more seldom than sodium ions the correlation factor should be much lower than in the intrinsic region. On the other hand, if H_m for the multivalent ion is intermediate in value between $Hm(Na^+)$ and $Hm(Rb^+)$ the correlation factor will be independent of temperature, or it may even increase as the temperature falls. This behaviour is consistent with both the temperature dependence and the low value of E observed experimentally in the extrinsic region.

VI. DIFFUSION IN TRANSITION METAL OXIDES

Unlike the majority of ionic compounds, many transition metal oxides can exist in non-stoichiometric compositions. These oxides contain non-stoichiometric defects whose concentration depends on temperature and on the oxygen partial pressure. We shall discuss only the oxides NiO, CoO, and FeO, all of which have the NaCl structure and can be described by the general formula $M_{1-x}O$ (in which cation vacancies are assumed to be the main non-stoichiometric defect). In order to preserve the electrical neutrality of the crystal an equal number of electron holes must be produced. At high temperatures the localised electron holes can migrate from one cation site to the next, giving rise to p-type semiconductivity.

In the absence of defect association the formation of cation vacancies in $M_{1-x}O$ can be described by the expression

$$\frac{1}{2}O_2 + \alpha M^{2+} \rightarrow O^{2-} + V_c^{\alpha'} + \alpha M^{3+},$$

where $V_c^{\alpha'}$ is a cation vacancy (negatively charged with respect to the lattice), M^{2+} and O^{2-} are a metal cation and an oxygen anion in their respective lattice sites, and M^{3+} is a cation bearing a localised hole. Obviously, the concentration of cation vacancies and of holes will be proportional to $p_{O_2}^{1/n}$ at a given temperature, where p_{O_2} is the equilibrium partial pressure of oxygen and $n = 2(\alpha + 1)$. Thus, if the electrical conductivity and the self-diffusion of cations are determined exclusively by electron holes and cation vacancies we expect both the cation self-diffusion coefficients and the electrical conductivity to be a function of p_{O_2}.

1. Self-diffusion in NiO and CoO

The effect of oxygen partial pressure on the self-diffusion of cations in NiO and CoO was studied by Volpe and Reddy[71], who found values of n (in the expression $D \propto p_{O_2}^{1/n}$) of 2.9, 3.3, and 3.6 for CoO at 1000, 1150, and 1350 °C respectively, and

6.25 and 5.0 for NiO at 1245 and 1380 °C respectively. The deviation of the n value from 4 (or 6) shows that the single defect model is incapable of interpreting the experimental results adequately. Non-integral values of n can be explained by postulating more than one type of ionised cation vacancy. Since electron holes are more mobile than cation vacancies, the ionised state of a cation vacancy can change many thousands of times during the life time of the vacancy. Hence, if more than one type of ionised cation vacancy is contributing to the equilibrium, a migrating vacancy can have an effective negative charge α which is not necessarily an integer. If we adopt this approach we must introduce a distinction between the mobilities of neutral, singly charged, and doubly charged vacancies in these materials.

Recent work on isotope effects in the self-diffusion of cations has helped to identify the diffusion mechanisms in CoO and NiO crystals. Measurements[72] of the diffusion of ^{55,60}Co in CoO gave $E_{60}^{55} = 0.58 \pm 0.01$ (independent of temperature between 1081 and 1411 °C). The temperature-independence of the isotope effect is evidence that the self-diffusion of Co in CoO involves only one mechanism, and the observed value of E_{60}^{55} suggests a single vacancy mechanism with $\Delta K = 0,75$. Volpe and coworkers[73] also studied the isotope effect for the self-diffusion of ^{57,66}Ni in NiO crystals, and obtained the value $E_{66}^{57} = 0.61 \pm 0.02$, independent of temperature in the range 1201–1678 °C. In an earlier paper[71] the same workers had suggested that a temperature-dependent (interstitial) mechanism may be needed, in addition to the vacancy mechanism, to account for the diffusion of cations in nickel oxide. However, their measurement of the isotope effect clearly shows that in NiO (as in CoO) cation transport occurs exclusively by the single vacancy mechanism, with $\Delta K = 0,78$.

2. Self-diffusion in $Fe_{1-x}O$

The wüstite lattice always contains an apparent excess of oxygen (at 1400 °C the range of compositions is $Fe_{0,95}O$–$Fe_{0,84}O$). The non-stoichiometric excess of oxygen is shown (by X-ray diffraction) to be due to a large number of cation vacancies[74]. At these high concentrations of defects we can no longer use the simple model of individual vacancies, and we must allow for the formation of defect associations (or clusters). Extended defects may give rise to whole regions having the spinel (Fe_3O_4) structure in wüstite. Thus, cluster formation perturbs the direct relationship between the diffusion coefficient and the departure from stoichiometry (x). Not surprisingly, early studies of this relationship gave inconsistent results. For example, a study of diffusion in $Fe_{1-x}O$ with radioactive indicators gave D values increasing with the extent of non-stoichiometry[75], whereas the D values calculated from chemical diffusion coefficients decrease as x increases.

A detailed study of the mechanism of diffusion of cations in wüstite and of the formation of clusters in this material (and its effect on diffusion) was based on measurements[76] of the diffusion coefficients and of the diffusion isotope effect of ^{52,59}Fe in $Fe_{1-x}O$. The results indicate a non-linear relationship between D and x. At high temperatures (1200 °C) and compositions in the range $0.05 \leq x \leq 0.10$ the D values increase by 20% as x increases, but at 800 °C they fall by 40%, and at 1000 °C they are almost independent of x. The measurements of the isotope effect are summarised in Fig. 3, which shows a plot of $E = f(x)$ for different temperatures.

As was pointed out above, the numerical values of E for NiO and CoO are consistent with the single-vacancy mechanism ($f = 0,78$ and $\Delta K = 0,78$ and 0,75 respectively), and are independent of temperature and composition. In wüstite of a given composition E is independent of temperature, but it decreases as the deviation from stoichiometry increases. This effect can be ascribed to changes in the correlation factor if we assume ΔK to be constant for wüstite and for NiO and CoO (a plausible assumption, since all three oxides have the same crystal structure). The fact that the E values are lower in FeO than in NiO and CoO suggests a contribution to the diffusion process from divacancies and even higher-order associations. The experimental results show that the iron cations diffuse by exchanging places with mobile vacancies, with a single mechanism operating over the whole range of composition (as shown by the constancy of the isotope effect parameters at different temperatures but constant x).[76]

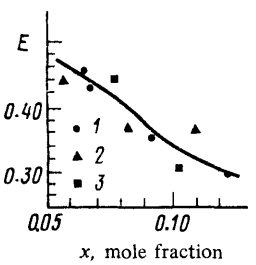

Figure 3. Isotope effect for the self-diffusion of ^{52,59}Fe in $Fe_{1-x}O$ as a function of x [76] at different temperatures: *1*) 1200, *2*) 1000, *3*) 807 °C.

At high concentrations of vacancies clusters are formed: different models of the cluster are discussed in Ref. 77. These defect associations are less mobile than single vacancies, and they show a higher degree of correlation, leading to lower E values at high x. Macroscopic diffusion along free vacancies tends to decrease as the deviation from stoichiometry increases. At a well defined temperature D is independent of x, since the increase in the concentration of free vacancies is balanced by the decrease in mobility and by the increased correlation effect (i.e. by the decrease in f). Lastly, if the temperature is increased still further the higher-order clusters begin to break down, causing D to increase with x.

3. Diffusion of Co in NiO

In order to throw light on the detailed features of impurity diffusion processes, and also to explain the influence of the interaction between impurity cations and defects on the self-diffusion of cations in oxides, Chen and Peterson[78] studied the isotope effect for the diffusion of Co in NiO, and also the simultaneous diffusion of Co and Ni in $(Ni_{1-c}Co_c)O$ crystals. The experimental values of $(f\Delta K)_{Co}$ in NiO increase from 0.45 ± 0.01 and 1179 °C to 0.61 ± 0.01 at 1649 °C. Using the value $\Delta K = 0.78$ obtained for the self-diffusion of Ni in NiO the authors[78] evaluated f_{Co} for the given temperature range (see Fig. 4). These values of f_{Co} were then used to calculate the ratio of the jump frequencies of the impurity ions and the solvent ions, from which was finally obtained the ratio of the diffusion coefficients of Co and Ni (D_{Co}/D_{Ni}) in pure NiO.

The D_{Co}/D_{Ni} values calculated from the diffusion isotope effect agree well with the values obtained directly from experiments on the simultaneous diffusion of Co and Ni in NiO. This agreement between calculation and experiment confirms the validity of the assumptions made in the calculation (including a low value of the energy H_b for the interaction between an impurity cation and a vacancy, i.e. $H_b \ll kT$).

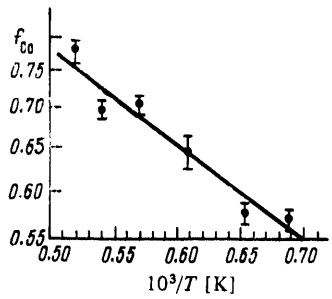

Figure 4. f_{Co} against $1/T$ for the diffusion of Co in NiO.[76]

VII. OTHER APPLICATIONS OF THE DIFFUSION ISOTOPE EFFECT

All the examples considered so far are typical of the practical application of the diffusion isotope effect in detailed studies of migration processes in metals and in ionic crystals. However, the possibilities of the isotopic method are not limited to these systems: the method can be used also to study van-der-Waals and molecular crystals.

Parker and coworkers[79] studied the diffusion of the krypton isotopes $^{78,86}Kr$ in solid argon, and found $E_{86}^{78} = 0.48 \pm 0.25$. This result suggests that the diffusion of Kr in solid Ar involves either a divacancy mechanism or a single vacancy mechanism with $f = 0.78$ and $\Delta K = 0.6$. The low value of ΔK is not surprising, since it can be shown that heavy impurity atoms have very small values of ΔK. Barton[80] calculated the isotope effect for this system theoretically, and obtained $\Delta K = 0.75-0.85$ (a value at the upper limit of experimental results). The calculated value of E_{86}^{78} for the divacancy mechanism is also not too different from the experimental value[79]. However, within the limitations of the model used it is not possible to select the preferred mechanism.

Fox and Sherwood[81] used the mass effect to identify the diffusion mechanism in solid benzene single crystals. The molecules $^{14}C\,^{12}C_5H_6$ and $^{12}C_6\,^2H_5\,^3H$ were used as tracers because their molar volumes are similar (and their spectral characteristics almost identical) to those of ordinary benzene. The authors therefore treated the labelled molecules as "isotopes" of benzene. The measured value $E = 0.8$ suggests mass transport by a single vacancy mechanism, with $f = 0.78$ and $\Delta K = 1$. Similar measurements were carried out on single crystals of naphthalene[82]. The equations for the diffusion isotope effect in solids have been used[83] to interpret data on the isotope effect in liquids. The diffusion of perdeuterobenzene and of ordinary benzene has been studied in chlorobenzene, n-octane, and cyclohexane. The results, which show a negligibly small "isotope effect" for the diffusion of benzene, made the authors conclude[83] that diffusion in these systems is controlled primarily by the viscosity of the solvent.

The diffusion isotope effect has been studied also in glasses (systems in which the structural units have no long-range order). Le Claire[84] observed a small isotope effect for the diffusion of sodium in a sodium silicate glass ($E_{24}^{22} = 0.24$) and concluded that mass transport in this system is by a relay mechanism. Similar measurements were made in other laboratories with the aim of determining the correlation factor or of identifying the mechanism of diffusion in glass[85,86].

A typical application of the diffusion isotope effect to the study of transport processes in disordered crystals was described by Robinson and Peterson[87], who measured the isotope effect for the diffusion of silver along the grain boundaries of metallic silver. The experimental value $\Delta K = 0.46$ can be used to select a series of f and ΔK values compatible with both experiment and theory[88]. The closest agreement between experiment and calculation was obtained for $\Delta K = 0.70-0.76$ and a correlation factor corresponding to the following vacancy–dislocation bond energies: 0.2 eV (vacancy at the centre of the dislocation), and 0.15 eV (vacancy at one interatomic distance from the centre of the dislocation). A measurement[87] of the isotope effect for the diffusion of silver in polycrystalline copper gave much lower values ($E = 0.16$), showing that the diffusion of silver impurity in copper has a high correlation, i.e. that the differences in the vacancy–dislocation bond energy are large. As a result, the silver tends to accumulate along the dislocations.

The separation of isotopes by diffusion has been studied also in geochemistry, because it yields information on the physicochemical conditions of natural processes and on their time scale. The isotopic variations of Mg, Ca, K, and Li in minerals have been examined in detail[89], and the migration parameters obtained have been used to reconstruct the thermal history of the minerals and to determine the temperature and time of their formation.

VIII. METHODS OF MEASURING THE DIFFUSION ISOTOPE EFFECT

According to Eqn.(8) the measurement of the diffusion isotope effect in practice reduces to determining the relative difference between the diffusion coefficients of the migrating isotopes. In order to obtain the E value with a precision of 5% the ratio $\Delta D/D_\beta$ must be measured with an error not exceeding 0.1%. In most experiments the parameters D_α and D_β cannot be measured to better than $\pm(1-2)\%$, and since the difference between the diffusion coefficients is usually between 2 and 3% this difference lies within the experimental uncertainty and is therefore not experimentally detectable.

The problem can be overcome by monitoring the diffusion of the two isotopes simultaneously. Since the diffusion conditions are identical, errors in the measurement of the diffusion temperature and time do not influence the ratio $\Delta D/D_\beta$. In an experiment of this type the precision of the measurement of $\Delta D/D_\beta$ is determined by the precision with which the isotope concentrations c_α and c_β are known. The ratio c_α/c_β can be determined by radio-isotope and mass-spectroscopic techniques to better than 0.1%. The most convenient (and therefore most often used) method is the radioactive indicator methods, which we shall examine in detail.

Mass-spectroscopic methods have been used in geochemical studies to measure the natural abundance ratios of stable isotopes[89]. The methods can be used also to study isotope effects in the diffusion of elements lacking convenient radioactive isotopes. Thus, E_7^6 for the diffusion of $^{6,7}Li$ in Na,[90] AfCl,[70] and TiO_2 [91] has been measured mass-spectrocopically. In this method of analysis the diffusion isotope effect can be calculated by the procedure proposed by Naumov and Ptashnik[70,92]. In the interpretation of mass-spectrometric data on the diffusion isotope effect it is very important to allow for the isotope fractionation which takes place in the ion source during the measurement. Neglect of this factor can lead to spuriously high (ten-fold, or even hundred-fold) results.

By using the radiometric method the concentration of the migrating isotopes can be determined in three ways.

1. If the difference between the half-lives $T_{1/2}^{\alpha}$ and $T_{1/2}^{\beta}$ is fairly large the ratio c_α/c_β can be determined by analysing the time dependence of the total activity.

$$c_{tot} = c_\alpha \exp(-\lambda_\alpha t) + c_\beta \exp(-\lambda_\beta t),$$

where c_{tot} is the measured total activity, λ_α and λ_β are the decay constants, and t is time (measured from the beginning of the experiment).

At present this procedure is the most widely used. If the half-life of one of the isotopes ($T_{1/2}^{\alpha}$, say) is small enough, a second measurement is made at time $t \geq 10T_{1/2}^{\alpha}$, when the short-lived isotope has decayed almost completely and the measured activity corresponds to the concentration of the long-lived isotope c_β. The concentration of the short-lived isotope is then given by the difference $c_\alpha = c_{tot} - c_\beta$.

2. If the isotopes used in the experiment are γ-emitters with their strongest spectral lines at sufficiently different energies, and if the isotopes decay to a significant extent during the measurement, the activity ratio of the isotopes can be expressed as

$$\frac{c_\alpha}{c_\beta} = \frac{(\lambda_\alpha/\lambda_\beta)(A_\alpha/A_\beta)\exp[(\lambda_\alpha - \lambda_\beta)t][1 - \exp(-\lambda_\beta\tau)]}{1 - \exp(-\lambda_\alpha\tau)};$$

where A_α and A_β are the areas under the gamma peak (corrected for background), t is the time elapsed from the beginning of the measurement on a series of samples, and τ is the time of the measurement of one particular sample.

3. If the chosen isotopes emit different radiations (one β-emitter and one γ-emitter, say) it is still possible to determine the concentrations of both isotopes simultaneously by placing the sample between suitable detectors.

We have dealt only with the measurement of the activity ratio of the migrating isotopes (c_α/c_β). We shall now show that this is sufficient for determining E_β^α. In this case of diffusion from a thin layer the concentration of the isotope (c) varies with the depth of penetration (x) and diffusion time (t) according to the expression

$$c = c_0 \exp(-x^2/4Dt),$$

where D is the diffusion coefficient of the isotope. For two isotopes we obtain the ratio

$$\frac{c_\alpha}{c_\beta} = \frac{c_{0\alpha}}{c_{0\beta}} \exp\left[-\frac{x^2}{4D_\alpha t} + \frac{x^2}{4D_\beta t}\right] = \frac{c_{0\alpha}}{c_{0\beta}} \exp\left[\frac{x^2}{4D_\alpha t}\left(\frac{D_\alpha}{D_\beta} - 1\right)\right];$$

$$\ln\frac{c_\alpha}{c_\beta} = \text{const} + \frac{x^2}{4D_\alpha t}\left[\frac{D_\alpha}{D_\beta} - 1\right] = \text{const} - \left[\frac{D_\alpha}{D_\beta} - 1\right]\ln c_\alpha.$$

Thus the relative difference between the diffusion coefficients of the isotopes can be obtained by analysing plots of $\ln(c_\alpha/c_\beta) = f(\ln c_\alpha)$. In this procedure the precision of the determination of the quantity $[D_\alpha/D_\beta - 1]$ depends primarily on the precision with which the relative activities of the isotopes (c_α/c_β) can be measured.

Because of the smallness of the diffusion isotope effect, most workers carry out a blank experiment (in parallel with the measurement of the concentration of the diffusing isotopes) in which the activity of an aliquot of the initial mixture of isotopes is monitored. A zero slope of the $\ln(c_\alpha/c_\beta) = f(\ln c_\alpha)$ plot for the blank experiment confirms that the observed effect arises wholly from diffusion phenomena.

The greatest care is needed in carrying out the isotope experiment. Not less than 10^6 counts should be used in the measurements of activity (in order to minimise the statistical error). In addition to $\ln(c_\alpha/c_\beta) = f(\ln c_\alpha)$ it is useful to plot also the relationship $\ln c_{\alpha,\beta} = f(x^2)$, which should be a straight line. The activity should change by at least three orders of magnitude with depth of penetration, because deviations from normal bulk diffusion, leading to distortions in the linear plot, can only be detected at considerable depths. The blank experiment is an essential part of the procedure. The importance of adhering to all these precautions is well illustrated by published measurements of the isotope effect for the diffusion of Ag in Pb. Herzig and coworkers[93] found $E_{111}^{105} = 1$, but a redetermination of the isotope effect in this system[53] gave $E_{111}^{105} = 0.25$. The latter value of the diffusion isotope effect satisfactorily explains the fast diffusion of Ag in Pb. This very large discrepancy between experimentally measured values of the isotope effect can be ascribed to the failure by Herzig and coworkers[93] to observe all the above precautions.

Isotope diffusion has been studied also in an electric field[59]. In this case the separation of the isotopes is more substantial, and can be used in practice to produce enrichment of the initial mixture with one of the isotopes. The precision of the measurement of the diffusion isotope effect increases with the extent of separation achieved. In these measurements the relative difference between the diffusion coefficients of the isotopes is replaced by its equivalent relative difference between the mobilities of the isotopes ($\Delta D/D_\beta = \Delta\mu/\mu_\beta$). Detailed discussions of the measurement of the diffusion isotope effect with the help of an electric field, and of the advantages of this method, are given in Refs.70 and 92.

---oOo---

In conclusion we note that the importance of the diffusion isotope effect as a new method of gaining information on the details of migration processes in solids is recognised by the inclusion of special chapters on the advantages and applications of this method in all the recently published reviews and monographs devoted to diffusion[94-96].

Reversible Recombination of Radicals

I.V.Khudyakov, P.P.Levin, and V.A.Kuz'min

The results of experimental studies on the kinetics of the reversible recombination of radicals in the liquid phase in relation to phenoxy-, C-centred, peroxy-, and nitroxy-radicals and radical-ions are surveyed. It is shown that steric hindrance has a decisive influence on the rate of recombination of many radicals. The influence of the solvent on the kinetics of the reversible recombination is considered and particular attention is given to the influence of the viscosity of the solvent on the kinetics of the recombination of radicals with a distinct anisotropy of their reactivity.
The bibliography includes 181 references.

I. INTRODUCTION

A typical reaction characteristic of all active short-lived radicals is rapid bimolecular recombination (dimerisation, disproportionation, and electron transfer); all other reactions of short-lived radicals compete with it. If the chemical bond formed in the dimer on recombination is weakened owing to the electronic influence of substituents or if the formation of the dimer entails steric hindrance, then the recombination of radicals is reversible†:

$$R + R \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} D. \qquad (1)$$

Comparatively stable radicals, characterised by a high degree of delocalisation of the unpaired electron, also undergo reversible recombination. Radical–dimer systems have been investigated by spectrophotometry, the temperature jump method, flash photolysis, NMR, kinetic EPR, and EPR combined with the rotating sector method. This review considers the results of experimental studies on the kinetics and thermodynamics of reaction (1) in the liquid phase. The study of the kinetics of the reversible recombination of radicals in various media is important for the understanding of the relation between the structure and reactivity of radicals and the influence of the chemical nature of the solvent and the viscosity of the medium on radical reactions. Data for the kinetics of fast reversible recombination reactions are important for the development of a theory of diffusion-controlled processes.

II. KINETICS OF THE DESTRUCTION OF RADICALS

If the radical–dimer system is displaced from the state of equilibrium (for example, by increasing the concentration of radicals with the aid of a light flash), then k_1 and k_{-1} can be obtained from the analysis of the subsequent relaxation of the system to equilibrium[1-6]. Direct or sensitised photochemical oxidation of compounds RH by flash photolysis can lead to the formation of radicals at an initial non-equilibrium concentration $[R]_0$; subsequently the system also relaxes to equilibrium, which makes it possible to determine the corresponding kinetic parameters[1-4,7]. In the majority of studies experiments yielded the values of K and k_1, k_{-1} being determined from the relation $k_{-1} = Kk_1$. The study of temperature relations makes it possible to obtain the thermodynamic parameters of reaction (1). The following relations were used: $K = \exp(\Delta S^\circ/R)\exp(-\Delta H^\circ/RT)$ (the van't Hoff equation) and $k = (k_B T/h)\exp(\Delta S^{\neq}/R)\exp(-\Delta H^{\neq}/RT)$ (the Wynn-Jones and Eyring equation).

The study of the NMR spectra of diamagnetic dimers present in solution in equilibrium with the corresponding radicals permits the determination of k_{-1} and the investigation of the kinetics of all the elementary reactions occurring in the radical–dimer system[8,9].

Together with reaction (1), irreversible radical destruction or irreversible dimer decomposition reactions can occur in the solution. Possible kinetic schemes for the destruction of radicals are described below[10].

Scheme I

$$D \underset{k_1}{\overset{k_{-1}}{\rightleftarrows}} 2R \xrightarrow{k_2} \text{stable products.}$$

When $k_1 \gg k_2$, one obtains

$$-d[R]/dt = 2k_2[R]^2/(1+4k_1[R]/k_{-1}).$$

If $4k_1[R]/k_{-1} \gg 1$, then the radical destruction reaction will obey a first-order law with $k_{obs} = k_2 k_{-1}/2k_1$, while subject to the condition $4k_1[R]/k_{-1} \ll 1$, the radical destruction will follow a second-order law with $k_{obs} = 2k_2$. Thus at high radical concentrations the destruction is a first-order process while at low concentrations it is a second-order process.

Scheme II

$$2R \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} D \xrightarrow{k_2} \text{stable products.}$$

† Here and henceforth it is assumed that $-d[R]/dt = 2k_1[R]^2 - 2k_{-1}[D]$, $K = k_{-1}/k_1$, and $\Delta X^0 = \Delta X^{\neq}_{-1} - \Delta X^{\neq}_1$, where X is a thermodynamic function.

When $k_{-1} \gg k_3$, one obtains,

$$-\mathrm{d}[\mathrm{R}]/\mathrm{d}t = \frac{2k_3k_1[\mathrm{R}]^2}{k_{-1}(1+4k_1[\mathrm{R}]/k_{-1})}.$$

Similarly, when $4k_1[\mathrm{R}]/k_{-1} \gg 1$, the radical destruction obeys a first-order law with $k_{obs} = k_3/2$, and, when $4k_1[\mathrm{R}]/k_{-1} \ll 1$, it obeys a second-order law with $k_{obs} = 2k_3k_1/k_{-1}$.

On the basis of kinetic data alone, it is difficult to distinguish Schemes I and II.

Scheme III

$$2\mathrm{R} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{D}; \quad \mathrm{R} \xrightarrow{k_4} \text{stable products.}$$

When $k_1[\mathrm{R}] \gg k_4$, one obtains

$$-\mathrm{d}[\mathrm{R}]/\mathrm{d}t = k_4[\mathrm{R}]/(1+4k_1[\mathrm{R}]/k_{-1}).$$

When $4k_1[\mathrm{R}]/k_{-1} \gg 1$, the radical destruction obeys a zero-law with $k_{obs} = k_4k_{-1}/4k_1$. When $4k_1[\mathrm{R}]/k_{-1} < 1$, a first-order radical destruction reaction with $k_{obs} = k_4$ should take place.

III. DIFFUSION-LIMITED RECOMBINATION OF RADICALS

The fundamental question which arises from the analysis of the kinetics of the fast recombination of radicals is whether the reaction is diffusion-limited. For bimolecular reactions fully limited by diffusion, the observed rate constant is directly proportional to the quantity T/η, where η is the viscosity of the solvent:

$$k \propto T/\eta. \tag{2}$$

For bimolecular reactions of radicals limited by translational diffusion, we have[15,34,52,64]

$$k = \frac{N}{1000} \cdot \sigma \cdot 4\pi\rho D \simeq \sigma \cdot \frac{8RT}{3000\eta}, \text{ litre mol}^{-1}\text{ s}^{-1},$$

where N is the Avogadro number, $\sigma = 1/4$ is a statistical factor taking into account the fact that only radical pairs which are in the singlet state during the encounter lead to the reaction products, ρ the reaction radius, and D the mutual diffusion coefficient of the radicals. For a reaction between identical radicals [reaction (1)],[15]

$$k_1 = k_{diff} \simeq \sigma \cdot \frac{4RT}{3000\eta}. \tag{3}$$

The choice of the numerical value of the coefficient $4\sigma/3000$ in Eqn.(3) is usually somewhat arbitrary: the questions of the value of σ ($1/4 < \sigma < 1$; see, for example, Nonhebel and Walton[11] and Buchachenko et al.[12]), of the replacement of the coefficient 4/3000 by 4/2000 (see, for example, Tyrrell[13]), etc. have been discussed.

For reactions controlled by translational diffusion, the following expression is valid[1,14]:

$$\Delta H^{\neq}_{diff} = B, \tag{4}$$

where B is the activation energy for the viscous flow of the solvent:

$$\eta = \eta_0 \exp(B/RT).$$

The study of the influence of the viscosity of the solvent on the observed rate of reaction makes it possible to discover, within the framework of the contact model[15], the relations between the rate constants for a diffusion-controlled reaction and the chemical reaction proper within the cage.

According to Noyes[15],

$$1/k_1 = 1/k_{diff} + 1/k_{chem.} \tag{5}$$

It is apparently always possible to select a solvent with sufficiently high viscosity in which the reaction will occur under the diffusion-dependent conditions. The relation $k_{chem} \gg k_{diff}$ and Eqn.(2) then hold. At sufficiently low viscosities deviations from Eqn.(2) may be observed and Eqn.(5) must be used.

The contact model of chemical reactions presupposes the diffusion of the reactants to the site of their contact where the distance between them is ρ and where there is a possibility of a chemical reaction with a rate constant k_{chem}. In the generalised contact model[16,52] account is taken of two important factors.

1. The last step in the process involving the mutual approach of the reactants differs from the previous step owing to the short-range interaction and is described as a jump over a finite distance at a frequency which, like the rate of irreversible process, depends on the solvation interactions of the reactants.

2. The rate of reaction between the reactants on contact is different for their different conformations or mutual orientations.

Allowance for the first condition leads to the subdivision of reactions into three stages: the mutual approach of the reactants to a distance $\rho^* > \rho$, insertion in the first coordination sphere, and the chemical reaction proper. This is reflected in the expression[16]

$$1/k = 1/k'_{diff} + 1/k_{ins} + 1/(gk_{chem}), \tag{6}$$

where $k'_{diff} = 4\sigma\pi\rho^*D$ (ρ^* is the radius of the second coordination sphere), k_{ins} is the rate constant for insertion in the first coordination sphere from the second, and the parameter g characterises the equilibrium radial distribution function. As a result of the introduction of the parameter g, Eqn.(6) takes into account the short-range order and the capacity of the reactants for the formation of complexes with the solvent ($g < 1$) or for the formation of dimers (complexes between the reactants) ($g > 1$), which increase their contact time. Evidently, like k_{diff}, the constant k_{ins} depends on the molecular mobility of the medium. However, k_{ins} can be comparatively small, whereupon the insertion in the first sphere and not translational diffusion limits the process in a viscous medium[16].

The distribution of unpaired electrons in radicals is in most cases anisotropic; the reactivity of radicals is therefore also anisotropic. The anisotropy of the reactivity is characterised by the geometrical steric factor f_g, equal to the probability of the occurrence of a mutual orientation favourable for recombination at the instant of the first contact on formation of the diffusional pair. It is usually assumed that the reactant is spherical and that the reaction region on the surface of the sphere is bounded by a circle characterised by an angle θ (the angle between the radius of the sphere bounding the reaction region and the radius directed to its centre). For bimolecular reactions between identical species, we then have $f_g = \sin^4(\theta/2)$. The anisotropy of the reactivity is partly or completely averaged out as a result of the rotational and translational movement of the reactants during their encounter (contact time)[17-21,32]. In the general case one can write for bimolecular reactions limited by molecular mobility

$$k = \sigma 4\pi\rho D f_{eff},$$

where f_{eff} is the effective steric factor and $f_g < f_{eff} \leq 1$.

The relations between f_{eff} and f_g have been considered in various theoretical studies[18–21,32].

A rigorous solution of the diffusional problem for a bimolecular reaction between anisotropic molecules (taking into account particular assumptions) usually has no simple analytical form and is carried out by numerical methods[19,20,32]. An approximate solution susceptible to an experimental test has been put forward[21]:

$$1/k = 2\,[\sigma k'_{chem}(1-\cos\theta)]^{-1} + 2\,[k_{diff}(1-\cos\theta)\theta]^{-1}, \quad (7)$$

where k'_{chem} is the recombination rate constant for a favourable mutual orientation of the reactants in the cage.

If it is assumed that the anisotropy of the reactivity is averaged out as a result of rare rotations of the reactant by large angles, the solution of the diffusional problem leads to the expression[12,18]

$$1/k = (\sigma f_g k'_{chem})^{-1} + (1 + f_g q^{1/2})\,[(1 + q^{1/2}) f_g k_{diff}]^{-1}, \quad (8)$$

where q is the ratio of the contact time in the formation of the pair and the characteristic rotational diffusion time ($q = \tau_c/\tau_{rot}$). For quantitative estimates, $q = 6$ has been used[14].

Analysis of experimental data for the kinetics of the rapid recombination of many radicals (see Sections IV–X) shows that steric hindrance in recombination, characterised by the quantity f_g, has a decisive influence on k_1.

Like k_1, the constant k_{-1} depends on k_{diff} (and hence on viscosity)[22–24]:

$$1/k_{-1} = 1/k_{diss} + k_{chem}/(k_{diss} k_{diff}), \quad (9)$$

or, in the case of anisotropic reactants[14,18],

$$1/k_{-1} = 1/k_{diss} + k_{chem}(1 + f_g q^{1/2})\,[(1 + q^{1/2})\, k_{diss}\, k_{diff}]^{-1}, \quad (10)$$

where k_{diff} is the elementary rate constant for the association of dimers into radicals in the cage.

IV. THE INFLUENCE OF SOLVENT VISCOSITY ON THE KINETICS OF THE REVERSIBLE RECOMBINATION

The study of the influence of solvent viscosity on the kinetics of fast reversible radical recombination reactions is important for tests of theoretical ideas concerning diffusion-controlled reactions (see Section III).

The influence of the viscosity of the medium on the kinetic and thermodynamic parameters of the reversible recombination of phenoxy-radicals has been studied[1,14,16,24–27]. Binary mixtures of solvents, with widely differing viscosities but of a similar chemical type, have been used, which made it possible to vary smoothly the viscosity over a wide range; under these conditions, other parameters of the binary mixtures changed only slightly. Fig.1 presents the variation of k_1 with the viscosity of the solvent for phenoxy-radicals of different structures (see Table 1). It follows from the data in Fig.1 that the kinetics of the recombination of radicals (I)–(V) obey Eqn.(2) as well as the relations $k_1 \propto T/\eta^{0.8}$ and $k_1 \propto T/\eta^{1.2}$; the majority of the constants k_1 are smaller than the values of k_{diff} calculated by Eqn.(3) (the discrepancy between the k_1 and k_{diff} is within an order of magnitude).

Note. ΔH and ΔS are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1} respectively; the average errors of the determinations are 20% in the constants, ±0.5 kcal mol^{-1} in ΔH, and ±2 cal mol^{-1} K^{-1} in ΔS. The viscosities are 0.58 for methanol, 0.59 for toluene, 18.4 for dibutyl phthalate (DBP), 19.9 for ethylene glycol (E), and 24.5 cP for the 5 : 1 (by volume) cyclohexanol–methanol (CH–M) mixture.

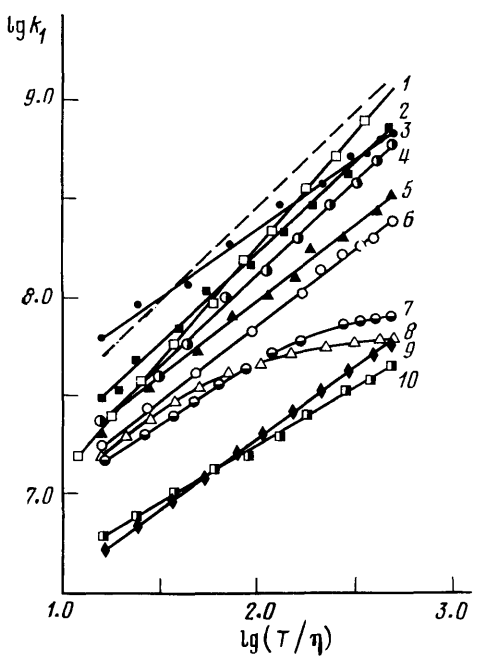

Figure 1. Relations between lg k_1 and lg (T/η) at 20 °C (η in cP) for phenoxy-radicals of different structure[1,14] [1) and 2) (I); 3) (II); 4) (III); 5) (IV); 6) (V); 7) (VIII); 8) (IX); 9) (X); 10) (XI)] in methanol–cyclohexanol (curve *1*), methanol–ethylene glycol (curve *8*), and toluene–dibutyl phthalate (curves *2–7*, *9*, and *10*) mixtures. Dashed curve—relation predicted by Eqn.(3). The names of the radicals are given in Table 1.

The discrepancy between the theoretical and experimental values of the rate constant for a diffusion-controlled reaction can apparently amount to not more than an order of magnitude due to the following causes: the lack of validity of the application of the Stokes–Einstein law; the uncertainty in the numerical value of the statistical factor σ (see Section III); the lack of validity of the assumption that the hydrodynamic radius is equal to half the reaction radius[5,16]. Thus the recombination of radicals (I)–(V) in a given range of viscosities is limited mainly by translational diffusion.

The rates of recombination of radicals (VIII) and (IX) (Fig.1) depend on the viscosity, but the reaction occurs under conditions intermediate between kinetic and diffusion-dependent. Numerical values of k_{chem} have been obtained[1,14] for these radicals using Eqn.(5) (Fig.2). For radicals characterised by linear relations between $\lg k_1$ and $\lg(T/\eta)$ (Fig.1), $k_{chem} \gg k_{diff}$ (Fig.2). The recombination of radicals (VIII) and (IX) in the cage apparently involves the overcoming of an activation barrier, since the given radicals form complexes with molecules of aromatic solvents (see Section X). The recombination probably involves desolvation, which is accompanied by the expenditure of a definite amount of energy.

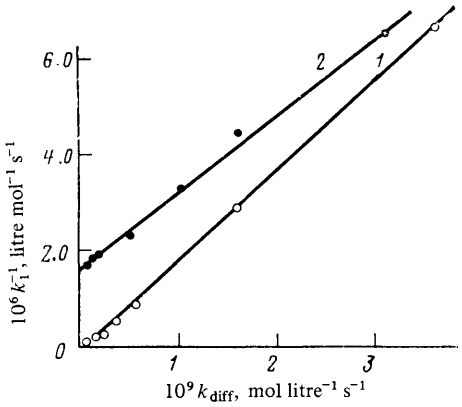

Figure 2. Relations between k_1^{-1} and k_{diff}^{-1} at 20 °C ($k_{diff} = 8RT/3000\eta$): 1) radical (I) in methanol–cyclohexanol mixture; 2) radical (IX) in methanol–ethylene glycol mixture[1].

The values of k_1 obtained for radicals (X) and (XI) are smaller by two orders of magnitude than k_{diff} (Table 1). The steric hindrance generated by the t-butyl groups leads to a low value of f_g for the recombination of radicals[7,14,25]. The value of f_g estimated by Eqn.(8) for 2,6-di-t-butylphenoxy-radicals is ~0.03.[14]

Eqn.(4) holds for radicals whose recombination is limited by translational diffusion[1,14,25]. For the recombination of radicals which occurs in only some of the encounters between the radicals in solution (for a low value of f_g), low and even negative $\Delta H_1^{\neq}$ are observed (Table 1 and Refs.7–9, 14, 25, and 28). In order to account for the low observed values of $\Delta H_1^{\neq}$, it is usually assumed that the recombination of radicals takes place not in one but in at least two stages[14,28]:

$$PhO^{\cdot} + PhO^{\cdot} \rightleftarrows (PhO^{\cdot} \ldots PhO^{\cdot}) \rightarrow \text{dimer} . \qquad (11)$$

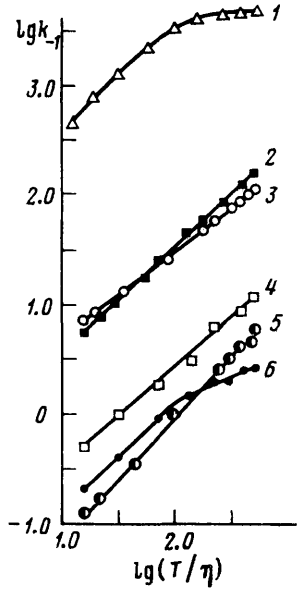
The formation of the complex should promote the averaging of the anisotropy of the reactivity as a result of the increase of the lifetime of the radical pair[14]. The radicals in the complex are apparently linked by dipole–dipole and dispersion interactions, which are not rigorously directional and do not prevent the rotation of the radicals relative to one another. The conversion of the complex into the dimer apparently involves the rotation of the radicals relative to one another in the complex and the rate of this reaction is inversely proportional to the viscosity[14]. The observed $\Delta H_1^{\neq}$ can then be expressed as follows[14]:

$$\Delta H_1^{\neq} \simeq \Delta H_c^{\circ} + B, \qquad (12)$$

where ΔH_C° is the heat of formation of the complex and B is the activation energy for the viscous flow of the solvent. Furthermore, $\Delta H_C^{\circ} < 0$ and $\Delta H_1^{\neq} < B$.

The relations in Fig.1 have a slope less than unity for the majority of radicals. This type of relation is predicted by the theory of diffusion-controlled reactions taking into account the rotation of the reactants[19], subject to the condition that the distribution of the reaction centre over the surface of a sphere is described by a smooth and not a stepped function. This hypothesis corresponds to reality to a greater extent than the hypothesis of a centre with sharply outlined boundaries[14].

The constants k_{-1} for radicals (I)–(XI) also depends strongly on the viscosity (Table 1, Fig.3). The dependence of $\lg k_{-1}$ on $\lg(T/\eta)$ is then of the same type as the corresponding relations between $\lg k_1$ and $\lg(T/\eta)$ (cf. Figs.1 and 3). This is consistent with the theory of diffusion-controlled reactions [see Eqns.(9) and (10)].[18,22–24] The rate constants for the decomposition of the dimers of radicals (VIII) and (IX) in the cage have been obtained[24].



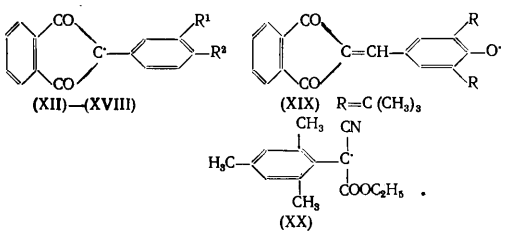


Figure 3. Relations between $\lg k_{-1}$ and $\lg(T/\eta)$ for the dissociation of the dimers of phenoxy-radicals[14,24] at 20 °C (η in cP): 1) radical (IX) in methanol–ethylene glycol mixture; 2)–6) radicals (I), (XI), (VII), (V), and (VIII) respectively in toluene–dibutyl phthalate mixture.

The relations between k_1 and η (Fig.4) have been obtained for C-centred and phenoxy-radicals having the following structures[5]:

Here R^1 = H and R^2 = $N(CH_3)_2$ (XII), R^1 = H and R^2 = $N(C_2H_5)_2$ (XIII), R^1 = H and R^2 = $N(n\text{-}C_3H_7)_2$ (XIV), R^1 = H and R^2 = $N(n\text{-}C_4H_9)_2$ (XV), R^1 = H and R^2 = $N(C_6H_5)_2$ (XVI), R^1 = R^2 = OCH_3 (XVII), and R^1 = Br and R^2 = $N(CH_3)_2$ (XVIII). Table 2 presents the kinetic and thermodynamic parameters of reaction (1) involving radicals (XII)–(XX) in chlorobenzene.

Table 2. Kinetic and thermodynamic parameters of reaction (1) involving C-centred and phenoxy-radicals (XII)–(XX) in chlorobenzene at 20 °C.[5]

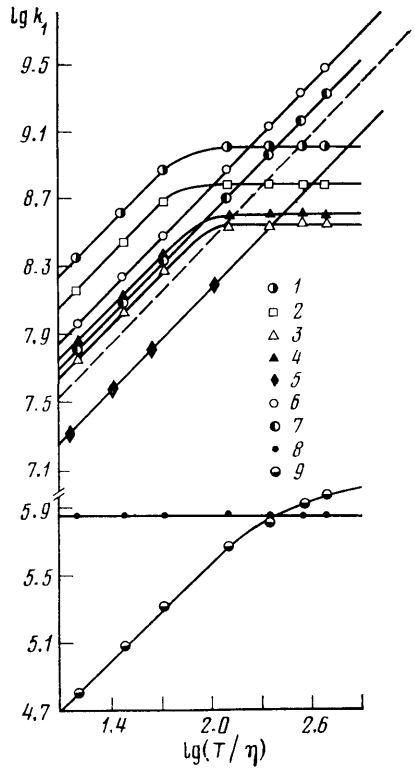
(XX)	0.06	5	0.48	80	2.8	15.2	12.4	21	−13	8

Note. ΔH and ΔS are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1} respectively; the errors of the determinations are 20% in k_1 and k_{chem}, 20% in K, 40% in k_{-1}, ±0.5 kcal mol^{-1} in ΔH, and ±2 cal mol^{-1} K^{-1} in ΔS.

The relations presented in Fig.4 for radicals (XVI)–(XVIII) are represented by straight lines with a slope of unity. The values of k_1 obtained for these radicals differ by not more than a factor of 2 from k_{diff} [Eqn.(3)] and $\Delta H_1^{\neq}$ is close to B (see Table 2). The recombination of radicals (XVI)–(XVIII) is limited by translational diffusion.

The recombination of radicals (XII)–(XV) for $\eta \geqslant 5$ cP takes place under diffusion-dependent conditions and the recombination for $\eta \leqslant 2$ cP takes place under kinetic conditions (Fig.4). The values of k_{chem} have been obtained for these radicals (Table 2). The recombination of radicals (XIX) takes place under kinetic conditions over the entire range of viscosities (Fig.4 and Table 2). The values of ΔH_1 obtained for the recombination of radicals (XIX) in toluene[5] and chlorobenzene (Table 2) exceed the corresponding values of B for solvents[5].

The constant k_1 for radical (XX) in the range of viscosities 2–18.4 cP varies with the viscosity in accordance with Eqn. (2), but the values of k_1 obtained for this radical are smaller than the corresponding k_{diff} almost by three orders of magnitude (Fig.4). The structural formula of radical (XX) shows that the reaction centre is strongly shielded by substituents and the radical is characterised by a pronounced anisotropy of reactivity ($f_g < 10^{-3}$). The recombination takes place when the necessary mutual orientation of the reactants is achieved on attainment of the radius of contact, which apparently occurs only in a few encounters out of a thousand between radicals (XX) in solution. It is only possible that the recombination of radicals (XX) is limited by the rate of insertion in the first coordination sphere [see Eqn.(6)].[5,16]



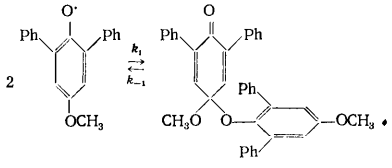


Figure 4. Relations between $\lg k_{-1}$ and $\lg(T/\eta)$ at 20 °C (η in cP) for aromatic C-centred and phenoxy-radicals in toluene–dibutyl phthalate mixture[5]: 1) (XII); 2) (XIII); 3) (XIV); 4) (XV); 5) (XVI); 6) (XVII); 7) (XVIII); 8) (XIX); 9) (XX). Dashed line—relation predicted by Eqn.(3). The formulae of the radicals are given in the text.

V. PHENOXY-RADICALS

The principal channel for the destruction of phenoxy-radicals in solutions in the absence of radical acceptors involves their reaction with one another. The fastest stage in this reaction is usually recombination. The C–C or C–O bond formed as a result of recombination is fairly weak (ΔH° = 10–30 kcal mol^{-1}; see, for example, Khudyakov et al.[29]). The recombination of phenoxy-radicals is therefore reversible, for example:

In many cases a fairly high value of $K = 10^{-8}$–10^{-3} mol litre^{-1} is then observed (see, for example, Khudyakov et al.[29]).

The structures of dimerising phenoxy-radicals as well as the structures and physicochemical properties of the phenoxy-radical dimers have been considered in a number of reviews and monographs[11,30,31,33,116,169]. However, numerous studies on the kinetics and thermodynamics of the reversible recombination of the radicals have been published recently and these will be considered in the present section.

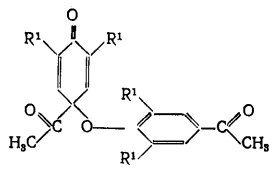
1. The Structures of Dimerising Phenoxy-Radicals

Different 2,4,6-substituted phenoxy-radicals, whose substituents do not contain reactive hydrogen atoms, can exist for a long time in solution in equilibrium with their dimers. 2,6-Di-t-butyl-4R-phenoxy-radicals[8,9,35–42,176,181], 2,6-diphenyl-4R-phenoxy-radicals[1–3,29,43–47], polyhalogenophenoxy-radicals[48,49], certain naphthoxy-radicals[50,170], radicals derived from phenanthrenols[51], and other phenoxy-radicals[181] are involved in equilibrium (1) in solution.

The equilibrium constant depends significantly on the steric hindrance due to the substituents and also on the influence of the substitutents on the electronic structures of the radical and the dimer. For example, the steric hindrance generated by the t-butyl groups in the 2,4,6-tri-t-butylphenoxy-radical precludes the formation of its dimers in solution even at −100 °C.[53,177] The 2,6-di-t-butyl-4-phenylradical[54] and the 2,6-di-t-butyl-4-methoxyphenoxy-radical[55] are also monomeric in solution. However, the replacement of one t-butyl group in the 2,4,6-tri-t-butylphenoxy-radical in the *ortho*-position by a benzene ring or a t-butoxy-group, which give rise to a smaller steric hindrance, makes the radical capable of the formation of dimers in the solution[56–59]. Sterically hindered phenoxy-radicals readily form dimers with sterically unhindered phenoxy-radicals[60–63,65–72].

If the substituent in the *ortho*- or *para*-position in a 2,4,6-substituted phenoxy-radical contains reactive hydrogen atoms, then the reaction between such radicals leads to the formation of stable products as a result of disproportionation. The disproportionation reaction can involve reversible dimerisation as an intermediate stage if the substituents in the phenoxy-radical do not give rise to an appreciable steric hindrance. For example, the disproportionation of the 2,6-di-t-butyl-4-methylphenoxy-radical[7,73–75], the 2,4,6-trimethylphenoxy-radical[73], the 4-methyl-2,6-diphenylphenoxy-radical[75], and the 2,6-diphenyl-4-diphenylmethylphenoxy-radical[7,75] takes place in this way.

The observed decrease of the equilibrium concentration of phenoxy-radicals as a result of the disproportionation reaction [after the establishment of equilibium (1)] obeys a first-order law when the condition $[\overline{PhO^{\cdot}}] \gg K/4$ holds (see Section II). The observed destruction of radicals was described in terms of a first-order law for the disproportionation of a series of 2,6-di-t-butyl-4R-phenoxy-radicals, where R = C_2H_5,[76] CH_2OCH_3, CH_2OCOCH_3, etc.[77,78] Consequently the fast reaction (1) takes place simultaneously with the disproportionation reaction.



The disproportionation of the 3,6-di-t-butyl-2-hydroxyphenoxy- and 2,6-diphenyl-4-(4′-hydroxy-3′,5′-diphenylphenoxy)phenoxy-radicals has been investigated[79,80]. It was suggested on the basis of kinetic data that the disproportionation reaction is accompanied by reversible recombination.

Phenoxy-radicals without substituents in the *ortho*- or *para*-positions recombine with formation of stable dimeric products. Metastable dimers having the structure of a diketone or quinol are formed in this reaction and then enolise irreversibly with formation of the final products. The formation of metastable dimers is also reversible[25,28,29,81,82].

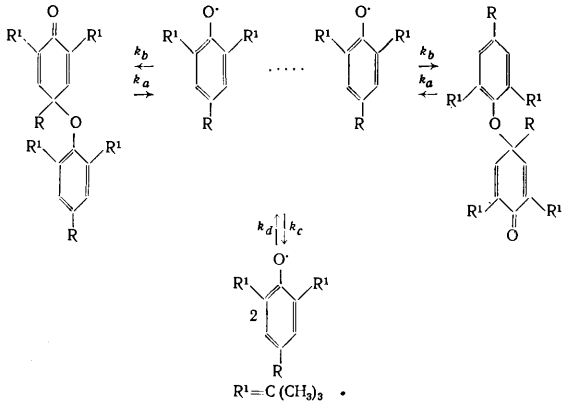
2. The Structures of Phenoxy-Radical Dimers

The dimerisation of phenoxy-radicals leads to the formation of C–O or C–C bonds. O–O dimers cannot be stable, since the high stabilisation energy of phenoxy-radicals (17.5 kcal mol^{-1}),[83] due to the delocalisation of the unpaired electron, leads to a low dissociation energy of the O–O bond[53].

On formation of the C–O bonds, the corresponding dimers have the structure of quinol ethers. This structure has been established reliably for dimers formed on recombination of the 2,4,6-tri-t-butylphenoxy-radical with various sterically unhindered phenoxy-radicals[60–63,65]. Dimerisation takes place via the carbon atom in the *para*-position in the 2,4,6-tri-t-butylphenoxy-radical with formation of a "heat-to-tail" structure. Quinol ethers are formed on dimerisation of the majority of 2,4,6-substituted phenoxy-radicals. The "head-to-tail" structures have been attributed to the dimers of 2,6-di-t-butylphenoxy-radicals containing the substituents CH_3,[84] OCOR,[35,37] and COR [8,9,35–37] (where R = alkyl) in the *para*-position, for example:

The dimers of the 2,4,6-triphenylphenoxy- [85,86] and 4-methoxy-2,6-diphenylphenoxy-radicals[87] have the same structure. The structure of quinol ethers has also been attributed to the dimers of radicals derived from phenanthrenol[51].

The dimerisation of 2,6-di-t-butyl-4R-phenoxy-radicals can also entail the formation of a C–O bond involving the carbon atom in the *ortho*-position. Such a structure has been postulated, for example, for the dimer of the radical with R = CO_2X (X = alkyl).[37] The third possible structure of dimers, where recombination results in the formation of a C–C bond involving the carbon atoms in the *para*-position (a "tail-to-tail" structure), is believed to be feasible for the dimers of the 2,6-di-t-butyl-4-ethoxycarbonylphenoxy-,[36] 2,6-di-t-butyl-4-diethylphosphinylphenoxy-, and 2,6-di-t-butyl-4-diethylphosphinodithionylphenoxy-radicals[88] and also in the case of the 6-t-butoxy-2,4-di-t-butylphenoxy-[59] and 2,4-di-t-butyl-6-phenylphenoxy-radicals[56]. The formation of an N–N bond on dimerisation of the 2,6-di-t-butyl-4-cyanophenoxy-radical has been postulated[30]. 2,6-Dialkyl-phenoxy-radicals containing the β-phthalylvinyl substituted in the *para*-position [e.g. radical (XIX)] dimerise with formation of a C–C bond[172].



The structure of the primary dimers formed on dimerisation of phenoxy-radicals without substituents in the *ortho*- or *para*-positions can be postulated on the basis of the structure of the final stable dimerisation products. Depending on the positions and bulk of the substituents and on the nature of the solvent, the transfer or elimination of hydrogen atoms can then result in the formation of C–O or C–C bonds[11,30].

The probability of the formation of C–C bonds on dimerisation increases in dimethylformamide (DMF) and in acids compared with non-polar solvents (and also on raising the temperature)[89], which can be explained by the increase of the stability of the primary dimers with a C–C bond and by the decrease of the stability of the primary dimers with a C–O bond with increase of solvent polarity[29]. For example, 2,6-diphenylphenol is oxidised in solvents of low polarity to 2,6-diphenyl-4-(2′,6′-diphenylphenoxy)phenol[89]; consequently the primary dimer has the structure of a quinol ether of the "head-to-tail" type. However, in DMF and in acids the product is the corresponding diphenoquinone[89], which shows that the primary dimers have the "tail-to-tail" structure.

3. Kinetics of the Reversible Recombination of Phenoxy-Radicals

The rate constants for the recombination of phenoxy-radicals (k_1) and for the dissociation of the resulting dimers (k_{-1}) depend significantly on the chemical nature, bulk, and positions of the substituents in the benzene ring (Table 3).

Recombination reaction. The kinetics of the recombination of 2,6-di-t-butyl-4R-phenoxy-radicals have been investigated by NMR,[8,9] flash photolysis[14,25], and EPR [176] (Tables 1 and 3). The following mechanism of reaction (1) with participation of 2,6-di-t-butyl-4R-phenoxy-radicals has been proposed[9] on the basis of NMR data:

The dissociation of the dimer with a rate constant k_a results in the formation of an intermediate of unknown structure—a complex between the radicals. The complex can be reconverted into the initial dimer with a rate constant k_b, or into a dimer in which the radicals have changed places (also with a rate constant k_b), or it can dissociate into two free radicals with a rate constant k_c. The radicals recombine to a

ΔH and ΔS are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1} respectively. The average errors of the determinations are 20% in k_1, 20% in k_{-1}, 30% in K, ±0.5 kcal mol^{-1} in ΔH, and ±2 mol^{-1} K^{-1} in ΔS.

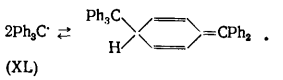
complex with a rate constant k_d. When the above complexes are stationary and $k_b \gg k_c$ (the validity of this assumption has been confirmed by experimental data[9]), we have $k_{-1} = k_a k_c / 2k_b$ and $k_1 = k_d$. The exchange of magnetically-non-equivalent parts in a dimer is called a "flip-flop" process and is characterised by a rate constant $k_a/2$.

We may note that the quantities k_1 (and k_d) are lower by several orders of magnitude than k_{diff} (Table 3), i.e. the given complex between the radicals is by no means formed in every encounter between them in solution. It may be that the formation of the complex is a non-elementary reaction, since negative values of $\Delta H_1^{\neq}$ ($\Delta H_d^{\neq}$) are observed (Table 3). The hypothesis of the existence of complexes between sterically hindered phenoxy-radicals makes it possible to explain also the low and even negative values of $\Delta H_1^{\neq}$ (Tables 1 and 3) observed for these radicals (Section IV). It can be assumed that the recombination of phenoxy-radicals takes place in the same way as the recombination of the "related" benzyl radicals[28]. Quantum-chemical calculations have shown that, when benzyl radicals approach one another to a distance of 2.9 Å, a "sandwich" type complex between the radicals is energetically favourable, while at shorter distances the "head-to-head" structure is preferred, which is converted into the final recombination product (bibenzyl).[28]

The quantity k_1 increases significantly when the t-butyl groups in the *ortho*-positions in the phenoxy-radical are replaced by benzene rings or methoxy-groups (Table 3). The decreased shielding of the oxygen atom of the phenoxy-radical by the benzene rings compared with t-butyl groups can be understood if one takes into account the fact that the phenyl group can rotate freely and, for angles of rotation close to 90° relative to the plane of the phenoxy-ring, the steric hindrance is small.

The dimerisation reactions of mono- and di-phenylphenoxy- and 4-alkoxy-2,6-di-phenylphenoxy-radicals are limited mainly by translational diffusion (see Section IV). The data in Table 3 show that, with increase of the number of carbon atoms in the hydroxyalkyl substituent in the 4-alkoxy-2,6-diphenylphenoxy-radical, k_1 decreases, which may be caused by the fact that, with increase of the bulk of the radical, the area of the reaction region apparently remains virtually unchanged; as a result, f_g and the rate constant diminish. On replacement of the hydroxyalkyl substituent by the phenyl substituent, a further decrease of k_1 is observed, which is due to the increase of steric hindrance on dimerisation of the radicals. The constant k_1 becomes smaller still on replacement of phenyl substituents in the *ortho*-positions by the more bulky cyclohexyl groups (Table 3).

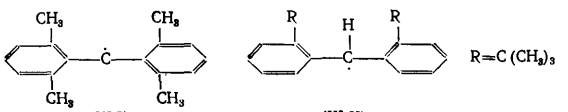
Thus the steric hindrance generated by substituents in the phenoxy-radical has a decisive influence on the kinetics of their recombination.



The dissociation of dimers. The rate constant for the dissociation of the dimers of 2,6-diphenyl-4R-phenoxy-radicals (k_{-1}) as well as $\Delta H_{-1}^{\neq}$ depend significantly on the nature of the substituent (Table 3). The quantity k_{-1} diminishes and $\Delta H_{-1}^{\neq}$ increases with enhancement of the electron-accepting capacity of the substituent. A similar relation has been observed for the dissociation of the 1:1 complexes formed by the 2,4,6-tri-t-butyl-phenoxy-radical with sterically unhindered phenoxy-radicals[28,71].

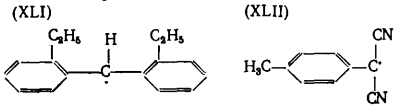
The constants k_{-1} for the dissociation of the complexes of the 2,4,6-tri-t-butylphenoxy-radical with *meta*- and *para*-substituted phenoxy-radicals are correlated with the parameters σ^+ of the substituents, the correlation having $\rho = -3.3$.[71] The ratio of the constant k_{-1} for the above 1:1 complexes ("dimers") to the rate constant for the abstraction of a hydrogen atom by the 2,4,6-tri-t-butylphenoxy-radical from the corresponding sterically unhindered phenol is almost independent of the substituent. Comparatively high values of k_{-1} have been observed[71] for radicals with substituents in the *ortho*-position; here $\Delta H_1^{\neq}$ were lower than the values expected on the basis of the electronic influence of the substituents. The explanation is that the *ortho*-substituents give rise to steric hindrance on dimerisation. The quinol ethers formed from the 2,4,6-tri-t-butylphenoxy-radical and *ortho*-substituted phenoxy-radicals are therefore less stable. For example, the strain energy of the C–O bond formed on dimerisation of the 2,6-dimethylphenoxy- and 2,4,6-trichlorophenoxy-radicals is 5 kcal mol^{-1}.[71]

VI. AROMATIC C-CENTRED RADICALS



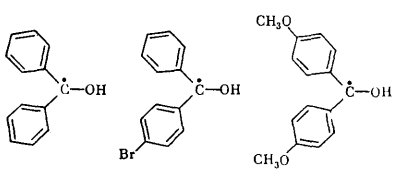
Different C-centred radicals with aryl substituents exist in solution in equilibrium with their dimers[5,6,91,92]. Phenyl substituents (±*E*-substituents) greatly facilitate the dissociation of substituted ethanes into arylmethyl radicals, stabilising the latter. The difference between the equilibrium constants for the mono-, di-, and tri-arylmethyl radicals can be explained by the method of perturbed molecular orbitals[93]. However, one should bear in mind that the steric hindrance in the recombination of radicals plays a more important role than the electronic effects; for this reason, hexa-arylethanes do not exist[93,94].

The triphenylmethyl radicals (XL) recombine reversibly with formation of 1-di-phenylmethylene-4-triphenylmethyl-2,5-cyclohexadiene[95–97]:



(XL)

The kinetic and thermodynamic parameters of reaction (1), which takes place with participation of the arylmethyl radicals (XX) and (XL)–(XLVII) are presented in Table 4.



(XLI) (XLII)

(XLIII) (XLIV)

The activation energy for the dimerisation of radicals (XL) is satisfactorily consistent with the familiar general relation between the activation energy and the heat of reaction $E = 11.5 - 0.25|Q|$, kcal mol^{-1}.[96]

(XLV) (XLVI) (XLVII)

After the radical (XL) had been obtained[98], different derivatives and analogues of the triphenylmethyl radical were synthesised. The properties of these radicals have been described in numerous reviews and monographs[11,91,92,94,101,109,169]. The values of K for triphenylmethyl radicals with different substituents have been obtained[102–104]. The following conclusions can be reached on the basis of experimental data[102–104] for the stability of substituted triphenylmethyl radicals: (1) the stability of the radicals increases with increase of the bulk and number of substituents in the *ortho*-, *para*-, and *meta*-positions; (2) the stability of the radicals is very high when bulky substituents are present in all three benzene rings in the *para*-positions.

The observed regularities can be explained mainly by steric factors. Thus, despite the fact that the introduction of *ortho*-substituents increases the deviation of the benzene rings from the plane and reduces the degree of delocalisation of the unpaired electron, the constant K then increases, since the *ortho*-substituents hinder recombination[102,103].

The degree of delocalisation of the unpaired electron does not influence K. Furthermore, steric models have shown that in many arylmethyl radicals the aromatic rings have been rotated by a specific angle (and do not lie in a single plane) owing to the repulsion of the *ortho*-protons or *ortho*-substituents[92]. As a result of this, the delocalisation of the unpaired electron among the benzene rings takes place to only a small extent or not at all.

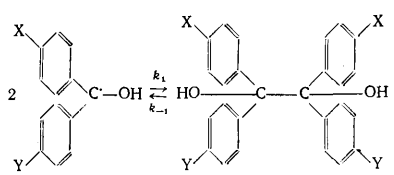
Note. ΔH and ΔS are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1} respectively. The average errors of the determinations are 20% in k_1, 20% in k_{-1}, 30% in K, ±0.5 kcal mol^{-1} in ΔH, and ±2 cal mol^{-1} K^{-1} in ΔS.

The introduction of substituents in the *para*-position also gives rise to certain difficulties in dimerisation via the *para*-carbon atoms (the second reaction centre)[102]. The *meta*-substituents are in the *ortho*-positions relative to the second reaction centre and act analogously to substituents in the *ortho*-position relative to the central carbon atom[102,104].

The influence of substituents on K is determined solely by their bulk and number. Regardless of whether they are donors or acceptors, substituents exert the same influence on the equilibrium[102,103]. Triphenylmethyl radicals containing both methoxy-groups and chlorine atoms in all the *ortho*-positions relative to the central carbon atom have been isolated in a pure state[101].

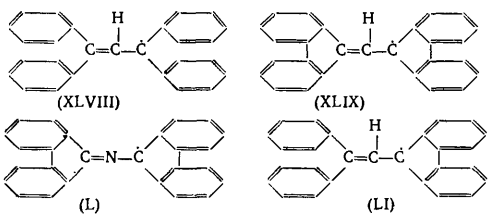
Analogous conclusions are applicable to diarylmethyl radicals. Equilibrium shifts towards the radicals when they contain sterically bulky substituents; for example, the dimer of the bis-2,5-di-t-butylphenylmethyl radical is fully dissociated in solution[105]. Bis-2,6-di-isopropylphenylmethyl radicals do not dimerise either[106].



The reversible recombination of triphenylmethyl and diarylmethyl radicals (XL)–(XLIII) has been studied by EPR and that of the monoarylmethyl radicals (XX) and (XLIV) has been investigated by flash photolysis and NMR (Table 4). The values of k_1 for radicals (XL)–(XLIV) are lower than $k_{diff} \approx 5 \times 10^9$ litre mol^{-1} s^{-1} and $\Delta H_1^{\neq}$ differs significantly from the activation energy for the viscous flow of *m*-xylene and chlorobenzene ($B \approx 2.0$ kcal mol^{-1}) (Table 4). The recombination of radicals (XL)–(XLIV) takes place in the kinetic region.

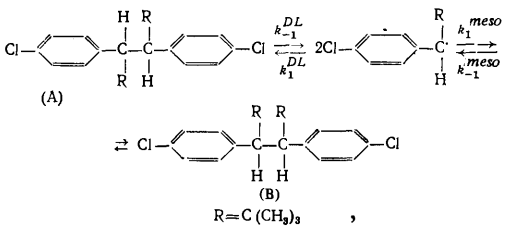
The very low rate constants for the recombination of radicals (XL)–(XLIII) are caused by steric hindrance, as shown by the large negative values of $\Delta S^{\neq}$ (Table 4). Owing to the steric hindrance due to the *ortho*-substituents, the recombination of the diarylmethyl radicals (XLI)–(XLIII) also leads to the formation of a dimer having the ethane and not the cyclohexadiene structure[97]. In the recombination of the radical (XX) via the α-carbon atom the steric hindrance is so great (see Section III) that an asymmetric dimer linked by a C–N bond is formed[107].

For the decomposition of the molecules into complex fragments, the average value of the pre-exponential factor A is 10^6 s^{-1} ($\Delta S_{-1}^{\neq} \approx 11$–$12$ kcal mol^{-1} K^{-1}).[108] Smaller values of $\Delta S_{-1}^{\neq}$ have been obtained for the decomposition of the dimers of radicals (XX) and (XL)–(XLIV) (Table 4). The steric hindrance in the transition state of the decomposition of the dimers apparently hinders the rocking and torsional vibrations relative to the bond undergoing dissociation, which leads to a decrease of $\Delta S_{-1}^{\neq}$ compared with the average value of this quantity[5,6,53].



The ketyl radicals formed in the decomposition of benzopinacols can be regarded as substituted diphenylmethyl radicals. Benzopinacol, 4,4″-dibromobenzopinacol, and 4,4′,4″,4‴-tetramethoxybenzopinacol exist in benzene and isopropyl alcohol in equilibrium with the corresponding ketyl radicals at 80–141 °C:[110]

X, Y = H or substituent.



The kinetic and thermodynamic parameters obtained for reaction (1) involving ketyl radicals are listed in Table 4. Values of $\Delta H_1^{\neq}$ smaller than the corresponding values of B for the solvents were observed (2.9 and 6.4 kcal mol^{-1} for benzene and isopropyl alcohol respectively). It is extremely likely that the recombination of unsubstituted ketyl radicals (XLV) is limited by diffusion[110].

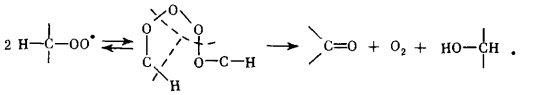
The recombination of tetraphenylallyl and related radicals has been studied by EPR and spectrophotometric methods[111]:

It was established that, in contrast to radicals (XLIX)–(LI), radical (XLVIII) does not form dimers in solution [benzene and ether, from −60° to 50 °C (20 °C)]. $\Delta H° = 12.2 \pm 0.4$, 8.9 ± 0.3, and 14.7 kcal mol^{-1} were obtained for radicals (XLIX), (L), and (LI) respectively. The bond in the dimer is formed between the α-carbon atoms or between the α- and γ-carbon atoms of the allyl groups. The inability of radical (XLVIII) to form a dimer can be explained by steric hindrance[111]. The extents of steric hindrance for radicals (XLIX) and (L) are the same and the differences between the $\Delta H°$ are then caused by the differences between the degrees of delocalisation of the unpaired electron.

Sterically hindered radicals can recombine diastereoselectively and exist in solution in equilibrium with two stereoisomeric dimers, for example[112]:

where (A) = DL-3,4-di-(*p*-chlorophenyl)-2,2,5,5-tetramethylhexane and (B) = *meso*-3,4-di-(*p*-chlorophenyl)-2,2,5,5-tetramethylhexane. The 1-(*p*-chlorophenyl)2,2-dimethylpropyl radicals, obtained on thermal decomposition of the corresponding azo-compound in 1-methylnaphthalene with 10 vol.% of thiophenol, are in equilibrium at ~300 °C with the *meso*- and DL-dimers; at 135 °C the ratio DL-dimer/*meso*-dimer equals 1.7.[112]

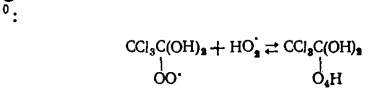
Like many C-centred radicals with phenyl substituents, 2-arylindan-1,3-dionyl radicals exist in solution in equilibrium with their dimers[5,6]. The interest in 2-arylindan-1,3-dionyl radicals increased recently, because they are effective inhibitors of liquid-phase oxidation processes[113]. The kinetic and thermodynamic parameters of reaction (1) involving the 2-arylindan-1,3-dionyl radicals (XII)–(XVIII) are listed in Table 2. Evidently the equilibrium constant depends significantly on the nature of the substituent in the phenyl fragment of radicals (XII)–(XVIII) (Table 2). In the recombination of radicals (XII)–(XVIII) (or the dissociation of the corresponding dimers), containing the phthaloyl fragment, the steric hindrance can be regarded as virtually identical and the difference between the values of *K* is therefore caused by electronic effects. In the dissociation of a dimer of similar structure, the C–C dimer of radical (XIX), equilibrium (1) is strongly displaced towards the formation of radicals compared with radicals (XII)–(XVIII) (Table 2). This is related to the fact that dissociation of the dimer (XIX) leads to the formation of relatively stable radicals, in which the unpaired electron is delocalised over the system of π-bonds, including the *p* orbital of the oxygen atom. The introduction of a bromine atom in the *ortho*-position relative to the dimethylamino-group in 1,2-bis-(4′-dimethylaminophenyl)diphthaloylethane fully displaces the equilibrium in this instance [radical (XVIII)] towards the formation of the dimer. The bromine atom displaces the dimethylamino-group from the plane of the ring, which leads to the breakdown of conjugation between the unshared electron pair of the nitrogen atom and the phenylindandionyl fragment[114] and hence reduces the degree of delocalisation of the unpaired electron.



Comparison of the kinetic and thermodynamic parameters of reaction (1) for the dimers of radicals (XII)–(XVIII) (Table 2), triphenylmethyl radicals (Table 4), and phenoxy-radicals (Tables 1 and 3) shows that the dimers of radicals (XII) to (XVIII) dissociate much less and are characterised by higher bond dissociation energies.

VII. PEROXY- AND NITROXY-RADICALS

Tertiary peroxy-radicals are in equilibrium with the corresponding tetroxides at low temperatures[99,100,115–119]:

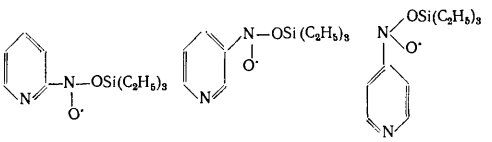


$$RO_2^{\cdot} + RO_2^{\cdot} \rightleftarrows ROOOOR \rightarrow \underset{\text{(cage)}}{[RO^{\cdot}\ldots O_2\ldots{}^{\cdot}OR]} .$$

The reactions were investigated by EPR. The values of *K* and $\Delta H°$ obtained for the peroxy-radicals are listed in Table 5. The data in this table show that the values of K, $\Delta H°$, and $\Delta S°$ depend little on the nature of the alkyl groups[100]. Consequently, the difference between the rates of chain termination on recombination of tertiary peroxy-radicals is caused mainly by the difference between the rates of the irreversible decomposition of the tetroxide[118]. The irreversible destruction of the tertiary alkylperoxy-radicals is negligible at $t < -115$ °C. There is evidence for the reversible formation of tetroxides from secondary peroxy-radicals[117–119]:

However, the thermodynamic parameters of the reversible formation of these tetroxides could not be obtained in view of the low concentration of the radicals and their rapid irreversible destruction even at $t < -115$ °C.[117,118] This mechanism of the destruction of secondary peroxy-radicals has been criticised by Benson[100].

The occurrence of reversible cross-recombination of the following radicals has been demonstrated by kinetic measurements[120]:



The equilibrium is displaced towards the formation of radicals (water, $t \cong 20$ °C). The tetroxide decomposes with liberation of oxygen.

The destruction of the phosphoranylperoxy-radical $C(CH_3)_3O(RO)_3POO^{\cdot}$, where R = CH_3, C_2H_5, or iso-C_3H_7, in cyclopropane takes place in the same way as the destruction of alkylperoxy-radicals[121]. In the range from −70° to −45 °C the destruction of these radicals obeys a first-order law and at $t < -90$ °C a second-order law. $k_1 \cong 10^4$ litre mol^{-1} has been obtained for three phosphoranylperoxy-radicals in

cyclohexane at −90 °C and $\Delta H_1^{\neq} = 4$ kcal mol^{-1} and $k_1 = 3 \times 10^4$ litre mol^{-1} s^{-1} (−90 °C) have been found for $C(CH_3)_3O(CH_3O)_3$. .POO· in the temperature range between −116° and −89 °C.[121]

Nitroxy-radicals of different structure also dimerise reversibly in solution[122–127,167]. Table 5 presents the kinetic and thermodynamic parameters of the dimerisation of nitroxy-radicals of different structure, obtained by EPR. It has been shown[127] that the destruction of nitroxy-radicals having the structure

in triethylsilane at temperatures in the range from −33° to 25 °C obeys a first-order law. It has been observed that the radicals are in equilibrium with diamagnetic dimers and that their destruction proceeds in accordance with Scheme II (see Section II).[127]

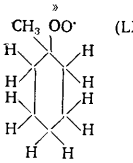
The thermodynamic parameters of the dimerisation of nitroxy-radicals in isopentane are close to the corresponding parameters of the reversible recombination of t-alkylperoxy-radicals in alkanes[116], for example of t-butylperoxy-radicals in isopentane (Table 5). However, the recombination of nitroxy-radicals leads to the formation of dimers via a 4-centre bond[122]

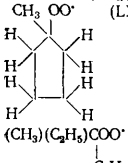
and not via the O—O linkage.

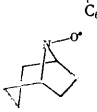
VIII. RADICAL-IONS

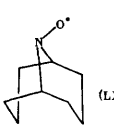
Despite electrostatic repulsion, radical-ions dimerise reversibly in solution[128–134]. The dimerisation of radical-ions was first described in detail by Michaelis and Schubert[135], who analysed titration curves. The dimerisation reaction is usually accompanied by the electron transfer reaction between radical-ions, but, having selected the appropriate conditions, it is possible to suppress fully one of these reactions[135].

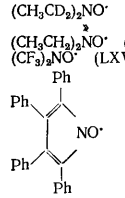
The following relation is valid for the reversible dimerisation of many aromatic radical-anions[136]:











$$\Delta G^0 = \Delta\xi_\pi + \text{const},$$

where $\Delta\xi_\pi$ is the change in the energy of π-electrons.

The dimerisation of ion pairs is a well known phenomenon, which is induced by Coulombic attraction[137]. Electrostatic forces promote the formation of π−π′ bonds between suitable reactants, which results in the formation of ion pair dimers having fundamentally new properties compared with electrostatically linked ion pairs[137].

The zinc-octaethylporphyrin radical-cations (LXX) form diamagnetic dimers in a 10:1 (by volume) methanol–chloroform mixture in the temperature range between −20° and 50 °C.[138] The reaction was investigated by optical spectroscopy, EPR, NMR, and the temperature jump method (Table 6). The porphyrin rings in the dimer are located in parallel planes and are linked by a π−π′ bond[138] formed as a result of the overlap of half-filled orbitals. This bond [bond dissociation energy 17 kcal mol^{-1} (Table 6)] is stronger than the usual covalent bond in "hexaphenylethane" [11 kcal mol^{-1} (Table 4)].

The reversible dimerisation of the radical-cations of substituted viologens (1,1'-di-R,4,4'-bipyridylium monocations) (LXXI)–(LXXVII) in methanol at temperatures between −90° and 40 °C was investigated by EPR.[129,139,140] Table 6 presents the thermodynamic parameters obtained for these radicals. With increase of the size of the radical-cation, the reaction becomes more endothermic and its entropy increases. At room temperature the entropy of reaction has the dominant influence and, with increase in the size of the radical, the equilibrium shifts towards the formation of radicals. A linear relation has been observed between $\Delta H°$ and $\Delta S°$.[139]

It was to be expected that $\Delta S° > 0$ for the decomposition of dimers; however, the data in Table 6 show that the majority of radical-cations $\Delta S° < 0$, which means that the opposite

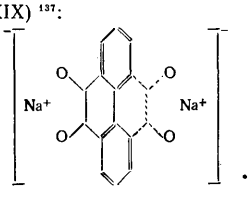
Note. *In tetrahydropyran at 25 °C. ** Here k_{-1} is expressed in litre mol^{-1} s^{-1} and K is a dimensionless quantity [see Eqn.(13)]. *** See Eqn.(14).
$\Delta H°$ and $\Delta S°$ are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1} respectively. The average errors of the determinations are 20% in k_1, k_{-1}, and K, ±0.5 kcal mol^{-1} in $\Delta H°$, and ±2 cal mol^{-1} K^{-1} in $\Delta S°$.

effect, causing an increase of entropy on dimerisation of two monomeric species, operates; this involves the removal of solvent molecules from the solvation shell of the radical-cation on dimerisation. With increase of the size of the radical-cation, the forces maintaining solvent molecules near it are weakened and ΔS° diminishes on desolvation during the dimerisation process. On this basis, one can assume that the radicals dimerise via a "plane-to-plane" mechanism, this type of dimerisation ensuring effective desolvation. By analogy with earlier studies[138,141], Evans et al.[139,140] suggested that the radicals in the diamagnetic dimer are linked by a $\pi-\pi'$ bond. Kosower and Cotter[142] postulated that the dimer (LXXII) is a biradical. The strongest bond between the viologen radical-cations is formed on dimerisation of (LXXVII) (Table 6). This behaviour can be due to the greater degree of delocalisation of the unpaired electron in (LXXVII), which ensures a more effective overlap between the π-type molecular orbitals of the radical-cations[140]. The reversible dimerisation of (LXXII) has also been observed by Blandmer et al.[143]

Apparently all alkali metal derivatives of aromatic ketyls are involved in equilibrium (1) in etheral solutions[144], which has been investigated by EPR and spectrophotometric methods. The ketyl dimer can have different structures and, depending on the solvent, can be paramagnetic or diamagnetic[144]. In non-polar solvents mainly the reversible conversion of the diamagnetic dimer into the paramagnetic dimer is observed:



In ethers the paramagnetic dimer is formed preferentially. The data for equilibrium (1) involving sodium fluorenyl (LXXVIII) are presented in Table 6.

The sodium salts of radical-anions (ion pairs) of 9,10-phenanthrenequinone (LXXIX) and acetonaphthoquinone form diamagnetic dimers linked by a $\pi-\pi'$ bond[137]:

$$2(PhQ^{\cdot-}, Na^+) \rightleftarrows (D^{2-}, 2Na^+) .$$

The reactions were investigated by stopped flow and spectrophotometric methods (Table 6). The following structure has been postulated for the dimer (LXXIX):[137]

(LXXIX)[137]:

The tetracyanoquinodimethane radical-anions (LXXX) dimerise reversibly in aqueous and aqueous alcoholic solutions at room temperature[130,145]. The value of k_1 obtained by the temperature jump method (Table 6) is smaller by a factor of 5 than that calculated by the Debye formula taking into account the electrostatic repulsion. It may be that reaction (1) is diffusion-limited[145].

p-Phenylenediamine bromide (LXXXI), *N*,*N*-dimethyl-*p*-phenylenediamine perchlorate (Wurster's red) (LXXXII), and *N*,*N*,*N'*,*N'*-tetramethyl-*p*-phenylenediamine perchlorate (Wurster's blue) (LXXXIII) dimerise reversibly in solution (Table 6), being apparently linked to a single counterion[131]:

$$2R^{\dot{+}} + X^- \rightleftarrows (R_2X)^+.$$

The weak binding of radical (LXXXIII) is caused by the steric repulsion of the methyl groups: this radical is present in solution at room temperature as the monomer[131].

The radical-anions of quinones are involved in reversible dimerisation reactions at reduced temperatures, apart from the disproportionation reaction via one-electron transfer[132]. Table 6 presents data for the chloranil radical-anion (LXXXIV).

Radical-anions and radical-cations undergo rapid reversible electron transfer reactions with one another:

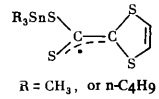
$$R^{\dot{+}} + Q^{\dot{-}} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} R + Q. \qquad (13)$$

For example, Table 6 presents data for reaction (13) involving radicals (LXXXIII) and (LXXX) obtained by the temperature jump method. This reaction can include a stage in which a charge-transfer complex (CTC) is formed:

$$R^{\dot{+}} + Q^{\dot{-}} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} CTC \rightleftarrows R + Q. \qquad (14)$$

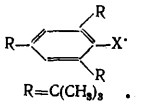
For example, the formation of both the corresponding radical-anions and CTC has been observed in polar solvents[148]. The kinetic and thermodynamic parameters of reaction (14) with participation of (LXXXIII) and the 2,6-diphenyl-1,4-benzoquinone radical-anion (LXXXV) have been obtained by flash photolysis and spectrophotometry (Table 6). The constant k_1 agrees satisfactorily with the rate constant for a reaction between charged radicals limited by translational diffusion[148].

IX. OTHER RADICALS



1-Alkyl-4-methoxycarbonylpyridyl radicals (LXXXVI)–(LXXXVIII) (Table 7) dimerise reversibly in isopentane at temperatures between −207° and −63 °C.[141,174] The reaction has been investigated spectrophotometrically. It has been suggested that the radical dimers are charge-transfer complexes[141] and it has been shown[149] that the irreversible destruction of 4-carbamoyl-1-methylpyridyl radicals in acid aqueous solution is preceded by reversible dimerisation[149]. Certain pyridyl radicals disproportionate reversibly via the transfer of a single electron[173].

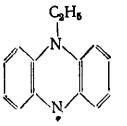
Diaryliminoxy-, alkylaryliminoxy-, and dialkyliminoxy-radicals having the structure



dimerise reversibly in benzene with formation of N–N, N–O, and C–O bonds[10]. Sterically unhindered dialkyliminoxy-radicals are involved in an equilibrium which is displaced towards the dimers. For the majority of the diaryliminoxy-, alkylaryliminoxy-, and sterically hindered dialkylimonoxy-radicals, the equilibrium is displaced towards the radicals. For these radicals, ΔH° = 15–20 kcal mol^{-1} in toluene[10]. Irreversible reactions also take place in the system[10].

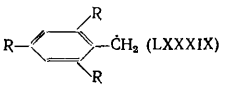
The 1-thioallyl radicals, having the structure

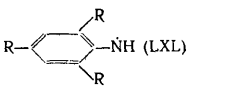
and obtained from tetrathiofulvalene, have been investigated by EPR.[150] It was established that these sterically hindered radicals are in equilibrium with diamagnetic dimers in toluene at 25 °C and below. The dimer is probably formed via the S–S coupling reaction[150].

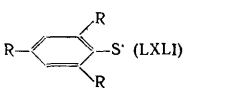


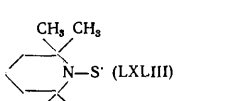
The recombination of 2,4,6-tri-t-butyl-substituted benzyl (LXXXIX), phenylaminyl (LXL), phenylthiayl (LXLI), and phenoxy-radicals in hydrocarbons as well as di-t-butyl peroxide has been investigated by EPR:[53]

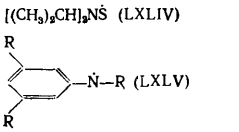
The radicals are isoelectronic and are characterised by the same extent of steric hindrance around the reaction centre. It has been established that the benzyl radicals recombine irreversibly to form bibenzyl (Table 7). The phenylaminyl radical is in equilibrium with the corresponding dimer (hydrazine) at room temperature (Table 7). The data in Table 7 show that the recombination of sterically hindered phenylaminyl radicals is slower by four orders of magnitude than that of benzyl radicals. The phenylthiyl radicals in solution are in equilibrium with the corresponding disulphide (Table 7).











The difference between the reactivities of radicals (LXXXIX)–(LXLI) is due to the difference between the dissociation energies of the bonds formed on "head-to-head" recombination. The dissociation energy of the bonds in the dimers varies in the sequence C–C > S–S > N–N > O–O; the O–O bond dissociation energy is apparently close to zero[53]. With increase of the strength of the bond formed, the rate of recombination of radicals also increases, which can be accounted for on the basis of Hammond's postulate. Indeed the more exothermic the reaction, the greater the similarity between the transition state and the reactants. For sufficiently exothermic reactions, the bond can then be formed over a comparatively large distance between the reactants, where the influence of t-butyl groups is small[53]. The values of $\Delta S_{-1}^{\neq}$ are much smaller than the "normal" value (see Section VI) for radicals (LXL) (Table 7) and (LXXXIX).[53]

The study of the absorption spectra and magnetic susceptibility of *N*-ethylphenazyl

(solvent 2 : 1 alcohol–ether) showed that the radicals dimerise reversibly at low temperatures (~–180 °C); the radicals in the dimer are located in parallel planes[146].

Biradicals can form diamagnetic dimers. Pyridyl biradicals having the structure

where $n = 3$ or 4, exhibit a significantly smaller paramagnetism than expected[151,174]. The ends of the pyridyl radicals are involved in intermolecular association and form a singlet (diamagnetic) species. There is virtually no association of radicals with $n = 2$, 5, and 10.[151,174]

The bimolecular reactions of the radicals $RSeC[C(CH_3)_3]_2$, where R = CH_3, $(CH_3)_3C$ (LXLII), CF_3, C_6H_5, $(n\text{-}C_4H_9)_3Si$, $(CH_3)_3Sn$, $(CH_3)_3Ge$, $(CH_3)_3CO$, or $(CH_3)_3CS$, have been investigated by EPR.[152] The majority of these radicals (possibly all of them) are in equilibrium with diamagnetic dimers at low temperatures. The dimers apparently have a "head-to-tail" structure:

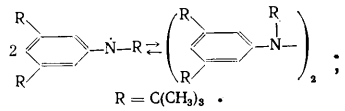
The data for radicals (LXLII) are presented in Table 7. Together with reversible recombination, the irreversible destruction of the radicals takes place. The destruction follows a first-order law in conformity with Scheme II (Section II).

The 2,2,6,6-tetramethylpiperidinylthiyl radical (LXLIII) and the diisopropylaminothiyl radical (LXLIV) have been obtained[153] by the photolysis of the corresponding disulphides in the resonator of the EPR spectrometer. The equilibrium

$$2R_2NS^{\cdot} \rightleftarrows R_2NSSNR_2$$

is established at 40–130 °C. The destruction of radicals (LXLIII) and (LXLIV) at room and lower temperatures obeys a second-order law in t-butylbenzene (Table 7); the rate of reaction is apparently limited by diffusion.

The recombination of the radicals $R_2NS^{\cdot}$ differs from the recombination of the related dialkylnitroxy-radicals $R_2NO^{\cdot}$ by the fact that it takes place via a "head-to-head" mechanism with formation of a stronger bond (Table 7). The nitroxy-radical dimers have a bond dissociation energy not exceeding 13 kcal mol^{-1} (Table 5).



Like arylethanes and the dimer (XL) (Section VI), arylhydrazines dissociate reversibly into diarylaminyl radicals on heating or irradiation:

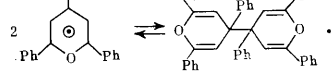
$$2Ar_2N^{\cdot} \rightleftarrows Ar_2N{-}NAr_2 .$$

This reaction has been described in monographs[11,101,168,169] and reviews[178,180]. The EPR spectra of diarylaminyl radicals containing the electron-donating substitutents $N(CH_3)_2$, CH_3O, and CH_3 in the aromatic ring have been recorded[179].

On thermal dissociation of arylhydrazines, not all substituents capable of delocalising the unpaired electron increase the degee of dissociation. The following sequence based on the influence of the substitutents is observed: $N(CH_3)_2 > OCH_3 > CH_3 > H > COOC_2H_5 > CN > NO_2$.[178] This sequence of substituents shows that the dissociation of substituted hydrazines is determined mainly by the interaction within the hydrazine molecule (the interaction of the unshared electron pair with the substituents in the *para*-position) and much less so by the delocalisation of the unpaired electron in the radical[178].

The *N*-3,5-tri-t-butylphenylaminyl radical (LXLV) recombines reversibly to a dimer at temperatures between −13° and −103 °C in methylcyclohexane (Table 7):[154]

R = $C(CH_3)_3$.



The reaction was investigated by EPR. At low temperatures ($t < -13$ °C) the equilibrium is fully displaced towards the formation of the dimer; the radical can be regenerated by photolysis and the kinetics of its destruction can be studied.

The value of $\Delta H°$ obtained (Table 7) is close to the dissociation energy of the N–N bond in hydrazobenzene (37.7 kcal mol^{-1}) [154] and the introduction of t-butyl groups into hydrazobenzene should reduce this quantity. The value of $\Delta S°$ obtained for this radical is extremely high compared with $\Delta S°$ for phenoxy- (Tables 1 and 3), nitroxy- (Table 5), triphenylmethyl (Table 4), and arylindan-1,3-dionyl (Table 2) radicals as well as radical-ions (Table 6). The given dimer is sterically hindered to an extremely large extent as a result of the coupling reaction and its decompositon leads to the possibility of the free rotation of the t-butyl groups.

The negative values of $\Delta H_1^{\neq}$ obtained for the recombination of radicals (LXLV) were observed also for other radicals—phenoxy (Tables 1 and 3) and nitroxy-radicals[123], and were interpreted on the assumption of an equilibrium preceding the slowest stage of the reaction. The high negative value of $\Delta S_1^{\neq}$ (Table 7) indicates a very rigid transition state in the recombination reaction. In fact the rate of recombination is controlled by the activation entropy.

The appreciable shielding of the N atom in aminyl radicals leads to the formation of dimers linked by C–N and even C–C bonds[155,178].

The 2,4,6-triphenylpyranyl radicals recombine reversibly to a dimer in acetonitrile at temperatures between −40° and 30 °C:[156]

The reaction was investigated by EPR and ultraviolet spectroscopy. $\Delta H_1^{\neq} = 6.4$ kcal mol^{-1} was obtained.

X. THE INFLUENCE OF THE SOLVENT ON THE KINETICS OF REVERSIBLE RECOMBINATION

The solvent is known to have a significant influence on the rates of radical reactions in the liquid phase[157]. The solvent viscosity, the formation of complexes by radicals with the solvent, and specific and non-specific solvation influence the reactivity of radicals. The difference between the degrees of solvation of the radicals and the dimer influences the constant of equilibrium (1). The rate of reaction (−1) in polar solvents depends on the ratio of the dipole moments of the transition states in this reaction. The influence of the solvent on reaction (1) for radicals of different classes is examined below.

1. Phenoxy-Radicals

The influence of specific solvation on the kinetics of the reversible recombination of phenyl-, methoxy-, and t-butylphenoxy-radicals has been studied in detail[1,7,25–27,29,75,90,158].

Tables 8 and 9 present the kinetic and thermodynamic parameters of reaction (1) involving phenoxy-radicals in various solvents.

Table 8. Kinetic and thermodynamic parameters of reaction (1) involving phenoxy-radicals in different solvents at 20 °C.

Note. The average errors of the determinations are 10% in k_1, 20% in K, and 30% in k_{-1}. See also Table 1.

The recombination reaction. V-shaped relations between k_1 and the empirical parameter E_T, characterising the solvent polarity, have been observed for phenylphenoxy-radicals (Tables 8 and 9).[1] The above relations are more pronounced for radicals whose recombination takes place under kinetic conditions [radicals (VIII) and (IX)] than for phenylphenoxy-radicals whose recombination is limited by diffusion[1,90]. This fact is consistent with the general observation that the solvent has a more significant influence on slow reactions than on fast reactions.

Phenylphenoxy-radicals form charge-transfer complexes with solvent molecules. The charge-transfer bands in the spectra of solutions of radical (IX) in different solvents have been observed.[159] The solvation of the radicals leads as a rule to a decrease of their diffusion coefficient and possibly to shielding of the reaction centre, which entails a decrease of k_1. Furthermore, the recombination of radicals is accompanied by the dissociation of complexes, which increase $\Delta H_1^{\neq}$. As a consequence, k_1 diminishes with increase of E_T from 31 (hexane) to 40 (chloroform). In chloroform k_1 has the lowest value; chloroform molecules form complexes with phenoxy-radicals as a result of interaction with the oxygen atom or the π-electrons of the benzene rings[158].

The causes of the increase of k_1 in solvents with $E_T > 40$ are less clear. DMF, acetonitrile, and alcohols have high dielectric constants and an unshared electron pair; alcohols are capable of forming hydrogen bonds with phenoxy-radicals. The redistribution of charges on the atoms of phenoxy-radicals due to their specific solvation by these solvents apparently promotes a rapid attainment of the required orientation for the recombination of the radicals in the cage[1,158]. As a result of this, the constant k_1 should increase. The V-shaped relation between k_1 and E_T for the recombination of radicals (VIII) and (IX) under kinetic conditions can be explained as follows[1,27,90]. The recombination of the radicals is accompanied by the dissociation of the complexes, which increases $\Delta H_1^{\neq}$. At the same time the decomposition of the complexes increases the degree of disorder and hence the activation entropy $\Delta S_1^{\neq}$. Since $\Delta H_1^{\neq}$ and $T\Delta S_1^{\neq}$ have opposite signs as components of $\Delta G_1^{\neq}$, the observed relation can occur when, on changing the solvent, k_1 is initially influenced predominantly by the change in $\Delta H_1^{\neq}$ and then by the change in $\Delta S_1^{\neq}$.

Polar solvents can also solvate the molecules of the dimers as a result of which the recombination of the radicals is not accompanied by the dissociation of the complexes[90]. Indeed, the recombination of radicals (VIII) is accompanied by an increase of $\Delta H_1^{\neq}$ in the sequence hexane < toluene (benzene) < chloroform (Tables 3 and 8), owing to the increase of the stability of the radical–solvent complex. At the same time an increase of $\Delta S_1^{\neq}$ is observed (compensation effect). However,

in a polar solvent (acetonitrile) low values of $\Delta H_1^{\neq}$ and $\Delta S_1^{\neq}$ are observed. In this case the dimer molecules as well as the radical are solvated and the solvation energies of the radical and the dimer are similar[90].

The influence of the composition of the binary mixture on k_1 for phenylphenoxy-radicals has been studied[1,26,27] using binary mixtures of solvents corresponding to different branches of the V-shaped relation between k_1 and E_T as well as binary mixtures one of the components of which was chloroform. The low value of k_1 in chloroform is caused by the specific solvation of the radical by the solvent and not by the properties of the medium as a "continuum"[1]. It was suggested that in binary hexane–chloroform and carbon tetrachloride–chloroform mixtures hexane and carbon tetrachloride do not form complexes with phenoxy-radicals (PhO$^{\cdot}$), while chloroform (S) forms 1 : 1 solvate complexes (PhO$^{\cdot}_S$):

$$PhO^{\cdot} + S \underset{}{\overset{K_{RS}}{\rightleftharpoons}} PhO^{\cdot}_S,$$

$$PhO^{\cdot} + PhO^{\cdot} \xrightarrow{k_1} \text{dimer},$$

$$PhO^{\cdot} + PhO^{\cdot} \xrightarrow{k_{RS}} \text{dimer},$$

$$PhO^{\cdot}_S + PhO^{\cdot}_S \xrightarrow{k_{SS}} \text{dimer}.$$

The kinetic parameters for which the given scheme describes the observed dependence of k_1 on the chloroform concentration in the binary mixture were estimated[1]:

$K_{RS}=0.9\pm0.2$ litre mol^{-1}, $k_{RS}=(1.2\pm0.5)\cdot10^7$ litre mol^{-1} s^{-1}

[radical (IX) in a chloroform–hexane mixture];

$K_{RS}=0.45\pm0.10$ litre mol^{-1}, $k_{RS}=(9.0\pm2.0)\cdot10^6$ litre mol^{-1} s^{-1}

[radical (IX) in a chloroform–carbon tetrachloride mixture];

$K_{RS}=0.18\pm0.05$ litre mol^{-1}, $k_{RS}=(2.0\pm1.0)\cdot10^8$ litre mol^{-1} s^{-1}

[radical (I) in a chloroform–carbon tetrachloride mixture]. In all cases $k_{SS} \ll k_{RS}^1$.

The above ideas proved to be inapplicable to binary mixtures containing an alcohol. The relations between $k_1\eta$ and the compositions of such binary mixtures showed maxima and minima[1,90], which is due to the fact that the mixtures have a complex structure which varies with the component ratio. The solutions differ significantly from regular solutions and there is a possibility of microlayer formation in the mixture. When methanol is diluted with carbon tetrachloride or chloroform, the fraction of alcohol dimers and trimers, which form more stable complexes with the radicals, increases[1].

The rate of the diffusion-controlled recombination of radicals reflects the changes in the structure of the solution as a function of its composition. In these mixtures the microviscosity differs significantly from the macroviscosity and the changes in k_1 are determined by the behaviour of excess thermodynamic functions. Thus the study of the rate of diffusion-controlled recombination reactions constitutes together with spin exchange in binary mixtures, a method for the quantitative study of phenomena of this kind[1].

The constants k_1 for t-butyl- and methoxy-phenoxy-radicals depend only slightly on the chemical nature of the solvent (Table 8). The data of Kuz'min et al.[160] permit the conclusion that the k_1 for the *o*-methylphenoxy-radical also depends on the nature of the solvent only slightly. Thus specific solvation has a significant influence on the recombination of only those phenoyx-radicals which contain aryl substituents.

It has been observed that k_1 for the *o*-methylphenoxy-radical diminishes with increase of the ionic strength of the aqueous solution[161], but this is apparently caused by the increased viscosity of the medium.

Dissociation reaction of the dimers. The solvent also has a significant influence on k_{-1}. For example, k_{-1} for radical (I) increases by more than an order of magnitude with increase of solvent polarity (Table 8). An analogous solvent effect was observed for radical (XXIV) (Table 8). For dimers with a "head-to-tail" structure, $\Delta H_{-1}^{\neq}$ decreases with increased solvent polarity [radicals (I), (VIII), (IX), and (XXIV); Tables 8 and 9]. Under these conditions, k_{-1} either increases [radicals (I) and (XXIV)] or depends only slightly on the solvent [radicals (VIII) and (IX)] due to the compensation effect.

The influence of the solvent on $\Delta H_{-1}^{\neq}$ has been examined[29] as a function of the ratio of the dipole moments of the transition state ($\mu^{\neq}$) and the initial dimer (μ_d). 2,6-Diphenyl-4R-phenoxy-radicals form dimers having the structure of quinol ethers ("head-to-tail"). An increase of the solvating capacity of the solvent lowers $\Delta H_{-1}^{\neq}$ for such dimers, since in this case $\mu^{\neq} > \mu_d$. The dimerisation of radicals (VII) results in the formation of C–C dimers ("tail-to-tail"). In this case $\mu^{\neq} < \mu_d$ and the increase of the solvating capacity of the solvent leads to an increase of $\Delta H_{-1}^{\neq}$ (Table 8).

2. Aromatic C-Centred Radicals

The values of K for the triphenylmethyl radical (XL) and its substituted derivatives in various solvents have been determined calorimetrically[162–164,175] and the constants k_{-1} have been obtained in experiments involving the addition of oxygen or nitric oxide to the dimer (Table 10). The values of k_{-1} obtained[162,175] for radical (XL) in 28 solvents at 0 °C varied from 1.1×10^{-3} to 4.2×10^{-3} s^{-1}.

Table 10. The equilibrium constants and enthalpies of reaction (1) involving radical (XL) in various solvents at 20 °C.[163]*

Solvent	$10^4\cdot K$, mol l^{-1}	ΔH^0, kcal mol^{-1}	Solvent	$10^4\cdot K$, mol l^{-1}	ΔH^0, kcal mol^{-1}
Propionitrile	1.20	11.1	Ethylene dibromide	3.90	11.4
Ethyl benzoate	1.67	12.0	Benzene	4.10	11.3
Acetophenone	1.70	11.5	Chloroform**	6.90	10.5
Dioxan	2.50	11.6	Carbon disulphide***	19.2	11.0
Bromobenzene	3.70	11.5			

Note. *See also Table 4; **$k_{-1} = 0.219$ s;[164] $k_1 = 3.2\times10^2$ litre mol^{-1} s^{-1}; ***$k_{-1} = 0.252$ s^{-1};[164] $k_1 = 1.3\times10^2$ litre mol^{-1} s^{-1}.
The errors of the determinations are ~5% in K and k_{-1}, ~10% in k_1, and ±0.3 kcal mol^{-1} in ΔH^0.

A relation of the Brønsted type, $\ln k = \alpha \ln K + \text{const.}$, is known to hold for a number of reactions[165]. It has been shown[165] that the relation holds satisfactorily for the dissociation of the dimer of (XL) in various solvents and $\alpha = 0.2$. According to the author, the transition state in the decomposition reaction resembles the dimer more than the radicals. The initial dimer and the transition state cannot interact with the solvent for steric reasons[165]. The influence of the solvent on the kinetics of

reaction (1) with participation of 2-aryl-indan-1,3-dionyl radicals having structures (XII) and (XVI) has been studied[166]. The values of k_1 for radical (XII) differ insignificantly in all the solvents investigated (Table 11).

Table 11. Kinetic and thermodynamic parameters of reaction (1) involving radicals (XII) in various solvents at 20 °C.[166]

Solvent	10^7 k_1, l mol^{-1} s^{-1}	10^2 k_{-1}, s^{-1}	10^6 K, mol l^{-1}	$\Delta H_1^{\neq}$	ΔH_{-1}	ΔH^0	$-\Delta S_1^{\neq}$	$\Delta S_{-1}^{\neq}$	ΔS^0
Toluene	10.5	2	$1.9 \cdot 10^{-1}$	3.5	24.2	20.7	3.9	16.2	20.1
Chloroform	8	7	$9.1 \cdot 10^{-1}$	2.6	21.9	19.3	7.5	10.9	18.4
Acetic acid	3.75	11.5	3.1	2.3	21.0	18.7	9.7	9.0	19.1
Tetrachloroethane	3.6	16	4.5	2.0	19.9	17.9	10.2	6.7	17.1
DMF	7.5	45	6.0	1.0	18.0	17.0	12.6	2.0	14.7

Note. ΔH and ΔS are expressed in kcal mol^{-1} and cal mol^{-1} K^{-1}. The errors of the determinations are 10% in k_1, 20% in K, 30% in k_{-1}, ±0.5 kcal mol^{-1} in ΔH, and ±2 cal mol^{-1} K^{-1} in ΔS; see also Table 2.

The linear relation observed[166] between $\Delta H_1^{\neq}$ and $\Delta S_1^{\neq}$ is apparently a consequence of purely random experimental errors. Generally speaking, the range of variation of $\Delta H_1^{\neq}$ for reaction (1) is very insignificant compared with the errors in the determination of this quantity; as a result, it is difficult to demonstrate the existence of an isokinetic relation for reaction (1). A V-shaped relation between k_1 and the parameter E_T has been observed[166] for radical (XVI) containing phenyl substituents, as for phenylphenoxy-radicals[1,25].

The constant K for radical (XLV) increases by a factor of 430 at 30 °C on transfer from benzene to isopropyl alcohol (Table 4).[110] This is caused by the specific solvation of the radical in isopropyl alcohol with formation of hydrogen bonds. The heats of formation of the benzopinacol dimer in benzene and isopropyl alcohol are approximately the same. According to estimates, the solvation of the above radical in isopropyl alcohol is more exothermic by 3–7 kcal mol^{-1} than in benzene[110]. The quantity $\Delta(\Delta S)$ for solvation is 10.8 cal mol^{-1} K^{-1} on transfer from benzene to toluene. Such values are usually observed on formation of a hydrogen bond with oxygen-containing acceptors[110].

3. Other Radicals

The thermodynamic parameters $\Delta H°$ and $\Delta S°$ for the dimerisation of the nitroxy-radicals (LXIV) and (LXVI) (Table 5) depend on the solvent. In isopentane, which is a poor solvent for nitroxy-radicals and their dimers, the thermodynamic parameters for the above two radicals are similar (Table 5). The radicals are more polar than the dimers and, on transfer from isopentane to polar solvents such as $CFCl_3$ and CF_2Cl_2, $\Delta H°$ and $\Delta S°$ diminish[122,123] (Table 5).

The solvent can solvate the radicals and dimers to different extents as a consequence of the difference in the steric hindrance around the active centre in the radical and the dimer. In the paramagnetic dimers of aromatic sodium ketyls two sodium ions are surrounded by two large ketyl anions and the solvation is therefore hindered[144]. In the monomer more space is available for solvent molecules and the radical pair is solvated to a greater extent than the dimer. The difference between the degrees of order in the solvent for the monomer and dimer is reflected in the negative values of $\Delta S°$ (−29 – −37 cal mol^{-1} K^{-1}).[144]

The thermodynamic parameters of equilibrium (1) involving the tetracyanoquinodimethane radical-anion (LXXX) in aqueous ethanol have been determined[128] and it has been established that $\Delta G°$ decreases with increase of the ethanol content, while $\Delta H°$ and $\Delta S°$ pass through a maximum. These relations have been explained on the basis of the proposed model of solvation: water molecules are more strongly attracted to the radical-anion dimer than ethanol molecules. The Li^+, Na^+, and K^+ counterions do not have an appreciable influence on the dimer–monomer equilibrium and are apparently not present in the vicinity of the anions.

---o0o---

Thus the reversible recombination of radicals in solution with formation of dimers is a fairly general phenomenon, characteristic of organic radicals of different classes, such as the arylmethyl, phenoxy-, alkylperoxy-, iminoxy-, nitroxy-, diarylaminyl, and many others. Numerous radicals present in solution at an appreciable concentration are not stable monomers and are involved in a dynamic equilibrium with the corresponding diamagnetic dimers. The solutions of these radicals are usually coloured and give rise to an EPR signal. The solutions do not obey the Beer–Lambert–Bouguer law. Heating or irradiation of the solutions increase the concentration of radicals.

In the study of the magnetic susceptibilities of solutions of organic free radicals, a deviation from the Curie law, caused by the equilibrium between the paramagnetic monomers and the diamagnetic dimers, is frequently observed.

Together with the reversible recombination reaction, irreversible radical disproportionation or dimer decomposition reactions can take place in solution. The decrease of the steady-state concentration of radicals frequently obeys a kinetic first-order law under these conditions. The dimers undergoing reversible decomposition have found a practical application as photochromic and thermochromic compounds[171] and also as effective inhibitors[113].

The Spectra and Structure of Transition Metal Complexes with Tetradentate Macrocyclic Ligands

K.B.Yatsimirskii and Ya.D.Lampeka

A systematic account is given of data on the structures and spectroscopic properties of transition metal complexes with synthetic tetradentate macrocyclic ligands. The principal types of the structures of such complexes are specified. On the basis of the analysis of electronic absorption spectra, a conclusion is reached concerning the mutual influence of the ligands, which is expressed by a consistent variation of the spectrochemical parameters.
The bibliography includes 191 references.

I. INTRODUCTION

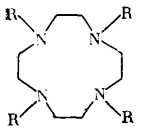
Macroheterocyclic compounds represent the structural elements of many important natural metal complexes such as haem, vitamin B_{12}, chlorophyll, and others. The chemistry of these compounds has now been thoroughly investigated[1] and many complexes of porphyrins and corrins have been synthesised *in vitro*[2,3]. Only high-intensity bands, associated with intraligand transitions and (or) charge-transfer bands, which mask the $d-d$ transition bands, have been observed in the electronic spectra of compounds of this type. The problems of the spectroscopy of porphyrin complexes have been described in detail in a monograph[4].

The chemistry of synthetic ligands, i.e. ligands which are not encountered in living nature and which constitute models of natural macrocycles, has developed vigorously during the last decade. There have been a number of reviews devoted to various aspects of the chemistry of metal complexes with ligands of this type[5-8], but the problems of the spectroscopy of these compounds have been considered only briefly in Busch's review[5] published in 1967.

This review deals with the crystal structures and electronic absorption spectra of complexes formed by metal ions having unfilled d shells with synthetic tetradentate macrocyclic ligands containing either donor atoms of one kind (nitrogen or sulphur) or donor atoms of different kinds (nitrogen, sulphur, and oxygen). The compounds under consideration include also complexes with ligands having a large number of donor atoms, among which only four are involved in coordination. Attention is concentrated on the absorption spectra associated with the excitation of the d electrons of the metal ions, which precludes the inclusion of porphyrin and corrin complexes in this review. The review covers the literature up to 1977 inclusive.

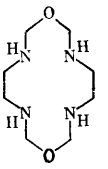
The ligands are designated using the namenclature proposed by Busch and coworkers[9,10], which we believe to be most suitable, despite some ambiguity.

Macrocyclic ligands, whose complexes are considered in this review, and their names are given in Fig.1. Other most frequently encountered names of individual ligands are given in brackets.



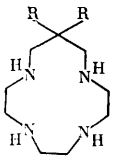
II. THE STRUCTURE OF COMPLEXES WITH MACROCYCLIC LIGANDS

In the majority of the complexes dealt with in this review the donor atoms of the macrocyclic ligand occupy the equatorial plane in the coordination sphere of the metal. This type of coordination enables the ligand to assume the most convenient conformation to which corresponds the minimum strain in the macroring. However, in such coordination another source of strain in the macroring is generated. The maximum overlap of the metal orbitals with the occupied donor orbitals of the ligand is observed when the latter are directed along the diagonals of the tetragon formed by the donor atoms. In the ligands considered below the size of the macroring prevents the ligands from assuming such a conformation and the incorporation of the metal ion in the plane of the donor atoms therefore leads to the occurrence of strain in the donor atom–carbon atom bonds.



The "ideal" metal–donor atom distances have been calculated as a function of the size of the macroring[11] by the ligand strain minimisation method. It follows from the results that a 14-membered macrocyclic ligand will experience the minimum strain on coordination to the cobalt(III) ion and that in the case of nickel(II), high-spin complexes a 15-membered macrocycle is most suitable. However, this does not rule out the possibility of the formation of planar complexes of these ions with ligands having larger or smaller macrorings. It has been suggested[12] that nickel can form such complexes even with 12-membered macrorings, but these complexes are in all probability of the low-spin type.

The picture becomes somewhat more complex when the macrocyclic ligand has different donor atoms or donor atoms of the same kind but of different chemical nature (for example amino- and imino-nitrogen atoms). In this case the metal–donor atom bond length will depend on the type of donor atom. In complexes of ligands of this type the metal ion may not be located in the centre of the plane of the donor atoms.



The types of the fundamental structures discovered in transition metal complexes with macrocyclic ligands (henceforth these complexes will be referred to, for brevity, as

macrocyclic complexes), are presented in Fig.2. Structure A is characteristic of the majority of nickel(II) complexes. Apart from nickel, complexes of this kind have been found only for copper(II)[13,14] and cobalt(II).[15] Structure B is obtained when the diameter of the plane of the macroring is too small for the given metal ion and the rigidity of the ligand prevents it from assuming another conformation more suitable for coordination. For complexes with a coordination number (C.N.) of 5 there is a possibility of structures of types C, D, and E. The structure of the complex in each specific case is determined by the characteristics of the structure of the macrocyclic ligand. Complexes having structure F are probably most common, but their X-ray diffraction analysis has been carried out in only a limited number of instances. Structure G is obtained when additional bidentate and monodentate ligands are involved in coordination apart from the macrocyclic ligands. In the last case[16] the structure is determined by the small size of the macroring, as a result of which the metal ion cannot be accommodated in the centre of the plane of the donor atoms.

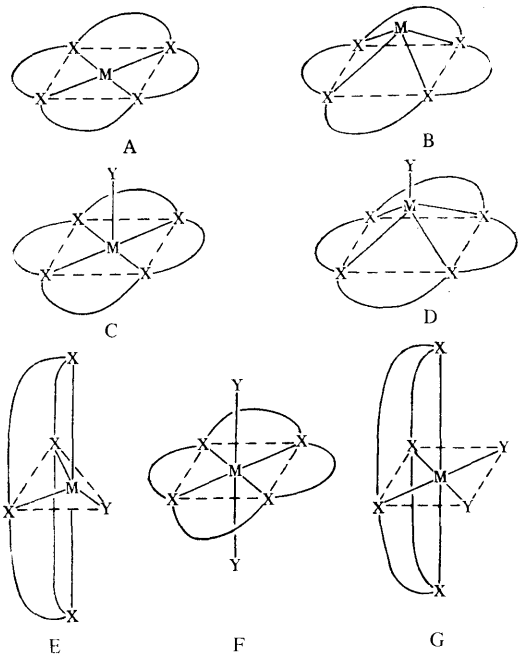

Figure 2. The types of structures of transition metal complexes with macrocyclic ligands (X = donor atoms of macrocyclic ligands; Y = donor atoms of additional ligands).

proton. However, the difference between the last two types of donor atoms is in many cases abolished owing to the conjugation in the six-membered chelate ring. If the complex formation reaction takes place with substitution of a proton at the nitrogen atom, then the imino- and ionic nitrogen atoms become equivalent. Subsequently they will be designated by N_{cov}. The equivalence of these two types of donor atoms in complexes of the above type has been confirmed by X-ray diffraction data (Table 1) and X-ray electronic spectroscopic data[37]. An analogous phenomenon has been observed also in porphyrin and phthalocyanine complexes[38,39]. In all probability the structures of such complexes are represented more correctly by formula I rather than II [in relation to compound No.18 (Table 1)].

*Here N_{py} is the nitrogen atom of pyridine.

1. Nickel(II) Complexes

The majority of nickel(II) complexes investigated by X-ray diffraction have a square planar structure, although compounds have been found with another structure. Table 1 presents the results of X-ray diffraction studies on the square-planar nickel(II) complexes. The donor atoms in macrocyclic ligands can be oxygen and sulphur atoms, the nitrogen atom N_{am} in a secondary amino-group, the nitrogen atom N_{im} in an imino-group (–CH=N–), and the nitrogen atom N_{ion} coordinated to the metal ion with elimination of a

As was to be expected, the length of the nickel–nitrogen bond depends on the size of the macrocyclic ligand and is shortest in a 13-membered macrocycle (square-planar complexes with twelve-membered macrocycles have not been synthesised). In all cases the Ni–N_{am} bond length is greater than the Ni–N_{im} bond length for the same macrocyclic ligand. This is probably because the imino-group can be involved in the formation of π-bonds as well as a simple donor–acceptor bond, which should enhance the nickel–nitrogen interaction and should lead to the shortening of the distance between these atoms (see also Section IV).

The metal–donor atom bond length is greatly influenced by the structure of the macrocyclic ligand. Thus the Ni–N_{am} and Ni–N_{im} bond lengths in complex No.10 are shorter than in the complex No.9 (Table 1), although the ligands differ only by the relative positions of the imino-bonds and the methyl substituents. The presence of substituents in the ethylenediamine bridge between the donor atoms lengthens the metal–nitrogen bond (cf., for example, complexes No.7 and 8 or complexes No.10 and 12 in Table 1), although the introduction of substituents in the propylenediamine bridge hardly influences the distance (cf. compounds No.3 and 5). The flexibility of the macrocyclic ligand also determines the nickel–nitrogen bond length. Thus the Ni–N_{am} distance in complex No.6 is shorter than the analogous distance in complexes of other 14-membered ligands. The presence of the pyridine ring apparently increases the rigidity of the ligand, which leads to a decrease of the nickel–nitrogen bond length.

The shortest bond between the nickel ion and the nitrogen donor atom among the compounds listed in Table 1 is observed in complex No.20. The ligand forming this complex can be coordinated in two ways [(III) or (IV)]. In the nickel complex version (IV) obtains, so that two types of Ni–N bond are observed. The presence of six double bonds in the macrocyclic ligand molecule decreases the size of its plane, which is reflected in a decrease of the nickel–nitrogen bond length.

It follows from the data in Table 1 that the nickel–nitrogen distance varies consistently as a function of the nature of the donor atom. It increases in the sequence Ni–N_{cov} < Ni–N_{im} < Ni–N_{am}.

The nickel–sulphur distance is virtually constant regardless of which donor atoms, apart from those of sulphur, are coordinated to the nickel ion.

All the compounds in Table 1 are diamagnetic. Certain paramagnetic nickel(II) compounds having C.N. > 4, have now been ivestigated (Table 2). It follows from the data in Tables 1 and 2 that the nickel–nitrogen distance in high-spin complexes is greater than in diamagnetic complexes. The length of this bond increases with the size of the macrocyclic ligand. The Ni–O bond length depends on the charge on the oxygen atom. If it is negative ($acac^-$, CH_3COO^-), the nickel–oxygen distance is shorter than in complexes with neutral oxygen-containing ligands (H_2O), the Ni–$O_{(H_2O)}$ distance being almost independent of the nature of the macrocyclic ligand.

Only two iodide ions, out of the four present, are coordinated in complex No.23 [Table 2 (V)] and the nickel atom has been raised 0.30 Å above the plane of the four nitrogen atoms in the direction of the iodide ion[40]. A similar deviation of the nickel atom from the plane of the donor atoms in the direction of the axial ligand (by 0.33 Å) has been observed also in complex No.27.[44]

Table 2. The metal–donor atom distances (in Å) in high-spin macrocyclic nickel(II) complexes.

32	[Ni(Bz_4[16]tetraeneN$_4$)I, H_2O]I	F	—	2.09	—	2.20	2.90	36

Remarks: [a] see Fig.2; [b] N_{ax} = donor nitrogen atom of the axial ligand; acac = acetylacetone.

The presence of the Ni–Ni bond has been demonstrated by X-ray diffraction in complexes with Me_4[14]4,6,11,13-tetraeneN$_4$ and Me_4[14]hexaeneN$_8$ ligands[49]. These diamagnetic coordination compounds have very similar structures and are dimeric both in the solid state and in solution with a nickel–nickel distance of approximately 3 Å. Nickel atoms are raised above the plane of the donor atoms towards one another.

2. Cobalt Complexes

The number of studies on the X-ray diffraction analysis of cobalt complexes of macrocyclic ligands is much smaller than for the nickel complexes. The results obtained are listed in Table 3. The general characteristics observed in the discussion of the stereochemistry of nickel complexes apply also to the cobalt complexes.

Table 3. The metal–donor atom distances (in Å) in certain macrocyclic cobalt complexes.

Remarks: [a]see Fig. 2; [b]distance in trigonal plane; [c]distance to the vertex of the trigonal bipyramid.

Table 3 shows that the Co–N_{am} distance is almost independent of the degree of oxidation of the cobalt ion and remains virtually constant regardless of the mode of coordination of the macrocyclic ligands. Evidently the ability of ligands to form structures with a bent conformation of the macroring (i.e. structures where the donor atoms of the ligand do not occupy the equatorial plane in the coordination sphere of the metal) enables the nitrogen atoms to occupy the most convenient position in relation to the cobalt ion and to avoid strain in the macroring.

As a rule, the Co–N_{am} bond length is greater than the Co–N_{im} bond length. The only exception is complex No. 138 (Table 3), which may be accounted for by steric interactions, since in the ligand involved the imino-nitrogen is linked to a carbon atom which is itself joined to a methyl group, while the amino-nitrogen is linked to a carbon atom without alkyl substituents. The cobalt–oxygen distance is determined both by the nature of the macroring and by the characteristics of the axial ligands. The shortest distances are observed when a Co–O ionic bond is formed.

As for the nickel complexes, the equalisation of the Co–N_{im} and Co–N_{ion} bond lengths is observed in the presence of conjugation in the propylene bridge of the macrocyclic ligand. The shortest cobalt–nitrogen distance has been found in complex No. 47. The type of coordination of the macrocyclic ligand in the cobalt complexes differs from that in the nickel complex [the cobalt ion is coordinated to the nitrogen atoms of the α-di-imino-groups, as shown in stucture (III)].

3. Other Transition Metal Complexes

A number of iron(II) and iron(III) complexes have been investigated by X-ray diffraction. Some of the results of these investigations are presented in Table 4. The Fe–N distances are various and depend mainly on the type of coordination of the macrocylic ligand and the donor nature of the nitrogen atom. In trigonal-bipyramidal complexes the distance is somewhat greater than in tetragonal compounds.

Comparison of the carbonyl and alkyl derivatives of cobalt and iron shows that, whereas the M–C(CO) distances vary insignificantly [1.77 Å for Co(II) and 1.75 Å for Fe(II)], the M–C(R) distances differ to a greater extent. In complex No. 51 (Table 4) the distances between the nitrogen atoms and the iron atom are various, which indicates the absence of the delocalisation of the π-electrons in the propylene bridge (as in complex No. 20, Table 1).

The amount of X-ray diffraction data on other macrocyclic complexes is slight (Table 4). Only square-planar[13,14,35] and trigonal-bipyramidal[68,69] structures have been observed for the copper compounds. The structures of the macrocyclic manganese(II) [59] and chromium(I) [70] complexes have also been determined.

Inspection of the data in Tables 1–4 reveals a consistent variation of the metal–nitrogen donor atom distance in complexes of different metals with macrocyclic ligands. In terms of the decrease of the length of the bond, the metals can be arranged in the following sequence†:

$$Fe^{3+} > Fe^{2+} > Ni^{2+}\ (S=1) > Cu^{2+} > Co^{3+} \simeq Co^{2+} > Ni^{2+}\ (S=0)\ .$$

This series holds for any donor nitrogen atom (N_{am}, N_{im}, and N_{cov}). In the nickel complexes the metal–donor atom distance is greatly influenced by the spin state of the metal ion.

III. ABSORPTION SPECTRA OF IRON COMPLEXES

There are literature data on the absorption spectra of different macrocyclic iron(II) and iron(III) complexes which include both high-spin and low-spin compounds. The results of these studies will be considered below.

1. Iron(III) Complexes

In high-spin iron(III) complexes the ground state is ^6S and is not split in a crystal field of any symmetry. Complexes of this type are characterised by a low intensity of the *d*–*d* transitions, because they all spin-prohibited. In the spectra of the compounds investigated charge-transfer $L–Fe^{III}$ bands have been observed at ~30000 cm^{-1} for halide complexes[71,72] and at ~19000 cm^{-1} for thiocyanate[72] complexes.

The magnetic moments of all these compounds are in the range 5.7–6.1 μ_B. The lower magnetic moments of some of the complexes[72] have been explained by the admixture of the excited ^4E_g and $^2B_{2g}$ states to the $^6A_{1g}$ ground state.

Very few low-spin iron(III) complexes are known and their *d*–*d* spectra have in general been poorly characterised[73–75]. Their magnetic moments are in the range 2.1–2.3 μ_B. With increase of the number of double bonds in the macrocyclic ligand, a steady decrease of the magnetic moment has been

†Here *S* is the overall spin of the ion.

observed for isotypical complexes: $\mu_{eff} = 2.30$, 2.13, and 2.06 μ_B respectively for *trans*-$[FeLCl_2]^+$, where L = Me_6-[14]dieneN$_4$, Me_6[14]trieneN$_4$ and Me_4[14]tetraeneN$_4$.

It follows from the study of Chan and Poon[72] that the spin state of the iron ion is greatly influenced by the relative positions of the ligands: the complexes $[Fe([14]anN_4)X_2]^+$, where X = NCS^-, Cl^-, or Br^-, are high-spin for the *cis*-disposition of the monodentate ligand and low-spin in the case of the *trans*-coordination.

2. High-Spin Iron(II) Complexes

Among the high-spin complexes of bivalent ions, compounds with coordination numbers of 5 (C_{4v} symmetry) and 6 (D_{4h} symmetry) have been observed. The data on the magnetic moments and the electronic absorption spectra of these compounds are presented in Table 5. In the spectra of complexes of this type one may expect the presence of three bands of the spin-allowed transitions $^5B_1 \leftarrow {}^5B_2$, $^5A_1 \rightarrow {}^5B_2$, and $^5E \leftarrow {}^5B_2$. In practice usually two of these are observed (those with higher energies) as broad bands with a low intensity. The ground state in these complexes is $^5B_2$, as shown by Mössbauer spectroscopy[71]. The square-pyramidal complexes of the type under consideration are probably subject to some trigonal distortion[66].

The $^5B_1 \leftarrow {}^5B_2$ transition is determined in the first place by the very strong field of the macrocyclic ligand, since the energy of the $^5A_1 \leftarrow {}^5B_2$ transition is determined by the nature of the axial ligand. In square-pyramidal macrocyclic iron(II) complex a very marked splitting of the "octahedral" ^5E_g state (~7000 cm^{-1}) is observed, which has been explained by the presence of only one axial ligand and by the unusually strong field of the donor atoms of the macrocycle.

The energy of the $^5B_1 \leftarrow {}^5B_2$ transition in the complexes $[Fe(Me_2py[14]aneN_4)X]^+$, where $X^- = Cl^-$, Br^-, or I^-, increases with decrease of the strength of the field of the axial ligand[71], which may reflect the mutual influence of the ligands in the macrocyclic complexes (see Section VII). In terms of increasing strength of the equatorial field, the macrocyclic ligands can be arranged in the following sequence:

$$Me_2py[14]aneN_4 < Me_6[14]tetraeneN_4 < Me_6[14]dieneN_4.$$

Somewhat unexpectedly the di-imine ligand has a stronger field than the tetraimine ligand (see Section IV). Evidently the introduction of additional imine bonds decreases the size of the macroring and leads to the expulsion of the metal ion from the plane of the donor atoms, which weakens the metal–nitrogen interaction and decreases the strength of the field of the macrocyclic ligand.

The magnetic moments of compounds of this type are in the range 4.95–5.20 μ_B, which is somewhat less than in the hexacoordinate complexes (see below). In all probability the marked splitting of the $^5E_g(O_h)$ state reduces μ_{eff} as a result of the orbital contribution.

The magnetic and spectroscopic data on the iron(II) complexes with C.N. = 6 are listed in Table 5. The majority of these compounds have the *trans*-coordination of the axial ligands; the *cis*-coordination has been postulated for the complexes $[Fe(Me_2py[14]aneN_4)CH_3COO]PF_6$ and $[Fe(Me_6[14].$ $.tetraeneN_4)phen](ClO_4)_2$ due to the bidentate coordination of the additional ligands. The symmetry of the chromophore should be pseudo-octahedral in this case and the presence of a single broadened spin-allowed band due to the $^5E_g \leftarrow {}^5T_{2g}$ transition may be expected in the electronic spectrum. In the spectrum of $[Fe(Me_2py[14]aneN_4)(N_3)_2]$, which the authors[71] believe to have a *trans*-structure, no splitting was observed, because the azide ligand gives rise to a field whose strength is similar to that of the macrocyclic ligand. This hypothesis is supported also by the magnetic moment of the above compound.

Table 5. The magnetic moments and absorption bands of high-spin iron(II) complexes[a].

Compound	μ_{eff}, μ_B	Solvent	$^5A_1 \leftarrow {}^5B_2$	$^5B_1 \leftarrow {}^5B_2$	Refs.

Remarks: [a]here and henceforth the positions of the absorption bands are given in units of 10^3 cm^{-1}, the values of ε, expressed in litre cm^{-1} mol^{-1}, being given in brackets; [b] $^5E_g \leftarrow {}^5T_{2g}$ transition for octahedral symmetry; [c]spectra of compounds in the solid state; phen = phenanthroline.

The positions of the absorption bands in the spectra of these complexes depend, as for the compounds with C.N. = 5, on the strength of the field of the equatorial axial ligands. In the complexes $[Fe(Me_6[14]aneN_4)X_2]$ there is a correlation between the energy of the *d*–*d* transitions and the magnetic moments. With increase of the strength of the field due to the axial ligand, i.e. with increase of the energy of the $^5A_{1g} \leftarrow {}^5A_{2g}$ transition, the $^5B_{1g} \leftarrow {}^5B_{2g}$ band shifts to the low-energy region, which indicates a decrease of the macrocyclic ligand field strength. If the axial ligands are arranged in terms of the increasing splitting of the $^5E_g(O_h)$ state (the $CH_3COO^- < Cl^- < Br^- < I^-$ sequence), then it follows from the data in Table 5 that the magnetic moments of the complexes formed by them decrease in the same direction. This confirms the above hypothesis concerning the contribution of the orbital moment of the μ_{eff} of these compounds.

It follows from the spectra of the complexes $[Fe([X]aneN_4)Y_2]$, where X = 15, or 16 and Y = NCS^- or CH_3CN, that[78] the strength of the field of the macrocyclic ligand is greater in the acetonitrile complexes than in the thiocyanate complexes. Evidently the greater the axial ligand field strength the lower the macrocyclic ligand field strength and conversely. On passing from complexes of a 15-membered ligand to those of a 16-membered ligand the strength of the field due to the macrocycle diminishes by 180 cm^{-1} for the acetonitrile complexes and by 150 cm^{-1} for the thiocyanate complexes.

A series of square planar iron(II) complexes, having the triplet ground state $^3B_{2g}$, have been obtained recently[79]. Their effective magnetic moments are 3.2–4.3 μ_B and their electronic absorption spectra are characterised by the presence of two absorption bands in the ranges 4000–7000 and 12000–15000 cm^{-1}.

3. Low-Spin Iron(II) Complexes

The spin state of iron(II) is determined by both macrocyclic and axial ligands involved in coordination. For example, the complexes [Fe([14]aneN$_4$)X$_2$] are low-spin for X = CH_3CN, NCS^-, or CN^-, while among the complexes of the [15]aneN$_4$ ligand only the cyanide compounds are low-spin[78]. In many instances the absorption spectra of these complexes contain intense charge-transfer of intraligand transition bands, which mask the d–d bands. Such cases will not be considered. A diagram of the states of the low-spin hexacoordinate iron(II) complexes is presented in **Fig. 3***a*. Evidently at least four bands due to spin-allowed transitions can be expected in the absorption spectra of the tetragonal complexes of bivalent iron. However, if the splitting of the "octahedral" $^1T_{1g}$ and $^1T_{2g}$ states is not observed, then the absorption spectra of such compounds are interpreted from the standpoint of pseudo-octahedral symmetry. The spectroscopic data for the hexacoordinate low-spin iron(II) complexes are presented in Table 6.

The energy of the $^1T_{1g} \leftarrow {}^1A_{1g}$ transition is $10\,Dq - C$.[80] A method has been developed[81] for the calculation of the crystal field parameters for tetragonal low-spin complexes of ions with the d^6 configuration. According to the results of this study, the energies of the transitions are described by the following equations:

$$E(^1A_{2g} \leftarrow {}^1A_{1g}) = 10Dq^{xy} - C = \nu_2,$$
$$E(^1E_g \leftarrow {}^1A_{1g}) = 10\,Dq^{xy} - 35/4Dt - C = \nu_1,$$
$$Dt = 4/7\,(Dq^{xy} - Dq^z).$$

Hence we have

$$Dq^{xy} = \nu_2 + C,$$
$$Dq^z = Dq^{xy} - 7/4\,Dt,$$
$$Dt = 4/35\,(\nu_2 - \nu_1),$$

where Dq^{xy} (or Dq^E) is the strength of the field due to the equatorial macrocyclic ligand, Dq^z (or Dq^A) is the strength of the field due to the axial ligands, Dt is the tetragonal distortion parameter, and C is the Racah coefficient. If $Dq^{xy} > Dq^z$, then $Dt > 0$ and the sequence of levels corresponds to that illustrated in **Fig. 3***a*. If $Dq^{xy} < Dq^z$, then $Dt < 0$ and the ^1E_g level lies above the $^1A_{2g}$ level. This case obtains in the macrocyclic iron(II) complexes with cyanide axial ligands. Having adopted the Racah coefficient $C = 3300$ cm^{-1}, it is possible to calculate from the absorption bands Dq^{xy}, Dq^z, and Dt (Table 6).

Examination of the results shows that Dq^{xy} is influenced by the structure of the macrocyclic ligand. With increase of the number of imino-nitrogen atoms, the parameter increases. The number of methyl substituents in the macroring has a much weaker influence, although as a rule the greater the number of such substituents the smaller Dq^{xy} {cf., for example, the values of Dq^{xy} for [14]aneN$_4$ and Me$_6$[14]aneN$_4$ in the cyanide complexes}.

The strength of the field due to this macrocyclic ligand also diminishes with increase of Dq^z of the axial ligand and conversely. As will be shown subsequently, this phenomenon is characteristic also of the tetragonal cobalt(III) and nickel(II) complexes[83].

With increase of the size of the macrocyclic ligand, the strength of the field generated by it diminishes, which can be seen in relation to the complexes [Fe([X]aneN$_4$)(CN)$_2$], where X = 13, 14, and 15. On passing from a 13-membered to a 14-membered ligand, Dq^{xy} decreases by 180 cm^{-1}; on further increase of the number of members in the ring by unity, Dq^{xy} decreases by 190 cm^{-1}. These values are close to those for the high-spin iron(II) complexes (see above). Hence it follows that the change in the parameters Dq^{xy} with increase of the number of members in the macroring does not depend on the spin state of the iron(II) ion.

The magnetic moments of the tetragonal iron(II) complexes are in the range 0.4–0.8 μ_B, but, one should note that there is a tendency towards an increase of μ_{eff} with decrease of Dq^z.

IV. ABSORPTION SPECTRA OF COBALT COMPLEXES

Among the macrocyclic cobalt(II) complexes, compounds with C.N. = 4, 5, and 6 have been observed. The tetracoordinate complexes are of the low-spin type, while those with C.N. = 6 are of the high-spin type. The vast majority of cobalt(III) complexes are diamagnetic and have C.N. = 6.

1. High-Spin Cobalt(II) Complexes

The spectra of high-spin cobalt complexes show that the metal ion has a pseudo-octahedral environment[84,85]. The spectra are characterised by the presence of three absorption bands in the visible region at 8000, 16000, and 19000 cm^{-1}, which corresponds to the spin-allowed transitions

Remarks: here and henceforth sh = shoulder.

$^4T_{2g} \leftarrow {}^4T_{1g}$, $^4A_{2g} \leftarrow {}^4T_{1g}$, and $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ respectively. The majority of complexes of this type are formed by macrocyclic ligands having nitrogen and oxygen donor atoms. In these complexes the macrocycles have a distorted conformation and the monodentate ligands occupy the *cis*-positions in the octahedron.

The cobalt compounds with the N-$(CH_2C_6H_5)_4$[12]aneN$_4$ ligand are high-spin complexes with a trigonal-bipyramidal coordination[84]. This structure of the complexes is determined by the structure of the macrocyclic ligand, which consists of a 12-membered ring and contains four tertiary nitrogen atoms with bulky substituents. A number of bands have been observed in the absorption spectra of these compounds, but these have not been assigned.

The magnetic moments of both pseudo-octahedral and trigonal-bipyramidal cobalt(II) complexes have values of the order of 4.5–5.0 μ_B, which corresponds to the presence of three unpaired electrons.

2. Low-Spin Cobalt(II) Complexes

Among the low-spin complexes of bivalent cobalt, square-planar, square-pyramidal, and trigonal-bipyramidal compounds have been found.

The square-planar structure of cobalt(II) complexes is formed by virtue of the characteristics of the structures of the macrocyclic ligands. A series of bands due to spin-allowed transitions are observed in the spectra of these compounds. The bands are presented in Table 7.

Since the energy of the $^2A_{2g} \leftarrow {}^2A_{1g}$ transition depends on Dq^{xy}, the relative strength of the field due to the macrocyclic ligands can be inferred from it. It follows from Table 7 that Dq^{xy} increases in the sequence Me$_6$[14]aneN$_4$ < Me$_2$[14]4,7dieneN$_4$ < Me$_6$[14]dieneN$_4$ < Me$_6$[14]dieneN$_4$ < Me$_6$[14]tetraene N$_4$.

In square-pyramidal complexes the energy of the $^2E \leftarrow {}^2A_1$ transition is related to Dq^z. In terms of the decrease of the energy of this band, the axial ligands can be arranged in the sequence $H_2O \cong CH_3CN > Cl^- > Br^- > I^-$, which corresponds to the spectrochemical sequence.

Table 7. Magnetic moments and absorption bands of low-spin cobalt(II) complexes.

Comparison of two cobalt complexes with ligands of identical structure (neutral and monoanionic) showed that the charged ligand has a higher value of Dq^{xy} (by 190 cm^{-1}) than the neutral ligand.

An absorption band at 30000 cm^{-1} is observed in almost all the spectra. It is associated with charge transfer from the metal to the π-antibonding orbital of the imino-group[82].

According to the results of long and Busch[88], the cobalt(II) complexes of Me$_2$py[14]dieneN$_4$ are low-spin and have a trigonal-bipyramidal coordination, but detailed studied on their absorption spectra have not been carried out.

3. Pseudo-Octahedral Cobalt(III) Complexes

According to their spectroscopic properties, all the cobalt(III) complexes can be divided into two large groups: pseudo-octahedral and tetragonal. The pseudo-octahedral complexes can be divided in their turn into compounds containing additional ligands, occupying two *cis*-positions in the octahedron (the macrocyclic ligand then assumes a bent conformation), and tetragonal compounds (with axial ligands in the *trans*-positions), in which the splitting of the "octahedral" absorption band is not observed.

Since the iron(II) and cobalt(II) ions have the same electronic configuration (d^6), the diagrams of their energy levels in octahedral and tetragonal fields are similar (Fig. 3*a*). The transition energies are as follows in the case of the pseudo-octahedral coordination[80]:

$$\nu_1 = E(^1T_{1g} \leftarrow {}^1A_{1g}) = 10\,Dq - C,$$
$$\nu_2 = E(^1T_{2g} \leftarrow {}^1A_{1g}) = 10\,Dq - C + 16\,B,$$

where C and B are Racah coefficients. Having adopted $C = 4B$, it is possible to calculate the parameters of the ligand field:

$$Dq = (3\nu_1 + \nu_2)/40 \quad B = (\nu_2 - \nu_1)/16\,.$$

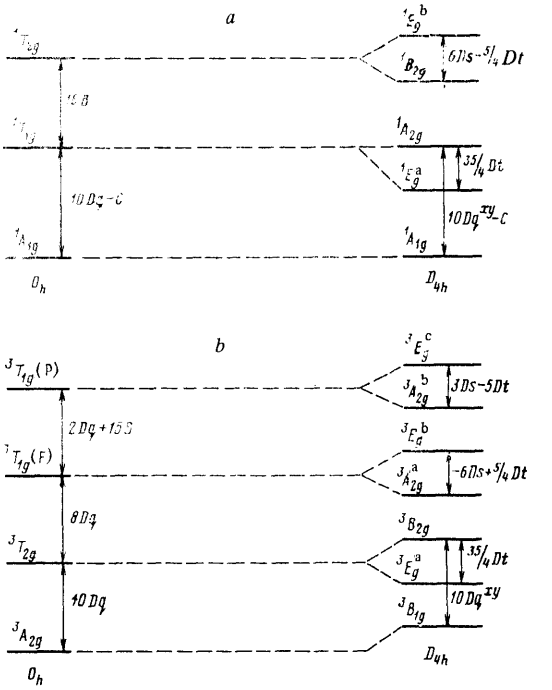

Figure 3. Diagrams and energies of the levels for the low-spin d^6 configuration (*a*) and the high-spin d^8 configuration (*b*) in octahedral (O_h) and tetragonal (D_{4h}) fields (the superscript a, b, and c are used to denote levels of identical symmetry and *Ds* and *Dt* are parameters of the tetragonal distortion).

The spectroscopic parameters of certain pseudo-octahedral complexes are listed in Table 8. They show that all the macrocyclic ligands can be arranged in the following sequence in terms of the decrease of Dq for a fixed bidentate ligand: $Me_6[14]dieneN_4 > 6,7,12,13Me_4[14]dieneN_4 > Me_2py[14]aneN_4 > [12]aneN_4 > Me_6[14]aneN_4 > 5,7,7,12,12,14Me_6[14]aneN_4$.

Comparison of the values of Dq for the oxalate and carbonate complexes shows that $Dq[CoLC_2O_4]^+ > Dq[CoLCO_3]^+$. The difference between them increases in the sequence of ligands $Me_2py[14]aneN_4 < Me_6[14]aneN_4 < [12]aneN_4$. The flexibility of the macroring increases in the same sequence: the pyridine ring in $Me_2py[14]aneN_4$ fixes the two ethylene bridges more rigidly than the six methyl groups in $Me_6[14]aneN_4$ and -[12]aneN$_4$, which have no substituents in the macroring.

The spectra of cobalt(III) complexes with monodentate ligands in the *cis*-positions[91,94,98] are very similar to the spectra of the compounds discussed above.

From the spectroscopic standpoint, the cobalt(III) ammines behave as octahedral compounds (Table 8). According to McClure[99], the splitting of the $^1T_{1g}$ and $^1T_{2g}$ levels in a field of D_{4h} symmetry arises owing to the difference between the σ- and π-antibonding properties of the equatorial and axial donor atoms. In the amine complexes this difference is too small to cause the splitting of the degenerate levels.

The value of Dq for the pseudo-octahedral complexes is determined by the rigidity of the ligand as well as the donor properties of all six atoms coordinated to cobalt. The more flexible the macrocyclic ligand, the much smaller the strain arising when it is coordinated to a cobalt ion, and the greater the overlap of the d orbitals of the latter with the orbitals of the donor ligand atoms.

Dq is also influenced by various other parameters: the number of substituents in the macroring and the number of double bonds and their relative positions. The influence of the latter factor is seen particularly clearly when the nephelauxetic coefficients β are compared. In terms of the increase of this parameter, the nitrogen donor atoms have been arranged in the sequence 4N(α-diim) < 2N(α-diim) + 2N(am) < 2N(im) + 2N(am) < 4N(am). This sequence reflects the decrease of the degree of covalence of the metal–nitrogen bond.

4. Tetragonal Cobalt(III) Complexes

From the point of view of composition, complexes of this type can be divided into three large groups. The first group includes compounds formed by a macrocyclic ligand and two identical axial ligands. The composition of complexes of the second group includes two different axial ligands, while the complexes of the third group are characterised by the presence of an axial cobalt–carbon σ-bond and the second axial ligand can be both an anion (Cl^-, Br^-, I^-, NCS^-, or CN^-) and a neutral molecule (PPh_3, py, CH_3CN, or H_2O).

The splitting of the band due to the $^1T_{1g} \leftarrow {}^1A_{1g}$ transition is observed in the spectra of all these compounds. In certain cases the higher-energy "octahedral" band is also split. This makes it possible to calculate the parameters Dq^{xy}, Dq^z, and Dt by the method described in the discussion of iron(II) complexes[81]. The Racah coefficient C for the cobalt(III) ion was assumed to be 3800 cm^{-1}.

Table 9 presents data on the absorption spectra of complexes of the first group and their spectroscopic parameters are given below in Tables 13 and 14. The tetragonal cobalt complexes of this type are ideal objects for the investigation of the influence of various factors, particularly the structure of macrocyclic ligands, on the spectroscopic parameters. Busch and coworkers[101] investigated the dependence of Dq^{xy} on the degree of unsaturation of the macrocyclic ligand in relation to the bis(acetonitrile) complexes with 14-membered ligands. Their data show that Dq^{xy} increases with the

number of double bonds in the macroring, which confirms the hypothesis that the amino-nitrogen is a more effective donor than the imino-nitrogen. This can be explained by the strong π-electronic interaction between the metal ion and the nitrogen donor atom: the rehybridisation of the unshared electron pair of the nitrogen, accompanying the conversion of the amine into the imine, should have a significant influence on Dq^{xy}. The fact that this parameter is virtually the same for the conjugated and non-conjugated tetraimines {cf., for example, the complexes with Me_4[14]tetraeneN$_4$ and Me_0[14]tetraeneN$_4$ or the di-imines Me_2[14]1,3dieneN$_4$ and Me_6[14]dieneN$_4$} shows that the reverse π-bond is not the main cause of the increase of Dq^{xy} when an amine is replaced by an imine. In all probability, the increase is caused by changes in the nature of the metal–nitrogen σ-bond. The decrease in ring size owing to the larger number of double bonds also makes a definite contribution to the increase of Dq^{xy} for imine ligands compared with amine ligands. Evidently the strengthening of the metal–nitrogen bond due to the π-electronic interaction and the decrease of the size of the macroring make the Co–N_{im} distance shorter than the Co–N_{am} distance (see Section II).

Regardless of the nature of the axial ligands, Dq^{xy} for macrocyclic ligands diminishes in the following sequence as a function of the nature of the nitrogen donor atoms: 4N(α-diimine) ≥ 4N(isolated imine) > 2N(α-diimine) + 2N(amine) ≅ *trans*-2N(imine, 6-membered ring) + 2N(amine) > *trans*-2N-(imine, five-membered ring) + 2N(amine) ≅ *cis*-2N(imine, six-membered ring) + 2N(amine) ≅ N(imine) + 3N(amine) > 4N(amine). In all probability this sequence of donor atoms is characteristic of all transition metals. The increase of Dq^{xy} in the sequence an < diene < tetraene for tetragonal iron(II) complexes had been noted previously and the same sequence is characteristic of nickel(II) complexes (see below).

Me_2py[14]dieneN$_4$ and Me_2py[14]aneN$_4$ are somewhat isolated in this series of macrocyclic ligands. Dq^{xy} for [Co(Me_2py[14]dieneN$_4$)($CH_3CN)_2$]($ClO_4)_3$ is greater than for the analogous complex with Me_4[14]tetraeneN$_4$. This effect cannot be explained exclusively by the donor properties of the pyridine nitrogen atom, because the values of Dq^{xy} for the cobalt(III) complexes of Me_2py[14]aneN$_4$ are close to those of the 2,3Me_2[14]aneN$_4$ complexes, while in the case of the nickel(II) complexes they resemble those for the complexes of saturated 14-membered ligands. In this instance a considerable increase of Dq^{xy} for the complexes of the Me_2py[14]dieneN$_4$ ligand can be explained by the conjugation between the pyridine ring and the α-di-imine groups of the macroring, which probably greatly increases the strength of the field due to this ligand.

The study of the influence of the size of the macroring on the spectroscopic properties of cobalt(III) complexes of the type [Co([X]aneN$_4$)Cl_2]ClO_4, where X = 13, 14, 15, and 16, showed[110] that Dq^{xy} increases with decrease of the size of the macroring. The authors of this study calculated the strain energy arising on coordination of the metal ion to the macrocyclic ligand. It is of interest to note that the Dq^{xy} are not correlated with the strain energy: Dq^{xy} increases in the sequence [16] < [15] < [14] < [13], while the sequence based on the decrease of the strain energy is [16] > [15] > [14] > [13]. Two important conclusions follow from this: (a) Dq^{xy} is related to the ratio of the sizes of the metal ion and the cavity within the macrocycle to a greater extent than to the overall strain energy of the ligand caused by coordination; (b) a 14-membered macrocycle is most suitable as regards size for the cobalt(III) ion.

The absorption spectra of cobalt complexes with two different axial ligands[90,91,95,105,107,108,111] resemble the spectra of the compounds discussed above.

Complexes with an axial cobalt–carbon σ-bond represent an interesting class of coordination compounds. They model vitamin B_{12} and their spectra are typical for tetragonal cobalt complexes and are presented in Table 10 together with certain calculated parameters. The large extinction coefficients of the absorption bands of these compounds can be explained by the high degree of covalence of their bonds. The parameters Dq^z(R) were calculated from the spectra in accordance with the additive rule $Dq^z(X+R) = \frac{1}{2}[Dq^z(X) + Dq^z(R)]$ subject to the condition that the values of Dq^z for CH_3CN, NCS^-, H_2O, Cl^-, Br^-, and I^- are 2180, 2000, 1720, 1460, 1300, and 1000 cm^{-1} respectively.

Compared with truly tetragonal complexes (i.e. complexes with identical axial ligands), in these compounds there is an additional factor which determines the value of Dq^z(R). Together with the influence of the macrocyclic ligand on Dq^z(R), the nature of the *trans*-axial ligand has also an effect. The maximum values of Dq^z have been obtained for compounds in which a second axial ligand is absent. In the presence of any *trans*-axial ligand Dq^z(R) is less than the maximum value. The values of this parameter can therefore be used as characteristics of the *trans*-influence of the ligands in macrocyclic complexes.

In compounds of the same macrocyclic ligand the *trans*-influence series of axial ligands in relation to the alkyl group is as follows {for example, for Me_4[14]tetraeneN$_4$ complexes}:

$$CH_3CN > NCS^- > Cl^- > Br^- > H_2O > I^-.$$

Some complexes do not show a splitting of the low-energy band and they can therefore be regarded as pseudo-octahedral. The values of β for these compounds are in the range 0.31–0.39, which confirms the high degree of covalence of their bonds.

V. SPECTRA OF NICKEL(II) COMPLEXES

Among nickel complexes with macrocyclic ligands, both high-spin and low-spin compounds have been found. All the low-spin complexes have a square-planar structure. The coordination number in the high-spin complexes is 5 or 6. From the standpoint of the symmetry of the chromophore, the pentacoordinate compounds can be classified as square-pyramidal (C_{4v}) or trigonal-bipyramidal (D_{3h}) complexes, while complexes with C.N. = 6 are pseudo-octahedral (O_h) or tetragonal-bipyramidal (D_{4h}).

1. Low-Spin Complexes

Depending on the relative strength of the field due to the axial and equatorial ligands, the ground state in the nickel(II) complexes (configuration d^8) can be both $^3B_{1g}$ (tetragonal high-spin complexes) and $^1A_{1g}$ (square-planar low-spin complexes). In the classical phthalocyanine and porphyrin compounds[114] the axial ligands are unable to compete with the strong field generated by the macroring and the triplet ground state of the nickel(II) ion does not occur. Synthetic macrocyclic ligands have Dq^{xy} smaller than for porphyrins but sufficiently large to form mainly low-spin complexes.

In nickel complexes of this type there is a possibility, in principle, of three spin-allowed transitions[80]. All the low-spin complexes which have been discovered have an absorption band in the range 18500–24000 cm^{-1} with an intensity of 20–500 litre cm^{-1} mol^{-1}, which the majority of investigators assign to the $^1A_{2g} \leftarrow {}^1A_{1g}(b_{1g} \leftarrow b_{2g})$ transition[92,93,97,115–153]. In a number of instances a band due to a second d–d transition has been observed in the range 25000–28000 cm^{-1}.[115–118] However, one should note that, if the assignment of the first band is correct, then its energy should correspond to $10Dq^{xy}$, but it has been found that the position of this band depends greatly on many factors—the non-coordinated anion, the ligand conformation, the solvent, the conditions used in the recording of the spectra, etc.

2. High-Spin Complexes

As already mentioned, square-pyramidal and trigonal-bipyramidal high-spin nickel(II) complexes with C.N. = 5 have been found. The absorption spectra of compounds of this type are characterised by the presence of four (rarely five) low-intensity absorption bands[119,154,155] due to transitions between split "octahedral" levels in a field of C_{4v} symmetry[80]. The magnetic moments of these complexes are in the range 2.80–3.20 μ_B.

The trigonal-bipyramidal nickel complexes have been obtained only with the alkylated macrocyclic ligands N-$(CH_2C_6H_5)_4$[12]aneN$_4$ [156] and N-Me_4[14]aneN$_4$.[120,157] The spectra of these complexes have at least five bands due to d–d transitions in the range 6000–25000 cm^{-1}, but the bands have not been assigned.

Nickel(II) complexes with C.N. = 6 can be divided, like the cobalt(III) complexes, into two large groups: pseudo-octahedral and tetragonal. The energy level diagrams for complexes of these types are presented in Fig. 3*b*. In terms of the one-electron approximation, the transition energies in the field of octahedral symmetry are as follows:

$$\nu_1 = E(^3T_{2g} \leftarrow {}^3A_{2g}) = 10\,Dq,$$
$$\nu_2 = E(^3T_{1g} \leftarrow {}^3A_{2g}) = 18\,Dq,$$
$$\nu_3 = E(^3T_{1g}(P) \leftarrow {}^3A_{2g}) = 12\,Dq + 15\,B.$$

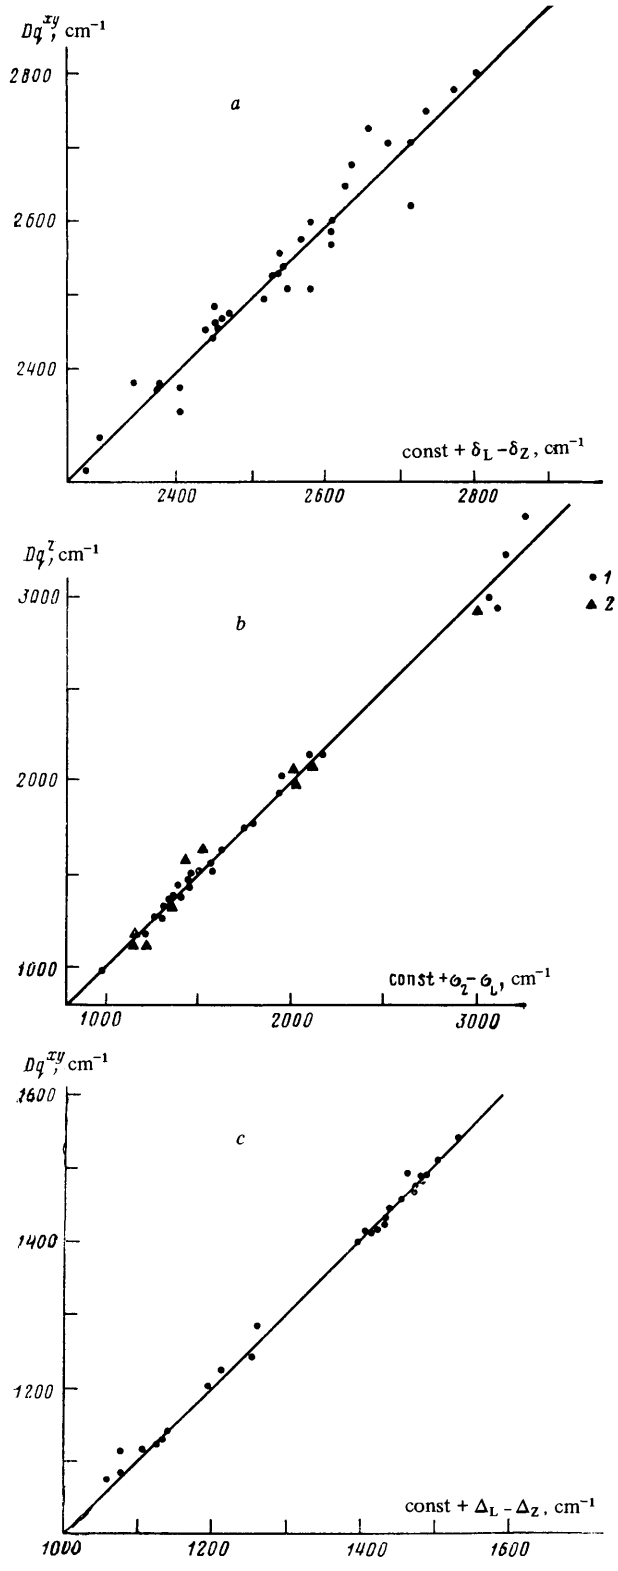

Figure 4. Correlation between Dq_{calc} and Dq_{exp}: *a*) for the values of Dq^{xy} in cobalt(III) complexes; *b*) for the values of Dq^z in cobalt(III) complexes [1) experimental points; 2) points obtained with the aid of Dq^{xy}_{calc}]; *c*) for the values of Dq^{xy} in nickel(II) complexes.

Numerous pseudo-octahedral nickel(II) complexes with macrocyclic ligands have been obtained and characterised[121-126,156-164]. Two or three bands due to *d*–*d* transitions have been observed in the spectra of these compounds in the ranges 10000–12000 (ν_1), 17000–19000 (ν_2), and 27000–29000 cm^{-1} (ν_3) with low extinction coefficients (10–40 litre cm^{-1} mol^{-1}). The values of *Dq* for compounds of this type are in the range 1000–1200 cm^{-1} and are independent of the macrocyclic ligand; they are typical for the amine complexes of nickel(II) and this also applies to the parameters β.

Among the complexes of the same macrocyclic ligand with different bidentate ligands, the highest value of *Dq* and the lowest of μ_{eff} have been found for the oxalate complexes[121], which are dinuclear compounds. Their magnetic moment is reduced owing to the Ni–Ni interaction via the $C_2O_4^{2-}$ bridge group.

A series of hexacoordinate complexes containing *cis*- and *trans*-monodentate ligands have also been isolated[122,123,157,161-163]. It is noteworthy that macrocyclic ligands containing nitrogen and sulphur donor atoms apparently have a low value of Dq^{xy}, since their complexes with Br^- and I^- ligands in the *trans*-positions do not show a splitting of the low-energy band[161,162].

Tetragonal distortion of the complexes entails the splitting of the degenerate levels (Fig. 3b), which permits the calculation of the parameters of the tetragonal field from the following formulae:

$$Dq^{xy} = 1/10E(^3B_{2g} \leftarrow {}^3B_{1g}),$$

$$Dt = {}^4/_{35}[E(^3B_{2g} \leftarrow {}^3B_{1g}) - E(^3E_g^a \leftarrow {}^3B_{1g})],$$

$$Dq^z = {}^1/_{10}[2E(^3E_g^a \leftarrow {}^3B_{1g}) - E(^3B_{2g} \leftarrow {}^3B_{1g})].$$

Remarks: for the designation of the energy levels, see Fig. 3b.

The absorption bands of tetragonal complexes of this type are presented in Table 11 (the parameters obtained from these spectra are compiled in Table 15). A series of tetragonal complexes, not listed in Table 11, have been obtained also for other macrocyclic ligands[119,122,123,127-130,161,165,166].

As for cobalt(III) complexes, the Me_2py[14]dieneN$_4$ ligand gives rise to the highest value of Dq^{xy} (1866 cm^{-1}) [167] among all the ligands investigated.

Dq^{xy} depends on the size of the macroring: [14]aneN$_4$ (1460 cm^{-1}) > [15]aneN$_4$ (1240 cm^{-1}) > [16]aneN$_4$ (1100 cm^{-1}) (the average values of Dq^{xy} were used, see Table 15). According to the data of Busch and coworkers[167], Dq^{xy} for the "ideal" Ni–N distance is 1213 cm^{-1}. The [15]aneN$_4$ ligand has a value of Dq^{xy} closest to the above (Table 15), which confirms the earlier hypothesis[11] that a 15-membered macroring is optimal for the high-spin nickel(II) ion.

As already mentioned, the introduction of electron-donating imino-groups instead of the amino-groups increases Dq^{xy}. Increments have been proposed[167] for the calculation of the values of Dq^{xy} from a specific value of this parameter—in the given instance from Dq^{xy}{[15]aneN$_4$}, as the most suitable for the high-spin nickel(II) ion. These increments are +210 cm^{-1} when a 15-membered ring is replaced by a 14-membered ring and −130 cm^{-1} when a 15-membered ring is replaced by a 16-membered ring; the replacement of the amino-group by an imino-group increases Dq^{xy} by 75 cm^{-1} for the first and second amino-groups, while the replacement of the third and fourth amino-nitrogen atoms by imino-nitrogen atoms increases Dq^{xy} by 155 cm^{-1}. The latter is due to the more marked decrease of the size of the macroring after the introduction of the third and fourth imino-groups compared with the introduction of the first and (or) the second.

The influence of the axial ligands on the Dq^{xy} parameters is examined below (see Section VII).

V. SPECTRA OF OTHER TRANSITION METAL COMPLEXES

Among the complexes of other transition metals, those of copper(II) have been most fully investigated. Unfortunately, the spectra of these compounds are characterised by a small number of broad absorption bands, which greatly diminishes the possibility of deriving information about them.

The absorption spectra of the majority of compounds investigated contain one broad band in the range 16000–20000 cm^{-1} with extinction coefficients of 50–200 litre cm^{-1} mol^{-1}.[92,93,97,125,130-133,169-176] There is apparently no direct correlation between the strength of the field due to the macrocyclic ligand and the position of this band, although an interesting relation has been observed[77] between the position of the above absorption band and the heat of formation of amine complexes of copper.

In a number of instances two[120,134,135,178] or even three[140] absorption bands have been observed in the spectra, but the amount of data is too small to make a correct assignment of these bands.

A square-pyramidal[171,179-181] or trigonal-bipyramidal[155] structure has been proposed for certain pentacoordinate copper compounds, the latter structure having been confirmed by X-ray diffraction[69]; however, the absorption bands were not assigned in the above studies.

Data on the absorption spectra of compounds of other transition metals are presented in Table 12. It is noteworthy that the energies of the $^4B_{2g} \leftarrow {}^4B_{1g}$ (for the d^3 configuration) and $^5B_{2g} \leftarrow {}^5B_{1g}$ (for the d^4 configuration) transitions correspond to values of $10Dq^{xy}$, which makes it possible to follow the variation of this parameter along the series

of transition metals. For compounds of the type $[M(Me_6[14]aneN_4)Cl_2]^{n+}$, the values of Dq^{xy} are as follows: 1700 cm^{-1} (V^{2+}), 1460 cm^{-1} (Cr^{3+}), 1940 cm^{-1} (Cr^{2+}), ~2410 cm^{-1} (Mn^{3+}), 2220 cm^{-1} (Fe^{2+}), 2450 cm^{-1} (Co^{3+}), and 1470 cm^{-1} (Ni^{2+}). It follows from this series that the values of Dq^{xy} for triply charged cations are greater than for doubly charged cations and are constant (~2450 cm^{-1}) within the limits of experimental error, while the values for M^{2+} increase markedly in the sequence Ni < V–Cr < Fe.

Table 12. Absorption bands and magnetic moments of tetragonal transition metal complexes.

Compound	μ_{eff}, μ_B	Solvent	ν_1	ν_2	ν_3	ν_4	Refs

Remarks: the assignments for the d^3 configuration (V^{2+} and Cr^{3+}) are as follows: ν_1—$^4E_g \leftarrow {}^4B_{1g}$ transition; ν_2—$^4B_{2g} \leftarrow {}^4B_{1g}$ transition; ν_3 and ν_4—transitions to the components of the split $^4T_{1g}$ level (A_{2g} and ^4E_g); the assignments for the d^4 configuration (Cr^{2+} and Mn^{3+}) are as follows: ν_1—$^5A_{1g} \leftarrow {}^5B_{1g}$ transition; ν_2—$^5B_{2g} \leftarrow {}^5B_{1g}$ transition; ν_3—$^5E_g \leftarrow {}^5B_{1g}$ transition.

It is of interest to note that, in contrast to the cobalt(III) complexes, in the macrocyclic rhodium(III) complexes no splitting of the octahedral band is observed even for compounds in which the *trans*-disposition of the axial ligands has been demonstrated[130 186–188].

Apart from the tetragonal complexes, trigonal-bipyramidal vanadium(II) complexes[182] and pseudo-octahedral chromium(III) [183] and ruthenium(III) [189] complexes have also been obtained.

VII. THE MUTUAL INFLUENCE OF THE LIGANDS IN MACROCYCLIC COMPLEXES

In the studies of the tetragonal complexes of iron(II), cobalt(III), and nickel(II) it has been shown that Dq^{xy} for macrocyclic ligands varies as a function of the nature of the axial ligands and conversely that Dq^z for a specific axial ligand depends greatly on the nature of the coordinated macrocyclic compound. Similar findings were also made for natural macrocyclic complexes[190]. This phenomenon reflects the mutual influence of the ligands and, since the axial ligand is in the *cis*-position with respect to the macrocyclic ligand, reflects the *cis*-influence in complexes of this type.

It has been shown for cobalt(III) [83] and nickel(II) [167] complexes that the dependence of the quantities Dq^{xy} and Dq^z on the nature of the ligands and their mutual influence can be represented by the following simple equations:

$$(\text{for } Dq^{xy} \text{ in the cobalt complexes}), \quad (1)$$

$$(\text{for } Dq^{z} \text{ in the cobalt complexes}), \quad (2)$$

$$(\text{for } Dq^{xy} \text{ in the nickel complexes})\dagger, \quad (3)$$

where δ_L, σ_Z, and Δ_L are increments taking into account the nature of the ligand, for which the value of Dq is determined by the equation, and δ_Z, σ_L, and Δ_Z are increments taking into account the nature of the ligand in the *cis*-position with respect to the ligand whose parameter is calculated by the equation.

The spectroscopic parameters of the macrocyclic complexes, calculated from the data in Tables 9 and 11, as well as the increments in Eqns.(1), (2), and (3) are listed in Tables 13, 14, and 15. The constants in these equations were selected on the basis of the most reliable data and are as follows: $Dq^{xy} = 2450$ cm^{-1} for $[Co(Me_6[14]aneN_4)(H_2O)_2]^{3+}$ in Eqn.(1); $Dq^z = 1500$ cm^{-1} for $[Co(Me_2py[14]aneN_4)Cl_2]^+$ in Eqn.(2), and $Dq^{xy} = 1399$ cm^{-1} for $[Ni(Me_6[14]aneN_4)(NCS)_2]$ in Eqn.(3). The graphical relations between Dq_{exp} and Dq_{calc} are presented in Fig.4. All the straight lines have a slope of unity and the correlation coefficients are 0.975, 0.994, and 0.997 for Eqns.(1), (2), and (3) respectively.

The increments σ_L and Δ_L are determined by the structure of the macrocyclic ligands and the donor properties of the nitrogen atom, the nature of which has already been discussed in connection with the consideration of the tetragonal cobalt(III) and nickel(II) complexes. The values of σ_Z reflect the spectroscopic properties of the axial ligands and increase in parallel with the spectrochemical series for these ligands $Br^- < Cl^- < H_2O < OH^- < N_3^- < NCS^- < CH_3CN < CN^-$ in the case of the cobalt(III) ion. The *cis*-influence of the axial ligands is expressed by the parameters δ_Z and Δ_Z and in the case of cobalt the ligands can be arranged in the following sequence in terms of the parameter δ_Z: $CH_3CN < H_2O < CN^- \leq Cl^- < NCS^- < Br^- < N_3^- < OH^-$.

The influence of the axial ligands on Dq^{xy} can be explained as follows. The part of the electron density orbital d_{z^2} associated mainly with the axial ligands is located in the equatorial plane XY and the mutual influence of the ligands can be transmitted via this orbital, because the maximum overlap of the atomic orbitals of the metal with the orbitals of the donor nitrogen atoms occurs in the XY plane. The influence of the macrocyclic ligand on Dq^z, expressed by the parameter σ_L, can be explained by the steric interactions between the alkyl or benzyl substituents in the macroring and the axial ligands, apart from the cause indicated above. This interaction has been observed in the ^1H NMR spectra of a series of macrocyclic complexes[191] and has also been characterised as the *cis*-influence.

The available data are as yet insufficient to construct a relation similar to Eqn.(2) for the Dq^z of the nickel complexes, although it has been shown for a limited number of ligands (Cl^-, Br^-, N_3^-, and NCS^-) [167] that there is a definite relation between the parameters Dq^{xy} and Dq^z, and that the susceptibility of the axial ligands to changes in Dq^{xy} increases in the sequence $Br^-(-0.54) = Cl^-(-0.54) < N_3^-(-0.39) < NCS(-0.33)$ (the slopes of the linear relations between Dq^z and Dq^{xy} are given in brackets).

It follows from the foregoing that Dq^{xy} and Dq^z are not constants and vary as a function of the properties of the ligands in the *cis*-positions. In the presence of various axial

#This equation is not quoted by Martin et al., [167] but follows from the results obtained.

ligands in the macrocyclic complex the situation is complicated still further, because in calculations of the parameters Dq^{xy} and Dq^{z} it is necessary to take into account the mutual influence of the *trans*-ligands as well as the influence of two different axial ligands on the macrocyclic ligand.

It follows from Table 12 that the position of the absorption band associated with Dq^{xy} depends on the nature of the axial ligands in the case of vanadium(II), chromium(II), chromium(III), and manganese(III) complexes. In all probability this phenomenon is general for all transition metals.

As shown in the present review, macrocyclic ligands constitute an interesting class of compounds forming complexes with metal ions. The wide variety of the structures of these complexes is determined both by the structure of the macrocyclic ligands and the properties of their donor atoms, on the one hand, and by the characteristics of the electronic structure of the metal ions, on the other.

Apparently, as for alkali and alkali earth metal complexes with macrocyclic polyethers[8], the relative dimensions of the cavity within the macrocyclic ligand and of the transition metal ion play an important role in determining various properties (kinetic, thermodynamic, spectrochemical, electrochemical, etc.) of their complexes. If the size of the macrocyclic ligand is insufficient for it to be coordinated to the metal in a planar conformation, then complexes of a different structure with a bent macrocyclic ligand are formed. Complexes of this type are formed also when a macrocyclic ligand of sufficient size contains bulky substituents in its ring (particularly at the nitrogen atoms) or when an additional bidentate ligand is involved in the coordination.

Complexes with macrocyclic ligands occupying the equatorial plane in the coordination sphere of the metal are subject to marked tetragonal distortion, which gives rise to a unique possibility for the investigation of the influence of various factors on the spectrochemical parameters of the complexes. It has been shown that the parameters obtained reflect the mutual influence of the ligands in these complexes.

From the spectrochemical point of view, macrocyclic compounds are as a rule some of the most powerful ligands for which the values of Dq have been determined and are inferior, as regards field strength, only to ligands of the type of cyanide ions or nitro-groups.

The Influence of Solvation on the Acid-Base Properties of Organic Compounds in Various Media

K.M.Dyumaev and B.A.Korolev

The influence of non-specific (electrostatic) and specific (with formation of a hydrogen bond) solvation of ions in water on the strength of different organic acids is considered by comparing their deprotonation constants (pK_d) in water, nitromethane (a solvent which serves as a model for electrostatic solvation), and in the gas phase. The decisive role of the electrostatic solvation of ions in the variation of pK_d and in the weakening of the influence of substituents on the pK_d for ammonium, anilinium, and pyridinium cations, benzoic acids, and phenols on passing from the gas phase to water and also in the differentiation of the basicities of primary, secondary, and tertiary amines in water is demonstrated. The pK_d for organic OH-, $\dot{O}H$-, NH-, $\dot{N}H$-, $\dot{P}H$-, and CH-acids in water, dimethyl sulphoxide, and nitromethane are compared, which permits the determination of the relation between the localisation of the charge in organic ions and dipolar species, on the one hand, and their solvation via hydrogen bonding and dispersion interaction in solution, on the other. The relation between the capacity of bridge groups to transmit electrons and the medium is considered.

I. INTRODUCTION

The considerable influence of solvation on the rate and direction of chemical reactions in solutions is generally known[1-5]. One of the reactions most convenient for the quantitative study and interpretation of the influence of solvation effects is the reversible acid–base interaction which consists of a very simple reversible system, whose equilibrium constant can be measured for a wide range of compounds in many different media:

$$HA \rightleftharpoons A^- + H^+, \quad K_d\ (\Delta G_d^\circ) \qquad (1)$$

$$BH^+ \rightleftharpoons B + H^+, \quad K_d\ (\Delta G_d^\circ) \qquad (2)$$

The standard free energy of the deprotonation reactions (1) and (2) in a solvent S ($\Delta G_d^{\circ S}$) is determined by the "internal" and "external" components of the free energy[1,4]:

$$\Delta G_d^{\circ S} = \Delta G_{d,\,int}^{\circ S} + \Delta G_{d,\,ext}^{\circ S} = \Delta G_d^{\circ g} + \Sigma \Delta G_s^{\circ S}. \qquad (3)$$

The internal component depends only on the structure of the acid and the conjugate base and is determined by the free energy of the process in the gas phase (g): $\Delta G^{S}_{d,int} = \Delta G^{g}_{d}$.

The external component is determined by the influence of the medium on the deprotonation process, i.e. by the free energy of solvation (ΔG^{S}_{s}) of all the species; for example, for reaction (1) we have

$$\Delta G^{S}_{d,ext} = \Sigma \Delta G^{S}_{s} = \Delta G^{S}_{s}(H^{+}) + \Delta G^{S}_{s}(A^{-}) - \Delta G^{S}_{s}(HA). \quad (3)$$

It follows from Eqn.(3) that, in order to elucidate the solvation effects in the solvent S, it is necessary to know the acid–base properties not only in this solvent but also in the gas phase. In the course of many decades chemists investigating protolytic equilibria in solutions (mainly in water) were unable to do this. However, during the last ten years the position changed radically: with the aid of methods developed recently, it has been possible to measure the acidities in the gas phase of a large number of organic compounds[6], for example, substituted aliphatic[7] and aromatic carboxylic acids[8], alcohols[9], phenols[10], and aliphatic and aromatic ammonium cations[11–15].

It is noteworthy that the characteristics of water—high dielectric constant ε, high capacity for the formation of hydrogen bonds (HB), and a highly developed structure—lead to very complex solvation interactions in an aqueous medium[16]. Since any type of solvation can influence the deprotonation constant pK_d and the transmission of the effects of substituents, an unambiguous interpretation of the results for the aqueous medium is difficult[1] even when data are available for the gas phase: thus the same experimental data for substituted $\overset{+}{N}H$-acids have been explained[17–20] by the effect of specific solvation (with formation of the $\overset{+}{N}H\ldots OH_2$ hydrogen bond), while in other studies[11,12] they have been accounted for by the non-specific (electrostatic) solvation of ammonium cations. The subdivision of the solvation effects under consideration into reactions (1) and (2) involves considerable fundamental difficulties[19]: for example, both effects are intensified with increase of the charge on the $\overset{+}{N}H$ group of the substituted ammonium cations; furthermore, the hydrogen bond with the ions (at any rate $\overset{+}{N}H\ldots OH_2$) is largely electrostatic[11,19,21] and is determined by the charge of the ions.

Despite the above difficulties[3], problems of this kind can be solved. One of the possible ways involves the consideration of the influence of solvation on the pK_d in a medium which serves as a model of only the electrostatic solvation of the ions A^- and BH^+, i.e. in a solvent with a fairly high dielectric constant and a greatly weakened capacity for the formation of hydrogen bonds with different hydrogen donors and acceptors. A comparative study of data for the gas phase, the model solvent, and water would make it possible to elucidate the influence of electrostatic solvation and solvation via hydrogen bonding on the acid–base properties in an aqueous medium. There is no doubt that the model solvent must be sought among aprotic polar solvents (APS) incapable of forming the $A^-\ldots HS$ bond. During the last 10 years, the acid–base properties of a large number of organic compounds have been determined quantitatively in a series of APS (see, for example, Refs.22–29), which permits an approach to the solution of the problem under consideration.

II. COMPARISON OF THE ABILITIES OF APROTIC POLAR SOLVENTS TO FORM HYDROGEN BONDS

Examination of numerous literature data shows that the model solvent which satisfies the conditions specified above most satisfactorily is nitromethane. Since its dielectric constant ($\varepsilon = 38.6$) is fairly high, the free energies of the electrostatic solvation $\Delta G_S(I^{\pm})_{el}$ of the ions $I^{\pm}$ in water ($\varepsilon = 80.1$) and nitromethane, calculated from the Born equation[1,30,31]

$$\Delta G_S(I^{\pm})_{el} = -\frac{e^2}{2r}\left(1 - \frac{1}{\varepsilon}\right) \quad (4)$$

(here e is the charge and r the radius of the ion), are similar and differ only by ~1%.

Table 1. The dielectric constants ε and indices of the capacity of the solvents S for electron-donating solvation.

Solvent	ε[35,38]	DN[36,37]	$\delta^{23}Na^{+}$[48]	$10^3\Delta g$[39]	$\Delta\nu_{PhOH\ldots S}$[40]	$\Delta\nu_{MeOD\ldots S}$[41]	$10^3(\Delta\nu/\nu)_{HOH\ldots S}$[42,43]	$K_{MeOH\ldots S}$[44]	$-\Delta H_{PhOH\ldots S}$[45]	$\lg W^{S}_{H^+}$

* From data in Ref.48; **toluene.

Notation: DN is the Gutmann donor number, $-\Delta H$ the heat of formation of the complexes $SbCl_5\ldots S$ in $C_2H_4Cl_2$ (kcal mol^{-1}), $\delta^{23}Na^{+}$ the shift of the $^{23}Na^{+}$ peak in the NMR spectrum of the $NaBPh_4$ solution in S (p.p.m), Δg the change in the parameter of the EPR spectrum of the copper complex in S, $\Delta\nu_{PhOH\ldots S}$ the shift of the vibration frequency of the OH group of phenol following the PhOH...S interaction in CCl_4 (cm^{-1}), $\Delta\nu_{MeOD\ldots S}$ the shift of the vibration frequency of the OD group in MeOD on passing from the gas phase to the solvent S (cm^{-1}), $(\Delta\nu/\nu)_{HOH\ldots S}$ the ratio of the vibration frequency shift of the OH group of water on passing from the gas phase to the solvent S to the frequency in the gas phase, $K_{MeOH\ldots S}$ the formation constant of the complex MeOH...S in CCl_4, $-\Delta H_{PhOH\ldots S}$ the enthalpy of formation of the complex PhOH...S in CCl_4 (kcal mol^{-1}), and $\lg W^{S}_{H^+}$ the coefficient of proton solvation (transition from water to the polar solvent S).

Nitromethane[32] belongs to the class of APS containing hydrogen atoms linked only to carbon atoms and exhibiting a very weak capacity for the specific solvation of anions via hydrogen bonds[2,16,33,34]. On the other hand, the molecules of the majority of APS contain electronegative O, N, and S atoms and are capable of relatively intense specific solvation of acid and cationic centres[16]. However, numerous experimental data (Table 1) have shown that nitromethane is in fact less capable, compared with all other APS, of specific electron-donating solvation of electrophilic and cationic centres, particularly solvation involving the formation of the $XH\ldots O_2N$Me bond.

Inspection of the data in Table 1 and also the values of *DN*, $\Delta\nu_{PhOH...S}$, $\Delta\nu_{MeOD...S}$, and other indices of the electron-donating capacity[48-53] for a wider range of solvents shows that, among the known (~15) APS, nitromethane exhibits the weakest capacity for specific electron-donating solvation, particularly with formation of hydrogen bonds with uncharged acids. In conformity with this conclusion, measurements of the dissociation constants of the salts BH^+Cl^- (BH^+ = quinuclidinium or tributylammonium)[37] have shown that nitromethane solvates ammonium cations much more weakly than, for example, propylene carbonate, dimethylformamide (DMF), and dimethyl sulphoxide (DMSO).

It also follows from the data in Table 1 that nitromethane resembles more closely alkanes and CCl_4, which are incapable of forming hydrogen bonds with hydrogen donors, than water†, DMF, or DMSO, i.e., compared with these solvents, the capacity of nitromethane to behave as a hydrogen acceptor in the formation of hydrogen bonds is very low. This has also been confirmed by studies of the dependence of ν for the OH groups of water[43] and phenol[54] and the NH group of pyrrole[42,55,56] in solutions on the dielectric constant of the solvent, where the point of nitromethane fits satisfactorily on the linear plot of $\Delta\nu/\nu$ against $(\varepsilon-1)/(2\varepsilon+1)$ for the gas phase, alkanes, and chloroalkanes, while the points for solvents forming the hydrogen bonds XH...S with water, phenol, and pyrrole, namely water, DMSO, acetonitrile, ketones, ethers, and amines, deviate from this relation. The weak# capacity of nitromethane for the formation of the XH...,O_2NMe bond is apparently due to the distribution of the partial negative charge in the nitro group between the two oxygen atoms, which sharply weakens its tendency towards interaction with hydrogen donors[32,57-59] compared with other APS.

Thus the capacity of nitromethane for specific donor and acceptor solvation and particularly for the formation of hydrogen bonds with the ions A^- and BH^+ is very low and constitutes an insignificant fraction of the corresponding property of water. Consequently nitromethane can be regarded as a model solvent suitable for the elucidation of the influence of hydrogen bonding on the pK_d of various acids in water.

The availability of data for a large series of neutral and cationic organic acids in nitromethane, in which the proton is attached to oxygen, nitrogen, phosphorus, and carbon atoms (see Tables 3, 4, and 6)§ also permits an approach to the problem of the relation between the structure and solvation of these compounds.

Table 2. The standard free energies of deprotonation (ΔG_d, kcal mol^{-1}) of organic acids in various media[a].

Medium	$\overset{+}{N}H_4$	$MeN\overset{+}{H}_3$	$Me_2\overset{+}{N}H_2$	$Me_3\overset{+}{N}H$	$PhN\overset{+}{H}_3$	$C_5H_5\overset{+}{N}H$	$Me_4\overset{+}{P}H$	*N*-Methyl-2-hydroxypyridinium	MeCOOH	PhCOOH	PhOH	Fluorene

DMF	12.9[73]	—	—	11[f,73]	6.0[74]	7[9]	—	—	18.5[74]	16.8[74]	25[72]	—
DMSO	14.3[70]	15[f,70]	14[f,70]	11[f,26]	5.0[26]	4.6[75]	7.0[75]	—	17[26]	15[26]	23[26]	31[26]
Water[27,76,77]	12.6	14.5	14.7	13.4	6.3	7.1	11.8[75]	0.4[64]	6.5	5.7	13.6	28.7[26]

[a] The values of ΔG_d in the solutions were calculated from the literature values of $pK_d^{25°}$ by the equation $\Delta G_d(\text{kcal mol}^{-1}) = 1.365pK_d^{25°}$.

[b] The values for $\overset{+}{N}H$-acids have been adjusted to $\Delta G_d^g(Me\overset{+}{N}H_3) = 203$ kcal mol^{-1}.[64]

[c] Quoted in accordance with the scale of Bauer and Foucqult[47] (see Korolev and Kashkovskaya[28]).

[d] $Et_3\overset{+}{P}H$; the values of pK_d for $Me_3\overset{+}{P}H$ and $Et_3\overset{+}{P}H$ in water and DMSO are virtually equal[75].

[e] Estimated from the $pK_d^{NM}-pK_d^W$ correlation for CH-acids (Table 6, series 5).

[f] Calculated from data for ethylamines (the difference between the basicities of the corresponding ethyl- and methyl-amines in water, $MeNO_2$,[27] and MeCN [69] agree to within 0.2 of a pK unit and have the following values: ~0 between $EtNH_2$ and $MeNH_2$ and between Et_2NH and Me_2NH; ~1.0 p*K* unit between Et_3N and Me_3N).

† In contrast to other solvents, the tendency of water to form hydrogen bonds is much greater (by a factor of 1.5 to 2)[17,53] than that[48] of isolated water molecules; in order to characterise water as a medium, the values of *DN* and $\Delta\nu_{PhOH...S}$, describing the properties of water molecules in dilute solutions in chloroalkanes, must be increased by a factor of 1.5–2. For example, for an aqueous medium *DN* ≅ 33.[48]

Contradictory views on this problem are still being expressed in the review literature (see, for example, Bell[34] and Yanovskaya[60]).

§ In the case of other APS data are available for a much more restricted range of compounds (4–6 series, see Tables 3 and 4) compared with nitromethane. The solvation-induced weakening of the sensitivity of the pK_d of three series of organic acids to the influence of substituents on passing from the gas phase to DMSO and water was examined in a recent study by J.E.Bartmess, J.A.Scott, and R.T.McIver, J.Amer. Chem.Soc., **101**, 6056 (1979).

III. CONTRIBUTION OF ELECTROSTATIC SOLVATION TO THE CHANGES IN THE RELATIVE STRENGTHS OF $\overset{+}{N}H$- AND OH-ACIDS ON PASSING FROM THE GAS PHASE TO APROTIC POLAR SOLVENTS AND WATER

It is known that the changes in the deprotonation constants [pK_d; Eqns.(1) and (2)] on passing from one medium to another are determined mainly by the solvation of the charged species[2,11,61,62]. More than 80% of the solvation energy of ions in polar solvents is determined by the non-specific electrostatic solvation[16], which depends on the dielectric constant ε; the specific solvation, which is to a large extent determined by the formation of hydrogen bonds[35], makes a smaller contribution. On passing from the gas phase ($\varepsilon = 1$) to polar solvents ($\varepsilon \geq 30$), the change in acid strength should therefore depend mainly on the electrostatic solvation. In other words, the values of pK_d should vary markedly on passing from the gas phase to water, nitromethane, and other APS and should vary comparatively little on passing from one polar solvent to another.

Table 3. Transmission of the electronic effects of substituents in $\overset{+}{N}H$-acids in different media.

No. of series	Acid[a] X–M–$\overset{+}{N}H$	Bridge group	ρ^g	ρ^{NM}	ρ^W	α^{NM}	$R^{NM,g}$	$R^{W,g}$	$R^{W,NM}$
1	X (X′) (X″) $\overset{+}{N}H$	—	6.5[b9]	4.1[b,c27]	3.2[b79–81]	0.73	1.6	2.0	1.3
2	$XC_5H_4\overset{+}{N}H$	C_5H_4	13.8[d]	7.6[88]	6.0[82]	0.80	1.8	2.3[12]	1.3
3	$XC_6H_4\overset{+}{N}H_3$	C_6H_4	7.5[d]	4.2[e65]	2.9[83]	0.72	1.8	2.6[13]	1.45

[a] X = substituent and M = bridge group; [b] the value of ρ^* is quoted; [c] the value of ρ^* in MeCN is 4.2;[24] [d] calculated from the values of $R^{W,g}$ and ρ^W; [e] the value of ρ in MeCN and MeOH is 4.1 [65] and that in DMSO is 3.8.[65]

Notation: $\alpha^{NM} = (\rho^g - \rho^{NM})/(\rho^g - \rho^W)$; $R^{NM,g} = \rho^g/\rho^{NM}$; $R^{W,g} = \rho^g/\rho^W$; $R^{W,NM} = \rho^{NM}/\rho^W$.

Table 4. Transmission of the electronic effects of substituents in OH-acids in different media.

No. of series	Acid[a] X-M-OH	Bridge group	ρ^g	ρ^{NM}	ρ^W	α^{NM}	$R^{NM,g}$	$R^{W,g}$	$R^{W,NM}$
4	XOH	—	7.0[b9]	4.6[c98]	2.7[b9]	0.6	1.5	2.6	1.7
5	XC_6H_4OH	C_6H_4	15.0[d]	4.5[e29]	2.2[83]	0.82	3.3	6.8[10]	2.0
6	XCOOH	CO	5.5[b9]	3.6[b,f28]	1.8[b99]	0.51	1.5	3.0	2.0
7	XC_6H_4COOH	C_6H_4CO	10.6[1e]	2.55[g65]	1.00	0.84	4.2	10.6	2.55

[a] X = substituent and M = bridge group; [b] the value of ρ^* is quoted; [c] the value of ρ^{*DMSO} is quoted instead of ρ^{*NM}, which is permissible, since the values of $\rho(\rho^*)$ for OH-acids in $MeNO_2$, DMSO, and DMF are similar (see Ref.33 and footnotes *e*, *f*, and *g*); [d] calculated from the values of $R^{W,g}$ and ρ^W; [e] $\rho^{MeCN} = 4.5$, $\rho^{DMF} = 4.5$, and $\rho^{DMSO} = 4.3$ [72]; [f] the values of ρ^* for MeCN, DMF, and DMSO are 3.5 [24]; [g] $\rho^{MeCN} = 2.4$ [100] and 2.6,[9] $\rho^{DMF} = 2.35$,[9,100] and $\rho^{DMSO} = 2.5$ [100] and 2.6.[9] For the significance of the notation, see Table 3.

This conclusion is fully confirmed by the experimental data in Table 2 and Fig.1: the change in ΔG_d for OH-, $\overset{+}{O}H$-, $\overset{+}{N}H$-, $\overset{+}{P}H$-, and CH-acids on passing from water to nitromethane and other APS (10–25 kcal mol^{-1}) amounts to a very small fraction (5–8%) of the decrease of ΔG_d in the transition gas phase → polar solvent (170–320 kcal mol^{-1}).¶ The solvation energy of the proton $\Delta G_s^S(H^+)$, which amounts to ~260.5 kcal mol^{-1} for water[11] and ~240 kcal mol^{-1} for nitromethane (calculated from $\lg {}^W\gamma_{H^+}^{NN}$; Table 1) plays a decisive role in the enormous increase of acidity in solutions. The energy of solvation of organic ions $\Delta G_s^S(I^\pm)$ (50–80 kcal mol^{-1}; [15,25] see Table 5) likewise plays an important role; the solvation of uncharged species is several times weaker[2,15].

Table 5. The solvation energies of organic ions determined by the charge [$-\Delta G_s^S(I^\pm)_{el+hb}$, kcal mole^{-1}*].

Ion $I^\pm$	Water	Nitromethane	Dimethyl sulphoxide
$\overset{+}{N}H_4$	80	71	86
$Me\overset{+}{N}H_3$	72 (8)	64 (7)	77 (9)
$Me_2\overset{+}{N}H_2$	65 (7)	58 (6)	69 (8)
$Me_3\overset{+}{N}H$	60 (5)	53 (5)	63 (6)
$C_5H_5\overset{+}{N}H$	58	50	60
$Ph\overset{+}{N}H_3$	67	56	70
$Me_3\overset{+}{P}H$	52	44	51
$MeCOO^-$	83	74	70
$PhCOO^-$	76	67	64
PhO^-	78	69	66

* The solvation energies were calculated from the equations[11,38] $\Delta G_s^S(BH^+)_{el+hb} = \Delta G_d^g - \Delta G_d^S + \Delta G_s^S(H^+)$ and $\Delta G_s^S(A^-)_{el+hb} = -\Delta G_d^g + \Delta G_d^S - \Delta G_s^S(H^+) + \Delta G_s^S(HA)_{hb}$. The values of ΔG_d^g and ΔG_d^S are listed in Table 2; $\Delta G_s^W(H^+) = -260.5$ kcal mole^{-1},[11] $\Delta G_s^{NM}(H^+) = -240$ kcal mole^{-1} (see above), and $\Delta G_s^{DMSO}(H^+) = -265$ kcal mol^{-1} (calculated from $\lg {}^W\gamma_{H^+}^{DMSO}$,[46] Table 1). Using Kolthoff's data[33] and assuming that the $\Delta G_s^S(HA)_{hb}$ for $PhNO_2$ and $MeNO_2$ are close to zero (see above), we have $\Delta G_s^W(HA)_{hb} \cong -5$ kcal mol^{-1} and $\Delta G_s^{DMSO}(HA)_{hb} \cong -7$ kcal mol^{-1}. The accuracy of the absolute values of $\Delta G_s^S(I^\pm)_{el+hb}$ is to within several kcal mol^{-1}, while the relative values are correct to within 1 kcal mol^{-1}. The effect of each methyl group in the ammonium cations is indicated in brackets.

When the pK_d are compared in a single medium, the proton solvation factor cancels out and the differences in the solvation of the ions BH^+ and A^- become of primary importance. Bearing in mind the foregoing, it is logical to assume that the change (weakening) of the influence of substituents on pK_d in the gas phase → water transition is caused mainly by the non-specific electrostatic solvation of ions. However, the literature data on this problem are contradictory. Thus the weakening (compared with the gas phase) of the influence of substituents on the basicity of amines and pyridines ($\overset{+}{N}H$-acids) and the differences in basicity between different classes of amines in water have been explained[17–20], in conformity with the most widely held view, by the specific hydration of ammonium cations via the hydrogen bonds $\overset{+}{N}H\ldots OH_2$,

¶ These figures correspond to the increase of K_d in solutions by a factor of 10^{125}–10^{230}. Fig.1 also shows that the effect of solvation on pK_d is much greater than that of the structure[1,63].

while other workers[11,12] explain it by the non-specific electrostatic hydration of cations due to the high dielectric constant. For neutral acids HA, the weakening of the influence of substituents on the pK_d in water can also be caused by both types of solvation of the anions A^- indicated above[78], but in many investigations only the formation of the $A^-...HOH$ hydrogen bond has been discussed[7,10,62].

Table 6. Parameters of the relations between the pK_d for acids in nitromethane[27-29,65-68,107-112] and water[22,73,77,113]: $pK_d^{NM} = R^{W,NM}\, pK_d^W + b$.

[a] Polynitroarylamines[107]; [b] approximate data; [c] 9-substituted fluorenes[107]; [d] Et_3PO,[110,113], $PhCH{=}CHP(O)Alk_2$;[111,113] the parameters of line 6 are close to those of the relation calculated[107] on the basis of the correlation between $pK_d^W(6)$ and $pK_d^{NM}(6)$ with $\Sigma\sigma^P$; [e] pyridones, $(H_2N)_2CO$, DMF, $MeCONH_2$, phenalenone[107]; [f] 6-substituted 2,4-diamino-*sym*-triazines[109]; [g] aliphatic and aromatic amines[27,65].

The results of the study of the relative roles of the above solvation factors with the aid of nitromethane as a model solvent[65] are presented in Tables 3 and 4. Before discussing the data in these two Tables, we shall consider the relations between the constants of equilibria (1) and (2) and ion solvation. It has been shown[11,33] that the change in the influence of substituents X on the pK_d for reactions (1) and (2) on passing from the gas phase to a polar solvent S is determined to a first approximation by the change in the free energy of solvation of the ions A^- and BH^+, which is due to the presence of the charge† and includes both the contribution ΔG_s^S.

† This quantity represents the solvation energy of ions A^- and BH^+, from which the neutral component, assumed equal to the solvation energy of the neutral species HA or B, has been subtracted[11,33]. It has been called[11,33] the "electrostatic" [11] or "electrical" [33] component, having in view solvation caused by the charge of the ion, i.e. solvation due to the purely electrostatic interaction and the formation of a hydrogen bond; we believe that this component is best referred to as the "solvation energy determined by the charge" and that it should be designated by $\Delta G_s^S(I^\pm)_{el+hb} = \Delta G_s^S(I^\pm)_{el} + \Delta G_s^S(I^\pm)_{hb}$.

$.(I^\pm)_{el}$ due to electrostatic solvation and the contribution $\Delta G_s^S(I^\pm)_{hb}$ due to the formation of the hydrogen bonds $A^-...HS$ and $BH^+...S$:

$$1.36(\delta p K_d^g - \delta p K_d^S) = \delta \Delta G_d^S (I^\pm)_{el} + \delta \Delta G_d^S (I^\pm)_{hb},$$

where the operator δ [4,17,18] denotes a change in the substituent, for example, $\delta pK_d(BH^+) = pK_d(XBH^+) - pK_d(BH^+)$. In order to elucidate the contribution of each of these components, the changes in δpK_d on passing from the gas phase to nitromethane (incapable of forming a hydrogen bond) and from the gas phase to water (forming strong hydrogen bonds) are considered in Tables 3 and 4:

$$\alpha^{NM} = (\delta p K_d^g - \delta p K_d^{NM})/(\delta p K_d^g - \delta p K_d^W).$$

Bearing in mind the limited number of known values of δpK_d for the same X in different media (for example, for aliphatic amines in the gas phase and in solutions), the quantities δpK_d can be conveniently expressed in terms of the values of ρ in the Hammett and Taft equations ($\delta pK_d^S = -\rho^S\sigma_X$):

$$\alpha^{NM} = (\rho^g - \rho^{NM})/(\rho^g - \rho^W).$$

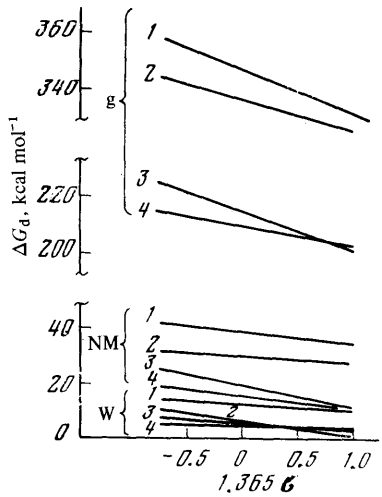

Figure 1. Schematic representation of the Hammett relations between the ΔG_d for the acids XC_6H_4OH (line *1*), XC_6H_4COOH (line *2*), $XC_5H_4\overset{+}{N}H$ (line *3*), and $XC_6H_4\overset{+}{N}H_3$ (line *4*) in the gas phase (g), nitromethane (NM), and water (W) and the σ constants of the substituents (according to the data in Tables 2, 3, and 4).

The data for ammonium cations of different structure in the gas phase, nitromethane, and water are compared in Table 3. For series 1–3, the values of ρ in nitromethane are much closer to those in water than in the gas phase; the values of α^{NM} show that the decrease of ρ on passing from the gas phase to nitromethane is 73–80% of the corresponding change in ρ on passing from the gas phase to water. Consequently the specific solvation of ammonium cations with formation of the $\overset{+}{N}H...OH_2$ hydrogen bond is responsible for only a small proportion (1/5–1/4) of the weakening of the influence of substituents in the gas phase → water transition and a major proportion of this effect is caused by the purely electrostatic hydration of the ammonium cations.

An interesting feature of amines is that, when $pK_d - \Sigma\sigma^*$ plots based on the variables of the Taft equation are constructed, the points for primary, secondary, and tertiary amines in the gas phase fit on a single straight line to a first approximation[9] #, while the points for the amines in water give rise to different straight lines[79,80]; the values of pK_d increase in the sequence $X_3\overset{+}{N}H < X_2\overset{+}{N}H_2 < X\overset{+}{N}H_3 < \overset{+}{N}H_4$, which is usually explained[9,79-81] by the formation of hydrogen bonds with different numbers of hydrogen atoms in the ammonium cations. According to the results already examined, the change in the degree of hydration of substituted ammonium cations must be determined not by hydrogen bonding but by electrostatic solvation and the relations between pK_d and $\Sigma\sigma^*$ for water and nitromethane should be similar. This conclusion has been confirmed by the data of Korolev et al.[27]: the distances between the $pK_d - \Sigma\sigma^*$ straight lines for $X_3\overset{+}{N}H$, $X_2\overset{+}{N}H_2$, and $X\overset{+}{N}H_3$ are similar for both solvents. Comparison of the basicities of the amines in the two solvents leads to the same results (see Section IV).

Consequently, a major proportion of the differences between the $pK_d - \Sigma\sigma^*$ straight lines for the conjugate acids of primary, secondary, and tertiary amines is caused by the electrostatic solvation of the ammonium cations in water and not by the number of $\overset{+}{N}H\ldots OH_2$ hydrogen bonds formed; it has been shown[11] that the increase in the degree of electrostatic solvation in the sequence $X_3\overset{+}{N}H < X_2\overset{+}{N}H_2 < X\overset{+}{N}H_3 < \overset{+}{N}H_4$ can be explained by the decrease of the effective radius of the cations, which is determined by the size of the cations and the degree of asymmetry of their charges.

These results show that the weakening of the influence of substituents on the pK_d and the differentiation of the basicities of the series of X_3N, X_2NH, and XNH_2 amines on passing from the gas phase to water are determined mainly by the change in the degree of non-specific electrostatic hydration of the ammonium cations. This conclusion is unexpected, because in most studies (specially devoted to this subject) it has been claimed up to the present time (see, for example, Refs.17–20, 81, and 96) that the above characteristics of the behaviour of amines in water are caused by the formation of the $\overset{+}{N}H\ldots OH_2$ hydrogen bonds§. However, the data presented above agree with those of Aue et al.[11], who concluded that the additional (compared with the metal cations or $X_4\overset{+}{N}$) interaction of the $\overset{+}{N}H_4$ ion with water is small and amounts to ~2 kcal mol^{-1} per hydrogen atom, while the decrease of the hydration energy in the successive transitions from $\overset{+}{N}H_4$ to $Me_4\overset{+}{N}$ is ~6–8 kcal mol^{-1} per hydrogen atom.

The data presented below (Table 5) confirm these conclusions. Indeed, the differences between the solvation energies of the $\overset{+}{N}H_4$, $Me\overset{+}{N}H_3$, $Me_2\overset{+}{N}H_2$, and $Me_3\overset{+}{N}H$ ions in solvents differing very greatly in their capacity for the formation of $\overset{+}{N}H\ldots S$ hydrogen bonds vary in the range 1–2 kcal mol^{-1} and, as might have been expected, they increase only slightly as the $\overset{+}{N}H\ldots S$ hydrogen bonds are strengthened in the sequence nitromethane, water, DMSO.

Inspection of the data in Table 4 for neutral OH-acids shows that their values of α^{NM} are in the range 0.5–0.8, i.e. that a considerable proportion of the weakening of the influence of substituents on the pK_d of the acids HA on passing from the gas phase to water is caused by the electrostatic solvation of the ions A^- in the aqueous medium. For benzoic acids and phenols, this proportion is 80%. Consequently, contrary to the widely held view[10,62], the $XC_6H_4COO^-\ldots HOH$ and $XC_6H_4O^-\ldots HOH$ hydrogen bonds are responsible for only 1/5 of the decrease of ρ in the gas phase → water transition¶.

We may note that McMagon and Kebarle[10] infer the degree of solvation of anions in water and APS from the factor by which ρ^g is greater than ρ^W and ρ^{APS}. However ρ^S is none other than ρ^g decreased as a result of the solvation of the ions; therefore in elucidating the solvation effects, one must consider not the factor by which ρ^W and ρ^{APS} have been reduced compared with ρ^g but the actual amount of the reduction. For example, for the XC_6H_4COOH series ($\rho^g = 10.6$, $\rho^{NM} = 2.55$, and $\rho^W = 1.00$), one must compare the differences $\rho^g - \rho^W = 10.6 - 1.00 = 9.6$ and $\rho^g - \rho^{NM} = 10.6 - 2.55 = 8.00$, which are fairly close, and not the ratios $\rho^g/\rho^W = 10.6/1 = 10.6$ and $\rho^g/\rho^{NM} = 10.6/2.55 = 4.2$, which differ considerably.

The possibility of a marked change in the degree of electrostatic solvation of the anions in APS follows from the results of studies[102-104] where the solvation of the halide, XO^-, $XC_6H_4O^-$, and $XC_6H_4COO^-$ ions was considered in DMSO, which is incapable of behaving as a hydrogen donor on formation of a hydrogen bond.

The significant role of the electrostatic solvation of the ions A^- and BH^+ in the decrease δpK_d on passing from the gas phase to water is due to the fact that ~80% of the entire solvation energy of ions in polar solvents (particularly in water) is determined by their electrostatic solvation[16]. The substituents X, which intensify (or weaken) the localisation of the charge in the organic ion, increase (or diminish) both the degree of electrostatic solvation[31] and the degree of ion solvation via hydrogen bonding[19]. Both these effects decrease δpK_d, but the much greater energy of the electrostatic solvation of ions explains its considerable role in the weakening of the influence of the substituent X on the pK_d in water. The
