It has been observed[15] that the points of alkyl substituents on this approximate straight line, common to alkyl and polar (electronegative) substituents, form linear groups with an increased slope, which has also been observed for other series for both the gas phase[9,84] and for solutions[35,85-88]. It has now been established that the effects of alkyl substituents are of a different type compared with the inductive influence of polar substituents[1] and that the effects of all groups cannot be described by a single Taft equation[21,35,89-94], i.e. in plotting pK_d against $\Sigma\sigma^*$ polar substituents should be used[21,35,93,94]. Bearing in mind that the points for amines with polar substituents in the gas phase do not exhibit a tendency towards the formation of individual straight lines, we think it most reasonable to consider the $\Delta G_d^g - \Sigma\sigma^*$ correlation for ammonium cations as an approximately single straight line[9] distorted by the specific effects of hydrocarbon substituents (for example, the effect of the polarisability of alkyl substituents[9,14,85,95]). Despite these distortions, the values of ρ^* obtained in this way[9] for amines (6.5) and alcohols (7.0) in the gas phase are apparently correct, since an approximate estimate of the transmission of only the inductive effect in the gas phase leads to similar values of ρ^* for these series (increased by ~15–20%; calculated from the data of Taft et al.[85]).

§ The view has been expressed[15,97] that the role of solvation in the changes of the relative basicities of amines in water is small.

¶ It has been shown recently[101] that the interaction of substituted pyridinium ions and phenoxides with a single water molecule in the gas phase (with formation of the $XC_5H_4\overset{+}{N}H\ldots OH_2$ and $XC_6H_4O^-\ldots HOH$ hydrogen bonds) leads to a much smaller (by a factor of ~5) weakening of the influence of substituents than the solvation of these ions in aqueous solution.

cause of the change in the degree of electrostatic solvation becomes clear[31,105] from an examination of the Born equation [Eqn.(4)]: the introduction of a substituent capable of delocalising the charge (for example, of an electron acceptor into the anion A^-) increases the effective ionic radius and leads to a corresponding decrease of the degree of electrostatic solvation of the ion. This effect is always directed towards the compensation of the influence of the substituent on pK_d.[105]

IV. THE INFLUENCE OF SOLVATION VIA HYDROGEN BONDING ON THE RELATIVE STRENGTHS OF ORGANIC ACIDS IN APROTIC POLAR SOLVENTS AND WATER

Examination of the data of the previous section shows that the change in the strength of acids and of their sensitivity to the influence of substituents on passing from the gas phase to polar solvents is determined mainly by the non-specific electrostatic solvation of ions. However, on passing from one polar solvent to another, the degree of electrostatic solvation of ions changes very little[16,106] and the difference in the specific solvation of ions, which is to a large extent caused by the formation of hydrogen bonds, may become of primary importance. In order to elucidate the role of hydrogen bonds, it was of interest to compare different types of acids in polar solvents with markedly different capacities for the formation of hydrogen bonds, for example, in water, DMSO, and nitromethane:

HB	A^-...HS	BH^+...S
Water	s.	s.
Dimethyl sulphoxide	v.w.	v.s.
Nitromethane	v.w.	v.w.

Notation: s., v.w., and v.s. denote strong, very weak, and very strong hydrogen bonds.

The experimental data obtained in the last ten years for DMSO and nitromethane (Tables 6 and 7) permit such a comparison[107]. We may note that if the specific solvation of the ions A^- and BH^+ [Eqns.(1) and (2)] were absent from all the solvents or were the same, then the points for all types of acids on the plot of pK_d^S against $pK_d^{S_1}$ should fall on a single straight line to a first approximation. The results of a comparison of the pK_d for 15 series of neutral and cationic oxygen, nitrogen, phosphorus, and carbon acids in these solvents, presented in Figs.2–4 and Tables 6–8, show that each structural series gives rise to an individual straight line displaced relative to the other series and having a slope different from unity. Consequently, each class of acids in the given solvent has a characteristic solvation energy, different from those of the other classes and depending on the substituents, the differences in the positions of the straight lines for different types of acids being fairly large (up to 10 pK units; see Fig.3).

Examination of the data in Fig.2 and Table 6 for the neutral acids HA (series 1–5) shows that the acids can be arranged in the following sequence in terms of the displacement relative to the pK_d^W axis (for example, for $pK_d^{NM} = 16$):

$$pK_d^W: XCOOH \ll XC_6H_4COOH < XC_6H_4OH < X_2NH \simeq X_3CH.$$

For $pK_d^{DMSO} = 10$, the acids HA give rise to a similar sequence of the plots of pK_d^{DMSO} against pK_d^W (Fig.3 and Table 7):

$$pK_d^W: XCOOH \ll XC_6H_4COOH < XC_6H_4OH < X_2NH < X_3CH.$$

This behaviour is explained by the fact that, in contrast to nitromethane and DMSO, water is a fairly powerful hydrogen donor in the formation of the A^-... HOH hydrogen bonds. This leads to additional stabilisation in water of anions with a localised charge and to a decrease of the pK_d of their conjugate acids in water. Thus the lowest values of pK_d in water are those of carboxylic acids in the conjugate bases of which (carboxylates) the charge is localised on the carboxylate group; on passing to phenoxides, where the degree of delocalisation of the charge is greater[10,29], and A^-...HOH hydrogen bond is weakened, and the pK_d for phenols are higher. The A^-...HOH hydrogen bond is weaker still for NH-acids (polynitroarylamines) and CH-acids (9-substituted fluorenes), where the charge on the anions is even more localised owing to the smaller electronegativity of the nitrogen and carbon atoms and the "electron withdrawing" influence of the nitrogroups.

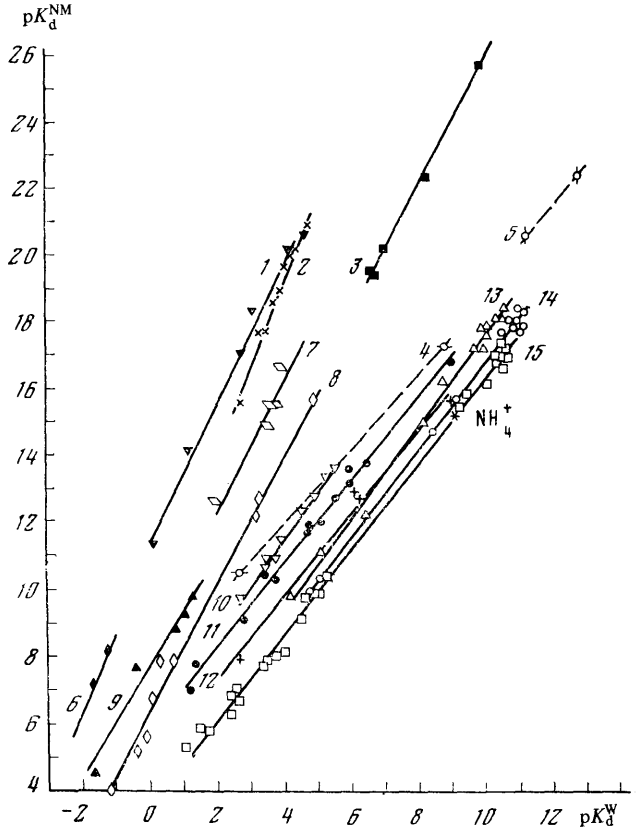

Figure 2. Relations between pK_d in nitromethane and water[65,107,109,112]: *1*)–*15*) see Table 6.

The intensification of ion solvation with formation of hydrogen bonds is known to weaken the influence of substituents of the pK_d,[3,61] which should lead to an increase of the slope R of the plots of pK_d^{NM} and pK_d^{DMSO} against pK_d^W. The data in Tables 6 and 7 show that the values of $R^{W,NM}$ and $R^{W,DMSO}$ to

a first approximation obey this rule for all the series (except XCOOH)#:

$$R^{W,NM}: XC_6H_4COOH\ (2.6) > XC_6H_4OH\ (1.95) > X_2NH\ (\sim 1.1) \sim X_3CH\ (\sim 1.2);$$
$$R^{W,DMSO}: XC_6H_4COOH\ (2.45) > XC_6H_4OH\ (2.15) > X_2NH\ (1.55) \geqslant X_3CH\ (1.45).$$

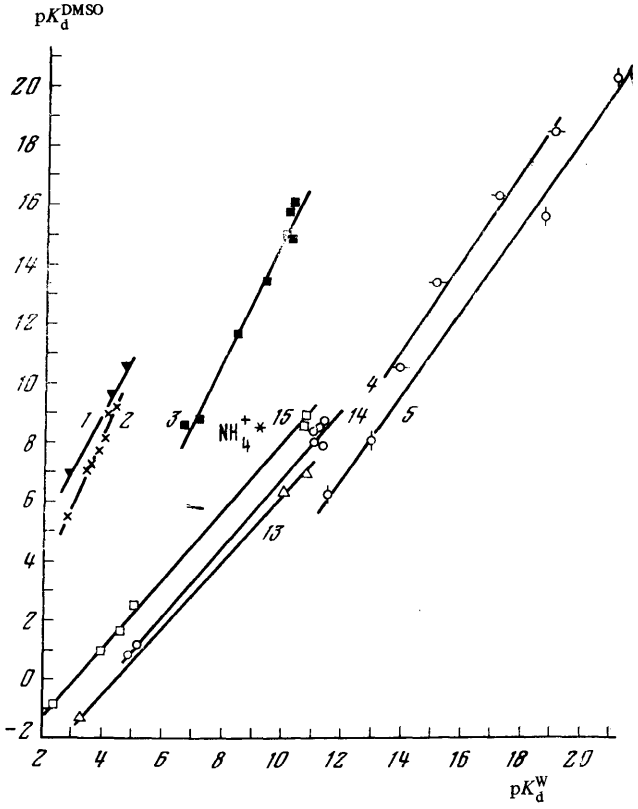

Figure 3. Relations between pK_d in dimethyl sulphoxide and water[65,107]: *1*)–*5*) and *13*)–*15*) see Table 7.

Taking into account the very weak ability of nitromethane and DMSO to function as hydrogen donors in the formation of hydrogen bonds, one may expect that the points for all neutral acids on the plot of pK_d in these solvents (Fig.4) should lie on a single straight line with a slope close to unity. Examination of Fig.4 shows that this prediction holds only for oxygen acids: the XCOOH, XC_6H_4COOH, and XC_6H_4OH series give rise to closely spaced straight lines with a slope of approximately unity. As regards NH- and CH-acids, their pK_d in DMSO are greatly reduced compared with OH-acids. The NH- and CH-acids investigated, forming anions with a highly delocalised charge, are apparently additionally stabilised in DMSO as a result of a disperson interaction[3], which is determined by the increased polarisability of DMSO compared with nitromethane[2]. This hypothesis is consistent with available data showing that the dispersion stabilisation of the carbanions in DMSO can lead to a decrease of the pK_d for CH-acids in DMSO by several pK units[61]. This factor must operate also in the correlation between pK_d in DMSO and water (Fig.3), where, together with the factor associated with the formation of the $A^-...HOH$ hydrogen bond, it leads to a decrease of pK_d for NH- and CH-acids in DMSO by up to 12 pK units compared with OH-acids.

Table 7. Parameters of the relations[107] between the pK_d for acids in DMSO [22,26,70,72,73,100] and water[22,73,77]: $pK_d^{DMSO} = R^{W,\,DMSO} pK_d^W + b$.

**Approximate data.

Proceeding now to the consideration of cationic acids BH^+, we may note that, according to the results of the previous Section, the $\overset{+}{N}H...OH_2$ hydrogen bonds should not play a major role in increasing the values of pK_d^W in the sequence $X_3\overset{+}{N}H < X_2\overset{+}{N}H_2 < X\overset{+}{N}H_3 < \overset{+}{N}H_4$. Examination of the relation between pK_d^{NM} and pK_d^W for $\overset{+}{N}H$-acids (Fig.2, series 13–15) confirms this conclusion, since primary, secondary, and tertiary amines form comparatively closely spaced straight lines (the distances between them are 0.3–0.5 of a pK unit, while the distance between the $pK_d^W - \Sigma\sigma^*$ straight lines is 1.1–2.5

The cause of the lower slope for the XCOOH series compared with XC_6H_4COOH was examined in Section V.

pK units). For DMSO, which is a much weaker hydrogen acceptor in the formation of a hydrogen bond than water, the influence of the number of $\overset{+}{N}H...OSMe_2$ hydrogen bonds is more appreciable: when pK_d^{NM} is plotted against pK_d^{DMSO} and pK_d^{DMSO} is plotted against pK_d^{W}, the straight lines of amines are displaced along the pK_d^{DMSO} axis in such a way that the values of pK_d^{DMSO} decrease in the sequence $\overset{+}{N}H_4 > X\overset{+}{N}H_3 > X_2\overset{+}{N}H_2 > X_3\overset{+}{N}H$ (Figs. 3 and 4).

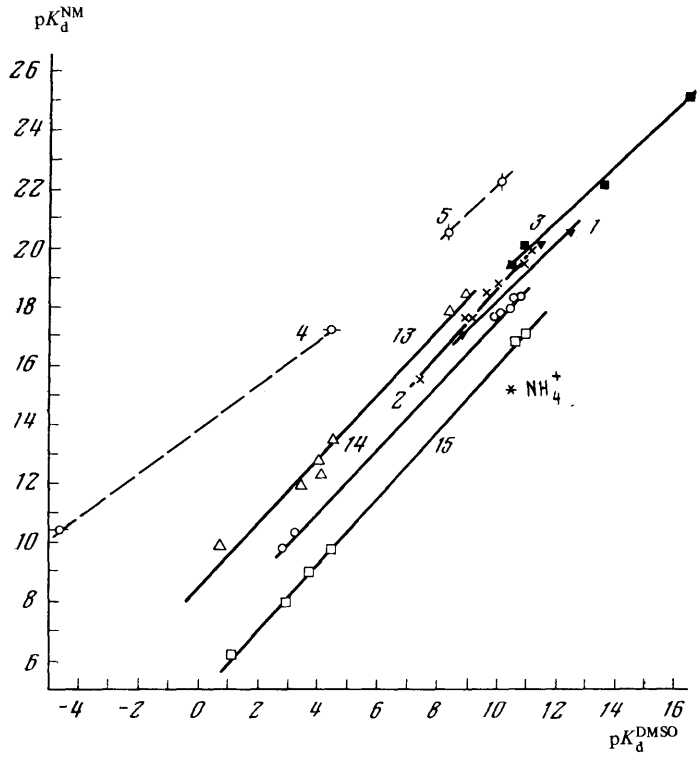

Figure 4. Relations between pK_d in nitromethane and dimethyl sulphoxide[65,107]: *1*)–**5**) and *13*)–*15*) see Table 8.

In contrast to OH-acids, where a significant increase in sensitivity to the influence of substituents is observed on passing from water, forming $A^-...HOH$ hydrogen bonds, to APS incapable of such solvation [$R^{W,S} = 2.0–2.6$ for S = nitromethane, DMSO, acetonitrile, or DMF (Table 4)[72,100]], for $\overset{+}{N}H$-acids the difference between water and nitromethane, which differ very markedly as regards their capacity for the formation of the $\overset{+}{N}H...S$ hydrogen bond, is small [$R^{W,NM} = 1.3–1.4$ (Table 3)]. Furthermore, the decrease of $R^{W,S}$ for $\overset{+}{N}H$-acids in the sequence acetonitrile (1.3-calculated from Korolev's data[65]) ≅ nitromethane (1.3) > DMSO(1.17) > water (1.0) agrees satisfactorily with the slight increase of the dielectric constants of the solvents in this sequence (Table 1). The data obtained confirm the conclusion that the $\overset{+}{N}H...OH_2$ hydrogen bonds play a very insignificant role in the decrease δpK_d for $\overset{+}{N}H$-acids in an aqueous medium. The increased energy of the hydrogen bonds formed by the anions of OH-acids ($XO^-...HOH$, $XCOO^-...HOH$) compared with the energy of the $\overset{+}{N}H...OH_2$ bond can apparently be explained by the considerable localisation of the negative charge on one or two electronegative oxygen atoms in these anions, while in $\overset{+}{N}H$-acids the positive charge is either distributed between the four hydrogen atoms in $\overset{+}{N}H_4$ or is delocalised by virtue of the substituent in $X_n\overset{+}{N}H_{4-n}$ (for example, the charge on the $\overset{+}{N}H$ group in $Me_3\overset{+}{N}H$ is only 0.3).[114]

The fact that the relative values of pK_d for pyridinium cations in water are lower by 0.6–1.0 of a pK unit than for tertiary ammonium cations (Fig. 2, series 11 and 13) is probably due to the difference between the capacities for the formation of hydrogen bonds: the $\rangle N...HOH$ bond is more favourable than $X_3N...HOH$. This conclusion is consistent with the results of a study[115] of the formation of complexes of pyridines and tertiary amines with *p*-fluorophenol. The basicity of 2,4-diamino-*sym*-triazines in water (Fig. 2, series 10; the proton adds to the ring nitrogen atom[109]) is lower by a further 0.4–0.7 of a pK unit, which can apparently be explained by the increased stabilisation of the bases in water via the formation of an N...HOH bond with several nitrogen atoms of the heterocycle and the amino-groups; the energy of these hydrogen bonds should diminish greatly after protonation. The results obtained show that, within the limits of the same type of acids, the positions of the straight lines for acids of different structure can be determined by the differences between the solvation of species without a formal charge.

Examination of the relations between pK_d^{NM} and pK_d^{W} for the cationic acids BH^+ of different types (Fig. 2, series 6–13) shows that they are displaced along the pK_d^{W} axis, forming the series

$$pK_d^W: X_3\overset{+}{P}OH < X_3\overset{+}{A}sOH < X_2C{=}\overset{+}{O}H \simeq XC_5H_4\overset{+}{N}OH < X_3\overset{+}{N}H \simeq X_3\overset{+}{P}H.$$

It is noteworthy that, in contrast to $\overset{+}{N}H$- and $\overset{+}{P}H$-acids, the conjugated bases of the $\overset{+}{O}H$-acids ($E{=}O - E^+{-}O^-$, where $E = \rangle P$, $\rangle As$, $\rangle N$, or $\rangle C$) carry a considerable partial negative charge localised on the electronegative oxygen atom, which cannot be stabilised by the formation of hydrogen bonds, with nitromethane, while in water they are very effectively solvated with formation of the $E^+{-}O^-...HOH$ bond. As a result of this, $\overset{+}{O}H$-acids exhibit an additional acidity in water compared with $\overset{+}{N}H$- and $\overset{+}{P}H$-acids. The increase of the acidity in water of the $\overset{+}{O}H$-acids in the series $\overset{+}{N}OH \cong \overset{+}{C}OH < \overset{+}{A}sOH < \overset{+}{P}OH$ can evidently be explained by the increased tendency towards the formation of $E^+{-}O^-...HOH$ hydrogen bonds in the series of bases $\overset{+}{N}{-}O^- \cong C{=}O < As{=}O < P{=}O$. This series is consistent with the relative increase of the strength of the hydrogen bonds between the above bases and *p*-fluorophenol; for example, for $pK_d^W \cong 0$, the enthalpies of formation of complexes with *p*-fluorophenol are $\overset{+}{N}{-}O^-$ (6.7 kcal mol^{-1}) ≦ C=O (7.0–7.1 kcal mol^{-1}) < P=O (8.7 kcal mole^{-1}).[116]

The slope of the plots of pK_d^{NM} against pK_d^{W} for the cationic acids BH^+ increases, as is to be expected, with increase in the degree of hydration of the conjugated bases via the formation of B...HOH hydrogen bonds (Table 6):

$$R^{W,NM}: X_3\overset{+}{P}H\,(1.2) \simeq X_3\overset{+}{N}H\,(1.2–1.3) < XC_5H_4\overset{+}{N}OH\,(1.65) \leqslant$$

$$\leqslant X_2C{=}\overset{+}{O}H\,(1.85) < X_3\overset{+}{A}sOH\,(1.95) < X_3\overset{+}{P}OH\,(2.4).$$

Thus, comparison of the strengths of the organic acids HA and BH^+ of different structure in water, DMSO, and nitromethane shows that the $A^-...HOH$ and B...HOH hydrogen bonds have an appreciable influence on their pK_d, increasing their acidity and weakening their sensitivity to the effects of substituents with increasing strength of the hydrogen bond,

which is associated with the increased localisation of the negative charge in the conjugate bases A^- and B; the influence exerted by the $BH^+...OH_2$ hydrogen bond is much smaller. The enhanced acidity of CH- and NH-acids in DMSO is consistent with additional dispersion stabilisation of the anions with a delocalised charge in this solvent.

V. THE INFLUENCE OF THE MEDIUM ON THE TRANSMISSION OF ELECTRONIC EFFECTS VIA BRIDGE GROUPS

Tables 3 and 4 present the values of $R^{W,g}$ characterising the weakening of the transmission of the electronic effects of substituents to the reaction centre on passing from the gas phase to water and also the values of $R^{NM,g}$ and $R^{W,\tilde{N}M}$. These data[65] show that the $R^{W,g}$ increase with increasing size of the bridge group M in series 1,2, and 3,4 and 5, and 6 and 7 (Tables 3 and 4). The values of R in the neutral acids HA increase to a particularly marked extent: the introduction of the phenylene bridge group entails an increase of $R^{W,g}$ by a factor of 2.6–3.5 ($R^{NM,g}$ increases by a factor of 2–3). If carboxylic acids are regarded as OH acids with a CO bridge group, then, despite the different reaction centres, the values of $R^{W,g}$ increase monotonically in the series X–M–OH, where M = –, CO, C_6H_4, or C_6H_4CO (Table 4). The increase of $\delta pK_d^g/\delta pK_d^W$ with increase of n has also been observed for the compounds $CF_3(CH_2)_n\overset{+}{N}H_3$ ($n = 1,2,3$).[14]

The above data show that the effect under discussion is probably general. It can be accounted for qualitatively[14] on the basis of the Kirkwood–Westheimer theory[21], which takes into account the effective dielectric constant of the medium between the substituent and the charged reaction centre: the greater the distance between the polar substituent and the charged centre, the greater proportion of its interaction with the charge takes place via the solvent and the effective dielectric constant of the space transmitting the influence of the substituent will approach the dielectric constant of the solvent. The greater increase of $R^{W,g}$ than that of $R^{NM,g}$ in the series 4 and 5 and 6 and 7 in Table 4 as well as the comparatively small but appreciable increase (by a factor of ~1.2) of the values of $R^{W,\tilde{N}M}$ in the same series can be understood from the standpoint of this theory.

The data presented have a direct bearing on the question of the dependence of the transmission coefficient π' (characterising the ability of the bridge group M to transmit electrons[117]) on the medium. According to the initial postulate, π' is determined by the structure of the bridge M and should be independent of the medium[118–120]. Many experimental data are consistent with this hypothesis[117,121], but there are some which conflict with it[35,122]. The results presented above§ show that in the general case the ability of the group M to transmit electrons cannot be independent of the medium in which its determined; it should remain unchanged only in media with comparatively similar dielectric constants.

§ The values of ρ_I for series 1,4, and 6 can be calculated from the relation $\rho_I = 6.23\,\rho^*$ (which follows from $\sigma^* = 6.23\,\sigma_I$),[117] taking into account the fact that the ρ_I for series 5 and 7 (Koppel' and Karel'son[9]) (and probably also series 3) are close to the values of ρ in Tables 3 and 4, which makes it possible to find the transmission coefficient π' characterising the transmission of the inductive effect via the phenylene group; for example, $\pi'(C_6H_4) = \rho_I(7)/\rho_I(6) \cong \rho(7)/6.23\rho^*(6)$. Hence it follows that the ratio of the values of π' in two series is equal to the ratio of the values of R for the two series in the same media.

---o0o---

The data presented in this review show that comparison of the pK_d of substituted organic acids in the gas phase and in water with the pK_d in aprotic polar solvents (particularly in nitromethane) can yield important information about the characteristics of the solvation of these compounds. Thus the results demonstrate the decisive role of the non-specific electrostatic hydration of the ions A^- and BH^+ in weakening the effect of the substituents on the pK_d for the ammonium, anilinium, and pyridinium cations, benzoic acids, and phenols on passing from the gas phase to water and in the differentiation of the basicities of primary, secondary, and tertiary amines in water. The influence of hydrogen bonds on the acid–base properties of organic compounds of various types in water has been elucidated; it has been found that, for identical protonation constants, the tendency of charged and dipolar species A^- and B towards the formation of the hydrogen bonds $A^-...HOH$ and B...HOH increases with the localisation of the charge: $X_3C^- \leqslant X_2N^- < XC_6H_4O^- < XC_6H_4COO^-$ and $X_3P \cong X_3N < XC_5H_4\overset{+}{N}O^- \cong X_2C{=}O < X_3As{=}O < X_3P{=}O$. The role of the dispersion solvation of anions with a delocalised charge (X_3C^-, X_2N^-) in solvents such as DMSO has been demonstrated. An appreciable increase of the ratio ρ^g/ρ^W with increase of the size of the bridge group has been observed for different $\overset{+}{N}H$- and OH-acids, which is qualitatively consistent with the Kirkwood–Westheimer theory and indicates the dependence of the ability of the bridge group to transmit electrons on the medium.

There is no doubt that the study of acid–base properties in the gas phase and in non-aqueous solvents, which is developing at a high rate, will make it possible to elucidate in the future new characteristics of the solvation of organic molecules, which are very important for the explanation and prediction of reactions which are not only of theoretical interest but also play an important role in industry.

The Structure of the Electronic Excitation of Molecules in Quantum-chemical Models

A.V.Luzanov

Methods for the analysis of the excited states of molecules and their electronic distribution are examined. The advantages of using procedures based on transition density matrices are noted. The application of the delocalisation numbers of the transition, reflecting the multiconfiguration nature of the electronically excited state, the excitation localisation numbers, providing a quantitative measure of the localisation of the transition in a particular molecular fragment, the interfragment charge transfer numbers, the atomic excitation energy indices, indicating the fraction of the molecular excitation energy which can be assigned to a given atom, etc., all of which have been introduced recently, are discussed. The structural-chemical factors favouring the isolation of the excitation of a single fragment are considered.
The bibliography includes 99 references.

I. INTRODUCTION

The theoretical and applied aspects of molecular spectroscopy have been closely related for a long time to quantum-chemical studies on the excited states of molecules. The role of theory in the interpretation of spectroscopic experiments, which are so common in modern physicochemical research techniques, still remains important. The experimental difficulties in the direct estimation of the parameters of the electronic structure, which determine the real behaviour of molecular systems, are not the only explanation. In this field many fundamental concepts follow naturally primarily from the theory which permits, in principle, the understanding of all the details of the behaviour of the electron shell in any of its states and sometimes even in states which are not observed.

Such claims do not imply in any way that all the fundamental problems of the theory of molecules have already been solved. The obstacles to the determination of detailed electronic-nuclear wave functions are generally known. However, intensive use of approximate quantum-chemical models has undoubtedly played a positive role in the understanding of the excited state by workers in the field of spectroscopy as a tangible feature with a specified internal structure, which can be inferred from the corresponding wave function. The latter is usually represented by a fairly complex set of the coefficient $c_{\mu i}$ of the expansion of the molecular orbitals, the coefficients d_{pi} of the configurational interaction, etc. Unfortunately, the abundance of numerical data frequently conceals from the investigator the very structure for the investigation of which the entire computation has been undertaken. Furthermore, the idea of the delocalisation of electrons, which is natural for quantum mechanics as a whole, at one time in the past made it impossible for chemists to see the familiar autonomy of the fragments of complex molecules. In this connection, many theoreticians attempted, while retaining the quantum-chemical rules of construction, to interpret excited and other electronic molecular states in terms of the more readily understood terms of localisation, charge transfer, etc.[1-6] However, in this field, which is so important for the understanding of the nature of the electronic spectra of complex molecules, rigorously proved criteria or quantitative characteristics had not been developed until recently. In the present review an attempt is made to consider the tendency, established in recent years, to carry out such analysis on the basis of a structural-chemical interpretation of the excited states of molecules.

II. THE INTERACTION OF THE CONFIGURATIONS AND THE TRANSITION OPERATORS IN THE THEORY OF ELECTRONIC SPECTRA

The methods used hitherto in calculations on large organic molecules and in the interpretation of their spectroscopic properties have been discussed in detail in monographs[7-12] and in a review[13]. Here we shall consider only comparatively new methods of calculation using the transition density matrix, which will prove to be the main instrument in the version of the analysis of the excited states to which we shall give preference.

The wave function $|\Phi>$ of the ground state of the molecule must be constructed with obligatory allowance for the electron–electron interaction. In the Hartree–Fock model, which has served as a standard hitherto, this is achieved by representing $|\Phi>$ in terms of a determinant of occupied molecular spin-orbitals $|\phi_1>, \ldots |\phi_i>, \ldots |\phi_N>$. Then, according to the Brillouin theorem[14], any determinant $|\Phi_{i\to p}>$, obtained from $|\Phi>$ by replacing a self-consistent spin-orbital $|\phi_i>$ by a vacant spin-orbital $|\phi_p>$, has zero matrix elements of the Hamiltonian H with the ground state $|\Phi>$:

$$\langle\Phi|H|\Phi_{i\to p}\rangle=0; \quad p=N+1, \ldots, M, \tag{1}$$

where M is the dimension of the spin-orbital basis set. Consequently the set of all the functions $|\Phi_{i\to p}>$ can be regarded as a basis set of N electronic functions on which the space of all possible excited states $|\Phi_*>$ has been superimposed

and, by virtue of Eqn.(1), the fulfilment of the natural condition of "excitation" is guaranteed for the latter:

$$\langle\Phi|H|\Phi_*\rangle=0. \quad (2)$$

After finding the self-consistent orbitals of the ground state, it is easy to achieve a configurational mixing of the type

$$|\Phi_*\rangle=\sum_{i=1}^{N}\sum_{p=N+1}^{M} d_{pi}|\Phi_{i\to p}\rangle, \quad (3)$$

which yields an approximation to the excited state made consistent with the Hartree–Fock description of the ground state $|\Phi\rangle$. The configurational coefficients d_{pi} as well as the excitation energy λ are then found from the secular equations for the configurational interaction matrix $||\langle\Phi_{i\to p}|H|\Phi_{j\to q}\rangle||$. This model of the excited state will be called the Tamm–Dancoff model, as is usually done in modern investigations of molecular theory (see, for example, Refs. 15–17) and the theory of the nucleus[18]. The semiempirical version of this model for π-electron systems is associated with the familiar studies by Pariser, Parr, and Pople and is also referred to as the PPP model, which has been discussed in detail[7,11,13].

PPP calculations on the electronic states of organic molecules are widely used at the present time, which is also due to the relative simplicity of the relevant computer programs[19,20]. Subsequently, in many instances, particularly for triplet energy states, attempts have been made to improve the results of the calculation by including higher doubly excited $|\Phi_{\substack{i\to p\\ j\to q}}\rangle$ configurations,[21–23] and even triply excited configurations[24].

New approaches based on the application of the transition density matrix have been used[25–29]. An equation for the Hermitian transition density matrix D in terms of the Tamm–Dancoff approximation, convenient for computational purposes, has been formulated[26]. Its spin-orbital generalisation can be represented[29] with the aid of the operator modulus of the Fock operator f and a projected antisymmetrised potential of the Coulombic interaction of the electrons g^A (12):

$$u(12)=\rho(1)\rho_\ominus(2)g^A(12)\rho_\ominus(1)\rho(2)+\rho_\ominus(1)\rho(2)g^A(12)\rho(1)\rho_\ominus(2), \quad (4)$$

where $\rho=\sum_{i=1}^{N}|\phi_i\rangle\langle\phi_i|$ is the density matrix of the ground Hartree–Fock state $|\Phi\rangle$, and $\rho_\ominus=\sum_{p=N+1}^{M}|\phi_p\rangle\langle\phi_p|=1-\rho$ is a matrix projected on to vacant one-electron states. The superoperator $\hat{\Pi}$, which generates another operator by acting on an operator D in accordance with the rule

$$\hat{\Pi}(D)=D\cdot|f|+|f|\cdot D+2\operatorname{Sp}_{(2)}u(12)D(2), \quad (5)$$

is introduced by means of these quantities.

The fundamental equation of the Tamm–Dancoff model can then be formulated in terms of the equations for the eigenvalues of the superoperator $\hat{\Pi}$, each eigenvector of which plays the role of a transitional matrix D of an excited state. The eigenvalue of the superoperator $\hat{\Pi}$ is the excitation energy λ:

$$\hat{\Pi}(D)=\lambda D. \quad (6)$$

The transition matrix D permits a representation of the type

$$D=\sum_{i=1}^{N}\sum_{p=N+1}^{M}(d_{pi}|\varphi_p\rangle\langle\varphi_i|+d_{pi}^*|\varphi_i\rangle\langle\varphi_p|), \quad (7)$$

where d_{pi} can be regarded as the configurational coefficients of the excited state $|\Phi_*\rangle$ of the type of Eqn.(3).

In the construction of $|\Phi_*\rangle$ condition (2) is not the only possible requirement, particularly since the approximation to the ground state $|\Phi\rangle$ does not as a rule satisfy the exact Schrödinger equation. For example, in the method based on the equations of motion without an explicit construction of a wave function for the ground state more accurate than the Hartree–Fock function it is possible to take into account, particularly in the calculation of the oscillator strengths, the correlation effects in the excited states which are not included in the Tamm–Dancoff method[30]. However, the lack of explicit wave functions or correct density matrices corresponding to them precludes in this instance a well-founded analysis of the excited states. Another approach to the construction of $|\Phi_*\rangle$ can be devised on the basis of a self-consistent perturbation theory, various aspects of which have been discussed[11,29,31].

The general relations of the quantum-mechanical perturbation theory contain the so-called energy denominators, which in the case of a perturbation of the ground state have the values of the excitation energies. Indeed, for the first correction $|\delta\Phi\rangle$ to the wave function $|\Phi\rangle$ arising from the perturbation δH, one can write (E is the energy of the system and I a unit operator)

$$(H-E)|\delta\Phi\rangle=-(I-|\Phi\rangle\langle\Phi|)\delta H|\Phi\rangle. \quad (8)$$

Here $H-E$ is the excitation operator with the eigenvalues $\lambda=E_*-E$. After reducing formula (8) to one-electron quantities, the operator $H-E$ is transformed into the superoperator $\hat{\Lambda}$ and the correction $|\delta\Phi\rangle$ is replaced by the one-electron transition operator corresponding to the N-electron Hermitian operator $|\delta\Phi\rangle\langle\Phi|+|\Phi\rangle\langle\delta\Phi|$.

The explicit form of the superoperator $\hat{\Lambda}$ for singlet states has been obtained[26]. Its relation with the random phase approximation, which constitutes a special case of the method of equations of motion, has been discussed[32,33]: on this basis, the theory of spin perturbations has been developed[34] and a perturbation theory has been devised for open shells in the unrestricted Hartree–Fock method[35]. The spin–orbital definition of $\hat{\Lambda}$ is similar in form to the formulation of the superoperator $\hat{\Pi}(5)$, but the potential $u(12)$ is now replaced by the half-sum $\frac{1}{2}[u(12)+\nu(12)]$, where $\nu(12)$ is a correlation operator describing particle–hole pair interactions of the electrons in the $|\phi_p\rangle$ and $|\phi_i\rangle$ states:

$$v(12)=\rho(1)\rho(2)g^A(12)\rho_\ominus(1)\rho_\ominus(2)+\rho_\ominus(1)\rho_\ominus(2)g^A(12)\rho(1)\rho(2).$$

The operator $\nu(12)$ is encountered in calculations on the correlation interaction, since it is in fact responsible for the mixing of $|\Phi\rangle$ with the doubly excited configurations, for the superposition of $|\Phi_*\rangle(3)$ on $|\Phi_{\substack{i\to p\\ j\to q\\ k\to r}}\rangle$, etc.[29,36] The presence of an additional term of this kind in the expression for $\hat{\Lambda}$ therefore indicates an indirect, average allowance for the correlations in relation to the Tamm–Dancoff approximation, although the number of variational parameters (the coefficients d_{pi}) is the same in the two instances. At the same time, for the functions $|\Phi_*\rangle$, constructed with the aid of $\hat{\Lambda}$, the explicit wave function parameter remains in the form of the same operator D, which carries all the necessary information about the excited state, constituting a superposition of singly excited configurations (3). As a result of this, the analysis of $|\Phi_*\rangle$ for the $\hat{\Pi}$ and $\hat{\Lambda}$ versions can be carried out in the same way.

The $\hat{\Lambda}$ matrix had previously been introduced in a different form by Thoules[37] in connection with the introduction into the self-consistent field theory of the concept of stable and unstable solutions which do and do not require respectively a local minimum in the Hartree–Fock energy E. A stable

solution arises only for a rigorously positive quadratic form made up of local second derivatives of E with respect to the parameters for small deviations from the self-consistent solution. The matrix of this quadratic form, which corresponds to the variational derivative $\delta^2 E/\delta\rho^2$, is the same as the supermatrix $\hat{\Lambda}$, and its eigenvalues λ, which appear as energy denominators in the perturbation theory, are therefore at the same time stability numbers of some kind for the Hartree–Fock model.

It has been suggested that in the case of closed electron shells the stability numbers for spin-free distortions of $|\Phi>$ be identified[26] with the singlet excitation energies and that in the case of triplet states the Tamm–Dancoff description be retained, which can be justified to some extent by taking into account the tendency not to change the spin properties of a triplet wave function[29]. However, it is easy to find all the spectroscopic series (singlet–singlet, triplet–triplet, transitions, etc.) solely with the aid of stability numbers, adopting in each case the lowest state of the specified multiplicity as the ground state for the given series.

Such calculations can be most simply carried out with the aid of the unrestricted Hartree–Fock method, as suggested by the present author and Umanskii[35,38]. For example, with the same parametrisation, it is possible to calculate satisfactorily the singlet–singlet transitions in many aromatic molecules with the aid of singlet stability numbers; the energy of the $S_0 \to T_0$ transition can be found from the difference between the total energy of S_0 and the energy of the T_0 state calculated by the unrestricted method (the unrestricted method yields as a rule the same value for S_0 as the restricted method), while the energy of the triplet–triplet absorption is identified with the triplet spin-free stability numbers of the self-consistent state T_0 (see Table 1).

Table 1. The Hartree–Fock stability numbers corresponding to the singlet and triplet transitions (in eV).

Note. The experimental data are given in brackets[8,11].

III. THE CONFIGURATIONAL–ORBITAL ANALYSIS OF EXCITED STATES. THE SPECIAL ROLE OF NATURAL ORBITALS

We shall now turn to the main problem discussed in this review—the analysis of excited states described by the standard superposition (3) of singly excited configurations. In the majority of studies involving specific calculations on excited states the largest configurational coefficients d_{pi}, from which one can infer the degree of configurational interaction[39–41], are usually quoted. This type of representation of the excited state is in certain respects (for example, as regards the cumbersome nature of the formulation) inapt and non-universal.

A form of the representation of Φ_*, which is independent of the explicit form of the occupied and vacant orbitals employed, can be regarded as universal in the given instance. In fact, these orbitals can be chosen quite arbitrarily not only as canonical molecular orbitals, i.e. as the eigenvectors of a single-particle Hamiltonian (the Fock operator f), but also as the eigenvectors of any other operator which commutes with the density matrix of the ground state ρ. This implies that the occupied orbitals $|\phi_i>$ can be mixed with one another in an arbitrary fashion but their orthonormalisation must be retained (i.e. unitary transformations are carried out). The vacant orbitals $|\phi_p>$ can also be subjected to a unitary transformation to the same extent. It is important that such transformations of the orbital set do not cause an overall alteration of the excited state Φ_*, but the configuration coefficients d_{pi} and the individual configurations $\Phi_{i\to p}$ are then considerably distorted. Consequently the coefficients d_{pi} do not yield an invariant description of the structure of the excited state (3) in the general case.

It is natural to attempt to isolate from all possible sets $\{d_{pi}\}$ an optimum set, which has the fewest members among all those permissible. The maximum number of configurations $\Phi_{i\to p}$, when all d_{pi} are non-zero (the least desirable situation from our point of view), can be found readily: it is equal to the product of the number of occupied orbitals N and the number of vacant orbitals $M-N$. As a rule the number of spin–orbital basis functions M is equal to or almost equal to twice the number of electrons $2N$. With increase in the size of the molecule, i.e. with increase of N, the maximum possible number of configurations $N(M-N) \cong N^2$ therefore increases in accordance with a quadratic law. It is found that there always exists a set of orbitals which the number of configurations is significantly smaller than and does not exceed the number of electrons in the system, i.e. varies linearly with N. It has been shown[42] that the most compact set of this kind is the set of natural spin–orbitals of the excited state Φ_*.

In the general case the natural orbitals of a certain state are the eigenvectors of a one-particle density matrix ρ_1 of this state[11]. In terms of the Hartree–Fock approximation, $\rho_1 = \rho$, so that the spin–orbitals $|\phi_i>$ are natural for any set of occupied molecular orbitals. The Tamm–Dancoff approximation (3) is characterised, in accordance with the work of Luzanov[17] and Mestechkin and Gutyrya[27], by a density matrix ρ_1^* of the type

$$\rho_1^* = \rho + D^2(\rho_\ominus - \rho). \tag{9}$$

The definition of the matrix D in form (7) makes it possible to find the identity $D\rho = \rho_\ominus D$, whence it follows, taking into account $\rho^2 = \rho$, that the occupied and vacant orbitals can be selected from the very beginning in the form of natural orbitals of the excited state investigated, because

$$\rho_1^*\rho = \rho\rho_1^*.$$

The natural orbitals are at the same time the eigenvectors of the matrix D^2.

This type of natural orbital will be designated by $|\phi_\alpha>$, if it is occupied in the ground state Φ, i.e. $\rho = \sum_{\alpha=1}^{N} |\phi_\alpha><\phi_\alpha|$ and by $|\phi_{N+\alpha}>$ if the natural orbital is populated only in the excited state. The matrix D then assumes the following form in terms of the basis set of the natural orbitals introduced[42]:

$$D = \sum_{\alpha=1}^{N} d_\alpha (|\varphi_\alpha\rangle\langle\varphi_{N+\alpha}| + |\varphi_{N+\alpha}\rangle\langle\varphi_\alpha|), \tag{10}$$

where the quantities d_α are the new configurational coefficients in the expansion of Φ_* in terms of (natural) configurations:

$$|\Phi_*\rangle = \sum_{\alpha=1}^{N} d_\alpha |\Phi_{\alpha\to N+\alpha}\rangle. \tag{11}$$

Here $\Phi_{\alpha\to N+\alpha}$ is formed as a result of the substitution of the natural occupied spin orbital $|\phi_\alpha\rangle$ in the main determinant Φ by the vacant orbital $|\phi_{N+\alpha}\rangle$. It follows from Eqns.(10) and (11) that the number of natural configurations never exceeds the number of electrons N; the transition to natural orbitals therefore sharply reduces the number of excited configurations and significantly simplifies the analysis of Φ_*, which can now be concentrated on only N values of d_α and not on N^2 coefficients d_{pi}. This reduction of the number of configurations (without a change in the overall wave function Φ_*) is clearly illustrated by the scheme of transitions in Fig.1.

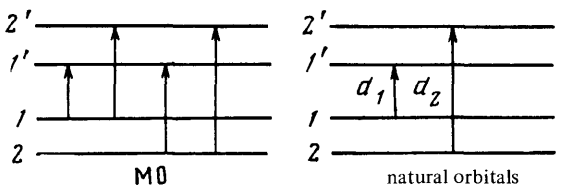

Figure 1. Decrease of the number of configurations on passing to natural orbitals of the excited state.

Fig.1 shows that, in the representation of the natural orbitals, all the cross-configurations $1\to 2'$, $2\to 1'$, etc. are missing; the excitation is described by the set of only the "diagonal" one-electron transitions $1\to 1'$, $2\to 2'$, etc. with the amplitudes d_1, d_2, etc. The numbers d_1, ..., d_α, ..., d_N are obtained from the matrix of the old configuration coefficients $d=||d_{pi}||$ by a kind of diagonalisation of this generally rectangular matrix, so that the number of non-zero terms of expansion (11) is equal to the rank $r\leq N$ of the matrix d:

$$|\Phi_*\rangle=\sum_{\alpha=1}^{r} d_\alpha|\Phi_{\alpha\to N+\alpha}\rangle. \qquad (12)$$

The number r is also an invariant characteristic of the matrix d, which remains constant in all the transformations of the basis set. In certain simple cases the rank of the matrix d is easily calculated and can yield direct information about the true nature of the configuration interaction.

As an example of this kind, we shall consider an excited state in which all the configurations $\Phi_{i\to p}$ are represented with the same weighting factor determined by the normalisation:

$$|\Phi_*\rangle=\frac{1}{\sqrt{N(M-N)}}\sum_{i;p}|\Phi_{i\to p}\rangle. \qquad (13)$$

It would appear that this is the extreme case of the maximum possible configuration interaction. Subject to condition (13), the matrix d assumes the following form:

$$d=[N(M-N)]^{-1/2}\begin{Vmatrix} 1 & 1 & \dots & 1\\ 1 & 1 & \dots & 1\\ . & . & \dots & .\\ . & . & \dots & .\\ 1 & 1 & \dots & 1 \end{Vmatrix}.$$

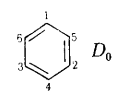
Evidently its rank is unity. Consequently the outwardly widest superposition (13), with the aid of which the idea of the delocalisation of transitions has been illustrated[43], can be reduced to only one determinant by a unitary transformation of vacant orbitals and orbitals occupied to different extents!

In this connection it is desirable to have a simple numerical characteristic which would indicate the number of significant configurations which cannot be reduced by any transformations. The average rank $\bar{r}$ of the matrix d, in which each natural configuration $\Phi_{\alpha\to N+\alpha}$ is included in proportion to its weighting factor d_α^2, can be used as such a quantity. An explicit expression for the average rank has been obtained[28,44]:

$$\bar{r}=1/\mathrm{Sp}\,(d^+d)^2=2/\mathrm{Sp}D^4, \qquad (14)$$

and a series of simple inequalities for Sp D^4 guarantees that the number $\bar{r}$ is between unity and the usual rank r of the matrix of configurational coefficients:

$$1\leq\bar{r}\leq r. \qquad (15)$$



The natural nature of inequality (15) justifies the term "average rank" for the quantity defined by Eqn.(14). With the aid of Eqn.(14), it is easy to calculate the average rank of state (13) and to show that in this case $\bar{r}=1$.

On passing to configurations with a regular spin symmetry, the matrix D is replaced by the spin-free matrix D_0 and the average rank is always proportionally doubled as a result of the spin multiplier $(|\alpha(1)\beta(2)\rangle\pm|\beta(1)\alpha(2)\rangle)/\sqrt{2}$ used in the construction of the singlet and triplet configurations. It is therefore convenient to introduce the spin-free rank κ, which has been called[44] the delocalisation number, defined by the relations

$$\kappa=1/\mathrm{Sp}\,D^4=1/2\,\mathrm{Sp}\,D_0^4,\quad 1\leq\kappa\leq r_0, \qquad (16)$$

where r_0 is the rank of the matrix of the corresponding spin-free configurational coefficients, which does not exceed the number of spin-free occupied or vacant molecular orbitals.

We shall calculate, for example, the delocalisation number of the excited state B_{1u} of the π-electron shell of the benzene molecule, where, in accordance with the study of Mestechkin and Gutyrya[27], we have in terms of the basis set of atomic orbitals,

$$D_0(B_{1u})=\begin{Vmatrix}\Delta & 0\\ 0 & \Delta\end{Vmatrix},\quad \Delta=[6(y^2+1)]^{1/2}\begin{Vmatrix} y & 1 & 1\\ 1 & y & 1\\ 1 & 1 & y\end{Vmatrix}. \qquad (17)$$

Here the first block refers to the set of atoms in the 1-, 2-, and 3-positions and the second refers to the remaining atoms; y is the parameter of the configurational mixing equal to -2 for the Hückel solution, to -1.620 for the singlet, and to -2.818 for the triplet. Calculation by Eqn.(16) yields

$$\kappa=3(y^2+2)^2/(y^4+12y^2+8y+6). \qquad (17')$$

Table 2. The delocalisation numbers of the transitions corresponding to the α-, p-, and β-absorption bands.

Molecule	α	p	p'	β	Molecule	α	p	p'	β
Naphthalene	2.09	1.34	1.68	2.01	Perylene	2.11	1.13	5.15	2.84
$(\text{Naphthalene})^{2+}$	1.51	1.19	1.57	1.56	Aniline	1.61	1.38	1.82	2.00
Anthracene	2.17	1.19	1.66	2.02	Benzonitrile	1.97	1.42	1.85	2.00
$(\text{Anthracene})^{2+}$	1.50	1.12	2.36	1.57	*p*-Aminobenzonitrile	1.86	1.21	2.14	1.82

For the Hückel solution, we obtain the natural value $\kappa=2$ and, when account is taken of the electronic interaction, we have $\kappa(^1B_{1u})=2.04$ and $\kappa(^3B_{1u})=2.94$. As a result of symmetry, all the remaining π-transitions in the benzene

molecule correspond strictly to two configurations, since the matrix relation $D_0^2 = 4D_0^4$ holds for them. Taking y to infinity in Eqn.(17'), we obtain the maximum possible delocalisation number $\kappa = 3$ for Eqn.(17).

The delocalisation numbers for the lowest transitions in a series of conjugated hydrocarbons have been found[44] (Table 2). Table 2 permits the following conclusions. All the lowest transitions involve a small number of configurations, the number of natural configurations not exceeding five. In uncharged systems the p band (the B_{2u}^+ state) corresponds as a rule to virtually only one configuration, while the α and β bands (the $B_{3u}^{\mp}$ states) correspond to at least two configurations. This is consistent with the familiar qualitative picture of the transitions used for alternant systems[45] (Fig.2).

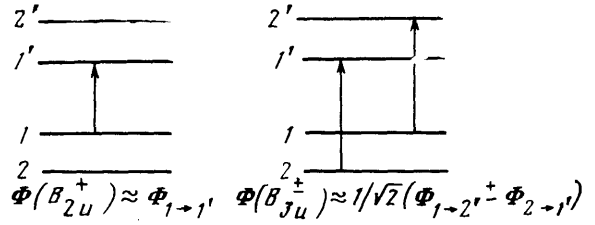


Figure 2. The principal one-electron transitions involved in the formation of the lowest excited states of alternant hydrocarbons.

For ions and substituted aromatic hydrocarbons, the alternant property disappears and the degree of delocalisation of these states diminishes. Table 2 also shows that the second transitions involve a higher degree of delocalisation compared with the first transitions of the same symmetry, i.e. the expansion of the set of configurations has a greater effect on the second and higher transitions than on the first.

One should note that the delocalisation numbers characterise not only the multiconfiguration nature of the excited state but also the degree of deviation of the excited state from the ground state. Indeed, the sum of squares of the changes in the charges and bond orders on excitation, which is the same as the quantity $\mathrm{Sp}\,(\rho_1^* - \rho)^2 = \mathrm{Sp}\,D^4 = 1/\kappa$, can serve as a characteristic of this deviation. Therefore, the higher the delocalisation number κ, the smaller the overall changes undergone by the molecular system as a result of the given excitation. In particular, those spectroscopic properties which are caused by changes in the electron density at the atoms (dipole moment, the influence of the substituent, etc.) should have the greatest influence on transitions with low delocalisation numbers. From this follows, for example (in conformity with the available experimental data[46]), a higher sensitivity to chemical substitution of the virtually one-configuration p bands than that of the two-configuration α and β bands. These factors can apparently also account for the greater polarisability of the excited p states, observed in the calculations[47], compared with the α states of aromatic hydrocarbons.

IV. THE METHOD OF EXCITATION LOCALISATION NUMBERS

While the degree of delocalisation of the transition is more in the nature of an "internal" than a purely theoretical characteristic necessary for the complete understanding of the structure of the wave function of the excited molecule, the localisation of the electronic transition plays a direct role in the interpretation of spectroscopic and certain other physicochemical experiments. The possibility of a real localisation of the excitation at individual fragments of the molecule is closely related to the additivity of a series of molecular properties described by the usual perturbation theory.

Suppose that the excitation is each time sufficiently localised at a particular group of atoms A. Then a certain observed property of the molecule, modelled as a second-order effect of the perturbation theory (polarisability, diamagnetic susceptibility, etc.)

$$E^{(2)} = \sum_a (1/\lambda_a) \cdot |\langle \Phi | \delta H | \Phi_*^{(a)} \rangle|^2,$$

can be represented by the sum of the contributions in terms of the fragments into which the molecule has been subdivided and in which each excitation $\Phi_*^{(a)}$ is significantly concentrated.

From the standpoint of the molecular orbital theory, it is to be expected that both occupied and vacant orbitals will in this case also be localised at individual atoms and bonds, which necessarily leads to the localisation of all possible transitions. Such localisation of orbitals is indeed possible but by no means obligatory. It can occur, as a rule, in saturated systems and this feature has been demonstrated by Lennard–Jones and coworkers for saturated hydrocarbons with a high degree of symmetry, while in the general case it has been demonstrated by Ruedenberg and coworkers[4] (see also Bazilevskii[48]).

However, in conjugated systems the additivity of properties of the type $E^{(2)}$ does not obtain, which indicates the impossibility of identifying all transitions with local transitions. This means that the localisation of the π orbitals is less extensive and the interaction of approximately localised orbitals cannot be neglected[4,5,13]. Therefore in the case of π systems it is difficult to expect the concentration of excitation at individual bonds. Nevertheless, in many instances large molecular fragments can be responsible for particular transitions. This factor has been frequently noted by spectroscopists[12,49–52] and required a theoretical interpretation. A logical quantum-chemical analysis must therefore extract directly from calculated data information about the localisation of transitions characterised by a readily calculable quantity. Until recently such a characteristic was not available and investigators usually confined themselves to a qualitative observation of the local nature of the transitions on the basis of the form of the molecular orbitals, provided that these orbitals had been localised beforehand (to the extent that this is possible)[53,54], or on the basis of the charges and bond orders, etc.[40,55]

The abandonment of the traditional orbital analysis and its replacement by the study of the transition density matrix D enabled Luzanov et al.[42] to put forward a logical quantitative characteristic of the localisation. We shall consider in greater detail the fundamental ideas of the above study[42] and the subsequent investigations[56–60]. As usual, we shall adopt the sum of squares of the moduli of the expansion coefficients $c_{\mu i}$ of the orbital $|\phi_i\rangle$ in terms of the atomic orbitals $|\chi_\mu\rangle$, referring to the fragment A investigated, as a measure of the degree of localisation of the molecular orbital. This quantity will be formulated thus:

$$L_A(\varphi_i) = \sum_{\mu \in A} c_{\mu i}^2, \qquad (18)$$

assuming for simplicity that all the quantities are real.

If we are dealing with a one-electron transition of the type $\Phi_{i\to p}$, then the localisation of the excitation of the fragment A can be naturally regarded as equally legitimately associated

with the localisation of both the occupied orbital $|\phi_i>$ and the vacant orbital $|\phi_p>$, i.e.

$$L_A\{\Phi_{i\to p}\} = \frac{1}{2}(L_A(\varphi_i) + L_A(\varphi_p)). \quad (19)$$

The coefficient 1/2 was introduced so that the sum of L_A and L_B, where B is the remainder of the molecule, was unity. The localisation number L_A introduced in this way represents the degree of involvement of the fragment A in the resultant excitation. If the molecule has been divided into a number of fragments larger than two, then a set of localisation numbers $\{L_A\}$, corresponding to the number of fragments, appears; these are also limited by the natural normalisation condition

$$\sum_A L_A = 1, \quad 0 \leqslant L_A \leqslant 1, \quad (20)$$

where the sum with respect to A is the sum with respect to all the fragments into which the molecule has been subdivided. In the limiting subdivision of the molecule into atoms, atomic localisation numbers L_μ arise, which we shall also refer to as the excitation indices. It is evident that

$$L_B = \sum_{\mu\in A} L_\mu. \quad (21)$$

The scheme described is in principle fairly natural and is in fact convenient for the analysis of one-configuration excited states.

We shall now consider the possible ways of extending it to the case of multiconfiguration excited state of type (3). A generalisation of the numbers L_A, which would take into account, with the aid of Eqn.(19), each configuration $\Phi_{i\to p}$ in proportion to its weighting factor d^2_{pi}, becomes immediately apparent, namely

$$L_A\{\Phi_*\} = \sum_{i,p} d^2_{pi} L_A\{\Phi_{i\to p}\}. \quad (22)$$

However, the numbers defined by Eqn.(22) suffer from a significant defect—they are not invariant relative to the transformation of the basis set of occupied and individually vacant molecular orbitals†. It is possible to eliminate this ambiguity by changing Eqn.(22) to the basis set of natural orbitals, which at the same time significantly simplifies Eqn.(22):

$$L_A = \sum_{\alpha=1}^{r} d^2_\alpha L_A\{\Phi_{\alpha\to N+\alpha}\}. \quad (22')$$

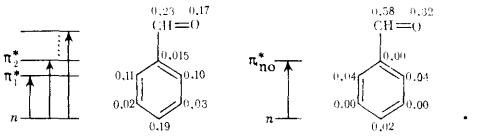
Using the explicit form [Eqn.(10)] of the Hermitian transition density operator D in terms of the natural basis set, we find an alternative form of Eqn.(22):

$$L_A = \sum_{\mu\in A} \langle\chi_\mu| D_0^2 |\chi_\mu\rangle. \quad (23)$$

Eqn.(23) does indeed exhibit the required invariance, because the transition operator D is, like the matrix ρ for the ground state, a fundamental invariant of the excited state (3). The requirement that L_A should be positive and the normalising condition (20) are satisfied automatically, because the matrix D_0^2 has been defined as a non-negative quantity and the normalisation of Φ_* yields $\mathrm{Sp}\, D_0^2 = 1$.

† Numbers of the type defined by Eqn.(22) have been introduced by Ohta et al.[61] to describe the localisation of the transition.

If each atom supplies several orbitals of different types (π, σ, etc.) to the valence shell, then the summation in Eqn. (23) must be carried out with respect to all the valence orbitals of the atoms of the fragment A. Accordingly, in calculating the excitation index of the atom L_μ, it is necessary to sum the elements D_0^2 for all the orbitals of each atom.



The choice of the quantity defined by Eqn.(23) as a measure of localisation was proposed by Luzanov et al.[42] on the grounds of other considerations. Namely, the localisation of the excitation was described in terms of the operator modulus of the change in the density matrix on excitation:

$$|\Delta\rho| = |\rho_1^* - \rho| = [(\rho_1^* - \rho)^2]^{1/2}, \quad (24)$$

which is exactly identical with the D^2 matrix in the Tamm–Dancoff model. The numbers L_A therefore automatically take into account the changes in both the charges and bond orders on excitation. In this connection, we may note that the employment in estimating the degree of localisation of the transition of only one of the above components, for example, only the changes in the charges, is not justified and the new quantity introduced on this basis[59] is not well founded.

With the aid of the quantities L_A in the form defined by Eqn.(22'), one observes immediately the fundamental role of the natural orbitals also in the localisation problem. Suppose that the excitation is almost fully localised at the fragment A, i.e. $L_A \cong 1$. Then, by virtue of the normalisation property $\Sigma d^2_\alpha = 1$, we must have $L_A\{\Phi_{\alpha\to N+\alpha}\} \cong 1$. Consequently $L_A(\phi_\alpha) = L_A(\phi_{N+\alpha}) \cong 1$; in other words, if the excitation is localised at a certain fragment, then the natural orbitals of the excited state are also localised at this fragment[42]. The natural orbitals as it were draw the excited electron cloud precisely to those sections of the molecule where the given excitation is largely concentrated. As regards the Hartree–Fock molecular orbitals, this claim is generally speaking invalid, so that the analysis of the degree of localisation of molecular orbitals can yield a distorted idea about the true nature of the distribution of the excitation.

A higher degree of localisation of natural orbitals compared with the molecular orbitals is manifested particularly clearly for the $n\pi^*$-states, where, as a consequence of the usual smearing of the n orbitals, the molecular orbital method cannot explain the experimental localisation of the excitation in the sections of the molecule adjoining the heteroatom which has an unshared electron pair[12,49]. The localisation numbers, defined by Eqn.(18), of the lowest vacant π_1^* molecular orbital and the natural orbital π_{no}^*, to which the electron of the unshared pair is transferred on excitation, are given below:

The numbers were taken from Luzanov and Pedash[60]. Evidently the degree of localisation of the natural orbital at the carbonyl group is a factor of two greater than the corresponding quantity for the π_1^* molecular orbital and reaches 90%. The use of the quantity defined by Eqn.(23) for carbonyl compounds made it possible[60] to estimate quantitatively the degree of localisation of the $n\pi^*$ excitation at C=O, which was found to diminish in a series of aromatic compounds investigated with increase in the size of the π system and amounted to $L_{C=O} = 0.88$–0.95. The decrease of the degree of localisation of the $n\pi^*$ transitions involving the carbonyl group as the conjugated system expands had been observed experimentally in a previous study[62].

It is significant that the determination of the numbers L_A from Eqn.(23) as well as the determination of the delocalisation numbers defined by Eqn.(16) do not require a special construction of natural states. It is sufficient to construct from the known configurational coefficients d_{pi} and the LCAO-MO coefficient $c_{\mu i}$ a matrix D_0 in terms of the atomic basis set, the elements of which can be identified with the quantities (n is the number of occupied molecular orbitals and m is the number of atomic orbitals)

$$D^0_{\mu\nu} = \frac{1}{\sqrt{2}} \sum_{i=1}^{n} \sum_{p=n+1}^{m} d_{pi} (c_{\mu p} c_{\nu i} + c_{i\mu} c_{\nu p}). \qquad (25)$$

Then one determines the atomic (orbital) excitation indices from the formula

$$L_\mu = \sum_{\nu=1}^{m} [D^0_{\mu\nu}]^2 \qquad (26)$$

and hence also the localisation numbers defined by Eqn.(21). In the methods for the calculation of the electronic spectra of molecules with the aid of the superoperators $\hat{\Lambda}$ or $\hat{\Pi}$ discussed in Section II, the matrix D_0 is usually calculated immediately in terms of the atomic basis set simultaneously with λ, so that the computational stage (25) becomes superfluous.

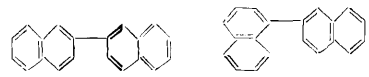
V. ISOLATION OF TRANSITIONS AT INDIVIDUAL FRAGMENTS AND MOLECULAR STRUCTURE

The relative simplicity of the calculation of the localisation numbers L_A and the clarity which they introduce into the interpretation of the electronically excited states permitted the analysis of the localisation of excitations for many molecular structures of an arbitrary degree of complexity[56-58,63]. With the aid of these calculations, it is natural to consider certain structural-chemical features, the presence of which favours the preferential concentration of excitation at an individual molecular fragment. Experimental studies, which stimulated such investigations, have been discussed in detail[12,49-52].

Numerous calculations have confirmed the natural hypothesis that a significant factor in the localisation of excitation at an individual section of the molecule is the asymmetry of the molecular structure. Indeed, for a combined system A+B, the type Λ excitation operator is described by the block supermatrix $||\Lambda_{AB,CD}||$, the diagonal blocks $\Lambda_{AA,AA}$ and $\Lambda_{BB,BB}$ of which characterise the excitation of the fragments A and B respectively and the blocks $\Lambda_{AB,AB}$ and $\Lambda_{BA,BA}$ characterise states with charge transfer from A to B and conversely, while the non-diagonal blocks $\Lambda_{AA,AB}$, etc. include the interaction between them. In the case of a weak interaction between the fragments, the approximate solutions (11) can be represented approximately by transitional matrices of three types generated by the corresponding diagonal blocks Λ:

$$\left\| \begin{matrix} D_A & 0 \\ 0 & 0 \end{matrix} \right\|, \left\| \begin{matrix} 0 & 0 \\ 0 & D_B \end{matrix} \right\|, \left\| \begin{matrix} 0 & D_{AB} \\ D^+_{AB} & 0 \end{matrix} \right\|. \qquad (27)$$

As a result of this, we have either $L_A \cong 1$, or $L_B \cong 1$, or even $L_A \cong L_B \cong 1/2$ [see Eqn.(23)].



The first two cases correspond to the concentration of excitation alternately first in one and then in another fragment, while the third corresponds to excitation throughout the molecule, the first two solutions of Eqn.(27) being valid only when the fragments are non-equivalent, i.e. when the A+B system is asymmetric. On the other hand, if B is a copy of A and the symmetry of the system is not below C_2, then solutions which have the correct symmetry are

$$\frac{1}{\sqrt{2}} \left\| \begin{matrix} D_A & 0 \\ 0 & D_B \end{matrix} \right\|,$$

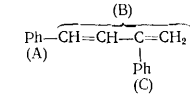
which evidently leads to a uniform localisation $L_A = L_B = 1/2$. Asymmetry is in fact the physically well-founded structural factor which distinguishes the so-called crossing conjugated systems where investigators sought, not without justification, quasi-autonomous excitation regions[51,52]. We may note that formally the same causes are responsible for the appearance of localised excitations in a molecular crystal, where the absorption bands of individual molecules are observed instead of exciton bands, but in the solid the asymmetry factors are the local deformation of the crystal, the presence of impurities, and defects, etc.[64]

Proceeding now to specific illustrations, we shall consider initially the excited states of the styrene molecule Ph–CH=CH_2. According to estimates in the literature[56,58], one may claim that the first transition involves mainly the phenyl group, since $L_{Ph} = 0.92$, while the second transition involves the molecule as a whole ($L_{Ph} = 0.64$). The same interpretation follows also from experimental data which have been discussed in detail in a monograph[50]#.

An apt example of the structure containing two equivalent fragments which can be joined symmetrically and asymmetrically is provided by the binaphthyl system Nh–Nh:

(28)

Evidently, for all transitions in the first molecule $L_{Nh_1} = L_{Nh_2} = 1/2$, while in the second it is most likely that $L_{Nh_1} = L_{Nh_2}$. Specific calculations showed that, in the first excited state of the asymmetric 1,2'-binaphthyl, we have $L_{Nh_1} = 0.63$, i.e. there is an almost uniform distribution of excitation, the second transition involves mainly the β-naphthyl group ($L_{Nh_1} = 0.16$), and, finally, the third transition is almost entirely concentrated in the first fragment ($L_{Nh_1} = 0.94$). Thus, in this example all three situations illustrated in formula (27) are clearly manifested. Another asymmetric structure is that of α-phenylnaphthalene, the values of L_{Ph} for the first three electronic excitations of which are respectively 7, 15, and 88%. Finally, in the compound

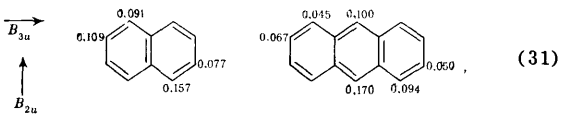


(29)

even a slight asymmetry (Ö is almost equivalent to N̈) leads to a sharp non-equivalence of the fragments in the first excited state (α-band)—95% of the entire excitation has been "collected" in the aniline fragment. These examples could be continued.

However, for asymmetry to have an effect in the direction indicated, it is necessary that the fragment should be weakly coupled, which obtains when the fragments are joined in the "minimal" manner, i.e. by only one bond (on dissociation of this bond, the molecule breaks up into at least two components). In the theory of graphs, such structures are assigned to graphs with edge connectivity 1 (graphs with a bridge). All the systems mentioned here belong to this type. In such systems the requirement that the interaction between the fragments is negligible compared with the overall interaction within the fragments, essential for the autonomy of the fragments[6], is readily fulfilled.

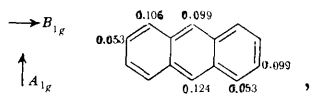
The 1,3-diphenylbutadiene molecule, where it is natural to distinguish three sections



(30)

In contrast to the second band, the first band is hardly displaced following chemical substitution in –CH=CH_2.

has a remarkable structure as regards the non-equivalence of the fragments. The π-electronic excitation for the first two singlet transitions is very highly localised at the A+B fragment ($L_{A+B}=0.959$ and 0.999 respectively), while the next two transitions are localised at the B+C fragment (0.997 and 0.892). These data were obtained by Luzanov et al.,[42] while those for the keto-derivative of compound (30), called a chalcone, were obtained by Sukhorukov et al.[59] Example (30) illustrates an additional structural-chemical factor favouring localisation—the presence in the π-system of a branch associated with the bridges of the graph, which in chemistry is sometimes referred to as cross-conjugation.



When the edge connectivity of the graph exceeds unity, rigidly bound systems of the type of condensed hydrocarbons are produced. Even when the fragments are differentiated within such molecules, the strong interaction between them via two or more carbon–carbon bonds significantly weakens the autonomy of the fragments on excitation. Nevertheless some non-uniformity is manifested in the distribution of excitation at the level of individual atoms. It has been shown[57] that under these conditions it is convenient to employ atomic excitation indices L_μ for the analysis of localisation. For example, in naphthalene and anthracene the following excitation index diagrams correspond to the two lowest energy transitions:

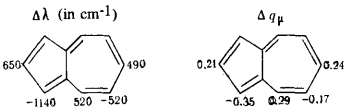
(31)

where the numbers in the upper half refer to the α band and those in the lower half refer to the *p* band, the arrow indicating the direction of polarisation of the transition. Comparison of the 1- and 2-positions of these molecules shows that the difference between the polarisations of the transitions of the α band (in the direction of the long molecular axis) and the *p* band (in the direction of the short axis) leads to the accumulation of excitation in the direction of polarisation.

However, for $T-T$ transitions this tendency is non-obligatory. For example, it has been reported[38] that the $^3B_{2u}\rightarrow{}^3B_{1g}$ (in the direction of the long axis) and $^3B_{2u}\rightarrow{}^3A_{1g}$ (in the direction of the short axis) transitions in anthracene can be represented by the following localisation diagram:

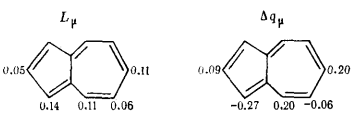
(32)

which shows that, despite the opposed polarisations of the bands, the excitation is localised in the direction of the short axis.



It has been suggested[57] that the excitation indices L_μ in alternant systems be used to estimate the spectral shifts $(\Delta\lambda)_\mu$ following the introduction of weak substituents X in the μ-position:

$$(\Delta\lambda)_\mu = K_X L_\mu. \qquad (33)$$



The spectroscopic substituent constant K_X was fitted on the basis of data for the corresponding benzene derivatives, where by virtue of symmetry $L_\mu = 1/6$. Conversely, it is possible to find by Eqn.(33) empirical localisation indices from the values of L_μ in an arbitrary alternant molecule and the previously determined substituent constants. For the naphthalene α band, the empirical $\bar{L}_\mu$ are $\bar{L}_1 = 0.081$ and $\bar{L}_2 = 0.108$, while for the phosphorescent $^1A_{1g}\rightarrow{}^3B_{2u}$ transition we have $\bar{L}_1 = 0.125$ and $\bar{L}_2 = 0.040$. These figures agree satisfactorily with the calculated values (0.091 and 0.109 for the α band and 0.174 and 0.072 for the $^2A_{1g}\rightarrow{}^3B_{2u}$ transition).

Thus we can assume that diagrams of types (31) and (32) make it possible to specify the substituent positions which are most sensitive as regards spectral shift. In the singlet case [formula (31)] one can therefore expect that the introduction of a substituent in the direction of the polarisation of the transition displaces the energy of this transition to a greater extent than the energy of the perpendicularly polarised transition. This rule, based on experimental observations, has been discussed[12,65] and has been extended to a triplet–triplet transition[65]. Diagram (32) shows, however, that this conclusion is by no means entirely general.

The influence of the insertion of a substituent X in the μ-position in non-alternant molecules can be estimated merely with the aid of the first correction to the excitation energy $\lambda_\mu^{(1)}$. Successive calculation of $\lambda_\mu^{(1)}$ shows that one of the main contributions to $\lambda_\mu^{(1)}$ is the term $\Delta q_\mu\cdot(\Delta\alpha)_X$, where Δq_μ is the change in the charge on the atom μ on excitation and $(\Delta\alpha)_X$ is the change in the Coulombic integral under the influence of the substituent X. In systems with a non-uniform distribution of charge both bathochromic and hypsochromic shifts can therefore arise[46]. For example, according to Godfrey and Murrell[66], reliable values of $(\Delta\lambda)_\mu$ for the first excited state of azulene are available and are satisfactorily correlated with the calculated Δq_μ[66]:

A similar correlation between Δq_μ and the values of $\lambda_\mu^{(1)}$ calculated exactly from the formulae of Luzanov et al.,[67] on the one hand, and the $(\Delta\lambda)_\mu$ for aromatic aza-hydrocarbons, on the other, have been discussed by Vysotskii[68]. In this case the excitation indices yield a distribution of excitation from which it is possible to infer only approximately the most reactive positions of the substituents in a given molecule without specifying the direction, which is apparently determined by the sign of Δq_μ[56]:

Excitation indices have found an unusual application in the qualitative description of the intercombination transition $S_1\rightsquigarrow T_0$. In the large molecules of aromatic hydrocarbons the symmetries of the fluorescent and phosphorescent states are the same. The spin–orbital coupling between these states, involving the cooperation of specific molecular vibrations, leads to the radiationless transition $S_1\rightsquigarrow T_0$, which is the main fluorescence quenching process in aromatic molecules. An exact calculation of the probability of this process is extremely difficult. In order to be able to draw qualitative inferences, it has been suggested[38] that one introduce the excitation overlap structure factor $\mathscr{P}$, which is defined as the product of the excitation indices $L_\mu(S_0\rightarrow S_1)$ of the fluorescent state S_1 and the excitation indices $L_\mu(S_0\rightarrow T_0)$ of the phosphorescent state T_0 as the quenching agent S_1:

$$\mathscr{P} = \sum_\mu L_\mu(S_0\rightarrow S_1)\,L_\mu(S_0\rightarrow T_0), \qquad (34)$$

where the summation is carried out with respect to all the atoms of the test system.

The factor $\mathscr{P}$ clearly reflects the likely assumption that the spin–orbital coupling of the states S_1 and T_0 is stronger the greater the degree of involvement of each atom μ simultaneously in the fluorescent and phosphorescent states. The greater the factor $\mathscr{P}$, the greater the probability of the

transition, and the lower the fluorescence quantum yield Φ_f. For molecules of a similar structural type, one may therefore hope for a correlation between $\mathscr{P}$ and the reciprocals of the quantum yields $1/\Phi_f$. In the class of condensed aromatic systems such correlation does in fact occur[69]:

Compound	Tetracene	Anthracene	Pyrene	Perylene
$\mathscr{P}$	0.271	0.121	0.091	0.088
$1/\Phi_f$[69]	0.58	0.38	0.17	0.13

In the case of a uniform distribution of excitations we have $\mathscr{P}=1/m$, in conformity with Eqn.(34), where m is the number of atoms in the molecule. If such uniformity did actually obtain, then, with increase of the size of the system, the probability of the transition would fall and the fluorescence quantum yield would increase. The non-uniformity of the distribution over the atoms in the excited state is in fact responsible for the greater overlap of the excitations and the lower yield Φ_f in tetracene (18 carbon atoms) than in the anthracene molecule with 14 carbon atoms. The data for polyphenyls show that $\mathscr{P}$ is close to $1/m$, since the decrease of $\mathscr{P}$ for these compounds is almost proportional to the increase of the number of rings.

VI. ANALYSIS OF CHARGE TRANSFER IN THE METHOD OF TRANSITION OPERATORS

In the discussion of the localisation of excitation in weakly coupled systems two significantly non-equivalent possibilities, reflected in Eqn.(27), were indicated: either the excitation is localised exclusively at the fragment A or B or there is excitation throughout the molecule, in which electrons, as it were, oscillate between different parts (A and B) of the molecule. Excited states of the latter type have come to be called charge-transfer states. The transition to such an excited state is as a rule characterised by a more pronounced redistribution of electron density and by a marked increase of the dipole moment (relative to the ground state) and hence by distinct solvatochromic effects, which in fact makes them attractive for spectroscopic investigation[70-72].

Charge-transfer states can be realised in a virtually "pure" form in excimers and charge-transfer complexes, whence both the terminology and the methods of identification have been taken[73]. Intramolecular charge-transfer is rarely fairly complete and the need to estimate the relative contributions of charge-transfer states led in its time to the development of special computational methods differing from the standard Pariser–Parr model. We have in mind primarily the so-called "molecule in molecule" method, which was initially developed by Longuet-Higgins and Murrell[1,66] and has found numerous adherents up to very recent times[2,74-77]. The essential feature of the method is that, having specified a certain subdivision of the molecule into fragments A, B, ..., C and using the orbitals for the individual fragments, one constructs the wave functions for the combined A + B + ... + C system. The basis set of N-electron functions employed in this procedure consists of products, antisymmetrised with the aid of the antisymmetrisation operator $\mathscr{A}$, comprising mainly the ground configuration $\Psi_0=\mathscr{A}\Phi_A\Phi_B\ldots\Phi_C$, where Φ_A denotes the determinant made up of the occupied molecular orbitals in the ground state in the fragment A and of different types of locally excited molecular orbitals:

$$\Psi_A^*=\mathscr{A}\Phi_A^*\Phi_B\ldots\Phi_C,\ \ldots,\ \Phi_C^*=\mathscr{A}\Phi_A\Phi_B\ldots\Phi_C^*, \qquad (35)$$

where the wave function of each fragment of the entire molecule is replaced by a singly excited configuration or a superposition of such configurations Φ_A^* made up of the molecular orbitals of only this fragment. In addition, all possible charge-transfer configurations are introduced:

$$\Psi_{A\to B}=\mathscr{A}\Phi_A^+\Phi_B^-\ldots\Phi_C,\ \ldots,\ \Phi_{C\to A}=\mathscr{A}\Phi_A^-\Phi_B\ldots\Phi_C^+, \qquad (36)$$

in which the occupied molecular orbital of one fragment is replaced by the vacant molecular orbital of another fragment.

In the basis set of the functions Ψ_0, $\{\Psi_A^*\}$, $\{\Psi_{A\to B}\}$ set up in this way one diagonalises the overall Hamiltonian of the molecule $H_{A+B+\ldots+C}$, the eigenvectors of which are identified (on the basis of the increase of the energy) with the resultant ground and excited states of the entire system. Since the molecular orbitals of the fragments are not self-consistent for the combined system, the resultant ground state comprises the locally excited states Ψ_A and charge-transfer states of the type $\Psi_{A\to B}$, apart from the ground configuration Ψ_0. Accordingly the excited states of the entire system include a contribution from the ground configuration Ψ_0. This factor leads to some inconsistency of the "molecule in molecule" method for the analysis of the structure of excited states in terms of the localisation of charge-transfer useful to the investigator.

In the method of Baba et al.[3] one begins with the Pariser–Parr wave functions of the excited states obtained from self-consistent molecular orbitals by the usual method of configuration interaction (see Section II). However, the contribution of charge-transfer states is estimated by a procedure similar to that in the "molecule in molecule" method. Namely, having selected for each fragment specific reference molecular orbitals, for example, the self-consistent molecular orbitals of these fragments, the coefficients of expansion of the functions Φ_* of type (3) for excited states in terms of the basis set $\Psi_0\{\Psi_A,\Psi_{A\to B}\}$ are found by linear transformations of the self-consistent molecular orbitals of the entire system into the reference molecular orbitals of the fragments. Thus the given method of analysis does not eliminate the difficulties in interpretation associated with the method of Murrell and Longuet-Higgins.

As a typical example of studies on electronic states in terms of this approach, we shall consider data for the ground and the lowest excited $\pi\pi^*$-states of the aniline molecule[78]. Charge-transfer states $\Psi_{NH_2\to Ph}$ with an overall contribution of 11.8%, reflecting the electron-donating function of the amino-group when it is incorporated in the overall π-system, are "imposed" on the ground state of this molecule. In the first $\pi\pi^*$-excited state the contribution of the above states increases to 28.5%. In the second excited state the contribution of $\Psi_{NH_2\to Ph}$ reaches 37.4%, but the ground configuration Ψ_0 with a 6% contribution also appears. As a result, it is difficult to understand how these figures reflect the charge transfer proper on excitation, this being a consequence of the lack of self-consistency of the reference molecular orbitals of the individual fragments in relation to the entire system made up of the given fragments. It is therefore difficult to compare such contributions even for different excited states of the same molecule. Apart from the cumbersome nature of the methods described, the contributions obtained are not invariant, because they depend on the form of the reference molecular orbitals of the fragments.

We may also note studies[53,54] where a set of orbitals localised at atoms and bonds is used in the construction and analysis of the Tamm–Dancoff excited state (3). However, the approximate nature of the localisation of the molecular orbitals, found by the Ruedenberg method or some other procedure, permits only qualitative inferences, which, owing to the lack of numerical characteristics, also hinder a comparative analysis of the excitations.

We shall now show how the problem of charge transfer is solved in the method of localisation numbers described in Section V. In order to extract the maximum amount of

information, it is necessary to employ in this case, instead of the Hermitian transition density matrix D, the overall one-electron matrix τ of the transition, which can be readily expressed in terms of D, and the density matrix ρ of the ground state, namely

$$\tau = D\rho. \tag{37}$$

The excited state (3) can then be represented as the result of the action of the operator (37) on the Hartree–Fock ground state Φ for each electron i:

$$|\Phi_*\rangle = \sum_{i=1}^{N} \tau(i)|\Phi\rangle.$$

The matrix elements $\tau_{\mu\nu}$ of the operator τ in terms of the atomic basis set can therefore be regarded as amplitudes of the electron transfer from the atom ν to the atom μ. Proceeding further to the spin-free quantities τ_0 and, putting, as before, $(\tau_0)_{\mu\nu} = \tau_{\mu\nu}$, we assume that the probability of a jump of the excited electron from the atom μ to the atom ν is characterised by the number

$$l_{\mu\to\nu} = 2\tau^2_{\nu\mu}. \tag{38}$$

If we are interested in the probability $l_{A\to B}$ of the electron transfer on excitation from the fragment A to the fragment B, it is necessary to carry out a summation of the probability defined by Eqn.(38) with respect to the corresponding atoms (orbitals):

$$l_{A\to B} = \sum_{\mu\in A}\sum_{\nu\in B} l_{\mu\to\nu}. \tag{39}$$

The positive quantities defined by Eqns.(38) and (39) will be called the *charge-transfer numbers*[79,80]. On the other hand, if A = B, then Eqn.(39) is converted into the partial localisation number:

$$l_A = 2\sum_{\mu,\nu\in A} \tau^2_{\mu\nu}, \tag{40}$$

which describes the probability that the excited electron is located in the fragment A, i.e. the probability of its local excitation. In particular, for the local excitation of the atom μ we have $l_\mu = 2\tau^2_{\mu\mu} = [(D_0)_{\mu\mu}]^2$.

There exists a simple relation, established with the aid of Eqn.(37), between the charge-transfer numbers defined by Eqns.(39) and (40) and the localisation numbers defined by Eqn.(23) and introduced previously:

$$L_A = l_A + {}^1/_2(l_{A\to B} + l_{B\to A}), \tag{41}$$

where B is a component of the overall molecule A + B in addition to A. If the molecule has been divided into a large number of fragments A + B + ... + C, then

$$L_A = l_A + {}^1/_2(l_{A\to B} + l_{B\to A} + \cdots + l_{A\to C} + l_{C\to A}). \tag{42}$$

Thus the overall localisation of the excitation in a certain fragment consists of the local excitation of the fragment proper (the number l_A), the charge transfer from the given fragment to all the remaining fragments, and the reverse transfer from all the remaining fragments to the given fragment. This conclusion is quite natural, because charge-transfer states involving simultaneously two fragments cause a rearrangement, on excitation, of the electron shells of the fragments and make a specific contribution, like local excitations, to the overall distribution of the excitation in the molecule.

An important feature of this approach is the fact that the introduction of the transfer numbers defined by Eqn.(39) eliminates the discrepancy, noted previously, between the charge transfer arising following the appearance of states of the type $\Psi_{A\to B}$ and the observed charge transfer (the change in electron density Δq_A in the fragment or the dipole moment of the molecule on excitation). Eqns.(9) and (37) permit the claim that the following relation is valid for the molecule A + B:

$$\Delta q_A = l_{B\to A} - l_{A\to B}, \tag{43}$$

while for the system A + B + ... + C we have

$$\Delta q_A = \sum_{B\neq A} (l_{B\to A} - l_{A\to B}). \tag{44}$$

Eqn.(43) implies that an increase of electron density in the fragment A takes place only at the expense of states involving charge transfer from the remainder of the molecule to the fragment A, while states with electron transfer from A to the remainder of the molecule merely decrease Δq_A. In other words, the transfer numbers $l_{A\to B}$ and $l_{B\to A}$ represent a kind of virtual charges of opposite sign, which are induced in the fragments following the excitation of the neutral molecule.

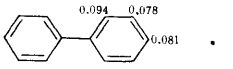
Thus Δq_A is a difference characteristic of the charge transfer and in the general case it can therefore yield only indirect evidence concerning the "charge transfer" nature of the excited state. Only in the case of an absolutely strong donor or acceptor does one of the components of Eqn.(43) disappear ($l_{B\to A}$ for the donor and $l_{A\to B}$ for the acceptor) and Δq_A is equal to the contribution of the charge states ($l_{A\to B}$ or $l_{B\to A}$).

In alternant systems $\Delta q_A = 0$ for any fragment, since, in conformity with the parity theorem, the excitation of such systems does not cause any changes in the charge density[27]. Hence follows also the finding that the charge-transfer numbers associated with transfer in opposite directions ($l_{A\to B}$ and $l_{B\to A}$) are the same. The contribution of the charged states of alternant molecules can therefore be characterised by the overall quantity $l_{AB} = 2l_{A\to B}$, and in the general case we have

$$l_{AB} = l_{A\to B} + l_{B\to A}. \tag{45}$$

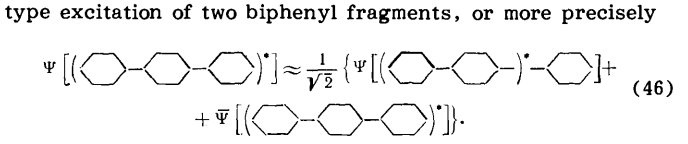
A method based on the employment of only the transition matrix D has been proposed[80] for the estimation of the overall charge transfer defined by Eqn.(45). The results of the calculation of l_{AB} by the two methods usually yields similar values.

We may note that, by analogy with the theory of excitons, locally excited states ($l_{AB} \cong 0$) can be naturally referred to also as small-radius excitations while charge-excitations involving the entire molecule ($l_{AB} \cong 1$) can be called large-radius excitations.



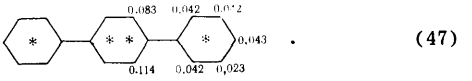
We shall now consider the results of the calculation of the charge-transfer numbers for specific hydrocarbon systems. For the α-, p-, and β-bands of biphenyl, these quantities have the following values:

Band	α	p	β
l_{Ph}, %	43	31	5
$l_{Ph,\,Ph}$, %	14	38	90

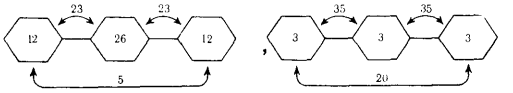


Evidently the α-band is caused by the small-radius excitation and can be identified with the benzene absorption band[81], in the p-band the contributions of the charged and locally excited states are comparable, while the large-radius excitation and hence the strongest linkage between the fragments correspond to the β-band. Naturally the asymmetric introduction of substituents into biphenyl leads to the removal of "degeneracy with respect to localisation" for the α-band and this results in the isolation of this excitation in one of the benzene rings; as a consequence of the strong interaction between the rings, the excitation involving the molecule as a whole persists for the p- and β-bands. The example of the 4-amino-4'-hydroxybiphenyl molecule [formula (29)] examined in Section V is fully consistent with this interpretation.

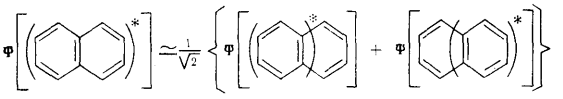
The similarity of the biphenyl α-band to the benzene band is manifested by the fact that the atomic localisation indices L_μ can be inferred fairly accurately from the values of L_μ



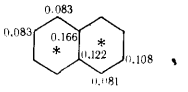
for the corresponding band in the benzene spectrum, where all the L_μ are 1/6 by virtue of symmetry. Then, having superimposed two diagrams of the benzene molecule and having renormalised the resulting numbers to unity, we find that all the L_μ should be close to $1/12 \cong 0.083$. Direct quantum-chemical calculation yields a diagram close to this uniform picture:



In terphenyl the α-band is also of the benzene type, but the central and lateral rings are not equivalent, since the excitation can be regarded as the result of alternate benzene-type excitation of two biphenyl fragments, or more precisely

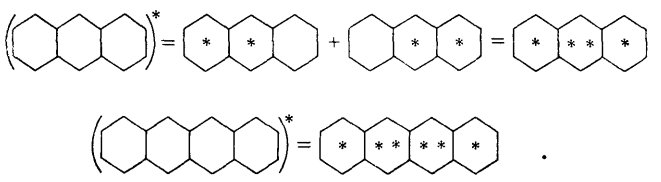


The central ring therefore contributes to the resultant excitation twice as much as the side rings, which can be represented by means of a scheme in which the indices L_μ, arising in this description, are indicated on top and the values calculated by Eqn.(25) are given below:



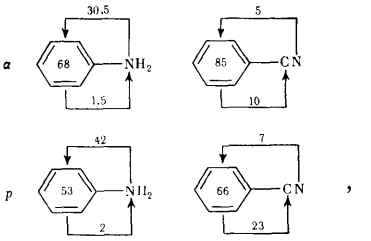
In the spectrum of the same molecule the p- and β-absorption bands are characterised by charge-transfer number diagrams similar to those for biphenyl:

The existence of a benzene-type α absorption band in the spectra of polyacenes indicates the possibility of a structural-chemical description of the corresponding excitation similar to that in formula (46). However, owing to topological features of such systems (marked edge connectivity), their molecules cannot be subdivided into a set of non-intersecting purely benzene-type fragments. Alternate excitation of superimposed benzene rings therefore corresponds to the α-band. For example, in naphthalene we have

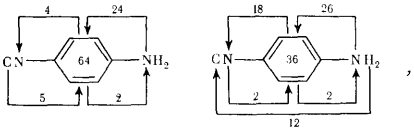


which gives rise to a diagram of L_μ indices of the type

where the numbers below are empirical values estimated by Luzanov and Umanskii[57].



In higher polyacenes benzene-type absorption arises as a result of the alternate benzene-type excitation of the naphthalene fragment migrating throughout the molecule. For anthracene and tetracene, this has the following implication:



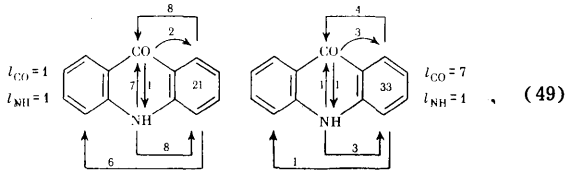
Thus, despite the rigid connectivity, in condensed hydrocarbons benzene-type absorption is also of a local type and therefore constitutes a small-radius excitation.

The study of the charge-transfer numbers in non-alternant molecules due to the charged states which lead to the observed physical effects, because $l_{A\to B} \neq l_{B\to A}$ is of special interest.

As an illustration, we shall consider the results of the calculation of the α- and p-bands of benzene derivatives. For aniline and benzonitrile, the charge-transfer number diagrams have the following form:

while for p-aminobenzonitrile we have

The absence in some of them of an arrow from A to B implies that the corresponding charge-transfer number $l_{A\to B} = 0$.



It is noteworthy that the charge transfer at right angles to the polarisation vector of the transition is smaller than in the case where the fragments between which charge transfer takes place are located on a line parallel to the polarisation vector. The α-bands therefore correspond to a less polar transition than the p-bands (cf. the numbers κ in Section II). In the same case, when the fragments are linear in a molecule with a symmetry of C_{2v} and higher, the charge-transfer number for a band polarised at right angles to the line of the fragments become rigorously equal to zero owing to symmetry factors, for example, in the case of $l_{NH_2 \rightleftharpoons CN}$ for p-aminobenzonitrile.

The case of p-aminobenzonitrile is of additional interest, because this compound contains electron-donating and electron-accepting groups simultaneously. As a consequence of symmetry factors, the long-wavelength band reflects the situation where there is no charge transfer whatever between the donor and the acceptor, while in the case of the p-band, which is identified as the charge-transfer band for molecules of this kind, the degree of charge transfer between the acceptor and the donor is smaller than the degree of charge transfer from the amino-group to the phenyl group and from the phenyl group to the nitrile group. However, since the change in the charge on CN following excitation is 0.28 and that on NH_2 is approximately −0.36, it may turn out that the charge is mainly transferred directly from the donor to the acceptor. Furthermore, diagram (48) shows that only one-third of the entire charge Δq_{NH_2} is removed in this way. The assignment of the corresponding band as one associated with charge transfer between the donor and the acceptor is therefore somewhat arbitrary, although the polar nature of such transitions, which are large-radius transitions, is significantly greater than that of the more localised small-radius transitions giving rise to α-bands. Additional illustrations have been published elsewhere[79].

Valuable information about the local nature of the transition can be obtained by considering the fine structure of molecular spectra[12]. Since electronic excitation is from the zero-point vibrational level of the ground state to the vibrational

levels of the excited state, the absorption spectra should exhibit progressions associated with the frequencies of the vibrational spectrum of the excited molecule and their intensity should be proportional to the square of the overlap of the vibrational functions of the ground and excited states. As a result of the concentration of the excitation in a certain molecular fragment, progressions generated by the characteristic vibrations of the given fragment in the excited state are the most intense. In the luminescence spectra one then observes the vibrational frequencies of the fragment in the ground state (corresponding to the infrared spectrum), because emission usually takes place as a result of the transition from the zero-point vibrational level of the excited molecule to the vibrational levels of the ground state.

We shall therefore consider the excitation diagrams for acridone, the spectrum of which has been studied in detail[82]. In the first excited singlet and triplet states the partial localisation and charge-transfer numbers yield the following distribution of excitations:

(49)

The degree of polarity of the singlet transition, treated as the sum of all the charge-transfer numbers $l_{AB}(A \neq B)$ is more than 50%. In the lowest triplet state, many of the properties of which are closer to those of the ground state than to the corresponding excited singlet state, the degree of polarity is smaller (26%). The vibrational structure of the phosphorescence spectrum makes it possible to determine the characteristic frequencies in the infrared spectrum of the benzene ring and the carbonyl group; in the latter they are not dominant (in contrast to $n\pi^*$-phosphorescence). Diagram (49) agrees with these observations—the local numbers for the benzene rings (0.33) prove to be much greater than for the carbonyl group (0.07).

We may note that the relation between the charge-transfer numbers and the fine structure of the band in the electronic spectrum is not unambiguous. However, one can assume that the individuality of the fragments under the conditions of pronounced charge transfer between them is lost, so that, other conditions being equal, the manifestation of the vibrational structure of the excited fragments is hindered.

The intensity of the corresponding transition is related to the polar nature of the excited state. Strictly speaking, theory does not predict a parallel variation of the degree of charge transfer and one can claim that, if $l_{AB}=1$, i.e. there is complete charge transfer, then the intensity of the π-band becomes zero. Complete charge transfer does not usually occur and the intensity of the transition is influenced by the topology of the molecule, its size, vibronic effects, intermolecular interaction, etc. In the systems considered above charge-transfer bands arose for transitions polarised in the direction of the long molecular axis. Their intensity is therefore greater than that of the α-bands polarised at right angles and related genetically to transitions of purely benzenoid systems, which are prohibited by the alternant properties.

For short-radius excitations, it is possible to establish in many instances definite relations between the parameters of the molecular shape and the intensity of the transition[83].

In conclusion we shall state an analogue of formula (22′) for charge-transfer numbers, namely, in terms of the basis set of natural orbitals, we have[80] $\tau=\Sigma\mu_\alpha^{1/2}\times|\phi_{N+\alpha}\rangle\langle\phi_\alpha|$; consequently, the charge-transfer numbers defined by Eqn.(39) can be expressed in terms of localisation orbitals defined by Eqn.(19):

$$l_{A\to B}=\sum_{\alpha=1}^{r}\mu_\alpha L_A(\varphi_\alpha)\cdot L_B(\varphi_{N+\alpha}).$$

This representation does not hold in terms of the basis set of canonical molecular orbitals, although attempts had been made earlier to use the corresponding quantities in order to estimate the degree of charge transfer[61].

VII. DISTRIBUTION OF EXCITATION ENERGY AMONG THE STRUCTURAL ELEMENTS OF THE MOLECULE

We shall now attempt to elucidate in what way selective localisation of excitation is related to changes in the properties of the molecule in the electronic transition. Apparently marked isolation of excitation in a single fragment implies that all the changes in the molecular characteristic $\mathscr{X}$ on excitation are associated precisely with this fragment, i.e. the corresponding physical quantity $\Delta\mathscr{X}=\mathscr{X}_*-\mathscr{X}$ is, as it were, localised in a given limited region of the molecule. In this connection the study of the spatial distribution of excitation energy assumes particular interest.

There is much experimental evidence for the possibility of the preferential concentration of the transition energy $\lambda=E_*-E$ at individual bonds or in other structural elements of the molecules[9]. In particular, the photochemical instability of the fragment is attributed to the localisation in the latter of a considerable proportion of the excitation energy[84].

The first attempts to explain what should be understood in terms of the spatial distribution of the electronic energy were made by Tatevskii[85]. However, the method of analogies which he used did not enable him to obtain any specific results, since the distribution of energy proved to be simply proportional to the electron density. This conclusion should have been surprising, since the energy of the system is determined not only by the one-particle density matrix, but also by the two-particle density, which averages the Coulombic interaction between the electrons in the calculation of E.

It must be emphasised that in the steady state the quantum-mechanical system possesses the total energy E observed in direct experiments as a unique quantity and the assignment to an isolated region of the molecule of a proportion of the energy localised in this region constitutes a non-trivial procedure with a controversial physical interpretation[86].

Strictly speaking steady states in which one could observe simultaneously with E also a local energy $\mathscr{E}(\mathbf{r})$ concentrated at a point $\mathbf{r}$ do not exist in the general case in quantum mechanics. However, in principle the operator corresponding to the required energy density $\mathscr{E}(\mathbf{r})$ can be set up on the basis of rules developed in the quantum field theory, where such an operator is known as the density of the Hamiltonian $\mathscr{H}(\mathbf{r})$.[87] Then, by calculating the average value of $\mathscr{H}(\mathbf{r})$ for the states of the system under investigation, we thereby obtain the required information about the spatial distribution of the energy in this state. The applied aspects of this approach[88] become evident if one takes into account the fact that regions with a low energy density (as a negative quantity) are most likely to exhibit the highest reactivity and the concentration of excitation energy (as a positive quantity) in the vicinity of specific atoms in the molecule indicates an increased photochemical reactivity of these atoms.

In order to calculate $\mathscr{E}(\mathbf{r})$, we should determine the density of the Hamiltonian as a Hermitian operator $\mathscr{H}(\mathbf{r})$, having the following form in terms of atomic units[87]:

$$\mathscr{H}(\mathbf{r})=\tfrac{1}{2}\nabla\psi^+(\mathbf{r})\cdot\nabla\psi(\mathbf{r})+U(\mathbf{r})\psi^+(\mathbf{r})\psi(\mathbf{r})+\tfrac{1}{2}\int\psi^+(\mathbf{r})\psi^+(\mathbf{r}')g(\mathbf{r},\mathbf{r}')\psi(\mathbf{r}')\psi(\mathbf{r})\,d\mathbf{r}',$$

where $\Psi^+(\mathbf{r})$ and $\Psi(\mathbf{r})$ are the electron generation and annihilation operators, the function $U(\mathbf{r})$ describes a one-particle interaction potential, and the function $g(\mathbf{r},\mathbf{r}')$ describes a two-particle interaction potential. In conformity with the approach adopted here, the required energy density $\mathscr{E}(\mathbf{r})$ is obtained by averaging $\mathscr{H}(\mathbf{r})$ with respect to the state investigated $|\Phi>$ in terms of a secondary quantisation representation:

$$\mathscr{E}(\mathrm{r}) = \langle\Phi|\mathscr{H}(\mathrm{r})|\Phi\rangle,$$

The total energy of the system E is obtained by integration with respect to the entire configurational space:

$$E = \int \mathscr{E}(\mathrm{r})\, d^3\mathrm{r}.$$

After introducing the spin-free single-particle density matrix $P(\mathbf{r}|\mathbf{r}')$ and the two-particle density matrix $R(\mathbf{r}_1,\mathbf{r}_2|\mathbf{r}_1',\mathbf{r}_2')$,

$$P(\mathrm{r}|\mathrm{r}') = \langle\Phi|\psi^+(\mathrm{r})\psi(\mathrm{r}')|\Phi\rangle, \qquad (50)$$

$$R(\mathrm{r}_1,\mathrm{r}_2|\mathrm{r}_1',\mathrm{r}_2') = \langle\Phi|\psi^+(\mathrm{r}_1)\psi^+(\mathrm{r}_2)\psi(\mathrm{r}_2')\psi(\mathrm{r}_1')|\Phi\rangle,$$

we find a more detailed expression for the density:

$$\mathscr{E}(\mathrm{r}) = \left[\left(\tfrac{1}{2}\frac{\partial}{\partial \mathrm{r}}\frac{\partial}{\partial \mathrm{r}'} + U(\mathrm{r})\right)P(\mathrm{r}|\mathrm{r}')\right]_{\mathrm{r}=\mathrm{r}'} + \int g(\mathrm{r},\mathrm{r}')\,R(\mathrm{r},\mathrm{r}'|\mathrm{r},\mathrm{r}')\,d^3\mathrm{r}'. \qquad (51)$$

In the special case of a system of non-interacting particles, only the first term remains in Eqn.(51) and, when a one-particle system is investigated, we have

$$\mathscr{E}(\mathrm{r}) = \tfrac{1}{2}|\nabla\varphi(\mathrm{r})|^2 + U(\mathrm{r})|\varphi(\mathrm{r})|^2,$$

where $\varphi(\mathbf{r})$ is the wave function of the particle. Even in this simple case $\mathscr{E}(\mathbf{r})$ differs from the electron density $E|\varphi|^2$ by the momentum $\frac{1}{2}(\varphi^* p^2\varphi - |p\varphi|^2)$, where $\mathbf{p}$ is the momentum operator.

We shall now turn to the details of the general formula (51) for a one-determinant description of the ground state of the molecule in terms of the Hartree–Fock approximation. For this purpose we express Eqn.(51) in a more convenient form by introducing the Hermitian energy density operator $\hat{\mathscr{E}}$ in the specified state $|\Phi>$ described by the overall density matrices of type (50) with the spin variables ρ_1 and ρ_2:

$$\hat{\mathscr{E}} = \tfrac{1}{2}([h,\rho_1]_+ - 1/2\,[\mathrm{p},[\mathrm{p},\rho_1]_-]_- + \underset{(2)}{\mathrm{Sp}}[g(1,2),\rho_2(1,2)]_+),$$

where the one-particle Hamiltonian $h = \frac{1}{2}\mathbf{p}^2 + U$ has been introduced. It can be readily shown that the diagonal elements $\hat{\mathscr{E}}$ in the coordinate representation $<\mathbf{r}|\hat{\mathscr{E}}|\mathbf{r}'>$ coincide exactly with the energy density (51) and $\mathrm{Sp}\,\hat{\mathscr{E}} = E$. In terms of the Hartree–Fock approximation, $\rho_1 = \rho \equiv \sum_{i=1}^{N}|i\times i|$, where $|i>$ is the population of the spin-orbital of the ground state and the two-particle density $\rho_2(1,2)$ is given by an antisymmetrised direct product: $\rho_2(1,2) = A_2\rho(1)\rho(2)$. Hence we find immediately the structure of the energy density operator in terms of the self-consistent field approximation:

$$\hat{\mathscr{E}} = \tfrac{1}{4}([f+h,\rho]_+ - [\mathrm{p},[\mathrm{p},\rho]_-]_-), \qquad (52)$$

where $f = h + 2G(\rho)$ is the Fock operator of the many-electron system investigated and $G(X) \equiv \underset{(2)}{\mathrm{Sp}} A_2 g(1,2)X(2)$.

The distribution of energy among the structural elements of the molecule, primarily atoms and bonds, rather than the local density $\mathscr{E}(\mathbf{r})$ is of direct interest for quantum-chemical purposes. The corresponding index can be determined by integrating $\mathscr{E}(\mathbf{r})$ in the region A investigated and leads to the replacement of $\mathscr{E}(\mathbf{r})$ by the quantities $\mathscr{E}_\mu = <\chi_\mu|\hat{\mathscr{E}}|\chi_\mu>$ in terms of the basis set of the atomic orbitals χ_μ, and $\mathscr{E}_A = \sum_{\mu\in A}\mathscr{E}_\mu$.

We shall now consider the special cases $\mathscr{E}_\mu$ in terms of the self-consistent field approximation [formula (52)]. Firstly, for neutral states of alternant hydrocarbons, one can show that, in terms of the π-approximation, the contributions of momentum to $\mathscr{E}_\mu$ become zero whatever the multiplicity of the electronic energy state. Furthermore, neglect of the inter-electron interaction in an alternant molecule is known to result in the Hückel model, for which we obtain, taking into account $\hat{\mathscr{E}} = h\rho = \rho h$, the following index of the localisation of energy§ at the atom μ, expressed in terms of the spin-free bond orders $P_{\mu\nu}$: $\mathscr{E}_\mu = \beta\sum_\sigma P_{\mu\sigma}$, where σ represents only centres adjoining μ. This is clearly none other than the free valence index of the atom to within constant terms. Thus the energetic indices $\mathscr{E}_\mu$ extend the reactivity index to the case of the Hartree–Fock description of arbitrary molecular systems.

In the light of the foregoing, it is not difficult to find the excitation energy density $\lambda(\mathbf{r})$, which we defined naturally as the difference between the densities in the ground $\mathscr{E}(\mathbf{r})$ and excited $\mathscr{E}_*(\mathbf{r}) = <\Phi_*|\mathscr{H}(\mathbf{r})|\Phi_*>$ states. We shall adopt the superposition of all the singly excited configurations, for which the density matrices have been obtained[17], as a fairly adequate approximation for the excited state Φ_* in relation to the Hartree–Fock ground state Φ. The final result of the calculation of $\lambda(\mathbf{r}) = \mathscr{E}_*(\mathbf{r}) - \mathscr{E}(\mathbf{r})$ leads to the following excitation localisation operator:

$$\hat{\lambda} = -\tfrac{1}{4}([f+h, D^2Y]_+ + [G(DY), DY]_+ - [G(D), D]_- + 2\,[G(D^2Y),\rho]_+ - [\mathrm{p},[\mathrm{p}, D^2Y]_-]_-),$$

the diagonal elements of which are the same as $\lambda(\mathbf{r})$ in terms of the coordinate representation, while combinations of the matrix elements in terms of the atomic basis set of type $\mathscr{E}_A$ are the same as the indices of excitation at atoms and bonds. In the stability matrix method we have a similar expression but without the second anticommutator ($Y \equiv 2\rho - I$).

As for the ground state, in the case of neutral alternant systems in the π-electron approximation the momentum contributions to the diagonal elements $\hat{\lambda}$ in terms of the atomic orbital basis set disappear. If we then again resort to the Hückel model, then the spin-free operator $\hat{\lambda}_0$ reduces merely to a single anticommutator, which can be readily transformed into a product:

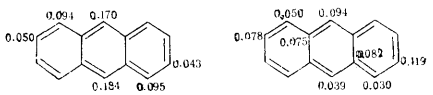
$$\hat{\lambda}_0 = -[h, D_0^2Y_0]_+ = -2hD_0^2Y_0,$$

where the subscript 0 indicates a spin-free quantity here and henceforth.

We shall consider in the same systems a one-electron transition from the $|i>$ orbital to the corresponding, in terms of alternant symmetry, vacant orbital $|i'>$, i.e. $D_0 = (|i><i'| + |i'><i|)/\sqrt{2}$, and, on the basis of the theory of parity, the one-electron energy is $\mathscr{E}_i = -\mathscr{E}_{i'}$. It is then easy to observe that $\hat{\lambda}_0(i\to i') = 2|\mathscr{E}_i|D_0^2$ and if we now introduce the energy localisation operator as the operator $\hat{\lambda}_0$ normalised with respect to unity and the corresponding localisation indices

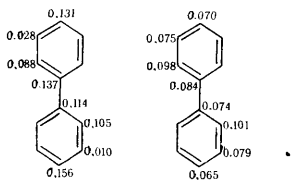
$$\hat{L}_0 = 1/\lambda\hat{\lambda}_0, \quad L_A^{\mathscr{E}} = \sum_{\mu\in A}\langle\chi_\mu|\hat{L}_0|\chi_\mu\rangle,$$

we observe in this instance ($\lambda = 2|\mathscr{E}_i|$) the identity of $\hat{L}_0$ and the matrix D_0^2.



Consequently the energetic localisation indices $L_A^{\mathscr{E}}$ for the diagonal transitions $i\to i'$ in terms of the Hückel approximation are identical with the localisation numbers L_A described

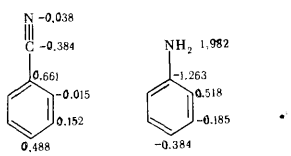
§ The Hückel energy indices (without momentum contributions) have been introduced[99] on the basis of intuitive considerations.



above. The inclusion of electronic interaction in terms of a self-consistent scheme for alternant systems causes an insignificant deviation of L_A^{ε} from L_A. However, in systems with an inhomogeneous charge distribution the excitation indices calculated from the operator $\hat{L}_0$ differ appreciably from the quantities defined by Eqn.(23).

For non-alternant systems, one fundamental difference between these operators is clearly manifested. In contrast to D_0^2 and despite the evident normalising property $\mathrm{Sp}\,\hat{L}_0 = 1$, the operator $\hat{L}_0$ is not in the general case defined as a non-negative quantity and its diagonal elements are therefore not definite. The possible negative sign of $\langle\chi_\mu|\hat{L}_0|\chi_\mu\rangle$ can, however, be interpreted as evidence for the existence of regions in the molecule which are not loosened on excitation but are actually stabilised to an even greater extent than in the ground state. This factor makes the localisation indices obtained from the energetic criterion particularly informative as regards the photochemical aspect.

The localisation numbers L_A (above) and the energetic indices L_A^{ε} (below) are given below for the p- and β-bands of anthracene



and biphenyl

The above diagrams show that, on excitation to the $^1B_{2u}$ state, the transition energy is distributed fairly non-uniformly among the atoms in the molecule, being concentrated in the 9- and 10-positions in anthracene (approximately 40% of the overall value of λ) and in the 4- and 4′-positions in biphenyl (>30% of λ). Data for the photodimerisation of anthracene and the Diels–Alder photoaddition[89] show that the atoms in the 9- and 10-positions are indeed photochemically active in anthracene.

An example of excitations for which positive and negative values of L_A^{ε} are possible is provided by the intense long-wavelength transitions (p-bands) in non-alternant molecules—benzonitrile and aniline:

The negative values of L_A^{ε} for the CN group indicate the photochemical stability of the latter. At the same time, the ring carbon atom closest to CN is greatly destabilised ($L_C^{\varepsilon} = 0.66$) and the chemical reactions in the excited state should therefore involve primarily this atom. In fact there is a tendency towards the photoaddition of trimethylethylene to benzonitrile in precisely this position[89]. On the other hand, in aniline the outer NH_2 group is the most active section of the excited molecule and this feature promotes the experimentally observed photoabstraction of hydrogen from the aniline NH_2.[90] The different signs of L_μ^{ε} in these molecules are consistent with the opposite directions of the charge transfer in them.

The uniform distribution of the excitation involving the molecule as a whole leads to smaller energetic localisation indices than for excitation isolated in a fragment and hence excited molecules which are photochemically more stable. In asymmetric systems the charge-transfer states are of this kind, as stated in Section V. In excited charge-transfer systems the photochemical stability is therefore higher than for local excitations[91].

The data presented in this review permit the formulation in a specific form of the quantum-chemical aspects of the concept of the "structure of electronic excitation".

The "internal" structure of the wave function Φ_* describing the excited state, namely the existence of the most important invariant elements of Φ_* of the type of independent singly excited configurations, the determination of orbitals which impart to Φ_* the simplest form, etc., was studied in the first place. The search for such invariant elements inevitably leads to natural orbitals of the excited state which are reconstructed anew for each electronic transition from the usual self-consistent molecular orbitals of the ground state. Analysis of model (3) yielded an important and somewhat unexpected conclusion—the greater the number of natural independent configurations in Φ_*, the smaller the changes undergone by the molecule as a whole on electronic excitation. This assertion shows how the internal structure determines the characteristic features of the external excitation structure in model (3). Our analysis of the external structure was concentrated on the study of the distribution of excitation in the direct structural-chemical sense (in atoms, bonds, whole fragments, etc.), on the elucidation of the physicochemical consequences of the selective localisation of excitation in fragments, on the determination of the relation between the localisation of excitation and charge transfer, etc.

The localisation numbers L_A and l_A, the charge-transfer numbers $l_{A\to B}$, and the energetic excitation indices L_μ^{ε} are all quantities arising in the method of transition density operators, which have demonstrated, in our view, a certain elegance and clarity in the interpretation of the external excitation structure mentioned above, which is important primarily for applied purposes.

The range of problems in the solution of which excitation indices defined by Eqns.(23) and (26) are used continues to be extended. An attempt has been made to apply the excitation localisation numbers in the analysis of data on the photoisomerisation of stilbene derivatives[92]. Studies have been made on the use of the indices L_A and l_{AB} for new classes of molecules[93–96]. Different analytical methods for excited states have been compared[97] and definite advantages of localisation numbers introduced by Luzanov and coworkers[42,80], compared with similar numbers introduced by other workers[59,61], have been pointed out.

Further efforts to generalise the above numerical characteristics of the wave function Φ_* (more accurate than in the initial model), adopted in this review (superposition of all singly excited configurations), therefore merit attention. One of the versions of such generalisation has been discussed by the present author in a paper[80], where it was suggested that the generalised matrix $\tilde{D}^2$ be constructed by analogy with Eqn.(34) using the normalised operator modulus of the change in the one-particle density matrix $|\rho_1^* - \rho_1|$ on transition from the ground state, not necessarily of the Hartree–Fock type, to an excited state, which does not necessarily reduce to approximation (3).

The internal excitation structure could be studied in a manner similar to the entropic analysis of wave functions considered by Bochvar et al.[98] In terms of the applied aspect, the application of the method of excitation indices[42,79] to nonconjugated molecules is not of interest solely as regards the

π-electron model, which has been used in all the computational studies quoted in this review. Such are apparently the likely prospects for the development of the methods of description of the electronic excitation structure of molecules discussed here.

Heptavalent Bromine Compounds

V.V.Gavrilov and V.K.Isupov

Publications on heptavalent bromine compounds which have appeared during the last 10 years are reviewed. The discussion includes the preparation and analysis of perbromates, the physical and chemical properties of perbromic acid and its salts, the "hot atom" chemistry and radiation chemistry of perbromates, and the practical utilisation of heptavalent bromine compounds. 80 references.

I. INTRODUCTION

Perbromates have long been classified among the compounds which cannot be prepared by ordinary chemical methods. However, the existence and widespread applications of their homologues (the perchlorates and the periodates) have stimulated renewed interest from theoreticians and experimentalists in the preparation of perbromates. The first attempts to prepare heptavalent bromine compounds were made in the middle of the 19th century. Experimental and theoretical work in this area is reviewed in Refs.1–4. The first successful preparation of perbromate (Appelman[5]) by the β^- disintegration of ^{83}Se in a selenate composition was described as recently as in 1968. By studying the chemical properties of microquantities of perbromate Appelman was able to develop[5] a macro-synthetic method for heptavalent bromine compounds.

Several dozen papers on heptavalent bromine compounds have appeared since the first successful synthesis of perbromate, but they do not include general reviews of the subject. The aim of this paper is to generalise existing information on heptavalent bromine compounds.

II. METHODS OF PREPARATION OF HEPTAVALENT BROMINE COMPOUNDS

The first successful synthesis of perbromate was carried out by the "hot atom" chemistry method, using the β^- disintegration of ^{83}Se in a selenate composition[5]. The resulting bromine-83 is radioactive, with a half-life of 2.4 h. Therefore the method does not yield weighable amounts of perbromates, but it does show that heptavalent bromine compounds are relatively stable and therefore can be prepared (in principle) in macro-amounts. The preparation was demonstrated by electrochemically oxidising lithium bromate in a neutral solution[5], using a partitioned cell with a platinum anode and an anodic current density of 10 A cm^{-2}. The yield of perbromate was ~2%.

The electrolytic oxidation of bromate was therefore not acceptable as a preparative method, because its yield was too low, and a search for more effective methods of preparing heptavalent bromine compounds was started. An aqueous solution of xenon difluoride, whose oxidation potential is 2.62 V, was added[6] to a fairly concentrated bromate solution, giving perbromate in 12% yield (calculated from the initial amount of xenon difluoride[7]).

Shortly after Appelman's preparation of heptavalent bromine compounds Brown and coworkers[8] demonstrated the formation of perbromate by irradiating caesium bromate with gamma-rays from ^{60}Co. The yield of caesium perbromate was 0.86% of the initial amount of caesium bromate. Irradiation of lithium bromate did not produce perbromate. No heptavalent bromine compounds were obtained by oxidising aqueous bromate solutions with sodium perxenate and persulphate at 100 °C,[5] or by treating bromate solutions with hydrogen peroxide in the presence of acid[9].

A more convenient method of preparing heptavalent bromine compounds relies[10] on the oxidation of sodium bromate by fluorine in an alkaline solution. This reaction gave a sodium perbromate yield of 20% of the initial amount of bromate:

$$F_2 + BrO_3^- + 2OH^- \rightarrow BrO_4^- + 2F^- + 2H_2O.$$

The preparation of sodium perbromate by this method is described in detail in Ref.11.

A simple method of separating sodium perbromate from the reaction mixture is extraction with acetone[12]. The sodium bromate solution after being oxidised with fluorine is evaporated to dryness under a heat lamp, and the residue is washed with acetone. Under these conditions the sodium perbromate is extracted into the liquid phase, and the sodium bromate and fluoride remain in the solid phase. The acetone is evaporated off, and the sodium perbromate is recrystallised first from acetone and then from ethanol.

The following perbromates have been prepared by neutralising perbromic acid with the appropriate hydroxide or oxide: lithium, sodium, potassium, rubidium, and caesium[13], magnesium, calcium, strontium, and barium[14], ammonium[15], silver[16], and uranyl[17]. Potassium, rubidium, caesium, and uranyl perbromates are recrystallised from aqueous solutions, silver perbromate by adding hexane to a benzene solution, and the other perbromates are usually recrystallised from acetone.

The reaction of potassium perbromate with antimony pentafluoride yields the highly reactive compound perbromyl fluoride[18–22], BrO_3F, which rapidly hydrolyses in air[23] and attacks glass even at room temperature. Isopropyl perbromate[16] also is unstable at room temperature, though it can be prepared by the reaction between isopropyl bromide and silver perbromate. On the other hand tetraphenylarsonium perbromate, prepared from tetraphenylarsonium chloride and sodium perbromate[8], is a very stable compound.

Thus, several compounds of heptavalent bromine have already been prepared.

III. PHYSICAL AND CHEMICAL PROPERTIES OF PERBROMIC ACID AND ITS SALTS

Perbromic acid is a strong monobasic acid. Potentiometric titration of 0.6 M $HBrO_4$ with a 0.6 M solution of sodium hydroxide gives a curve very similar to that of $HClO_4$ under the same conditions[10]. In aqueous solutions perbromic acid is stable up to a concentration of 55% (6 M), but it decomposes at higher concentrations. A 6 M solution of $HBrO_4$ is stable indefinitely at room temperature. When heated on a water bath the solution becomes weakly yellow after one hour, but its oxidising power is reduced by only 1%. Mass spectrometric measurements have shown[24] that perbromic acid is a very stable compound, and is less volatile than perchloric acid. Samples in which the concentration of perbromic acid is as high as 83% can be obtained by vacuum distillation at room temperature. Rapid removal of the water produces crystals of $HBrO_4 \cdot 2H_2O$, which quickly become liquid when stored in air.

Perbromic acid is a slow-acting oxidising agent. In dilute solutions it oxidises iodide and bromide ions quite slowly, and it does not react with chloride ions. This may explain early failures to detect perbromates, which were always sought among the most reactive (rather than the most inert) compounds. On the whole, perbromates are the least reactive of all oxy-halogen compounds (except the perchlorates). However, at high concentrations perbromic acid is no longer a slow-acting oxidiser. Thus, 12 M $HBrO_4$ rapidly oxidises chloride ions and reacts explosively with filter paper; 3 M $HBrO_4$ rapidly oxidises stainless steel, and 6 M $HBrO_4$ at 100 °C easily oxidises bivalent manganese to MnO_2, tervalent chromium to dichromate, and tervalent cerium to Ce(IV).[10] These reactions occur also at room temperature if the acid is dehydrated under vacuum.

Perbromic acid and its salts have the same u.v. and Raman spectra, showing that identical anions are present in both cases. The similarity between the Raman spectra of solid $KBrO_4$ and those of its solutions[25] confirms that these anions are also present in the crystals. By comparing the Raman and the i.r. spectra of solid $KBrO_4$ we find that two of the four Raman bands are active in the i.r.: assignment of these frequencies suggests a tetrahedral structure for $KBrO_4$. The fundamental vibrational frequencies of BrO_4^- [10] are compared with those of ClO_4^- and IO_4^- [26] in Table 1.

Table 1. Vibrational frequencies of ClO_4^-, BrO_4^-, and IO_4^- ions in the i.r. region.

Anions	Vibrational frequencies, cm^{-1}			
	ν_1	ν_2	ν_3	ν_4
ClO_4^-	935	460	1060	630
BrO_4^-	798	331	883	410
IO_4^-	791	256	853	325

The lack of fast oxygen exchange between the perbromate ion and water shows that this ion (unlike the periodate ion[27]) does not undergo the fast hydration reaction

$$IO_4^- + 2H_2O \rightleftarrows H_4IO_6^- .$$

The most fully investigated of the salts of perbromic acid is potassium perbromate: $KBrO_4$, a white crystalline substance with a density of 3.08 g cm^{-3}.[28] The enthalpy of formation of potassium perbromate is -68.74 ± 0.14 kcal $mole^{-1}$, and its enthalpy of dissolution is 11.61 kcal $mole^{-1}$.[29] The potassium perbromate crystals belong to the $BaSO_4$ structure type, with the rhombic lattice parameters $a = 8.930$, $b = 5.921$, and $c = 7.488$ Å. The BrO_4^- ion has a tetrahedral structure, with a Br–O bond length of 1.61 Å and an O–Br–O bond angle of 109–110°.[28] The bond order, calculated by the Long–Plane–Pauling formula, is 1.93,[30] as compared with a Br–O bond order of 1.56 [31] in perbromyl fluoride. The mean-square vibrational amplitudes and the Coriolis interaction constants have also been calculated[32–35].

The chemical shift in the photo-electronic spectra of potassium perbromate (as compared with potassium bromide) was lower than for the corresponding chlorine compounds but higher than for the iodine analogues[36]. This is consistent with the differences in bond energy for the three halogens calculated by the Hartree–Fock method. Quantum-chemical calculations[37,38] have shown that the perbromate ion can be less stable than the perchlorate and the periodate, but that the difference is very small. The standard electrode potential of the bromate–perbromate couple is variously reported as 1.74 V,[39] 1.76 V,[29,40] and 1.82 V,[41] which should be compared with 1.23 V for the chlorate–perchlorate couple and 1.64 V for the iodate–periodate couple.

Ammonium perbromate is another salt of perbromic acid which has been adequately studied[15]. It is a white crystalline compound, indefinitely stable in air. Its density is 2.5 g cm^{-3}, and its crystal lattice has a rhombic unit cell with lattice parameters $a = 9.20$, $b = 6.04$, and $c = 7.63$ Å.[15] NH_4BrO_4 is very much less hygroscopic than ammonium perchlorate. Thus at 95% relative humidity ammonium perbromate absorbs only 4% of water, after which its weight remains constant, whereas ammonium perchlorate absorbs 23% of water and becomes visibly wet. The solubility of ammonium perbromate in water increases with temperature[15] (9.5, 13.9, 17.8, and 26.3 g per 100 g of solution at 0, 15, 25, and 45 °C respectively). Ammonium perbromate is soluble in methanol, acetone, ethanol, and acetonitrile.

In the alkali metal perbromates the solubility in water decreases in the sequence from lithium perbromate to caesium perbromate. Whereas lithium and sodium perbromates are very soluble in water, the solubility of $KBrO_4$ is only 0.2 mole $litre^{-1}$, and rubidium and caesium perbromates are only sparingly soluble at room temperature. On the other hand the perbromates of the alkaline earth metals, magnesium, silver, and uranyl are very soluble in water as well as in acetone.

When stored in air the anhydrous perbromates of lithium and sodium are converted into crystal hydrates of composition $LiBrO_4 \cdot 2H_2O$ and $NaBrO_4 \cdot H_2O$ respectively, but potassium, rubidium, and caesium perbromates are much less hygroscopic. Crystals of alkaline-earth, magnesium, and uranyl perbromates deliquesce very rapidly in the air, and have to be handled in a dry-box.

Alkali, alkaline-earth, and magnesium perbromates decompose to the bromates, after losing all their water, when heated[13,14], whereas the decomposition products of ammonium perbromate are N_2, Br_2, H_2O, and small amounts of N_2O and NO_2.[15] Temperature ranges and decomposition temperatures of the alkali, alkaline-earth, magnesium, and ammonium perbromates are listed in Table 2.

It is clear from Table 2 that the thermal stability of the alkali metal perbromates increases in the sequence $LiBrO_4 < NaBrO_4 < KBrO_4 < RbBrO_4 < CsBrO_4$, whereas the alkaline-earth and magnesium perbromates are indistinguishable as regards thermal stability (within experimental error). The alkali metal perbromates decompose at higher temperatures than the perbromates of the alkaline-earth metals, but the decomposition temperatures are very sensitive to the purity

of the sample. Thus, a sample of $KBrO_4$ which had been prepared without recrystallisation began to decompose at 150 °C, whereas a recrystallised sample remained unchanged up to 260 °C.[10] Obviously, even traces of bromate impurity are able to catalyse the thermal decomposition of perbromates.

Table 2. Temperature ranges and decomposition temperatures of alkali, alkaline-earth, magnesium, and ammonium perbromates.

Compound	Decompn. temperature range, °C	Decompn. temperature, °C	References
$LiBrO_4$	185—220	210±10	13
$NaBrO_4$	246—289	226±10	13
$KBrO_4$	255—282	271±5	13
$KBrO_4$	260—280	275	10
$RbBrO_4$	272—300	291±5	13
$CsBrO_4$	200—319	302±5	13
NH_4BrO_4	180—260	—	15
$Mg(BrO_4)_2$	181—199	191±5	14
$Ca(BrO_4)_2$	180—201	193±5	14
$Sr(BrO_4)_2$	180—207	192±5	14
$Ba(BrO_4)_2$	174—203	187±5	14

Other salts of perbromic acid, such as silver and uranyl perbromates, have been much less fully investigated. Baum and coworkers[16] prepared $AgBrO_4$ as a white, hygroscopic salt which was stable for several months at room temperature. Silver perbromate is soluble in benzene but insoluble in saturated hydrocarbons. Uranyl perbromate is a light-green, very hygroscopic salt. As in the case of the uranyl perchlorates[42], samples of $UO_2(BrO_4)_2 \cdot nH_2O$ containing up to 7 moles of water per mole of salt can be prepared[17]. Uranyl perbromate pentahydrate (unlike the perchlorate) can be obtained only in a narrow range of water vapour pressures. From the i.r. and Raman spectra of the uranyl perbromates we may conclude[17] that the force constants of the UO_2^{2+} bonds in $UO_2(BrO_4)_2$ are similar to the corresponding values for $UO_2(ClO_4)_2$. The i.r. spectra of the hydrated uranyl perbromates indicate the existence of different types of bond in these compounds [as in the case of $UO_2(ClO_4)_2 \cdot .nH_2O$].[43]

IV. ANALYTICAL CHEMISTRY OF HEPTAVALENT BROMINE COMPOUNDS

Various methods can be used to detect and to determine perbromates. For qualitative analysis the main reaction is a drop test with an acidified solution of potassium iodide. The perbromate spot, unlike that of many other oxidising agents, does not appear at once: the rate of development of the spot increases with the concentration of potassium iodide and with the acidity of the solution. The perbromate ion can be detected by a Methylene Blue drop reaction, which produces a crimson spot of perbromate on a blue background[44], and also by the reaction with manganese sulphate in phosphoric acid, which produces a violet colour[45].

The most sensitive spot test for perbromate ions on paper is the benzidine reaction[46]. The chromatograms are sprayed with a 2% solution of benzidine in 10% acetic acid, and heated in a jet of hot air. The spot due to the perbromate ion is initially blue, but on being heated it becomes dark grey. The sensitivity of the reaction is 0.01 μg of potassium perbromate. The main drawback of all these qualitative reactions is their lack of specificity: many oxidising agents will seriously interfere with the detection of heptavalent bromine compounds.

Perbromates can be determined quantitatively by a variety of methods. One of the simplest is the reduction of perbromate to bromide ions, using 12 M HBr.[10] A five-fold (by volume) excess of concentrated HBr is added to the sample for analysis, and the resulting solution is allowed to stand for 10 min in a closed vessel. The reaction goes to completion in this time if the concentration of HBr is not less than 11.5 M: at an HBr concentration of 10.4 M 40 min are required to complete the reaction. The solution is then diluted 10-fold with a 2% solution of sodium iodide containing NaH_2PO_4, and titrated with thiosulphate. If the perbromate solution contains substantial amounts of lower oxygen compounds of bromine it is first reduced with dilute HBr, and the resulting bromine is swept out of the solution by a stream of argon. If the concentration of HBr is held between 0.5 and 1 M the perbromate is practically unaffected by this operation.

An alternative oxidation–reduction method uses $SnCl_2$ for the determination of perbromate ions[5]. The perbromate solution is made 6 M in hydrochloric acid, and Mo(VI) is added to it to a 0.04 M concentration. After adding an excess of $SnCl_2$ an aliquot of the solution is heated for 30 min on the water bath, in order to reduce the perbromate to bromide, and the latter is oxidised by chlorine to BrCN in a neutral solution of cyanide. The solution thus obtained is acidified and titrated with thiosulphate after adding KI.

Another method of determining perbromate in the presence of bromate includes the reduction of BrO_4^- to BrO_3^- by iodine in a weakly alkaline medium (pH 7–9) at 100 °C.[47] Evolution of free iodine is prevented by adding a known amount of Na_3AsO_3, and the excess of this reagent is titrated with iodine with starch indicator. The total amount of bromate is determined by titration with acidified thiosulphate. The perbromate ion can be reduced to bromate simply by adding a solution of KI, but in this case two weeks must be allowed for the reaction to go to completion, whereas with hydroiodic acid the reduction of BrO_4^- to Br^- is instantaneous at room temperature[48].

In addition to the redox methods, gravimetry methods of determining perbromate have been described. They involve precipitation of the perbromate as $RbBrO_4$ [5] or as tetraphenylarsonium perbromate[8]. The latter is precipitated by adding tetraphenylarsonium chloride to the solution containing perbromate and bromate ions. The precipitate is washed with water to remove traces of bromate and with 50% aqueous ethanol, and dried in a vacuum desiccator at room temperature.

As an alternative to the gravimetric end-determination, perbromate can be determined as tetraphenylarsonium perbromate by potentiometric titration with a solution of tetraphenylarsonium chloride[49]. Anions such as chlorate, chloride, bromate, bromide, fluoride, sulphate, and chromate do not interfere with the titration. However, in the presence of periodate ions this method cannot be used.

Polarographic measurements have given a single wave for solutions containing bromate and perbromate ions in 0.05 M $HClO_4$, corresponding to the reduction of BrO_4^- and BrO_3^- to Br^-, whereas in neutral or in alkaline media two distinct waves are observed. The first corresponds to the reduction of perbromate ions to bromate, and the second to the reduction of bromate to bromide, thus allowing the method to be used for the determination of BrO_4^- in the presence of BrO_3^-.[50] The error of the determination of perbromate by this method is 2%. The electrochemical reduction of BrO_4^- is discussed also in Refs. 51–54.

Small amounts of perbromate in the presence of traces of other bromine anions have been determined by colorimetric methods[55] and by extraction photometry, using Crystal Violet[56]. In the latter method the presence of bromate at concentrations up to 10^{-3} g-ion litre^{-1} does not interfere with the determination of perbromate, whereas bromide at concentrations greater than 5×10^{-4} M lowers the optical density of solutions of Crystal Violet containing BrO_4^-. The method is suitable for determining perbromate ions at concentrations between 10^{-6} and 10^{-5} M.

Perbromate ions can be separated from mixtures with other anions by ion-exchange, thin-layer, and paper chromatography methods. Lederer and Sinibaldi[44] studied the chromatographic behaviour of perbromate ions on paper and on thin cellulose and silica gel layers, using the ethanol–water–ammonia and butanol–pyridine–1 M NH_4OH systems. BrO_4^- was found to be more mobile than BrO_3^- under these conditions. The same is true in the isopropanol–1.5 M NH_4OH system[45], but in this case substantial reduction of the perbromate ion occurs, and therefore the system is not suitable for the quantitative determination of perbromate.

Table 3. Chromatographic separation of chemical forms of bromine by thin-layer and paper chromatography.

Chemical form	R_f values for chromatography on Al_2O_3		R_f values for paper chromatography	
	Acetone–water (8:1)	Acetone–water–ethanol (6:2:1)	Acetone–water–ethanol (6:2:1)	Acetone–water–pyridine (6:1:2)
BrO_4^-	0.60±0.02	0.68±0.02	0.89±0.02	0.82±0.02
BrO_3^-	0.08±0.01	0.14±0.02	0.39±0.01	0.26±0.02
Br^-	0.27±0.02	0.41±0.02	0.53±0.05	0.14±0.01

A method free from this drawback is described in Ref. 57. Bromine compounds were separated on thin layers of Al_2O_3 and on paper by using the following solvent systems: acetone–water, acetone–water–ethanol, and acetone–water–pyridine. The R_f values were determined by measuring the ^{82}Br activity with an MST-17 end-window counter: the results are summarised in Table 3.

Separation of bromate and perbromate ions on a thin layer of Al_2O_3 has been achieved also by using aqueous solutions of the salts, acids, and bases[58]. As in the case of paper electrophoresis, the perbromate ion has the higher mobility. The sharpest separation was obtained with solutions of thorium nitrate and zirconyl chloride[44].

A reliable method of separating the different chemical forms of bromine is ion-exchange chromatography on the strongly basic anion exchangers AV-17 and Dowex-1.[57] Selective separation of bromine compounds in different states of oxidation was achieved by elution with potassium bicarbonate and nitrate solutions. Bromite ions were washed out by elution with 0.5 M $KHCO_3$, bromate ions with 1 M $KHCO_3$, bromide ions with 1 M KNO_3, and perbromate ions with 2 M KNO_3. On the other hand, hypobromite ions were absorbed at the top of the column and were not eluted: apparently, these ions react with the anion exchange resin by brominating it.

On anion-exchange paper the perbromate ions are adsorbed as strongly as perchlorate and periodate ions: the Rf values of all these ions are very similar[45]. The best separation of BrO_4^- from BrO_3^- is obtained by using diethylaminocellulose.

V. "HOT ATOM" CHEMISTRY OF CRYSTALLINE PERBROMATES

The "hot atom" chemistry of crystalline perbromates has great theoretical and practical interest. Its theoretical importance stems from the possibility of predicting chemical forms and of setting up a kinetic theory of chemical reactions involving atoms with an excess of energy. The practical interest lies in the preparation of sources of radioactive bromine with a high specific activity.

One possible way of obtaining radioactive isotopes of bromine is to irradiate perbromates in a nuclear reactor. The radioactive isotopes are usually stabilised in chemical forms different from the original compound. The distribution of atoms of the radioactive isotope ^{82}Br over the different chemical forms after irradiation with thermal neutrons is shown in Table 4 for the perbromates of alkali[59] and alkaline-earth metals, and of magnesium and ammonium[60].

Table 4. Yield of chemical stabilisation forms of ^{82}Br in neutron-irradiated perbromates.

Irradiated compound	Yield of bromine-82, %				
	BrO_4^-	BrO_3^-	BrO_2^-	BrO^-	Br^-
$LiBrO_4 \cdot H_2O$	2.1±0.3	44±2	4.4±0.5	4.4±0.5	45±2
$NaBrO_4$	2.1±0.4	36±1	1.0±0.6	0.8±0.3	60±1
$KBrO_4$	2.3±0.4	44±3	1.1±0.3	1.7±0.3	51±3
$RbBrO_4$	2.6±0.4	33±1	3.0±0.3	2.0±0.3	59±2
$CsBrO_4$	2.2±0.4	31±1	5.1±0.5	3.5±0.5	58±2
NH_4BrO_4	1.6±0.4	<0.3	<0.3	0.4±0.3	98±1

The distribution of ^{82}Br over the different chemical forms in alkali metal perbromates irradiated with neutrons was studied also by Hassan and Heitz[61], who found that 74% of the ^{82}Br was present as bromide, 24% as bromate, and 1% as perbromate, in general agreement with other workers[59,60], but (surprisingly) they claim that the $^{82}BrO_4^-$ ions remained in the original spot in their paper electrophoresis method of analysis whereas $^{82}BrO_3^-$ had a much higher mobility (in contrast to earlier reports[44,58]).

After thermal annealing of neutron-irradiated perbromates the yields of the chemical forms of ^{82}Br show some major changes[60–62]. In the alkali metal perbromates the content of ^{82}Br as BrO_4^- increases initially to a maximum, and then decreases, but in this case the changes are not very great. The main reaction occurring when alkali metal perbromates are annealed is the oxidation of $^{82}Br^-$ to $^{82}BrO_3^-$, the size of the effect being very dependent on the nature of the cation. For example, in neutron-irradiated lithium perbromate the yield of $^{82}BrO_3^-$ was 98% at the end of the heat treatment, for $NaBrO_4$ it was 93%, for $KBrO_4$ 89%, for $RbBrO_4$ 80%, and for $CsBrO_4$ 58%. Similar effects are reported in Ref. 63, but thermal annealing of neutron-irradiated potassium perbromate near its decomposition temperature (275 °C) was found to give a sudden increase in retention, similar to the increased retention of ^{128}I produced by heating irradiated potassium periodate[64]. The maximum retention of ^{82}Br (80%) was reached after heating $KBrO_4$ for 1 h at 275 °C. Above 300 °C all the bromine oxy-anions decompose.

In the alkaline-earth metal and magnesium perbromates the retention of ^{82}Br decreases, and at the end of the heat treatment it is as low as 2.0%. The changes in yield of $^{82}BrO_3^-$ caused by thermal annealing again depend on the nature of the cation[60]. The bromine and oxygen recoil atoms recombine with formation of bromate ions during thermal annealing of neutron-irradiated perbromates. On the other hand, the oxygen atoms can recombine together to give oxygen molecules. Therefore the oxidation of $^{82}Br^-$ to $^{82}BrO_3^-$ is not usually quantitative, in spite of the fact that stable perbromate molecules give off oxygen atoms during radiolysis.

Table 5. Yield of chemical stabilisation forms of ^{82}Br and ^{80m}Br recoil atoms in neutron-irradiated lithium and sodium perbromates.

Irradiated compound	Isotope	Yield of radioactive bromine, %				
		BrO_4^-	BrO_3^-	BrO_2^-	BrO^-	Br^-
$LiBrO_4$	^{82}Br	2.1±0.2	45±1	3.4±0.8	4.8±0.6	46±1
	^{80m}Br	1.9±0.2	60±2	2.9±0.6	4.2±0.9	31±1
$NaBrO_4$	^{82}Br	2.0±0.1	41±2	1.5±0.3	0.7±0.2	55±2
	^{80m}Br	1.1±0.1	55±2	0.9±0.2	1.2±0.5	41±1

Irradiation of perbromates with thermal neutrons produces, in addition to ^{82}Br, also ^{80m}Br, and this allows us to compare the yields of the chemical forms of these isotopes, i.e. to look for an isotope effect. The results of these experiments, made with lithium and sodium perbromates[65], are shown in Table 5.

During thermal annealing the yield of $^{82}BrO_3^-$ in neutron-irradiated sodium perbromate increases from 41 to 91% in 15 min at 150 °C, whereas the yield of $^{80m}BrO_3^-$ increases from 55 to 86% during the same time. Longer heating times have no effect, and at the end of the anneal the isotope effect amounts to 5%. In lithium perbromate the yields of ^{82}Br and ^{80m}Br as bromate ion are equal at the end of the anneal, possibly as a result of the production of fission fragments from ^6Li by the thermal neutrons. These fragments cause strong ionisation of their surroundings and tend to mask any differences in the dislocation regions where the ^{82}Br and ^{80m}Br recoil atoms are accommodated.

Crystal defects play an important role in determining the fate of the bromine recoil atoms during thermal annealing of neutron-irradiated perbromates. In order to quantify the influence of crystal defects on the annealing operation the effect of previous heat treatment of the crystals (before neutron irradiation) has been investigated[66]. These experiments showed that in sodium perbromate which has been heat treated before irradiation the retention of ^{82}Br is unchanged by annealing, and the yield of bromate ions is lower than in ordinary samples which have been similarly annealed. Since all the samples had been irradiated under identical conditions, differences in behaviour of the recoil atoms during annealing can be interpreted as differences between the crystals, i.e. as differences in the relative distribution over energy levels with activation energies corresponding to different temperatures.

Whereas the retentions of ^{82}Br and ^{80m}Br formed by neutron irradiation of crystalline perbromates of the alkali metals seldom exceed 2.6%, the retention of the radioactive bromine isotopes formed by isomeric transition and β^- disintegration is substantially higher. Thus, the retention of ^{80}Br formed by isomeric transition from ^{80m}Br in a lithium perbromate composition is 31 ± 1%,[60] and the retention of ^{83}Br formed by β^- disintegration from ^{83}Se in potassium selenate is 24%.[67]

Whereas irradiation of perbromates in a nuclear reactor produces radioactive bromine isotopes, the interaction of stable bromine atoms with high-energy protons produces a whole series of radioactive isotopes of different elements. Radiochemical and gamma-spectroscopic analyses have shown that the irradiation of crystalline sodium perbromate with 1 GeV protons leads to the formation of oxygenated krypton compounds, produced from bromine by a (p, xn) reaction[68]. The retention of radioactive krypton isotopes in a chemically bound state was 30 ± 9% for krypton-74, 7 ± 3% for krypton-76, and not more than 0.3% for krypton-77 and krypton-79. No attempt was made to identify the krypton compounds formed. However, by analogy with the formation of xenon compounds by β^- disintegration of ^{131}I, ^{133}I, and ^{135}I in periodate, iodate, and iodine pentoxide compositions[69], in which the preferred chemical form of the bound xenon is XeO_3, we may assume the formation of KrO_3. Krypton trioxide may be formed by the interaction of krypton recoil atoms with various fragments, produced in sodium perbromate by the radiolytic interaction of the proton beam, secondary particles, gamma radiation, and the recoil atoms themselves. One possible fragment is O_3^-, which has been detected by ESR in potassium perbromate irradiated with X-rays[70]. The interaction of these ions with krypton recoil atoms can stabilise the latter in the form of KrO_3. The formation of oxygen compounds of krypton, xenon, and radon has been observed also after irradiation of uranyl sulphate with high-energy protons[71].

Thus, previously unknown oxygen compounds of krypton have been prepared by studying perbromates. The perbromates themselves, on the other hand, can be prepared by using xenon difluoride[7] and krypton difluoride[72].

VI. RADIATION CHEMISTRY OF HEPTAVALENT BROMINE COMPOUNDS

Boyd and Brown[73] have studied the stable radiolysis products formed in crystalline potassium perbromate irradiated with gamma rays from ^{60}Co. The irradiation was carried out at ~35 °C with two sources, having activities of 3 and 11.5-kCi respectively. The dose of radiation absorbed was 9.3×10^{17} eV g^{-1} H_2O min^{-1} for the first source and 3.8×10^{18} eV g^{-1} H_2O min^{-1} for the second source. The dose absorbed by crystalline potassium perbromate was calculated by multiplying the dose for water by the ratio of the number of electrons per gramme of $KBrO_4$ to the number of electrons per gramme of H_2O: it was found to be 1.5×10^{23} eV $mole^{-1}$. The i.r. spectrum of $KBrO_4$ irradiated with this dose contains, in addition to the BrO_4^- absorption bands, only the absorption bands due to BrO_3^-. No bands which could be assigned to BrO_2^- were detected. A possible explanation[73] is that the dose to which the sample was exposed was too small.

However, even at higher doses the bromate ion is practically the only product of the radiolysis of crystalline potassium perbromate (4.36×10^{24} eV $mole^{-1}$) and sodium perbromate (3.98×10^{24} eV $mole^{-1}$).[60] The preferential formation of bromate ions during radiolysis of perbromates is explained by the far higher probability of breaking one bromine–oxygen bond than two, three, or (especially) all four bonds in a perbromate ion irradiated with gamma rays from ^{60}Co.

Irradiation of alkali metal perbromates in a reactor also leads to extensive radiolysis with formation of bromate ions, the radiation-chemical yield $G(-BrO_4^-)$ being 3.9 ± 0.3 for

lithium perbromate, 2.8 ± 0.3 sodium, potassium, and rubidium perbromates, and 3.2 ± 0.3 for caesium perbromate. These yields are very large in comparison with $G(Br^-)$, which is never greater than 0.02.[60]

Hassan and Heitz[74] studied the radiolytic reduction of potassium perbromate in aqueous solutions (both aerated and de-aerated) under the influence of gamma rays from ^{60}Co. In acid solutions only one reaction is observed: $H^{\bullet}(HO_2^{\bullet}) + BrO_4^-$ [with a yield $G(-BrO_4^-) = 3.5$]. In a neutral solution the perbromate ion is reduced by solvated electrons. However, the yield of this reaction [$G(-BrO_4^-) = 5.3$] suggests that species other than solvated electrons are also involved in the reduction. The photolysis and the radiolysis of potassium perbromate solutions are discussed also by Byberg and Linderberg[75].

Irradiation of potassium perbromate single crystals with X-rays (of 50 kV energy) at 10, 26, and 77 K produces four types of centre [A, BrO_4^{2-}; C, $BrO_4^{\bullet}$; D, $(BrO_4)_2^-$; G, O_3^-] which can be detected by ESR. At 10 K only BrO_4^{2-}, $BrO_4^{\bullet}$, and $(BrO_4)_2^-$ are observed, but at temperatures above 20 K O_3^- is produced by thermal processes from BrO_4^{2-}, and BrO_2 from $BrO_4^{\bullet}$. As a result of these annealing effects only O_3^- and BrO_2 can be detected in the potassium perbromate single crystal at 240 K.

The ESR method has been used also to study the radiolysis products of frozen solutions of potassium perbromate[76]. $BrO_3^{\bullet}$, $BrO_4^{\bullet}$, and BrO_4^{2-} were identified in an irradiated polycrystalline solution of potassium perbromate; the $KBrO_4$ reacted with electrons even in a frozen (glassy) solution in 10 M NaOH, but under these conditions bromine-containing radicals could not be detected.

The pulsed radiolysis of aqueous solutions of potassium perbromate with electrons of 10 MeV energy in a neutral solution saturated with argon produced the reaction

$$BrO_4^- + e^-_{hybr} = BrO^- + O^-,$$

whose rate constant was 7×10^9 litre mole^{-1} s^{-1}.[77] Measurements of the yield of $OH^{\bullet}$ radicals in acid or neutral argon-saturated solutions and of the yield of O_3^- in alkaline oxygen-saturated solutions of potassium perbromate showed that interactions of $H^{\bullet}$, $OH^{\bullet}$, and O^- with BrO_4^- all have rate constants smaller than 10^7 litre mole^{-1} s^{-1}.

Polarographic, optical spectroscopy, and ESR methods have been used to study the photolysis products of aqueous solutions of potassium perbromate at room temperature and at 77 K.[78] Irradiation was carried out at a wavelength $\lambda = 253.7$ nm. At 77 K the O^- centre was detected, but this centre disappears at 160 K with formation of O_2^- and O_3^-. BrO_3^-, BrO_2^-, HO_2^-, and molecular oxygen were detected when a solution of potassium perbromate in 0.1 M NaOH was irradiated.

VII. PRACTICAL APPLICATIONS OF PERBROMIC ACID AND ITS SALTS

Perbromates are still laboratory compounds, and are not yet handled on an industrial scale. However, they are beginning to find wide uses in the laboratory, for example in studies of the electrical double layer[79,80] and of the synthesis of oxygen compounds of krypton[68]. Perbromic acid and its salts can be used as special oxidising agents, and also for the quantitative determination of rubidium and caesium (whose perbromates are sparingly soluble in water at 0 °C). Mixed with nitric acid, $HBrO_4$ has been used for wet ashing organic compounds. Concentrated perbromic acid is one of the strongest oxidising agents, whereas dilute perbromic acid (like perchloric acid) can be used as a reaction medium. Since most perbromates are fairly soluble, perbromic acid and its salts can be used in metal treatment processes such as electroplating, etching, and polishing. Perbromic acid can also be used in organic synthesis for separating alcohols, ketones, and amines from resinous materials.

Perbromates can be used as sources of radioactive bromine (in the form of bromide ions) with a high specific activity, because most of the radioactive bromine isotopes in neutron-irradiated perbromates are stabilised as bromide ions, and the yield of Br^- during radiolysis is negligible. A high specific activity is important in medical and biological investigations, in which the application of radioactive bromine isotopes is increasing every year.

Thus, heptavalent bromine compounds will undoubtedly find increasingly wide applications in industry and in the national economy as well as in scientific research.

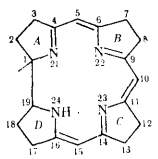
Synthesis of Corroles and Octadehydrocorrins

N.S.Genokhova, T.A.Melent'eva, and V.M.Berezovskii



A survey has been made of methods for the synthesis of corroles and their complexes with various metals, and also methods for the synthesis of metal complexes of 1,19-disubstituted octadehydrocorrins from biladienes, bilenes, and bilatrienes and of nickel complexes of 1-substituted octadehydrocorrins by the oxidative and non-oxidative cyclisation of biladienes. Aspects of the structure of corroles and metal complexes of corroles and octadehydrocorrins are discussed. A list of 76 references is included.

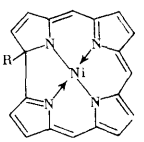
I. INTRODUCTION



Corroles and octadehydrocorrins are tetrapyrrole macrorings related both to corrin (I)—a partly hydrogenated tetrapyrrole system present in biological catalysts, e.g.vitamin B_{12} and its coenzymes—and to porphyrin (II), which forms the framework of chlorophyll, haemin, and cytochromes.

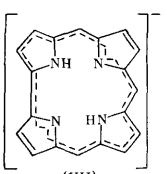
(IV)

(V)

(VI)

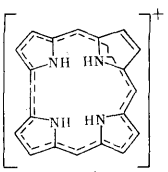
Octadehydrocorrins† are known as the neutral nickel complexes of 1-substituted derivatives (III) and in the cationic form of metal complexes of 1,19-disubstituted derivatives (IV). Corroles (V), like octadehydrocorrins, contain a direct $\alpha\alpha'$-bond between two pyrrole rings, but unlike them are aromatic compounds, thereby approaching the porphyrin system (II). Corroles are known also as metal complexes (VI).

Corroles and metal complexes of octadehydrocorrins differ from porphyrins and also corrins both in chemical and physicochemical properties and in methods of synthesis. Furthermore, the cobalt complexes of octadehydrocorrins catalyse the oxidation of reduced nicotinamide–adenine dinucleotide, one of the most important links in the electron-transport system of the living cell[2]. It is therefore of undoubted interest to examine routes and methods for the synthesis of corroles and octadehydrocorrins.



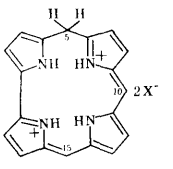
Foreign reviews[3–8] covering the synthesis of tetrapyrrole macrorings devote only individual chapters to corroles and octadehydrocorrins. The main advances in this field were surveyed[9] in 1969. The present Review covers all published information on methods for the synthesis of corroles and octadehydrocorrins, paying special attention to work appearing during the past decade.

† The name *octadehydrocorrin* applies to the macroring in (III) and (IV); it has been recommended by the Commission for Biochemical Nomenclature of the International Union of Pure and Applied Chemistry and the International Union of Biochemistry[1].



II. SYNTHESIS OF CORROLES

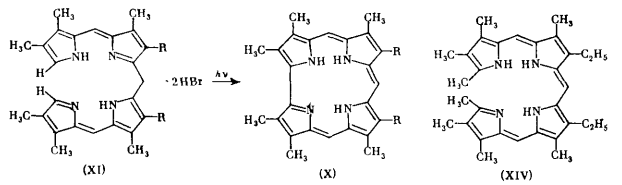
1. Structure and Properties of Corroles



The search for synthetic routes to corrin led to the synthesis of corroles (V), which forms red crystals. It contains an aromatic cyclic system with eighteen π-electrons, as indicated by an intense Soret band (~400 nm) in its electronic absorption spectrum, which contains also bands in the region of 540, 550, and 600 nm.[10]

(VII)

(VIII)



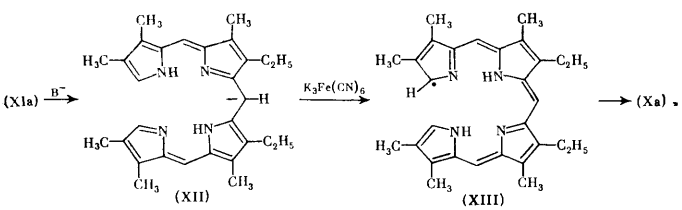
(IX)

Addition of dilute alkali to solutions of corroles readily converts them into stable aromatic anions (VII),[10–12], which distinguishes them in particular from porphyrins[13]. Corroles readily undergo monoprotonation when treated with a dilute solution of hydrobromic acid in acetone. This involves formation of crystalline monohydrobromides, existing as aromatic ambident cations (VIII).[12] The green solutions of corroles in concentrated sulphuric acid do not contain a Soret band in the electronic spectrum, which indicates the appearance of the "blocked" conjugated structure of the tautomeric non-aromatic dication (IX) with the additional protonation at carbon atom 5,[11] not at $C_{(10)}$ as assumed previously[10,11]. Addition of alkali to a solution of the dication (IX) converts the latter back into the original corrole (V).

2. Synthesis of Corroles from Biladienes-*ac*

The free bases of corroles (X) have been synthesised from 1,19-dideoxybiladienes-*ac* (XI) containing hydrogen atoms at positions 1 and 19, by the photocyclisation of their dilute methanolic solutions in the presence of a small excess of

ammonia or aqueous sodium acetate[11,14], and also by the photocyclisation of aqueous solutions in the presence of ammonia and potassium hexacyanoferrate(III):[15]

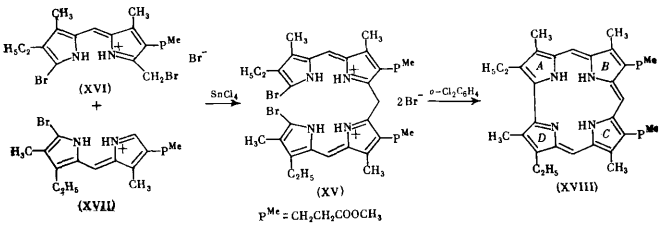


(XI) (X) (XIV)

a) R = C_2H_5, b) R = $CH_2CH_2COOH_3$

On the assumption that formation of corroles had a free-radical mechanism[16,17] an examination was made of the influence of various initiators (of free-radical processes) and one-electron oxidising agents on cyclisation of the 1,19-unsubstituted biladiene-*ac* (XIa). It was found that cyclisation occurred very rapidly in the presence of ammonia and potassium hexacyanoferrate(III), iron(III) chloride, cerium sulphate, and hydrogen, benzoyl, and t-butyl peroxides; in all cases the corresponding corrole (X) was isolated in 68 to 84% yield[16].

These reactions require the presence of a base, which indicates initial detachment of a proton from a 10-methylene group of biladiene during photocyclisation. This is confirmed by the fact that 10,10-dimethylbiladienes are not cyclised to a corrole[18]. Formation of corroles is appreciably accelerated by ultraviolet irradiation of solutions of biladienes; yet replacement of atmospheric oxygen by nitrogen has no appreciable effect on the course of the reaction. Cyclisation apparently involves successive formation of an anion (XII) and an intermediate radical (XIII):

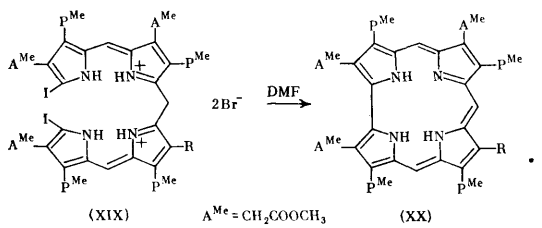


(XII) (XIII)

In an attempt to synthesise the corrole (X) from 1,19-dimethylbiladiene-*ac* ultraviolet irradiation of the methanolic solution yielded mainly the bilatriene (XIV) with some porphyrin[19].

The synthesis of corroles[10] by the photolysis of alkaline solutions of biladienes-*ac* in which positions 1 and 19 are unsubstituted is restricted by the methods for obtaining these intermediate compounds, in whose formation the degree of symmetry of the β-substituents plays an important part.

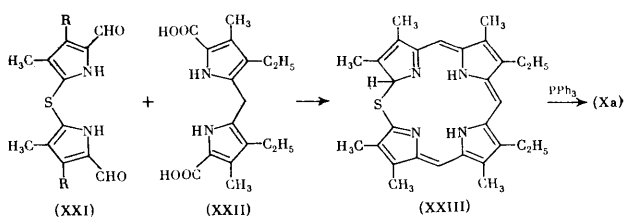
Corroles having an unsymmetrical arrangement of β-substituents have been obtained by the thermal cyclisation of 1,19-dibromobiladienes-*ac*. Thus 1,19-dibromo-1,19-dideoxybiladiene-*ac* dihydrobromide (XV), obtained by condensation of the dipyrromethene (XVI) with the 5′-unsubstituted 5-bromodipyrromethene (XVII) in the presence of tin(IV) chloride, was converted into the corrole (XVIII) by boiling with *o*-dichlorobenzene[20]:



(XVI) (XVII) (XV) (XVIII)

P^{Me} = $CH_2CH_2COOCH_3$

Corroles having non-alkyl β-substituents in rings A and D were unknown until 1975,[21] perhaps because groups larger than methyl in positions 2 and 18 prevent the photocyclisation of 1,19-biladienes-*ac*.[10]

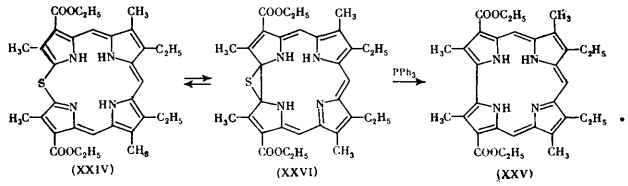


A more promising method for synthesising corroles having different substituents in rings A and D was thermal cyclisation of 1,19-dibromobiladienes-*ac* (XV) in *o*-dichlorobenzene[20] or of 1,19-di-iodobiladienes-*ac* (XIX: R = CH_3, A^{Me}) in dimethylformamide (DMF).[21] 1,19-Dideoxy-1,19-di-iodobiladienes-*ac* (XIX) with acetic and propionic residues in β-positions were more reactive than the corresponding 1,19-dibromo-derivatives[20], the former yielding corroles (XX: R = CH_3, A^{Me}) when heated in DMF:[21]

(XIX) A^{Me} = CH_2COOCH_3 (XX)

3. Synthesis of Corroles via Sulphur-containing Compounds

Corroles have been obtained by cyclising linear dipyrrole compounds containing sulphur. The condensation of bis-5-formylpyrrol-2-yl sulphide (XXIa) with methane-2,2′-dipyrrole-5,5′-dicarboxylic acid (XXII) at −10 °C in the presence of hydrogen chloride gives a 10–20% yield of a dark red product (XXIII), which when boiled with excess of triphenylphosphine in *o*-dichlorobenzene is converted into the corresponding corrole (Xa):[22]



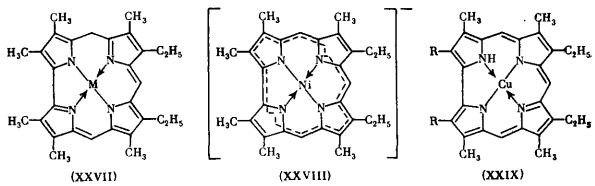
(XXI) (XXII) (XXIII)

a) R = CH_3, b) R = $COOC_2H_5$

However, when the sulphide (XXIb) is condensed with the dicarboxylic acid (XXII), the dark blue crystalline *meso*-thiaphlorin (XXIV) of non-aromatic character is obtained[22], whose desulphurisation in boiling *o*-dichlorobenzene leads to

formation of the corrole (XXV) in 35–40% yield, apparently with intermediate formation of a thi-iran derivative (XXVI):[8]

(XXIV) (XXVI) (XXV)



Conducting the reaction in the presence of triphenylphosphine increases the yield of the corrole (XXV) to 60%.

III. SYNTHESIS OF METAL COMPLEXES OF CORROLES

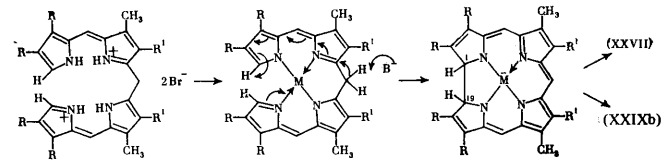
1. Structure of Complexes of Corrole with Bivalent Metals

In metal complexes of corrole a bivalent metal (zinc, nickel, palladium) replaces only two of the three imino-hydrogen atoms; the third hydrogen atom moves to another site in the chromophore. The aromatic conjugated system is disrupted in such complexes, as indicated by the absence of an intense Soret band from the electronic spectra of the above three metal complexes[10,15,23,24]. Such absence indicates that these complexes (XXVII: M = Ni, Pd) are derivatives of a tautomeric non-aromatic base corresponding to a dication of type (IX).[12]

For a long time the site of the "extra" hydrogen atom in the ligand could not be established, since the paramagnetic nature of nickel octa-alkylcorroles prevented the use of nuclear magnetic resonance spectroscopy for this purpose. The atom was arbitrarily located at $C_{(10)}$.[15] In order to solve this structural problem an examination was made of the protonation of corrole in fluorosulphuric acid, which established that in the formation of dications protonation is considerably more rapid at $C_{(5)}$ than at $C_{(10)}$.[12] On this basis the structure (XXVII) was ascribed to complexes of corroles with bivalent metals.

(XXVII) (XXVIII) (XXIX)

a) R = C_2H_5, b) R = CH_3.



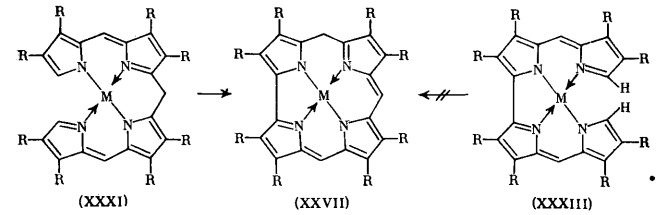
Addition of alkali to the green solutions of the nickel complex of corrole (XXVII: M = Ni) produces a Soret band in the electronic spectrum, apparently owing to formation of the stable ambident aromatic anion (XXVIII), whose solutions are red. This colour change is reversed on acidification.

Spectral data for the copper complexes of corroles indicate the presence of a continuous π-chromophore, and therefore the formula (XXIX) was suggested[15].

2. Synthesis of Nickel, Copper, Zinc, and Palladium Complexes of Corrole

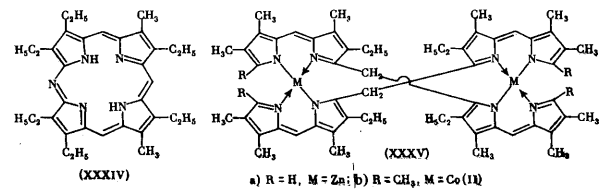
Metal complexes of corroles can be obtained both by the cyclisation of 1,19-disubstituted 1,19-dideoxybiladienes-*ac* in the presence of metal acetates in hot methanol and by introduction of the metal into the free base of corrole[10].

Corrole complexes of nickel (XXVII: M = Ni) and copper (XXIXb) have been synthesised by the ultraviolet irradiation of methanolic solutions of biladienes-*ac* (XXX) containing terminal hydrogen atoms, in the presence of nickel or copper ions and a base[10,11]. Initially a metal–biladiene complex (XXXI) is apparently formed, in which the metal has a coordinating effect on positions 1 and 19, draws them together, and thereby facilitates cyclisation:



(XXX) (XXXI) (XXXII), M=Ni, Cu

a) R = CH_3, R' = C_2H_5; b) R = R' = CH_3; c) R = R' = C_2H_5.

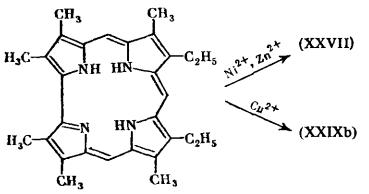


In the presence of a base a proton is detached from the $C_{(10)}$ atom in the metal complex (XXXI) and an anion (XXXII) is formed, which then passes into a neutral metal–corrole complex, (XXVII) [10,11] or (XXIX) [15] depending on the metal.

Whereas metal–corrole complexes (XXVII) are readily formed from metal–biladiene complexes (XXXI),[10] it has not proved possible to cyclise metal complexes of 5,5'-bisdipyrromethenes (XXXIII), which also contain terminal hydrogen atoms[18]:

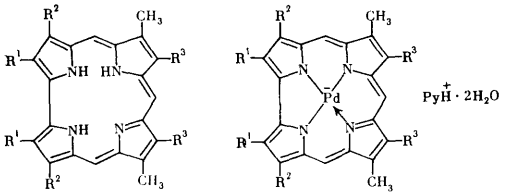
(XXXI) (XXVII) (XXXIII)

Bulky β-substituents present at positions 2 and 18 in a biladiene-*ac* deactivate positions 1 and 19, and have an adverse influence on formation of a direct αα'-bond. Other reactions can then occur, e.g. formation of the azaporphyrin (XXXIV) by photocyclisation of an ammoniacal solution of the biladiene-*ac* (XXXc) containing ethyl groups at positions 2 and 18, whereas the corresponding 2,18-dimethylated compounds are converted under these conditions into a corrole[10].



(XXXIV) (XXXV)

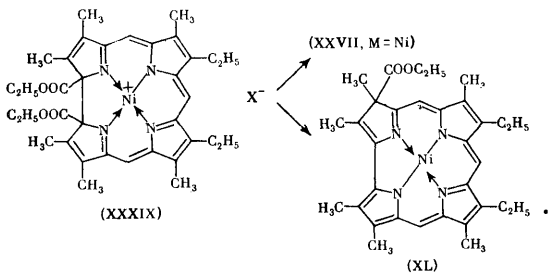
a) R = H, M = Zn; b) R = CH_3, M = Co(II).



Zinc–biladiene-*ac* complexes could not be converted into corroles[10], since they have a tetrahedral configuration (XXXVa),[25] with the terminal α-hydrogen atoms occupying positions unfavourable to formation of a direct αα'-bond.

Corrole complexes of bivalent zinc and nickel (XXVII: M = Ni, Zn) and also copper (XXIXb) were obtained[10] by adding the cations to a solution of the corrole (XXXVI) in either pyridine or aqueous ammonia:

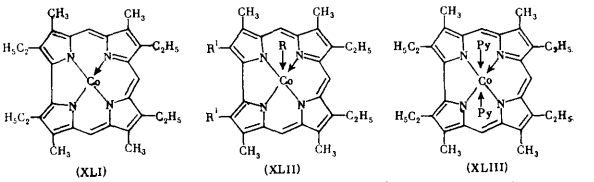
(XXXVI)



Treatment of the corrole (XXXVII) with palladium acetate in pyridine solution leads to the formation of crystalline pyridinium salts of palladium–corrole anions (XXXVIII) in 89–92% yield, isolated as the dihydrates[15], which are aromatic like the original corrole (XXXVII). On treatment with acids these salts pass into unstable, apparently neutral palladium complexes of the corroles, which could not be isolated.

(XXXVII) (XXXVIII)

a) $R^1 = R^3 = CH_3$, $R^2 = C_2H_5$; b) $R^1 = R^3 = C_2H_5$, $R^2 = CH_3$



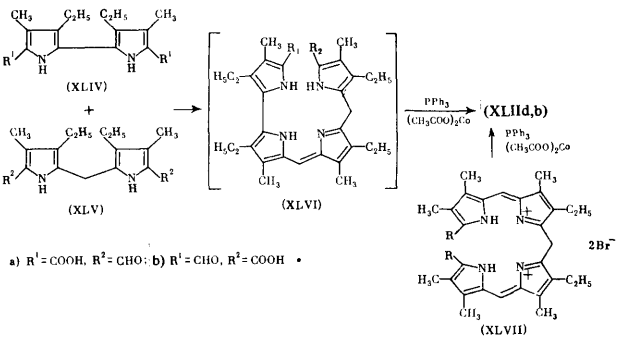
Nickel–corrole complexes can be obtained[26,27] from the corresponding complex of the octadehydrocorrin (XXXIX) containing angular ethoxycarbonyl substituents. Successive hydrolysis and decarboxylation of the angular groups in the complex (XXXIX: X = NO_3) gave the nickel–corrole complex (XXVII),[26] but heating the nitrate or chloride of octadehydro-1,19-diethoxycarbonylcorrin (XXXIX: X = NO_3, Cl) in chlorobenzene led to isolation of the nickel–corrole complex (XL):[27]

(XXXIX) (XL)

3. Structure and Properties of Cobalt Complexes of Corrole

Two types of cobalt–corrole complexes are known, the first of which do not contain axial ligands. Because of their paramagnetism they were originally regarded as cobalt(II) complexes[10], but are paramagnetic square–planar cobalt(III)–corrole complexes (XLI).[26–30] Complexes of the second type are formed in the presence of pyridine, triphenylphosphine, or *p*-tolyl isocyanate, and are five-coordinated cobalt(III)–corrole complexes (XLIIa–d) containing these compounds as axial ligands[31]. Addition of excess of pyridine to solutions of both types of complexes leads to the formation of octahedral dipyridine–cobalt(III)–corrole (XLIII), which is stable only in the presence of excess of pyridine[31].

(XLI) (XLII) (XLIII)



a) R = Py, $R^1 = C_2H_5$; b) R = PPh_3, $R^1 = CH_3$; c) R = *p*-$CN \cdot C_6H_4 \cdot CH_3$, $R^1 = C_2H_5$; d) R = PPh_3, $R^1 = C_2H_5$

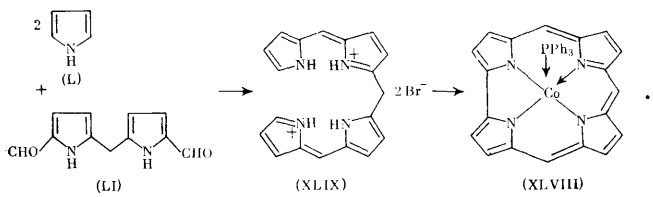
Thus cobalt is tervalent in all its complexes with corroles: i.e. in these compounds all three imino-hydrogen atoms have been replaced. The complexes are either square–planar, pyramidal, or octahedral depending on the number of axial ligands[31]. In contrast, nickel[24], palladium, and copper[15] form only square–planar complexes of corroles in which these metals are bivalent.

4. Synthesis of Cobalt Complexes of Corrole

The synthesis of tetrapyrrole macrocycles such as corroles[10], octadehydro-1-methylcorrins[32], and 1,19-dialkyloctadehydrocorrin salts[33], which contain a direct bond between two pyrrole rings, involves the cyclisation of linear tetrapyrrole derivatives, e.g. 1,19-dideoxybiladienes-*ac*, bilenes-*b*, or bilatrienes. In 1973 the first [2 + 2] synthesis of corrole was accomplished that did not involve formation of a direct bond in the last stage of cyclisation[31].

Reaction between 3,3′-diethyl-4,4′-dimethyl-2,2′-bipyrrole-5,5′-dicarboxylic acid (XLIVa) [19] and 3,3′-diethyl-5,5′-diformyl-4,4′-dimethyldipyrromethane (XLVa) [10] in the presence of hydrobromic acid in methanol at 0 °C gives a red deposit, which when heated in methanol containing cobalt(II) acetate and triphenylphosphine is converted into the cobalt(III) complex (XLIId) having a triphenylphosphine group as an axial ligand:

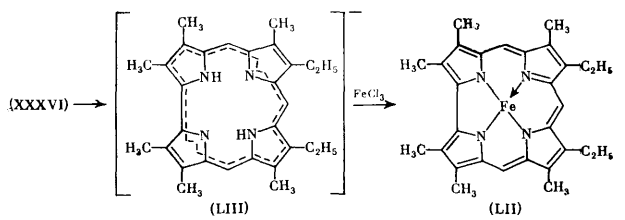
a) R^1 = COOH, R^2 = CHO; b) R^1 = CHO, R^2 = COOH



The same product (XLIId) can be obtained by condensing the bipyrrolyl (XLIVb) with the dipyrromethanedicarboxylic acid (XLVb).

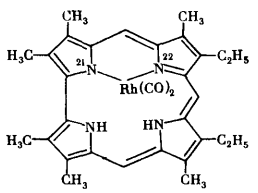
These reactions may involve intermediate formation of *a*-norbilenes-*c* (XLVIa,b). The successful cyclisation of (XLIV) and (XLV) into a corrole emphasises the importance of cobalt both in stabilising the intermediate compound and in conferring a favourable configuration on it, since it had previously proved impossible to convert (XLIV) and (XLV) into a corrole in the absence of a complexing metal[31].

The corresponding cobalt(III) complex of corrole containing an axial triphenylphosphine ligand (XLIIb: R = $(C_6H_5)_3P$) has been obtained by cyclising 1,19-dideoxybiladiene-*ac*



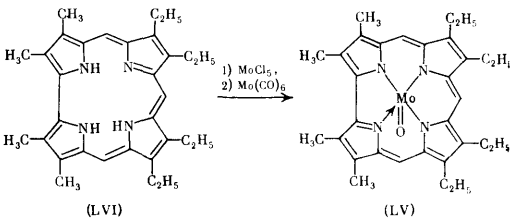
dihydrobromide (XLVII: R = H) in the presence of cobalt(II) acetate and triphenylphosphine in hot methanol. On the other hand, when a biladiene-*ac* containing methyl groups at the terminal positions 1 and 19 (XLVII: R = CH_3) is heated with cobalt(II) acetate and triphenylphosphine in methanol, a paramagnetic green product separates that proves to be a dimeric form of the cobalt complex of the biladiene (XXXVb).[25,31,33,34]

The stabilising effect of a coordinated triphenylphosphine ligand in the synthesis of cobalt corroles has been used in the synthesis of the triphenylphosphinecobalt(III) complex of corrole itself (containing no β-alkyl substitutents). This complex (XLVIII) has been obtained[31] by cyclising in the presence of cobalt(II) acetate and triphenylphosphine the dihydrobromide of 1,19-dideoxybiladiene-*ac* (XLIX), which is formed when pyrrole (L) is condensed with 5,5'-diformylmethane-2,2'-dipyrrole (LI) [35,36] and which, like its 1,19-disubstituted analogue[36], decomposes when an attempt is made at isolation or cyclisation in the absence of triphenylphosphine[37]:



5. Synthesis of Iron Complex of Corrole

Besides the cobalt(III)—corrole complexes a paramagnetic crystalline complex of tervalent iron (LII) has been synthesised by treating with iron(III) chloride the corrole anion (LIII) obtained from 8,12-diethyl-2,3,7,13,17,18-hexamethylcorrole (XXXVI):[31]



6. Synthesis of Rhodium and Molybdenum Complexes of Corroles

Rhodium[38,39] and molybdenum[40] complexes of corroles have been obtained quite recently. Reaction between the corroles (XXXVI) and di-μ-chlorobisdicarbonylrhodium $Rh_2(CO)_4Cl_2$ leads to formation of a monorhodium complex

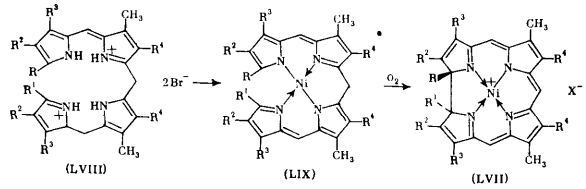
as in the case of thiaphlorins, whereas dirhodium complexes are formed with porphyrins and azaporphyrins. The type of rhodium complex depends on the number of imino-hydrogen atoms present in the central portion of the tetrapyrrole macroring[38]. Each coordinated dicarbonylrhodium unit requires the presence of one imino-group and one nitrogen atom devoid of a hydrogen atom. Since corroles on alkylation form di-*N*-alkyl derivatives at the adjacent nitrogen atoms 21 and 22,[12] the structure (LIV) has been suggested for the monorhodium—corrole complex. The latter breaks down on crystallisation, and is less stable than the bisdicarbonylrhodium complex of porphyrin.

The discovery of superconducting materials[41] was followed by attempts to obtain conductors comprising planar metal complexes located one above the other and containing a metal—metal bond. These led to synthesis of the molybdenum—corrole complex (LV) [40] by the action of the corrole (LVI) either on molybdenum pentachloride or on hexacarbonylmolybdenum in decalin in an atmosphere of nitrogen:

However, the resulting oxomolybdenum(V) 7,8,12,13-tetraethyl-2,3,17,18-tetramethylcorrole (LV) proved to be a monomeric five-coordinated oxomolybdenum complex having an axial oxygen atom.

IV. SYNTHESIS OF METAL COMPLEXES OF 1,19-DISUBSTITUTED OCTADEHYDROCORRINS

1. Structure and Properties of Metal Complexes of 1,19-Disubstituted Octadehydrocorrins



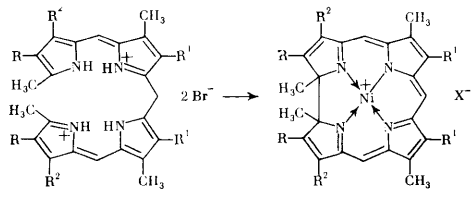
The metal complexes of 1,19-disubstituted octadehydrocorrins are macrocyclic tetrapyrrole compounds in which two pyrrole rings form a direct bond between the αα-carbon atoms at positions 1 and 19. They contain 1,19-angular substituents having a *trans* configuration. This series of compounds became known only in 1964.[26]

1,19-Disubstituted octadehydrocorrins form crystals of violet or dark cherry colour. Their electronic absorption spectra contain three principal bands in the ranges 280—300, 350—365, and 500—580 nm, and are devoid of the Soret band (at ~400 nm) characteristic of aromatic macrocycles such as corroles and porphyrins. The metal atom cannot be removed from an octadehydrocorrin complex without destruction of the organic macroring.

2. Synthesis of Nickel Complexes of 1,19-Disubstituted Octadehydrocorrins from Biladienes-*ac*

The traditional method for obtaining nickel complexes of 1,19-disubstituted octadehydrocorrins (LVII) is base-catalysed oxidative cyclisation of the 1,19-disubstituted 1,19-

dideoxybiladienes-*ac* (LVIII) [42] in alcoholic solution in the presence of excess of nickel acetate[33,43]:

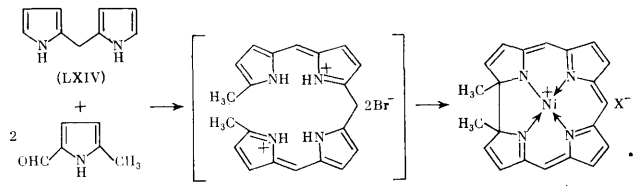


(LVIII) (LIX) (LVII)

(a) R=R¹=R²=R³=CH₃, R⁴=C₂H₅, X=NO₃, Cl;
(b) R=R¹=R³=R⁴=CH₃, X=ClO₄;
(c) R=R¹=R³=R⁴=CH₃, R²=OCH₂C₆H₅, X=Br;
(d) R=R¹=R³=R⁴=CH₃, R²=COOC₂H₅, X=ClO₄.
(e) R=R¹=R³=R⁴=CH₃, R²=CN, X=ClO₄;
(f) R=R¹=COOC₂H₅, R²=R³=CH₃, R⁴=C₂H₅;
(g) R=R¹=OCH₃, R²=R³=R⁴=CH₃;
(h) R=COOC₂H₅, R¹=R²=R³=CH₃, R⁴=C₂H₅;
(i) R=R¹=R³=R⁴=CH₃, R²=CH₂COOH, X=ClO₄;
(j) R=R¹=R²=R³=CH₃, R⁴=CH₂CH₂COOH, X=ClO₄;
(k) R=R¹=R³=CH₃, R²=CH₂COOH, R⁴=CH₂CH₂COOH, X=ClO₄.

Thus boiling 8,12-diethyl-1–3,7,13,17–19-octamethylbiladiene-*ac* (LVIIIa) with nickel and sodium acetates in methanol for a short time (30 s) gives the nickel–biladiene complex (LIXa), which on further aeration followed by treatment with nitrate ions is converted into the nitrate of the crystalline nickel–octadehydrocorrin complex (LVIIa), and into the corresponding crystalline chloride (LVIIa) when chloride ions are used. The decasubstituted octadehydrocorrin–nickel compex has been obtained as the perchlorate (LVIIb).[44,45] Similarly, cyclisation of the biladiene-*ac* (LVIIIc) gives the nickel complex (LVIIc) with benzyloxy-groups at positions 3 and 17,[46] and a nickel complex (LVIId) with ethoxycarbonyl substituents at positions 2 and 18 has been obtained from the biladiene (LVIIId).[47] A nickel complex of 2,18-dicyano-octadehydrocorrin (LVIIe) could not be synthesised in the usual way[47]: it has been obtained by aerating a chloroform solution of the biladiene (LVIIIe) containing hydrobromic acid, since in alcoholic solution or on addition of sodium acetate this biladiene is converted into a bilatriene, which under these conditions cannot be cyclised to the octadehydrocorrin.

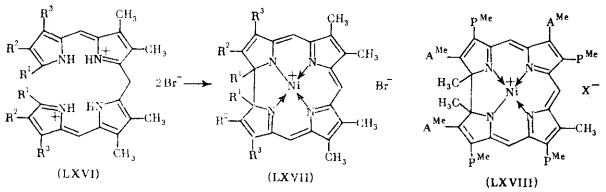
The oxidative cyclisation of biladienes enables us to obtain metal complexes of octadehydrocorrins containing angular ethoxycarbonyl (LVIIf) [33] and methoxyl (LVIIg) [48] substituents. The 1,19-diethoxycarbonyl derivative (LVIIf) could be obtained in higher yield (85%) than the compounds (LVIIa, b). Nickel complexes of octadehydrocorrins having two different angular substituents have also been synthesised by oxidative cyclisation, e.g. the nickel complex (LVIIh) from 1,19-dideoxy-1-ethoxycarbonyl-19-methylbiladiene-*ac* (LVIIIh).[33]



Oxidative cyclisation of biladienes[43,49] has been used also to obtain nickel complexes of 1,19-disubstituted oxydehydrocorrins having partly vacant β-positions[43,50,51]. Nickel complexes with unsubstituted positions 2 and 18 (LXa,b),[43,51,52] 8 and 12 (LXc),[50] and also 2, 3, 17, and 18 (LXd) [43] are obtained in the usual way[33] from the corresponding biladienes-*ac* (LXIa–d):[42]

(LXI) (LX)

(a) R=H, R¹=C₂H₅, R³=CH₃, X=ClO₄;
(b) R=H, R¹=R²=CH₃, X=ClO₄;
(c) R=R²=CH₃, R¹=H, X=ClO₄;
(d) R=R²=H, R¹=CH₃.

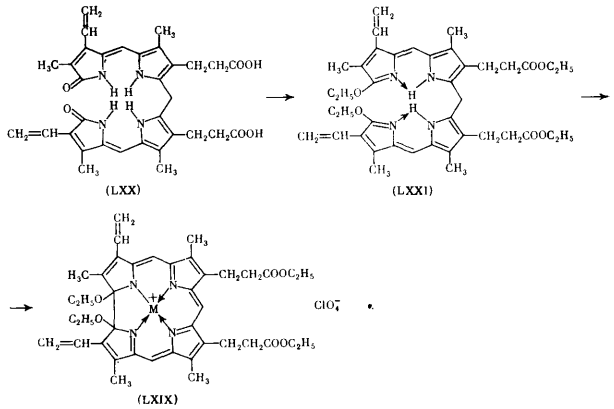


However, several difficulties were encountered in synthesis of the nickel complex (LXII) of octadehydro-1,19-dimethylcorrin with completely unsubstituted β-positions[36,53]. The initial 1,19-dideoxy-1,19-dimethylbiladiene-*ac* (LXIII), formed by the condensation of 2,2′-dipyrrolylmethane (LXIV)[35] with excess of 2-formyl-5-methylpyrrole (LXV) in chloroform solution in the presence of hydrogen bromide, was subjected to cyclisation without being isolated, owing to its extreme instability:

(LXIV) (LXV) (LXIII) (LXII)

The reaction was conducted in methanol in the presence of nickel and sodium acetates at room temperature for 3 h, and gave 2–22% yields of the nickel–octadehydrocorrin complex (LXII). If DMF is used as solvent, cyclisation goes more smoothly for 15 min even without the addition of sodium acetate, and the yield rises to 26%.[36,53]

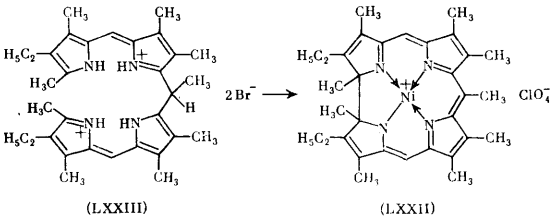
The interest in the synthesis of octadehydrocorrins containing residues of acetic and propionic acids as β-substituents arises understandably from the presence of such substituents in naturally occurring corrin and porphyrin macrocycles. As early as 1969 perchlorates were obtained of several nickel complexes of octadehydrocorrins containing propionic ester groups in various positions in the pyrrole rings[54]. It then proved possible by the cyclisation of biladienes-*ac* (LXVI) to prepare nickel complexes of octadehydrocorrins (LXVII) [55] containing acetic and propionic ester groups at positions 2, 3, 17, and 18 in rings A and D:



(LXVI) (LXVII) (LXVIII)

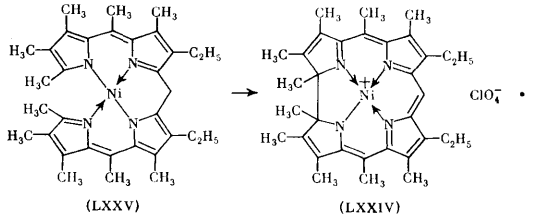
R¹=CH₃, COOC₂H₅, COOCH₂C₆H₅; R² и R³=CH₃, CH₂COOCH₃, CH₂COOC₂H₅, CH₂CH₂COOCH₃, CH₂CH₂COOC₂H₅
A^Me=CH₂COOCH₃, P^Me=CH₂CH₂COOCH₃.

Finally, a nickel–octadehydrocorrin complex (LXVIII) containing propionic and acetic ester groups at all β-positions in the macroring was obtained[56] in 1975. Cyclisation of the corresponding biladiene was accomplished in the presence of nickel acetate. It is noteworthy that this biladiene is an intermediate compound in the synthesis of porphyrins[54] and corroles[10]. Other nickel–octadehydrocorrin complexes contain acetic ester residues at positions 2 and 18 (LVIIi) [50] and propionic ester groups at positions 8 and 12 (LVIIj) [47] have also been obtained; in the complex (LVIIk) all four positions are occupied by ester substituents[47].



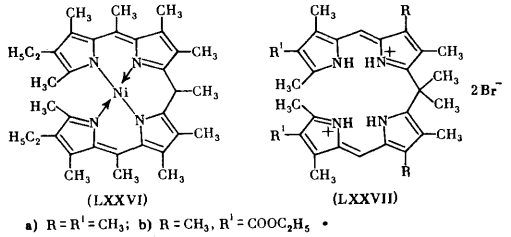
A nickel–octadehydrocorrin complex has been prepared also from the natural yellow pigment bilirubin (LXX),[57] which on treatment with triethyloxonium tetrafluoroborate in di-isopropylethylamine and dichloromethane was converted into the biladiene-*ac* (LXXI),[58] cyclisation of which in the presence of

nickel acetate and sodium perchlorate with heating in air led to formation of the complex (LXIX: M = Ni):[57]



(LXX) (LXXI) (LXIX)

An interesting extension of the cyclisation of 1,19-disubstituted biladienes-*ac* is its application to biladienes containing *meso*-methyl groups. The nickel complex of octadehydro-2,18-diethyl-1,3,7,8,10,12,13,17,19-nonamethylcorrin (LXXII) was obtained by cyclising the corresponding 10-methylbiladiene (LXXIII):[33]

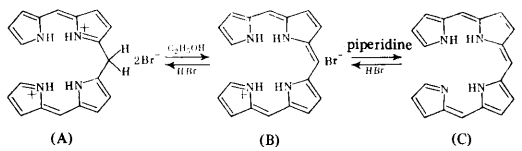


(LXXIII) (LXXII)

The nickel–octadehydrocorrin complex (LXXIV) containing methyl groups at the *meso*-positions 5 and 15 was obtained by aerating the 1,19-dideoxybiladiene-*ac* complex (LXXV):[33]

(LXXV) (LXXIV)

The nickel complex (LXXVI) of completely *meso*-substituted biladiene-*ac*,[33] like the 10,10-dimethylbiladiene (LXXVII),[18] could not be converted into the octadehydrocorrin complex.

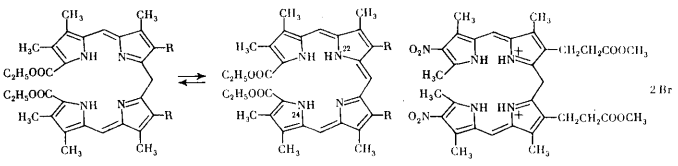


(LXXVI) (LXXVII)

a) R = R' = CH_3; b) R = CH_3, R' = $COOC_2H_5$.

An important condition for the cyclisation of biladienes-*ac* into octadehydrocorrins is the formation of metal complexes of 1,19-dideoxybiladienes (LIX). The first stage in the cyclisation[33] of the biladiene-*ac* dihydrobromide (LVIII) into the 1,19-disubstituted octadehydrocorrin consists in formation of the nickel–biladiene complex (LIX), which was isolated under controlled conditions, and in the presence of sodium acetate and air converted into the cyclic nickel–octadehydrocorrin complex (LVII).

In the absence of a metal it has proved impossible to achieve the cyclisation of biladienes into octadehydrocorrins [16,33], in contrast to the formation of corroles[10,16]. The initiating reaction is probably detachment of a proton from the central methylene group in the metal–biladiene complex (LIX). Involvement of the methylene group of 1,19-dideoxybiladienes is indicated by the absence of cyclisation when the two 10-hydrogen atoms have been replaced by two methyl groups[18], whereas the 10-methyl derivative (LXXIII) cyclises only slightly more slowly than does the unsubstituted compound. Yet the rate of cyclisation of the 5,15-dimethyl derivative (LXXV) is of the same order as that of the *meso*-unsubstituted compound.

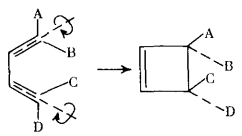


Data on the acidic properties of protons attached to carbon atom 10 in 1,19-dideoxybiladienes-*ac* have been obtained from a study of the visible absorption spectra[16]. Biladiene dihydrobromides (A) form red solutions in chloroform, benzene, and dichloromethane, but yellow solutions in methanol, ethanol, and dimethyl sulphoxide (DMSO); the solutions become green on addition of an organic base, e.g. piperidine. These colour changes are consistent with abstraction of a proton by polar solvents with formation of 1,19-dideoxybilatriene-*abc* monohydrobromides (B), which are converted by excess of piperidine into the corresponding free bilatriene bases (C):[6,19]

(A) (B) (C)

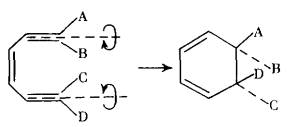
The monohydrobromides (B) are characterised by intense absorption at 420–450 and 750–800 nm, whereas the corresponding bases (C) have absorption bands at 400 and 650 to 750 nm. If a biladiene contains a 10-methyl group, its ethanolic solution does not absorb in the range 650–750 nm when piperidine is present, but the spectrum of a 10,10-dimethylbiladiene in fact remains unchanged with variation in the type of solvent[16].

Detachment of a 10-proton is faciliated by the presence of electron-accepting substituents in the biladiene-*ac*.[16,47,59–61] Yet biladienes containing alkyl, hydrogen, or iodine at positions 1 and 19 exist only as salts like the dihydrobromide (A),[59] and 1,19-diethoxycarbonylbiladienes are equilibrium mixtures of a biladiene salt of type (A) and bilatrienes of types (B) and (C).[59] For example, biladiene-*ac* (LXXVIIIa) is present in chloroform solution partly as a bilatriene salt of type (B),[16] but (LXXVIIIb) exists in dichloromethane solution partly as the tautomeric 22,24-dihydrobilatriene (LXXIX):[60]



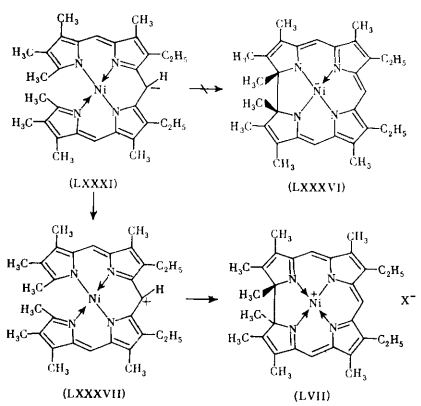
(LXXVIII) (LXXIX) (LXXX)

a) R = C_2H_5; b) R = CH_3.



Dinitrobiladiene (LXXX) [61] is present in chloroform solution as a mixture of a neutral bilatriene of type (C) and a monocation of type (B), but the 2,18-dicyanobiladiene dihydrobromide (LVIIIe),[47] when dissolved in chloroform, passes into a 2,18-dicyanobilatriene hydrobromide of type (B), which is converted in methanol into the free 2,18-dicyanobilatriene base of type (C).

The action of a base on the intermediate nickel–biladiene complex (LIX) yields the anion (LXXXI), which is a 22-π-electron system (or an 18-π-electron system if the two cross-conjugated double bonds are neglected). Two further stages—electrocyclic formation of a direct 1,19-bond and an oxidation stage—are required to convert this anion into the nickel complex of octadehydro-1,19-dimethylcorrin (LVII). The sequence of these stages has been established from a determination of the stereochemistry of (LVII), which has a *trans*-configuration of the angular 1- and 19-alkyl substituents[5,62]. In electrocyclic processes[63] conjugated acyclic 4*n*-π-electron systems undergo cyclisation in a conrotatory manner, e.g.



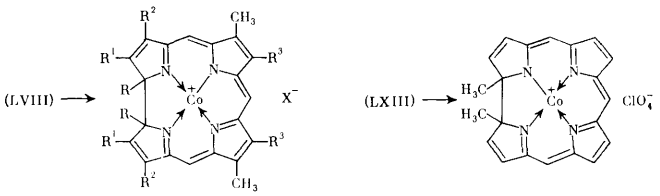
(LXXXII) (LXXXIII)

whereas (4*n* + 2)-π-electron systems cyclise in a disrotatory manner, e.g.

LXXXIV) (LXXXV)

The cyclisation of (LXXXI), which is of the second type, should also involve rotation of terminal groups in opposite sense with formation of the *cis*-isomer (LXXXV), which on oxidation may be converted into the *cis*-octadehydrocorrin–nickel complex. Since, however, the 1,19-disubstituted octadehydrocorrin (LVII) exists in the *trans*-form, the anion (LXXXI) probably undergoes initial two-electron oxidation to the cation (LXXXVII), which is a 4*n*-π-electron system, and on cyclisation is converted into the *trans*-compound (LVII):[8]

(LXXXI) (LXXXVI)



(LXXXVII) (LVII)

The action of several one-electron oxidants in DMSO was examined[54] in the search for milder methods of cyclising 1,19-disubstituted biladiene salts into octadehydrocorrin macrorings containing labile side-chains. Cyclisation of the nickel–biladiene-*ac* complex (LXXV) in the presence of ammonium cerium nitrate in DMSO yields the nickel–octadehydro-1,19-dimethylcorrin complex (LXXIV), which was isolated as the perchlorate in 39% yield.

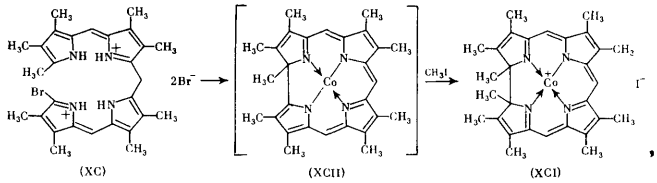
Cyclisation of 1,19-dideoxybiladienes-*ac* into octadehydrocorrins in the presence of one-electron oxidants apparently occurs also by a free-radical mechanism with intermediate formation of bilatrienes-*abc*.

3. Synthesis of Cobalt and Palladium Complexes of 1,19-Disubstituted Octadehydrocorrins from Biladienes-*ac*

Cyclisation of the 1,19-disubstituted biladiene-*ac* (LVIIIa) is far more rapid in the presence of cobalt acetate than of nickel acetate. Aeration of a methanolic solution at room temperature gives the perchlorate (LXXXVIIIa) of the cobalt–octadehydrocorrin complex in 71% yield[33]:

(LVIII) (LXXXVIII) (LXIII) (LXXXIX)

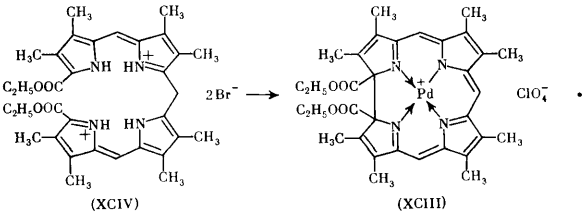
LXXXVIII: a) R=R¹=R²=CH₃, R³=C₂H₅, X=ClO₄; b) R=R¹=R²=R³=CH₃, X=ClO₄;
c) R=COOC₂H₅, R¹=R²=CH₃, R³=C₂H₅, X=ClO₄;
d) R=R¹=R³=CH₃, R²=OCH₂C₆H₅, X=Br;
e) R=R¹=R³=CH₃, R²=(CH₂)₂COOH, X=ClO₄;
f) R=R²=CH₃, R¹=CH₂COOH, R³=(CH₂)₂COOH, X=ClO₄.



The decamethylated complex (LXXXVIIIb) has also been obtained as the perchlorate[44,45]. The 1,19-diethoxycarbonylbiladiene (LVIIIf) cyclises more rapidly in the presence of cobalt acetate than does the 1,19-dimethyl derivative (LVIIIa), and forms the complex (LXXXVIIIc) in 80% yield[33].

A cobalt–biladiene complex analogous to the nickel complex (LIX) could not be isolated[33]. Aeration of a suspension of the biladiene (LVIIIa) in methanol in the presence of cobalt acetate caused immediate separation of a small quantity of a green crystalline compound (XXXVb) containing two tetrahedral cobalt atoms and two quadridentate 1,19-dideoxybiladiene ligands[25,33]. Cyclisation of the biladiene-*ac* (LVIIIc) yields the cobalt–octadehydrocorrin bromide (LXXXVIIId) having benzyloxy-groups at positions 3 and 17.[46]

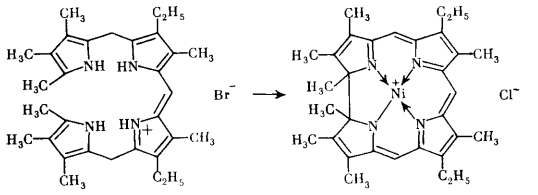
The cobalt–octadehydrocorrin complex (LXXXIX) with completely unsubstituted β-positions[36,53] was obtained from the biladiene-*ac* (LXIII) in 26% yield by the use of cobalt acetate in DMSO.[53] Cobalt complexes containing residues of acetic and propionic acids at β-positions are, like the nickel complexes, difficultly accessible because of the lability of the side-chains. However, octadehydrocorrins have been prepared containing residues of propionic esters in all the pyrrole rings[54] and residues of acetic and propionic esters at positions 2, 18 and 3, 17,[55] as well as those containing both acetic and propionic ester groups in all the pyrrole rings[56]. The cobalt complex (LXXXVIIIe) with propionic groups at positions 8 and 12, and (LXXXVIIIf) with acetic and propionic acid residues together at positions 2, 8, 12, and 18, are formed in lower yields than are the corresponding nickel complexes[47]. The cobalt complex (LXIX: M = Co) is obtained[57] similarly to the nickel complex (LXIX: M = Ni) from bilirubin (LXX).



When 1-bromo-19-methylbiladiene-*ac* (XC) undergoes cyclisation in the presence of cobalt acetate in a degassed solvent, addition of iodomethane in the absence of oxygen leads to isolation of a crystalline iodide of the cobalt–octadehydro-1,19-dimethylcorrin complex (XCI), apparently an

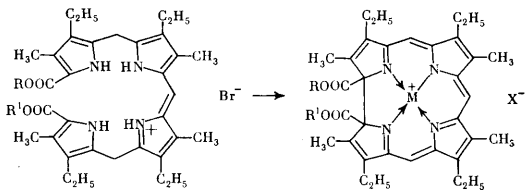
alkylation product of the intermediate cobalt–octadehydro-1-methylcorrin complex (XCII):[64]

(XC) (XCII) (XCI)



The palladium–octadehydrocorrin complex (XCIII) containing angular 1,19-ethoxycarbonyl substituents has been obtained by aeration of an alcoholic solution of the biladiene-*ac* (XCIV) (yield 35%):[65]

(XCIV) (XCIII)

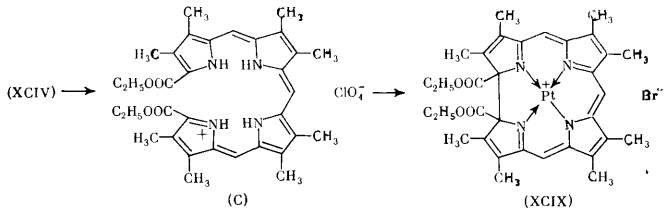


4. Synthesis of Nickel and Cobalt Complexes of 1,19-Disubstituted Octadehydrocorrrins from Bilenes-*b*

Johnson's oxidative cyclisation[33] can be applied not only to 1,19-dideoxybiladienes-*ac* but also to bilenes-*b* (XCV) to give metal complexes of octadehydrocorrins[43,66]. The cyclisation of 1,19-dimethylbilenes-*b* to nickel complexes of octadehydro-1,19-dimethylcorrins is accomplished under the same conditions as that of the corresponding salts of 1,19-dideoxy-1,19-dimethylbiladienes-*ac*.[43,66] For example, aeration of the bilene-*b* (XCV) in the presence of nickel and sodium acetates in boiling methanol followed by treatment with dilute hydrochloric acid gives the nickel–octadehydro-1,19-dimethylcorrin chloride (XCVI):[43]

(XCV) (XCVI)

Nickel and cobalt complexes of octadehydrocorrins with various substituents at positions 1 and 19 (XCVIII) have been obtained[66] from bilenes-*b* (XCVII):



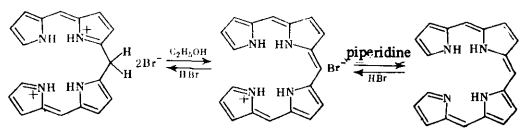
(XCVII) (XCVIII)

a) R = R' = C_2H_5; b) R = R' = $CH_2C_6H_5$; c) R = C_2H_5, R' = $CH_2C_6H_5$.

Far more severe conditions (DMF as solvent aerated at 70 °C for 4 h) are required[66] to obtain the cobalt–octadehydrocorrin complex (XCVIIIa: X = ClO_4) from bilene-*b* than to obtain a similar compound from the biladiene-*ac*.[33]

5. Synthesis of Platinum, Nickel, Cobalt, and Palladium Complexes of 1,19-Disubstituted Octadehydrocorrins from Bilatrienes-*abc*

Until 1977 octadehydrocorrins had been obtained only in the form of nickel[33,43], cobalt[33,67], and palladium complexes. Discovery of the antitumour activity of platinum complexes coordinated with nitrogen[68] led to the synthesis[69] of a platinum–octadehydrocorrin complex (XCIX), which was obtained only in insignificant quantities[69] by oxidative cyclisation[33,43] from the biladiene-*ac* dihydrobromide (XCIV). This complex was prepared in higher yields (15%) from the 1,19-dideoxybilatriene-*abc* hydroperchlorate (C),[16] which is formed when a methanolic solution of the biladiene-*ac* (XCIV) is heated with zinc perchlorate[69]. Boiling a suspension of platinum chloride, sodium acetate, and the bilatriene (C) in acetonitrile yields the platinum–octadehydrocorrin complex (XCIX):



(XCIV) (C) (XCIX)

The synthesis of metal complexes of 1,19-diethoxycarbonyl derivatives of octadehydrocorrin from the bilatriene salt (C) gives better yields[69] of nickel, cobalt, and palladium complexes analogous to (XCIX) than those obtained from the biladiene-*ac* (XCIV). This applies especially to the palladium complex (yield 66%), previously obtained from the biladiene in 35% yield[65].

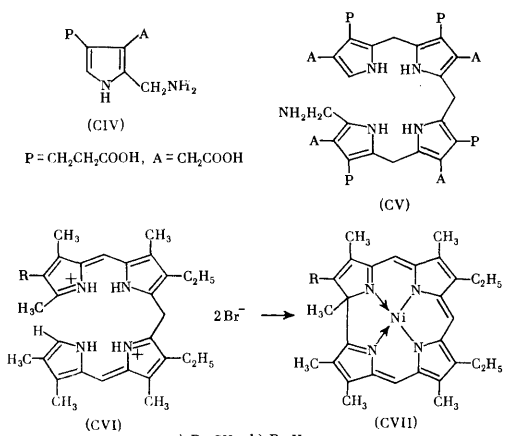
6. Nickel and Cobalt Complexes of 1,19-Disubstituted Octadehydrocorrins by Metal Exchange

A novel approach to the preparation of cobalt complexes of octadehydrocorrins, by the replacement of nickel using reductive fission of the macroring, was suggested[60] in 1974. When a metal–octadehydrocorrin complex, e.g. (CI: M = Ni), is treated with a reducing agent (hydrogen sulphide, sodium dithionite), it adds two electrons and passes into a negatively charged complex B, which after rupture of the $C_{(1)}$–$C_{(19)}$ bond is converted into the metal complex of 22,24-dihydrobilatriene (CII: M = Ni); protonation of the latter at $C_{(10)}$ converted it into the neutral biladiene complex (CIII):

(A) (B) (C)

At this stage nickel is easily replaced by cobalt. Thus the nickel complex (CIII) is readily demetallised by the action of such acids as trifluoroacetic and hydrochloric, and the resulting biladiene (LXXVIIIb) can be recyclised in the presence of atmospheric oxygen and nickel or cobalt acetate to form the corresponding metal complex, e.g. (CI).[60]

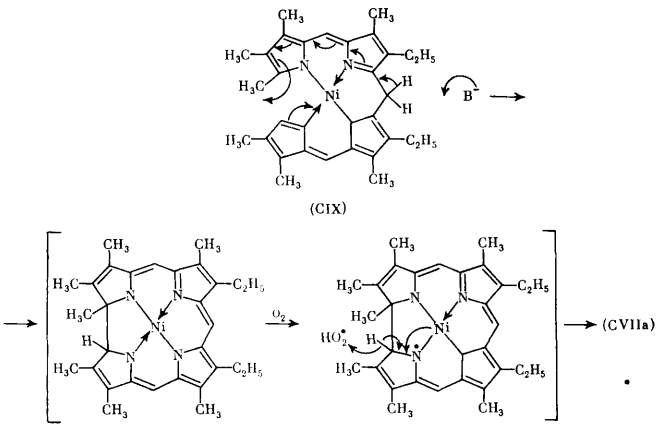
Cobalt complexes occupy a special position, since they undergo ring cleavage even under very mild conditions (hydrogen sulphide at room temperature)[60].



V. SYNTHESIS OF NICKEL COMPLEXES OF 1-SUBSTITUTED OCTADEHYDROCORRINS

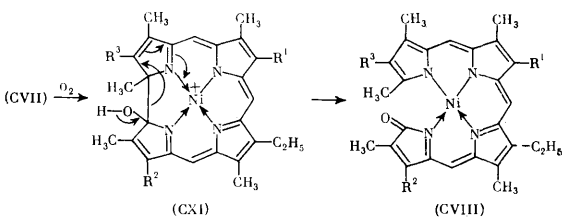
1-Alkyloctadehydrocorrins are neutral complexes of bivalent nickel. The tetrapyrrole macroring contains only one angular substituent. Only nickel complexes of 1-alkyloctadehydrocorrins are known.

1. Synthesis of Nickel Complexes of 1-Substituted Octadehydrocorrins by the Oxidative Cyclisation of Biladienes-*ac*



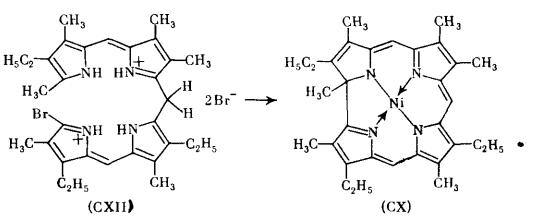
Nickel complexes of octadehydro-1-methylcorrin are formed[7] by the cyclisation of 1-methylbiladienes-*ac*[76] when alkaline solutions are aerated in the presence of nickel ions.

The biosynthesis of the corrin chromophore of vitamin B_{12} involves porphobilinogen (CIV), which is probably converted into a bilane derivative of the type (CV).[70–73] The cyclisation of 1,19-dideoxybiladienes containing an unsubstituted α-position (CVI) was examined[72] to ascertain whether a similarity exists in the mechanisms of the cyclisation of the bilane (CV) and biladienes-*ac*. Such cyclisation was effected[43,70] by heating the biladienes (CVIa,b) in methanol containing nickel acetate and piperidine, which in the presence of oxygen gave the octadehydro-1-methylcorrin–nickel complexes (CVIIa,b) in the respective yields 56% and 59%:



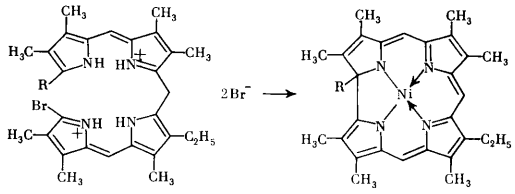
a) R = CH_3, b) R = H

Although cyclisation of α-unsubstituted biladienes (CVI) is caused by aeration with oxygen[43], conversion of (CVIa) into the complex (CVIIa) requires partial degasification of the methanolic solution of biladiene and nickel acetate containing piperidine (in contrast to the cylisation of metal complexes of 1,19-disubstituted octadehydrocorrins, which occurs in the presence of excess of atmospheric oxygen), but in such a way that the quantity of oxygen remaining is sufficient for cyclisation and insufficient to oxidise (CVIIa) to the lactam (CVIII).[32] Formation of octadehydro-1-methylcorrin apparently involves free-radical intermediate compounds resulting from the action of oxygen on a carbanion obtained by detachment of a proton from the metal–biladiene complex (CIX) under the influence of a base[43]:



The mechanism of oxidation of the nickel complex (CVII) and (CX) to the lactam (CVIII) has not been established, although intermediate formation of octadehydro-1-hydroxy-19-methylcorrin (CXI) has been postulated[32,43]:

a) $R^1 = C_2H_5$, $R^2 = R^3 = CH_3$; b) $R^1 = CH_3$, $R^2 = R^3 = C_2H_5$.



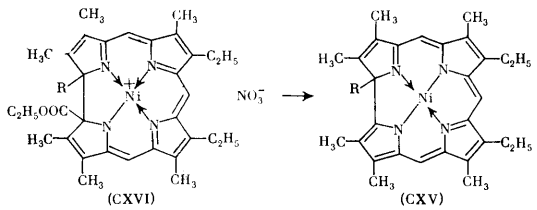
2. Synthesis of Nickel Complexes of 1-Substituted Octadehydrocorrins from Biladienes-*ac* by Non-oxidative Cyclisation

Nickel complexes of octadehydro-1-methylcorrins (CX) are formed by the cyclisation of dihydrobromides not only of 1-substituted biladienes-*ac* but also of 1-bromo-19-methylbiladienes-*ac* (CXII) in the presence of nickel ions and a base[5,32,33,74]:

This probably takes place in the absence of oxygen[32], which distinguishes it significantly from the cyclisation of dihydrobromides of 1,19-dimethyl- and 1-methyl-biladienes-*ac*, requiring an oxidation stage. When the reaction was conducted in the presence of oxygen, the lactam (CVIIIb) was isolated[32]. The cyclisation of (CXII) was extended to the

dihydrobromides of 1-bromo-19-ethyl(and isopropyl)biladienes-*ac* (CXIIIa,b), which gave the corresponding nickel octadehydro-1-alkylcorrins (CXIVa,b) in high yields[32]:

(CXIII) a) R = C_2H_5, b) R = $(CH_3)_2CH$ (CXIV)



Nickel complexes of 1-alkyloctadehydrocorrins have been synthesised from 1-alkylbiladienes-*ac* containing various 19-substituents, e.g. alkoxy[75] and iodo[21], which are removed during the reaction, but the use of such initial compounds is less convenient than that of 19-bromobiladienes-*ac*.

Attempts to obtain cobalt complexes of octadehydro-1-methylcorrins by cyclisation of the corresponding biladienes in the presence of cobalt acetate in various solvents proved unsuccessful[32,64]. Such behaviour contrasts sharply with the ease of formation of cobalt complexes of 1,19-disubstituted octadehydrocorrins[33].

The attempted cyclisation of 1-bromo-19-methylbiladiene to the corresponding octadehydro-1-methylcorrin in the presence of copper acetate proved unsuccessful[32]. The reaction gives a low yield (8–25%) of a copper–porphyrin complex[42].

3. Synthesis of Nickel Complexes of 1-Substituted Octadehydrocorrins from 1,19-Disubstituted Octadehydrocorrins

Nickel complexes of 1-substituted octadehydrocorrins (CXVa,b) have been obtained from those of 1,19-disubstituted octadehydrocorrins (CXVIa,b) containing a 19-ethoxycarbonyl group[27,32]:

(CXVI) a) R = CH_3, b) R = $COOC_2H_5$ (CXV)

Hydrolysis and decarboxylation of the ethoxycarbonyl group in (CXVIa) gave a nickel complex of octadehydro-1-methylcorrin (CXVa) [32] identical with the compound obtained from the corresponding 19-bromo-1-methylbiladiene-*ac*. Rapid treatment of the octadehydro-1,19-diethoxycarbonylcorrin (CXVIb) [33] with aqueous caustic soda and rapid separation gives a good yield of the nickel complex of octadehydro-1-ethoxycarbonylcorrin (CXVb).[27]

---o0o---

Thus a great deal of experimental information has accumulated during the past decade on the synthesis of metal complexes of octadehydrocorrins and corroles. This opens up the possibility of a broad study of these interesting and complicated compounds, akin to porphyrins and corrins, and possessing biological activity.

Chemistry of α-Halogenonitroalkanes

A.L.Fridman (deceased), V.D.Surkov, and S.S.Novikov (deceased)

Methods of preparation of α-halogenonitroalkanes and their functional derivatives are surveyed, together with the chief results obtained for the geometric parameters, electronic structure, and ultraviolet, infrared, and nuclear magnetic and quadrupole resonance spectroscopy, as well as acid - base properties. Reactions involving reduction, addition at multiple bonds, substitution of halogen atoms and the nitro-group, and interaction with diazoalkanes are analysed, and the most important mechanisms are discussed. Data are given on the toxicity, physiological activity, and practical use of these compounds. A list of 316 references is included.

I. INTRODUCTION

The chemistry of aliphatic nitro-compounds is now a well studied field. Aspects of the preparation, structure, and chemical behaviour of nitroalkanes and their many derivatives have been quite widely discussed in several reviews[1-10] and in a monograph[11]. However, α-halogenonitro-compounds either are not discussed at all in these publications[1-3,9] or are only partly covered[4-8,10,11]. Yet their unique properties merit a separate review. This unusual class of substances has long attracted the attention of chemists and other specialists, as is indicated by the large number of original peprs in this field. The possibility of the direct use of α-halogenonitro-compounds as agricultural chemicals, and also as intermediates in the production of novel biologically active compounds, explosives, and rocket fuel components, still maintains this interest even at the present time.

α-Halogenonitroalkanes are undoubtedly also of theoretical interest. The combination of a nitro-group and a halogen attached to the same carbon atom confers on the halogen special properties differing markedly from those in ordinary halogenated aliphatic compounds. This difference is especially characteristic of α-halogenopolynitroalkanes, which exhibit the properties of compounds having a "positively" polarised halogen atom[12]. The reactions of α-halogenonitroalkanes involve either homolytic or heterolytic fission of the carbon–halogen bond depending on the nature of the halogen and the conditions: the heterolytic process may release the halogen as either a cation or an anion, so that a wide range of reactions can be accomplished. Furthermore, reactions involving the nitro-group or an α-hydrogen atom can also occur.

The present Review summarises the literature up to 1977 on methods of preparation, structure, and characteristic reactions. Since the bibliography on these compounds comprises more than 500 sources, we considered it advisable to give references to the most recent work, from which the early primary sources can usually be found. The concluding Section gives information available to us on the biological activity and practical utilisation of α-halogenonitroalkanes.

II. METHODS OF PREPARATION

1. Replacement by Halogen of an α-Hydrogen Atom in Nitroalkanes and their Derivatives

Halogenation of nitroalkanes and their functional derivatives is usually accomplished in the presence of a base, the most common method for obtaining α-halogenonitro-compounds[11]. The process is applied to a solution of the nitroalkane in aqueous alkali[13-15]; sometimes organic solvents are used[14,15].

The action of chlorine and bromine on primary mononitroalkanes may form mono- and di-halogenated derivatives, but nitromethane can also give trihalogenitromethanes, when each succeeding hydrogen atom is replaced more easily than the previous one:

$$CH_3NO_2 \xrightarrow{Br_2,NaOH} CH_2BrNO_2 \xrightarrow{Br_2,NaOH} CHBr_2NO_2 \xrightarrow{Br_2,NaOH} CBr_3NO_2 .$$

Kinetic studies have been made of the bromination of nitromethane and nitroethane[16,17]. The rate constants of the formation of mono-, di- and tri-halogenonitromethanes are in the proportions 1 : 200 : 10 000.[16] Simultaneous chlorination and bromination of salts of nitroalkanes gives bromochloronitroalkanes[18].

Hydrolysis[19] and interaction with nitroalkane salts[20-22] have been observed as side reactions accompanying the halogenation of nitroalkanes:

$$RCH{=}NOO^-Na^+ + RCH(NO_2)Cl \rightarrow RCH_2NO_2 + RC(Cl){=}NOO^-Na^+ ,$$

$$RC(Cl){=}NOO^-Na^+ \begin{cases} \xrightarrow{H_2O} RC(OH){=}NOO^-Na^+ + HCl \rightarrow RCHO + HNO_2 + NaCl \\ \xrightarrow{RCH(NO_2)Cl} RCH(NO_2)CCl(NO_2)R + NaCl . \end{cases}$$

Halogenation is conducted with equimolecular quantities of reactants at low temperatures in order to suppress side reactions[23].

Halogenated 1,1-dinitroalkanes and trinitromethane are readily formed from alkali-metal salts of the nitro-compounds[25-27]:

$$RC(NO_2)_2^-M^+ + X_2 \rightarrow RC(NO_2)_2X + MX ,$$

$R{=}NO_2$, Alk; M=Na, K, NH_4; X=Cl, Br .

However, dinitromethane in aqueous alkali gives only dihalogenodinitromethanes[28,29]:

$$CH(NO_2)_2^-K^+ + 2X_2 + KOH \rightarrow C(NO_2)_2X_2 + 2KX + H_2O \quad X=Cl, Br .$$

Dichloro- and dibromo-dinitromethanes are easily converted by alkali into the corresponding salts of the monohalogenodinitromethanes[29,30]:

$$C(NO_2)_2X_2 + 2KOH \rightarrow XC(NO_2)_2^-K^+ + KOX + H_2O .$$

In an attempt to obtain monohalogenated derivatives of dinitromethane by acidifying their salts the dihalogenodinitromethanes were isolated[30]:

$$2XC(NO_2)_2^-K^+ + H_2SO_4 \rightarrow C(NO_2)_2X_2 + K_2SO_4 + N_2O + CO_2 + H_2O \quad X=Cl, Br, I .$$

Bromodinitromethane was reported[28] to be formed when the potassium salt of dinitromethane was treated with excess of bromine in a neutral medium.

The halogenation of nitroalkanes takes place by an ionic mechanism. The rate-determining stage is isomerisation of the true nitro-compound into the *aci*-form[16,17]. α-Halogenated polynitroalkanes are formed by halogenation of the anions of the latter, which result directly from the nitroalkane without intermediate formation of the *aci*-form[31].

Among other halogenating agents used are interhalogen compounds[28,32], sodium hypochlorite and hypobromite[33], *N*-chloro-*N*-nitroamines, *N*-bromo- and *N*-chloro-succinimide, and sodium *N*-chlorobenzenesulphonamide[34]. In several cases the selectivity is enhanced and the yield of required products increased[34]. Salts of nitro-compounds are smoothly chlorinated by chlorine fluorosulphate[35]:

$$RC(NO_2)_2^-M^+ + ClOSO_2F \rightarrow RC(NO_2)_2Cl + MOSO_2F ,$$
$$R=NO_2, CN; \quad M=Na, K .$$

Fluorination of salts of nitro-compounds is effected with elementary fluorine in water[36]. Secondary mononitroalkanes are converted into satisfactory yields of α-fluoromononitroalkanes[37], whereas the primary compounds give low (5–14%) yields of fluoro-derivatives[36]. The latter are obtained by replacing an α-hydrogen atom in the mononitroalkane by an alkoxycarbonyl group, which after fluorination is removed by alkaline hydrolysis[11]:

$$\begin{matrix} RC{=}NOO^- \\ | \\ COOC_2H_5 \end{matrix} \xrightarrow{F_2,\,N_2} \begin{matrix} RCFNO_2 \\ | \\ COOC_2H_5 \end{matrix} \xrightarrow{C_2H_5O^-} RCF{=}NOO^- \xrightarrow{H^+} RCHFNO_2 .$$

Fluorination with elementary fluorine in water is used to obtain α-fluoropolynitroalkanes[26,36,38–40]. Solid-phase fluorination of nitroform and its salts with elementary fluorine is accompanied by fluorolysis, difluorodinitromethane being formed with fluoronitroform[41].

α-Fluoromononitroalkanes have been prepared by fluorinating salts of the mononitroalkanes with elementary fluorine in methanol at −30 to −60 °C,[42] with yields of 58–73%. Another method for obtaining α-fluoronitroalkanes consists in the action of perchloryl fluoride on the sodium salts of secondary nitroalkanes and nitrocycloalkanes[43]:

$$RR'C{=}NOO^-Na^+ + FClO_3 \rightarrow RR'CFNO_2 + NaClO_3 .$$

Alkali-metal salts of 1,1-dinitroalkanes and trinitromethane are also readily converted by perchloryl fluoride into α-fluoropolynitroalkanes[44–47]:

$$RC(NO_2)_2^-M^+ + FClO_3 \rightarrow RC(NO_2)_2F + MClO_3 ,$$
$$R=NO_2, CH_3, C_6H_5, C_6H_5CH_2; \quad M=Na, K, NH_4 .$$

Undecafluoropiperidine fluorinates smoothly the sodium salt of 2-nitropropane in methanol[48].

Fluoro-chloro-, -bromo-, and -iodo-dinitromethanes are obtained by the halogenation of bisfluorodinitromethylmercury[49]:

$$Hg[C(NO_2)_2F]_2 + 2X_2 \rightarrow 2XC(NO_2)_2F + HgX_2 ,$$
$$X=Cl, Br, I .$$

In contrast to bromo-, chloro-, and fluoro-nitroalkanes, α-iodonitroalkanes have been inadequately studied, owing to the difficulty of preparing them and their instability. The action of iodine on alkali-metal salts of mononitroalkanes led to the isolation of dimeric products, formed by reaction between the nitroalkane anion and the iodonitroalkane[20–22]:

$$2C_6H_5CH{=}NOO^-Na^+ + I_2 \rightarrow C_6H_5CH(NO_2)CH(NO_2)C_6H_5 + 2NaI .$$

α-Iodopolynitroalkanes cannot be obtained in this way, because of occurrence of the reverse reaction[24]

$$RC(NO_2)_2I + KI \rightarrow RC(NO_2)_2^-K^+ + I_2 ,$$
$$R=NO_2, Hal, Alk .$$

They are formed by the action of iodine on silver salts of polynitroalkanes in organic solvents. Iodotrinitromethane has thus been prepared with ether as solvent[27,50]. Many α-iodonitro-derivatives have been obtained by iodinating anions of mono- and poly-nitroalkanes with iodine chloride[28,32,51].

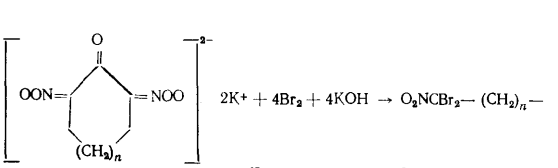
Replacement of an α-hydrogen atom in a nitro-compound by halogen in the presence of a base is a general method for obtaining functional α-halogenonitro-compounds. The reaction is selective and is not complicated by the presence of a group such as keto[52,53], amino[54], ester[55–57], nitrile[57,58], amide[59], sulphonyl[59,60], hydrazino[61] or an unsaturated bond[62].

Chlorination and fluorination of potassium salts of 2,2-dinitroethyl ethers of oximes readily yield halogeno-derivatives without affecting the C=N bond[63]:

$$RR'C{=}NOCH_2C(NO_2)_2^-K^+ \begin{cases} \xrightarrow{FClO_3} RR'C{=}NOCH_2C(NO_2)_2F , \\ \xrightarrow{Cl_2} RR'C{=}NOCH_2C(NO_2)_2Cl . \end{cases}$$

Treatment of nitroalcohols with caustic alkalis[64] or alkali-metal alkoxides[65] forms salts, whose halogenation in water or in an organic solvent yields halogenonitroalcohols:

$$RCH(OH)C(NO_2)_2^-K^+ + X_2 \rightarrow RCH(OH)C(NO_2)_2X + KX ,$$
$$(HOCH_2)_2C{=}NOO^-Na^+ + X_2 \rightarrow (HOCH_2)_2C(NO_2)X + NaX ,$$
$$X=F, Cl, Br .$$



Fluoro-, chloro-, and bromo-derivatives of nitroalcohols and nitrodiols have been obtained in this way[37,39,44,65–69]. Similarly, salts of nitroalkyl ethers[70], sulphides[71], and sulphones[60] are halogenated to the corresponding halogenonitro-derivatives:

$$H_3COCH_2C(NO_2)_2^-K^+ + Br_2 \rightarrow H_3COCH_2C(NO_2)_2Br + KBr ,$$
$$RSO_2C(NO_2)_2^-Na^+ + Cl_2 \rightarrow RSO_2C(NO_2)_2Cl + NaCl .$$

Bis-1-nitroalkyl disulphides are converted by halogens into 1-halogeno-1-nitroalkylsulphenyl halides[72,73]:

$$RCH(NO_2)S{-}SCH(NO_2)R \xrightarrow{Cl_2} RCCl(NO_2)SCl .$$

Cyclic αα′-dinitro-ketones react with bromine in an alkaline medium with cleavage of the ring and formation of tetrabromodinitroalkanes[74]:

$$2K^+ + 4Br_2 + 4KOH \rightarrow O_2NCBr_2{-}(CH_2)_n{-}$$
$$-CBr_2NO_2 + K_2CO_3 + 4KBr \quad n=2–5 .$$

2-Nitrodimedone, 2-nitroindanedione, and analogous compounds are readily brominated and chlorinated in aqueous solution without preliminary conversion into their salts[75]. 2-Iodo-2-nitrodimedone has been obtained in 92% yield by iodinating 2-nitrodimedone with an iodine monochloride–dioxan complex in acetic acid[76].

The halogenation of mononitroalkanes, which are weak carbon–hydrogen acids, is quite rapid in acid media[16,17]. The first stage is assumed[77–79] to involve an acid-catalysed prototropic change with formation of a nitronic acid, which, passing through a stage of formation of the ion of the nitro-compound, readily adds a halogen or a hypohalic acid to form the 1-halogenonitroalkane:

$$\rangle CHNO_2 + H^+ \rightleftarrows \rangle CHNO_2H^+ \rightleftarrows \rangle C{=}NOOH + H^+$$
$$\rangle C{=}NOOH \rightleftarrows \rangle C{=}NOO^- + H^+$$
$$\rangle C{=}NOO^- + X_2 \rightarrow \rangle CXNO_2 + X^- .$$

The rate of the acid-catalysed halogenation of nitroalkanes is independent of either the nature of the concentration of the halogen, and the reaction is first order with respect to the nitro-compound[77,78].

Hydrogen can be replaced by halogen without preliminary conversion into a salt also in polynitroalkanes, which are strong carbon–hydrogen acids. This reaction was first observed by Shishkov[80], in the action of bromine on trinitromethane in sunlight:

$$CH(NO_2)_3 + Br_2 \xrightarrow{h\nu} C(NO_2)_3Br + HBr .$$

Treating polynitroalkanes with perchloryl fluoride in a solvating aprotic solvent yields the corresponding fluoro-derivatives[45]:

$$RCH(NO_2)_2 + FClO_3 \rightarrow RC(NO_2)_2F + HClO_3 ,$$
$$R{=}NO_2, F, CH_3 .$$

Fluorotrinitromethane has been prepared by the action of elementary fluorine on trinitromethane in water and in various organic solvents[26,38].

Chloro- and bromo-nitroforms are readily produced when nitroform is treated with the corresponding halogens or hydrohalic acids in a mixture of sulphuric and nitric acids[81].

2. Halogenation of Conjugated Nitroalkenes

In chloroform, tetrachloromethane, or carbon disulphide conjugated nitroalkenes readily add chlorine and bromine to form the *vic*-dihalogenated derivatives[82–85]:

$$-C{=}CNO_2 + X_2 \rightarrow -\overset{|}{\underset{X}{C}}-\overset{|}{\underset{X}{C}}-NO_2 ,$$
$$X{=}Cl, Br .$$

Bromine can be replaced by its pyridine complex to obtain dibromo-derivatives[86]. The reaction has a heterolytic mechanism, and the rate of electrophilic addition of halogen is greatly diminished by electron-accepting substituents. For example, halogens cannot be added to *vic*-dinitroalkenes under normal conditions. To obtain dichloro-derivatives a mixture of the dinitroalkene and liquid chlorine is exposed to sunlight for a long time[87]. 1,2-Dinitroethylene adds bromine in the presence of hydrobromic acid in acetic acid[88].

Addition of bromine and chlorine to nitroalkenes is hindered also by the presence of a halogen at the double bond. Trichloro- and tribromo-nitroethylenes are brominated only at high temperatures, with formation of 1,2-dibromo-1,2,2-trichloronitroethane and pentabromonitroethane respectively. Arylated 1-bromo-1-nitroalkenes are not brominated at the double bond[82].

Addition of chlorine and bromine is more difficult to 1,4-dinitrobuta-1,3-diene than to nitroalkenes: 1,2,3,4-tetrahalogeno-derivatives are formed at 56–61 °C.[85,89–91] On recrystallisation the tetrabromide is converted into 1,4-dibromo-1,4-dinitrobuta-1,3-diene[85]. Under normal conditions 2,3-dimethyl-1,4-dinitrobuta-1,3-diene reacts very slowly with bromine, forming 1,4-dibromo-2,3-dimethyl-1,4-dinitrobuta-1,3-diene. This reaction is accelerated by addition of a catalytic quantity of hydrobromic acid[85].

Phenyl substituents in dinitrobutadienes create considerable hindrance to bromination. 1,4-Dinitro-2,3-diphenylbuta-1,3-diene reacts slowly with bromine, but the 1,4-diphenyl isomer under normal conditions does not add bromine at the double bond[82].

The halogenation of conjugated nitroalkenes enables polyhalogenated nitroalkanes to be obtained that are difficult to prepare by other methods.

3. Nitration of Halogenated Alkenes and Other Halogenated Compounds

The nitration of chloro- and bromo-alkenes with nitrogen dioxide yields a complicated mixture of products including α-halogenonitroalkanes[92–94]. Addition of nitrogen dioxide at the double bond depends in considerable measure on the nature of the halogenoalkane and the reaction conditions; dinitro-derivatives and alkyl nitrites may be formed. Furthermore, the process is complicated by substitution of a nitro-group for halogen and by formation of nitrosyl halides, which add to the halogenoalkenes to give nitroso-compounds[95–97]. The action of nitrogen dioxide on vinyl, propenyl, isopropenyl, and isobutenyl bromides and on α- and β-bromostyrenes forms dinitro-derivatives only with the last three compounds, in the respective yields 33.0%, 14.5%, and 9.7%.[92,93]

When halogenoethylenes are heated with nitrogen dioxide, the corresponding 1,2-dinitro-derivatives are formed[94,98]:

$$X_2C{=}CX_2 + 2NO_2 \rightarrow X_2C(NO_2)C(NO_2)X_2 ,$$
$$X{=}Cl, Br .$$

The yields of dinitro-derivatives are increased by the presence of anhydrous aluminium chloride[94].

In 1948 the first results were published on the nitration of fluorinated ethylenes with nitrogen dioxide[99]. Subsequently this reaction was studied in greater detail[100–104]. It was accomplished in the gas phase[100], and in non-polar solvents[101] at room or elevated temperatures and pressures[102–104]. The resulting *vic*-dinitroalkanes were accompanied by alkyl nitrites[101].

On passing from perfluoroethylene to perfluoropropene and perfluoroisobutene, the first of which reacts explosively with nitrogen dioxide in the absence of a solvent, more severe conditions are required (100 and 180 °C respectively)[101–103].

The nitration of fluoroalkenes by nitrogen dioxide is assumed to have a radical mechanism[102,103]:

$$CF_3-CF{=}CF_2 \xrightarrow{\dot{O}NO} CF_3-\dot{C}F-CF_2NO_2 \xrightarrow{\dot{O}NO} CF_3-\overset{NO_2}{\overset{|}{C}}F-CF_2NO_2$$
$$\downarrow \dot{O}NO$$
$$CF_3-\underset{ONO}{\overset{|}{C}}F-CF_2NO_2 \xrightarrow{H_2O,H_2SO_4} CF_3-\underset{O}{\overset{\|}{C}}-CF_2NO_2 .$$

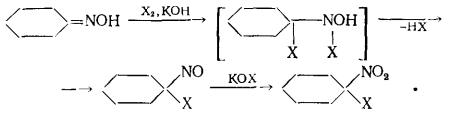
Hydrolysis of the halogenonitroalkyl nitrites yields the corresponding halogenated nitroalcohols[105–107] and nitrocarboxylic acids[100,102,107].

Nitrosyl chloride and bromide react with halogenoalkenes yielding the corresponding nitro-derivatives, which are formed by oxidation of the nitroso-derivatives by a second molecule of the nitrosyl halide. Addition of the nitrosyl halides takes place in conformity with the polarisation of the double bond[95,108,109].

Oxides of nitrogen react in hydrofluoric acid with halogenoalkenes to form the 1-halogeno-2-fluoronitroalkanes[110–112].

The nitration of halogenoalkenes by concentrated nitric acid is accompanied by degradation of the alkene molecule and yields halogenonitromethanes. Thus treatment of trichloroethylene and tetrabromoethylene leads to the isolation respectively of dichlorodinitromethane[113] and dibromodinitromethane[114]; but the main product of the degradative nitration of tetrachloroethylene is chlorodinitromethane, accompanied by small quantities of trichloronitromethane[114].

Chlorinated nitromethanes are obtained by nitrating chloroacetone with nitric acid, or by treating acetone with nitric acid saturated with chlorine[115] or in the presence of sodium chloride[116].



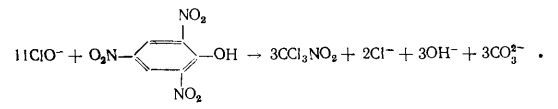
The nitration of halogenoalkenes and other halogenated compounds by nitric acid is accompanied by the oxidising action of oxides of nitrogen and halogens formed in the reaction, which results in complicated mixtures, so that this procedure is rarely used as a method of preparation.

4. α-Halogenonitro-compounds from Oximes

The halogenation of oximes in alkaline medium enables halogenated mononitroalkanes of diverse structure to be obtained[7,117,118]:

$$RR'C{=}NOH + 2X_2 + 3NaOH \rightarrow RR'C(NO_2)X + 3NaX + 2H_2O$$
$$X{=}Cl,\ Br\ .$$

Aliphatic and especially alicyclic ketoximes readily undergo this reaction[119,120]. It involves three stages—addition of halogen at the C=N bond in the oxime, formation of a halogenonitroso-derivative, and oxidation of the latter to the halogenonitro-derivative[117]:



This mechanism is supported by the ease of oxidation of chloronitroso-compounds to the corresponding chloronitro-derivatives[118]. Bromonitroso-derivatives are readily formed by the action of *N*-bromosuccinimide on ketoximes[119,120]. The nitroso-group is smoothly oxidised to a nitro-group by nitric acid or its mixture with 30% hydrogen peroxide[121]. In this way 2-bromo-2-nitropropane, 2-bromo-2-nitrobutane, and 3-bromo-3-nitropentane have been obtained in yields of 18%, 46%, and 38% respectively[120], as well as other α-chloro- and α-bromo-nitroalkanes[121].

The use of oximes for the preparation of α-halogenonitro-compounds extends considerably the range of starting materials. This is important in cases in which the corresponding nitroalkanes are not available to the research worker.

5. Other Methods

When 2,4,6-trinitrophenol is treated with hypochlorite or hypobromite, the aromatic ring is cleaved to form the trihalogenonitromethanes[122]:

This method is used in industry to obtain trichloronitromethane. Picric acid, which is sparingly soluble in water, can be replaced by calcium picrate, and chlorine can be used instead of hypochlorite.

Hydrolytic cleavage of α-halogeno-α-nitro-ketones yields α-halogenonitroalkanes[123–126]:

$$CH_3\overset{\overset{O}{\|}}{C}CBr(NO_2)R \xrightarrow{H_2O} RCHBrNO_2 + CH_3COOH\ ,$$
$$CF_3\overset{\overset{O}{\|}}{C}F_2NO_2 \xrightarrow{H_2O(NaOH)} F_2CHNO_2 + CF_3COOH\ .$$

Halogenonitromethanes are formed also by the hydrolysis of halogenonitroacetyl chlorides[127].

Bromopolynitroethanes are obtained from tribromonitromethane and potassium cyanide. The resulting tetrabromo-1,2-dinitroethane is easily converted into 1,2-dibromotetranitroethane[128,129].

Several α-fluorodinitroalkanes are obtained by alkylating the silver salt of fluorodinitromethane[130]:

$$CF(NO_2)_2^-Ag^+ + RX \rightarrow RC(NO_2)_2F + AgX\ ,$$
$$R{=}CH_3,\ C_3H_7,\ C_3H_5CH_2,\ CH_2{=}CH{-}CH_2;\ X{=}Br,\ I\ .$$

It has recently been shown that α-halogenonitroalkanes are formed by halogenating α-nitroalkylsulphonium salts[131]:

$$(CH_3)_2\overset{+}{S}CH(NO_2)_2\ HSO_4^- \xrightarrow{X_2} CH(NO_2)_2X\ ,$$
$$X{=}Cl,\ Br\ .$$

The action of nitrogen dioxide on fluoro-carboxylic acids or their silver salts yields fluoronitroalkanes[132,133].

Fluoro- and chloro-trinitromethanes have been obtained by nitrating fluoro- and chloro-dinitromethanes respectively with nitryl fluoride[134]:

$$CH(NO_2)_2X + FNO_2 \rightarrow C(NO_2)_3X\ ,$$
$$X{=}F,\ Br\ .$$

Halogenotrinitromethanes are formed by reaction between tetranitromethane and chlorine, *NN*-dichlorobenzenesulphonamide[135], sodium *N*-chlorobenzenesulphonamide[136], or an alkali-metal halide[137–139].

Electrochemical methods of preparing α-halogenonitroalkanes have also been reported[140,141].

III. SPECTRAL PROPERTIES AND STRUCTURE

1. Geometrical Parameters and Electronic Structure

Structural investigations have been made only on the simplest α-halogenonitroalkanes. Gas-phase electron diffraction has been used to determine geometrical parameters for chloronitromethane[142,143], trihalogenonitromethanes[144–147], and halogenotrinitromethanes[143,148,149].

In chloronitromethane free rotation is observed about the carbon–nitrogen bond, which has the usual length for organic nitro-compounds. A conformational peculiarity of chloronitromethane is that the chlorine–carbon–nitrogen angle (114°) is considerably larger than the corresponding angle in trichloronitromethane.

The carbon–halogen distances in trifluoro-, trichloro-, and tribromo-nitromethanes are almost the same as in other similar molecules. The bond angles of the trihalogenomethyl group are close to the tetrahedral values. A conformational peculiarity of trihalogenonitromethanes is a considerable increase in the carbon–nitrogen bond length (1.56–1.59 Å) in comparison with ordinary nitroalkanes, and the presence of a barrier to internal rotation about this bond. Trifluoronitromethane vapour contains two rotational isomers—with staggered and eclipsed forms—in the proportions 2 : 1; the CNO_2 group is non-planar, and the angle between each of the nitrogen–oxygen bonds and the plane containing the carbon–nitrogen bond is $\gamma = 9°35'$.[144] Tribromonitromethane vapour contains only the rotational isomer having the staggered form; the CNO_2 group is non-planar, and $\gamma = 8°33'$.

Electron diffraction and microwave spectroscopy give considerably different results for carbon–nitrogen bond lengths and barriers to internal rotation in trihalogenonitromethanes. The latter method indicates free rotation about the carbon–nitrogen bond in trifluoronitromethane and the usual bond length for nitroalkanes[150]. The reasons for the discrepancy have not been elucidated.

Gas-phase electron diffraction shows C_3 conformations for trinitromethane and its chloro- and bromo-derivatives, with the HCNO, etc. dihedral angles respectively 26°, 49°, and 49°.[143] According to X-ray diffraction[151] the carbon atom in iodotrinitromethane is located at the centre of an almost regular tetrahedron, with mean angles of 71° between the planes of the nitro-groups.

Increasing use has recently been made of theoretical conformational analysis to examine the structure of nitro-compounds. Angles of rotation of the nitro-group and barriers to internal rotation about the carbon–nitrogen bond in halogenated mono-, di-, and tri-nitromethanes determined by this method[152–155] agree well with experiment. The electronic structures of several α-halogenonitroalkanes have been investigated by quantum-chemical methods[153–155]. Thus calculation shows a decrease in negative charge on the halogen atom and a shift in electron density to the trinitromethyl group on passing from fluoro- to iodo-trinitromethane. The negative charge on the oxygen atoms and the carbon–nitrogen bond order diminish, while the order of the nitrogen–oxygen bonds increases, on passing from mono- to di-nitro-compounds.

Valuable information on the electronic structure of α-halogenonitroalkanes has been obtained from studies of molecular dipole moments[156–158]. Interaction of the nitro-groups with the halogen atom leads to considerable changes in the electron shell of the molecules and is responsible for differences between calculated and experimental dipole moments. Additive resolution of the dipole moment among bonds in a molecule has yielded the values

$$\mu^{+}_{C-F} = 1.0^{156};\ \mu^{+}_{C-Cl} = 0.23;\ \mu^{+}_{C-Br} = 0.15;\ \mu^{+}_{C-I} = 1.39\ D^{157}$$

for the halogenotrinitromethanes. These dipole moments differ markedly from those of the same bonds in halogenoalkanes, owing to a mesomeric effect. Quantum-chemical calculations on halogenotrinitromethanes are consistent with this view[153].

2. Vibrational Spectra

Results obtained in the numerous investigations on the vibrational spectroscopy of nitro-compounds, including α-halogenonitroalkanes, have been surveyed in reviews[6,159] and in a monograph[11]. The antisymmetric and symmetric stretching frequencies of the nitro-group are important characteristics of the vibrational spectra of α-halogenonitroalkanes. In nitroalkanes they may lie in the respective ranges 1500–1600 and 1300–1370 cm^{-1}.[6] Replacement of hydrogen by halogen atoms in nitroalkanes raises the frequency of antisymmetric and lowers that of symmetric stretching vibrations of the nitro-group, as well as lowering the carbon–nitrogen stretching frequency. A similar pattern is observed with increase in the number of nitro-groups.

The position of the absorption band of antisymmetric nitro-stretching vibrations in the infrared spectra of α-halogenonitroalkanes is determined mainly by the inductive effect of substituents[160–163], and the frequency correlates quite well with the inductive constants of the latter[162,163]:

$$\nu_{as\,(NO_2)} = 1562 + 12\sigma^{*}.$$

Furthermore, the frequency is influenced by steric factors and the conjugation effect.

The position of symmetric nitro-stretching vibrations in a series of nitroalkanes is influenced mainly by the steric factor[159], the shifts caused by different substituents being additive. The shift depends on the bulk of the substituent and is independent of its electron-acceptor or electron-donor properties. The position of these vibrations is almost uninfluenced by inductive and conjugation effects.

The solvent has an insignificant effect on the position of absorption bands corresponding to nitro-stretching vibrations in the infrared spectra and on their integral intensity[159].

The mutual influence of nitro-group and halogen is clearly evident in the vibrational spectra of halogenotrinitromethanes. Their Raman and infrared spectra show a high intensity in bands corresponding to characteristic carbon–halogen vibrations and abnormally low frequencies—366 and 344 cm^{-1} for chloro- and bromo-trinitromethanes respectively[164], compared with the range 600–700 cm^{-1} for ordinary alkyl halides—the fall in frequency being so great that it cannot be attributed solely to the inductive effect of the trinitromethyl group. It is probably due to a mesomeric effect leading to a decrease in negative charge on the halogen and a redistribution of the carbon–nitrogen and nitrogen–oxygen bond orders.

3. Electron Spectra

Two absorption bands are usually observed in the ultraviolet spectra of mono- and poly-nitroalkanes: a strong band at 200–210 nm lies in a region that is marginal for the instruments used in practical spectroscopy, and is usually disregarded; most studies are devoted to a weak band at 270 to 280 nm attributed to an $n-\pi^{*}$ transition[165,166]. The latter has no fine structure, its intensity depends on the number of nitro-groups in the molecule, and its position varies with the solvent, increase in whose polarity shifts the band to shorter wavelengths[165]. The position of this band is influenced also by substituents[6]. The introduction of halogen atoms α to the nitro-group leads to a slight bathochromic displacement and an increase in intensity, which is explained by interaction of the electron shells of nitrogen–oxygen and carbon–halogen bonds[167].

The absorption coefficent increases with the accumulation of nitro-groups in the molecule, but not in proportion to their number[165].

Anions of halogenodinitroalkanes give an intense broad band ($\varepsilon > 10\,000$) with maximum absorption at 365–380 nm.

4. Microwave Spectroscopy

The chemical shift of protons in the nuclear magnetic resonance spectra of α-halogenonitro-compounds is determined mainly by the total inductive effect of the substituents[6,11]. The presence of such electronegative substituents as nitro, fluoro, chloro, bromo greatly diminishes the shielding of α- and β-protons and produces a downfield shift of signals in the n.m.r. spectra of α-halogenonitroalkanes. The variation in the chemical shift of a 1-proton in the spectra of nitroalkanes on the introduction of electronegative substituents other than a fluorine atom parallels the variation in the acid ionisation constants of these compounds[168].

During recent years the structure of α-halogenonitroalkanes has been increasingly investigated by n.m.r. not only with hydrogen but also on nitrogen-14, carbon-13, and oxygen-17 nuclei[169–173]. Chemical shifts of the nitrogen-14

signal in n.m.r. spectra of these compounds depend linearly on the total inductive effect of the substituents[169]:

$$\delta = -25.0 + 13.8\sigma^*.$$

Increase in the electronegativity of a substituent leads to a diamagnetic shift in the signal in the spectra of mono- and poly-nitroalkanes, which indicates displacement of electron density of the nitrogen–oxygen bond from the oxygen to the nitrogen atom.

The replacement of hydrogen atoms in a nitroalkane by halogen produces a diamagnetic shift of the oxygen-17 signal in the n.m.r. spectrum. Accumulation of nitro-groups in a molecule has little influence on this chemical shift. The tendency of the latter to vary in aliphatic nitro-compounds cannot be due to inductive effects as with nitrogen-14. Perhaps it is caused by the interaction of non-bonded atoms, and also by other effects.

The introduction of halogen or a nitro-group at carbon atom 1 causes a paramagnetic shift in the carbon-13 signal, which increases in the sequence Br < CH_3 < Cl < NO_2.

Fluorine-19 n.m.r. spectroscopy has provided information on the electronic structure of the fluorine atom in α-fluoronitroalkanes[174].

Nuclear quadrupole resonance on chlorine-35, bromine-79, and iodine-127 nuclei has been used to investigate the structure of α-halogenonitro-compounds. Chloronitroalkanes have been studied in greater detail[175,176], bromo- and iodo-nitroderivatives in less detail[174,177]. The n.q.r. spectra of α-halogenonitroalkanes exhibit displacement of the halogen signal to higher frequencies than in alkyl halides, which indicates a decrease in electron density on the halogen atom in the former.

A relation has been found between the ^{35}Cl n.q.r. frequencies and the induction constants of the substituents in a series of chloronitroalkanes[175]:

$$\nu^{35}_{Cl} = 34.68 + 1.63\sigma^*.$$

The frequencies $\nu_{^{35}Cl}$ for chlorodinitromethane and chlorofluorodinitromethane depart from the regression line, by 0.86 MHz to higher frequencies and 1.2 MHz to lower frequencies respectively. In the former case the departure is due to hydrogen bonding between chlorodinitromethane molecules; in the latter case it has been interpreted as resulting from conjugation of *p*-electrons of fluorine with the carbon–chlorine bond.

5. Acid–Base Properties

In polar solvents α-halogenonitroalkanes containing an α-hydrogen atom eliminate a proton and form a halogenonitroalkane anion. Deprotonation of the molecule and protonation of the anion occur by a mechanism of general acid–base catalysis[178–180]:

$$\mathrm{R{-}\underset{\mathrm{Hal}}{\underset{|}{C}}HNO_2} + B^- \rightleftarrows \mathrm{R{-}\underset{\mathrm{Hal}}{\underset{|}{C}}{=}NOO^-} + BH\ .$$

At ordinary temperatures they take place at a moderate rate, and kinetic measurements can easily be made. The rate constants correlate well with the pK_b values of the bases[179,181] and satisfactorily with the pK_a values of the α-halogenonitroalkanes[181–183].

The acid–base properties of α-halogenonitroalkanes vary over a wide range depending on the nature of the halogen and the structural parameters of the substituent. The dependence of the acidity on the total inductive effect of the substituents cannot be described by a single correlation equation[184,185]. Ionisation constants for compounds containing substituents having closely similar polar effects may differ substantially. Thus for difluoronitromethane pK_a = 12.4,[168] but the value for bromodinitromethane is 3.47.[185]

The complicated structural dependence of the acidity of α-halogenonitroalkanes is responsible for the diversity of views on this problem. Among factors determining the pK_a of nitroalkanes are inductive, steric, and mesomeric effects, $p-\pi$-electronic repulsion, solvation, and also purely formal features such as the numbers of α- and β-hydrogen atoms[186–190].

In view of the above considerations the results provided by physicochemical investigation of the structure of α-halogenonitroalkanes cannot be adequately explained in terms of the theory of the inductive effect, and most workers apply the concept of a mesomeric effect. The combination of a nitro-group and a halogen attached to the same carbon atom will obviously lead to electronic interaction between nitrogen–oxygen and carbon–halogen bonds. Such interaction affects primarily and mainly the latter bond, with the appearance of special properties in the halogen, differing substantially from the halogen in alkyl halides and constituting one reason for the peculiar chemical behaviour of α-halogenonitroalkanes.

IV. CHEMICAL PROPERTIES

1. Molecular Complexes

The specific chemical behaviour of α-halogenonitroalkanes is due primarily to the way in which the carbon–halogen bond is polarised. In ordinary alkyl halides—chlorides, bromides, and iodides—the halogen carries a strong negative charge: the dipole moments of the carbon–halogen bonds in chloro-, bromo-, and iodo-methanes lie between −1.55 and −1.17 D.[157] In the formation of complexes they usually act as *n*-donors. In α-halogenonitroalkanes the carbon–halogen bond is polarised differently: the dipole moments of such bonds in chloro-, bromo-, and iodo-trinitromethanes are resepctively −0.23, +0.15, and +1.39 D.[157] In contrast to alkyl halides these compounds act as electron-acceptors in complex formation, exhibiting the properties of pseudohalogens.

Iodo- and bromo-trinitromethanes readily form molecular complexes with various electron-donors (dioxan, *N*-, *S*-, and *P*-oxides, αα′-dioxodiazo-compounds, nitrosamines):[177,191,192]

Nuclear quadrupole resonance spectra indicate complex formation also by chlorotrinitromethane[177]. The chlorine-35, bromine-79, and iodine-127 signal frequencies in the spectra of halogenotrinitromethane complexes increase with the electron-donor power of the ligand and are higher than for these nuclei not combined in such complexes. Analogous signal shifts to higher frequencies are observed in the n.q.r. spectra of the iodine, iodine monochloride, and iodine monobromide complexes[193]. The regularity in the variation of the ^{35}Cl, ^{79}Br, and ^{127}I n.q.r. frequencies indicates an increase in the "positive" character of the halogen in the halogenotrinitromethane complexes.

Molecular complexes may play a definite part in effecting particular reactions of α-halogenonitroalkanes. A quantitative relation can apparently be expected between the frequency changes in the n.q.r. spectra of the complexes and their chemical activity in reactions involving rupture of the

carbon–halogen bond. This relation is readily seen qualitatively in the reaction with iodomethane[177]:

$$IC(NO_2)_3 + S \rightleftarrows S \cdot IC(NO_2)_3 ,$$
$$S \cdot IC(NO_2)_3 + CH_3I \rightleftarrows CH_3C(NO_2)_3 + I_2 + S ,$$

where S represents dimethyl sulphoxide, dioxan, etc. The ease of formation of 1,1,1-trinitroethane increases on passing from halogenotrinitromethanes to their complexes and with increase in the electron-donor power of the ligand[177,194–196].

2. Electrochemical Reduction

Assessment of the reactivity of α-halogenonitroalkanes can be approached by studying their electrochemical reduction. The first wave on a polarogram represents fission of the carbon–halogen bond, but subsequent waves are due to reduction of the nitro-group[197,198]. The half-wave potential $E_{1/2}$ serves as criterion of their chemical activity. These compounds are reduced at more positive potentials than are the corresponding halogenoalkanes, which indicates that the carbon–halogen bond is considerably weaker in the former.

When bromo- and chloro-nitromethanes are reduced, each gives a characteristic two-electron wave ($E_{1/2}$ = −0.05 and −0.45 V) and a wave corresponding to the reduction of nitromethane[199]:

$$CH_2(NO_2)X + 2e \rightarrow CH_2{=}NOO^- + X^- ,$$
$$CH_2{=}NOO^- + H^+ \rightarrow CH_3NO_2 ,$$
$$CH_3NO_2 + 4H^+ + 4e \rightarrow CH_3NHOH + H_2O ,$$

Polarograms obtained for dibromo- and dichloro-nitromethanes contain their own waves ($E_{1/2}$ = +0.03 and −0.12 V), waves due to CH_2NO_2Br (or CH_2NO_2Cl), and a wave due to CH_3NO_2. Trichloro- and tribromo-nitromethanes give their own waves (+0.01 and +0.02 V) and waves corresponding to the reduction of di- and mono-halogenonitromethanes, as well as a nitromethane wave. The reduction of halogenated derivatives of nitroethane[199] and 2-nitropropane[200] have been studied.

The ease of polarographic reduction of α-halogenonitroalkanes increases on passing from chloro- to iodo-derivatives and with increase in the number of nitro-groups. Chlorides are reduced with greater difficulty than are bromides, but this difference diminishes with the accumulation of nitro-groups, which facilitates also rupture of the carbon–nitrogen bond[201]. In α-fluoropolynitroalkanes the first stage of reduction corresponds to fission of this bond, not of the carbon–fluorine bond[202–204]:

$$FC(NO_2)_3 + 2H^+ + 2e \rightarrow CH(NO_2)F + HNO_2 .$$

Bromo- and iodo-trinitromethanes are reduced in the first stage to the trinitromethyl anion ($E_{1/2}$ = +0.036 and +0.42 V),[197] further reduction of which depends on the pH.[198,204] The reduction of chlorotrinitromethane takes place in two ways in the first stage—with rupture of the carbon–chlorine bond ($E_{1/2}$ = +0.248 V) and of a carbon–nitrogen bond[201].

Electron spin resonance indicates intermediate formation of radical-anions and -dianions in the electrochemical reduction of 1-halogenonitroalkanes[205–207].

3. Reactions with Nucleophilic Reagents

(a) Hydrolysis

α-Halogenonitroalkanes are slowly hydrolysed by water: the reaction goes to completion on heating in the presence of alkalis. Kinetic study of the hydrolysis of 1-chloro- and 1-bromo-1-nitroethanes showed that the reaction is preceded by a comparatively slow stage of isomerisation of the nitro- into the *aci*-form, and the latter is attacked by the solvent[180,208]:

$$CH_3CH(NO_2)Cl \xrightarrow{OH^-} CH_3C(Cl){=}NOO^- \xrightarrow[-Cl^-]{H_2O} CH_3C(OH){=}NOOH \rightarrow CH_3CHO + HNO_2 .$$

The action of bases on α-halogenopolynitroalkanes, in contrast to the mononitro-compounds, results in replacement of the halogen by the cation of the base[27,209]:

$$CH_3C(NO_2)_2X + 2KOH \rightarrow CH_3C(NO_2)_2^- K^+ + KOX + H_2O ,$$
$$3C(NO_2)_3X + 6KOH \rightarrow 3C(NO_2)_3^- K^+ + 2KX + KXO_3 + 3H_2O ,$$
$$X{=}Cl, Br, I .$$

Halogenotrinitromethanes are hydrolysed even by water[81,210]:

$$C(NO_2)_3X + H_2O \rightleftarrows HC(NO_2)_3 + HOX ,$$
$$X{=}Cl, Br, I ,$$

The equilibrium constants for the hydrolysis of chloro-, bromo-, and iodo-trinitromethanes are 8×10^{-12}, 3×10^{-11}, and 4×10^{-7} M^{-1} respectively[211].

Fluorotrinitromethane, unlike the other halogenotrinitromethanes, splits off a nitro-group on treatment with a base[44]. The action of alcoholic alkali breaks not only a carbon–nitrogen but also a carbon–fluorine bond[44,212].

(b) Action of reductants

Results obtained for the electrochemical reduction of α-halogenonitroalkanes provide evidence of the extraordinary ease of reduction of the halogen. In addition, the nitro-group is one of the functional groups most sensitive to reduction. Therefore reduction can occur in two directions depending on the nature of the α-halogenitroalkane and the selectivity of the reducing agent.

Chemical reduction of the halogen provides extremely interesting results. The action of reductants of basic character involves replacement of the halogen by the cation of the base with formation of a nitroalkane salt. The halogen that is eliminated behaves as an oxidant. Ease of reduction increases with the "positive" character of the halogen in the α-halogenonitroalkane, which can be explained by facilitation of nucleophilic attack by the reductant anion on the halogen atom.

More detailed research has been undertaken on the reaction with potassium iodide, which is widely used to characterise compounds having a "positively" polarised halogen atom[12]. α-Halogenopolynitroalkanes readily oxidise potassium iodide[24,210,213]:

$$RC(NO_2)_2X + 2KI \rightarrow RC(NO_2)_2^- K^+ + KX + I_2 ,$$
$$R{=}Alk, Hal, NO_2; \quad X{=}Cl, Br, I, NO_2 .$$

This reaction is used for the quantitative determination of halogen in iodo- and bromo-polynitroalkanes, as well as in chlorotrinitromethane[24]; chloro-derivatives of dinitroalkanes and halogenomononitroalkanes are less reactive[214]. The "positive" polarisation of the halogen atom diminishes in the same sequence of α-halogenonitroalkanes[156,157,174].

Various views are held on the mechanism of the reaction of α-halogenonitroalkanes with the iodide ion. From general considerations on the action of bases on α-halogenopolynitroalkanes it has been suggested[10] that the first stage involves formation of the polynitroalkyl anion (nucleophilic substitution at the halogen atom):

$$C(NO_2)_3X + I^- \xrightarrow{slow} C(NO_2)_3^- + XI ,$$
$$XI + I^- \xrightarrow{rapid} I_2 + X^- .$$

This hypothesis is supported by an investigation of the mechanism of the reaction of tetranitromethane with hydrogen peroxide and alkyl peroxide anions[215]:

$$ROO^- + C(NO_2)_4 \rightarrow \left[ROO^- \dashrightarrow O{=}N^+{-}C(NO_2)_3\right] \rightarrow ROOON \rightarrow O + C(NO_2)_3^-,$$

$$ROOON \rightarrow O \xrightarrow{H_2O} ROH + O_2 + HNO_2.$$

An alternative mechanism, based on kinetic data, involves a stage of bimolecular nucleophilic substitution of halogen by the iodide ion followed by reduction of the iodopolynitroalkane by a second molecule of potassium iodide[216–219]:

$$RC(NO_2)_2X + I^- \underset{\text{slow}}{\rightleftharpoons} RC(NO_2)_2I + X^-,$$

$$RC(NO_2)_2I + I^- \xrightarrow{\text{rapid}} RC(NO_2)_2^- + I_2.$$

The reaction is thus regarded as a particular case of nucleophilic substitution of the halogen attached to the carbon atom in the initial compound.

Fluorotrinitromethane undergoes denitration under the influence of the iodide or hydrogen peroxide ion[217,220]:

$$C(NO_2)_3F + 2KI \xrightarrow{H_2O} CH(NO_2)_2F + I_2 + KNO_2 + KOH.$$

Chlorotrinitromethane forms with the hydrogen peroxide ion a mixture of trinitromethane and chlorodinitromethane[10]. Tribromonitromethane reacts peculiarly with potassium iodide or cyanide in the presence of potassium nitrite[129]:

$$2CBr_3NO_2 + 6KI + 2KNO_2 \rightarrow K^+{}^-(O_2N)_2C{-}C(NO_2)_2^-K^+ + 6KBr + 3I_2.$$

The complex hydrides of alkali and alkaline-earth metals are extremely promising for the selective reduction of halogen in α-halogenonitroalkanes, because of the relative stability of nitro-groups to the action of hydride anions. A method was worked out for reducing aliphatic and alicyclic α-bromonitrocompounds with sodium tetrahydroborate in aqueous methanol to the corresponding nitroalkanes (in 15–80% yield).[119,121] This complex hydride was used also to reduce ααωω-tetrabromodinitro-compounds[74]:

$$CBr_2(NO_2)CH_2CH_2C(NO_2)Br_2 \xrightarrow{NaBH_4} CH_2(NO_2)CH_2CH_2CH_2NO_2.$$

Liquid ammonia[221] and hydrazine[222] reduce α-halogenonitroalkanes with evolution of nitrogen:

$$3C(NO_2)_2X_2 + 8NH_3 \rightarrow 3C(NO_2)_2X^-NH_4^+ + 3NH_4X + N_2,$$

$$2C(NO_2)_3X + H_2N{-}NH_2 + 4KOH \rightarrow 2C(NO_2)_3^-K^+ + 2KX + N_2 + 4H_2O.$$

Other reducing agents that are used are sodium thiosulphate, sulphide, and hydrogen sulphide[213], potassium cyanide and hexacyanoferrate(II),[223] and triphenylphosphine[224–226]. Other methods have been reported for the selective reduction of halogen in 1-halogenonitroalkanes, e.g. by the action of arsenic sesquioxide in caustic potash solution or of an aqueous–ammoniacal solution of hydrogen sulphide[227].

Still other methods reduce not only halogen but also the nitro-group. Among them are reduction with hydrogen in the presence of platinum-group metals, zinc, or iron and with tin(II) chloride in an acid medium[227].

(c) Relacement of halogen by the nucleophile

A most important property of α-halogenonitroalkanes is their ability to exchange the halogen atom for a nitro-group in the presence of alkaline potassium or sodium nitrite[11]:

$$RCH(NO_2)X + KNO_2 \xrightarrow{K_2CO_3} RC(NO_2)_2^-K^+ + KX,$$

X=Cl, Br.

This reaction, first described by ter Meer for 1-bromo-1-nitro-derivatives of ethane and propane, is now widely used to prepare *gem*-dinitroalkanes. It has been employed to obtain 1,1-dinitroethane[228–230], 1,1-dinitropropane[228,230], 1,1-dinitropentane[228], dinitromethane[231], and also ααωω-tetranitroalkanes[128].

The ter Meer reaction does not take place by the usual mechanism of nucleophilic substitution of the halogen in the *aci*-form of the α-halogenonitroalkane, as had previously been assumed[233], but is a radical-chain process[232]:

$$CH_3CH(NO_2)Cl \xrightarrow{e} CH_3CH(NO_2)Cl^{\cdot-} \xrightarrow{-Cl^-} CH_3\dot{C}HNO_2 \xrightarrow{NO_2^-} \rightarrow CH_3CH(NO_2)_2^{\cdot-} \xrightarrow{CH_3CH(NO_2)Cl} CH_3CH(NO_2)_2 + CH_3CH(NO_2)Cl^{\cdot-} \rightarrow \text{etc.}$$

Iodotrinitromethane is converted into tetranitromethane by the action of silver nitrite[27].

A typical reaction of 1-halogenonitroalkanes is detachment of the halogen by the anions of nitro-compounds with formation of a new carbon–carbon bond[20–22]. It has been examined in detail on salts of secondary nitroalkanes interacting with their halogeno-derivatives[234–236]:

$$(CH_3)_2C(NO_2)X + (CH_3)_2C{=}NOO^- \xrightarrow{-X^-} (CH_3)_2C(NO_2){-}C(NO_2)(CH_3)_2,$$

X=Cl, Br.

Dinitroalkenes are formed similarly[237,238]:

$$CH_3CH(NO_2)Cl + CH_3CCl{=}NOO^- \xrightarrow{-Cl^-} CH_3CH(NO_2){-}CClCH_3 \xrightarrow{-H^+} \rightarrow CH_3C(NOO^-){-}CClCH_3(NO_2) \xrightarrow{-Cl^-} CH_3C(NO_2){=}CCH_3(NO_2).$$

These reactions can occur either by normal nucleophilic substitution[239,240] or by a radical-anion mechanism[234–236].

Kornblum et al. have shown[241] that the reaction with alkali-metal sulphinates has the latter mechanism:

$$(CH_3)_2C(NO_2)I + PhSO_2^- \rightarrow (CH_3)_2C(NO_2)I^{\cdot-} + PhSO_2^{\cdot},$$

$$(CH_3)_2C(NO_2)I^{\cdot-} \rightarrow (CH_3)_2C\dot{N}O_2 + I^-,$$

$$(CH_3)_2C\dot{N}O_2 + PhSO_2^- \rightarrow [(CH_3)_2C(NO_2)SO_2Ph]^{\cdot-},$$

$$[(CH_3)_2C(NO_2)SO_2Ph]^{\cdot-} + (CH_3)_2C(NO_2)I \rightarrow (CH_3)_2C(NO_2)SO_2Ph + (CH_3)_2C(NO_2)I^{\cdot-}.$$

The action on halogenotrinitromethanes of aryl derivatives of magnesium, mercury, and tin involves a stage of electron transfer from the organometallic compound with formation of a radical-anion of the halogenotrinitromethane[242–244]:

$$PhMgCl + BrC(NO_2)_3 \rightarrow \left[\begin{matrix}BrC(NO_2)_3^{\cdot-}\\ PhMgCl^+\end{matrix}\right] \rightarrow Ph^{\cdot} + {}^1/_2Mg[C(NO_2)_3]_2 + {}^1/_2MgCl_2 + Br^{\cdot}.$$

The appearance of radical-anions in the action of nucleophilic reagents on difluorodinitromethane and fluorotrinitromethane has been confirmed by electron spin resonance[245–247]:

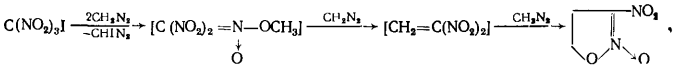
$$CF_2(NO_2)_2 + ArO^- \rightarrow CF_2(NO_2)_2^{\cdot-} + ArO^{\cdot}$$

The radical-anions can break down with fission of either a carbon–nitrogen or a carbon–halogen bond[248]:

$$C(NO_2)_3X^{\cdot-} \rightarrow \begin{cases} C(NO_2)_3^- + X^{\cdot} & (X{=}Cl, Br, NO_2),\\ C(NO_2)_2X^- + NO_2^{\cdot} & (X{=}F, Cl, Br, NO_2).\end{cases}$$

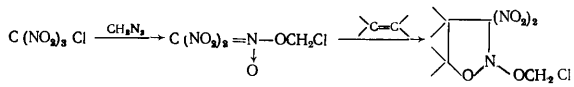
It has recently been established[138,139,249] that fluorotrinitromethane and tetranitromethane, under the influence of alkali-metal halides in anhydrous polar solvents, form products in which a nitro-group has been replaced by a halide ion; under these conditions chlorotrinitromethane forms both nitro-substitution and halogen-substitution products:

$$XC(NO_2)_3 + MY \rightarrow \begin{cases} XC(NO_2)_2Y & (X{=}F, NO_2),\\ XC(NO_2)_2Y + YC(NO_2)_3 & (X{=}Cl),\\ YC(NO_2)_3 & (X{=}Br),\end{cases}$$



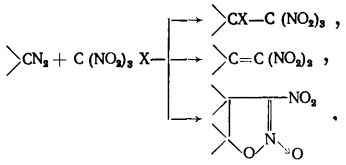
M=K, Li, Rb, Cs; Y=F, Cl, Br.

It is supposed that bimolecular nucleophilic substitution at the carbon atom is involved[216]. In electron-donor polar solvents intermolecular halogen exchange occurs in halogenated derivatives of di- and tri-nitromethanes[250]:



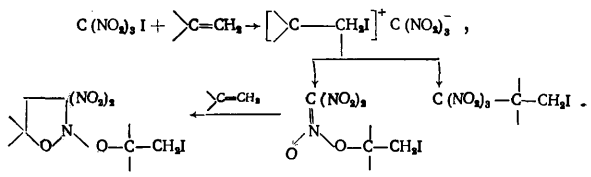
$$C(NO_2)_3Cl + C(NO_2)_2Br_2 \rightleftarrows C(NO_2)_3Br + BrC(NO_2)_2Cl\ ,$$
$$2BrC(NO_2)_2Cl \rightleftarrows C(NO_2)_2Br_2 + C(NO_2)_2Cl_2\ .$$

(d) Reaction with diazoalkanes



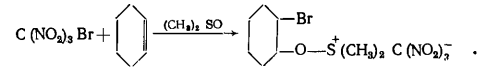
The action of diazomethane on chloro-, bromo-, and iodotrinitromethanes is accompanied by detachment of a nitro-group and of halogen, and yields 3-nitroisoxazoline *N*-oxide[251,252] with intermediate formation of *O*-alkyl esters of trinitromethane followed by 1,1-dinitroethylene[252]:

In the case of chlorotrinitromethane the *O*-chloromethyl ester of trinitromethane is formed as intermediate[252]:



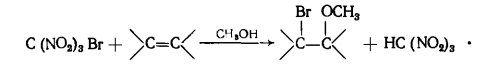
When halogenotrinitromethanes are treated with diazomethane derivatives—9-diazofluorene, diazoanthrone, diazoacetic ester—derivatives of 1-halogeno-2,2,2-trinitroethane, *gem*-dinitroalkenes, and 3-nitroisoxazoline *N*-oxide can be isolated depending on the nature of the reagents and the conditions[251]

(e) Reaction with alkenes



Electrophilic addition at the double bond occurs with iodo- and bromo-trinitromethanes, which is explained by the considerable "positive" character of the halogen. Chlorotrinitromethane does not undergo this reaction.

Iodotrinitromethane reacts exceptionally with alkenes[253–255], forming with ethylene *N*-2′-iodoethoxy-3,3-dinitroisoxazoline and 1-iodo-3,3,3-trinitropropane. Electrophilic attack at the double bond gives the corresponding carbocation and the ambident trinitromethyl anion, which is able to react with either the carbon or the oxygen centre depending on the cation and the solvent[253]:



Only *O*-alkylated products are formed with cyclohexene[254] and with trimethylsilylethylene[255].

The reaction between bromonitroform and alkenes has been studied in detail[256–259]. Hardly any reaction occurs in non-polar or weakly polar solvents (benzene, chloroform), but in dimethyl sulphoxide it takes place even at room temperature. However, the products are not nitronic esters of trinitromethane, as had been supposed earlier[256,257], but sulphonium derivatives[258]:

Addition of bromonitroform is slowed down by the presence of electron-accepting substituents at the double bond: cinnamic acid, acrylic esters, and 2,3-dibromopropene do not form adducts even after an hour[256]. Addition of bromotrinitromethane to methyl vinyl ketone and to isopropyl vinyl ether gives *C*-alkylated products[260,261].

In alcoholic solution the reaction of bromotrinitromethane involves intermediate formation of an alkyl hypobromite, which with the alkene gives the final product[262]:

Aromatic hydrocarbons are brominated in the ring by bromotrinitromethane[259].

4. Nucleophilic Addition at Multiple Bonds

(a) Michaelis reaction

Primary α-halogenonitroalkanes are added at an activated double bond[263–266]. The activating influence of substituents diminishes in the sequence[267]

$$CHO > COR > CN > COOR > NO_2.$$

The reactivity of these compounds is determined by their acidity, with fluoro- and chloro-dinitromethanes reacting especially readily[53,263,265,266]:

$$CH(NO_2)_2X + CH_2{=}CHR \rightarrow XC(NO_2)_2CH_2CH_2R\ ,$$
R=CHO, COR′, $COOCH_3$, CN, NO_2; X=F, Cl, Br .

(b) Condensation with aldehydes and ketones (Henry's reaction)

1-Halogenonitroalkanes resemble other compounds containing a mobile hydrogen atom in undergoing condensation with aldehydes:

$$RCH(NO_2)X + R'CHO \rightarrow RC(NO_2)(X)CHR'(OH)\ ,$$
R=H, Alk; R′=H, CH_3; X=F, Cl, Br .

The reaction goes especially smoothly between the lower homologues[268–271]. It is assumed that an aldol-type condensation is involved. The rate depends on the nature of the reactants, the catalyst, the ionising power of the solvent, and other factors.

Alcohols and glycols can be obtained from monohalogenonitromethanes depending on the proportions of the reactants[271,272]. Difluoronitromethane condenses with aldehydes when heated (100–120 °C) in the presence of potassium carbonate[103,268]:

The condensation of α-halogenonitroalkanes with aldehydes may be accompanied by dehydration with formation of alkenes[273].

The action of formaldehyde on halogenodinitromethanes yields the corresponding halogenodinitroethanols[44,53,68], which readily break down to give the original α-halogenonitroalkane[185]:

$$XC(NO_2)_2CH_2OH + H_2O \rightleftarrows XCH(NO_2)_2 + CH_2(OH)_2 ,$$
$$X=F, Cl, Br .$$

Fluorodinitromethane condenses with acetaldehyde[270] and with glycollaldehyde[68] in the absence of a catalyst at room temperature. With dialdehydes fluorodinitromethane forms the corresponding tetranitro-diols[270]. With glyoxal at 45 °C it forms also β-fluoro-α-hydroxy-ββ-dinitropropionic acid[68]:

$$\begin{matrix}CHO\\|\\CHO\end{matrix} + FCH(NO_2)_2 \rightarrow FC(NO_2)_2-\underset{\underset{OH}{|}}{CH}-\underset{\underset{OH}{|}}{CH}-C(NO_2)_2F + FC(NO_2)_2\underset{\underset{OH}{|}}{CHCOOH} .$$

The reaction with pyruvaldehyde involves only the formyl group[68].

Less detailed study has been made of the condensation of α-halogenonitroalkanes with ketones[263,266,274,275]. With the lower ketones in the presence of potassium carbonate difluoronitromethane gives nitroalkanols[268,274]:

$$R-\underset{\underset{O}{\|}}{C}-R + F_2CHNO_2 \rightarrow RR\underset{\underset{OH}{|}}{C}C(NO_2)F_2 .$$

With unsaturated aldehydes and ketones the reaction involves primarily the carbon–carbon double bond, and only then is the carbonyl group affected[263,266].

An unusual method of obtaining *gem*-dinitro-alcohols is to boil 1-bromo-1,1-dinitro-compounds with aqueous formaldehyde[209,276]; the process is analogous to Henry's reaction:

$$RC(NO_2)_2Br + CH_2O \xrightarrow{H_2O} RC(NO_2)_2CH_2OH ,$$
$$R=CH_3, CH_2CH_2COOH .$$

Under these conditions dibromidinitromethane is converted into 2,2-dinitropropane-1,3-diol[277]. ββ-Dinitro- and βββ-trinitro-alcohols are formed by the action of formalin on halogenotrinitromethanes, when the course of the reaction varies[277–279]:

$$C(NO_2)_3X + CH_2O + H_2O \begin{cases} \rightarrow C(NO_2)_3CH_2OH & (X=Br, I) ,\\ \rightarrow XC(NO_2)_2CH_2OH & (X=Cl) ,\\ \rightarrow XC(NO_2)_2CH_2OH + (HOCH_2)_2C(NO_2)_2 & (X=F, NO_2) . \end{cases}$$

5. Radical Reactions

(*a*) Thermolysis

The gas-phase thermolysis of α-halogenopolynitroalkanes involves as first stage rupture of a carbon–nitrogen bond[280–284]:

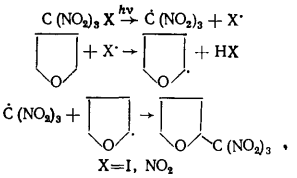
$$RC(NO_2)_2X \rightarrow R\dot{C}(NO_2)X + NO_2^{\cdot} ,$$
$$R=CH_3, C_2H_5, NO_2, F, C(NO_2)_2F, C(NO_2)_3;$$
$$X=F, Cl, Br, I.$$

In all cases the reaction is predominantly homogeneous and unimolecular. Only 1-chloro-1,1-dinitroethane shows a surface effect, which is due to loss of resulting chlorine atoms on the walls of the reaction vessel[281]. Loss of the halogenonitroalkyl radical in systems containing nitric oxide and nitrogen dioxide occurs broadly similarly in all the α-halogenonitroalkanes investigated, and can be represented by the scheme

$$CH_3\dot{C}(NO_2)X \begin{cases} \xrightarrow{NO_2} CH_3-\underset{\underset{NO_2}{|}}{\overset{X}{\overset{|}{C}}}-ONO \rightarrow CH_3C\overset{O}{\underset{X}{<}} + NO + NO_2 ,\\ \xrightarrow{NO} CH_3-\underset{\underset{NO_2}{|}}{\overset{X}{\overset{|}{C}}}-NO \rightarrow CH_3\dot{C}(NO)X + NO_2 \rightarrow CH_3CN + XO^{\cdot} . \end{cases}$$

The rate of the gas-phase thermal decomposition of trichloronitromethane depends on the initial pressure and on additions of inhibitors (toluene, formaldehyde)[285].

The dependence of the carbon–nitrogen bond dissociation energy on α-substituents has been established. Chlorine, bromine, and iodine atoms lower this energy in α-halogenonitroalkanes, but a fluorine atom has an insignificant effect comparable with that of hydrogen. The rate of decomposition increases in the sequence of substituents from nitro through chloro and bromo to iodo[281–284]. This dissociation energy is closely similar in magnitude to the activation energy of thermolysis, which is evidence of a radical mechanism of decomposition with initial rupture of a carbon–nitrogen bond in α-halogenonitroalkanes.



Products of the thermal breakdown of the potassium salts of chloro- and bromo-dinitromethanes in aprotic solvents have been studied[286,287]. The reaction probably involves intermediate formation of dinitro- and halogenonitro-carbenes[287].

(*b*) Other reactions

The possibility of homolytic fission of a carbon–halogen bond in an α-halogenonitroalkane was first shown in the oxidation of tetralin catalysed by bromo- and chloro-trinitromethanes[288], and was later demonstrated in the polymerisation of methyl acrylate in the presence of an α-halogenonitroalkane[289].

It has recently been found that iodotrinitromethane and tetranitromethane react with cyclic ethers (oxolan, oxan) by a non-chain radical mechanism with intermediate formation of the trinitromethyl radical[290–294]:

$$C(NO_2)_3X \xrightarrow{h\nu} \dot{C}(NO_2)_3 + X^{\cdot}$$

$$X=I, NO_2$$

However, the photolysis of tetranitromethane and of fluoro- and chloro-trinitromethanes in dimethylformamide and in hydroxylated solvents involves decomposition of the polynitroalkanes to give only anions of the latter[295].

Radical addition of tribromonitromethane at a double bond has been reported[296].

V. PHYSIOLOGICAL ACTIVITY AND PRACTICAL USE

Halogenonitro-compounds are of interest as a consequence of their great physiological activity. Accumulation of nitro-groups at the same carbon atom in α-halogenonitroalkanes leads to an increase in acute toxicity, and a similar effect is observed with increase in the number of halogen atoms. Dihalogenodinitromethanes are the most toxic. Bromonitroalkanes are usually more toxic than their chlorinated analogues[297]. The majority of α-halogenonitroalkanes (but not 1,1-dichloro-1-nitroethane) have a lachrymatory action, which diminishes with increase in molecular weight[298,299].

The antibacterial activity of α-halogenonitroalkanes has been studied[297,300]. Derivatives of nitroethane are more active than those of nitromethane towards *Escherichia coli* and *Staphylococcus aureus pyogenes*[297]. The accumulation of bromine atoms in nitroalkanes leads to an increase in antibacterial activity. The bactericidal activity of α-halogenonitroalkanes is usually attributed to their oxidising power[300].

α-Halogenonitroalkanes exhibit a broad spectrum of activity and possess insecticidal[298–301], fungicidal[302–306], herbicidal[307], bactericidal[308], and nematocidal[302,308,309] properties. Trichloronitromethane and 1,1-dichloro-1-nitroethane are used as insecticides and fungicides either alone or mixed with other compounds[305,310]. "Mixed" α-halogenonitroalkanes, which possess greater activity, have been proposed as fumigants. Thus it is recommended that bromodifluoronitromethane should be used in amounts of 0.15–0.30 g m^{-3} to combat granary pests, and at doses below 448 kg per hectare to treat soil against nematodes[302]. Bromochloronitroalkanes containing 1–5 carbon atoms possess insecticidal and fungicidal activity[302,303].

α-Halogenonitroalkanes can be used also an antibacterial additives in diesel fuels, lubricating oils, and hydraulic fluids[311,312]. They have been recommended for combination with tetraethyl-lead in antiknock compositions, for the thinning and dispersion of oils[313], and for the deparaffination of diesel fuels and oils[314].

1-Chloro-1-nitroethane is an excellent agent for preventing the gelling of rubber additives[315].

α-Halogenonitroalkanes are used also as intermediates in the production of biologically active compounds[316], explosives, and rocket fuel components[137,224].

Studies in the Field of Boron-substituted Functional Derivatives of Carbaboranes(12)

V.N.Kalinin

The advances in the synthesis and chemical reactions of boron-substituted functional derivatives of carbaboranes are described. The qualitative and quantitative differences between the reactivities of the functional groups linked to the hexacoordinate boron atom in carbaboranes and the functional groups in the corresponding derivatives of tri-coordinate boron are demonstrated.
The bibliography includes 115 references.

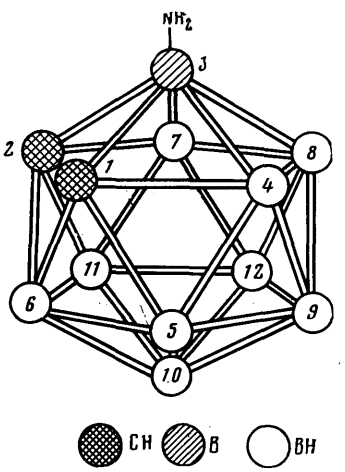
III. The electronic effects of *B*-carbaboranyl groups 1093

I. INTRODUCTION

One of the most important and interesting fields in the chemistry of carbaborane systems involves the study of the properties of boron-substituted carbaboranes. The increased coordination number of boron atoms in carbaboranes(12), which is 6, alters radically the properties of the functional groups linked to them compared with the compounds of tri-coordinate boron. The presence of an incomplete electron octet in the boron atom in the latter in many respects determines the high reactivity of compounds of this class, since attack by a given reagent is directed primarily to the central atom and this is responsible for the easy cleavage of the boron–element bonds. Boron-substituted carbaboranes exhibit a high chemical stability as regards the rupture of the boron–element bond and resemble chemically the corresponding aliphatic and aromatic derivatives. The lack of convenient methods for the introduction of functional groups at the boron atoms of the carbaborane nuclei retarded for a long time the development of this promising field and only the discovery in 1967 of the reaction involving the introduction of an amino-group into the carbaborane nucleus made it possible to develop extensively the chemistry of boron-substituted carbaboranes and to discover the characteristics and specific features of the behaviour of compounds of this class.



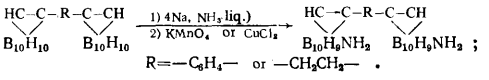
This review reflects the advances in the chemistry of boron-substituted functional derivatives of carbaboranes containing B–N, B–O, B–S, B–C, and B–element (element = metal or non-metal) bonds. The fundamental characteristics of the electrophilic and radical halogenation of carbaboranes will not be considered, since this problem has been described in detail in Grimes's monograph[1] and in dissertations[2–4]. One should only note that the method involving the use of *B*-halogenocarbaboranes for the synthesis of a wide variety of boron-substituted derivatives, which was at first sight seemingly extremely promising, did not justify the hopes associated with it because of the extremely low reactivity of the halogen in *B*-halogenocarbaboranes[5–7].

II. THE SYNTHESIS AND PROPERTIES OF BORON-SUBSTITUTED CARBABORANES

1. Carbaboranes with a B–N Bond

In 1967 Zakharkin and Kalinin found[8] that the dicarbadodecaborate(14) dianions, obtained as a result of the addition of two electrons to carbaboranes, react with liquid ammonia at a low temperature with liberation of hydrogen and the formation of *B*-aminated dianions. On oxidation with $KMnO_4$ or $CuCl_2$ in liquid ammonia, the latter are selectively converted into *o*-carbaborane derivatives containing the amino-group in the 3-position (see Figure):

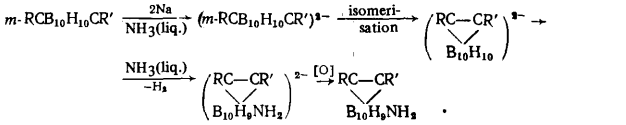
$$RC{-}CR' \xrightarrow[NH_3(liq.)]{2Na} \left(RC{-}CR'\right)^{2-} \xrightarrow[-H_2]{NH_3(liq.)} \left(RC{-}CR'\right)^{2-} \xrightarrow[NH_3(liq.)]{KMnO_4(CuCl_2)} RC{-}CR'$$
$$B_{10}H_{10} \qquad B_{10}H_{10} \qquad B_{10}H_9NH_2 \qquad B_{10}H_9NH_2$$



The structure of 3-amino-*o*-carbaborane.

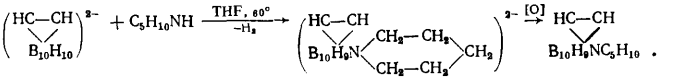
The amination of the dicarbadodecaborate(14) dianion represents nucleophilic substitution at the boron atom linked to the hydrogen atom exhibiting the greatest hydride mobility[8,9]. It has been shown[10] that, in the amination of the dianions, the attacking species is the amide ion. We believe[11] that the possibility of using catalytic amounts of sodium amide in the amination of the dianions apparently arises because the NH_2 group in the amino-derivative of the dianion is less acidic than ammonia. The mechanism of the amination of the dianions remains obscure since final data on the structure of the dicarbadodecaborate(14) dianions have not as yet been obtained.

On the basis of general considerations, one can assume that, when the dicarbadodecaborane(14) dianion is acted upon by ammonia, its *closo*-structure is opened (in the case of a closed structure of the dianion) and the amide ion attacks a specific boron atom, which differs from all others. In the case of an open structure of the dianion the amide ion also attacks only a specific boron atom, linked to the hydrogen atom exhibiting the greatest hydride mobility. On treatment with oxidants, a transition from the *nido*- to the *closo*-structure and the formation of *B*-amino-*o*-carbaborane are observed. This is supported also by the finding that only the monoamino-*o*-carbaborane is formed on amination, while derivatives of *o*-carbaborane with more than one NH_2 group cannot be obtained. Nor was the formation of isomeric *B*-amino-*o*-carbaboranes observed; the reaction product is always only 3-amino-*o*-carbaborane(11).



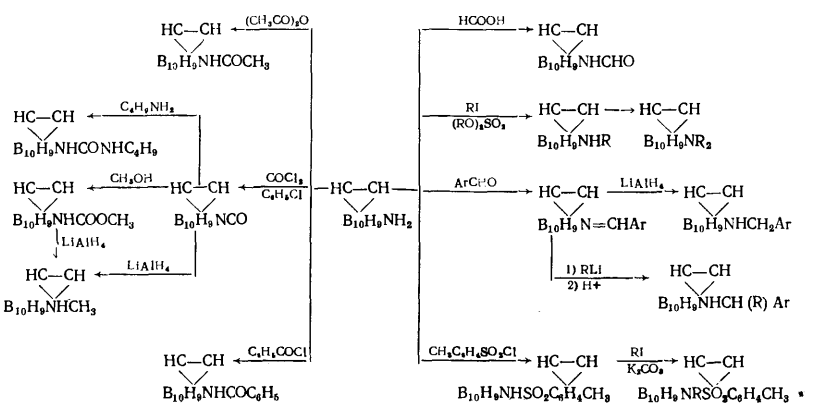
The reaction of dicarbadodecaborate(14) dianions with ammonia is influenced significantly by substituents at the carbon atoms. Whereas the dianion obtained from 1,2-dimethyl-*o*-carbaborane is aminated smoothly with formation of a *B*-amino-derivative, the dianion obtained from 1,2-diphenyl-*o*-carbaborane does not undergo the amination reaction. This is apparently associated with the large bulk of the phenyl groups compared with the methyl groups, which gives rise to steric hindrance to amination. The dianion derived from 1,1′-bis-*o*-carbaborane also does not undergo the amination reaction. *o*-Carbaboranes containing only one substituent at the carbon atom, i.e. 1-substituted *o*-carbaboranes, form dianions which readily undergo the amination reaction.

The application of this reaction to derivatives of *o*-carbaboranes containing two carbaborane nuclei proved to be of interest. It was found that *p*-bis-(*o*-carbaboranyl)benzene and 1,2-bis-(*o*-carbaboranyl)ethane combine with 4 equivalents of sodium to form bisdianions, which interact with ammonia and after oxidation give rise to *p*-bis-(3-amino-*o*-carbaboranyl)benzene and 1,2-bis-(3-amino-*o*-carbaboranyl)-ethane respectively[12,13]:

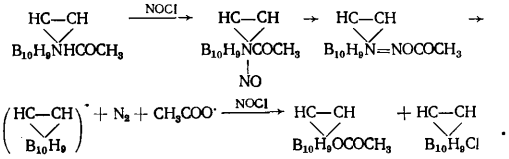


Polyamides[14] and polyureas[15] have been obtained from bis-(aminocarbaboranyl)ethane.

When an attempt is made to obtain *B*-amino-*m*-carbaborane by the reaction of the dianion derived from *m*-carbaborane with ammonia, only 3-amino-*o*-carbaborane is always formed[9]. As shown for the first time by Zakharkin et al.,[16] this is because the dianion obtained from *m*-carbaborane isomerises to the *o*-carbaborane dianion, which subsequently reacts with ammonia:



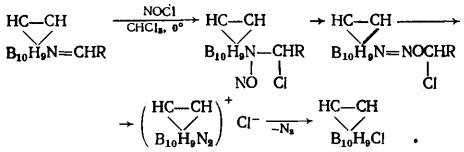
It was found that the dicarbadodecaborate(14) dianion can react with amines to form, after oxidation, derivatives with a B–N bond. Thus, on heating the dicarbadodecaborate(14) dianion in tetrahydrofuran (THF) with piperidine and subsequent oxidation with potassium permanganate in liquid ammonia, *N*-(3-*o*-carbaboranyl)piperidine was obtained[9]:



3-Amino-*o*-carbaboranes are colourless readily crystallisable substances resistant to the action of water, aqueous solutions of acids and alkalies, atmospheric oxygen, and heat. They undergo reactions characteristic of aliphatic and aromatic primary amines and are readily acylated by formic acid, acetic anhydride, benzoyl chloride, and *p*-toluenesulphonyl chloride to form the corresponding 3-acylamino-*o*-carbaboranes (Scheme 1).

Scheme 1

3-*o*-Carbaboranylamides of *p*-toluenesulphonic acid have NH groups exhibiting a considerable acidity and are readily alkylated by alkyl halides in acetone solution in the presence of potassium carbonate. When an attempt was made to obtain 3-(*N*-acetamido-*N*-nitroso)-*o*-carbaborane by treating 3-acetamido-*o*-carbaborane with nitrosyl chloride in a mixture of acetic acid and acetic anhydrides in the presence of sodium acetate, the reaction products were 3-acetoxy- and 3-chloro-*o*-carbaboranes[17]. The formation of these two compounds suggests that the decomposition of 3-(*N*-acetamido-*N*-nitroso)-*o*-carbaborane apparently proceeds similarly to the decomposition of *N*-acetyl-*N*-nitrosoarylamines, via a rearrangement to diazoacetate and radical cleavage of the latter. The 3-*o*-carbaboranyl radical formed on decomposition readily reacts with the acetoxy-radical to form 3-acetoxy-*o*-carbaborane, while on interaction with an excess of NOCl it abstracts the chlorine atom and is converted into 3-chloro-*o*-carbaborane:

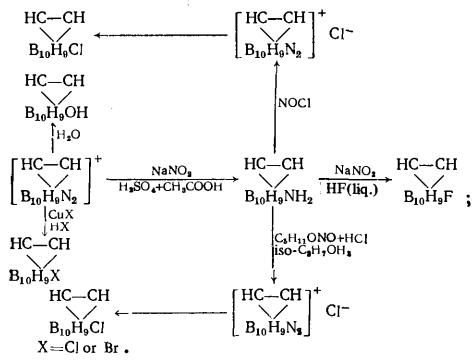


When phosgene is passed into a boiling solution of 3-amino-*o*-carbaborane in chlorobenzene, 3-*o*-carbaboranyl isocyanate is formed readily (Scheme 1). 3-*o*-Carbaboranyl isocyanates exhibit properties characteristic of aliphatic and aromatic isocyanates. For example, they readily react with alcohols and amines to form urethanes and asymmetrically substituted ureas respectively (Scheme 1). However, one should note the high hydrolytic stability of 3-*o*-carbaboranyl isocyanates, which are not hydrolysed on prolonged storage in a moist atmosphere.

The reduction of 3-*o*-carbaboranyl isocyanate with lithium tetrahydroaluminate in ethereal solution yields 3-methylamino-*o*-carbaborane, which is also formed on treatment of methyl 3-*o*-carbaboranyl-carbamate with lithium tetrahydroaluminate.

Like aliphatic and aromatic amines, 3-amino-*o*-carbaboranes condense with aromatic aldehydes to form analogues of Schiff bases containing a B—N bond[17]. *o*-Carbaborane Schiff bases can be readily reduced with lithium tetrahydroaluminate in ethereal solution to the corresponding *N*-arylalkylamines of the 3-*o*-carbaborane series.

o-Carbaborane Schiff bases readily react with organolithium compounds to form products of addition to the C=N double bond; on subsequent hydrolysis, 3-(*N*-alkyl-*N*-arylamino)-*o*-carbaboranes were obtained. *o*-Carbaborane azomethines are readily cleaved to the initial 3-amino-*o*-carbaborane and the aldehyde when they are chromatographed on alumina, which is an effective catalyst of the hydrolysis of azomethines.

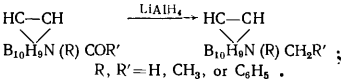


Nitrosyl chloride also cleaves *o*-carbaborane Schiff bases in chloroform, giving rise to *o*-carbaboranyldiazonium chloride, unstable at 0 °C, which decomposes with the liberation of nitrogen and the formation of 3-chloro-*o*-carbaborane[17]:

It is noteworthy that the 3-amino-*o*-carbaboranes themselves readily react with nitrosyl chloride to form 3-chloro-*o*-carbaboranes.

3-Amino-*o*-carbaboranes proved to be capable of being diazotised on treatment with various nitrosating agents with formation of 3-halogeno- and 3-hydroxy-*o*-carbaboranes (Scheme 2).

Scheme 2



When the diazonium salt obtained by the diazotisation of 3-amino-*o*-carbaborane with nitrosylsulphuric acid in acetic acid is decomposed, the product is 3-hydroxy-*o*-carbaborane[9,18,19]. However, rapid addition of a solution of the diazonium salt to a solution of a copper(I) salt in hydrochloric acid leads readily to the corresponding 3-halogeno-*o*-carbaboranes.

3-Amino-*o*-carbaboranes are also diazotised on treatment with pentyl nitrite in isopropyl alcohol saturated with hydrogen chloride. On subsequent increase of temperature, 3-chloro-*o*-carbaborane is formed[9]. 3-Amino-*o*-carbaboranes readily undergo the Schiemann reaction—the NH_2 groups is substituted by fluorine in liquid HF under the influence of sodium nitrite[9,20].

The decomposition of diazonium salts of the 3-*o*-carbaborane series in polar media apparently proceeds via the intermediate formation of the 3-*o*-carbaboranyl cation, which readily combines with a negative species (OH^-, Cl^-, Br^-, F^-) to form hydroxy- or halogeno-derivatives of the 3-*o*-carbaborane series.

3-Amino-*o*-carbaboranes are alkylated by alkyl sulphates or halides to form secondary and tertiary alkylaminocarbaboranes. The reduction of the corresponding acyl derivatives constitutes a method of synthesis of alkylated aminocarbaboranes which is preparatively more convenient[17]:

The arylation of 3-amino-*o*-carbaborane, which occurs readily when it is refluxed in an aromatic amine, for example, aniline or *p*-toluidine, in the presence of *p*-toluenesulphonic acid, is an interesting reaction[21,22]:

When 3-amino-*o*-carbaborane is heated to 200–300 °C in benzene under pressure, bis-(*o*-carbaboran-3-yl)amine is formed and NH_3 is evolved:

However, in the presence of an equimolar amount of *p*-toluenesulphonic acid, the unusual reaction involving the substitution of the NH_2 group in the *o*-carbaboranyl nucleus by the OH group takes place; the main product is 3-hydroxy-*o*-carbaborane. At the same time bis(carbaboranyl)amine and bis-(*o*-carbaboranyl) ether were isolated from the reaction products[22]:

The method involving the insertion-synthesis of dicarbollide ions with dialkyldiarylaminoboron dichlorides can be used to synthesise tertiary amines of the carbaborane series[23,24]:

$$7,8\text{-}C_2B_9H_{11}^{2-}2Na^+ + R_2NBCl_2 \rightarrow \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NR_2\end{matrix};$$
$$R = C_2H_5 \text{ or } C_6H_5 .$$

Primary and secondary amines of the 3-*o*-carbaboranes series readily interact with phenyl isocyanate to form asymmetrically substituted ureas[17]:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NHR\end{matrix} \xrightarrow{C_6H_5NCO} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NRCONHC_6H_5\end{matrix} .$$

Secondary amino-*o*-carbaboranes are readily nitrosated on treatment with sodium nitrite in acetic acid to form stable *N*-nitroso-derivatives. When 3-methylamino-*o*-carbaborane was treated with the nitrating mixture, 3-(*N*-alkylamino-*N*-nitro)-*o*-carbaborane was obtained:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(NO_2)R\end{matrix} \xleftarrow[H_2SO_4]{HNO_3} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NHR\end{matrix} \xrightarrow[CH_3COOH]{NaNO_2} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(NO)R\end{matrix} .$$

Treatment of 3-dimethylamino-*o*-carbaborane with methyl iodide in nitromethane leads to the formation of a quaternary salt—3-*o*-carbaboranyltrimethylammonium iodide; thermal decomposition of the salt gives rise to the initial tertiary amine only[17]:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(CH_3)_2\end{matrix} \xrightarrow[CH_3NO_2]{CH_3I} \left[\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(CH_3)_3\end{matrix}\right]^+ I^- \xrightarrow{200^\circ} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(CH_3)_2\end{matrix} .$$

This mode of thermal cleavage of the quaternary salt indicates a greater stability of the B—N bond compared with the C—N bond in this compound.

When an attempt is made to obtain 3-*o*-carbaboranyltrimethylammonium hydroxide by treating 3-*o*-carbaboranyltrimethylammonium iodide with moist silver oxide, the carbaborane nucleus is cleaved to the dicarbaundecaborate(13) anion with formation of an inner salt[17]:

$$\left[\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(CH_3)_3\end{matrix}\right]^+ I^- \xrightarrow{Ag_2O} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_9H_9^-{-}\overset{+}{N}(CH_3)_3\end{matrix} \xleftarrow[K_2CO_3]{CH_3I} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9N(CH_3)_2\end{matrix} .$$

The powerful electron-accepting effect of the trimethylammonium group in the 3-position in the *o*-carbaborane nucleus apparently destabilises the *o*-carbaborane system with respect to the action of bases. When tertiary amines of the *o*-carbaboranes series are synthesised by the direct alkylation of 3-amino-*o*-carbaborane with alkyl halides or dialkyl sulphates in the presence of potassium carbonate, the yield of the tertiary amine is apparently low and the main product is the inner salt of dicarbadodecahydro-*nido*-undecaborate(13). An interesting property of the inner salt is its ability to sublime *in vacuo* without decomposition.

Like aliphatic and aromatic formamides[25], the formyl derivatives of 3-amino-*o*-carbaboranes react with phosphoryl chloride in pyridine to form 3-*o*-carbaboranylisonitriles, which are capable of rearranging, after brief heating in boiling dodecane, to the corresponding 3-cyano-*o*-carbaboranes[26,27]:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NHCHO\end{matrix} \xrightarrow[C_5H_5N]{POCl_3} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NC\end{matrix} \xrightarrow{220^\circ} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9CN\end{matrix} .$$

This rearrangement is the first example of the migration of the carbaboranyl group with dissociation of the B—N bond and the formation of a B—C bond. The migration of the C≡N group in the carbaborane nucleus was not observed under these conditions.

m-Carbaboranes containing amino-groups attached to boron atoms are now known. They can be synthesised by several methods. The reaction of *N*-diphenylaminoboron dichloride with the 7,9-dicarbollide ion led to the synthesis of 2-diphenylamino-*m*-carbaborane[24]:

$$7,9\text{-}C_2B_9H_{11}^{2-}2Li^+ + (C_6H_5)_2NBCl_2 \rightarrow m\text{-}HCB_{10}H_9[2\text{-}N(C_6H_5)_2]CH .$$

Treatment of 2-carboxy-*m*-carbaborane (see Section III) with hydrazoic acid in H_2SO_4 (the Schmidt reaction) leads to the migration of the 2-*m*-carbaboranyl group with an excess of electrons towards the nitrogen atom, which has an electron sextet, and after hydrolysis the product is 2-amino-*m*-carbaborane[28,29]:

$$m\text{-}HCB_{10}H_9(2\text{-}COOH)CH \xrightarrow[H_2SO_4]{HN_3} m\text{-}HCB_{10}H_9(2\text{-}CONH{-}\overset{+}{N}{=}N)CH \xrightarrow{-N_2}$$
$$\rightarrow m\text{-}HCB_{10}H_9\left(2\text{-}\begin{matrix}C\\ \|\\ O\end{matrix}{-}\overset{+}{N}H\right)CH \xrightarrow{-H^+} m\text{-}HCB_{10}H_9(2\text{-}N{=}C{=}O)CH \xrightarrow{H^+}$$
$$\rightarrow m\text{-}HCB_{10}H_9(2\text{-}NH_2)CH .$$

A novel method of synthesising *B*-amino-*m*-carbaboranes involves the thermal isomerisation of 3-amino-*o*-carbaborane[22]. It was found that, when 3-amino-*o*-carbaborane is passed through a quartz tube at 550—600 °C *in vacuo*, equal amounts of 2- and 4-amino-*m*-carbaboranes are formed in high yields:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NH_2\text{-}3\end{matrix} \xrightarrow{550\text{-}600^\circ} m\text{-}HCB_{10}H_9(2\text{-}NH_2)CH + m\text{-}HCB_{10}H_9(4\text{-}NH_2)CH .$$

An interesting method for the synthesis of 3-alkyl-2-amino-*m*-carbaboranes consists in the treatment with alkyl iodides in liquid ammonia of the dianion derived from *o*-carbaborane subjected to preliminary amination[30,31]:

$$\left(\begin{matrix}RC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_{10}\end{matrix}\right)^{2-} \xrightarrow[-H_2]{NH_3(liq.)} \left(\begin{matrix}RC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_9NH_2\end{matrix}\right)^{2-} \xrightarrow{Alkl} \begin{matrix}RC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_8(NH_2)(Alk)\end{matrix} .$$
$$R = H, CH_3$$

The structure of the compounds obtained was demonstrated by X-ray diffraction of their reaction products—3-alkyl-2-chloro-9-iodo-*m*-carbaboranes—obtained as a result of the replacement of the amino-group by chlorine with subsequent monoiodination[32].

It has been found[22] that 2- and 4-amino-*m*-carbaboranes exhibit properties typical for organic amines and differ little in their chemical behaviour from 3-amino-*o*-carbaborane.

Thus it has been shown in relation to the reactions of aminocarbaboranes that the behaviour of the NH_2 group in these compounds differs little from that of the behaviour of the same group in aliphatic and aromatic amines. In contrast to the readily hydrolysable and oxidisable classical aminoboranes, aminocarbaboranes are stable organoelemental compounds capable of undergoing a wide variety of reactions via the NH_2 group. This is true also of other carbaborane derivatives containing the B—N bond, which were examined in this section.

2. Carbaboranes with a B—C Bond

A number of *B*-alkyl and *B*-aryl derivatives of carbaboranes have been obtained. A patent[33] reports the alkylation of *o*-carbaborane with methyl iodide in the presence of $AlCl_3$, which results in the formation of a mixture of different polymethylated carbaboranes, none of which have been isolated in a pure form:

$$\begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_{10}\end{matrix} + CH_3I \xrightarrow{AlCl_3} \begin{matrix}HC{-}CH\\ \diagdown\ \diagup\\ B_{10}H_{10-n}(CH_3)_n\end{matrix};$$
$$n = 1\text{—}8 .$$

o-Carbaboranes and *m*-carbaboranes are alkylated in exactly the same way under the conditions of the Friedel—Crafts reaction with ethyl bromide and isopropyl bromide[34].

Up to eight ethyl groups can be introduced into the *o*- and *m*-carbaborane molecules, but in the case of isopropyl bromide the main products are mono- and di-substituted derivatives. The rate of electrophilic alkylation of *m*-carbaborane is lower than that of *o*-carbaborane.

The reaction of a mixture of 1- and 2-ethyldecaboranes with acetylene in acetonitrile yields a mixture of 8- and 9-ethyl-*o*-carbaboranes[35]:

$$HC{\equiv}CH + 1\text{- и } 2\text{-}B_{10}H_{13}C_2H_5 \xrightarrow[-H_2]{CH_3CN} \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9C_2H_5 \end{matrix}\text{-(8 and 9)}.$$

A convenient method for the synthesis of alkyl and aryl derivatives of *o*-carbaboranes is based on insertion synthesis with 7,8-dicarbollide ion to form the icosahedral structure with alkyl- and aryl-boron dihalides, discovered by Hawthorne and Wegner in 1965[36,37]:

$$7,8\text{-}C_2B_9H_{11}^{2-}2Na^+ + RBCl_2 \rightarrow \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9R\text{-}3 \end{matrix}.$$

The structure is formed in such a way that the substituent is bound to the boron atom in the 3-position of the *o*-carbaborane nucleus. 3-Methyl-,[29] 3-ethyl-,[37] 3-propyl-,[38] 3-butyl-,[38] 3-vinyl-,[39] and 3-phenyl-*o*-carbaboranes[36,37] as well as various 3-aryl-*o*-carbaboranes substituted in the benzene ring, and *p*- and *m*-tolyl and *p*- and *m*-fluorophenyl-*o*-carbaboranes[40-44] have been synthesised in this way.

It is of interest to note that 3,6-diethyl- and 3,6-diphenyl-*o*-carbaboranes have been synthesised by this method[37]:

$$C_2B_9H_{11}^{2-} + RBCl_2 \rightarrow \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9R \end{matrix} \xrightarrow[2)\ NaH]{1)\ C_2H_5ONa} C_2B_9(R)H_{10}^{2-} \xrightarrow{RBCl_2} \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_8R_2 \end{matrix};$$
$$R = C_2H_5 \text{ or } C_6H_5.$$

The preparation of 1,4-bis-(3-*o*-carbaboranyl)butane containing two 3-*o*-carbaboranyl groups in the molecule has been reported[38]:

$$2C_2B_9H_{11}^{2-} + Cl_2B(CH_2)_4BCl_2 \rightarrow \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9(CH_2)_4B_{10}H_9 \end{matrix} \quad \begin{matrix} HC{-}CH \\ \diagdown\diagup \end{matrix}.$$

Insertion synthesis of structures with the aid of alkyl(aryl)-boron dihalides has been extended to the 7,9-dicarbollide ion and 2-vinyl-[28,29] and 2-aryl-*m*-carbaboranes[45] have been obtained by this procedure:

$$7,9\text{-}C_2B_9H_{11}^{2-}2Li^+ + RBCl_2 \rightarrow m\text{-}HCB_{10}H_9(2\text{-}R)CH;$$
$$R = CH_2{=}CH,\ C_6H_5,\ FC_6H_4 \text{ or } CH_3C_6H_4.$$

A general method of synthesis of substituted *o*-carbaboranes containing a B–C bond consist in the interaction of the dicarbadodecaborate(14) dianions with organolithium and organomagnesium compounds, resulting in the formation of *B*-alkyl(alkenyl, aryl) dianions, which give rise to *B*-alkyl-(alkenyl, aryl)-*o*-carbaboranes after oxidation with $CuCl_2$[46-48]:

$$(HCB_{10}H_{10}CH)^{2-} + RM \xrightarrow[20^\circ]{THF} (HCB_{10}H_9RCH)^{2-} \xrightarrow{CuCl_2} \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9R \end{matrix};$$
$$M = Li \text{ or } MgX;\ R = CH_3,\ C_4H_9,\ CH_2{=}CH,\ C_6H_5CH{=}CH,$$
$$C_6H_5,\ CH_3C_6H_4, \text{ or } FC_6H_4.$$

The reaction is not selective—a mixture of *B*-substituted carbaboranes containing the substituent in the 3-, 4-, 8-, and 9-positions in the *o*-carbaborane nucleus is always formed. X-Ray diffraction analysis of 1,2-dimethyl-9-phenyl-*o*-carbaborane and 4-(*p*-tolyl)-*o*-carbaborane has been carried out[48].

The reaction of the dianions with organometallic compounds is influenced significantly by the acidity of the hydrocarbon conjugate acid of the carbanion of the organometallic compound. For example, this reaction is not undergone by indenyl-lithium, fluorenyl-lithium, phenylethynyl-lithium, carboranyl-lithium, and cyclopentadienyl-lithium[46].

When the dicarbadodecaborate(14) dianion, obtained from *p*-carbaborane, interacts with arylmagnesium halides and the product is then oxidised, mainly a mixture of *B*-aryl-*m*-carbaboranes is obtained[47,48]:

$$p\text{-}HCB_{10}H_{10}CH \xrightarrow[THF]{2Na} (HCB_{10}H_{10}CH)^{2-} + ArMgX \rightarrow (HCB_{10}H_9ArCH)^{2-} \xrightarrow{CuCl_2} m\text{-}HCB_{10}H_9ArCH.$$

Apart from insertion syntheses of the 7,9-dicarbollide ion, high-temperature gas-phase isomerisation of 3-aryl-*o*-carbaboranes *in vacuo*, leading to 2- and 4-aryl-*m*-carbaboranes, has been proposed as a method of synthesis of aryl-*m*-carbaboranes[49,50]:

$$\begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9Ar \end{matrix} \xrightarrow{550-600^\circ} m\text{-}HCB_{10}H_9(2\text{-}Ar)CH + m\text{-}HCB_{10}H_9(4\text{-}Ar)CH.$$

Mironov and coworkers found[51-55] that trichlorovinylsilane alkylates *o*-, *m*-, and *p*-carbaboranes and their derivatives under the conditions of the Friedel–Crafts reaction via the B–H bonds of the carbaborane nuclei:

$$HCB_{10}H_{10}CH + CH_2{=}CHSiCl_3 \xrightarrow{AlCl_3} HCB_{10}H_{10-n}(CH_2CH_2SiCl_3)_nCH;$$
$$n = 1-3.$$

Chloromethylvinylsilanes also alkylate carbaboranes under analogous conditions, but, in view of the lower reactivity, the yields of the corresponding products are sharply reduced[55]:

$$HCB_{10}H_{10}CH + CH_2{=}CHSi(CH_3)_xCl_{3-x} \xrightarrow{AlCl_3} HCB_{10}H_{10-n}[CH_2CH_2Si(CH_3)_xCl_{3-x}]_nCH.$$

The mechanism of the silylalkylation of carbaboranes is analogous to the mechanism of the Friedel–Crafts reaction, the sites of the highest electron density in the nuclei being attacked; the trichlorosilylethyl group is therefore located at the boron atoms in the 9(12)-positions in *o*-carbaborane, the 9(10)-positions in *m*-carbaborane, and the 2-position in *p*-carbaborane. The structure of 1,7-bis(trimethylstannyl)-9-[β-(trimethylsilyl)ethyl]-*m*-carbaborane has been confirmed by X-ray diffraction[56].

Studies of the infrared and mass spectra of *B*-substituted carbaboranes have been carried out[57-59].

The formation of aminated *B*-alkyl-*m*-carbaboranes was mentioned above. The special case of the reaction of methyl iodide with the dianion derived from 1,2-di-methyl-*o*-carbaborane in liquid ammonia, resulting in the formation of a mixture of alkylated isomers of *o*- and *m*-carbaboranes[31], is noteworthy:

$$\left(\begin{matrix} CH_3C{-}CCH_3 \\ \diagdown\diagup \\ B_{10}H_{10} \end{matrix}\right)^{2-} \xrightarrow[2)\ CH_3I]{1)\ Ni(NH_3)_6\ (ж)} \underset{(2\text{-isomers})}{CH_3CB_{10}H_9(CH_3)CCH_3} + \underset{(2\text{-isomers})}{CH_3CB_{10}H_8(CH_3)_2CCH_3}.$$

One of the isomers is 1,2,3,6-tetramethyl-*o*-carbaborane[31].

The first functional derivative in the series of carbaboranes, containing a B–C bond, was obtained by Zakharkin and Kalinin in 1968.[39] Oxidation of 3-vinyl-*o*-carbaborane with chromium trioxide in a mixture of acetic and sulphuric acids gives a high yield of 3-carboxy-*o*-carbaborane:

$$\begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9CH{=}CH_2 \end{matrix} \xrightarrow{CrO_3} \begin{matrix} HC{-}CH \\ \diagdown\diagup \\ B_{10}H_9COOH \end{matrix}.$$

2-Carboxy-*m*-carbaborane has been obtained by an analogous mechanism from 2-vinyl-*m*-carbaborane[28,29].

o-Carbaborane- and *m*-carbaborane-carboxylic acids have been synthesised by the hydrolysis of 3-cyano-*o*-, 2-cyano-*m*-, and 4-cyano-*m*-carbaboranes[27,60]. Owing to the considerable bulk of the carbaborane nuclei, *B*-cyanocarbaboranes can be hydrolysed only by a two-stage method: in the first stage hydrolysis with sulphuric acid results in the formation of an amide, which is converted into the acid on subsequent treatment with sodium nitrite:

$$HCB_{10}H_9(CN)CH \xrightarrow[CH_3COOH,\ 110^\circ]{H_2SO_4} HCB_{10}H_9(CONH_2)CH \xrightarrow[10^\circ]{NaNO_2} HCB_{10}H_9(COOH)CH.$$

The oxidation of *B*-trimethylsilylethylcarbaboranes with chromium trioxide in a mixture of acetic and sulphuric acids gave 9-carboxy-*o*- and 9-carboxy-*m*-carbaboranes[61,62]:

$$HCB_{10}H_9[9\text{-}CH_2CH_2Si(CH_3)_3]CH \xrightarrow{CrO_3} HCB_{10}H_9(9\text{-}COOH)CH .$$

3-Carboxy-*o*-carbaboranes have the properties of the usual organic acids. They are soluble in aqueous solutions of alkalies and form 3-methoxycarbonyl-*o*-carbaboranes on reaction with diazomethane in ether. In contrast to 1-carboxy-*o*-carbaboranes, 3-carboxy-*o*-carbaboranes are esterified with methanol in the presence of H_2SO_4:

$$\underset{B_{10}H_9COOH}{HC-CH} \xrightarrow[\text{or } CH_3OH,\ H_2SO_4]{CH_2N_2,\ (C_2H_5)_2O} \underset{B_{10}H_9COOCH_3}{HC-CH} .$$

Treatment of 3-carboxy-*o*-carbaboranes with PCl_5 in benzene or with $SOCl_2$ leads to the formation of acid chlorides whose properties are similar to those of the usual carboxylic acid chlorides:

$$\underset{B_{10}H_9COOH}{HC-CH} \xrightarrow[\text{or } SOCl_2]{PCl_5,\ C_6H_6} \underset{B_{10}H_9COCl}{HC-CH} \begin{cases} \xrightarrow{LiAlH_4} \underset{B_{10}H_9CH_2OH}{HC-CH} \\ \xrightarrow[AlCl_3]{C_6H_6} \underset{B_{10}H_9COC_6H_5}{HC-CH} \end{cases} .$$

The reduction of the acid chloride with lithium tetrahydroaluminate in ether leads smoothly to the formation of 3-hydroxymethyl-*o*-carbaborane, while its refluxing in benzene in the presence of $AlCl_3$ gave 3-benzoyl-*o*-carbaborane via the Friedel–Crafts reaction[63].

The reduction of 3-benzoyl-*o*-carbaborane with lithium tetrahydroaluminate in ether led to the formation of a secondary alcohol, while the reaction with CH_3MgI gave a tertiary alcohol[63]:

$$\underset{\substack{B_{10}H_9C(OH)(CH_3)(C_6H_5)}}{HC-CH} \xleftarrow{CH_3MgI} \underset{B_{10}H_9COC_6H_5}{HC-CH} \xrightarrow{LiAlH_4} \underset{B_{10}H_9CH(OH)C_6H_5}{HC-CH} .$$

The large bulk of the *o*-carbaboranyl group influences the state of the OH group in primary, secondary, and tertiary alcohols of the type $B_{10}H_9\underset{}{\overset{HC-CH}{}}CRR'OH$. Whereas the infrared spectrum of 3-hydroxymethyl-*o*-carbaborane exhibits a broad absorption band at 3200–3500 cm^{-1} due to the OH group of the associated alcohol, the infrared spectrum of (3-*o*-carbaboranyl)phenylmethanol has two absorption bands due to the OH group: a broad band at 3200–3500 cm^{-1}, characteristic of associated alcohols, and a narrow band at 3550–3580 cm^{-1}, characteristic of unassociated alcohols. The infrared spectrum of the tertiary alcohol shows a single narrow band at 3550–3580 cm^{-1}, which indicates the existence of this alcohol solely in the unassociated state. A similar behaviour has been observed for primary, secondary, and tertiary alcohols, where the substituent was the 1-*o*-carbaboranyl group[64].

The hydroxy-group in 3-hydroxymethyl-*o*-carbaborane is readily substituted by chlorine on refluxing with PCl_5 or $SOCl_2$ in benzene:

$$\underset{B_{10}H_9CH_2OH}{HC-CH} \xrightarrow[\text{or } SOCl_2]{PCl_5,\ C_6H_6} \underset{B_{10}H_9CH_2Cl}{HC-CH} .$$

3-Chloromethyl-*o*-carbaborane formed a Grignard reagent in ethereal solution, the carboxylation of which led to the formation of 3-*o*-carbaboranylacetic acid[63]:

$$\underset{B_{10}H_9CH_2Cl}{HC-CH} \xrightarrow[(C_2H_5)_2O]{Mg} \underset{B_{10}H_9CH_2MgCl}{HC-CH} \begin{cases} \xrightarrow[2)\ H^+]{1)\ CO_2} \underset{B_{10}H_9CH_2COOH}{HC-CH} \\ \xrightarrow{H^+} \underset{B_{10}H_9CH_3}{HC-CH} \xleftarrow{7,8\text{-}C_2B_9H_{11}^{2-}} +CH_3BCl_2 . \end{cases}$$

The hydrolysis of 3-*o*-carbaboranylmethylmagnesium chloride yielded 3-methyl-*o*-carbaborane, which is also formed when the disodium salt of the 7,8-dicarbollide ion reacts with methylboron dichloride in THF.[29,65]

3-Carboxy-*o*-carbaborane can interact with four equivalents of methyl-lithium in ether and after hydrolysis the product is 3-acetyl-*o*-carbaborane. A ketone can also be obtained when three equivalents of methyl-lithium react with 3-cyano-*o*-carbaborane:

$$\underset{B_{10}H_9COOH}{HC-CH} \xrightarrow{4CH_3Li} \underset{\substack{B_{10}H_9C(OLi)(CH_3)(OLi)}}{LiC-CLi} \xrightarrow{H^+} \underset{B_{10}H_9COCH_3}{HC-CH} \xrightarrow{H^+}$$

$$\underset{B_{10}H_9CN}{HC-CH} \xleftarrow{3CH_3Li} \underset{\substack{B_{10}H_9C(NLi)(CH_3)}}{LiC-CLi} .$$

The chemical properties of 3-carboxy-*o*-carbaborane examined above are also characteristic of other representatives of carbaboranecarboxylic acids—2- and 4-carboxy-*m*-carbaboranes[60] and 9-carboxy-*o*- and 9-carboxy-*m*-carbaboranes[55,61,62].

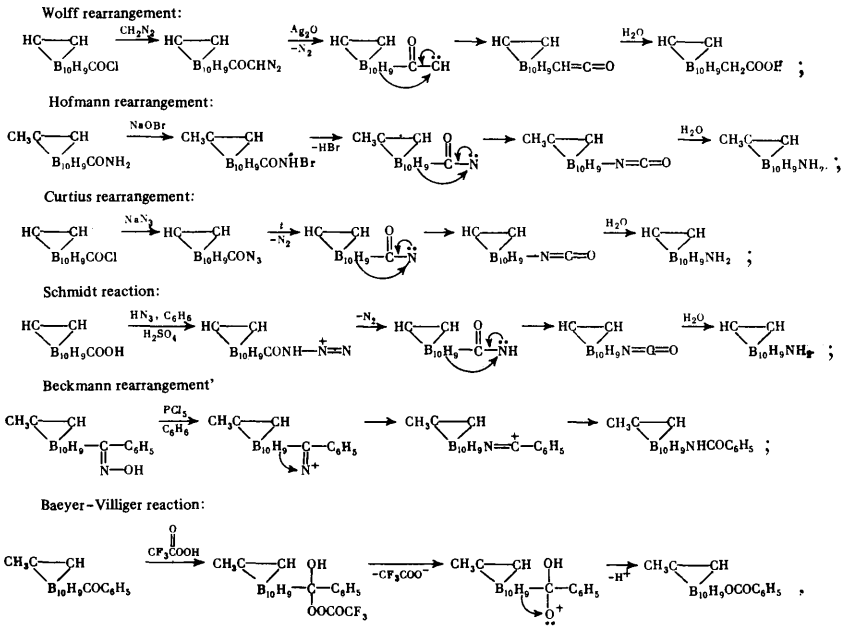
Silyl and stannyl derivatives of these acids have been obtained from 9-carboxy-*o*-carbaborane and hexamethyldisilazane or hexaethyldistannoxane[62]:

$$\underset{B_{10}H_9COOSi(CH_3)_3}{HC-CH} \xleftarrow[-NH_3]{(CH_3)_3SiNHSi(CH_3)_3} \underset{B_{10}H_9COOH}{HC-CH} \xrightarrow{(C_2H_5)_3SnOSn(C_2H_5)_3} \underset{B_{10}H_9COOSn(C_2H_5)_3}{HC-CH} .$$

A remarkable feature of *B*-carboxycarbaboranes and their derivatives is the possibility of nucleophilic molecular rearrangements accompanied by the dissociation of the B–C bond and the migration of the carbaboranyl group with an electron pair to an electron-deficient reaction centre[63]. The carbaboranyl group migrates to a carbenoid carbon atom (the Wolff rearrangement), a nitrene (the Hofmann, Curtius, and Beckmann rearrangements and the Schmidt reaction), or an oxygen atom with a positive charge (the Baeyer–Villiger reaction) (Scheme 3):

It has been established that these rearrangements proceed intramolecularly, the electron pair does not migrate to other boron atoms in the carbaborane nuclei, and the new B–C, B–N, and B–O bonds are formed with the same boron atom to which the functional group had been linked initially.

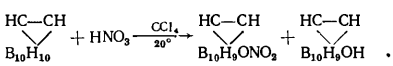
Analysis of the literature data for the Curtius rearrangement[66] and the Baeyer–Villiger reaction[67] in the series of polyhedral ions $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ suggests that molecular nucleophilic rearrangements typical for organic chemistry are applicable to the dissociation of the B–C bond when the boron atom forms part of polyhedral borane anions or carbaboranes.



B-Alkenylcarbaboranes undergo the usual reactions characteristic of double bonds. For example, treatment of 3-vinyl-*o*-carbaborane with ozone yields 3-formyl-*o*-carbaborane[39] and hydrostannylation of 2-vinyl-*m*-carbaborane leads to a high yield of 2-triethylstannyl-*m*-carbaborane[68]:

$$\underset{B_{10}H_9CH=CH_2}{HC-CH} \xrightarrow{O_3} \underset{B_{10}H_9CHO}{HC-CH} ;$$

$$м\text{-}HCB_{10}H_9(-CH=CH_2)CH \xrightarrow{(C_2H_5)_2SnH} м\text{-}HCB_{10}H_9[-CH_2CH_2Sn(C_2H_5)_3]CH .$$



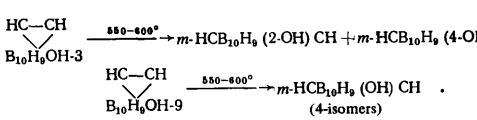
The study of the chemical properties of carbaborane derivatives containing a B–C bond and with functional groups attached to boron atoms, namely carboxy-*o*-carbaboranes and their derivatives, acyl derivatives of carbaboranes, and hydroxy- and chloromethyl-carbaboranes, showed that their chemical properties are similar to those of the corresponding aliphatic and aromatic organic derivatives with *C*-functional groups.

Scheme 3

3. Carbaboranes with a B–O Bond

Historically *B*-hydroxycarbaboranes have been the first known type of compounds containing a functional group attached to a boron atom. In 1965 it was noted[69,70] that prolonged oxidation of *o*-carbaboranes with 100% nitric acid in CCl_4 results in the formation of *B*-hydroxycarbaboranes and the corresponding nitrates:

The sites with the highest electron density in the carbaborane nucleus are the first to be oxidised by nitric acid, i.e. the *B*-hydroxycarbaboranes obtained are largely 9-substituted isomers.



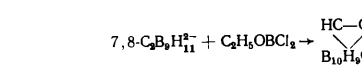
It was found subsequently[71,72] that *o*-, *m*-, and *p*-carbaboranes undergo oxidative hydroxylation on treatment with $KMnO_4$ in acetic acid with formation of all possible isomers: four in the case of *o*- and *m*-carbaboranes and one in the case of *p*-carbaborane:

The oxidation of carbaboranes by treatment with CrO_3 is more selective and in this case the formation of mainly 9-substituted products was observed for *o*- and *m*-carbaboranes[72].

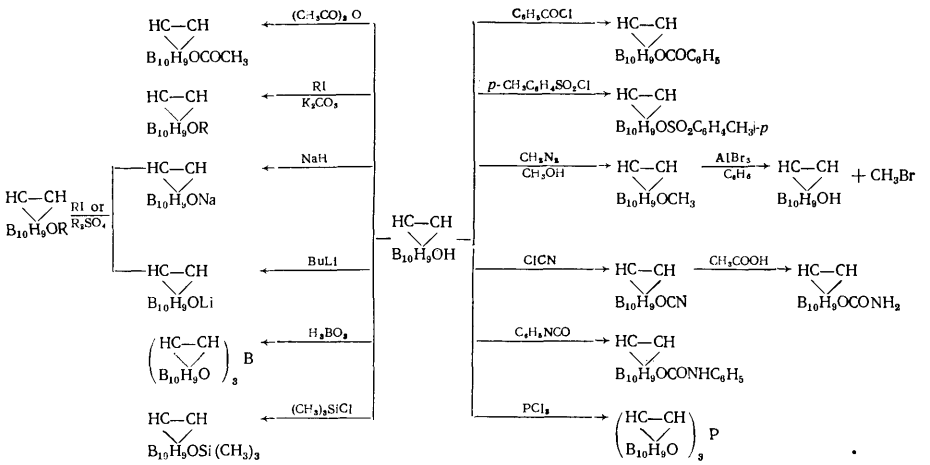
The diazotisation of *B*-amino-*o*-carbaborane with nitrosylsulphuric acid is a convenient method for the synthesis of 3-hydroxy-*o*-carbaboranes[18,19].

Thermal isomerisation of 3-hydroxy-*o*-carbaborane in a flow system at 550–600 °C leads to the formation of 2- and 4-hydroxy-*m*-carbaboranes only, while the isomerisation of 9-hydroxy-*o*-carbaborane gives rise to a mixture of all possible isomeric *B*-hydroxy-*m*-carbaboranes[60]:

3-Hydroxy-*o*- and 2-hydroxy-*m*-carbaboranes readily undergo intramolecular and nucleophilic cleavage in an alkaline medium, forming the corresponding dicarbaundecaborate(13) anions[73]:



B-Hydroxycarbaboranes have the properties of the usual organic hydroxy-derivatives. We shall consider their chemical behaviour in relation to the most thoroughly investigated 3-hydroxy-*o*-carbaboranes. They readily react with acylating agents, such as acetic anhydride, benzoyl chloride and *p*-toluenesulphonyl chloride, forming the corresponding acyloxy-derivatives[19] (Scheme 4):

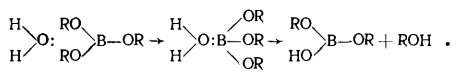


3-*o*-Carbaboranyl tosylates proved to be relatively unreactive in nucleophilic substitution reactions. When 3-*o*-carbaboranyl tosylate was heated with NaI in acetone at 140 °C for 10 h, no substitution products were observed. This result is consistent with the low reactivity of *B*-halogeno-*o*-carbaboranes in nucleophilic substitution reactions[11].

The following procedures can be used to synthesise 3-alkoxycarbaboranes (Scheme 4): (a) treatment of 3-hydroxy-*o*-carbaborane with diazomethane in methanol solution; (b) heating of an acetone solution of 3-hydroxy-*o*-carbaborane with an alkyl iodide in the presence of potassium carbonate; (c) treatment with alkyl iodides or dialkyl sulphates of lithium or sodium 3-*o*-carbaboranoxides prepared by the reaction of butyl-lithium or sodium hydride with 3-hydroxy-*o*-carbaboranes.

3-Ethoxy-*o*-carbaborane has been obtained by the insertion synthesis reaction of the 7,8-dicarbollide ion with ethoxyboron dichloride[23]:

Scheme 4



In contrast to boric acid esters, carbaborane ethers are resistant to hydrolysis but, on heating of 3-methoxy-*o*-carbaborane with $AlBr_3$ in benzene, the C–O bond is cleaved with exclusive formation of 3-hydroxy-*o*-carbaborane, while the B–O bond remains unaffected[19].

In this respect 3-methoxy-*o*-carbaboranes behave similarly to mixed aliphatic-aromatic ethers, the 3-*o*-carbaboranyl group playing the role of an aromatic group.

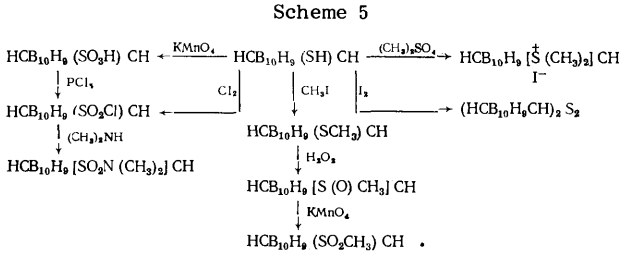
3-Hydroxy-*o*-carbaboranes react smoothly with boric acid, chlorotrimethylsilane, and phosphorus trichloride to form the corresponding ester or ether (Scheme 4).[19]

When 3-hydroxy-*o*-carbaborane reacts with chlorocyanogen in acetone in the presence of triethylamine, 3-*o*-carbaboranyl cyanate is formed smoothly. 3-Carbaboranyl cyanates are solid crystalline substances, which are stable in air. In contrast to aliphatic cyanates, they do not tend to isomerise and trimerise even in the presence of an active catalyst such as $AlCl_3$. 3-*o*-Carbaboranyl cyanates react with acetic acid to form carbamates. The reaction of 3-hydroxy-*o*-carbaborane with phenyl isocyanate leads to the corresponding urethane[11].

In contrast to alkyl(aryl)boronic acids and dialkyl(diaryl)-borinic acids, *B*-hydroxy-*o*-carbaboranes have chemical properties similar to those of aliphatic and aromatic hydroxy-derivatives. The unusually high hydrolytic stability of tris-(3-*o*-carbaboranyl) borate, which is not decomposed by water to boric acid and 3-hydroxy-*o*-carbaborane, in contrast to the readily hydrolysable alkyl and aryl borates[74], proved to be of interest. In the light of the mechanism proposed for the hydrolysis of borate esters[74], the hydrolytic stability can apparently be accounted for by the large bulk of the carbaborane nuclei, which hinders the formation of an intermediate complex with water:

Kalinin and Zakharkin[75,76] discovered an interesting reaction involving the formation of the B–O bond in carbaboranes, which consists in the interaction of the dicarbadodecaborate(14) dianions with aromatic aldehydes and subsequent oxidation of the intermediates to neutral carbaboranes. It was found that the dicarbadodecaborate(14) dianion, obtained from *o*-carbaborane, resembles in terms of some of its properties the tetrahydroborate anion BH_4^-. This is reflected in the ability of the dianion derived from *o*-carbaborane to add to the carbonyl group of benzaldehyde, as a result of the dissociation of the B–H bond with formation of *B*-benzyloxy-dianions, the oxidation of which with copper(II) chloride in THF leads to *B*-benzyloxy-*o*-carbaboranes in high yields:

Although the structure of the dicarbadodecaborate(14) dianions has not been elucidated, there is no doubt that their addition to the carbonyl group of benzaldehyde should proceed via the B–H bonds exhibiting the highest hydride mobility. The main products of the oxidation of benzyloxy-dianions are 3-benzyloxy-*o*-carbaborane (75–80% yield) and 4-benzyloxy-*o*-carbaborane (20–25% yield). 4-Benzyloxy-*o*-carbaborane has been investigated by X-ray diffraction[77].



4. Carbaboranes with a B–S Bond

A general method of synthesis of *B*-mercaptocarbaboranes, consisting of the treatment of carbaboranes with elemental sulphur in the presence of $AlCl_3$, has been developed[78,79]:

The sulphur atom in *B*-mercaptocarbaboranes is linked to the boron atom in the 9-position in *o*- and *m*-carbaboranes and in the 2-position in *p*-carbaborane. The chemical properties of 9-mercapto-*o*- and 9-mercapto-*m*-carbaboranes, the main transformation cycle of which is illustrated in Scheme 5, have been investigated in detail[80,81]:

Scheme 5

The oxidation of mercaptans with $KMnO_4$ leads to sulphonic acids, which can be readily converted into sulphonyl chlorides and dimethylamides. In an alkaline medium mercaptans are readily *S*-alkylated by virtually any alkylating agents with formation of, for example, methylthiocarbaborane and carbaboranyldimethylsulphonium iodide. The oxidation of methylthiocarbaborane yields either carbaboranyl methyl sulphoxide or the corresponding sulphone, depending on the oxidation potential of the reactant. When mercaptocarbaboranes are treated with iodine, biscarbaboranyl disulphides are formed smoothly and can be reduced in their turn with zinc in acetic acid to mercaptans[78,80,81].

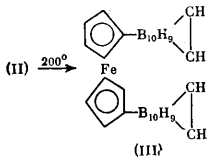
One may conclude that the sulphur derivatives of carbaboranes containing a B–S σ-bond have properties analogous to those of sulphur derivatives with a C–S bond.

5. Carbaboranes with a B–Metal Bond

A number of carbaborane derivatives containing a bond between boron and a transition or non-transition metal are known. It now appears that there are favourable prospects for the development of the chemistry of this extremely interesting class of compounds.

o-Carbaborane derivatives containing a σ-bond between boron and a transition metal were first obtained[82] via acyl derivatives. The reaction of the chloride of 3-*o*-carbaboranecarboxylic acid with $NaFe(CO)_2C_5H_5$-π leads to σ-(*o*-carbaboranyl-3-carbonyl)-π-cyclopentadienyliron dicarbonyl, the decarbonylation of which yields σ-(*o*-carbaboran-3-yl)-π-cyclopentadienyliron dicarbonyl (I):

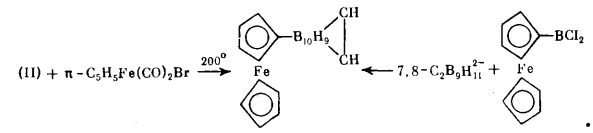
$$\mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9COCl}) + \mathrm{NaFe(CO)_2C_5H_5}\text{-}\pi \xrightarrow[\mathrm{THF}]{-70^\circ} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9COFe(CO)_2C_5H_5}\text{-}\pi) \xrightarrow[-\mathrm{CO}]{170^\circ} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9Fe(CO)_2C_5H_5}\text{-}\pi)\ (\mathrm{I})\ .$$



The rhenium derivative has been obtained via a similar mechanism[83]:

$$\mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9COCl}) + \mathrm{NaRe(CO)_5} \xrightarrow[\mathrm{THF}]{-70^\circ} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9CORe(CO)_5}) \xrightarrow{t^\circ} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9Re(CO)_5})\ .$$

The reaction of halogens with a complex containing a B–Fe bond is of interest. The reaction of compound (I) with chlorine or bromine entails a rearrangement accompanied by the dissociation of the B–Fe bond and the migration of the carbaboranyl group to the cyclopentadienyl ring with formation of π-[(*o*-carbaboran-3-yl)cyclopentadienyl]dicarbonyliron halide (II)[84,85]:



$$(\mathrm{I}) \xrightarrow[\mathrm{CCl_4}]{\mathrm{X_2}} \pi\text{-}\left(\mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9C_5H_4})\right)\mathrm{Fe(CO)_2X}\ ;\quad \mathrm{X = Cl\ or\ Br}\ (\mathrm{II})\ .$$

Heating of compound (II, X = Br) at 200 °C in decalin leads to 1,1′-bis-(*o*-carbaboran-3-yl)ferrocene (III)[85,86]:

(III)

If complex (II) is heated in the presence of $\pi\text{-}C_5H_5Fe(CO)_2.Br$, then (*o*-carbaboran-3-yl)ferrocene is obtained together with ferrocene and compound (III); (*o*-carbaboran-3-yl)-ferrocene has also been obtained by specific synthesis from ferrocenylboron dichloride and the 7,8-dicarbollide ion[85,86]:

The polarographic reduction of carbaborane complexes with a B–Fe σ-bond proceeds in the same way as for the usual σ-alkyl derivatives and the primary products are the anions $[\pi\text{-}C_5H_5Fe(CO)_2]^-$ and $[RCB_{10}H_9CR]^-$.[87]

In contrast to reactions with the halogens, complex (I) interacts with mercury(II) chloride in the normal manner, yielding the first example of carbaborane derivatives with a B–Hg bond: 3-*o*-carbaboranylmercury chloride[85,86]:

$$(\mathrm{I}) + \mathrm{HgCl_2} \xrightarrow{110^\circ} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9HgCl}) \xrightarrow{\mathrm{Br_2}} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_9Br})\ .$$

When the latter is treated with bromine, demercuration takes place readily.

Further development of this branch of the chemistry of carbaborane derivatives with *B*-functional groups was associated with the discovery in 1976 of the reaction involving the mercuration of carbaboranes[88]. It was found that a powerful mercurating agent, such as mercury trifluoroacetate, reacts with *o*-, *m*-, and p-carbaboranes to form carbaboranylmercury trifluoroacetate, in which the trifluoroacetate anion is readily exchanged for chlorine or iodine[88–90]:

$$\mathrm{HCB_{10}H_{10}CH} \xrightarrow{(\mathrm{CF_3COO)_2Hg}} \mathrm{HCB_{10}H_9(HgOCOCF_3)CH} \xrightarrow{\mathrm{NaX}} \mathrm{HCB_{10}H_9(HgX)CH}\ ;\quad \mathrm{X = Cl\ or\ Br}\ .$$

The electrophilic monomercuration of *o*-carbaborane leads to the formation of 15–20% of the 8-substituted derivative and 80–85% of the 9-substituted derivative, while the mercuration of *m*-carbaborane takes place in the 9-position to the extent of 99%. The formation of *B*-polymercurated carbaboranes has also been observed[89,91]. In the reaction of *o*-carbaborane with mercury trifluoroacetate in CF_3COOH mono-, di-, tri-, tetra-, and penta-mercuri-derivatives are formed in succession[89,91]:

$$\mathrm{HC{-}CH}\ (\mathrm{B_{10}H_{10}}) + \mathrm{Hg(OCOCF_3)_2} \rightarrow \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_{10-n}(HgOCOCF_3)_n})\ ;\quad n = 1-5\ .$$

In the case of *m*-carbaborane the reaction proceeds with greater difficulty and after 30 h mainly the trimercuri-derivative is formed[91]:

$$m\text{-}\mathrm{HCB_{10}H_{10}CH} + \mathrm{Hg(OCOCF_3)_2} \rightarrow m\text{-}\mathrm{HCB_{10}H_{10-n}(HgOCOCF_3)_nCH}\ ;\quad n = 1-3\ .$$

Carbaboranes are also mercurated on treatment with mercury acetate in CH_3COOH in the presence of catalytic amounts of $HClO_4$.[91]

Carbaboranes have been thallated under similar conditions with formation of derivatives having a B–Tl bond[92,93]:

$$\mathrm{HCB_{10}H_{10}CH} + \mathrm{Tl(OCOCF_3)_3} \rightarrow \mathrm{HCB_{10}H_9[Tl(OCOCF_3)_2]CH}\ .$$

Symmetrisation of salts of *B*-mercurated carbaboranes is achieved by treatment with a solution of the naphthalene radical-anion or (better) with cadmium amalgam[89,90]:

$$\mathrm{HCB_{10}H_9(HgOCOCF_3)CH} \xrightarrow[\text{or } \mathrm{Cd/Hg}]{\mathrm{C_{10}H_8^-\,Li^+}} \mathrm{(HCB_{10}H_9CH)_2Hg}\ .$$

Asymmetric carbaboranylmercury compounds have been obtained by the reaction of carbaboranylmercury trifluoroacetate with a Grignard reagent:

$$\mathrm{HCB_{10}H_9(HgOCOCF_3)CH} + \mathrm{C_2H_5MgBr} \rightarrow \mathrm{HCB_{10}H_9(HgC_2H_5)CH}\ .$$

Asymmetric *B*-mercuricarbaboranes are much less stable than their *C*-analogues—they disproportionate even at 100 °C with formation of symmetrical products:

$$HCB_{10}H_9(HgC_2H_5)CH \xrightarrow{100^\circ} (HCB_{10}H_9CH)_2Hg + (C_2H_5)_2Hg .$$

In contrast to *C*-mercuricarbaboranes, symmetrical *B*-substituted compounds readily react with $HgCl_2$, Br_2, and HCl:[89-91]

$$HCB_{10}H_9(HgCl)CH \xleftarrow{HgCl_2} (HCB_{10}H_9CH)_2Hg \begin{cases} \xrightarrow{Br_2} HCB_{10}H_9BrCH \\ \xrightarrow{HCl} HCB_{10}H_9(HgCl)CH \end{cases} .$$

The enhanced electron affinity of the B–Hg bond in *p*-carbaborane under the conditions of polarographic reduction, relative to the corresponding derivatives of *o*- and *m*-carbaboranes, has been noted[94,95].

Bis-carbaboranyl derivatives of mercury can be used in reactions with non-transition metal salts in order to synthesise other derivatives containing a σ-bond between boron and the non-transition element[92,93,96-98]:

$$\left(\begin{matrix}HC-CH\\ \diagdown\ \diagup\\ B_{10}H_9\end{matrix}\right)_2 Hg + EX_3 \xrightarrow{\Delta} \begin{matrix}HC-CH\\ \diagdown\ \diagup\\ B_{10}H_9EX_2\end{matrix} + \begin{matrix}HC-CH\\ \diagdown\ \diagup\\ B_{10}H_9HgX\end{matrix} ;$$

E = As, Sb, or Tl .

When biscarbaboranylmercury is treated with $SnCl_2$, a tin derivative containing a B–Sn bond is formed smoothly[98]:

$$(HCB_{10}H_9CH)_2Hg + SnCl_2 \rightarrow (HCB_{10}H_9CH)_2SnCl_2 .$$

Heating of bis-*m*-carbaboranylmercury with sulphur in a sealed tube at 350 °C leads to the formation of biscarbaboranyl disulphide:

$$(HCB_{10}H_9CH)_2Hg + S \rightarrow (HCB_{10}H_9CH)_2S_2 + Hg .$$

An interesting compound containing a B–S–Hg–B bond has been obtained on adding tetrabutylammonium iodide to a mixture of biscarbaboranylmercury and sulphur[98]:

$$(HCB_{10}H_9CH)_2Hg + S \xrightarrow[DMF]{I^-} \begin{matrix}HCB_{10}H_9CH\\ |\\ S\\ |\\ Hg\\ |\\ HCB_{10}H_9CH\end{matrix} .$$

The formation of derivatives with B–Ge and B–P bonds has been claimed[96].

Biscarbaboranyl derivatives of mercury can be used to synthesise carbaboranes with B–C bonds. For example, when bis-*o* or bis *m*-carbaboranylmercury is acted upon by CH_3COCl in the presence of $AlCl_3$, *B*-acetylcarbaborane is formed[99]:

$$(HCB_{10}H_9CH)_2Hg + CH_3COCl \xrightarrow{AlCl_3} HCB_{10}H_9(GOCH_3)CH + HCB_{10}H_9(HgCl)CH .$$

Mercury derivatives have also been used in the synthesis of carbaboranes with a B–Pt σ-bond by the oxidative addition of 9-chloromercuri-derivatives of *o*- and *m*-carbaboranes to $Pt(Ph_3P)_3$:[100]

$$HCB_{10}H_9(HgCl)CH + Pt(Ph_3P)_3 \xrightarrow[20^\circ]{C_6H_6} HCB_{10}H_9[PtCl(Ph_3P)_2]CH .$$

The intramolecular oxidative addition of the B–H bond in 1-dimethylphosphino-*o*-carbaborane to an iridium atom is of interest.[101,102] It proceeds via the intermediate formation of the complex L_3IrCl, which has not been isolated in a pure state:

$$[Ir(C_8H_{14})_2Cl]_2 + 6\,(CH_3)_2PC(H)-CH(B_{10}H_{10}) \xrightarrow{\Delta} [2\,L_3IrCl] \rightarrow \begin{matrix}(CH_3)_2PC(H)-CH(B_{10}H_{10})\\ |\\ L\\ \diagdown\\ L-Ir-B_{10}H_9\\ \diagup\\ Cl\ \ H\end{matrix} ;$$

$$L = (CH_3)_2PC(H)-CH(B_{10}H_{10}) .$$

The iridium atom is coordinated to the boron atom in the 4(5)-positions in the *o*-carbaborane nucleus.

Another version of the synthesis of complexes with B–Ir bonds involves the intermolecular oxidative addition of the B–H bonds in *o*-, *m*-, and *p*-carbaboranes to the corresponding iridium complexes[102,103]:

$$L_2IrCl + HCB_{10}H_{10}CH \rightarrow \underset{(IV)}{HCB_{10}H_9(IrL_2HCl)CH} ;$$

$$L = Ph_3P \text{ or } Ph_3As .$$

When CO is passed through a solution of compound (IV) in benzene or when compound (IV) is heated with triphenylphosphine in toluene, the σ-linked carbaboranyl ligand is readily split off[102]:

$$HCB_{10}H_{10}CH \xleftarrow{CO} (IV) \xrightarrow{Ph_3P} HCB_{10}H_{10}CH .$$

III. THE ELECTRONIC EFFECTS OF *B*-CARBABORANYL GROUPS

As a consequence of the non-uniformity of the distribution of electron density in carbaborane nuclei, the electronic effects of the carbaboranyl groups depend on the site in the nucleus to which the substituent is linked. This postulate was put forward in 1966 by Zakharkin, Kalinin, and Shepilov in connection with the determination of the electronic effects of the 3-*o*-carbaboranyl group[41]. As a result of the advances made in the synthesis of various boron-substituted carbaboranes, the electronic effects of the *B*-carbaboranyl groups have now been investigated in fair detail. The known σ-constants of the *B*-carbaboranyl groups are compiled in the Table.

The σ-constants of the carbaboranyl groups.

Carbaboranyl group	Hammett constants*		References	Inductive and resonance constants**		References
	σ_p	σ_m		σ_I	σ_R^0	
1-*o*-	0.46	0.47	104	0.375	0.003	104
1-*o*-	0.43	0.49	42	0.38	0	43
3-*o*-	0.19	0.19	42	0.11	0.07	43

* Determined from the reaction series for the ionisation of carbaboranylbenzoic acids in 75% ethanol.

** Determined from the ^{19}F chemical shifts in the NMR spectra of fluorophenylcarbaboranes in inert solvents by the Taft method using the equations $\delta_m^F = -7.10\sigma_I + 0.6$ and $\delta_p^F - \delta_m^F = -29.5\sigma_R^0$.

The electronic effects of the *B*-*o*-carbaboranyl groups, for which a change in the nature of the electronic influence from the electron-accepting 3-*o*-carbaboranyl group to the virtually electrically neutral 4-*o*-carbaboranyl group and then the highly electron-donating 9-*o*-carbaboranyl group has been observed, have been studied most fully.

The inductive constants have been calculated for the 3-*o*- and 2-*m*-carbaboranyl groups by Charton's method from the ionisation constants of carbaboranylacetic acids in 80% methylcellosolve. The values of σ_I obtained amount to 0.12 and 0.11 respectively[63].

Evidently the electronic effects of the carbaboranyl groups are to a large extent determined by the charges on the corresponding carbon and boron atoms. Despite the somewhat approximate nature of the quantum-chemical calculations on carbaboranes, which are complex multiatomic systems, the available data (see the relevant reviews[106,107]) for the partial charges on the boron and carbon atoms are consistent with the pK_a of hydroxy-, amino-, and carboxy-carbaboranes[11].

The introduction of substituents at the boron atoms in the carbaborane nuclei is reflected in the nature of the C–H bond. For example, the significant influence of the electronic effects of the substituents at the boron atoms on the integral intensity of the C–H stretching vibration band in the region of 3060 cm^{-1} [108] and on the equilibrium CH acidity of carbaboranes[109] has been demonstrated.

---o0o---

A series of studies of interest for the problem under consideration have been published recently. The decarboxylation of oxomercury salts of 9-*o*- and 9-*m*-carbaboranecarboxylic acids under the influence of peroxide initiators or ultraviolet radiation leads to salts of 9-*o*- and 9-*m*-carbaboranylmercury[110]. The first examples of peroxides containing the B–C–O–O bond system have been synthesised from the chloride of 9-*m*-carbaboranecarboxylic acid and t-butyl hydroperoxide or hydroxymethyl t-butyl peroxide[111]. 9-Amino-*m*- and 2-amino-*p*-carbaboranes have been obtained and their pK_a determined[112]. The pK_a of 9-carboxy-*o*-, 9-carboxy-*m*-, and 2-carboxy-*p*-carbaboranes have been revised in the same study. Detailed data on the synthesis of 9-acetyl-*o*- and 9-acetyl-*m*-carbaboranes via the corresponding biscarbaboranylmercury derivatives have been published[113]. $LiAlH_4$ has been proposed as a convenient symmetrising agent for 9-chloromercuricarbaboranes[113]. The unusual chemical and thermal stabilities of borothallated carbaboranes compared with their aryl analogues have been noted[114]. A new method for the introduction of substituents at the boron atoms of carbaboranes has been proposed[115].

The Mechanism of the Catalytic Polymerisation of Olefins Based on the Number of Active Centres and the Rate Constants for Individual Stages

V.A.Zakharov, G.D.Bukatov, and Yu.I.Ermakov

New data on the numbers of active centres and rate constants for individual stages in the catalytic polymerisation of olefins in the presence of two-component catalysts, obtained by the method of selective radioactive inhibitors, are considered. Certain general aspects of the mechanism of the catalytic polymerisation of olefins are examined on the basis of these data as well as the results of the study of one-component organometallic catalysts and quantum-chemical investigations of the propagation reaction.
The bibliography includes 102 references.

I. INTRODUCTION

One of the main problems arising in the study of the kinetics and mechanism of catalytic polymerisation involves the determination of the number of active centres (AC). The active centre (propagation centre) is understood as a transition metal compound containing metal–carbon alkyl-type σ-bond whereby the monomer is inserted in this bond via repeated addition steps:

$$L_xM-CH_2\sim\sim + CH_2=CH_2 \rightarrow L_xM-CH_2-CH_2-CH_2\sim\sim, \qquad (I)$$

where M is the metal, L_x are ligands, and $CH_2\sim\sim$ is the polymer chain.

For solid catalysts, the active centre is an organometallic surface compound. Information about the influence of the composition and conditions of the preparation of the catalyst, the polymerisation conditions, and the nature of the monomer on the number and reactivity of the AC constitutes the basis of the study of processes involving the formation of AC, their composition, and the polymerisation mechanism.

The difficulty of determining the number of AC arises from the fact that this quantity constitutes as a rule a small fraction of the total number of transition metal atoms in the catalyst. Studies designed to determine the number of AC in the catalytic polymerisation of olefins were begun by Natta[1,2], Chien[3], and Feldman and Perry[4]. Subsequently numerous investigations were devoted to this problem and have been considered in a number of reviews[5–9]. The greatest difficulties in the determination of the number of AC arise for polymerisation in the presence of two-component Ziegler–Natta catalysts, since in this case the reaction medium contains, apart from the active titanium–polymer bonds, also inactive aluminium–polymer bonds, formed as a result of the transfer of the polymer chain with the organoaluminium compound. It has therefore been suggested that selective radioactive inhibitors, which interact, like the olefin, with the active transition metal–polymer bond but not with aluminium–polymer bonds, be used to determine the number of AC in two-component systems[10,11]. This approach to the determination of the number of AC has been used recently to investigate catalytic systems based on titanium chlorides. A series of new data were obtained concerning the influence of the composition of the catalyst and the polymerisation conditions on the number of AC and the rate constants for the individual stages; together with the results of the study of polymerisation mechanism in the presence of one-component organometallic catalysts and individual organometallic compounds as well as quantum-chemical investigations of the mechanism of the propagation reaction, these data make it possible to consider certain general aspects of the mechanism of the propagation reaction in catalytic polymerisation.

II. DETERMINATION OF THE NUMBER OF PROPAGATION CENTRES USING SELECTIVE RADIOACTIVE INHIBITORS

1. General Remarks Concerning the Method

The determination of the number of AC by the method of radioactive inhibitors is based on the introduction of a radioactive label into the growing polymer chain when the inhibitor interacts with the active metal–polymer bond:

$$L_xM-CH_2\sim\sim + RO^3H \rightarrow L_xM-OR + {}^3HCH_2\sim\sim. \qquad (IIa)$$

Calculations of the number of AC (c_p = mol per mol of transition metal) and the propagation rate constant (k_p) are performed using the following equations:

$$c_p = Ag/aQ, \qquad (1)$$

$$k_p = v/3{,}6c_p c_m M, \qquad (2)$$

where A is the radioactivity of the polymer (c g^{-1}), g the amount of the polymer (g), a the amount of the catalyst (mol of transition metal), Q the specific radioactivity of the inhibitor (c mol^{-1}), k_p the propagation rate constant (litre mol^{-1} s^{-1}), v the rate of polymerisation at the instant of the introduction of the inhibitor (g per mmol of transition metal per hour), c_m the concentration of the monomer (M), and M the molecular weight of the monomer.

The principal criteria for the quantitative determination of c_p are as follows: (1) agreement between the values of c_p and k_p obtained using different inhibitors, interacting with

the metal–polymer active bond via different mechanisms; (2) the independence of the k_p determined with the aid of the same inhibitor of the polymerisation termination conditions, for example, of the concentration and specific radioactivity of the inhibitor, its residence time in the reaction medium after the cessation of polymerisation, the rate of polymerisation at the instant of the introduction of the inhibitor, etc.

Table 1. The values of c_p and k_p for the polymerisation of ethylene in the presence of $TiCl_2$ at 75 °C with $c_m = 0.33$ M (residence time of ^{14}CO in the reaction medium 20 min).

Inhibitor	Q, μc mol^{-1}	c_i, mol/mol Ti	v, s/mmol Ti h	$10^5 c_p$, mol/mol Ti	$10^{-4}k_p$, litre mol^{-1} s^{-1}	Refs.
^{14}CO	1210	0.01	9.2	2.3	1.2	10
$^{14}CO_2$	2760	0.04	14.5	3.4	1.25	10,16
$^{14}C_3H_7I$	450	0.85	7.5	2.2	1.0	10,15
$^{35}SO_2$	2230	0.02	20	4.5	1.35	16
$CH_3O^{32}H$	2680	0.14	37	3.6	31	16

Note. Q is the specific activity of the inhibitor, c_i the concentration of the inhibitor, and γ the kinetic isotopte effect.

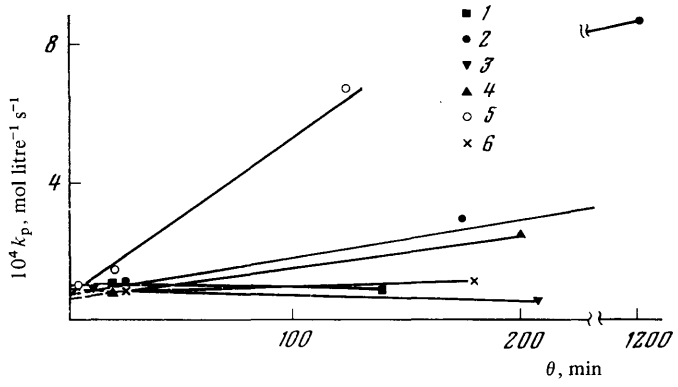

Figure 1. Dependence of the calculated quantity $1/k_p$ on the residence time of inhibitors of various types in the reaction medium after the cessation of polymerisation at 75 °C; $[C_2H_4] = 0.33$ M;[18] 1)–3) $TiCl_2$ catalyst; 4)–6) $TiCl_2$ + $AlEt_2Cl$ catalyst (Al/Ti = 1); 1) and 4) $^{14}CO_2$; 2) and 5) ^{14}CO; 3) and 6) $^{35}SO_2$. $1/k_p$ is proportional to the number of radioactive labels in the polymer.

^{14}CO and $^{14}CO_2$ have been suggested as selective inhibitors[10,11]. Labelled carbon dioxide can be used to determine the number of active bonds (for example Ti–C) in the presence of organoaluminiumhalogeno-compounds:

$$L_xTi{-}CH_2{\sim\!\sim} + {}^{14}CO_2 \rightarrow L_xTi{-}O{-}\overset{\overset{O}{\|}}{{}^{14}C}{-}CH_2{\sim\!\sim}. \qquad \text{(IIb)}$$

It is known that, in contrast to trialkyl derivatives of aluminium, CO_2 does not interact with the Al–C bond when even one alkyl group at the aluminium atom is substituted by a halogen[12]. The use of ^{14}CO as the selective inhibitor is based on the familiar reaction involving the insertion of carbon monoxide in the transition metal–carbon bond[13]:

$$L_xM{-}R + CO \rightleftarrows \underset{\downarrow}{\overset{CO}{L_xM}}{-}R \rightarrow L_xM{-}\overset{\overset{O}{\|}}{C}{-}R. \qquad \text{(IIc)}$$

This reaction proceeds via the preliminary coordination of CO to the transition metal ion, as has been suggested for the olefin in the polymer chain propagation reaction[14].

2. The Use of Radioactive Inhibitors for One-Component Catalysts

The possibility of using ^{14}CO and $^{14}CO_2$ for the quantitative determination of c_p has been tested[10,14,16] on the one-component $TiCl_2$ catalyst active in the absence of an organoaluminium cocatalyst. The propagation rate constants in the polymerisation of ethylene in the presence of $TiCl_2$, determined with the aid of various inhibitors, are similar (Table 1). A more convenient inhibitor for the above catalytic system is $^{14}CO_2$, since, unlike the system with ^{14}CO, in this case there is no accumulation of the labels in the polymer as a function of the residence time of the inhibitor in the reaction medium (Fig.1). Quantiative data for the interaction of $^{14}CO_2$ with the propagation centre in the polymerisation of ethylene in the presence of $TiCl_2$ have been obtained[16] in experiments where the polymerisation termination conditions were varied (the concentration of the inhibitor, its specific radioactivity, the rate of polymerisation at the instant of termination, the yield of polymer, etc).

3. The Use of Selective Inhibitors for Two-Component Catalysts

A preliminary study of the possibility of determining c_p with the aid of ^{14}CO and $^{14}CO_2$ in the presence of organoaluminium compounds was made in the presence of the $TiCl_2$ + $AlEt_2Cl$ catalytic system[9,10]. With increased residence time of these inhibitors in the reaction medium after the cessation of polymerisation, an increase in the number of labels in the polymer is observed, and hence a decrease of the calculated k_p (Fig.1). The increase of the number of labels in the $TiCl_2$ + $AlEt_2Cl$ + $^{14}CO_2$ system (Fig.1, curve *4*) can apparently be accounted for by the regeneration of the active centre by the organoaluminium compound:

$$L_xTi{-}O{-}\overset{\overset{O}{\|}}{{}^{14}C}{-}CH_2{\sim\!\sim} + AlEt_2Cl \rightarrow L_xTi{-}Et + EtAl(Cl){-}O{-}\overset{\overset{O}{\|}}{{}^{14}C}{-}CH_2{\sim\!\sim}. \qquad \text{(IId)}$$

The involvement of $AlEt_2Cl$ in this process is indicated by the finding that the number of labels in the polymer in the presence of the $TiCl_2$ + $^{14}CO_2$ system (in the absence of $AlEt_2Cl$) is almost independent of the residence time of $^{14}CO_2$ in the reaction medium (Fig.1, curve *1*).

In the $TiCl_2$ + $AlEt_2Cl$ + ^{14}CO system the increase of the number of labels in the polymer with the residence time of ^{14}CO (Fig.1) can be attributed to the slow copolymerisation of carbon monoxide with the olefin, apart from a reaction analogous to (IId). The possibility of this reaction was demonstrated in the polymerisation of ethylene in the presence of the $TiCl_2$ one-component catalyst, for which there is no reaction (IId). It was found that, for a sufficiently long residence time of ^{14}CO (more than 20 min), the number of labels in the polymer exceeds the number of propagation centres determined using other inhibitors[14].

The possibility of a quantitative determination of the number of propagation centres with the aid of ^{14}CO has been tested in detail on the $TiCl_2$ + $AlEt_2Cl$ [10] and $TiCl_3.0.3AlCl_3$ +

$AlEt_3$ [17] catalytic systems in the polymerisation of ethylene and on the $TiCl_3.0.3AlCl_3$ + $AlEt_2Cl$ system[11,17,18] in the polymerisation of propene and the following data were obtained.

(1) The nature of the variation of the number of labels in the polymer with the residence time of ^{14}CO after the cessation of polymerisation indicates a sharp alteration of the rate of accumulation of labels in the first minutes after the termination of polymerisation (Fig.2).[18] Apparently there is initially a fairly rapid insertion of the first ^{14}CO molecule in the Ti–C bond, after which a slow increase of the number of labels in the polymer is observed as a result of the copolymerisation of ^{14}CO with the olefin. It is noteworthy that the processes involving the accumulation of labels in the polymer as a function of the inhibitor residence time are fairly slow when either ^{14}CO or $^{14}CO_2$ are used. Extrapolation of the number of labels to the initial instant, when the influence of side processes leading to the accumulation of radioactivity has been reduced to a minimum, shows (Fig.1) that, regardless of the inhibitor employed, the constant k_p in the polymerisation of ethylene in the presence of $TiCl_2$ lies within a fairly narrow range of values [$(1.5 \pm 0.5) \times 10^4$ litre mol^{-1} s^{-1}].

(2) the insertion of ^{14}CO in the Ti–C bond is an irreversible process (there is no decarboxylation reaction), which is indicated by the conservation of the number of labels in the polymer after the removal of ^{14}CO from the reaction medium, despite the restoration of the activity of the catalytic system under these conditions[18].

(3) The copolymerisation process can be stopped by adding phosphine to the reaction medium. The constant k_p, determined from the number of labels in experiments with the addition of PH_3 for long reaidence times of the ^{14}CO + PH_3 mixture in the reaction medium, is close to the value of k_p found for short residence times of ^{14}CO.[11]

(4) The constant k_p calculated from the number of labels after a short residence time of ^{14}CO is independent of the polymerisation termination conditions—the inhibitor concentration, the yield of the polymer, the surface concentration of the propagation centres, etc.[17]

(5) As for the catalysts based on $TiCl_2$, the value of k_p found using ^{14}CO for the $TiCl_3$ + $AlEt_2Cl$ + C_3H_6 system is close to that found with the aid of another inhibitor—$^{14}CO_2$.[11]

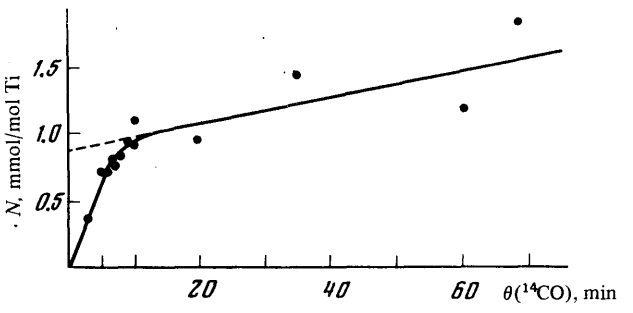

Figure 2. Dependence of the number of labels (N) in non-atactic polypropylene on the residence time of ^{14}CO in the reaction medium after the cessation of polymerisation[18]; catalyst—δ-$TiCl_3.0.3AlCl_3$ + $AlEt_2Cl$; 70 °C; [Ti] = (1–2) × 10^{-3} M; [$AlEt_2Cl$] = 3 × 10^{-3} M; [C_3H_6] = 1 M; molar ratio $^{14}CO/Ti$ = 0.5–1.0.

Thus a quantitative determination of c_p and k_p in the polymerisation of olefins in the presence of two-component catalysts is possible when the ^{14}CO and $^{14}CO_2$ selective catalysts are used. ^{14}CO is preferable, since $^{14}CO_2$ is a less effective inhibitor (at the same concentrations) than ^{14}CO and can be used only in two-component systems containing a halogen-substituted cocatalyst.

4. The Use of an Alcohol RO^3H as an Inhibitor

The use of an alcohol RO^3H as an inhibitor in two-component catalysts is possible, as stated previously[19], when the following factors are taken into account. Firstly, in the case of non-stationary polymerisation kinetics, where c_p varies with the reaction time, the number of propagation centres must be determined from the dependence of the total number of metal–polymer bonds on the yield of the polymer but not on the polymerisation time. Secondly, the use of an alcohol for the determination of c_p is possible when the number of inactive metal–polymer bonds differs comparatively little from c_p. This can be observed either for very low yields of the polymer or under conditions and for catalytic systems such that the rate of formation of inactive metal–polymer bonds is fairly low, for example, in the polymerisation of 4-methylpent-1-ene in the presence of VCl_3 + $Al(iso\text{-}Bu)_3$.[20] Thirdly, in the study of the influence of polymerisation conditions and catalyst composition on the number of propagation centres, account must be taken of the fact that, when these parameters are varied, there is a possibility also of a change in the rate of formation of metal–polymer bonds.

Table 2. The values of ν_{max}, c_p^{max}, and k_p for "massive" and deposited catalysts based on titanium chlorides.

Catalyst	Cocatalyst [(3–10) × 10^{-3} M]	ν_{max}, g/polymer/mmol Ti h atm	$10^4 c_p^{max}$, mol/mol Ti	$10^{-2}k_p$, litre mol^{-1} s^{-1}
Polymerisation of ethylene, 75 °C				
$TiCl_2$	—	8.0	1.1	120[10,16]
$TiCl_2$	$AlEt_2Cl$	5.5	0.75	120[10]
α-$TiCl_3$	$AlEt_3$	35.0	4.0	140[17]
δ-$TiCl_3$·0,3 $AlCl_3$	$AlEt_3$	72.0	9.7	120[17]
δ-$TiCl_3$·0,3 $AlCl_3$	$Al(iso\text{-}Bu)_3$	96.0	11.2	140[17]
$TiCl_3$ on SiO_2	$AlEt_3$	960	110	140[23]
α-$TiCl_3$·0,5 $AlCl_3$ on polyethylene	$AlEt_3$	720	89	130[23]
$TiCl_4$ on R_xMgCl_y	$AlEt_3$	29 000	3600	130[23]
Polymerisation of propene, 70 °C				
$TiCl_2$	—	0.005	0.013	0.76[10]
$TiCl_2$	$AlEt_2Cl$	0.004	0.0085	0.94[10]
α-$TiCl_3$	$AlEt_2Cl$	0.11	0.33	0.71[17]
δ-$TiCl_3$·0,3 $AlCl_3$	$AlEt_2Cl$	7.7	17	0.90[11,17]
δ-$TiCl_3$·0,3 $AlCl_3$	$AlEt_3$	28	58	1.00[17]
δ-$TiCl_3$·0,3$AlCl_3$	$Al(iso\text{-}Bu)_3$	36	80	0.90[17]
α-$TiCl_3$·0,5$AlCl_3$ on polyethylene	$AlEt_2Cl$	10	20	1.0

Note. In the case of the polymerisation of propene data are given for the polymer fractions insoluble in boiling ether (for $TiCl_3$) and n-heptane (for $TiCl_2$).

The correct application of a radioactive alcohol as an inhibitor enabled some workers to obtain values of k_p = 20–50 litre mol^{-1} s^{-1} in the polymerisation of propene in the presence of the $TiCl_3$ + organoaluminium cocatalyst system[21,22], differing comparatively little from the corresponding k_p obtained with the aid of ^{14}CO and $^{14}CO_2$ (Table 2).

III. THE NUMBER OF PROPAGATION CENTRES AND PROPAGATION RATE CONSTANTS FOR CATALYSTS BASED ON TITANIUM CHLORIDES

1. The Number and Composition of Propagation Centres

The number of AC depends significantly on the catalyst preparation and polymerisation conditions (for example, the purity of the reactants). When problems concerning the composition of the AC and the mechanism of their formation are considered, data concerning the maximum number of AC (c_p^{max}) for the system investigated are important. The quantity c_p^{max} can be calculated from the maximum observed rate of polymerisation and k_p for the given catalytic system.

Table 2 presents the values of c_p^{max} for different catalytic systems based on titanium chlorides[24]. Evidently the conditions in the preparation of titanium chlorides and the catalyst composition as well as the nature of the organoaluminium cocatalyst and the monomer influence significantly the number of AC. In the case of the $TiCl_2$ one-component catalyst (specific surface 25 $m^2\ g^{-1}$) the maximum number of propagation centres (approximately 10^{-4} mol per mol of titanium) does not exceed approximately 0.3% of the number of surface titanium atoms[16], which is apparently associated with the fact that the alkylation of titanium ions by ethylene takes place only on surface defects of the $TiCl_2$ crystals with a high degree of coordination unsaturation. Naturally, the fraction of such surface atoms cannot be large. For $TiCl_2$ and $TiCl_3$ 0.1–1 μm crystals (specimens which are not specially activated by grinding), the fraction of surface titanium atoms having one or two chlorine vacancies is 10^{-2}–10^{-3} and 10^{-4}–10^{-6} mol/mol Ti respectively. The latter value agrees with the number of propagation centres for $TiCl_2$ (Table 2).

In typical Ziegler–Natta catalysts based on $TiCl_3$, the number of propagation centres depends significantly on the preparation conditions and composition of titanium trichloride. The maximum number of propagation centres in catalysts based on $TiCl_3$ is 1×10^{-2} mol/mol Ti, i.e. 1% of the total content of titanium ions in the catalyst (Table 2). In estimating the surface concentration of propagation centres, account must be taken of the possibility of a change in the specific surface as a result of the comminution of the catalyst by the crystalline polymer in the polymerisation process; experimental evidence for this has been obtained in a number of studies[25,26]. Comminution of the catalyst in the polymerisation process apparently constitutes the physical basis of the correlation observed[27,28] between the size of the primary crystallites, determined by X-ray diffraction, and the activity in the polymerisation of propene. In this case the number of propagation centres must be referred to the surface area of the primary crystallites (calculated from their dimensions), which is formed in the polymerisation process as a result of the comminution of the catalyst and can be significantly greater than the surface area of the initial catalyst.

When titanium chloride is deposited on silica gel or powdered polyethylene, it is possible to increase the number of propagation centres in the polymerisation of ethylene approximately by an order of magnitude and to attain the same values as in the polymerisation of propene in the presence of massive $TiCl_3$ (Table 2). A finely dispersed $TiCl_3$ phase is formed as the active component on the surface of silica gel and polyethylene[29,30]. The use of these carriers hardly influences the number of propagation centres in the polymerisation of propene (Table 2).

Titanium–magnesium catalysts, obtained by depositing $TiCl_4$ on magnesium chloride or alkylmagnesium chloride, exhibit a maximum activity among all known catalytic systems[31]. In this case the number of AC can reach approximately 40% of the total number of titanium atoms in the catalyst (Table 2). The activity of the above catalysts probably reaches a limiting value for catalytic systems based on titanium chlorides. Strong binding of titanium tetrachloride to magnesium chloride is achieved by the insertion of titanium ions in defect sites of the disordered crystal structure of magnesium chloride[32]. This type of the interaction ("structural" binding) ensures a high degree of utilisation of titanium ions and their stability under the polymerisation conditions[33].

The difference between the activities of catalytic systems based on titanium chlorides, reaching four orders of magnitude (Table 2), is also caused by the change of the number of AC; the reactivity of a single propagation centre for a given olefin hardly changes. These data show that the AC in Ziegler catalysts are monometallic, i.e. their composition includes only one transition metal ion.

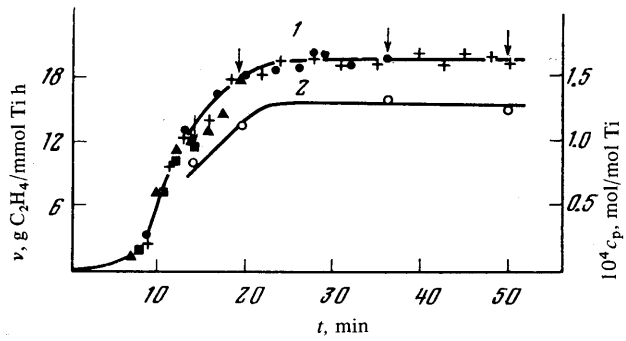

Figure 3. Dependence of the rate (v) of polymerisation of ethylene (curve *1*) and of the number of propagation centres (c_p) (curve *2*) on the polymerisation time *t*; $TiCl_2$ catalyst; 60 °C; $[C_2H_4] = 0.2$ M.[16] The arrows indicate the instants of the introduction of the $^{14}CO_2$ inhibitor in individual experiments where the number of propagation centres was determined.

2. Description of the Kinetics on the Basis of the Number of Propagation Centres

Data have been obtained[16,17,34,35] for the influence of polymerisation conditions (time, monomer concentration, and temperature) on the rate of polymerisation, the number of propagation centres, and the propagation rate constant in the polymerisation of ethylene and propene in the presence of the $TiCl_2$, δ-$TiCl_3.0.3AlCl_3$ + $AlEt_3$, and δ-$TiCl_3.0.3AlCl_3$ + $AlEt_2Cl$ catalysts. The variations of the rate of polymerisation of ethylene and of the number of propagation centres with the reaction time are compared in Fig. 3 for $TiCl_2$. Evidently the rate of polymerisation and the number of AC vary in parallel. Similar relations have been obtained also for other catalysts[17]. These results show that the propagation rate constant being determined is independent of the polymerisation time and of the yield of the polymer. Consequently the

hypotheses, occasionally encountered in the literature, concerning the influence on k_p of the length of the polymer chain or diffusion-dependent limitations in the polymer formed in the presence of such catalysts are not well founded. The constant k_p is independent of the monomer concentration[17,34]; the number of AC , which determines the steady-state reaction rate, is also independent of the monomer concentration.

On the basis of data for the variation of the steady-state rate of polymerisation, k_p, and c_p with the reaction temperature, it is possible to calculate the corresponding effective activation energies E_{eff}, the activation energies for the propagation step E_p, and the temperature coefficient of the change in the number of active centres ($E_{c_p} = E_{eff} - E_p$).

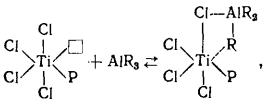
The energies obtained (kcal mol^{-1}) for the polymerisation of ethylene and propene in the presence of titanium trichloride[35] are listed below:

Catalyst	Monomer	E_{eff}	E_p	E_{c_p}
$TiCl_3$+$AlEt_3$	ethylene	6.0	3.0	3.0
$TiCl_3$+$AlEt_2Cl$	propene	11.0	5.5	5.5

Evidently appreciable differences between E_p and E_{eff} are observed for two-component catalysts. This is caused by the increase of the number of propagation centres with increase of polymerisation temperature, which is associated with the reversible adsorption of the organoaluminium cocatalyst on the propagation centres[10,35,36].

The values of E_p found for titanium chlorides are low compared to the activation energy in radical polymerisation (Table 3).

Table 3. The coefficients of the equation $k_p = 10^5 A_p \cdot \exp(-E/RT)$ for the catalytic polymerisation of olefins.



Catalyst	Monomer	A_p, litre mol^{-1} s^{-1}	E_p, cal mol^{-1}	Refs.
CrO_3/SiO_2	C_2H_4	4.5	4 500	37
$TiCl_3$+$AlEt_3$	C_2H_4	8.0	3 000	35
$TiCl_3$+$AlEt_2Cl$	C_2H_4	3.0	5 500	35
$AlEt_3$	C_3H_6	0.02	12 000	62
Radical initiator	C_2H_4	67	5 000	38

3. The Role of the Organometallic Cocatalyst

Comparative study of the one-component $TiCl_2$ catalyst and $TiCl_n$ + AlR_xCl_y two-component systems gives rise to new possibilities for the elucidation of the role of the organometallic cocatalyst in the regulation of the activity and stereospecificity of Ziegler–Natta catalytic systems.

The stereospecificity of the active centres. The data obtained for the polymerisation of propene in the presence of $TiCl_2$ concerning the stereoregular structure of the polymer (60% of X-ray-amorphous atactic polymer and 25% of the highly crystalline fraction)[10,36] show that at least two types of active centres exist on the surface of titanium chloride—non-stereospecific centres leading to the formation of the atactic polymer and isospecific centres giving rise to the stereoregular polymer. The difference between them apparently consists in the number and steric dispositions of the chloride ions surrounding the titanium ion (in conformity with the ideas of Cossee and Arlman[39,40]).

Adsorption of the organoaluminium catalyst on the active centre. It has been shown[9,10] that the rate of polymerisation of ethylene and propene decreases following the addition of $AlEt_2Cl$ to $TiCl_2$. Under these conditions, there is mainly a decrease in the number of non-stereospecific polymerisation centres. This explains the higher stereospecificity of the $TiCl_2$ + $AlEt_2Cl$ system compared with $TiCl_2$ alone. When the organoaluminium cocatalyst (OAC) is added to $TiCl_2$, it apparently undergoes equilibrium adsortion on the AC:

(III)

(P is the polymer chain and □ a free coordination site), as a result of which the propagation centre passes temporarily from the active to the inactive state.

Ideas concerning the possibility of the reversible adsorption of the OAC on the active centres of the VCl_3 + AlR_3 catalyst were also formulated by Tait and coworkers[41].

Analogous processes can occur during chain propagation also in the presence of $TiCl_3$. The adsorption of the OAC on the propagation centres formed on the $TiCl_3$ surface can explain the experimentally observed decrease of c_p with decrease of temperature, i.e. $E_{c_p} > 0$, and with increase of the OAC concentration[42]. The equilibrium constant for the adsorption of $AlEt_3$ on the AC (K_A) of the $TiCl_3.0.3AlCl_3$ + $AlEt_3$ catalytic system was calculated from the temperature variation of c_p. It amounts to $3.9 \times 10^{-10} e^{18\,500/RT}$ litre mol^{-1} [42] and the effective heat of adsorption of $AlEt_3$ on the active centre is approximately 10 kcal mol^{-1} after the subtraction of the heat of dissociation of the dimeric molecule $[AlEt_3]_2$.

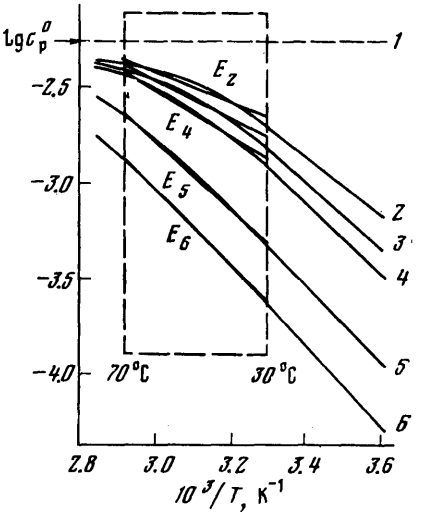


Figure 4. Calculated relations between the number of propagation centres (c_p) and the polymerisation temperature at different $AlEt_3$ concentrations[42]: 1) 0; 2) 6×10^{-3}; 3) 1.5×10^{-2}; 4) 3×10^{-2}; 5) 3×10^{-1}; 6) 1.5; corresponding activation energies (kcal mole^{-1}): $E_2 = 2.8$; $E_4 = 5.0$; $E_5 = 8.3$; $E_6 = 9.2$.

The number of AC (and correspondingly the rate of polymerisation) can be calculated from K_A at different temperatures and $AlEt_3$ concentrations (Fig.4). The temperature coefficient of the change in the number of propagation centres E_{c_p}, characterising the slope of the curves in Fig.4, varies both with polymerisation temperature at the same $AlEt_3$ concentration and as the OAC concentration is varied for the same temperature range. In the range 30–70 °C, which is most commonly investigated, the quantity E_{c_p} varies only slightly with temperature at the same $AlEt_3$ concentration (within the limits of experimental error). More appreciable changes in E_{c_p} in the above temperature range are observed as the $AlEt_3$ concentration is varied (Fig.4, cf. curves *2* and *6*). Thus, at a fairly high OAC concentration, amounting to 1.5 M, calculation leads to the expectation of an increase in the effective activation energy for the polymerisation of ethylene and propene up to 12 and 14.5 kcal mol^{-1} respectively, which is close to the experimental values of E_{eff} obtained under these conditions[42].

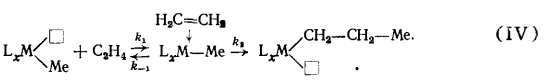
It follows from the data in Fig.4 that at low temperatures a change in the OAC concentration can influence c_p appreciably. Indeed at 30 °C in the $AlEt_3$ concentration during the experiment leads to a significant alteration of the rate of polymerisation, which is reversible and agrees satisfactorily with calculated data[42].

The influence of the nature of the organoaluminium cocatalyst on activity and stereospecificity. Since the OAC does not enter into the composition of the propagation centres, the influence of the type of OAC on the catalytic properties can be due to a change in the total number of propagation centres and the ratios of the numbers of centres of different types. In the polymer chain propagation stage this can occur as a result of the adsorption of the OAC on the AC. The influence of the nature of the OAC on the nature and heat of chemisorption can be determined by two factors: the Lewis acidity and the size of the OAC molecule.

Accordingly, in the case of the $TiCl_2$ + AlR_xCl_y catalyst one should expect a decrease of activity in the sequence $AlEt_3$ > $AlEt_2Cl$ > $AlEtCl_2$, which has been confirmed by experimental data[36]. The decrease of the degree of isotacticity of polypropylene in the same sequence can apparently be accounted for by the influence of the size of the OAC on adsorption on centres with different steric environments. Evidently, in adsorption on isospecific propagation centres, which are least accessible, the influence of the size of the OAC molecule is greater than in adsorption on non-stereospecific centres. With decreased size of the OAC molecule, one should expect a decrease in the fraction of isospecific propagation centres in the active state.

For $TiCl_3$, the heat of adsorption also depends on the type of OAC. Among the organoaluminium cocatalysts investigated by the present authors[35], $Al(iso\text{-}Bu)_3$ shows the least tendency towards complex formation and there is correspondingly an insignificant temperature variation of the number of propagation centres in its presence (E_{c_p} = 1.5 kcal mol^{-1}). When $AlEt_2Cl$, with the smallest size and highest Lewis acidity among the cocatalysts employed, is used as a cocatalyst, an appreciable decrease of the number of propagation centres with decrease of polymerisation temperature is observed (E_{c_p} = 5.5 kcal mol^{-1}). For $AlEt_3$, we have E_{c_p} = 3 kcal mol^{-1}.

For two-component catalytic systems based on $TiCl_3$, the influence of the OAC is manifested to a large extent in the stage involving the formation of propagation centres (alkylation of surface titanium ions). For all such catalysts, the nature of the OAC can therefore influence both the total number of AC and the ratios of the propagation centres of different stereospecificity already in the initiation stage and hence can determine the activity and stereospecificity of the catalytic system as a whole. The nature of the transition metal compound can play a significant role in this process. Hence, whereas for one transition metal compound it is possible to observe a particular series based on the changes in stereospecificity as a function of the type of organometallic cocatalyst, for another transition metal compound the series may be completely different[43]. However, despite this, the stereospecific propagation centres for catalysts of different compositions can have the same structure. The ^{13}C NMR data indicating the identical structures of the most stereoregular polymer fraction, insoluble in boiling n-heptane (or octane), for catalysts with different transition metal compounds ($TiCl_2$, δ-$TiCl_3$, β-$TiCl_3$, $CrCl_3$, and $ZrCl_4$) can serve as experimental confirmation of this[44,45].



IV. THE MECHANISM OF THE PROPAGATION REACTION

1. One-Stage and Two-Stage Mechanisms

Two main mechanisms of the propagation reaction are considered in the literature.

(1) The one-stage mechanism, in which the propagation reaction takes place as a result of the interaction of a bulk-phase olefin molecule directly with the metal–carbon bond[5,7,46]; in this case the rate of the propagation reaction corresponds to the rate of the insertion reaction.

(2) The two-stage mechanism proposed by Natta[47] and analysed in greater detail by Cossee[48]. According to this mechanism, the propagation reaction includes a preliminary stage, in which the olefin is adsorbed on the transition metal ion with subsequent insertion of the adsorbed olefin in the metal–carbon bond:

(IV)

In this case the experimental constant k_p is defined by the following expression:

$$k_p = k_1k_2/(k_2 + k_{-1} + k_1c_m). \quad (3)$$

Depending on the ratios of the rate constants for the individual elementary stages, the following instances can be observed:

$$\text{(a)}\ k_2 \gg k_{-1} + k_1c_m,\ k_p = k_1; \quad (4)$$

$$\text{(b)}\ k_{-1} \gg k_2 + k_1c_m,\ k_p = k_2k_1/k_{-1}; \quad (5)$$

$$\text{(c)}\ k_1c_m \gg k_{-1} + k_2;\ k_p = k_2/c_m. \quad (6)$$

The observed first order kinetics of the propagation reaction with respect to the monomer can correspond to either the one-stage mechanism or to cases (a) and (b) of the two-stage mechanism.

Table 3 presents the experimental quantities E_p, k_p, and pre-exponential factors for the polymerisation of ethylene and propene in the presence of catalysts of different composition. The table includes for comparison the propagation rate constants in the radical polymerisation of ethylene and the rate contants for the addition of propene to the aluminium–carbon bond in triethylaluminium.

The experimental pre-exponential factors can be compared with the calculated values for the elementary stages, which may constitute the propagation reaction (Table 4). The experimental data for different types of catalysts (the chromium oxide catalyst, titanium trichloride) are consistent with

the two-stage mechanism, which can include as the limiting stage the adsorption of the olefin on the transition metal ion with formation of a π-complex. At the same time, low values of the pre-exponential factor can also be observed for the one-stage mechanism, which involves direct interaction of the olefin with the metal–carbon bond, leading to the formation of a four-centre transition state. Thus the pre-exponential factor cannot serve as a criterion which would permit a differentiation between one- and two-stage mechanisms. For this purpose, one must use other experimental data. We shall enumerate briefly the experimental evidence available hitherto, which confirms the two-stage mechanism of the propagation reaction.

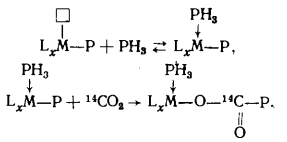


Table 4. The calculated pre-exponential factors of the rate constants for the possible elementary reactions constituting the propagation reaction in the catalytic polymerisation of olefins.

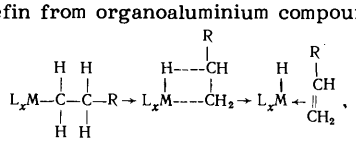
Elementary stage	Method of calculation	$10^{-5}A$, litre mol^{-1} s^{-1}
Adsorption of ethylene on a titanium ion	collision theory (Ref.34)	10^3 (7–70)
Adsorption of ethylene on a transition metal ion with formation of a π-complex	activated complex method (Ref.34)	0.3–3
Bimolecular impact interaction between bulk-phase ethylene and the metal–carbon bond	collision theory (Ref.7)	10^5
Interaction of bulk-phase propene with the metal–carbon bond to form a four-centre activated complex	activated complex method	0.1–1

1. In a study of the relative reactivities of different styrene derivatives in copolymerisation reactions, Natta[47] established that the rate of the propagation reaction is independent of the nature of the terminal unit of the polymer chain linked to the titanium ion. These data suggest that the reaction proceeds in two stages and that the adsorption of the monomer on the titanium ion is rate-limiting.

2. In the catalytic polymerisation of olefins the propagation reaction is usually first order with respect to the monomer. For certain types of Ziegler catalysts, a transition of the propagation reaction from first to zero order with respect to the monomer was observed[49–51]. This is possible in the two-stage mechanism of the propagation reaction, where virtually all the centres are "complexed" by the adsorbed monomer and the insertion of the coordinated olefin in the metal–carbon bond constitutes the rate-limiting stage.

3. An important condition, necessary for the operation of the two-stage mechanism of the propagation reaction, is coordination unsaturation of the metal ions on the active centre, which in the given instance is understood to be the ability of the transition metal ion to increase its coordination number in the adsorption of the olefin. Direct experimental evidence for coordination unsaturation was obtained in a study of the interaction of radioactive inhibitors of different types with the propagation centres. In particular, when compounds such as phosphine are introduced into the polymerisation medium, the polymerisation ceases, but metal–polymer bonds (M–P) are preserved [reaction (V)]. This can be demonstrated on the basis of the radioactivity of the polymer formed by the subsequent decomposition of the metal–polymer bonds by radioactive alcohol or carbon dioxide; the number of labels in the polymer in experiments with preliminary introduction of PH_3 corresponded to the number of propagation centres[14]:



(V)

(VI)

Data showing a preliminary coordination of ethylene on the metal ion in the active centre were also obtained in EPR studies of a number of deposited organometallic catalysts[52,53]. In particular, it has been shown that at low temperatures the benzyl and hydride titanium(III) and zirconium(III) complexes, fixed on the carrier surface, adsorb ethylene, while, following an increase of temperature, ethylene is bound irreversibly, which corresponds to the insertion of the adsorbed ethylene in the metal–hydrogen and metal–benzyl bonds.

2. The Rate-Limiting Stage of the Propagation Reaction

The observed first order of the polymerisation reaction with respect to the monomer can correspond to cases (a) and (b) of the two-stage mechanism [Eqns.(4) and (5)]. It is possible to estimate the pre-exponential factor (A_p) for the propagation rate constant in case (b). For a single unimolecular desorption reaction, a normal value $A_{-1} = 10^{13}$–10^{14} s^{-1} is to be expected. At the same time, in the case of a unimolecular reaction involving the insertion of the adsorbed olefin, proceeding with a low activation energy via an involved four-centre activated complex, one may expect a pre-exponential factor significantly lower than the theoretical value. Pre-exponential factors of 10^8–10^{10} s^{-1} have been quoted in the literature[54,55] for reactions proceeding via the formation of a four-centre activated complex, for example, for the β-elimination of an olefin from organoaluminium compounds:

(VII)

Low-pre-exponential factors for the insertion rate constant (A_2) compared with A_{-1}, i.e. $A_2 \ll A_{-1}$, can also be expected for the insertion of a coordinated olefin, which proceeds via a similar transition state. Consequently in case (b) [Eqn.(5)] we have $A_p = A_1A_2/A_{-1} \ll A_1$. The closeness of the experimental values of A_p to the calculated pre-exponential factor associated with the rate constant for the adsorption of the olefin on the metal ion (Tables 3 and 4) suggests that the rate-limiting stage of the propagation reaction is the adsorption of the olefin on the active centre [case (a), Eqn.(4)].

Low activation energies for the propagation reaction (3–6 kcal mol^{-1}) (Table 3), which do not exceed E_p for radical polymerisation, are characteristic of the catalytic polymerisation of olefins in the presence of transition metal compounds. On passing from transition metal compounds to those of non-transition elements, the activation energy for the propagation reaction (the addition of the olefin to the metal–carbon bond) increases appreciably (see the next Section).

The energy diagram for the two-stage propagation reaction has been examined[56] on the assumption of a linear relation between the change in the activation energy ΔE and in the heat of reaction Δq, of the type

$$\Delta E = \alpha \Delta q \quad (0 < \alpha < 1). \qquad (7)$$

It follows from this diagram that an increase in the heat of adsorption of the olefin on the metal ion can lead to a

decrease of the activation energy for the propagation reaction in both case (a) [Eqn.(4)] and case (b) [Eqn.(5)].

We may note that, whereas the donor–acceptor interaction makes the main contribution to the metal–olefin bond, which is entirely likely for Group IV metals in the highest oxidation states and has been confirmed by quantum-chemical calculations (see subsection 4 of this Section), following a decrease of electron density on the metal ion, a decrease of the activation energy for the propagation reaction is to be expected.

3. The Mechanism of Reactions Involving the Addition of Olefins to Aluminium–Carbon and Aluminium–Hydrogen Bonds

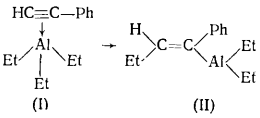
The catalytic oligomerisation of ethylene in the presence of triethylaluminium, which includes reactions involving the addition of the olefin to aluminium–carbon and aluminium–hydrogen bonds, can be represented as follows[12]:

$$R_2Al{-}R + CH_2{=}CH_2 \rightarrow \underset{(A)}{R_2Al{-}CH_2{-}CH_2{-}R}, \qquad (VIII)$$

$$A \xrightarrow{(CH_2=CH_2)} \underset{(B)}{R_2Al\,(CH_2{-}CH_2)_{n+1}{-}R}, \qquad (IX)$$

$$B \rightarrow R_2AlH + CH_2{=}CH{-}(CH_2{-}CH_2)_n{-}R, \qquad (X)$$

$$R_2AlH + CH_2{=}CH_2 \rightarrow R_2Al{-}CH_2CH_3. \qquad (XI)$$



Depending on the process conditions (pressure and temperature), it is possible to obtain α-olefins ranging from C_4 to C_{20}. The interaction of aluminium trialkyls with higher α-olefins takes place as a rule under conditions where the addition of the first olefin molecule is followed by the β-elimination reaction [as in reactions (VII) and (X)]. In this case the process can be catalytic in relation to dialkylaluminium hydride, since the insertion of the α-olefin in the Al–H bond under these conditions is followed again by the β-elimination reaction with formation of a new α-olefin[12].

The catalytic olefin polymerisation processes in the presence of transition metal compounds and processes leading to the formation of higher α-olefins in the presence of organoaluminium compounds are based on reactions involving the addition of olefins to metal–carbon and metal–hydrogen bonds. The observed quantitative differences between the rates of the processes and between the degrees of polymerisation can be attributed to the differences between the rate constants for the chain propagation and termination reactions involving the above groups of catalysts, provided that all these reactions have a single mechanism. Thus reactions involving the addition of olefins to aluminium–hydrogen and aluminium–carbon bonds can be regarded as models for reactions of this type.

Numerous kinetic studies of the addition of olefins to the aluminium–carbon bond in trialkylaluminium[57–63] have shown convincingly that the active centre is the monomeric form of the trialkylaluminium molecule, which is as a rule present in solution in the associated form as Al_2R_6 dimers. The addition of the monomeric coordination-unsaturated form of the organoaluminium compound in the addition reaction ensures the possibility of a preliminary interaction of the olefin with the free *p* orbitals of the aluminium ion to form a π-complex before the step involving the insertion of the olefin in the aluminium–carbon bond[57,58].

The first order with respect to the monomer[57–59,63–66] suggests that the concentration of π-complexes relative to the monomeric form of the OAC is low and they cannot therefore be detected by physical methods at elevated temperatures under the reaction conditions. With decrease of temperature, one may expect an increase in the concentration of these complexes, but under these conditions the dimerisation of the OAC molecules predominates, the dimer being incapable of coordinating with the olefin.

On the other hand, in many special cases data have been obtained concerning the possibility of the formation of π-complexes of olefins with the monomeric form of the OAC. For example, the formation of π-complexes in the reaction of phenylacetylene with triethylaluminium has been demonstrated[67] by ^{1}H NMR. The heat of this reaction is 0.7 ± 0.2 kcal mol^{-1}. When account is taken of the heat of dissociation of the Al_2Et_6 molecule, amounting to 17 kcal mol^{-1},[68] the strength of the π-bond between phenylacetylene and the aluminium ion is estimated as 9 kcal mol^{-1}. The insertion of phenylacetylene in the aluminium–ethyl bond is of first order with respect to π-complex (I), in conformity with the reaction equation

(I) (II) (XII)

The formation of intramolecular π-complexes in aluminium trialkenyls has been established[69–71] by infrared spectroscopy and ^{1}H NMR:

In contrast to their alkyl analogues, the alkenyl compounds of aluminium exist in the monomeric form. The energy of formation of the π-complex should be in this case more than 2–5 kcal mol^{-1} in order to stabilise them in the monomeric form[71].

The necessity for a free coordination site in the trialkylaluminium molecule for the addition of the olefin to take place has received significant confirmation by data concerning the influence of electron-donating compounds on the kinetics of this reaction. The kinetics of the addition of oct-1-ene to triethylaluminium in diphenyl ether, which reduces sharply the rate of this reaction, have been studied by ^{1}H NMR.[72] Under the given conditions, there is a system of equilibria

(XIII)

It has been established[72] that only the monomeric form of triethylaluminium is active in the olefin addition reaction, while the complex $Et_3Al.Ph_2O$ is inactive.

The rate constants for the addition of olefins to the Al–C and Al–H bonds. Table 5 presents the activation energies and the pre-exponential factors associated with the rate constants for the addition of olefins of different structures to triethylaluminium. Some uncertainty in the determination of the rate constants for this reaction is associated with the possibility of using in the calculations of the concentration of the monomeric form of triethylaluminium of different dissociation constants K_d of the dimeric molecule Al_2Et_6 obtained in different investigations[60,62,68,74]. The results presented in Table 5 have therefore been grouped in accordance with the values of K_d used in the calculations. In the series from propene to oct-1-ene the activation energies increase from 12.2–15.4 to 16.6–19.4 kcal mol^{-1}. The pre-exponential factors also tend to increase in this series by about an order of magnitude.

The addition of olefins to $Al(Me)_3$ is much slower than the addition of $AlEt_3$, which is associated, firstly, with the higher heat of dissociation of the $[AlMe_3]_2$ molecule[74,75] and with the higher activation energy for the addition reaction (Table 6).

The interaction of ethylene with triethylaluminium has been studied in the gas phase under the conditions of the preferential formation of α-butylene[66,76]. The kinetic characteristics obtained for this reaction are listed in Table 6. One must bear in mind that, in the calculation of the rate constants for the addition reaction, a number of addition assumptions were introduced in this instance concerning the concentrations of different forms of the OAC and the ratio of the rate constants for different reactions. Apparently not all the assumptions are valid and the activation energies for the addition of ethylene in Table 6 are too high. In this connection one should note that Ziegler[12,77] established the following series based on the variation of the reactivity in the addition of olefins to organoaluminium compounds: $CH_2{=}CH_2 > CH_2{=}CHR > CH_2{=}CR_2$.

Table 5. The activation energies E (kcal mol^{-1}) and the pre-exponential factors A of the rate constants for the addition of olefins to triethylaluminium.

$AlEt_3$	18.4	6.6	16.8	6.2
$AlMe_3$	20.5	6.7	22.7	7.2

On passing from metal–carbon to metal–hydrogen bonds, there is a sharp increase of reactivity for the addition of olefins due to the decreased activation energy (Table 7). The activation energy for the addition to the Al–H bond is virtually the same for different monomers and for a single monomer increases in the sequence $R_2AlH < R_2GaH < R_2BH$.

The data examined above are in best agreement with the hypothesis that the addition of olefins to the metal–carbon bond takes place via a single two-stage mechanism for compounds of both transition and non-transition metals. The reaction proceeds with participation of coordination-unsaturated metal alkyls via the intermediate formation of π-complexes. The pre-exponential factors associated with the rate constant for this reaction are close for active centres of different compositions and the higher reactivity of transition metal compounds compared with organoaluminium compounds is determined mainly by the low activation energy for this process. Many facts show that the polarity of the bonds does not determine the reactivity of the metal alkyls in the addition of olefins. Presumably the most significant factor is the ability of metal alkyls to form π-complexes with the possibility of interaction with the metal–carbon bond via a concerted mechanism.

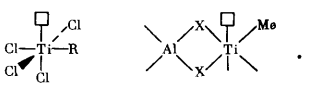

Table 7. The activation energies for the addition of olefins to the metal–hydrogen bond in the organometallic compound $(iso\text{-}C_7H_9)_2MH$.

4. Quantum-Chemical Analysis of the Mechanism of the Propagation Reaction†

The first studies on the quantum-chemical analysis of the propagation reaction in the polymerisation of olefins were carried out by Cossee[82,83]. The ideas developed in these investigations have been widely accepted. Later a further series of studies were carried out[84–89], including some using improved computational methods[85–89].

The AC models. The AC model proposed by Cossee[82,83], incorporating an octahedral titanium(III) complex which exists on the surface of the titanium trichloride crystal [complex (IV)], is fully consistent with the experimental data discussed above. The titanium ion in this complex contains an alkyl group and a chlorine vacancy. This AC model has been used in many computational studies[82–84,89]. AC models of more complex composition, for example the Ti_2Cl_{10} cluster[90], and simplified models containing either no metal–alkyl bond or a free vacancy[91–94] have also been analysed.

(IV) (V)

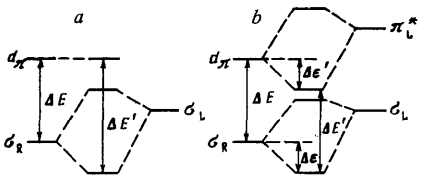
The AC model proposed for soluble catalytic systems has been analysed[85,86]. In this case the AC consists of a titanium(IV) complex linked to an organoaluminium compound [complex (V)].

The metal–alkyl bond and the influence of the coordination of the olefin on its strength. The Ti–C bond is predominantly covalent with $Ti^{\delta+}$–$C^{\delta-}$ polarisation[89]. The titanium–carbon bond length changes only slightly on passing from the methyl to the ethyl complex, i.e. the properties of this bond are presumably independent of the chain length. On

† This Section was written together with V.I.Avdeev and I.I.Zakharov.

formation of a π-complex with ethylene, an appreciable proportion of the electron density is transferred to the titanium ion (~0.25e).

The metal–olefin bond is formed as a result of the donor–acceptor and dative interactions[95,96]. Fig.5 illustrates the variation of the energy ΔE of transition from the σ_R orbital, involved in the formation of the metal–alkyl bond, to the half-filled or vacant d_π orbital of the metal on coordination of the olefin to the titanium ion. Presumably the lower the value of ΔE, the higher the probability of the $\sigma_R \rightarrow d_\pi$ transition and hence the more effective is the electron transfer from the metal–carbon bond to the metal. This process leads to an increased electron density on the metal and to a decrease in the M–C bond strength. If only the donor–acceptor interaction between the AC and the ligand is taken into account (Fig.5*a*), then the energy of the $\sigma_R \rightarrow d_\pi$ transition increases on complex formation ($\Delta E' > \Delta E$) and the M–C bond is strengthened. When account is taken of both the donor–acceptor and the dative interactions (Fig.5*b*), it is possible to obtain $\Delta E' > \Delta E$ or $\Delta E' < \Delta E$ depending on their relative contributions ($\Delta\varepsilon$ and $\Delta\varepsilon'$ respectively). In the first case the coordination of the olefin strengthens the M–C bond, while in the second it destabilises it.



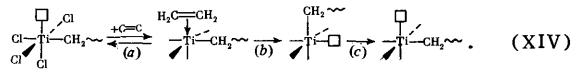


Figure 5. A simplified scheme of the changes in the one-electron levels of the AC (σ_R, d_π) in the interaction with the donor (σ_L) and acceptor (π^*_L) orbitals of the coordinating ligand[89]: *a*) allowance for the donor–acceptor interaction of the AC and the ligand; *b*) allowance for the donor–acceptor and dative interactions.

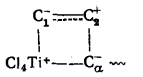
The nature of the metal–olefin bond. In the early studies[82–84] no estimates were made of the relative contributions of these interactions. The hypothesis[83] of the dominant role of the dative interaction does not appear convincing, since the metal ions in the highest oxidation states [for example the d^1 configuration for titanium(III)] can hardly transfer effectively the electron density from the d_π orbitals (which are actually unoccupied) to the antibonding π* orbitals of ethylene. It is therefore not surprising that Armstrong[85] arrived at the opposite conclusion for titanium(IV) complexes on the basis of calculations by the CNDO method, namely that the contribution of the donor–acceptor interaction predominates. This conclusion has been confirmed by calculations on the π-complexes $Ti^{3+}F_5.C_2H_4$ and $Ti^{3+}Cl_5.C_2H_4$ carried out by the Slater–Johnson method[91,92]. According to these calculations, the contribution of the dative interaction does not exceed 12% for the fluoride complexes and is significantly lower for the chloride complex. Thus the calculated data suggests that the metal–olefin bond in the AC incorporating titanium(III) ions is formed mainly as a result of the donor–acceptor interaction.

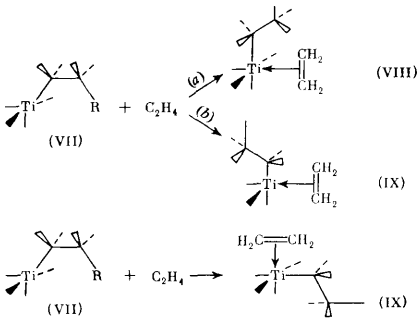
The monomer insertion stage. Cossee[82,83] was the first to analyse this reaction theoretically, assuming that it is the rate-limiting stage of the propagation reaction [stage (b) in reaction (XIV)]:



(XIV)

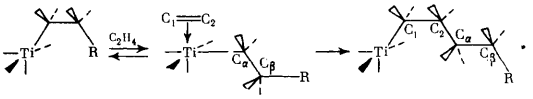
After the *cis*-insertion of the monomer, the geometry of the active centre is restored but with an interchange of the vacant site and the alkyl. Analysis of the orbital contributions to the molecular orbital localised at the Ti–C bond shows that the metal–alkyl bond persists along the entire reaction pathway. The vacant d_{xy} orbital of titanium plays an important role in this process. The energy losses on passing from the Ti–C_α bond to the Ti–C_1 bond do not exceed 20% of the bond strength and are fully compensated by the formation of a new C_2–C_α bond [reaction (XVII)].[89] Cossee[83] classified such reactions as concerted and characterised by a synchronous redistribution of electron density in the ruptured and reformed bonds, which is the reason for the low activation energies for these reactions.

On the basis of calculated data demonstrating a marked destabilisation of the σ_R and d_π orbitals and an increase of ΔE (Fig.5) in the monomer insertion process, Cossee[83] proposed a relation between the activation energy for the propagation reaction and ΔE. The same conclusion was reached by Begley and Penella[84] using the same computational methods, on the basis of estimates of ΔE for the series of complexes CH_3TiCl_3, $CH_3TiCl_4.\square$ (octahedron with a vacancy), and $CH_3TiCl_4.C_2H_4$. They postulated that $\Delta E'$ (Fig.5) represents the energy barrier which is overcome when the coordinated olefin is introduced into the metal–carbon σ-bond and $\Delta E'$ can therefore be compared with the activation energy for the chain propagation reaction. However, this conclusion was not confirmed in calculations by the more effective CNDO method[85,86,89]. It has been shown[89] that $\Delta E'$ depends greatly on the metal–alkyl and metal–ethylene bond lengths chosen, it is therefore important to determine the equilibrium lengths of these bonds by minimising the total energy. This factor was not taken into account by Cossee et al.[83] and Begley and Penella[84] and the attempt to relate the activation energy for the insertion reaction to $\Delta E'$ is therefore unjustified.



The insertion reaction for the AC [complex (V)] in a homogeneous catalyst has been analysed[85,86] by the CNDO method. It was observed that the behaviour of the one-electron levels following the insertion of ethylene is analogous to that found earlier by Cossee and the process is activated but the total energy of the system decreases along the reaction coordinate. Hence the authors[85,86] concluded that the insertion stage does not have an activation energy. In contrast to earlier workers[83–86], Avdeev et al.[89] attemped to determine the optimum reaction pathway in the insertion of ethylene taking into account the mutual influence of the metal–olefin and metal–alkyl bonds. We may note certain characteristic features of the insertion stage, which follow from the results of this study. In the initial stage of the process a four-centre complex (VI) of the type

is formed, its polarisation ensuring its energetic suitability compared with the initial complex. The transition to the final stage, where the *cis*-opening of the double bond is completed, requires that an insignificant energy barrier be overcome (approximately 1 kcal mol^{-1}), which is consistent with



the results of Armstrong et al.[85] and Novaro et al.[86] However, Avdeev et al.[89] found that the stable state of the AC corresponds to structure (VII) [Eqns.(XV) and (XVI)], in which the Ti–C bond occupies a position intermediate between the octahedral sites and the propyl group has the *cis*-configuration.

Coordination of the olefin. Armstrong[85] was the first to note that the total energy of the AC decreases when the structure is deformed to a trigonal bipyramid. Formally there is no vacancy in such a deformed AC, so that it is necessary that in the adsorption of ethylene the octahedral geometry of the AC should be restored. Such a rearrangement requires energy, which can be identified as the activation energy for the adsorption stage. Avdeev et al.[89] analysed in detail, within the framework of the CNDO method, the stage involving the coordination of ethylene on the active centre, having structure (VII), which they showed to correspond to the free energy minimum. There are several ways in which ethylene can be incorporated in the coordination sphere of the metal ion:

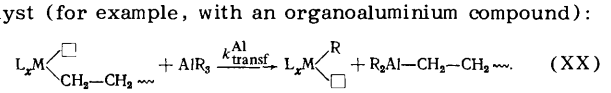
A characteristic feature of the first case [reaction (XV)] is that the olefin and the alkyl change places in the coordination sphere of the metal ion during the chain propagation process. The second case [reaction (XVI)] corresponds to the adsorption of the monomer to the same coordination site in repeated propagation steps. Calculation of the potential surfaces for coordination of ethylene in relation to reaction (XV) shows that it involves the overcoming of an energy barrier [approximately 25 kcal mol^{-1} for reaction (XV*a*) and 65 kcal mol^{-1} for reaction (XV*b*)]. The coordination of etheylene via reaction (XVI) is also activated, but with a much smaller activation energy (approximately 4 kcal mol^{-1}). The low activation energy in the latter case is due to the fact that the energy evolved on coordination of the monomer compensates for the energy expended in the migration of the alkyl group and its transition to the *trans*-configuration. On the other hand, in reaction (XV) the rearrangement of the AC must take place before the energy compensation due to the adsorption of ethylene begins. The conclusions reached on the basis that the monomer is adsorbed at the same site in the coordination sphere of titanium provide a more natural explanation of the isospecificity of the addition of the monomer in the polymerisation of α-olefins in the presence of titanium chlorides. The need to introduce a special alkyl migration stage, proposed in some investigations[48,82] [reaction (XIV*c*)], is eliminated.

Comparison of the one-stage and two-stage mechanisms. The potential energy surface has been calculated[89] for the one-stage mechanism of the propagation reaction; the results obtained were compared with data for the adsorption reaction and the insertion of the coordinated olefin. It was found that the insertion of ethylene in the metal–polymer bond directly from the gas phase requires that a considerably larger energy barrier be overcome than in its insertion via preliminary coordination. Consequently the two-stage mechanism of the propagation reaction is preferable, and according to Avdeev et al.[89] it can be represented as follows:

(XVII)

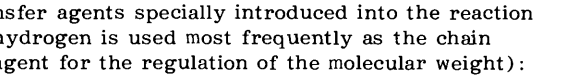
V. POLYMER CHAIN TRANSFER REACTIONS

In the catalytic polymerisation of olefins the following main reactions which limit the propagation of the polymer chain take place.



1. Transfer with the monomer:

(XVIII)



2. Spontaneous chain transfer reaction:

(XIX)

3. Reaction involving chain transfer with the organometallic cocatalyst (for example, with an organoaluminium compound):

(XX)

4. Reactions involving chain termination by impurities or chain transfer agents specially introduced into the reaction medium (hydrogen is used most frequently as the chain transfer agent for the regulation of the molecular weight):

(XXI)

All the reactions enumerated above are polymer chain transfer reactions, after which the kinetic chain is preserved and a new polymer molecule is formed on the AC. In the catalytic polymerisation of olefins a large number of polymer molecules (from tens to thousands) are therefore formed as a rule on a single AC.

The equation proposed by Natta is usually employed to calculate the chain transfer rate constants:

$$\frac{1}{\bar{P}_W} = \frac{k^{M}_{transf}}{k_p\omega} + \left(\frac{k^{sp}_{transf}}{k_p\omega} + \frac{k^{Al}_{transf}[Al]^n}{k_p\omega} + \frac{k^{X}_{transf}[X]^m}{k_p\omega} \right) \frac{1}{c_M}, \qquad (8)$$

where $\bar{P}_W$ is the weight-average degree of polymerisation, k^{M}_{transf}, k^{sp}_{transf}, k^{Al}_{transf}, and k^{X}_{transf} are the rate constants for the corresponding transfer reactions [see schemes (XVIII)–(XXI)], c_M, [Al], and [X] are the concentrations of the monomer, the organoaluminium cocatalyst, and the chain transfer agent X, for example, hydrogen, and ω is the coefficient of the polydispersity of the polymer. The ratios of the chain transfer rate constants to the chain propagation rate constant (k^{i}_{transf}/k_p) can be calculated by Eqn.(8) from the experimental relations between the molecular weight of the polymer and the concentrations of the chain transfer agents[97,98]. The values of k_p, determined independently by the method of radioactive inhibitors (see Sections II and III), were used[16,34,99,100] for the subsequent calculation of the absolute rate constants, listed in Table 8, for chain transfer with the monomer and hydrogen as well as spontaneously. The rate constants for chain transfer with the organoaluminium cocatalyst, listed in Table 8,[19,100] were calculated from

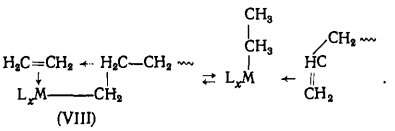
the experimental relations between the number of metal–polymer bonds (q) and the yield of the polymer (G) in accordance with the expression[2,6,19]:

$$[q]=c_p+\frac{k^{Al}_{transf}[Al]^n G}{k_p c_m}, \qquad (9)$$

where $[q]$ is the total number of aluminium–polymer and titanium–polymer bonds, determined by a method involving the termination of the polymerisation by a radioactive alcohol RO^3H. In the calculation of k^{Al}_{transf} the values of k_p determined independently by a method involving the termination of polymerisation by ^{14}CO were also used[17,23].

Chain transfer with the monomer and spontaneous chain transfer are the main chain transfer processes in the case of one-component catalysts. Chain transfer with the monomer predominates at temperatures below 90 °C,[16,101] whilst spontaneous transfer predominates above 120 °C.[101] For two-component catalysts based on $TiCl_3$ chain transfer with the monomer predominates at 70–80 °C.[99,100] Experimental data concerning the molecular structure of the polymers {vinyl unsaturation for polyethylene and vinylidene unsaturation for polypropylene arising via reactions (XVIII) and (XIX)} confirm the occurrence of these processes under the conditions investigated[99,100].

Table 8. The rate constants for chain transfer in the catalytic polymerisation of olefins[16,19,34,99,100].



Catalyst	k^{M}_{transf}/ω, litre mol^{-1} s^{-1}	k^{Al}_{transf}, litre$^{0.5}$ mol$^{-0.5}$ s^{-1}	$k^{H_2}_{transf}/\omega$, litre$^{0.5}$ mol$^{-0.5}$ s^{-1}	$\bar{\tau}\cdot\omega$, s*
CrO_3/SiO_2**	$1.2\cdot10^8\exp(-11\,700/RT)$; 0.0064	—	—	60

$TiCl_4/MgCl_2+AlEt_3$	0.22	1.7	—	10

*The average polymer chain propagation time $\bar{\tau}$ was calculated from the relation $\bar{\tau}=\bar{P}_W/\omega k_p c_m$ with $c_m = 0.5$ M at 80 °C for ethylene and at 70 °C for propene.

**k^{sp}_{transf}/ω, $c^{-1} = 2.2\times10^5\exp(-13\,500/RT)$.

***Monomer—C_3H_6; the rate constants for 70 °C are indicated; in the remaining cases the monomer is C_3H_6 and the rate constants for 80 °C are indicated.

The pre-exponential factors associated with the rate constant for chain transfer with the monomer (Table 8) are close to the calculated pre-exponential factor of the rate constant for the adsorption of monomer on the metal ion with formation of a π-complex (Table 4) or to the pre-exponential factor of the propagation rate constant (Table 3). Presumably chain transfer with the monomer, like the propagation reaction, proceeds via a stage in which the monomer is adsorbed on the metal ion in the AC [reactions (XV) and (XVI)]. Depending on the steric disposition of the adsorbed olefin and the alkyl group, either the insertion reaction takes place in this instance [after the formation of complex (IX) via reaction (XVI)] or reaction (XXII), involving the transfer of hydrogen from the β-carbon atom of the alkyl group to the adsorbed monomer [provided that complex (VIII) is formed via reaction (XVa)]:

(VIII) (XXII)

As mentioned in the previous Section, the formation of a π-complex of type (VIII) via reaction (XVa) is energetically less favourable than the formation of complex (IX) via reaction (XVI), which is apparently due to the higher activation energy for chain transfer with the monomer compared with the propagation reaction.

The spontaneous chain transfer process (XIX) is a reaction involving the β-elimination of the olefin with formation of a metal hydride complex. This reaction is well known for organoaluminium compounds[12]. The low pre-exponential factors of the rate constants for the unimolecular spontaneous transfer process (Table 8) and the reactions involving the β-elimination of olefins from aluminium alkyls[54,55] are apparently caused by the fact that the process proceeds via an involved activated complex [reaction (VII)] the formation of which requires a specific steric disposition of the alkyl group, favourable for the migration of a hydrogen atom to the transition metal ion. When this reaction takes place in the coordination sphere of the metal, the C–H bond is dissociated with a relatively low activation energy [13.5 kcal mol^{-1} for the chromium oxide catalyst (Table 8) and 26–30 kcal mol^{-1} for organoaluminium compounds[54,55]].

Chain transfer with the organoaluminium cocatalyst plays a notable role in two-component catalysts. This reaction consists in essence of the exchange of the alkyl ligands between the OAC and the AC and apparently includes the following stages: dissociation of the dimeric OAC molecule and adsorption of the monomeric form of the OAC on the AC followed by desorption of the OAC molecule, in which the alkyl group is replaced by the polymer chain[19,102]:

$$[AlR_3]_2 \rightleftarrows 2\,AlR_3, \qquad (XXIII)$$

(XXIV)

Within the framework of this mechanism, it is possible to account for the experimental data[19,32] concerning the influence of the nature of the OAC [$AlEt_3$ and $Al(iso\text{-}Bu)_3$] and the monomer on k^{Al}_{transf}. For steric reasons, the adsorption of $Al(iso\text{-}Bu)_3$ on the AC via reaction (XXIV) should be hindered. This reduces the rate constant for chain transfer from $Al(iso\text{-}Bu)_3$ compared with $AlEt_3$. In the polymerisation of propene the presence of methyl substituents in the polymer chain, bound to the metal ion in the AC, gives rise to greater difficulties in the adsorption of the OAC compared with the polymerisation of ethylene. The rate constant for chain transfer from $AlEt_3$ in the polymerisation of propene is therefore significantly lower than in the polymerisation of ethylene (Table 8).

VI. CONCLUSION

The data obtained for the influence of the composition of catalysts and polymerisation conditions on the number of AC and the propagation rate constant constitute the experimental basis for the analysis of kinetic data and for the discussion of problems concerning the composition of the AC and the mechanism of the propagation reaction.

The basic cause of the comparatively low activity of the usual Ziegler–Natta catalysts is the small number of AC, not exceeding 0.01 mol per mol of the transition metal. In practice this quantity is considerably lower in most instances. A

sharp increase of the number of centres has been achieved using deposited catalysts. The employment of carriers such as polyethylene and silica gel, on the surfaces of which the active component exists as a finely dispersed titanium chloride phase, makes it possible to increase the number of AC in the polymerisation of ethylene approximately by an order of magnitude. The maximum number of propagation centres is attained as a result of the "structural" binding of titanium chloride by anhydrous highly dispersed magnesium chloride having a disordered structure.

The most important characteristic of the catalytic polymerisation, which to a large extent determines the process kinetics, is the influence of the polymerisation conditions and the composition of the reaction medium on the number of AC. Observations such as the influence of the polymerisation temperature and the nature and concentration of the OAC on the number of AC were explained in this connection by an adsorption mechanism for the reversible interaction of the OAC with the monometallic AC.

Numerous data, particularly those concerning the absence of an effect of the nature of the OAC on k_p, are consistent with the monometallic composition of the AC.

Increasing amounts of experimental data have been accumulated at the present time concerning the preliminary coordination of the monomer to the metal ion before the step involving the insertion of the olefin either into the transition metal–carbon bond in the far-reaching polymerisation of olefins or into the aluminium–carbon bond in the oligomerisation of the olefins. Kinetic as well as calculated data suggest that in many instances this stage can be rate-limiting in the propagation reaction.

The high reactivity of the AC containing a transition metal is determined by the low activation energy for the propagation reaction, which is comparable to the activation energy for radical polymerisation. The insertion of the olefin in the transition metal–carbon and aluminium–carbon bonds proceeds via the same two-stage mechanism, but in the case of a transition metal a significant decrease of the activation energy for the propagation reaction is achieved.

The method based on the inhibition of the polymerisation by a radioactive alcohol is useful for the direct determination of the rate constant for the transfer of the polymer chain from the OAC. This constant depends on the nature of the OAC and the structure of the polymer chain, which is due to the adsorption mechanism of this reaction. The rate constants for other chain transfer processes have been determined from the k_p.

Further development of ideas concerning the elementary stages in the propagation and polymer chain termination reactions can be achieved by using quantum-chemical and physical methods in the study of these reactions. In the formulation of investigations using physical methods it is as a rule necessary to employ catalysts in which the number of AC constitutes an appreciable fraction of the content of the transition metal in the catalyst; it is then necessary to estimate this value quantitatively. As a result of the selection of the optimum composition and preparation conditions for the catalyst (particularly in the deposition of a transition metal compound on a carrier), it is possible to increase sharply the number of AC and to obtain highly active one- and two-component catalysts. These catalysts are widely used nowadays and are at the same time convenient for the investigation of the composition of the AC and the polymerisation mechanism by physical methods. The results obtained by physical research methods together with the determinations of the rate constants for individual stages can serve as a basis for the establishment of relations between the composition of the AC, the state of the transition metal in the AC, and their reactivity in chain propagation and transfer reactions.

The Attaching of Biologically Active Compounds to the Surfaces of Optical Materials

A.Baigozhin

The methods of forming chemisorbed molecular films with fungicidal, hydrophobic, and other useful properties on the surfaces of optical materials as well as the prospects for the employment of such films are surveyed.
The bibliography includes 105 references.

CONTENTS

I. Introduction 1112
II. Methods for the formation of biologically active films on the surfaces of optical components 1112
III. The grafting of biologically active compounds to the surfaces of optical materials 1113
IV. The mechanism of the fungicidal action of organoelementosiloxane films bound chemically to the surfaces of optical glasses 1116

I. INTRODUCTION

Under the conditions of a moist tropical climate, materials are infected with microorganisms, which leads to their premature ageing. Microscopic fungi cause considerable damage to materials such as leather, textiles, rubber, optical glass, and others[1-18]. It is known that under moist tropical conditions the surfaces of optical components (lenses, prisms, etc.) in instruments are coated by growing microscopic fungi and are damaged by them[2-12,17,18]. Even small amounts of fungi on the surface of optical components, invisible to naked eye on other materials, lower the quality of the optical systems of instruments. Many valuable optical instruments and optical equipment have been put out of order as a consequence of infection by microorganisms[3-6].

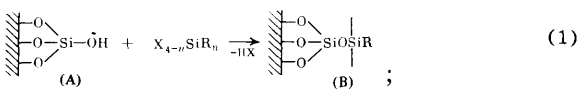
In order to protect from biological damage materials and articles designed for use under tropical conditions, it is suggested that substances with fungicidal or fungistatic properties be used; with the aid of fungicides, it is possible to increase the reliability and the useful lifetime of articles under the conditions of a moist tropical climate[16-18].

Volatile fungicides have been proposed[4,5,14,17,19-21] (impregnation of packing material, fungicide placed in cartridges and in porous materials, introduction of fungicide into greases, putty, and varnishes, used in the inner spaces within apparatus). However, these attempts did not yield the desirable results, because certain fungicidal substances, while protecting the instrument from biological growth, caused the corrosion of metallic components or, by condensing, formed deposits on the surfaces of optical components which impaired their light transmittance. In order to impart biological stability to different materials, they have been frequently impregnated with fungicidal solutions or emulsions[16-23]. In this case the fungicides protect the materials only for a short time, since they are washed away. Much attention has therefore been devoted to the creation of materials in which biologically active compounds would be attached to the surface by chemical bonds[18,22-24,49-54].

During recent years extensive experimental data have accumulated on the formation of chemisorbed molecular biologically active films on the surfaces of optical components, which do not change the optical properties of glasses but effectively protect them from biological growth and damage. This review is a brief survey of research devoted to the attaching of compounds with biological activity and other useful properties to the surfaces of optical materials. Its aim is to survey the accumulated data in this field, which is of significant theoretical importance and has a wide variety of practical applications.

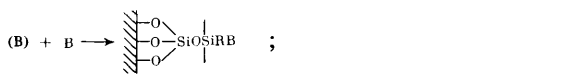
II. METHODS FOR THE FORMATION OF BIOLOGICALLY ACTIVE FILMS ON THE SURFACES OF OPTICAL COMPONENTS

The classical study by Academician Grebenshchikov on the chemistry of glass has shown that the surface properties of glass are determined mainly not by its composition but by new formations arising in the course of its interaction with water[25]. Grebenshchikov used the term "prosvetlemie optiki" [deposition of non-reflective layers on optical glass] for the formation on glass of thin films leading to a decrease of the amount of light reflected from its surface. Studies on the coating of optical glass and the formation of thin transparent films on its surface have been surveyed in monographs[26,27]. Further investigation of the mechanism of the production of new formations and of their properties made it possible to modify specifically the properties of the surfaces of optical glasses over a wide range[28-30,51]. One of such methods involves the attaching of organoelemental compounds, with biological activity and other useful properties, to the surfaces of optical materials.



The attachment of biologically active compounds directly to the surfaces of optical materials presents considerable difficulties. The unmodified surface of the glass cannot retain appreciable amounts of the substance preventing the development of microscopic fungi. The modification of the surfaces of silicate materials by organosilicon compounds in order to impart to them hydrophobic properties[27,31,32], to form optical coatings[27,33,34], to reduce[35,36] or increase[36,37] the adhesion of polymeric resins, or as a finish to reinforced plastics has been the subject of a large number of studies surveyed in a series of reviews and monographs[27 31,37,43,47,48]. However, in these investigations the problems of attaching biologically active compounds to the surfaces of optical materials were not considered.

A series of investigations have been devoted to the development of fundamentally new methods, based on chemical reactions, for the specific modification of the surface properties of optical materials[18,49-54]. It was of interest to synthesise biologically active films by the chemical modification of glass. Such films must satisfy the following requirements:

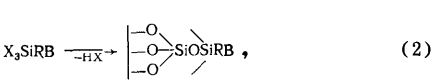


(a) they must adhere effectively to the glass and must be mechanically strong; (b) they must be stable during use under specified climatic conditions; (c) they must not impair the optical properties of glasses; (d) they must not act on the materials forming part of the construction of the instrument or apparatus.

For the chemical modification of the surface of glass, it proved promising to investigate organosilicon compounds of the type R_nSiX_{4-n}. The interest in this group of substances is due to the fact that they contain two types of reactive groups among which groups X (chlorine or lower alkoxy-groups) react with the OH groups on the surface of glass and groups R (organic substituent containing functional groups) interact with the binders. As a result of this, it is possible to carry out a wide variety of reactions on the basis of compounds of this type as a function of the type and nature of the functional groups and the reacting (binding) substances. Carbofunctional organosilicon compounds have found extensive applications for increasing the adhesion of polymeric resins to various materials[38–48] and particularly for increasing the resistance of transparent plastics to water[43,48].

The possibility of attaching biologically active substances to the surfaces of optical materials with the aid of organosilicon compounds containing functional groups has been demonstrated in a number of studies[18,49–54]. Biologically active films are synthesised via mechanisms (1) and (2):

(1)



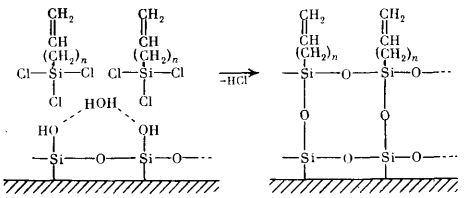
;

R=CH=CH₂, CH₂—CH=CH₂,
—(CH₂)₃—O—CH₂—CH—CH₂, —(CH₂)₃NH₂, X = Cl, OCH₃, or OC₂H₅ .

Here (A) is the surface of the glass, (B) the modified surface of the glass, and B the biologically active compound inhibiting the development of microorganisms.

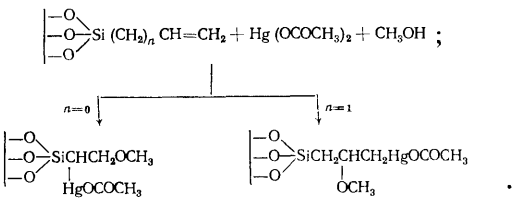
Films are synthesised in two stages via mechanism (1)—initially a carbofunctional organosilicon compound and then the biologically active substance are deposited on the surface of the glass. This yields organoelementosiloxane films which protect the surfaces of optical components from microbiological growth and damage[49–52,54].

The synthesis of surface-active compounds via mechanism (2), where biologically active groups are already contained in the initial organosilicon compound, i.e. in the organic group R, is more promising and technologically more useful[53]. Thus it is possible to graft biologically active compounds to the surfaces of glass or other materials in a single stage:



(2)

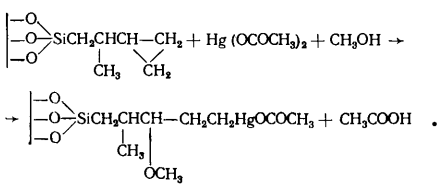
where R is an organic substitutent or a substituent containing a functional group, B is a biologically active group (for example, HgR′, AsR'_2, and SnR'_3, where R′ is an organic substituent or an acid residue), and X = OCH_3 or OC_2H_5.



Mechanism (2) has been studied very little, since the methods of synthesis of organosilicon compounds containing biologically active fragments have been developed only recently [55–58]. The modification of the surfaces of materials by organoelemental siloxanes via mechanism (2) in order to alter specifically their surface properties is undoubtedly of great interest. Examples of the attaching of biologically active compounds to the surfaces of optical materials via the mechanisms described above will be considered below.

III. THE GRAFTING OF BIOLOGICALLY ACTIVE COMPOUNDS TO THE SURFACES OF OPTICAL MATERIALS

It is known that organomercury compounds are the most universal fungicides, effective against a wide range of microorganisms and active at very low concentrations[59–62]. For example, alkyl(aryl)mercury acetates prevent the growth of a wide variety of microorganisms at a dilution of $1 : 8 \times 10^6$ and some of them at a dilution of $1 : 2 \times 10^7$. A two-stage method for the synthesis of organomercurisiloxane films on the surfaces of optical glasses has been developed[49,50,54]. Optical components made of different brands of silicate glasses are treated initially with a solution of trichlorovinyl(or allyl)-silane in a non-polar solvent or with solution of triethoxy-vinyl(allyl)silane in water or alcohol. In the hydrolysis of alkenyltrichloro(ethoxy)silanes the aqueous film and the hydroxy-groups present on the surface of the glass are involved in the reaction. The reaction of alkenylsilanes with the surface of the glass is represented schematically as follows[38,44,50]:



Hydrophobic alkenylsiloxane films are then formed on the surface of the component. These components are then treated further with a methanol solution of mercury acetate. Mercury acetate in methanol or aqueous solutions is known to add quantitatively to the ethylene linkage[62–66]. The reaction of the alkenylsiloxane film with mercury acetate can be represented by the following scheme:

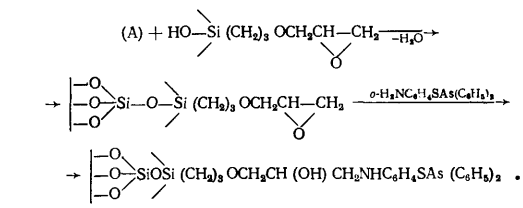
As a result of the exposure to a methanol solution of mercury acetate of glass treated with trichloro(ethoxy)vinyl(or allyl)silane, molecular films of α-acetoxy-β-methoxymercuriethylsiloxane and 3-acetoxy-2-methoxymercuripropylsiloxane are formed respectively. The addition of mercury acetate in methanol to vinylsiloxane takes place contrary to the Markovnikov rule, the mercury atom with the acid residue forming a bond with the carbon atom containing fewer hydrogen atoms, which is caused by the electropositive properties of the silicon atom; the addition to allylsiloxane proceeds in conformity with the Markovnikov rule. The validity of these reaction mechanisms has been confirmed by the model synthesis with trimethylvinylsilane[67].

A method has been proposed for attaching an organomercury compound on the surface of glass using trichloro-2-(cyclopropyl)propylsilane instead of alkenylchlorosilanes[18]. Cyclopropane derivatives are capable of undergoing a reaction, involving the opening of the ring, with mercury acetate in methanol[68], and the products exhibit an extremely high

biological activity[69]. The formation of an organomercury compound on the surface of the glass can be represented by the following scheme:

The addition of mercury acetate to alkenylsiloxane groups proceeds in the course of 1–2 h (complete saturation with mercury), while the addition to 2-(cyclopropyl)propylsiloxane groups is somewhat slower: complete saturation takes place only after six days, but the resulting molecular film of 5-acetoxy-3-methoxy-2-methylmercuripentylsiloxane is stable over a period of time[18].

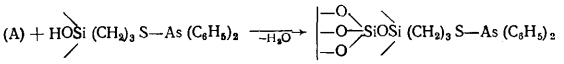
The addition of mercury acetate has been monitored on the basis of the variation of the wetting angle for the wetting of organosiloxane films with water, by determining the amount of mercury on the surface of the glass, and on the basis of the results of microbiological tests[18,50,51].



It has been shown[18] that the calculated area per hydroxy-group of the SiO_2 surface hydrated to the maximum extent varies from 10.4 to 16.8 Å^2. It has been established[70] that the actual surface of polished quartz is 2.4 times greater than the geometrical surface. On the basis of these data, it is easy to show in relation to a monomolecular layer that there should be approximately 0.9×10^{-6} g of mercury per cm^2 of the treated surface of the glas [it has been found[18,50] that the amount of mercury per cm^2 is $(1.0–1.2) \times 10^{-6}$ g].

Microbiological tests have demonstrated[50,51,71,72] that optical glasses coated by organomercurisiloxane films are not damaged by moulds when they are deliberately infected by aggressive fungal cultures under conditions imitating a moist tropical climate in the course of one and a half years, while control glasses are damaged by such fungi after 10–15 days. These results were confirmed by a special investigation under natural subtropical and moist tropical conditions[18,50,51]. One should note that the surface of the glass treated solely with organosilanes or solely with a methanol solution of mercury acetate without a preliminary deposition of an alkenyl- or cyclopropyl-siloxane film does not prevent the development of the spores of moulds or exhibits only a very weak activity which disappears after the first month of tests.

One should note that fungicidal organomercurisiloxane films with a thickness of 10–15 Å do not influence the optical properties of glasses[50–51]. These films can be formed on all optical silicate materials. They are also applicable to non-silicate materials when non-reflective layers are deposited on their surfaces. Optical materials are as a rule coated using refractory metal oxides (Ti, Zr, Hf, Se, etc. oxides). Non-reflective layers made of these oxides are obtained by a chemical method or by vacuum sputtering[27] and in multilayer coating the last layer is usually silica.

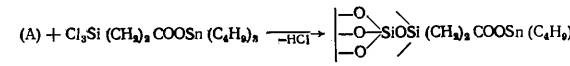


2. Organosiloxane Films Containing Arsenic

In order to obtain fungicidal films, certain organoarsino-siloxanes have been investigated. They are of interest, because they combine the known properties of polysiloxane with the ability to prevent the development of various micro-organisms. These properties permit their use both as agents imparting hydrophobic properties and as fungicides. According to mechanism (1), the glasses are initially treated for this purpose with an ethanol solution of 2,3-epoxypropoxypropyl-triethoxysilane and then with a toluene solution of *o*-amino-phenylthiodiphenylarsine[18]:

Optical glasses treated in accordance with this scheme are not affected by moulds under conditions imitating those in a moist tropical climate.

In recent years methods have been developed for the formation of trialkoxysilylalkyl esters of arsenic(III) thioacids[73,74]. The most active compound—triethoxy-γ-(diphenylarsinothio)-propylsilane—forming thin transparent fungicidal films on the surface of glass, was selected from these esters[53]:

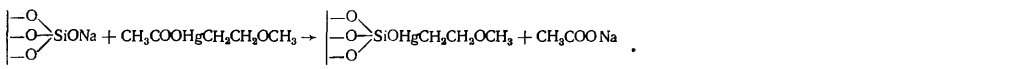


The γ-(diphenylarsinothio)propylsiloxane film is mechanically strong and is not washed away by organic solvents. Optical glasses protected in this way are resistant to microbiological growth[85].

3. Films Based on Organotin(Silicon) Compounds

It has been established[75,76] that organotin compounds of the type R_3SnX, where R = alkyl and X is an organic or inorganic acid residue, exhibit an extremely high fungicidal activity, comparable to that of mercury compounds. In contrast to R, the nature of the acid residue does not have a significant influence on the activity of the compound. It has been shown[76] that, among asymmetric acyltrialkylstannanes, maximum toxicity to fungi is shown when the total number of carbon atoms is 9–12, regardless of the nature of the individual groups.

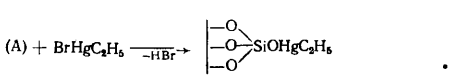
Organotin compounds of the type indicated above have found extensive applications for the protection of a wide variety of materials against microbiological growth[77–83]. Among compounds of this class, triethylmethacryloxystannane (TEMS) proved to be of greatest interest. Its alcoholic solutions form on the surface of glass transparent but mechanically weak films. This disadvantage was eliminated by combining TEMS with tetraethoxysilane and polydimethylphosphorosiloxane (GSF-3).[84,85] Films obtained from a mixture of solutions of the above compounds are mechanically strong and effectively protect optical components made of chemically unstable glasses (of the type STK, TBF, TFK, and others) against biological damage[85]. Furthermore, TEMS mixed with a PTFE varnish forms a film on the surfaces of optical components made of LiF crystals, which does not alter the optical properties of the crystals and protects them against moisture and biological growth[86].



These films can be used to protect silicate and non-silicate materials. At the same time methods have been proposed for the grafting of organotin(silicon) compounds by treating the glass with solutions of trialkyltin trichlorosilylalkanoates, for example, tributyltin β-trichlorosilylpropionate[87]:

The β-(tributylstannylcarboxy)ethylsiloxane film is hydrolytically unstable and therefore protects the glass against biological growth only for a short time. A film with an increased hydrolytic stability has been obtained on the basis of β-(triethylstannylthio)ethyltriethoxysilane[105].

4. Films Containing the Si–O–M Group

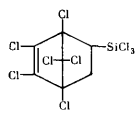


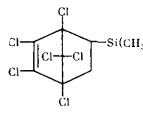
It has been suggested that glasses be treated with an ethanol solution of methoxyethylmercury acetate in order to protect optical components from damage by moulds[88,89]. It is suggested that such treatment results in the formation of a fungicidal coating—methoxyethylmercury silicate—via the mechanism[89]

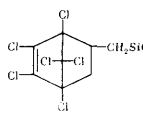
When sodium ethyl- or methyl-siliconate is deposited on textile fabrics, the surfaces of the latter become hydrophobic. There is evidence[90,91] that, when fabrics treated in this way are immersed in an aqueous solution of a copper salt, sodium ions are replaced by copper ions and the fabric then requires resistance to moulds. On this basis and bearing in mind the use of the oligodynamic properties of noble metals, it was of interest to obtain such compounds on the surface of glass. For this purpose, glasses were initially coated with sodium ethyl- or methyl-siliconate and then with solutions of copper, silver, and platinum salts; as a result of such treatment, the glasses were not affected by fungi for two months[18,50].

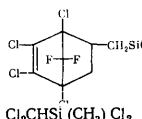
It has been suggested that optical components be protected by depositing coatings from a mixture of an alcoholic solution of tetraethoxysilane, lead acetate, and boric acid[92]. Heat treatment (at ~400 °C) of this coating results in the formation of silicon, boron, and lead oxides on the surface of the glass; the oxides retard the development of moulds, but rapidly become turbid on the surface of the glass under the influence of atmospheric moisture. The composition of this coating resembles that of lead borate glasses (BSZ, TS8, etc.), which are chemically unstable and require protection from atmospheric moisture.

The authors of a patent[93] deposited a fungicidal coating from hydrolysable solutions of silicate and titanate esters in the presence of soluble copper or mercury compounds. However, the deposition of fungicidal coatings on the surface of glass from hydrolysable solutions of tetraethoxysilane with introduction of copper, silver, mercury, and lead salts as well as certain organic fungicides—chlorophenols, nitro-(fluoro)benzenes, and other compounds—proved to be insufficiently effective against damage by moulds[18,50,94]. A method has been proposed[95] for protecting optical components in accordance with the scheme









The fungicidal coating thus obtained inhibit the development of microorganisms only for a short time (for 2–3 months). This is because compounds containing the group $\geq$Si–O–M (where M = Hg, Ag, Cu, Pb, or B) are readily hydrolysed under the influence of atmospheric moisture, losing their fungicidal properties.

5. Halogeno-organosiloxane Films

The comparative study of the properties of chloro- and fluoro-derivatives of organosiloxanes on the surfaces of optical glasses appeared of interest because in many instances the introduction of a fluorine atom instead of chlorine or their joint presence in the composition of organic molecules greatly increases the fungicidal action of the compound. On this basis, films of compounds of the type R_nSiX_{4-n} [R = organochloro(fluoro)-group], the formulae of which are given in the Table, have been obtained on the surface of glass[18,50]. These compounds contain active chlorosilyl groups, which interact chemically with the surface of the glass on which there are covalently bound hydroxy-groups and adsorbed water molecules, and give rise to thin halogeno-organosiloxane films,

The fungicidal activities of organofluoro(chloro)siloxane films on the surface of glass[18,50].

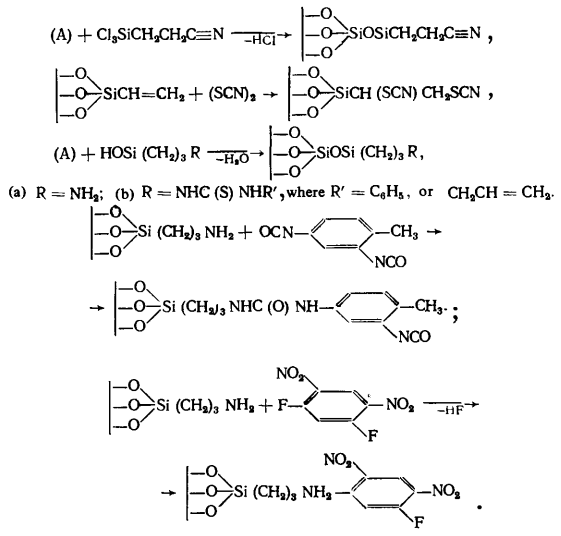
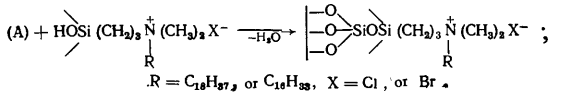
Note: "–"—not resistant to fungi; "+"—resistant to fungi.



Chloro-organosiloxane films on the surface of glass do not prevent the development of moulds. Fluoro-organosiloxane films, obtained from compounds Nos.15–17 (see Table), suppressed the development of the spores of moulds in the course of 3–4 months, but subsequently the growth of fungi intensifies. The remaining fluoro-derivatives of silanes listed in the Table do not protect glass from the growth of moulds[18,50].

Iodine and its compounds are classical antiseptics. It is known that iodine adds quantitatively to unsaturated organic compounds and it has been shown that glasses with an

attached vinylsiloxane film, treated in iodine vapour or a solution of iodine in chloroform[18,52] are not overgrown by moulds in the course of 5 months under conditions imitating those in the tropics. However, iodo-organosiloxane films on the surface of glass have absorption bands in the visible region of the spectrum and in addition are unstable under the influence of light.



6. Nitrogen-Containing Organosiloxane Films

Since nitrogen-containing organosilicon compounds exhibit a high biological activity[55,56,97,99], it appeared of interest to attempt to use them for the formation of protective films on the surface of glass. For this purpose, the following reactions were carried out in succession on the surface of glass (A):[18,50,98,99]

Organosiloxane films containing cyano-, thiocyanato-, amino-, and phenyl(allyl)-thiourea groups and formed on the surface of the glass do not prevent the development of moulds. Fluoro(nitro)phenylaminopropylsiloxane films arrest the growth of fungi for a short time[18,50].

It has been shown[100] that the surfaces of materials, including glasses, are reistant to the action of a wide range of micro-organisms when they are treated with a solution of *N,N*-dimethyl-*N*-octadecyl-*N*-(3-trimethoxysilylpropyl)-ammonium chloride. As a consequence of a further development of these studies, the glasses were then treated with the products of the hydrolysis of organosilicon quaternary ammonium salts via the mechanism

Films obtained from the above compounds and tested by the method developed by Rodionova and coworkers[71,72] protected glasses from the growth of moulds for a short time.

It is noteworthy that the organosilicon quaternary ammonium compounds indicated above, deposited on the surface of glass, orient nematic liquid crytals homogeneously or homeotropically, depending on the functional groups in the organic substituent attached to the silicon atom and are used in the manufacture of liquid crystal devices[101].

IV. THE MECHANISM OF THE FUNGICIDAL ACTION OF ORGANOELEMENT SILOXANE FILMS BOUND CHEMICALLY TO THE SURFACES OF OPTICAL GLASSES

One of the current problems is the elucidation of the chemical mechanism of the action of fungicides, which is linked directly to their structure and reactivity. Numerous studies, surveyed in a number of reviews and monographs[61,102–104], have been devoted to the mechanism of the action of fungicides.

The majority of the known fungicides have been discovered empirically. Although complex biochemical and physicochemical mechanisms of the action of fungicides at a molecular level have been investigated inadequately, a definite idea about them has already been formulated. Three main types of action of fungicides have been distinguished[102–104]:

(1) inhibition of bioenergetic processes (cell respiration, oxidative phosphorylation, etc.);

(2) inhibition of the biosynthesis of low-molecular-weight (aminoacids, vitamins, etc.) and high-molecular-weight (proteins, DNA, RNA) compounds;

(3) the breakdown of the permeability of cell membranes (physicochemical breakdown of cell structures).

In general, the mechanisms of the action of fungicides bound chemically to the surface of glass agree with the mechanisms of the action of the usual fungicides indicated above, but they can have their characteristic features requiring amplification and refinement. It is known that enzymes (as biocatalysts) are involved in all biochemical processes in the cell and thus promote its growth and development. In this connection, we believe that the main function of organosiloxane films, containing biocidal groups in the organic substituent and bound chemically to the surface of glass, is to act against enzymes, i.e. the films should inhibit or disrupt the activity of vitally important "transport" enzymes with sulphydryl groups SH. This task can be fulfilled by organosiloxane films containing in the organic substituent heavy metal atoms, particularly Hg and Sn atoms. The methods for the synthesis of such organomercuri- and organostannyl-siloxane films on the surface of glass and their properties were examined above. These molecular films, with a thickness of ~10–15 Å, protect the glass from the growth of mould without altering its optical properties.

Next one must consider another possible mechanism of the action of organoelementosiloxane films on microorganisms. The majority of the cells in a living organism approach to some extent the crystalline state. A wide variety of types of molecules, occupying a more or less fixed position and oriented in a specific manner, exist in a "crystal-like state" in the cell. It is therefore possible that certain organoelementosiloxane films disrupt a specific orientation of the molecules within the cell and hence alter the normal cell metabolism, which suppresses its vital activity, i.e. the films act as fungistatic agents. For example, γ-trifluoropropyl- and bis-(γ-trifluoropropyl)-siloxane films prevent the development of fungi for 3–4 months under conditions where they are deliberately infected with the spores of moulds[18,50]. At the same time, it is known that organosiloxane films containing functional groups in the organic substituent give rise to a time-invariant orientation of the molecules of nematic liquid crystals towards the surface of the glass either homogeneously or homeotropically, depending on the type of substituents and their functional groups[101].

On the basis of experimental data, it is possible to arrive at quite definite conclusions concerning the principles governing the search for and selection of highly effective biologically active compounds and their use for the formation of molecular films on the surfaces of optical components,

which do not alter the optical properties of the glasses but protect them from microbiological growth and damage.

Evidently, according to the proposed working mechanisms (1) and (2), it is possible to set up organoelementosiloxane films with fungicidal and other useful properties. It has been shown that organomercuri(stannyl)siloxane films exhibit for a long time a fungistatic activity at very low concentrations, which is important for the protection of specific properties of materials. New highly effective fungicides have been found—film-forming tin compounds of the type R_3SnX, where R = ethyl or butyl and X is a residue of an unsaturated carboxylic acid (as, for example, in triethylmethacryloxystannane).

Tests on various organoelementosiloxane films on the surfaces of optical materials led to the following findings:

1. If the biologically active atom or group of atoms is bound to the organosiloxane fragment by a strong covalent bond, then the films do not prevent the development of moulds.

2. If the biologically active atom or group of atoms is bound to the organosiloxane fragment by an ionic, coordinate, or polar covalent bond, the films protect the optical components from the grown of moulds. The duration of action of the film depends on the nature of the chemical bond formed by the atom or group of atoms; it increases in the sequence ionic < coordinate < polar covalent bond.

In conclusion we may note that the data described above indicate fairly convincingly the extensive possibilities for the occurrence of a wide variety of reactions leading to the formation on the surfaces of optical materials of molecular films with useful properties. Similar reactions can be used to form films on other solid materials with covalently bound hydroxy- or other reactive groups on the surface. The present author believes that organoelementosiloxane films on the surfaces of materials can be used to set up models of enzymes or antienzyme systems, protein substances, highly effective medicinal preparations with a wide spectrum of therapeutic action, selective catalysts, corrosion inhibitors, orienting coatings for liquid crystals, and other systems.

Oxidative Decarboxylation of Carboxylic Acids

Yu.A.Serguchev and I.P.Beletskaya

The present state of studies on the decarboxylation of carboxylic acids by various oxidation systems is described and the dependence of the yield and composition of the reaction products on the structure of the carboxylic acid, the type of oxidant and its ligand environment, the nature of the solvent, and the reaction mechanism is considered. The intermediate involvement of radicals and ions, produced by successive one-electron transfer processes, in the formation of a wide variety of decarboxylation products is discussed.
The bibliography includes 156 references.

I. INTRODUCTION

The decarboxylation of carboxylic acids by the fusion of their alkali metal salts with caustic alkali and by the anodic oxidation of the acids and their salts (the Kolbe reaction) are familiar methods for the synthesis of alkanes. Together with alkanes, alkenes, alcohols, esters, and ethers are also formed in the Kolbe reaction and under certain conditions their yields can exceed that of alkanes[1-4].

The oxidative decarboxylation of carboxylic acids by transition metal salts and persulphates has been investigated vigorously in recent years. The practical value of the oxidative decarboxylation consists in the fact that, with the aid of this process, it is possible to obtain a series of important chemical products (alkanes, alkenes, ethers, esters, alcohols, alkyl halides, etc.). Decarboxylation takes place in the living organisms with participation of enzymes; some of these reactions are reversible and play an important role in the biological assimilation of carbon dioxide.

In the study of the mechanism of the oxidation process it is important to know whether the reaction takes place as a result of consecutive one-electron stages or as a two-electron process in a single stage. The yield and composition of the products depend in many respects on the kind of intermediate species formed—radicals and carbonium ions. Thus oxidative decarboxylation of carboxylic acids is a process in which the specific formation of the required synthetic products is closely related to the theoretical aspects of the oxidation reactions.

The decarboxylation of carboxylic acids by lead tetra-acetate has been used by a number of workers as a synthetic method[5-13]. The study of the mechanism of the decarboxylation of carboxylic acids was begun in the 1960s by Waters in aqueous media[14] and by Kochi in non-aqueous media[15]. The general mechanism of the decarboxylation reaction under the influence of oxidants[16] as well as anodic decarboxylation[4] is

represented as follows:

$$\mathrm{RCOOH} \begin{cases} \xrightarrow{-e,-H^+} \mathrm{RCOO^\cdot} \rightarrow \mathrm{R^\cdot} + \mathrm{CO_2} \\ \qquad\qquad\quad \downarrow -e \\ \xrightarrow{-2e,-H^+} \mathrm{R^+} + \mathrm{CO_2} \end{cases} \quad (1)$$

The radicals R· can react with hydrogen donors (for example, with the molecules of the solvent SH), giving rise to alkanes [Eqn.(2*c*)] and also dimerising with formation of R–R products [Eqn.(2*a*)] and disproportionating into alkanes RH and alkenes R(-H) [Eqn.(2*b*)]:

$$\mathrm{R^\cdot} \begin{cases} \xrightarrow[a]{\mathrm{R^\cdot}} \mathrm{R{-}R} \\ \xrightarrow[b]{\mathrm{R^\cdot}} \mathrm{RH} + \mathrm{R(-H)} \\ \xrightarrow[c]{\mathrm{SH}} \mathrm{RH} + \mathrm{S^\cdot} \end{cases} \quad (2)$$

Further oxidation of the radicals by metal salts leads to the formation of elimination products (alkenes) and substitution products (ethers, alcohols, and alkyl halides) via two-electron transfer mechanisms, which are known in inorganic chemistry as outer-sphere and inner-sphere mechanisms[16,17]:

$$\begin{array}{c} \mathrm{R^\cdot} + \mathrm{ML}_n \xrightarrow{a} [\mathrm{R^\cdot ML}_n] \xrightarrow{c} \mathrm{R^+} + \mathrm{ML}_{n-1} + \mathrm{L^{-1}} \\ \qquad\quad {\scriptstyle b}\swarrow \qquad\qquad {\scriptstyle d}\downarrow \mathrm{An^-(L)} \\ \mathrm{R(-H)} + \mathrm{RL} + \mathrm{ML}_{n-1} \qquad \mathrm{RA}\ (\mathrm{RL}),\ \mathrm{R(-H)}. \end{array} \quad (3)$$

In conformity with the inner-sphere mechanism or the ligand-transfer mechanism, substitution takes place in the complex without the intermediate formation of carbonium ions [Eqns.(3*a*) and (3*b*)]. The mechanism can therefore also yield alkenes. In the outer-sphere, solvolytic, or classical carbonium ion mechanism, carbonium ions are formed as intermediates and their subsequent transformation leads to alkenes as a result of the loss of a proton or to substitution products as a result of the interaction of the carbonium ion with an anion [Eqns.(3*a*), (3*c*), and (3*d*)]. The yield and composition of the oxidative decarboxylation products depend significantly on the oxidant, the structure of the carboxylic acid, and the nature of the anions and the ligands associated with the metal cations.

The aim of the present review is to examine and, as far as possible, to survey the results of studies on the decarboxylation of carboxylic acids under the influence of various oxidation systems. The literature quoted in the review covers mainly the period of the last thirty years. The review does not include the decarboxylation reactions of silver salts of carboxylic acids, which take place under the influence of halogens in aprotic solvents and lead to alkyl halides (the Borodin–Hunsdiecker reaction) and to esters (the Simonini reaction). A review[18] has been devoted to the Borodin–Hunsdiecker reaction, after which there were few publications in the literature concerning this process. Furthermore, both these reactions are of a complex type and their mechanisms are not altogether clear. Their study is frequently complicated by heterogeneous reaction conditions.

Decarboxylation under the influence of electrophiles (bromine, H^+) in protic media, decarboxylation in basic solvents, and enzymatic decarboxylation, which has its specific features, have also been excluded from consideration. A monograph has been devoted to decarboxylation reactions leading to organometallic compounds[19] and we shall therefore confine ourselves to considering only the general characteristics of reactions of this type. This also applies to decarboxylation reactions coupled with oxidation[20], i.e. to the reaction involving the oxidation of the hydrocarbon group of the acid, which is accompanied by decarboxylation.

II. THERMAL OXIDATIVE DECARBOXYLATION UNDER THE INFLUENCE OF TRANSITION METAL SALTS AND PERSULPHATES

The reactions of carboxylic acids with transition metal salts have been studied as a rule in water, acetonitrile, benzene, and the carboxylic acids themselves. The formation of the metal carboxylates constitutes a rapid pre-equilibrium stage of the decarboxylation reaction in carboxylic acids and in benzene in the presence of metal salts:

$$\mathrm{M(OAc)}_n + n\,\mathrm{RCO_2H} \rightleftarrows \mathrm{M(O_2CR)}_n + n\,\mathrm{HOAc}\ .$$

Metal carboxylates have been studied in detail by various physicochemical methods. Investigation of infrared and ultraviolet (220–270 nm) absorption spectra of lead carboxylates made it possible to classify them as charge-transfer complexes[21]. Solutions of cerium(IV) acetate in carboxylic acids have a yellow orange colour[22] and are stable for several days when kept in the dark in the absence of water and air. The cerium complex of acetic acid in aqueous solutions has an absorption band with a maximum at 286 nm.[23] Monomeric, dimeric, and trimeric cerium complexes of acetic acid have been detected spectrophotometrically[24]. Thallium(III) valerate in cyclohexane has a broad absorption band in the near ultraviolet below 360 nm.[25] Studies of the mass spectra of thallium(III) carboxylates led to the detection of the ions $(CH_3CO_2)_3Tl^+$ and $(C_6H_5CO_2)_nTl^+$, where $n = 1$ or 2.[26] In cobalt(III) acetate, which exists in a dimeric form in acetic acid, the acetoxy-groups are easily substituted by the anions of butyric, isobutyric, and pivalic acids[27]. Apparently one cannot always expect the complete substitution of the acetoxy-groups in metal acetates by the carboxylate groups of higher acids—incomplete substitution has been observed in the reaction of manganese(III) acetate with pivalic acid[28]:

$$\mathrm{Mn(OAc)_3} + \mathrm{RCO_2H} \rightleftarrows \mathrm{Mn(OAc)}_{3-n}\mathrm{(O_2CR)}_n + n\,\mathrm{HOAc}\ .$$

In an aqueous medium the Ce^{4+} [23] and Co^{3+} [14] cations interact with the undissociated forms of the acids:

$$\mathrm{Ce(H_2O)_8^{4+}} + \mathrm{RCO_2H} \rightleftarrows [\mathrm{Ce(H_2O)_7\,RCO_2}]^{3+} + \mathrm{H^+} + \mathrm{H_2O}\ ;$$

$$\mathrm{Co(H_2O)_6^{3+}} + \mathrm{RCO_2H} \rightleftarrows [\mathrm{Co(H_2O)_5\,RCO_2}]^{2+} + \mathrm{H^+} + \mathrm{H_2O}\ .$$

The decomposition of metal carboxylates, accompanied by decarboxylation, can occur on heating; we have called this process thermal oxidative decarboxylation. The yield and composition of the products of this reaction depend on the structure of the acid. Literature data are therefore considered below for different types of carboxylic acids.

1. Alkane- and Arylalkane- Carboxylic Acids

Thermal oxidative decarboxylation of alkane- and arylalkane-carboxylic acids yields alkanes, alkenes, esters, and other products, the yield of which depends significantly on the structure of the carboxylic acid RCOOH. For the same oxidant, the yield of alkenes and esters decreases in the following sequence of groups R: tertiary > secondary > primary. This sequence is correlated with the increase of the ionisation potentials of the radicals and with the decrease of the stability of the carbonium ions[16].

The yield and composition of the decarboxylation products also depend significantly on the kind of oxidant and on the reaction mechanism, so that further consideration of the thermal oxidative decarboxylation in this Section can be usefully related to the characteristics of the reaction mechanism for the following groups of oxidants: one-electron (Ce^{4+}, Ag^{2+},

Co^{3+}, and Mn^{3+}), two-electron (Pb^{4+} and Tl^{3+}), binary systems containing Cu^{2+} (Pb^{4+}–Cu^{2+}, Mn^{3+}–Cu^{2+}, and Co^{3+}–Cu^{2+}), and persulphates.

(a) *One-electron oxidants.* The equations of the decarboxylation reactions under the influence of Co^{2+},[27] Mn^{3+},[28] Ce^{4+},[29] and Ag^{2+},[30] in which mainly the products of one-electron and two-electron oxidation are formed, are as follows:

$$M^n(O_2CCH_2CH_2CH_3)_n \rightarrow M^{n-1}(O_2CCH_2CH_2CH_3)_{n-1} + CH_3CH_2CH_3 + CO_2 ,$$

$$2M^n[O_2CC(CH_3)_3]_n \rightarrow 2M^{n-1}[O_2CC(CH_3)_3]_{n+1} + (CH_3)_2C{=}CH_2 + CO_2 + (CH_3)_3CCOOH .$$

It is interesting to consider how the composition of the thermal oxidative decarboxylation varies with the type of metal ion. A clear-cut dependence of the yield of the decarboxylation products on the normal reduction potentials of the metal ions was not observed[16]. Thus the reduction potential of Cu^{2+} (0.153 eV) is much lower than that of Co^{3+} (1.84 eV), Ag^{2+} (2.0 eV), Ce^{4+} (1.70 eV), and Mn^{3+} (1.51 eV), but the yield of the total oxidation products (alkenes and esters) is greater when the reaction is carried out in the presence of Cu^{2+}.[15,16,31]

It follows from a series of data[27–30] that the dependence of the ratio of the yield of total oxidation products to the yield of one-electron oxidation products (alkanes) on the type of oxidant is different for acids of different structure. For butyric acid, the ratio varies in the sequence $Ag^{2+} > Ce^{4+} > Mn^{3+} > Co^{3+}$, for isobutyric acid the sequence is $Ce^{4+} > Ag^{2+} > Mn^{3+} > Co^{3+}$, and for pivalic acid the sequence is $Ag^{2+} \cong Co^{3+} > Mn^{3+} > Ce^{4+}$. However, the data presented above were taken from several investigations in which the reaction conditions were not identical, so that it is extremely difficult to reach reliable conclusions concerning the dependence of the yield of the reaction products on the type of oxidant. The yield and composition of the reaction products apparently depends to a much greater extent on the decarboxylation mechanism than on the reduction potential of the metal ion.

Kinetic studies have shown[23] that the rate-limiting stage in the decarboxylation of acetic acid on treatment with Ce^{4+} in an aqueous medium is the decomposition of the complex:

$$[Ce(H_2O)_7OAc]^{3+} \rightarrow [Ce(H_2O)_6]^{3+} + H_2O + OAc^{\cdot}$$

Further decomposition of the acetoxy-radical to the methyl radical leads to the formation of methane as the main product. The reaction is faster in the water–acetonitrile mixture than in pure water.

The kinetics of the oxidative decarboxylation by Ce^{4+} of alkane- and arylalkane-carboxylic acids have been studied in an aqueous medium[32–37] and Ag^{2+}.[38] The rate of reaction is described by a second-order kinetic equation (first order with respect to the oxidant and first order with respect to carboxylic acid). The reaction is catalysed by added Ag^+ and H^+ ions. According to the authors, the adduct of an acid molecule and Ag^+ is initially formed reversibly and then decomposes under the influence of Ce^{4+} with formation of the acyloxy-radicals $RCOO^{\cdot}$. The rate of reaction is limited by the stage involving the decomposition of the complex; this has received additional confirmation by the fact that the equilibrium constants of the process involving the formation of the Ce^{4+}–alcohol complex are insensitive to electronic effects[39], while the rate of decarboxylation depends significantly on the type of substituent. This is seen from the following data[23] {50°, $I = 1,2$, $[H^+] = 1M$}:

Carboxylic acid	Isobutyric	Propionic	Acetic	Chloroacetic
$10^4 k_2$, litre mol^{-1} s^{-1}	17.5	3.25	1.25	0.71

The logarithms of the relative rate constants for the decarboxylation of substituted phenylacetic acids in aqueous acetonitrile are correlated with the σ^+ constants of the substituents[40]. The quantity $\rho = -2.93 \pm 0.48$ obtained indicates a polar structure of the transition state:

$$ArCH_2COOH + Ce^{4+} \rightarrow ArCH_2\overset{O}{\underset{O}{\diagdown\!\diagup}}{:}Ce^{4+} \rightarrow ArCH_2^{\cdot} + CO_2 + Ce^{3+} + H^+ .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad H$$

The formation of benzyl radicals in this reaction is indicated by the increased yield of benzaldehyde in the presence of oxygen.

It has been suggested[23] that the mechanism of the oxidation of carboxylic acids on treatment with Ce^{4+} is of the inner-sphere type. An analogous mechanism has been attributed to the reaction of carboxylic acids with Co^{3+} salts, in which the formation of benzyl radicals has been confirmed by the detection of bibenzyl in the reaction products (1%).[14] The formation of intermediate radicals in the oxidation of ω-phenylalkanecarboxylic acids by cobalt salts in aqueous acetone solutions was demonstrated using bromoform as a trapping agent and identifying the alkyl bromides obtained[41]. The rate of decarboxylation of aliphatic acids under the influence of Co^{3+} varies in the following sequence[14]:

$$CH_3COOH < CH_3CH_2COOH < (CH_3)_2CHCOOH < (CH_3)_3CCOOH .$$

In this sequence the activation energy decreases by 4 kcal mol^{-1} on replacement of the α-hydrogen atom by the methyl group. Since the inductive influence of the CH_3 group on the homolysis of the O–Co bond via the R–COO system should be weak, there is a possibility of a two-stage decomposition of the complex with the preliminary formation of an acyloxy-radical. However, since the stability of the radicals increases in the sequence $CH_3 < C_2H_5 <$ iso-$C_3H_7 <$ t-C_4H_9, the authors[14] believe that a synchronous mechanism for the decomposition of cobalt carboxylates is more likely[14].

The appreciable dependence of the rate of reaction on the nature of the alkyl groups in the carboxylic acid in accordance with the sequence pivalic acid > isobutyric acid > butyric acid under the influence of Co^{3+},[14,27] Mn^{3+},[28] or Ag^{2+}[38] leads to the conclusion that the formation of alkyl radicals $R^{\cdot}$ involves a synchronous mechanism. On the other hand, the small difference between the rates of decarboxylation of acids of different structure under the influence of Ce^{4+} [23,29] indicates the formation of acyloxy-radicals $RCOO^{\cdot}$.

The study of the kinetics of the decarboxylation of carboxylic acids by Co^{3+} [27] and Mn^{3+} [28] in solutions in the carboxylic acids themselves showed that the power exponent of the concentration of the corresponding metal carboxylate in the kinetic equation for the reaction is unity. The activation energy for the oxidation of pivalic acid by cobalt salts at 61–100 °C is 30 kcal mol^{-1}, while under the influence of manganese salts in the presence of 3.5M acetic acid the activation energy is 34.6 kcal mol^{-1}. These values are close to the energies of the decomposition of the carboxylates, which are less than 40 kcal mol^{-1}. The rate constant for the oxidation of pivalic acid by Mn^{3+} ($\sim 4.5 \times 10^{-4}$ s^{-1}, 70 °C) is higher than the rate constant for the analogous reaction with Co^{3+} ($\sim 0.8 \times 10^{-4}$ s^{-1}, 71 °C). For these two oxidants, different yields of products are also observed. On passing from Mn^{3+} to Co^{3+}, the ratio of the yield of the total oxidation products (alkenes, esters) to the yield of the one-electron oxidation products (alkanes) changes from 0.3 to 0.2 in the decarboxylation of butyric acids and from 0.5 to 0.3 in the decarboxylation of isobutyric acid. The increase of the yield of alkenes and esters is probably associated with the fact that the rate of oxidation of the radicals to carbonium ions by Mn^{3+} is greater than the rate of oxidation by Co^{3+}.

The concentration of protons in solution has a significant influence on the rate of decarboxylation and the yield of reaction products. The rate of decarboxylation of acetic acid by Ce^{4+} in an aqueous medium increases with increase in proton concentration, apparently as a consequence of the increase of the redox potential of the Ce^{4+}–Ce^{3+} system, which indicates a greater activity of the non-hydrolysed complexes[23]:

$$[Ce(H_2O)_7OH]^{3+} + H^+ \rightleftharpoons [Ce(H_2O)_8]^{4+} \quad .$$

In the reaction of carboxylic acids with Co^{3+} in water the hydrolysed complex having the composition $[Co(H_2O)_5(OH)]^{2+}$ interacts with acids more readily than the unhydrolysed complex, so that, with increase of the $HClO_4$ concentration, the rate of decarboxylation diminishes[14]. However, when carboxylic acids themselves are used as solvents, the carboxylation under the influence of all metals (Mn^{3+},[28] Co^{3+},[27] and Ce^{4+} [29]) is catalysed by added strong acids ($HClO_4$ and ClCCOOH). Under these conditions, the yield of alkenes and esters as a rule increases. It has been suggested that this is associated with the formation of a positively charged complex:

$$Ce(O_2CR)_4 + H^+ \rightleftharpoons [Ce(O_2CR)_3]^+ + RCOOH \quad .$$

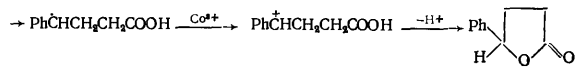
which, being coordination unsaturated, undergoes oxidation-reduction decomposition with greater ease than the corresponding neutral complex[29]:

$$[Ce^{IV}(O_2CR)_3]^+ \rightarrow [Ce^{III}(O_2CR)_2]^+ + RCOO^{\cdot} \text{ etc.}$$

It is of interest to note that the hydrocarbon chain oxidation reactions compete with the decarboxylation of phenylacetic acids[14,42]:

$$PhCH_2COOH \begin{cases} \longrightarrow PhCH_2^{\cdot} + CO_2 \\ \longrightarrow PhC^{\cdot}HCOOH \end{cases} .$$

The H–C bond is oxidised fairly readily in the interaction of formic acid with Ag^{2+},[43] Mn^{3+},[44] Tl^{3+},[45] and Hg^{2+}.[46]



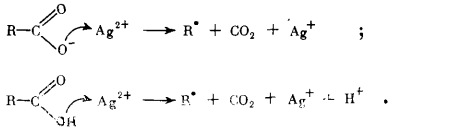
On the basis of the high value of ρ, atypical for a free-radical process, and the observation of EPR signals due to radical-cations, Dessau and Heiba[42] suggested that the oxidative decarboxylation of arylacetic acids by cobalt acetate in an aqueous medium includes a stage involving the one-electron oxidation of the benzene ring. A similar value of ρ, equal to −2.91, was obtained in the oxidative decarboxylation of substituted phenylacetic acids by cerium ammonium nitrate in 30% aqueous acetonitrile[40]. The intermediate formation of a radical-cation was observed also in the electrochemical oxidation of salts of methoxyphenylacetic acid[47–49].

One should note that, whereas the formation of free radicals in the first decarboxylation stage in aqueous solutions has been demonstrated fairly convincingly, their subsequent oxidation to carbonium ions has been studied to a much smaller extent. This is apparently due to the difficulty of the quantitative isolation and identification of the products in an aqueous medium and also to the possibility of secondary processes involving the oxidation of the products obtained from the radicals. The most convincing evidence for the intermediate formation of carbonium ions in the oxidation of arylacetic acids by cobalt salts in acetic acid is high (50 to 100%) yields of phenylacetates[42]:

$$PhCH_2COOH \xrightarrow[-Co^{3+}]{Co^{3+}} (PhCH_2COOH)^{+} \xrightarrow[-H^+]{-CO_2} PhCH_2^{\cdot} \xrightarrow[-Co^{2+}]{Co^{3+}} PhCH_2^{+} \xrightarrow{OAc^-} PhOAc \; .$$

The radical-cation mechanism of the decarboxylation of arenecarboxylic acids by cobalt salts is also supported by the formation of γ-phenylbutyrolactone (yield >25%) when γ-phenylbutyric acid interacts with cobalt acetate:

$$PhCH_2CH_2CH_2COOH \xrightarrow{Co^{3+}} (PhCH_2CH_2CH_2COOH)^{+} \xrightarrow{-H^+} \rightarrow PhCHCH_2CH_2COOH \xrightarrow{Co^{3+}} PhCHCH_2CH_2COOH \xrightarrow{-H^+}$$



.

It has been suggested[29] that the oxidation of the radicals in the oxidative decarboxylation of carboxylic acids by Ce^{4+} takes place via an inner-sphere mechanism involving the formation of an alkylcerium intermediate. The latter is converted into Ce^{3+} and a carbonium ion, from which alkenes and esters are formed:

$$R^{\cdot} + Ce^{4+} \rightleftharpoons [RCe]^{4+} \rightarrow Ce^{3+} + R^+ \quad .$$

The mechanism of the oxidation of alkyl radicals by other one-electron oxidants, such as Cu^{2+}, Co^{3+}, and Mn^{3+}, is similar to the mechanism of the oxidation by Ce^{4+}.[16]

The problem of whether or not metal ions interact with undissociated acid molecules or with carboxylate ions is more complex. The rate of reaction of Ce^{4+} with formic acid is proportional to the $HClO_4$ concentration, which is attributed to the presence of the complexes $Ce^{4+}.HCOOH$ and $Ce^{4+}.HCOO^-$. It is assumed that the reaction proceeds almost exclusively with participation of the complex $Ce^{4+}.HCOO$.[50] It is believed that[38] the interaction of Ag^{2+} with carboxylic acids in an aqueous acid medium takes place with participation of both species—RCOOH and $RCOO^-$:

(b) *The two-electron oxidants Pb^{4+} and Tl^{3+}.* Two reviews have been devoted to the oxidative decarboxylation of carboxylic acids by lead tetra-acetate[16,51]. The reactions of alkane- and arylalkane-carboxylic acids with $Pb(OAc)_4$ yield mainly alkanes, alkenes, and esters, the yield of which depends on the structure of the acid. The relative rates of decarboxylation of the acids RCOOH by lead tetra-acetate decrease as a function of R in the following sequence: tertiary > secondary > primary. The yield of alkenes and esters decreases and the amount of alkanes increases in the same sequence. The stoichiometric equations for the decarboxylation of pivalic[52] and formic[53] acids by lead tetra-acetate show that the oxidant is of the two-electron type:

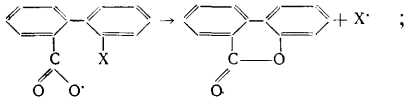
$$Pb(O_2CR)_4 \begin{cases} \longrightarrow Pb(O_2CR)_2 + RCO_2R + CO_2 \\ \longrightarrow Pb(O_2CR)_2 + R(-H) + RCO_2H + CO_2 \end{cases} ;$$

$$Pb(O_2CH)_4 \rightarrow Pb(O_2CH)_2 + HCOOH + CO_2 \quad ; \quad R = C(CH_3)_3 \quad .$$

It was assumed initially[53,54] that the reaction mechanism includes the heterolytic splitting of lead tetracarboxylates with formation of lead dicarboxylate and acyloxonium or carbonium ions as intermediates:

$$(RCO_2)_4Pb \rightarrow RCOO^+ + Pb(OCOR)_2 + RCOO^- \quad ,$$
$$(RCO_2)_4Pb \rightarrow R^+ + CO_2 + Pb(OCOR)_2 + RCOO^- \quad .$$

However, subsequently Kochi's work showed[15,52] that the decarboxylation of carboxylic acids by $Pb(OAc)_4$ is inhibited by oxygen and accelerated by radical reaction initiators, proceeding as a chain process via the following mechanism:



$Pb(OCOR)_4 \rightarrow Pb(OCOR)_3 + CO_2 + R^{\cdot}$ (initiation stage);
$Pb(OCOR)_3 \rightarrow Pb(OCOR)_2 + CO_2 + R^{\cdot}$ (chain propagation);
$Pb(OCOR)_4 + R^{\cdot} \rightarrow Pb(OCOR)_3 +$ alkene, ester;
$Pb(OCOR)_3 + R^{\cdot} \rightarrow Pb(OCOR)_2 +$ alkene, ester (chain termination);
$R^{\cdot} + SH$ (solvent) $\rightarrow RH + S^{\cdot}$
$R^{\cdot} + R^{\cdot} \rightarrow$ dimers, disproportionation products.

The decarboxylation of carboxylic acids by $Pb(OAc)_4$ begins, as in the case of other oxidants, with the pre-equilibrium formation of lead carboxylates[15,21]:

$$Pb(OAc)_4 + n\,RCO_2H \rightleftharpoons Pb(OAc)_{4-n}(O_2CR)_n + n\,HOAc \quad .$$

In the presence of pyridine, which accelerates decarboxylation, the pre-equilibrium complex has the form $Pb^{IV}(O_2Cr)_n.Py_m$. The reactions are promoted also by the addition of other nitrogen bases (triethylamine) as well as salts (acetates).

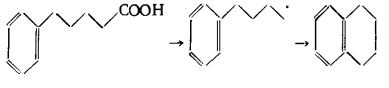
Lead carboxylates decompose with formation of Pb^{3+} and RCOO· or R·. The intermediate formation of carboxy-radicals was detected in certain cases from the yield of the corresponding products. When 2'-substituted biphenyl-2-carboxylic acids interact with lead tetra-acetate in boiling benzene under a nitrogen atmosphere, 3,4-benzocoumarin is formed in a high yield[55]:

X=H, CO_2H, Cl, NO_2, OCH_3, or CO_2CH_3 .

The formation of alkyl radicals was confirmed by EPR in the photolysis of lead carboxylates at low temperatures[21,56]. No evidence was obtained for the formation of Pb^{3+} by EPR,[57] but its formation is indicated by the results of kinetic studies of the oxidation of Co^{2+} and Ce^{3+} by lead tetra-acetate. The rates of these reactions are described by a common second-order kinetic equation (first-order with respect to each reactant), which suggests the intermediate formation of Pb^{3+} as a result of one-electron transfer in the rate-limiting stage of the reaction[58].

The involvement of alkyl radicals in a number of reactions has been demonstrated with the aid of spin-trapping agents, for which nitroso-compounds are used[59]:

$$R'NO + R\cdot \rightarrow R'\underset{\displaystyle O\cdot}{\underset{|}{N}}-R \quad .$$



At −40 °C free radicals R' were trapped in methylene chloride as asymmetric nitroxy-radicals. At 25 °C secondary radicals, obtained as a result of the abstraction of α-hydrogen from the acid molecule, were trapped:

$$R\cdot + R''CH_2COOH \rightarrow R''\dot{C}HCOOH \xrightarrow{R'NO} R'-\underset{\displaystyle O\cdot}{\underset{|}{N}}-\underset{\displaystyle COOH}{\underset{|}{CH}}-R'' \quad .$$

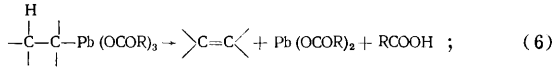
In the presence of oxygen alkyl radicals can give rise to side products[15]:

$$CH_3CH_2\dot{C}HCH_3 + O_2 \rightarrow \underset{\displaystyle O_2\cdot}{\underset{|}{CH_3CH_2CHCH_3}} \rightarrow CH_3CH_2COCH_3 + CH_3CH_2CHOHCH_3 \quad .$$

In certain cases the intermediate radicals are converted into cyclic reaction products. The cyclisation of alkyl radicals in the decarboxylation of ethyl 2-carboxy-5-phenylvalerate by lead tetra-acetate leads to the formation of tetralincarboxylate derivatives[60]. The oxidative decarboxylation by lead tetra-acetate of 5-phenylvaleric acid in benzene solution in a nitrogen atmosphere yields tetralin as the main product[61]:

A similar reaction takes place with *p*-nitro- and *p*-methoxy-derivatives of phenylvaleric acid and also with 5-(*p*-methoxyphenyl)-5-phenylvaleric and 5-(β-naphthyl)valeric acids[62]. The oxidation of *o*-benzoylbenzoic acid by lead tetra-acetate in benzene leads to benzophenone, *o*-phenylbenzophenone, and fluorenone[63].

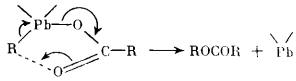
Thus the process is undoubtedly of a radical type. The question arises of the pathways whereby alkenes and esters are obtained in the reaction. These pathways can include further oxidation of the radicals to carbonium ions as a result of electron transfer [reaction (4)] or oxidative heterolysis [reaction (5)] of the organolead compound $RPb(OCOR)_3$, which is formed either via a reaction of the S_N2 type or by the interaction of the radical with $Pb(OCOR)_3$:



$$R\cdot + Pb(OCOR)_4 \rightarrow R^+ + Pb(OCOR)_3^- + RCO_2^- \quad ; \qquad (4)$$

$$R\cdot + Pb(OCOR)_4 \rightarrow RPb(OCOR)_3 + R\cdot + CO_2 \quad ;$$

$$R\cdot + Pb(OCOR)_3 \rightarrow RPb(OCOR)_3 \quad ;$$



$$RPb(OCOR)_3 \rightarrow R^+ + Pb(OCOR)_2 + RCO_2^- \quad . \qquad (5)$$

The organolead compound can be converted into alkenes and esters without the intermediate formation of carbonium ions, as a result of the elimination [reaction (6)] or reactions (7) of the S_N2 type:

$$RCO_2^- + RPb(OCOR)_3 \rightarrow RCOOR + Pb(OCOR)_2 + RCO_2^- \quad . \qquad (7)$$

The possibility of the formation of esters directly in the decomposition of lead carboxylates via an intramolecular S_Ni mechanism (not only cations but also radicals should then be formed as intermediates) has also been suggested[66]. However, this mechanism (ligand transfer) is more likely for the decomposition of the organolead compound[65]:

Tertiary alkyl radicals are readily oxidised by lead tetra-acetate; on the other hand, primary radicals are oxidised with difficulty, as a result of which the decarboxylation under the influence of $Pb(OCOCH_3)_4$ leads mainly to the formation of alkanes. A thermodynamic assessment of the reactions[64] agrees with these results. The electrode potential of the Pb^{2+}/Pb^{4+} system ($E^0 = 1.69$ V) is not sufficiently high for the oxidation of primary radicals ($E^0 = 2.07$ V for the $C_2H_5/C_2H_5^+$ system) but is sufficient for the oxidation of secondary and tertiary radicals ($E^0 = 1.59$ V for iso-$Pr^{\cdot}$/iso-Pr^+ and $E^0 = 1.27$ V for t-Bu·/t-Bu) as well as allyl ($E^0 = 1.7$ V) and benzyl ($E^0 \cong 1.5$ V) radicals.

The electrode potential for the two-electron process $C_2H_5.COO^- \rightarrow R^+ + CO_2 + 2e^-$, equal to 1.68 V, is close to the potential for the Pb^{2+}/Pb^{4+} system, which accounts for the formation of esters from primary carboxylic acids.

It is of interest that, on decarboxylation of crystalline α-isobutyric acid by lead tetra-acetate at low temperatures, even tertiary radicals are not oxidised to carbonium ions and are converted quantitatively into alkanes[21].

The oxidation of primary alkyl radicals can proceed effectively via the ligand transfer mechanism. The decarboxylation of carboxylic acids under the influence of lead tetra-acetate in the presence of LiCl or LiBr results in almost quantitative formation of alkyl halides[67]. The reaction is important for the synthesis of alkyl chlorides, but it also proceeds with bromides and iodides. The optimum conditions require one equivalent of LiCl per equivalent of $Pb(OCOCH_3)_4$. The yield of alkyl halides obtained by this method decreases in the sequence of acids RCOOH as a function of the nature of R: tertiary > secondary > primary.

The 1.37–1.43 : 1 ratio of *erythro*- and *threo*-2-chloro-3-phenylbutanes in the halogenodecarboxylation of *erythro*- and *threo*-2-methyl-3-phenylbutyric acids indicates a radical mechanism of this process, since, on treatment of these acids with lead tetra-acetate, the *erythro*- and *threo*-acetates are formed via an ionic mechanism in equal amounts[68]. Furthermore, the halogenodecarboxylation is strongly inhibited by oxygen. On this basis, the following radical mechanism has been proposed for the halogenodecarboxylation reaction:

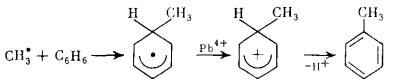
Pre-equilibrium stage:

$$Pb^{IV}(O_2CR)_4 + X^- \rightleftharpoons [(RCO_2)_4 Pb^{IV}X]^- \ .$$

Initiation stage:

$$[(RCO_2)_4 Pb^{IV}X]^- \rightarrow R^{\cdot} + CO_2 + [(RCO_2)_3 Pb^{III}X]^- \ ;$$
$$[(RCO_2)_4 Pb^{IV}X]^- \rightarrow X^{\cdot} + [(RCO_2)_4 Pb^{III}]^- \ .$$

Chain propagation:



$$R^{\cdot} + [(RCO_2)_4 Pb^{IV}X]^- \rightarrow RX + [(RCO_2)_4 Pb^{III}]^- \text{ (ligand transfer)};$$
$$X^{\cdot} + [(RCO_2)_4 Pb^{IV}X]^- \rightarrow X_2 + [(RCO_2)_4 Pb^{III}]^- \ ;$$
$$[(RCO_2)_4 Pb^{III}]^- \rightarrow R^{\cdot} + CO_2 + [(RCO_2)_3 Pb^{II}]^- \ ;$$
$$R^{\cdot} + X_2 \rightarrow RX + X^{\cdot}, \text{ etc.}$$

Chain termination:

$$R^{\cdot} + [(RCO_2)_3 Pb^{III}X]^- \rightarrow RX + [(RCO_2)_3 Pb^{II}]^- \ .$$

The halide formation reaction proceeds via the ligand transfer mechanism. This is indicated particularly by the finding that the halogenodecarboxylation of cyclobutanecarboxylic and β,β-dimethylbutyric acids proceeds without a rearrangement and is accompanied by the formation of cyclobutyl chloride and neopentyl chloride[67]. It has been shown[69] that the ligand transfer reaction in the decarboxylation of phenylacetic acid and its substituted derivatives (R = *p*-NO_2 or *p*-Cl) is little influenced by the polarity of the substituent, while in the absence of LiCl both the products and the rate of reaction depend greatly on the substituents.

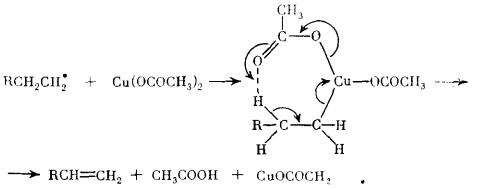
The oxidative decarboxylation of tertiary acids by lead tetra-acetate has been studied in relation to t-butylperoxy-2-methylpropanoic acid in benzene[70]. The mechanism of the formation of toluene proposed in the above study, according to which the active methyl radical obtained in the decomposition of the t-butoxy-radical adds to benzene and the subsequent oxidation of this product and the elimination of a proton lead to toluene, is of interest:

The decarboxylation of 2,3,3-trimethylbutyric acid by lead tetra-acetate in benzene and acetic acid yields mainly 3,3-dimethyl-2-butyl acetate and, when Cu^{2+} is involved in the reaction, the main product is 3,3-dimethylbut-1-ene.[65] The low yield of rearranged products in both cases suggests that ionic intermediates are not formed in the reaction. Organocopper and organolead compounds are apparently formed as intermediates in the reaction and decompose as a result of β-elimination with formation of alkenes [Eqn.(6)] or intramolecular substitution (ligand transfer mechanism or S_Ni mechanism) with formation of acetates.

The decarboxylation of carboxylic acids[25] in benzene by Tl^{3+} is much slower than under the influence of Pb^{4+}. All types of acids give rise to a large amount of radical products and a small amount of esters, which is due to the low reduction potential of the Tl^{3+}/Tl^{+} pair ($E^0 = 1.25$ V) and $Tl^{3+} + Cl^-/TlCl$ ($E^0 = 1.36$ V). The yield of esters decreases in the following sequence for acids RCOOH with different R: $C_6H_5CH_2$ (~20%) > tertiary (10–20%) > secondary > primary. This process is not greatly promoted by the addition of acetate salts and pyridine. However, the reaction is appreciably accelerated when it is carried out using carboxylic acids as solvents. The addition of strong acids ($HClO_4$, BF_3, CF_3.COOH) increases the rate of reaction still further. Under these conditions, the decarboxylation of isobutyric and butyric acid yields mainly esters and small amounts of alkanes and alkenes. The stoichiometric reaction equation obtained in this case indicates a two-electron mechanism of this process:

$$(RCO_2)_3 Tl^{III} \rightarrow \begin{cases} \rightarrow R{-}R + 2CO_2 + Tl^{I}O_2CR \\ \rightarrow R(-H) + CO_2 + RCO_2H + Tl^{I}OCOR \\ \rightarrow RCO_2R + CO_2 + Tl^{I}OCOR \end{cases} .$$

(c) *Binary systems containing* Cu^{2+}. The oxidative decarboxylation of carboxylic acids by the binary systems Mn^{3+}–Cu^{2+},[28] Co^{3+}–Cu^{2+},[27] Ag^{2+}–Cu^{2+},[30] and Pb^{4+}–Cu^{2+} [31] leads to an appreciable increase of the yield of alkenes. In the presence of catalytic amounts of copper salts the rate of decarboxylation increases appreciably and the reaction becomes of preparative importance for the synthesis of alkenes[31,52]. This type of effect has been explained by the marked ability of copper ions to trap and oxidise intermediate alkyl radicals. The rate constants for the oxidation of primary and secondary alkyl radicals by copper salts are 10^6–10^9 litre mol^{-1} s^{-1},[69,71,72] which indicates the following mechanism of the formation of alkenes:



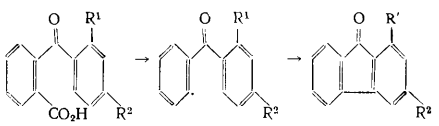
$$R^{\cdot} + Cu^{2+} \rightarrow R(-H) + Cu^{+} \ .$$

Under these conditions, the copper(I) ion is oxidised by lead tetra-acetate, propagating the chain:

$$Pb^{IV}(OCOR)_4 + Cu^{I}OCOR \rightarrow Pb^{III}(OCOR)_3 + Cu^{II}(OCOR)_2 \text{ etc.}$$

Torssell[64] believes that the low oxidation-potential of the Cu^{+}/Cu^{2+} (0.17 V) and $CuCl/Cu^{2+} + Cl^-$ (0.57 V) systems is inconsistent with this mechanism. However, since a large amount of alkenes and a small amount of esters, coupling products, and alkanes are formed in the oxidation of carboxylic acids in the presence of copper ions, the β-elimination mechanism has been proposed. The process $C_2H_5COO^- \rightarrow C_2H_4 + CO_2 + H^+ + 2e$ is characterised by the quantity $E^0 = 0.31$ V. $E^0 = 0.64$ V has been calculated for the $C_2H_5^{\cdot} \rightarrow C_2H_4 + H^+ + e$ system. These data suggested that the specific oxidising effect of copper ions involves simultaneous action on the β-hydrogen and the unpaired electron. Radicals without β-hydrogen should not then be actively oxidised by copper ions. Indeed the products and rate of decarboxylation of phenylacetic acid by lead tetra-acetate with and without added Cu^{2+} differ little. The weak influence of added copper salts on the decarboxylation of RCOOH with a tertiary substituent R on treatment with lead tetra-acetate is probably associated with this factor[57].

It has been suggested[73] that, when the copper ion interacts with a radical, an organocopper compound is formed, its β-elimination via a cyclic transiton state leading to a multiple bond:



(d) *Persulphates.* The decarboxylation of aliphatic acids and their salts by sodium persulphate was studied initially by Fichter and coworkers in a series of investigations[74-77]. The reaction products are alcohols and olefins with an admixture of aldehydes and saturated hydrocarbons.

Decarboxylation in alkaline and acid media leads to products having different compositions. When acetic acid was oxidised with sodium persulphate in acid media, methane and succinic acid, which can be obtained from the intermediate free radicals, were detected in addition to CO_2 and CO. In alkaline media further-oxidation products (methanol and ethylene) were found in addition to methane and succinic acid. The oxidation of sodium acetate in the presence of sodium carbonate yielded methanol. Under the same conditions, sodium propionate yields ethanol and ethylene, the oxidation of sodium butyrate leads to the formation of propene, while isobutene and isobutyl isovalerate are obtained from the salt of isovaleric acid[75]. Such variation of the composition of the products with increase of chain length and with branching of the alkyl residue is apparently associated with the facilitation of the oxidation of the intermediate radicals R· and with the increase of the stability of the intermediate carbonium ions formed under these conditions.

The formation of radicals in the oxidation of phenylacetic acid and a number of related acids in an aqueous medium on treatment with the $Na_2S_2O_8$–Tl^{3+} system has been demonstrated by EPR.[78] The formation of aryl radicals in the decarboxylation of benzoic, phenylacetic, and diphenylacetic acids with $Na_2S_2O_8$ has been confirmed by the isolation of the products by the dimerisation of the corresponding radicals—biphenyl, 1,2-diphenylethane, and 1,1,2,2-tetraphenylethane[79]. In the presence of pyridine the oxidation of benzoic acid results in the formation of approximately 5% of phenylpyridines.

The cyclisation of the intermediate radicals on decarboxylation of substituted *o*-benzoylbenzoic acids yielded substituted fluorenones[79]:

R^1=H, R^2=H, Cl, Br, CH_3, or OCH_3; R^1=R^2=OCH_3, or CH_3 .

Active oxidising agents arise in the homolytic decomposition of persulphate ions on heating. The energy of this reaction is approximately 30 kcal mol^{-1} [80]:

$$S_2O_8^{2-} \xrightarrow{k_1} 2SO_4^{\cdot-} \quad .$$

Further reactions of the radical-anion in an aqueous medium in the presence of a carboxylic acid are described by the following equations[79,81]:

$$SO_4^{\cdot-} + H_2O \xrightleftharpoons{k_2} HSO_4^- + OH^{\cdot} \quad ;$$

$$SO_4^{\cdot-} \text{ (or } {}^{\cdot}OH) + RCO_2^- \xrightleftharpoons{k_3} SO_4^{2-} \text{ (or } {}^{-}OH) + RCOO^{\cdot} \longrightarrow \underset{\text{products}}{\searrow} R^{\cdot} + CO_2 \quad .$$

This reaction mechanism has been confirmed by the composition of the products and by the form of the kinetic equation[81]:

$$\frac{d[CO_2]}{dt} = \frac{d[RCO_2^-]}{dt} = k_3[SO_4^{\cdot-}][RCO_2^-] \quad .$$

Measurement of the relative rate constants for substituted phenylacetic acids demonstrated a correlation between the logarithms of the rate constants and σ^+ with a low value of ρ, characteristic of radical reactions:

$$\lg(k/k_0) = -0.436\,\sigma^+ + 0.06 \quad (r = 0.983,\ s = 0.035) \quad .$$

The rate of decarboxylation of acids by sodium persulphate increases in the presence of Ag^+ and the reaction is of first order with respect to the silver ion and peroxydisulphate and of zero order with respect to the acid[82,83]:

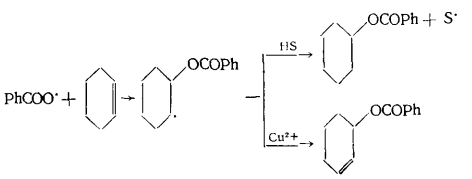
$$\frac{d[CO_2]}{dt} = \frac{d[S_2O_8^{2-}]}{dt} = k_2[Ag^+][S_2O_8^{2-}][RCOOH]^0 \quad .$$

The mechanism of the reaction involving silver ions includes the formation of the unstable Ag^{2+} ion in the rate-limiting stage, which rapidly reacts with the carboxylic acid:

$$Ag^+ + S_2O_8^{2-} \rightarrow Ag^{2+} + SO_4^{2-} + SO_4^{\cdot-} \quad ;$$
$$Ag^+ + SO_4^{\cdot-} \rightarrow Ag^{2+} + SO_4^{2-} \quad ;$$
$$Ag^{2+} + RCOOH \rightarrow Ag^+ + RCOO^{\cdot} + H^+ \quad ;$$
$$RCOO^{\cdot} \rightarrow R^{\cdot} + CO_2 \quad ;$$
$$R^{\cdot} + Ag^{2+} \rightarrow R^+ + Ag^+ \text{ etc.}$$

The intermediate radicals give rise to alkanes by reacting with the carboxylic acid or another hydrogen donor *HS*. The mechanism has been confirmed by the increased yield of alkanes on increasing the concentration of carboxylic acid. In this case the stoichiometry of the reaction corresponds to the following equation:

$$2RCOOH + S_2O_8^{2-} + 2HS \xrightarrow{Ag^+} 2RH + 2CO_2 + H^+ + 2SO_4^{2-} + S_2 \quad .$$



As the carboxylic acid concentration is reduced, the reaction equation becomes

$$RCOOH + S_2O_8^{2-} \xrightarrow{Ag^+} R^+ + H^+ + CO_2 + 2SO_4^{2-} \quad .$$

The yield of alkanes then falls and the yield of alkenes, esters, alcohols, and further-oxidation products (ketones and aldehydes) increases.

Catalytic amounts of copper sulphate cause a sharp increase in the yield of alkenes in the decarboxylation products on treatment with the $Na_2S_2O_8$–Ag^+ system[82]. The effect of Cu^{2+} consists in the trapping and oxidation of intermediate alkyl radicals. Under these conditions, peroxydisulphate interacts with Cu^+, regenerating the initial Cu^{2+} ion. The intermediate formation of benzyl radicals in the decarboxylation of phenylacetic acids by the $Na_2S_2O_8$–Ag^+ system has been demonstrated by their reactions with substituted pyridines, which give rise to 2-benzylpyridines[83]. The alkylation of quinoline, 2-methylquinoline, isoquinoline, acridine, and substituted pyridines with the aid of a radical R· [R = CH_3, C_2H_5, $CH_3(CH_2)_2$, $CH_3(CH_2)_3$, $(CH_3)_2CH$, $(CH_2)_5CH$, or $(CH_3)_3C$], obtained by the oxidative decarboxylation of aliphatic carboxylic acids by the $Na_2S_2O_8$–Ag^+ system, has been investigated[84,85].

The oxidation of sodium benzoate and its derivatives by the $(NH_4)_2S_2O_8$–Cu^{2+} system in the presence of alkenes (cyclohexene and α-pinene)[86] leads to the formation of intermediate benzoyloxy-radicals, which add to the double bond, forming new alkyl radicals. The interaction of alkyl radicals with hydrogen donors leads to the formation of alkanes and their subsequent oxidation by Cu^{2+} ions to the corresponding cations results in the formation of alkenes and alcohols:

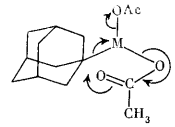
Intermediate phenyl radicals were detected in the decarboxylation of PhCOOH under the influence of the $Na_2S_2O_8$–Ag^+ system[87].

An extremely interesting fact is noteworthy: the decarboxylation of benzoic acids by the persulphate–Ag^+ or persulphate–Cu^{2+} system in an aqueous medium proceeds incomparably more readily than the decarboxylation under the influence of transition metal salts in non-aqueous solvents. This may be associated with the easier decarboxylation of carboxylate anions compared with undissociated molecules.

Thermal oxidative decarboxylation of alkane- and arylalkanecarboxylic acids has also been studied by a number of other workers[88-91].

2. Cycloalkanecarboxylic Acids

The decarboxylation of cycloalkanecarboxylic acids has been carried out mainly with lead tetra-acetate or its mixture with Cu^{2+}. Typical products are cycloalkanes and esters, which are believed to be formed[15,16] as a result of the intermediate involvement of carbonium ions.



The decarboxylation of cyclopropane-[92] and cyclobutanecarboxylic acids[93] proceeds with partial ring opening and the formation of rearranged acetates, which supports the formation of ionic intermediates.

The intermediate involvement of carbonium ions is believed[54] to be indicated by the results of the decarboxylation of the optically active *endo*- and *exo*-norbornane-2-carboxylic acids by lead tetra-acetate in benzene and acetonitrile. This reaction yields almost exclusively the *exo*-acetates with an appreciable retention of optical activity. The results of the above workers[54] have been explained[94] by the fact that racemic norbornyl acetates are obtained from bridged carbonium ions, while the chiral *exo*-acetates are formed from classical carbonium ions. As a result of a skeletal rearrangement, the reaction of lead tetra-acetate with *exo*- and *endo*-bornane-2-carboxylic acids[95] yields camphene and other products as well as the *exo*- and *endo*-acetates in proportions of 68 : 32. The formation of a mixture of *exo*- and *endo*-acetates in this instance has been explained[94] by the involvement of classical and non-classical carbonium ions in the reaction.

The study of the products of the decarboxylation of bicyclo[3,2,1]octane-2-carboxylic and bicyclo[2,2,2]octane-2-carboxylic acids altered this view, showing that, apart from the pathway with participation of carbonium ions, there is a possibility also of other pathways[94]. The small difference in the proportions of the acetates obtained by the decarboxylation of *exo*- and *endo*-bicyclo[3,2,1]octane-2-carboxylic acids suggests that a radical is formed as a common intermediate. The subsequent formation of the organolead compound $RPb(OAc)_3$ and its heterolysis can lead to a non-classical carbonium ion with its subsequent conversion into an acetate. This is indicated particularly by the similar yields of the acetates in the decarboxylation and acetolysis of the corresponding tosylates[96]. However, the contribution of this reaction pathway is only 50%. Another pathway involves ligand transfer in the organolead compound via the S_Ni mechanism; this pathway is in fact responsible for the partial retention of the stereochemical configuration. In the light of these ideas, it is also possible to account for the results obtained in the decarboxylation of bornane-2-carboxylic[95] and norbornane-2-carboxylic[54] acids.

By analogy with the above data, it has been suggested that, in the decarboxylation of adamantane-2-carboxylic, adamantane-1-carboxylic, and *cis*- and *trans*-decalin-9-carboxylic acids by lead tetra-acetate in benzene in the presence of Cu^{2+} ions (or in their absence), the acetates are formed as a result of heterolysis and ligand transfer (S_Ni substitution) in the organometallic compound obtained by the interaction of the intermediate free radical with lead or copper carboxylate[65].

The high yields of acetates (89 and 93% respectively) in the decarboxylation of adamantane-1-carboxylic acid with $Pb(OAc)_4$ and $Pb(OAc)_4$–$Cu(OAc)_2$ (despite the fact that the oxidation of bridged radicals to carbonium ions should proceed with greater difficulty than the oxidation of related acyclic radicals) may indicate, according to the authors[76], a considerable contribution of the S_Ni mechanism:

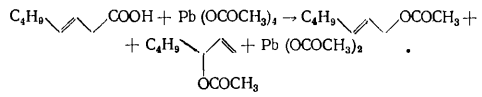
M = $Pb(OAc)_2$, or Cu.

The formation of equal amounts of *cis*- and *trans*-decalinyl acetates on decarboxylation of *cis*- and *trans*-decalin-9-carboxylic acids by lead tetra-acetate and $Pb(OAc)_4$–$Cu(OAc)_2$ apparently takes place as a result of the heterolysis of organocopper and organolead compounds.

Finally, the preferred formation of the thermodynamically less stable $\Delta^{1,9}$-octalin compared with $\Delta^{9,10}$-octalin on decarboxylation of *cis*- and *trans*--decalin-9-carboxylic acids suggests, according to the authors[76], that the unsaturated cyclic compounds are obtained as a result of β-elimination from the organometallic compounds and not as a result of the deprotonation of the intermediate carbonium ion.

The products of the oxidative decarboxylation of cycloalkanecarboxylic acids have also been studied in a series of other investigations[97-103].

3. Unsaturated Carboxylic Acids



Decarboxylation of unsaturated carboxylic acids has been studied in a series of investigations[104-108]. In the decarboxylation of *trans*- and *cis*-cinnamic acids with lead tetra-acetate in benzene in an atmosphere of nitrogen, it was found unexpectedly that the main product is β-methylstyrene. It is suggested that it is formed as a result of the abstraction of the methyl radical from the intermediate complex formed by the styryl radical and lead tetra-acetate[104,107].

The general validity of this mechanism (differing from the general mechanism proposed by Kochi—see subsection 1 above) is confirmed by data obtained in the decarboxylation of a mixture of cinnamate and β-methylbutyrate salts. This reaction also leads to the formation of a radical recombination product—3-methyl-1-phenylpent-1-ene, which proved to be inactive when the optically active acid was used as the starting material. According to the authors[104], the reaction takes place as a result of the following sequence of transformations:

$$PhCH{=}CHCOOPb^{IV}OCOR \rightarrow CO_2 + [PhCH{=}CH^{\cdot} \ldots Pb^{III}OCOR] \rightarrow 2CO_2 +$$
$$+ [PhCH{=}CH^{\cdot} + R^{\cdot}] + Pb^{II} \rightarrow 2CO_2 + PhCH{=}CHR + Pb^{II} .$$

The influence of substituents in the benzene ring of cinnamic acid on the yield of products has been studied[105]. It was found that, in the presence of *p*-NO_2 and *p*-Cl substituents the main product is β-methylstyrene, as for the unsubstituted acid[104]. On the other hand, the decarboxylation of *p*-methoxycinnamic acid gives only traces of β-methylstyrene and the main products are acetates, which are believed to be formed on further oxidation of the unsaturated radical. The oxidative decarboxylation of 3-octenoic acid by lead tetra-acetate in 17% benzene solution of acetic acid leads to the formation of 3-acetoxyhept-1-ene (21%) and 1-acetoxyhept-2-ene

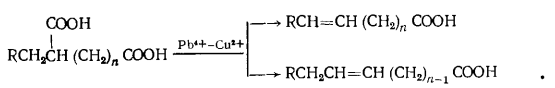
(30%) as the main products[69]:

The reaction is accelerated by a factor of 16 after the addition of 7% Cu^{2+}. Under these conditions, the ratio of the 3-acetoxyhept-1-ene and 1-acetoxyhept-2-ene formed is 85:15. The addition of 0.08 M pyridine increases the rates of reaction by a further factor of 5 and the ratio of the acetates changes to 55:45. The oxidative decarboxylation of vinylacetic acid by lead tetra-acetate gives rise to allyl acetate (70%) and is five times faster than the decarboxylation of 3-octenoic acid. The addition of 0.01M Cu^{2+} increases the yield of esters to 87%, but propene and hexa-1,5-diene are not formed[69]. The authors[69] suggest that the oxidation of aryl radicals by Pb^{4+} and Pb^{4+}–Cu^{2+} with participation of pyridine proceeds via a carbonium ion like the oxidation of benzyl and tertiary radicals.

The kinetics of the oxidation of unsaturated acids by cobalt perchlorate in aqueous acetonitrile in the presence of $HClO_4$ have been investigated[106]. The rate of reaction is directly proportional to the concentrations of the oxidant and the unsaturated acid and is inversely proportional to the acidity of the solution. The study of the reaction products revealed the occurrence of two simultaneous processes: oxidative decarboxylation (5–20%) and oxidation of the double bond (80–95%). The oxidative decarboxylation leads to the formation of mainly aldehydes and ketones, for example:

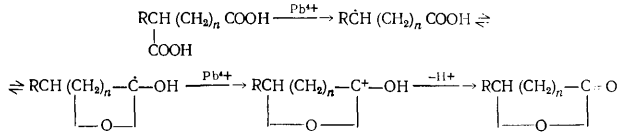
The main pathway—the oxidation of the double bond—results in the complete cleavage of the latter.

Acids whose double bond is conjugated with a benzene ring are oxidised more readily than acids with an unconjugated double bond. The presence of methyl or phenyl substituents at the double bond of cinnamic acid hinders oxidation. Unsaturated acids are more readily oxidised by tervalent cobalt in an aqueous medium than the corresponding saturated acids[41].



4. Dibasic Carboxylic Acids

The oxidative decarboxylation of dicarboxylic acids is usually carried out with systems containing Pb^{4+} or Pb^{4+}–Cu^{2+}. The rate of decarboxylation of alkanedicarboxylic acids having the general formula $RCH_2CH(CH_2)_nCOOH$, where



$n = 1$, 2, 3, or 10, and the composition of the reaction products depend significantly on the positions of the carboxy-groups relative to one another[109]. As the COOH groups approach one another, the decarboxylation under the influence of lead tetra-acetate slows down. The decarboxylation of the same acids by the Pb^{4+}–Cu^{2+} system proceeds equally readily for all the acids investigated. At the same time, the structure of R has virtually no influence on the decarboxylation reaction.

When equimolar amounts of the dicarboxylic acid and Pb.$(OAc)_4$ are used in the presence of copper acetate, selective decarboxylation of the carboxy-group at the secondary carbon atom takes place[109,110]. This results in a high yield of alkenoic acids in the *cis*- and *trans*-forms (in approximately equimolar amounts):

The unsaturated carboxylic acids formed can undergo further decarboxylation and conversion into alkadienes and alkenyl acetates.

The oxidation of 1,3- and 1,4-dicarboxylic acids by lead tetra-acetate yields predominantly γ- and δ-lactones[109,111]. It has been suggested that, as in the decarboxylation of monocarboxylic acids, the oxidation of dicarboxylic acids proceeds with the intermediate formation of radicals, which undergo subsequent cyclisation and oxidation:

In addition, unsaturated and saturated monocarboxylic acids are formed in this reaction.

The high yield of lactones in the decarboxylation of 2,3-diphenylglutaric and camphoric acids by lead tetra-acetate has been explained[112] by the ease of elimination of carboxy-groups at the secondary and tertiary carbon atoms respectively. The oxidative decarboxylation of glutaric acid and its monoesters (methyl, ethyl, isopropyl, and benzyl) under the influence of $Na_2S_2O_8$–Ag^+ leads to the formation of butyric acid, alkyl butyrates, and γ-butyrolactones[113]. The oxidative decarboxylation of glutaric and adipic acids by the $Na_2S_2O_8$–$AgNO_3$–$CuSO_4$ system leads to the selective formation of γ-butyrolactone and δ-valerolactone respectively[114].

When cycloalkane-1,2-dicarboxylic acids are treated with $Pb(OAc)_4$,[115–119] bisdecarboxylation takes place and results in 50–80% yields of cycloalkenes. On treatment of α,β-dicarboxylic acids with PbO_2, the yield of olefins is reduced to 25%.[120] The decarboxylation of diphenic acid under the influence of lead tetra-acetate in the acetonitrile–pyridine mixture leads to the formation of 3,4-benzocoumarin (50%); under these conditions, benzoic and phthalic acids are not decarboxylated[121].

The formation of *trans*-stilbene as the main product in the oxidative decarboxylation of *meso*- and d,*l*-1,2-diphenylsuccinic acids under the influence of Pb^{4+} [154] suggests that the bisdecarboxylation is not a synchronous β-elimination process, but includes the formation of an intermediate carbonium ion.

It has been suggested[122] that the oxidative decarboxylation of disubstituted malonic acids by lead tetra-acetate results in the formation of the diacetates $RR'C(OAc)_2$ as intermediates, whose hydrolysis leads to the ketones RR'CO. The decarboxylation of bicyclo[3,2,0]heptane-3,3-dicarboxylic acid apparently proceeds analogously, since it led to the isolation of bicyclo[3,2,0]heptan-3-one.[123]

The study of the reaction of cerium sulphate with dicarboxylic acids in sulphuric acid showed that unsaturated dicarboxylic acids (fumaric and maleic) and succinic acid are not oxidised, while phthalic, tartaric, malonic, and citric acids are oxidised on heating to 95 °C.[124] Oxalic acid readily reacts with cerium sulphate at room temperature, which makes it possible to use this reaction as an analytical method[125].

On treatment with bivalent copper, aminomalonic acid is decarboxylated with formation of glycine[126].

5. α-Hydroxyacids

Carboxylic α-hydroxyacids contain two functional groups, which can be acted upon by oxidants. Oxidative decarboxylation of α-hydroxyacids on treatment with $Pb(OAc)_4$, first investigated by Oeda[127], obeys the stoichiometric equation

$$R_1R_2CCOOH + Pb(OAc)_4 \rightarrow R_1CR_2 + CO_2 + 2CH_3COOH + Pb(OAc)_2 \quad .$$
$$\quad\quad\quad

(up to 10%) in the photodecarboxylation of $Tl(OCOR)_n$, where R is a primary group, indicates, according to the authors[25], that alkenes are formed as a result of the disproportionation of alkyl radicals:

$$2R^{\cdot} \rightarrow R(-H) + RH \quad .$$

The decrease of the yield of alkenes and esters obtained from the acids in the series based on R (tertiary > secondary > primary) shows that the reaction proceeds via the mechanism

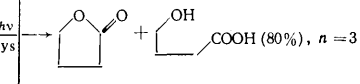
$$Tl^{3+} + R^{\cdot} \rightarrow Tl^{2+} + [R^{+}] \text{ etc.}$$

In the presence of Cu^{2+} the mechanism changes:

$$R^{\cdot} + Cu^{2+} \rightarrow R(-H) + Cu^{+} + H^{+} ;$$
$$Cu^{+} + Tl^{3+} \rightarrow Cu^{2+} + Tl^{2+} \quad .$$

The rates of photochemical decarboxylation of the acids RCOOH with primary, secondary, and tertiary groups R on treatment with Ce^{4+} differ little[29]. On treatment with Pb^{4+},[15,57] a significant difference is observed between the rates of decarboxylation in accordance with the sequence pivalic acid > isobutyric acid > butyric acid, which is probably associated with the increase of the activation energy for the homolysis of the bond in the lead carboxylates in this sequence.

In addition to pyridine and lithium acetate and trifluoroacetate in the photochemical oxidative decarboxylation of butyric acid by Ce^{4+} does not have an appreciable influence on the rate of reaction[29], while the addition of strong acids ($HClO_4$, BF_3, CF_3COOH) increases the rate appreciably. In the latter case the yield of alkenes and esters increases and the amount of alkanes falls. Oxygen decreases significantly the rate of reaction and lowers the yield of alkanes in photodecarboxylation by lead tetra-acetate[57]. Under these conditions, products of the oxidation of the radical by oxygen appear:



$$(CH_3)_3C^{\cdot} + O_2 \rightarrow (CH_3)_3COO^{\cdot} ;$$
$$2(CH_3)_3COO^{\cdot} \rightarrow O_2 + 2(CH_3)_3CO^{\cdot} \begin{cases} \rightarrow (CH_3)_3COOC(CH_3)_3 \\ \xrightarrow{SH} (CH_3)_3COH + S^{\cdot} \\ \rightarrow (CH_3)_2CO + CH_3^{\cdot} \end{cases} .$$

When pivalic acid interacts with lead tetra-acetate in the presence of oxygen, the formation of di-t-butyl peroxide (3%), acetone (9%), and t-butyl alcohol (78%) is observed.

The formation of free radicals in the photochemical decarboxylation of carboxylic acids by lead tetra-acetate has also been demonstrated by EPR.[57] Irradiation in the cell of the spectrometer of solutions of lead carboxylates in acids, benzene, or pyridine, from which oxygen had not been removed, led to the detection of alkylperoxy-radicals derived from pivalic, 2,2-dimethylbutyric, 2,2-dimethylvaleric, and 2,2-dimethyloctanoic acids (singlet, $g = 2.0152$).

The chain mechanism of the photochemical decarboxylation of carboxylic acids has been demonstrated in the determination of the quantum yield. In the oxidation of pivalic and dimethylbutyric acid by lead tetra-acetate the exact quantum yield could not be measured, but, according to a preliminary estimate, the chain length is approximately 200.[57] The quantum yield in the photochemical decarboxylation of acids by Ce^{4+} depends on the concentration of the latter and on the type of acid. At a 0.1M concentration of cerium acetate and 3500 Å a quantum yield is 1.11 ± 0.07 for pivalic acid, 0.81 ± 0.05 for isobutyric acid, and 0.52 ± 0.05 for butyric acid.

The photochemical decarboxylation of dibasic acids (succinic, glutaric, and adipic) on treatment with a 0.02M $FeCl_3$ solution (3500 Å, 38 °C) proceeds

$$HOOC(CH_2)_nCOOH \xrightarrow[2\text{-}6\ \text{days}]{FeCl_3, h\nu} \begin{cases} \rightarrow Cl(CH_2)_2COOH\ (78\%),\ n=2 \\ \rightarrow \text{  }\ (80\%),\ n=3 \\ \rightarrow Cl(CH_2)_4COOH\ (70\%),\ n=4 \end{cases} .$$

As a result of the reaction, chloro-substituted monobasic acids are formed from succinic and adipic acids, while glutaric acid leads mainly to γ-butyrolactone and a certain amount of a hydroxyacid. In the absence of $FeCl_3$ and in the dark the reaction does not take place. Special experiments have shown that neither β-hydroxypropionic nor γ-chlorobutyric acid are intermediates.

The decarboxylation of metal acetates, mainly mercury acetates, which proceeds with formation of organometallic compounds, has been considered in detail in a monograph[19]. The most probable mechanism of the photodecarboxylation of mercury salts of carboxylic acids (in benzene and acetic acid as solvents) is described by the following equations.

$$(RCOO)_2Hg \rightarrow RCOO^{\cdot} + {}^{\cdot}HgOCOR ;$$
$$RCOO^{\cdot} \rightarrow R^{\cdot} + CO_2 ;$$
$$R^{\cdot} + {}^{\cdot}HgOCOR \rightarrow RHgOCOR ;$$
$$R^{\cdot} + (RCOO)_2Hg \rightarrow RHgOCOR + RCOO^{\cdot} ;$$
$$2\,HgOCOR \rightarrow Hg_2(OCOR)_2 ;$$
$$Hg_2(OCOR)_2 \rightarrow Hg + (RCOO)_2Hg .$$

In this mechanism the $R^{\cdot} + (RCOO)_2Hg + RHgOCOR + RCOO^{\cdot}$ state, which presupposes a chain reaction mechanism, has not been supported by direct evidence. The photochemical reaction leads to the formation of a considerable amount of mercury(I) salts and organomercury compounds. In addition, similar reactions of free radicals result in the formation of saturated and unsaturated hydrocarbons [Eqn.(2)] as well as metallic mercury. The reaction is of preparative interest for the synthesis of alkylmercury salts. Mercury salts of aromatic acids are decarboxylated with much greater difficulty than the salts of aliphatic acids.

The decomposition of lead tetracarboxylates $(RCOO)_4Pb$ ($R = C_6H_5$, $o\text{-}CH_3C_6H_4$, $p\text{-}CH_3C_6H_4$, $o\text{-}O_2NC_6H_4$, $p\text{-}O_2NC_6H_4$, C_6H_{11}, or C_5H_9) in benzene by ultraviolet light or peroxides[140] is hindered when a substituent is present in the benzene ring of the arenecarboxylic acid. The radicals $RCOO^{\cdot}$, generated in the reaction, react with one another: $2RCOO^{\cdot} \rightarrow RCOOR + CO_2$, or decompose into CO_2 and radicals $R^{\cdot}$, which interact with benzene, leading to the formation of biaryls and disproportionation products.

IV. INITIATED DECARBOXYLATION

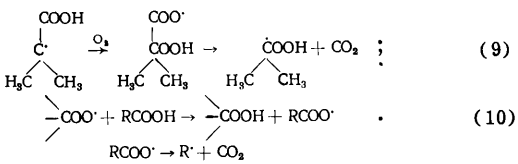
The initiated decarboxylation of aromatic acids (benzoic and toluic) in aprotic solvents (*o*-dichlorobenzene, nitrobenzene) takes place in the presence of oxygen and t-butyl peroxide or t-butyl hydroperoxide at temperatures sufficiently high to cause the homolysis of the peroxide (125 to 200 °C).[141,142] It has been suggested that the reaction mechanism involves the formation of aroyloxy-radicals when the acid interacts with a radical:

$$ArCOOH + X^{\cdot} \rightarrow ArCOO^{\cdot} + HX \quad .$$

Since the reaction does not take place in the absence of oxygen, it has been postulated that the radicals obtained from the initiator (methyl and t-butoxy-radicals, etc.) do not abstract hydrogen from the carboxy-group. Peroxy- and hydroxy-radicals (X = RCOO· or HO·) are apparently reactive. The aroyloxy-radicals are readily decomposed into CO_2 and an aryl radical, which interacts with the molecules of the aromatic solvent to form biphenyls. The initiated decarboxylation is catalysed by cobalt(III) naphthenates probably as a result of the direct oxidation of the acid by metal ions. The yield of biphenyl reaches 50% in this case.

Mercury salts of carboxylic acids are decarboxylated by acetyl, di-t-butyl, benzoyl, etc. peroxides or ultraviolet light with formation of organomercury compounds[19,143]. The reaction is carried out in acetic acid, benzene, and their mixtures at 80–98 °C:

$$RCOOHgOOCR + R'^{\cdot} \rightarrow R'HgOCOR + RCOO^{\cdot} \; ;$$
$$RCOO^{\cdot} \rightarrow R^{\cdot} + CO_2 \quad .$$



It has a radical chain mechanism, as shown by the virtually quantitative conversion of the mercury salts of carboxylic acids for comparatively small amounts of peroxy-compounds (molar ratio mercury carboxylate : peroxide ≅ 6 : 1) and also by the presence of small amounts of alkanes and alkenes in the reaction products. The mercury salts of lower representatives of homologous series of alkanecarboxylic acids react more readily than the salts of the higher and aromatic acids. The introduction of substituents into the aromatic ring prevents the decarboxylation of the mercury salts of aromatic carboxylic acids. The introduction of electronegative substituents into the molecule of an aliphatic mercury carboxylate also hinders the initiated decarboxylation reaction, the magnitude of the effect diminishing as the substituent becomes more remote from the carboxy-group[19].

Mercury(I) salts also react with diacyl peroxides, forming organomercury compounds:

$$RCOOHg-HgOOCR + (R'COO)_2 \rightarrow 2R'HgOCOR + 2CO_2 \quad .$$

A series of organomercury compounds have been obtained with the aid of these reactions: the salts of aryl-, methyl-, ethyl-, and propyl-mercury[143], cyclopropyl- and cycloheptyl-mercury[144], cyclohexyl- and cyclopentyl-mercury[145], n-butyl-, n-pentyl-, and n-nonyl-mercury[146], and α-naphthylmercury[147].

The decarboxylation of carboxylic acids is frequently accompanied by the liquid-phase oxidation of organic compounds. Data for this process, which is called "decarboxylation coupled with oxidation" or "oxidative decarboxylation", have already been surveyed[20,148] and will not be considered in this review. One should note that such reactions can also be classified as initiated decarboxylation, since the decarboxylation takes place under the influence of radicals obtained by the oxidation of organic admixtures or the carboxylic acids themselves. The mechanism of reactions of this kind can include intramolecular decarboxylation [reaction (9)], when the molecules being oxidised are also decarboxylated, and intermolecular decarboxylation [reaction (10)], when molecules of one type are oxidised and those of another are decarboxylated:

$$\xrightarrow{O_2} \quad \text{(9)}$$

$$\text{(10)}$$

$$RCOO^{\cdot} \rightarrow R^{\cdot} + CO_2$$

V. THE EFFECT OF LIGANDS IN THE OXIDATIVE DECARBOXYLATION OF CARBOXYLIC ACIDS

Strong acids accelerate the decarboxylation of carboxylic acids under the influence of Pb^4,[32,57] Mn^{3+},[28] Co^3,[27] and Tl^{3+}[25] ions. This effect is attributed to the formation of cationic complexes, which are stronger oxidants than their neutral analogues:

$$M(O_2CR)_n + H^+ \rightleftarrows M(O_2CR)^+_{n-1} + RCO_2H \quad .$$

The decarboxylation of alkanecarboxylic[15,31] and dicarboxylic[109] acids by lead tetra-acetate in benzene is appreciably accelerated in the presence of pyridine. The acceleration of the reaction in the presence of acetate and trifluoroacetate has been observed in the decarboxylation of acids by Co^{3+},[27] and Mn^{3+}[28] ions. The influence of acetate ions on the rate of reaction has been explained by the formation of labile complexes of the type $[Pb^{IV}(OAc)_6^{2-}$,[149] $[Co^{III}_2 \cdot (O_2CR)_7^-]$, and $[Co^{III}(O_2CR)_4^-]$.[27] Spectrophotometric measurements have shown that the addition of 3 M $LiOCOCH_3$ to lead tetra-acetate in acetic acid causes a hypsochromic shift in the ultraviolet spectrum (there is a shoulder at 280 nm), which increases after the addition of small amounts of triethylamine.

Certain complexes of lead carboxylates with pyridine have been isolated and investigated[149]:

$$Pb(OAc)_{4-n}(O_2CR)_n + m\,Py \rightleftarrows Pb(OAc)_{4-n}(O_2CR)_n Py_m \quad .$$

There exists a view[15] that the accelerating influence of pyridine is associated with the fact that the formation of metal carboxylates is facilitated in the pre-equilibrium stages:

$$Pb(OAc)_4 + n\,RCO_2H \rightleftharpoons Pb(OAc)_4HOCOR\ ;$$
$$Py + Pb(OAc)_4HOCOR \rightleftharpoons PyH^+ + Pb(OAc)_4OCOR^-\ ;$$
$$Pb(OAc)_4OCOR^- \rightleftharpoons OAc^- + Pb(OAc)_3OCOR\ .$$

The oxidative decarboxylation of mandelic acid by lead tetra-acetate in acetic acid is catalysed by different basic compounds such as water, methanol, DMF, 2,6-lutidine, 2,4-lutidine, triethylamine, and acetate salts[133]. The process consists of two fluxes, one of which constitutes the non-catalytic reaction and the other the base-catalysed reaction. In the range of concentrations up to 3M for methanol and up to 1M for water, the reaction is of first order with respect to methanol and water. At higher concentrations of the additives the reaction order increases to two. The concentrations of acetate salts and amines are included in the kinetic equation with an exponent close to unity. In terms of their catalytic effect, the additives can be arranged in the following sequence [the values of k_2 (litre mol^{-1} s^{-1}) are indicated in brackets]: H_2O (0.065) < CH_3OH (0.13) < LiOAc (73.5) < NaOAc (193) < KOAc (263). The catalytic action of bases is explained by the modification of the oxidant as a result of the change in the ligand environment of the lead ion. Apart from kinetic relations, this is indicated by a series of physicochemical measurements. When lead tetra-acetate is dissolved in methanol, the brown-red colour of the complex appears and then vanishes after the addition of 5% acetic acid without loss of the oxidising properties of the oxidant. Furthermore, the complex $Pb(OAc)_2(OCH_3)OH$ has been isolated from methanol and characterised. The relative catalytic activities of acetate salts decrease in the sequence KOAc > NaOAc > LiOAc, i.e. with decrease of the degree of dissociation of the ion pairs into ions[150,151]. However, it has been suggested that, apart from ions, ion pairs also exhibit a catalytic effect in the reaction. Since amines can participate in the formation of acetate ions (in accordance with the equation $Py + HOAc \rightleftharpoons PyH^+OAc^-$), which accelerate the reaction, their catalytic effect is difficult to isolate in a pure form. Acrylonitrile accelerates the reaction to a greater extent than acetonitrile, which indicates a specific effect of bidentate ligands.

The catalytic decarboxylation of dicarboxylic β-ketoacids has been reviewed[152-154]; in view of its specificity, this reaction will not be considered here. It is also characterised by catalytic effects of basic ligands (pyridine, quinoline, bipyridyl, phenanthroline, etc.). The explanation of the catalytic effects in these reactions given by Bonchev[155] can also be applied to the oxidative decarboxylation of carboxylic acids with the aid of transition metal ions. The accelerating effects of π-ligands have been explained[155] by the presence of a reverse π-dative bond between the metal and the ligand (M → L), which increases the positive charge of the metal ion and hence increases its catalytic activity. The interaction of the metal ion with the ligand has been confirmed experimentally by NMR and also by absorption spectroscopy and EPR.

The effect of ligands should be significant also in the second stage of the decarboxylation involving successive oxidation of the free radicals formed in the first stage of the reaction. This is indicated particularly by Kochi's study[156] of the oxidation of alkyl radicals by copper(II) salts. The replacement of the acetate ligand by the weakly coordinated perchlorate and triflate ligands in the oxidation of radicals in acetic acid results in a sharp decrease of the yield of alkenes. When the n-butyl radical is oxidised by $Cu(ClO_4)_2$ and $Cu(O_3SCF_3)_2$, the amount of alkenes falls to 34.1% (compared with the 94% yield of alkenes in the oxidation by copper acetate) with a simultaneous increase of the yield of alkyl acetates. Analysis of the composition of the products of the oxidation of radicals by various copper(II) salts led the authors[156] to the conclusion that the acetate ligand promotes oxidative elimination, which increases the yield of alkenes; on the other hand, the capacity for oxidative solvolysis increases with increase of the stability of the carbonium intermediate, which is also promoted by weakly coordinated ligands such as perchlorate and triflate.

The Synthesis of Polymers by Modification Methods

V.V.Korshak

The present state of the syntheses of polymers by modification methods is considered and the characteristics of the polymer modification reactions, determined by the specific macromolecular features of the polymers, are discussed. The applicability of the concept of the heterounit structure to polymers obtained by the modification procedure is demonstrated. Typical groups of reactions modifying natural and synthetic polymers and their features are specified and the characteristics of such reactions, involving substitution, structure formation, degradation, addition, elimination, isomerisation, and exchange, are considered. The prospects for the development of modification processes as a leading trend in the field of the synthesis of polymers are described.
The bibliography includes 130 references.

III. The heterounit structure of polymers obtained by the modification procedure 1138
IV. Typical chemical polymer modification reactions 1138

I. INTRODUCTION

The modification of polymers is one of the ways of synthesising high-molecular-weight compounds, which, together with polymerisation and polycondensation, has been used for a long time to synthesise polymers.

Whereas the polymerisation and polycondensation reactions are processes based on the conversion of monomers into polymers, the third procedure (modification) is a process based on the interconversion of polymers (Fig.1).

Consequently, *chemical modification of polymers is a process in which the initial polymer is subjected to physical or chemical influences, as a result of which it is converted into a new polymer with a different chemical structure*†.

The polymer modification reaction was first achieved by the French worker Braconnot, who obtained nitrocellulose in 1833 by treating cellulose with nitric acid[1]. Similar reactions were later carried out on a series of natural polymers. Different derivatives of cellulose, starch, proteins, rubber, and other natural polymers were obtained[2]. Subsequently synthetic polymers such as poly(vinyl chloride), polystyrene, polyethylene, and others began to be subjected to modification reactions at an increasing frequency[2].

Such wide-scale use of the modification reactions is due to the fact that the initial polymers do not meet all the practical requirements as regards their properties. Thus many insoluble polymers can be converted by modification into soluble high-molecular-weight compounds. A striking example of this kind is provided by cellulose, whose esters are readily soluble in organic solvents; chlorinated poly(vinyl chloride) and polyethylene become readily soluble. The introduction of carboxy- and amino-groups into polystyrene imparts to it acid and basic properties respectively, which are essential for ion-exchange resins. The introduction of nitrate ester groups into cellulose imparts explosive properties to the latter. The introduction of phosphate groups as well as chlorine, fluorine, bromine, and certain other elements into polymers renders them incombustible.

† According to this definition, the copolymerisation of monomers should not be classified as chemical modification of polymers.

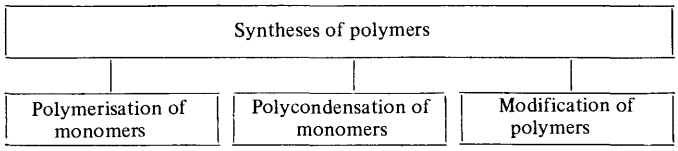
Thus the modification of polymers constitutes an extremely universal method whereby it is possible to vary within a wide range their physical and chemical properties in the desired direction. Because of this, the modification of polymers has now become one of the most important procedures whereby a large number of polymers are synthesised both in the laboratory and in industry. In industry modification processes have found extensive applications in the synthesis of many polymers, produced on a large scale, such as nitrocellulose, acetylcellulose, other cellulose esters and ethers, poly(vinyl alcohol), acetals of poly(vinyl alcohol), chlorinated poly(vinyl chloride), chlorinated and sulphochlorinated polyethylene, and others. There is no doubt that in the future modification will acquire still greater importance in industry.

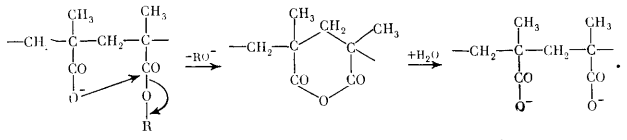
The aim of the present review is to outline the present state of the modification processes and the likely prospects for their utilisation. The characteristics of the polymer modification reactions, determined primarily by their macromolecular nature, are considered at the beginning of the review. A feature of polymers such as their heterochain structure, which in many respects determined their characteristic set of physical and chemical properties, merits particular attention. Next, typical reactions used at present for the modification of polymers are described.

II. CHARACTERISTICS OF POLYMER MODIFICATION REACTIONS

A characteristic feature of the polymer modification processes is the fact that all reactions of this kind do not as a rule go to completion and are accompanied by side reactions, which has a significant influence on the course of the process and its results. This is caused by the influence of a number of significant physical and chemical factors, manifested in a specific manner in various polymer modification reactions. Such factors include the influence of the nature of the reagents and catalysts, the structure and degree of crystallinity of polymers, temperature, the nature of the solvent, and others. Ultimately, the reactions therefore result in a mixture of macromolecules of different structure, each of which contains different units in a wide variety of combinations. The final polymer is chemically inhomogeneous, i.e. has a heterounit structure[3].

Consequently reactions in the polymer chain obey much more complex rules than the analogous reactions of low-molecular-weight compounds. The explanation is that not only the structure of the reacting groups but also a number of specific influences, determined by the macromolecular nature of one or both reactants, play a significant role here. The chain effect, the effect of the neighbouring group, and configurational, conformational, electrostatic, and supermolecular effects are usually isolated from such influences as the most significant[3-5].





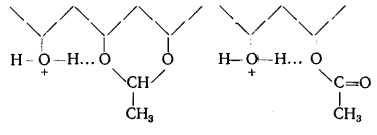


Figure 1. Different processes leading to the synthesis of polymers.

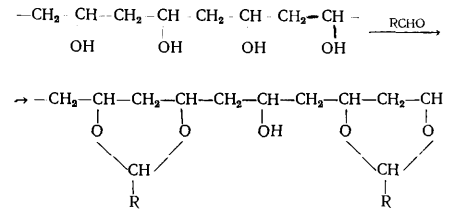
The relative steric disposition of different groups in the polymer chain has a significant steric or electrostatic (polar) influence on their reactivity. This influence can be shown both in the activation and passivation of neighbouring groups. The increase of the rate of reaction under the influence of a neighbouring group, known as "anchimeric assistance", is exhibited mainly when five- or six-membered rings can be formed. Thus it is observed for succinate esters. In exactly the same way, owing to the steric proximity of a neighbouring group, isotactic poly(methyl methacrylate) hydrolyses faster than the syndiotactic and atactic polymers, because in the isotactic polymer the neighbouring functional groups are distributed more favourably for their interaction with one another, leading to the formation of an intermediate cyclic anhydride[6,7]. The distribution function of the compositions of polymers has been considered in a number of investigations[8,9].



As already stated, one of the causes of the formation of anomalous units in polymer modification processes is the influence of neighbouring units which have already reacted (the "neighbour effect")[10]. A characteristic example of the acceleration of the reaction by the "neighbour effect" is the hydrolysis of the methacrylate–methacrylic acid copolymer[11]:

In the case of the partially hydrolysed poly(vinyl acetate) or polyvinylacetal this interaction takes place via the formation of a hydrogen-bonded ring[12], which facilitates the hydrolysis of acetals and acetates by increasing their reactivity[13] via the mechanism

As a result of the "neighbour effect", not all the initial hydroxyls in poly(vinyl alcohol) are converted into the acetal by treatment with aldehydes. According to Flory's calculations[14], approximately 13.53% of the hydroxyls should remain unsubstituted:

As another example, one may take polyethylene, which is readily chlorinated up to a chlorine content of 60%, whereupon the reaction slows down and, after the attainment of a chlorine content of 73%, ceases, although theoretically the chlorine content could reach 85.5%.[15] The explanation is that CCl_2 groups are not formed and the first stage proceeds with formation of the $-CH_2CHCl-$ groups up to a chlorine content of 56.8%. The next stage consists in the formation of the $-CHClCHCl-$ groups up to a chlorine content of 73.2%, whereupon the chlorination reaction stops. The retarding effect of the chlorine atoms in the $-CHCl-$groups on the chlorination of neighbouring CH groups can be accounted for by the inductive effect[13,16].

Thus in substitution reactions the "neighbour effect" as well as the steric and electrostatic influence of the initial side groups play a significant role[13].

Examples are known in which different effects are superimposed. Thus the alkaline hydrolysis of polymethacrylamide does not go to completion[17] and the methacrylamide–methacrylic acid copolymer hydrolyses with greater difficulty the smaller its methacrylamide content[18]. The loss of reactivity by the amide groups in these cases occurs both as a consequence of their being blocked by two ionised carboxy-groups and as a result of the electrostatic repulsion by the latter of hydroxide ions which catalyse the hydrolysis[19].

Attention should be drawn to the fact that, in order to characterise fully the polymer formed as a result of chemical modification, it is important to establish not only the presence of anomalous units and their number but also their sequence in the polymer macromolecule. Thus the frost resistance and physical properties of vulcanised rubbers are determined not only by the ratio of the *cis*- and *trans*-units but also by their sequence in the macromolecules[20]. Yet another example is provided by chlorinated polyethylene containing 56% of chlorine, the properties of which differ appreciably from those of poly(vinyl chloride) with the same chlorine content[21]. In the former case we have an irregular and in the latter a regular arrangement of chlorine atoms, as can be seen from the formulae of these polymers:

$$-CH_2-CH_2-CHCl-CHCl-CH_2-CH_2-;\ (-CH_2-CHCl-)_x.$$

Polyethylene chlorinated in solution in carbon tetrachloride and in an aqueous suspension has different arrangements of chlorine atoms and, for the same content of the latter, these two types of polymers have appreciably different properties[22].

It has been found that the hydrolysis of isotactic polyacrylonitrile converts it into an atactic polymer[23], while polymethacrylate esters hydrolyse without change of configuration[24], which constitutes a specific illustration of the influence of the steric structure on the chemical properties of these polymers and particularly on the structure of their reaction products.

When the causes responsible for the chemical inhomogeneity of the products, i.e. the formation of heterounit polymers, are considered, one should bear in mind that the physical structure of the initial polymer plays a by no means subsidiary role[25,26]. Its role is particularly significant when the reaction takes place in a heterogeneous system. This is necessary when there is no suitable solvent for the reaction or when one has to retain the initial form of the polymer, as, for example, in the treatment of fibres and films. Finally, the tendency towards the manufacture of polymers with the greatest possible elimination of all solvents has been recently assuming an increasing importance. Together with economical and ecological causes, this is associated with the fact that reactions in solution are sensitive to the nature of the solvent and to the properties of the solution, which can be significantly reflected in the degree of conversion and in the structure of the modification products formed.

The compatibility of the polymers is also significant, because, as the reaction proceeds, their composition changes very considerably with a corresponding alteration of their properties. Incompatibility can cause phase separation or coiling of the chains. As a result of the latter, the reaction is localised on the surfaces of compact coils or becomes diffusion-controlled. The accessibility of the functional groups of the polymer to the low-molecular-weight reagent is thus altered, which affects the degree of the modification reaction and the structure of the product[27].

Factors such as the supermolecular structure of the polymers, the orientation of the macromolecules in solution, and the solubility and compatibility of the polymers and reagents in solutions also exert a considerable influence on the result of reactions involving substitution in macromolecules. The influence of the supermolecular structure of the polymer in a reaction carried out in a heterogeneous system, where the solid polymer is acted upon by liquid reagents, is associated with the fact that the rate and degree of conversion depend on the rate of diffusion of the liquid reagent into the bulk of the polymer structure. This diffusion takes place more readily in an amorphous polymer and in the amorphous regions of crystalline polymers. Macromolecules in the amorphous regions react faster and are more fully acted upon by chemicals than macromolecules in the ordered crystalline state.

The hydrolysis of poly(ethylene terephthalate)[28], the chlorination[29] and oxidation[30] of polyethylene, the grafting of styrene onto polyamides[31], and the heterocyclisation of polyhydrazides to polyoxadiazoles[32] proceed much more readily in the amorphous regions than in the crystalline regions, since the orientation of polymer chains in the latter hinders both the accessibility of the macromolecules to the reagents and the interaction of the functional groups of the macromolecules with one another.

It has been shown for the sulphochlorination of polyethylene that the number of sulpho-groups which have entered the polymer corresponds to the degree of crystallinity of the latter determined by X-ray diffraction[33]. It has been found that the degree of acetylation of cellulose also depends markedly on the supermolecular and morphological structures of the initial cellulose[25,34]. The degree of crystallinity of cellulose affects not only the distribution of the substituted groups along the chain of the macromolecule but also the mode of substitution in the glucose residues. Thus, although the primary hydroxy-group at the sixth carbon atom is more reactive, the heterogeneous xanthate substitution reaction takes place preferentially at the less reactive secondary hydroxyls attached to the second or third carbon atoms. The explanation is that the hydroxyl at the sixth carbon atom is blocked by intramolecular and intermolecular hydrogen bonds[35,36].

The study of the oxidation and chlorination of isotactic poly-4-methylpentene showed that these processes take place preferentially at the bends in the chains, since the lowest activation energy is required at these sites as a consequence of internal stresses[37].

The nature of the reagents is also very important. Thus acetic anhydride and nitric acid react with all the hydroxy-groups of cellulose, while trityl chloride reacts only with the primary groups[38]. The reaction temperature also plays a significant role. All possible polymer modification reactions take place more readily at temperatures above the glass point of the polymer[39].

In view of the above characteristics of the reactions in heterogeneous systems, in chemical modification reactions an attempt is made to dissolve the polymers or at least to obtain them in a gel, i.e. in a swollen state, which facilitates the substitution process[40–42].

Substitution reactions in solution, i.e. in a homogeneous system, take place faster and result in a more complete substitution of the functional groups and a more uniform disposition of the substituting groups along the chain than in a heterogeneous system. Thus acetylation of poly(vinyl alcohol) in a homogeneous solution makes it possible to obtain a virtually fully substituted product, while a considerable number of unsubstituted hydroxy-groups remain after acetylation in a heterogeneous system[42]. The distribution of free hydroxy-groups and correspondingly acetyl groups in the cellulose acetate obtained under homogeneous conditions is more regular than in the acetate obtained under heterogeneous conditions[43]. Since a single treatment of the polymer with the reagent does not lead to complete substitution, the treatment must be frequently repeated. Fig.2 shows how the content of methoxy-groups in methylated cellulose depends on the number of repeated treatments[44].

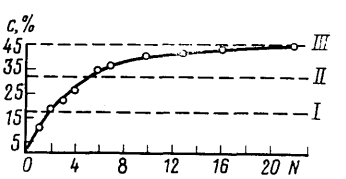


Figure 2. Dependence of the content of methoxy-groups (c) in methylated cellulose on the number of repeated treatments: I) monomethylcellulose; II) dimethylcellulose; III) trimethylcellulose. The continuous curve represents the variation of the content of methoxy-groups in the specimen.

As already mentioned, the polymer modification reactions never go to completion and they therefore lead to heterounit polymers containing the initial units as well as the final and intermediate units. The study of the resulting polymers shows that the substituents are usually distributed at random along the polymer chain. Fig.3 illustrated the distribution of substituents for different degrees of substitution.

III. THE HETEROUNIT STRUCTURE OF POLYMERS OBTAINED BY THE MODIFICATION PROCEDURE

One of the characteristic features of the modification reactions is their failure to reach completion, as a consequence of which some of the initial functional groups do not react and remain in the unchanged state. At the same time there is a possibility of a wide variety of side reactions, which also lead to the formation of units of a different chemical type and give rise to chemical heterogeneity in the macromolecules, referred to as the heterounit structure of polymers[45–48].

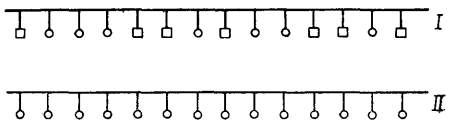

Figure 3. Distribution of substituents in the macromolecule for different degrees of substitution of the functional groups: I) partial, irregular substitution in heterounit polymers; II) complete substitution.

The heterounit polymers obtained as a result of various modification reactions differ by the presence of anomalous units in the macromolecule, i.e. are chemically heterogeneous. Whereas the structure of a normal homounit polymer can be represented by the usual formula $-(-M-)_x-$, the macromolecule of a heterounit polymer contains anomalous A units:

$$-M-M-M-A-M-M- \quad .$$

Consequently the structure of a heterounit polymer can be represented by the following formula in the general case:

$$-[-(-M-)_{\overline{[m]}}-(-A-)_{\overline{[n]}}-]_x$$

where M are normal units, A are anomalous units, and $[\overline{m}]$ and $[\overline{n}]$ are coefficients indicating a statistical distribution of the units in the macromolecule of the heterounit polymer obtained by one of the modification methods[45–48].

As an example, one may quote the formula of heterounit cellulose nitrate[49]:

$$-[-C_6H_7O_2(OH)_3-]_{\overline{[m]}}-[-C_6H_7O_2(OH)_2(ONO_2)-]_{\overline{[n]}}$$
$$-[-C_6H_7O_2(OH)(ONO_2)_2-]_{\overline{[p]}}-[-C_6H_7O_2(ONO_2)_3-]_{\overline{[q]}} \quad .$$

Thus we may expect the presence of units of at least four different types in the macromolecules of this cellulose ester, disregarding the anomalous units which might have been present in the initial cellulose.

Yet another example of a heterounit polymer is provided by chlorinated polyethylene, the general structure of which can be expressed by the following formula:

$$-(-CH_2-CHCl-)_{\overline{[m]}}(-CH_2-CH_2-)_{\overline{[n]}}-(-CHCl-CHCl-)_{\overline{[p]}} \quad .$$

Naturally the coefficients depend on the degree of the modification and its conditions.

Fig. 4 illustrates the fundamental reactions—both normal reactions and secondary reactions—which can occur in the modification of polymers and which we designate as the "set of modifying reactions". The data in Fig. 4 readily lead to the conclusion that the causes responsible for the heterounit structure of the products of the modifying reactions are fairly numerous. It is therefore not surprising that all the modification methods lead to the formation of chemically heterogeneous heterounit polymers. This conclusion is very significant, because it relates the structure of polymers to their properties[50].

It had been shown earlier for a large number of polymers that the heterounit structure is a factor which exerts a very significant influence on the entire set of physical and chemical properties of heterounit polymers[45]. Thus a statistical distribution of units of different chemical types in the macromolecules of heterounit polymers is frequently responsible for their ready solubility, a decrease of the melting point and thermal stability, an increase of elasticity, and the simultaneous decrease of strength[46].

On the basis of the concept of the heterounit structure, the modification reactions must be represented with allowance for the formation of anomalous units. For example, the nitration of cellulose can be represented thus:

$$-[-C_6H_7O_2(OH)_3-]_x \xrightarrow{HNO_3}$$
$$\rightarrow -[-C_6H_7O_2(OH)_3-]_{\overline{[m]}}-[-C_6H_7O_2(OH)_2(ONO_2)-]_{\overline{[n]}}$$
$$-[-C_6H_7O_2(OH)(ONO_2)_3-]_{\overline{[p]}}-[-C_6H_7O_2(ONO_2)_3-]_{\overline{[q]}} \quad .$$
$$x = m + n + p + q$$

The hydrolysis of poly(vinyl acetate) can be represented by the equation

$$-\left[-CH_2-\underset{OCOCH_3}{CH}-\right]_x- \xrightarrow{H_2O} -\left[-CH_2-\underset{OCOCH_3}{CH}-\right]_{\overline{[m]}}-\left[-CH_2-\underset{OH}{CH}-\right]_{\overline{[n]}} \quad .$$
$$x = m + n$$

The chlorination of polyethylene is described schematically by the following equation:

$$-[-CH_2-CH_2-]_x \xrightarrow{Cl_2}$$
$$\rightarrow -[-CH_2-CH_2-]_{\overline{[m]}}-[-CH_2-CHCl-]_{\overline{[n]}}-[-CHCl-CHCl-]_{\overline{[p]}} \quad .$$
$$x = m + n + p$$

Naturally, this type of expanded representation of the modification reactions requires much space and for the sake of economy we shall henceforth represent only the extreme units in the chain of transformations occurring in the modification processes.

IV. TYPICAL CHEMICAL POLYMER MODIFICATION REACTIONS

Polymer modification processes are based on the use of a series of chemical reactions. In considering the polymer modification reactions known at the present time, one should note their large number and wide variety. Among these reactions, there are both processes based on the interactions of polymers with low-molecular-weight reagents and reactions of polymers with polymers. To facilitate the discussion of these reactions, we combined them into seven groups in terms of their chemical similarity. Examples of typical reactions in each group are given in Table 1, which shows that a series of different reactions are widely used in polymer modification processes. Here we encounter both substitution and elimination reactions, on the one hand, and reactions involving addition to multiple bonds, structure formation, and degradation of polymers, on the other. In addition, reactions involving the isomerisation of macromolecules and extremely unusual exchange type reactions of heterochain polymers are used for this purpose.

An interesting feature of all these reactions is that each has a specific influence on the structure of the polymer

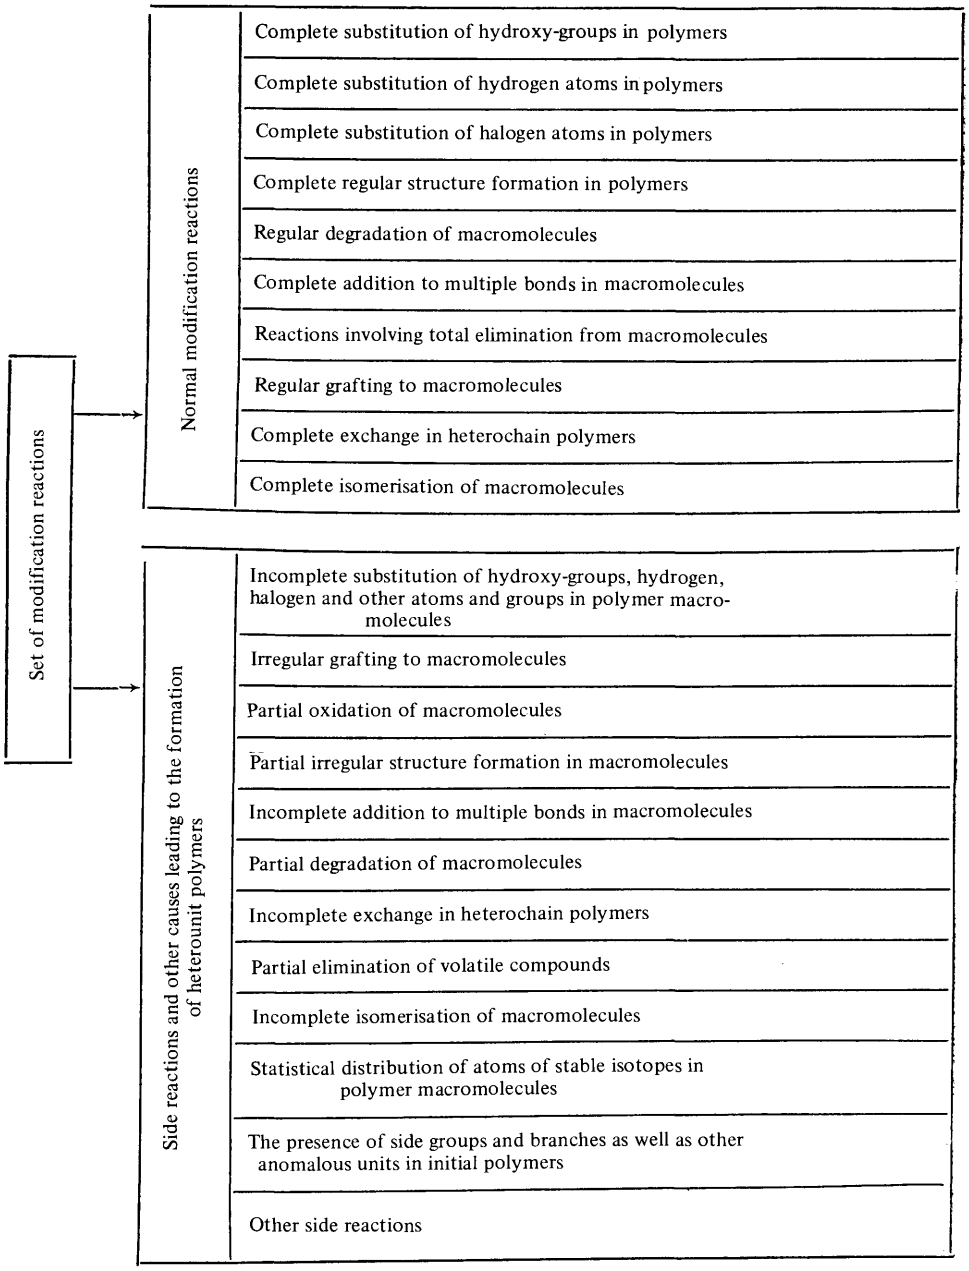

Figure 4. The set of modification reactions.

macromolecule formed as a result of the modification. Fig. 5 illustrates schematically the changes in the structure of macromolecules occurring as a result of the modification processes. It shows that in reactions of type (1) the structure of the polymer chain is retained, as in fact should have been the case in reactions of the polymer-analogue type to which these processes belong. In all the remaining types of reactions the structure of the macromolecule changes significantly. The remaining modification reactions cannot therefore be included in the class of polymer-analogue transformations.

In considering the modification reactions, one must bear in mind not only their chemical nature but also the way in which they are carried out (in solution, in the melt, in an emulsion, and in the solid), since the result of the process depends significantly on its conditions.

1. Polymer Modification Reactions Involving Substitution

We shall now consider in detail reactions of each type, examples of which are given in Table 1. We shall begin their consideration with the widely used substitution reactions.

The substitution reactions in Table 2 can be subdivided into the following subgroups: (1) substitution of a hydroxy-group by acyl and alkyl groups as well as inorganic acid residues; (2) substitution of a hydrogen atom by deuterium, a halogen, halogeno-, nitro-, phosphino-, and sulpho-groups, as well as alkyl groups in grafting reactions; (3) hydrolysis of derivatives of polymeric carboxylic acids; (4) substitution of a halogen and other groups for a hydroxy- or amino-group; (5) oxidation of side groups.

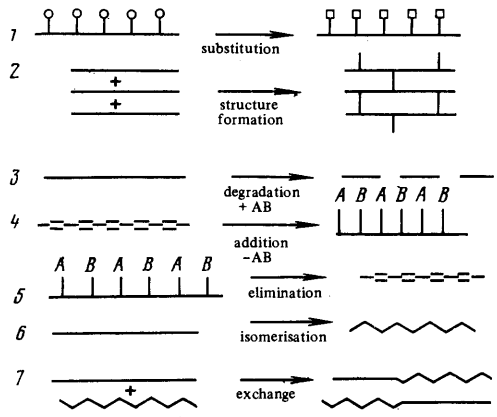

Figure 5. The change in the structure of macromolecules as a result of the modification reaction (the numbers of the reactions have the same significance as in Table 1).

Table 1. Examples of typical chemical polymer modification reactions.

Name and equation of modification reaction	References
Substitution of atoms and groups in macromolecule $-[-C_6H_7O_2(OH)_3-]_x- \xrightarrow{HNO_3} -[-C_6H_7O_2(ONO_2)_3-)_x-$	1
Structure formation in polymers $-CH_2-CH_2-CH_2- \xrightarrow{h\nu} -CH_2-\underset{\displaystyle CH_2-CH-CH_2-}{\overset{\displaystyle |}{CH}}-CH_2-$	51
Degradation of macromolecules $-[-CH_2-CH=CH-CH_2-CH_2-]_x- \xrightarrow{WCl_6(CH_3)_2Si(CH_2)_2Si(CH_3)_3}$ $\rightarrow -[-CH_2-CH=CH-CH_2-CH_2-]_{x/n}-$	52
Reactions involving addition to multiple bonds in macromolecule $-[-CH_2-CH=CH-CH_2-]_m- \xrightarrow{+Cl_2} -[-CH_2-\underset{Cl}{\overset{|}{CH}}-\underset{Cl}{\overset{|}{CH}}-CH_2-]_m-$	53
Reactions involving elimination from macromolecules $-(-CH_2-CCl_2-)_x- \xrightarrow{-HCl} -(-C\equiv C-)_x-$	54
Isomerisation reactions of macromolecules $-[-C\equiv C-C\equiv C-]_x- \rightarrow =[=C=C=C=C=]_x=$	55
Exchange reactions of heterochain polymers $-R-\overset{+}{COO}-R- \quad -R-\overset{+}{COO}-R'$ $-R'-\overset{+}{COO}-R'- \rightarrow -R'-\overset{+}{COO}-R-$	56

These reactions have certain common features consisting in the nature of the alteration of the structure and the properties of the resulting polymers. We may note that the replacement of a hydroxy-group in the polymer by an acid residue or an alkyl group makes the polymer soluble in inorganic solvents; the substitution of hydrogen by a halogen has a similar influence. In contrast, the substitution of an alkyl group in an ether by a hydroxy group impairs the solubility of such a polymer in organic solvents.

The majority of polymer modification reactions involving substitution belong to the type designated as polymer-analogue reactions. Their characteristic feature is retention of the main macromolecular skeleton, only the nature of the substituents surrounding the main chain being altered. The specific features of reactions of this type were considered previously.

2. Polymer Modification Reactions Involving Structure Formation

The modification of polymers by structure formation is a process in which the macromolecules pass through a stage with branched structures and are ultimately converted into infusible and insoluble three-dimensional structures. In the first stage of this process the polymer interacts with the cross-linking agent, which leads to the formation of bonds between the macromolecules. An industrial structure formation process, known as vulcanisation, is widely used in the processing of polymers, particularly elastomers. Vulcanisation imparts to rubbers resistance to wear and other mechanical influences and resistance to oxidation and the action of solvents.

Examples of reactions involving structure formation in polymers are presented in Table 3, which shows that peroxide and radiation vulcanisations are widely used for modification by structure formation. In addition, in the case of rubbers vulcanisation by sulphur and its derivatives is used.

The cross-linking effect of bifunctional reagents and reagents with a larger number of functional groups is used for cellulose, poly(vinyl alcohol), and other polymers. As a result of these reactions, branching takes place initially and is followed by structure formation in polymers with different degrees of cross-linking, determined by the number of links between branching nodes (a), as shown below in Fig.6. Each branching node can then contain between three and eight and more branches (Fig.7).

In the limit the structured polymer has a molecular weight equal to that in the entire volume which it occupies. However, there is a possibility also of another type of structure formation, where the initial macromolecule contains in each unit a group capable of combining, as a result of the reaction, with one end of another macromolecule. A branched polymer, also occupying the entire space, is then formed. The structure of such a polymer branched to the maximum extent is illustrated in Fig.8. It is in essence a regularly grafted copolymer.

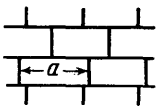

Figure 6. Schematic representation of a three-dimensional polymer.

Figure 7. Schematic representation of the possible branching.

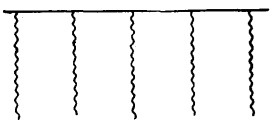

Figure 8. Schematic representation of a regularly branched polymer.

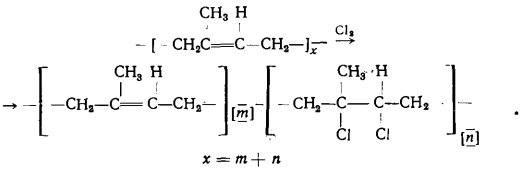
The data in Table 3 show that the structure formation reaction is used to modify different polymers as a procedure involving the conversion of linear polymers into three-dimensional structures. The cross-linked three-dimensional polymers formed are stronger, are insoluble, and exhibit a greater thermal stability than the initial linear polymer: this accounts for the wide-scale employment of this modification method, particularly in the rubber industry.

3. Polymer Modification Reactions Involving Degradation

Degradation is a process directly opposed to structure formation and is used to decrease the molecular weight of polymers. Degradation is widely used as a polymer modification method, particularly in the processing of natural polymers such as rubber and cellulose. With the aid of degradation by mechanochemical and oxidative methods, one obtains polymers with the optimum size of the macromolecules. Table 4 presents examples of certain polymer degradation reactions.



The degradation of carbochain polymers is carried out by a mechanical procedure (on rollers or other machines). In the case of cellulose oxidative degradation by atmospheric oxygen is used. In metathetical reactions in the presence of tungsten- or molybdenum-containing catalysts the carbon–carbon double bonds also become extremely labile and capable of degradative transformations[52].

The data in Table 4 show that hydrolysis, acidolysis, and aminolysis are widely used degradation reactions of heterochain polymers, which lead to the rupture of polar bonds such as ether, amide, acetal, etc. bonds.

4. Polymer Modification Reactions Involving Addition

Addition reactions are used as a procedure for the modification of polymers. When polymers contain multiple carbon–carbon bonds, halogens, oxidants, hydrogen, and other reagents can add to them. At the same time, there also exist metathetical reactions via the addition to carbon–carbon double bonds in unsaturated cyclo-olefins as well as the addition of epoxyalkanes to ester linkages.

As an example of the formation of a heterounit polymer, we may quote the rubber chlorination reaction:

$x = m + n$

An analogous process occurs in the synthesis of block copolymers from polyethers, having terminal hydroxy-groups, and di-isocyanates. In this case the addition involves the double bonds of the di-isocyanates.

Hydrolytic degradation of β-propiolactone copolymers $\ldots-CH_2-\underset{\displaystyle CH_2Cl}{\overset{\displaystyle CH_2Cl}{\overset{|}{C}}}-CH_2-OCH_2-CH_2-\overset{\displaystyle O}{\overset{\|}{C}}-(OCH_2-CH_2-\overset{\displaystyle O}{\overset{\|}{C}})_n-OCH_2-\ldots \xrightarrow{H_2O}$ $\rightarrow \ldots-CH_2-\underset{\displaystyle CH_2Cl}{\overset{\displaystyle CH_2Cl}{\overset{|}{C}}}-CH_2-OCH_2-CH_2-\overset{\displaystyle O}{\overset{\|}{C}}-OH+H[OCH_2CH_2COO]H+HOCH_2-\ldots$	96

Table 5 presents examples of different reactions involving addition to polymers. Polymers modified by the addition of halogens usually become more soluble and chemically stable. The data in Table 5 show that the addition of halogens, hydrogen, or oxygen to polymers having double bonds in the macromolecule is one of the most important modification methods. Such addition leads to heterounit polymers.

Addition of alcohol to poly(methacrylic anhydride) 	108

The modification of heterochain polyesters by the addition of epoxyalkanes to the latter, which results in the formation of polyesters containing ether linkages, is very unusual[97]. The reactions involving the formation of various complexes of cellulose, polyhydrazides, and other polymers with different metals are very interesting. The ozonisation of rubbers, leading to the formation of unstable ozonides, is widely used in the analysis of rubbers.

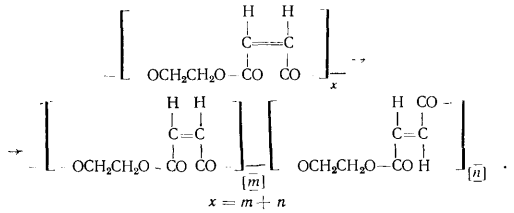
5. Polymer Modification Reactions Involving Elimination

The elimination of low-molecular-weight substances such as water, alcohols, hydrogen halides, etc. is one of the important polymer modification methods. As a result of the elimination of low-molecular-weight substances, a double or triple bond or even a heterocycle is formed in the macromolecule of the initial polymer.

All these reactions involving the elimination of low-molecular-weight substances are used to modify polymers, as shown in Table 6. According to the data in Table 6, the elimination of such low-molecular-weight substances results in the appearance of multiple bonds in the polymer chain or rings are produced.

As an example of a reaction leading to the formation of a heterounit polymer in such processes, we may quote the dehydrochlorination of poly(vinyl chloride):

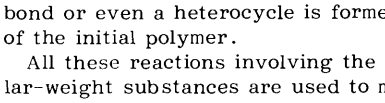


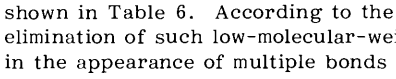
$x = m + n$

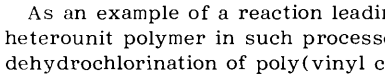
6. Polymer Modification Reactions Involving Isomerisation

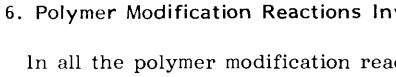
In all the polymer modification reactions considered above, the composition of the resulting product differed from that of the initial polymer. The next group of polymer modification reactions involves isomerisation reactions which, in contrast to the previous ones, proceed without a change in the elemental composition of the polymer and consist in the rearrangement of the basic skeleton of the macromolecule. Isomerisation requires a vigorous treatment, such as heating, sometimes combined with a high pressure. Table 7 presents examples of polymer isomerisation reactions.

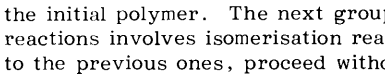
As an example of the formation of a heterounit polymer in isomerisation reactions, we shall consider a more detailed scheme for the transformation of poly(alkylene maleate) into poly(alkylene fumarate):











$x = m + n$

7. Polymer Modification Reactions Involving Exchange

All the modification methods examined previously led to the formation of polymers in which the structure of the initial polymer chain remained unaltered in most cases. In contrast to this, the next modification method, based on the use of exchange reactions between macromolecules, leads to the formation of a polymer containing the units of both initial polymers in the chain. The macromolecules of this polymer therefore constitute in essence a copolymer whose composition corresponds to that of the initial mixture of polymers. Consequently, this modification method also constitutes simultaneously an unusual copolymerisation method.

Table 8. Examples of the modification of polymers by exchange reactions between heterochain polymers.

Name and equation of exchange reaction	Refs.
Exchange reaction between heterochain polyesters 	56
Exchange reaction between heterochain polyamides 	124
Exchange reaction between heterochain polyesters and polyamides 	125
Exchange reaction between polysulphides	126
Synthesis of block copolymers by exchange reaction between heterochain polyamides	127
Formation of block copolymers by the polydisproportionation reaction (metathesis) 	128,129
Synthesis of deuterated polyesters by treating poly(ethylene sebacate) with diethyl 2,3-deuterosuccinate 	130

An important feature of this method is that heterochain polymers with fairly polar bonds between the units can be used as the starting materials for the reaction. On the other

hand, if heteroatoms are incorporated in the composition of the aromatic heterocycles, then polymers of this kind do no undergo exchange reactions[123]. It was believed previously that carbochain polymers are also unsuitable for these reactions, but it has now been established that the metathetical reaction makes it possible to carry out exchange reactions also between carbochain polymers[128,129]. Table 8 presents examples of the modification of polymers by exchange reactions between different polymers.

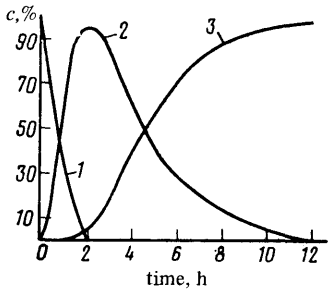


Figure 9. An exchange reaction between two polyamides. Variation of the contents (*c*) of homopolymers (curve *1*), block copolymers (curve *2*), and statistical copolymers (curve *3*).

An interesting feature of the exchange reactions is that after a time they lead to the formation of different products depending on the duration of the reaction.

Fig.9 shows which intermediates are formed in an exchange reaction between two polymers[127]. Evidently in the initial stage of the process there is a mixture of the two initial polyamides with an increasing admixture of a block copolymer. After 2 h, the final product is the block copolymer and then its content decreases and, when 12 h have elapsed, the only product becomes a statistical copolymer of the two initial diamine salts. Thus, by interrupting the process for any period at any stage, it is possible to obtain a large set of polymers of different structure and with different properties.

---o0o---

In conclusion we must consider the problem of the prospects for the development of polymer modification processes. We may note in the first place that the number of reactions used to modify polymers is increasing and that the relevant research is being presented on a rapidly widening front. Our knowledge of this field has now become much deeper and fairly clear ideas have been developed concerning the characteristics of the polymer modification processes and their specific features, due to the polymeric nature of the starting materials, have been established. The fundamental characteristics of these reactions, which determine the results of the substitution reaction, have been discovered. It has been established that the polymers obtained in modification reactions contain in their macromolecules anomalous units and are therefore of the heterounit type. A definite relation between the properties of heterounit polymers obtained by modification methods and their structure has been demonstrated.

Advances in the Chemistry of Compounds with the Cyclodisilazane Structure

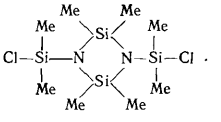
D.Ya.Zhinkin (deceased), Yu.M.Varezhkin, and M.M.Morgunova

Data on the monomeric four-membered cyclic silazane systems are surveyed and arranged systematically. The available methods for the synthesis of these compounds are examined in detail, the results of studies on the mechanism of the formation of organocyclodisilazanes are described, and the mechanisms of individual stages of this process are considered. The review includes an exhaustive bibliography on monomeric organocyclodisilazane compounds up to 1978, comprising 116 references.

CONTENTS

I. Introduction 1149
II. Fundamentals of the nomenclature and certain characteristics of organocyclodisilazane compounds 1149
III. Synthesis of organocyclodisilazanes 1150

I. INTRODUCTION



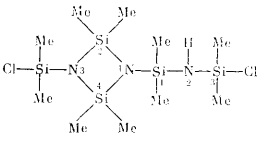
Studies in the field of organosilicon compounds containing a silicon–nitrogen bond have developed particularly vigorously in the last two decades. During this period, it has been shown that such compounds are of great theoretical interest and can be of practical importance as valuable heat-resistant materials capable of being used at high temperatures and exhibiting high thermal and chemical stabilities, great mechanical strength, and effective electrical insulating, semiconducting, and other valuable properties; in addition, they can be hardened at room temperature and exhibit an effective adhesion to various materials.

The principal trend in the development of the chemistry of compounds containing the ≡Si—Ni= bond has been until recently the synthesis of open-chain silazanes and silylamines and the study of their properties. However, nowadays cyclic compounds with the silazane structure, particularly four-membered cyclic silazane systems—cyclodisilazanes and polymers with alternating units comprising such systems—have attracted increasing attention. Studies in recent years on the properties and practical applications of four-membered cyclic silazane systems have shown that such compounds have a striking thermal stability.

Until now, there have been no reviews on monomeric four-membered cyclodisilazane systems. Isolated information about the methods of synthesis and chemical properties of these compounds can be found in a few publications[1-4]. This review surveys the published literature data on the synthesis of monomeric four-membered cyclic silazane systems.

II. FUNDAMENTALS OF THE NOMENCLATURE AND CERTAIN CHARACTERISTICS OF ORGANOCYCLODISILAZANE COMPOUNDS

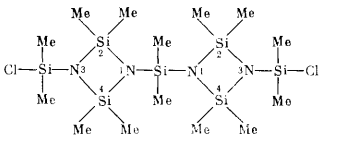
In the literature there is no clear-cut system of nomenclature for four-membered cyclic silazane systems, but the majority of authors adhere to the following methods for the naming of such substances, which can be illustrated in relation to the compound.



(1) *N,N'*-bis(chlorodimethylsilyl)tetramethylcyclodisilazane;

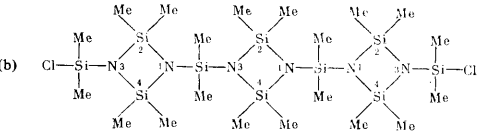
(2) 1,3-bis(dimethylchlorosilyl)-2,2,4,4-tetramethylcyclodisilazane;

(3) 1,3-bis(dimethylchlorosilyl)-2,2,4,4-tetramethyl-1,3,2,4-diazadisiletidine;



(4) 1,3-bisdimethylchlorosilyl-1,3-diaza-2,2,4,4-tetramethylcyclodisilazane.

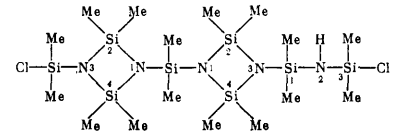
Nomenclatures (1) and (2) are most widely used. From our point of view, the second system is most convenient as regards simplicity and yields the maximum information about the structure of the compound and will in fact be used in this review. An advantage of this system is its universality and rationality. The names of compounds containing a single cyclodisilazane ring are derived from the name of this ring; for example,



is 1-(1,1,3,3-tetramethyl-3-chlorodisilazanyl)-2,2,4,4-tetramethyl-3-dimethylchlorosilylcyclodisilazane.

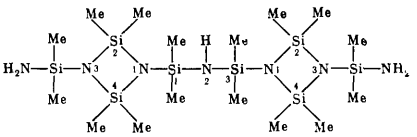
The names of cyclodisilazane oligomers containing repeating cyclodisilazane fragments are constructed on the basis of the "central symmetry" rule; for example, in case (a) the dimethylsilyl unit is central and two similar cyclodisilazane fragments are located symmetrically relative to it, so that this unit is adopted as the basis for the name:

(a) 



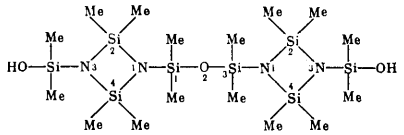
is dimethylbis(2,2,4,4-tetramethyl-3-dimethylchlorosilyl-1-cyclodisilazanyl)silane.

In case (b) the name is based on the cyclodisilazane ring, which is the centre of the oligomer molecule:



(b) 

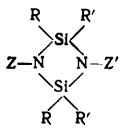
is 1,3-bis[dimethyl(2,2,4,4-tetramethyl-3-dimethylchlorosilylcyclodisilazanyl)silyl]-2,2,4,4-tetramethylcyclodisilazane.



In all the remaining cases the molecular fragment most convenient for the construction of the name is adopted as central—the dimethylsilyl unit for (c), the disilazane unit for (d), and the disiloxane unit for (e):

(c) 

is dimethyl(2,2,4,4-tetramethyl-3-dimethylchlorosilyl-1-cyclodisilazanyl)-[2,2,4,4-tetramethyl-3-(1,1,3,3-tetramethyl-3-chlorodisilazanyl)-1-cyclodisilazanyl]silane.



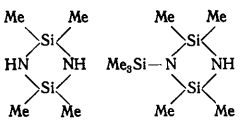
(d) 

is 1,1,3,3-tetramethyl-1,3-bis(2,2,4,4-tetramethyl-3-aminodimethylsilyl-1-cyclodisilazanyl)disilazane.

(e) 

is 1,1,3,3-tetramethyl-1,3-bis(2,2,4,4-tetramethyl-3-hydroxydimethylsilyl-1-cyclodisilazanyl)disiloxane.

All the known monomeric four-membered cyclic silazane systems can be divided into three groups:

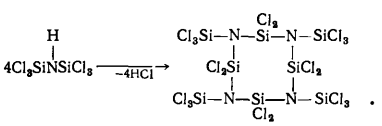


(1) Symmetrical or asymmetric 1,3-bis(organo)-substituted cyclodisilazanes (Z and Z′ are organic groups of H);

(2) symmetrical or asymmetric 1,3-bis(silyl)-substituted cyclodisilazanes (Z and Z′ $=SiR''_3$ or SiR''_nHal_{3-n}, where R″ is an organic group or H and Hal is a halogen atom);

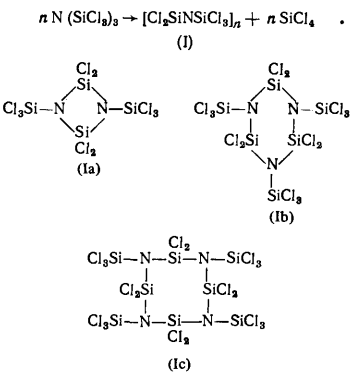
(3) asymmetric 1,3-substituted cyclodisilazanes (one of the substituents is an organic group and the other is a triorganosilyl, diorganohalogenosilyl, organodihalogenosilyl, or trihalogenosilyl group).

2,2,4,4-Tetramethylcyclodisilazane[5] and 1-trimethylsilyl-2,2,4,4-tetramethylcyclodisilazane[6] can be quoted as the simplest representatives of the series of organocyclodisilazanes containing hydrogen atoms at the endocyclic nitrogen atoms and methyl groups at the silicon atoms:



1,3-Bis(silyl)-substituted organocyclodisilazanes are thermally and hydrolytically stable; these compounds are fairly reactive via their functional groups, which makes it possible to obtain oligomeric and polymeric products based on them.

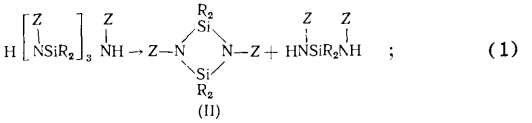
The high thermal and hydrolytic stability of 1,3-bis(silyl)-substituted organocyclodisilazanes can be accounted for by a number of factors. An increase of the electronegativity of the substituents at the nitrogen or silicon atoms (H, Me, $SiMe_3$, Ph) causes a corresponding decrease of electron density at this atom and an increase of the hydrolytic stability of the endocyclic silicon–nitrogen bond[1,7]. The p_π–d_π interaction of the exocyclic organosilyl groups with an endocyclic nitrogen atom reduces the electron density at the nitrogen atom with a simultaneous increase of electron density at the exocyclic silicon atoms, which leads to an increase of the thermal and hydrolytic stability of 1,3-bis(silyl)-substituted organocyclodisilazanes[8,9].



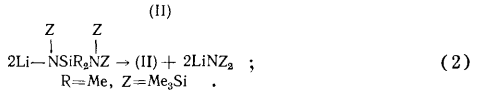
The high degree of hyperconjugation in the ring, which is characteristic of four-membered cyclic silazane systems and leads to a change in bond lengths, a deformation of angles[1,10], and a decrease of the basicity of the endocyclic nitrogen[6], determines to a significant extent the reactivity and physical properties of organocyclodisilazanes[11]. Thus, the high degree of conjugation in the 1-trimethylsilyl-2,2,4,4-tetramethylcyclodisilazane ring leads to an increase of the acidity of the protons at the nitrogen atoms and to a corresponding increase of the reactivity of this compound[6]. On the other hand, the electronic nature of the substituents at the nitrogen atom also affects the properties of the compounds. Thus the temperature range of the decomposition is 450–500 °C for cyclodisilazanes with organosilyl groups at a nitrogen atom, 400–450 °C for cyclodisilazanes with organic substituents, and 320–360 °C for hexaorganocyclotrisilazanes[11,12].

III. SYNTHESIS OF ORGANOCYCLODISILAZANES

For a long time the existence of four-membered cyclic silazane compounds with alternating silicon–nitrogen bonds gave rise to doubts. Thus in 1953 a new compound was obtained by the condensation of hexachlorodisilazane, for which the authors suggested the cyclotetrasilazane structure[13]:



Somewhat later an analogous cyclic perchlorosilazane was obtained by a different procedure[14]—the condensation of tris(trichlorosilyl)amine (isolated from the product of the pyrolysis of the $SiCl_4/N_2$ mixture), for which the authors proposed structures (Ia), (Ib), and (Ic):

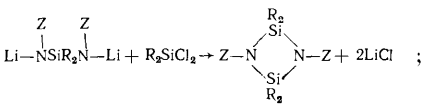


But the authors[14] gave preference to the cyclotetrasilazane structure (Ic) for their compound, having excluded the four-membered system (Ia) in view of the expected high ring strain. However, in 1958 it was demonstrated for the first time that the compound had in fact the cyclodisilazane structure[15].

1. N-Alkyl-, N-Trialkylsilyl, and N-Aryl-substituted Organocyclodisilazanes

1,3-Bis(trimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (II) was obtained by the thermolysis of long-chain or metallated silazanes[16,17] via reactions (1) and (2):

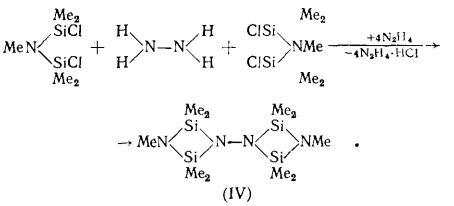
(1)



(2)

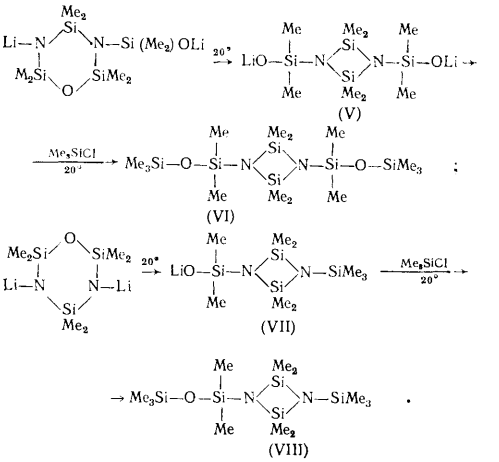
Compound (II) can also be obtained by the thermolysis of *N*-trimethylsilylated cyclotri- and cyclotetra-silazanes; compound (III, R = Z = Me), having an analogous structure, is obtained by the thermolysis of permethylated cyclosilazanes[18,19].

The structure of four-membered silazane systems was established by X-ray diffraction[10] and by specific synthesis[1].



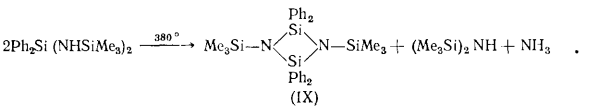
1,3-Bis(trimethylsilylated) organocyclodisilazanes can be obtained in high yields by the reaction of doubly metallated octamethyltrisilazane with organodichloro- and organotrichloro-silanes or with silicon tetrachloride[16,18]. Cyclodisilazanes (II) and (III) with methyl substituents at a nitrogen atom were obtained similarly from the doubly metallated bis(methylamino)dimethylsilane[20,21]:

(II): R = Me, Z = Me_3Si;



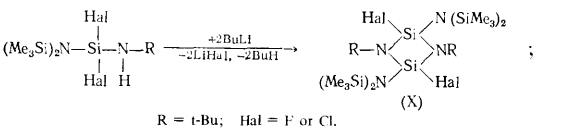
(III): R = Z = Me .

The interesting *N*-methyl-substituted biscyclodisilazane (IV) was obtained by the reaction of 1,3-dichloropentamethyldisilazane with hydrazine[22]:



(IV)

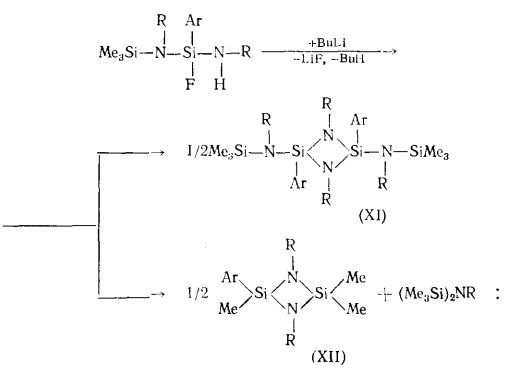
Symmetrical and asymmetric *O*-lithiocyclodisilazanes (V) and (VII) have been isolated after condensing six-membered *N*-lithio-organocyclosiloxazanes at room temperature and their subsequent treatment with trimethylchlorosilane yielded *N*-substituted organocyclodisilazanes (VI) and (VIII):[23,24]



(V), (VI), (VII), (VIII)

Organoaminosilanes containing phenyl groups linked to the silicon atom cyclise on thermal condensation to form 1,3-bis-(trimethylsilyl)phenylcyclodisilazanes. Thermal condensation of *N,N'*-bis(trimethylsilylamino)diphenylsilane leads to the formation of 1,3-bis(trimethylsilyl)-2,2,4,4-tetraphenylcyclodisilazane (IX):[25,26]

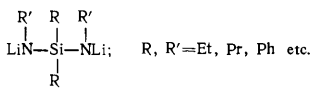
(IX)



Symmetrical organocyclodisilazanes containing fluorine or chlorine atoms or amino-groups attached to a silicon atom have been obtained[27,28]:

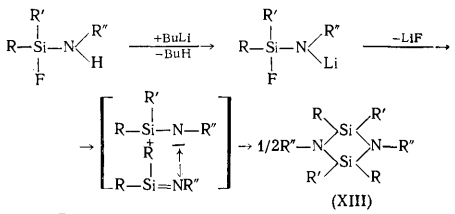
(X)

R = t-Bu; Hal = F or Cl.



This reaction proceeds fairly smoothly when alkylaminobis(trimethylsilyl)aminodifluorosilane is used but, when one fluorine atom at a silicon atom is replaced by an aryl residue and the trimethylsilyl group is replaced by the t-butyl group, the symmetric cyclodisilazane (XII) is formed instead of the symmetrical compound (XI);[27] as a result of steric hindrance, a 1,3-rearrangement of the Me anions at the silicon atoms with subsequent cyclisation takes place instead of the expected cyclodimerisation:

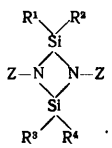
(XI), (XII)



R = t-Bu .

Other *N*-alkylated and *N*-arylated cyclodisilazanes (see Table 1 below) have been obtained analogously from dilithio-derivatives of the corresponding silylamines[29–34]:

R, R′=Et, Pr, Ph etc.



or by the reaction of aminofluorosilanes with butyl-lithium[35]:

(XIII)

R = Me or Ph; R′=Me, *s*-Bu, or Ph; R″ = iso-Pr, t-Bu, -Bu, 2, 4, 6-$Me_3C_6H_2$

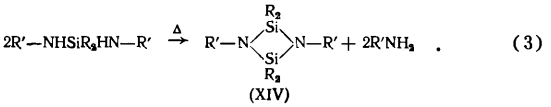
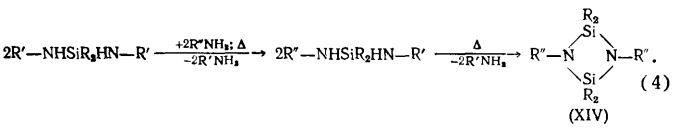
*Only the references to the main literature are given.



The mechanism of the latter reaction was demonstrated by mass spectrometry and NMR.[35]

The direct reaction of dilithio-derivatives of primary, preferentially aromatic, amines [or compounds described by the formula $R''R_2SiNSi(R_2)NSiR_2R''$] with diorganodichlorosilanes can also be used to synthesise the corresponding organocyclodisilazanes (XIV):[29,30,33,36–38]

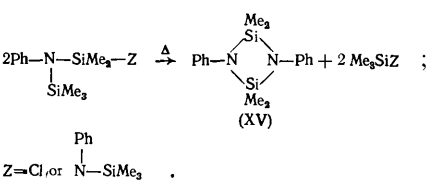
(XIV)



The pyrolysis of diaminodiorganosilanes at 200–450 °C is used particularly widely for the synthesis of *N*-alkylated and *N*-arylated cyclodisilazanes[29–31,39]:

(XIV) (3)

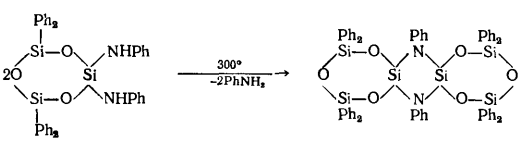
It has been suggested[40–43] that cyclodisilazanes of type (XIV) be synthesised by heating the diaminosilanes $R'-NHSiR_2HN-R'$ (R = substituted alkyl, alkenyl, cycloalkyl, aryl, arylalkyl, or alkoxy-group; R′ = organic group) or the asymmetric disilylamines $XR_2Si-NR'-SiR_2R''$ (R, R′, R″ = organic groups; X = halogen).



Reaction (3) (particularly for R′ = aryl) is as a rule used only for compounds whose decomposition temperature is much above the boiling point. If the removal of the high-boiling amine formed as a result of the reaction is difficult, the initial diaminosilane is sometimes subjected to a preliminary transamination with subsequent formation of cyclodisilazanes[29,31,32,44,45]:

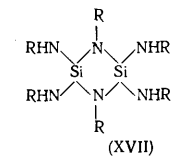
(XIV) (4)

Reaction (4) takes place only when the boiling point of $R''NH_2$ is higher than that of $R'NH_2$.



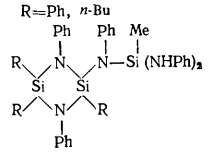
The synthesis of *N*-phenylated tetramethylcyclodisilazanes (XV) is based on the pyrolysis of *N*-phenyl-substituted di- and tri-silazanes[29] in accordance with the mechanism

(XV)



Cyclodisilazanes (XV) are also formed[46] on thermal condensation of tetra-aminosilane with dimethyldianilinosilane at 360–400 °C.

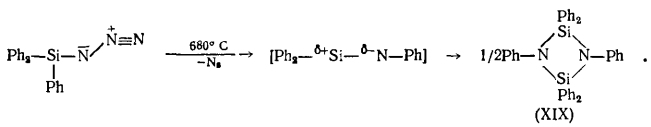
Thermal condensation of 2,2-dianilinotetraphenylcyclotrisiloxane, which takes place with the liberation of aniline only above 300 °C, led to the isolation of an *N*-phenylated four-membered silazane ring having the complex structure (XVI):[47]



(XVI)

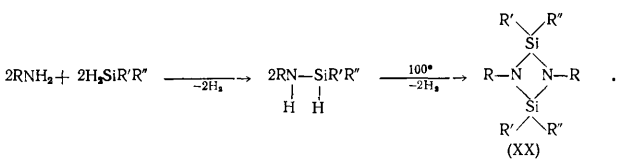
At low degrees of conversion the polycondensation of tetra(arylamino)- and tetra(alkylamino)-silanes proceeds with formation of the corresponding *N*-substituted cyclodisilazanes (XVII).[48] Asymmetric *N*-phenylated cyclodisilazanes (XVIII) have been obtained by the pyrolysis of methyltris(anilino)silane at 400 °C:[49]

(XVII)



R=Ph, *n*-Bu

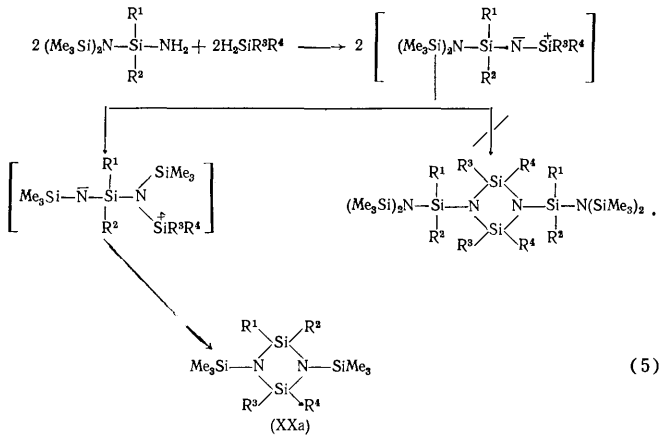
(XVIII)



R = Me or NHPh

Hexaphenylcyclodisilazane (XIX) is formed in the pyrolysis of triphenylsilyl azide at 680 °C:[50]

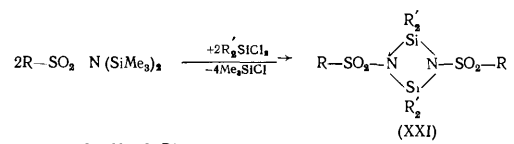
(XIX)



Organocyclodisilazanes can be synthesised by silylating primary aliphatic and aromatic amines or organosilylamines by diorganosilanes in the presence of alkali metals or their hydrides[51–58]:

(XX)

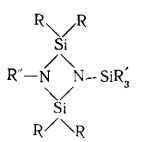
This results in the formation of the cyclodisilazanes (XX), where R′ and R″ are unsubstituted or substituted alkyl, alkenyl, cycloalkyl, arylalkyl, aryl, or polymethylene chains, while R is a lower alkyl, phenyl, benzyl, tolyl, xylyl, quinolinyl, etc. This reaction, which proceeds at a higher rate and with a quantitative field of organocyclodisilazanes, can be carried out in both polar (tetrahydrofuran, 1,2-dimethoxyethane, diethyl ether) and non-polar (benzene and hexane) solvents or altogether without a solvent.



Compound (XXa) with different organic groups at the silicon atom in the ring and with trimethylsilyl groups at the nitrogen atoms can be obtained by reaction (5) via an unstable intermediate. It has been shown[51] that the intermediate does not dimerise but rearranges with migration of the trimethylsilyl group and subsequent formation of the cyclodisilazane:

(XXa) (5)

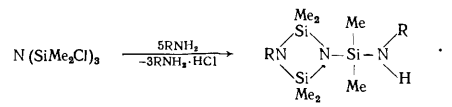
Organocyclodisilazanes containing halogen atoms or amino-groups in the substituent linked to a nitrogen atom can be obtained by heating the organodisilazanes $X_{3-n}R_nSi-NZ-SiR_nX_{3-n}$ (R is an organic substituent, X a halogen, $n = 0–3$, and Z is a halogenoaryl, halogenoalkylaryl, alkylaminoaryl, cyclohexylamino-, or phenylamino-group) in the absence of oxygen[59–61].



Disilylated sulphamide reacts with the dimethyl- or diphenyl-dichlorosilane to form the corresponding cyclodisilazanes (XXI):[62]

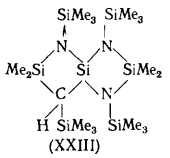
(XXI)

R=OC_4H_8N or Me_2N; R′= Me or Ph.



Asymmetric organocyclodisilazanes (XXII) with one triorganosilyl group (R and R′ are different or identical alkyl substituents containing between one and five carbon atoms or aryl, vinyl, and allyl groups; R″ = H, Me, Et, or Pr) have been obtained by the reaction of ammonia or amines R″ – NH_2 with tris(organosilyl)amines $(XR_2Si)_2NSiR'_3$, where X = H, Cl, Br, or I, in an inert solvent at 18–20 °C:[63–65]

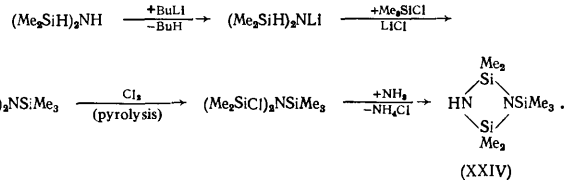
(XXII)



Analogous *N*-alkyl-, *N*-aryl-, or *N′*-triorganosilyl-cyclodisilazanes have been synthesised by the reaction of an asymmetric trisilylamine, for example, bis(chlorodimethylsilyl)(trimethylsilyl)amine or bis(chlorodimethylsilyl)(dimethylphenylsilyl)-amine with primary amines at low temperatures (between –20° and –60 °C).[66–67] The reaction of tris(dimethylchlorosilyl)-amine with primary amines at room temperature yielded asymmetric organocyclodisilazanes containing an amino-group in one of the substituents linked to an endocyclic nitrogen

atom[68]:

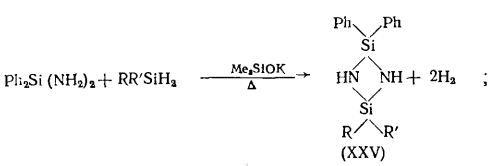
R = Me, Ef, or *iso*-Pr



The cyclodisilazane (XXIII), asymmetric relative to the endocyclic silicon atoms and containing a cyclic system as a substituent at one of them, has been obtained by the interaction of $SiCl_4$ with $NaN(SiMe_3)_2$ at 200 °C:[69]

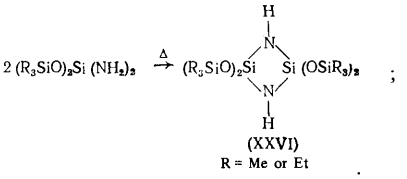
(XXIII)

Its structure was established by ^{1}H NMR [69] and X-ray diffraction[70].



As already mentioned above, *N*-substituted (particularly *N*-triorganosilylsubstituted) organocyclodisilazanes are stable. However, since the cyclodisilazane ring is a highly strained system, the replacement of one of the substituents at a nitrogen atom by hydrogen leads to chemically fairly reactive compounds[6,71], for example, the cyclodisilazane (XXIV):

(XXIV)

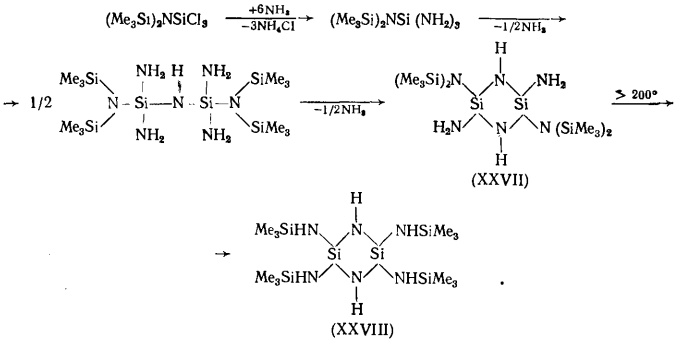


In the spectra of these compounds there is an anomalous distribution of the absorption bands associated with stretching vibrations. Thus in the spectrum of compound (XXIV) the "upper" band due to the NH bond is displaced to 3510 cm^{-1}, which indicates an increased acidity of the proton at the nitrogen atom, and the corresponding shift of the "lower" band to 1000 cm^{-1}. The absorption band of the $\equiv Si-N-Si\equiv$ group, corresponding to anti-symmetric stretching vibrations, which probably also characterises the cyclodisilazane ring[21], is located[6] in the region of 870 cm^{-1}.

Andrianov and coworkers obtained organocyclodisilazanes containing hydrogen at both endocyclic nitrogen atoms by heating diphenyldiaminosilane with diphenylsilane or methylphenylsilane in molar proportions of 1 : 1 in the presence of potassium trimethylsilanoxide[72,73] or by prolonged heating of bis(triorganosiloxy)diaminosilanes[74,75] (at 212–304 °C for R = Me and 280–340 °C for R = Et):

(XXV)

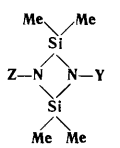
R=R′=Ph; R=Me, R¹=Ph .



(XXVI)

R = Me or Et

Compounds (XXVI) having an analogous structure were isolated in the ammonolysis of the corresponding bis(triorganosiloxy)dichlorosilanes at elevated temperatures (55 °C for R = Me and 75 °C for R = Et).[75]



The ammonolysis of hexamethyldisilylaminotrichlorosilane with gaseous ammonia in benzene leads to the formation of products with the cyclodisilazane structure, which contain hydrogen at the endocyclic nitrogen atoms and amino-groups at the silicon atoms[25]:

(XXVII)

(XXVIII)

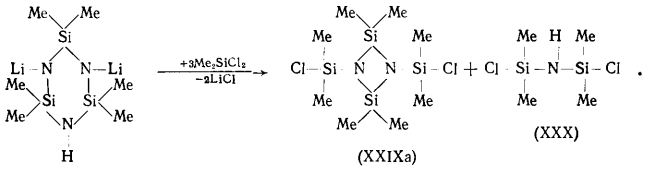
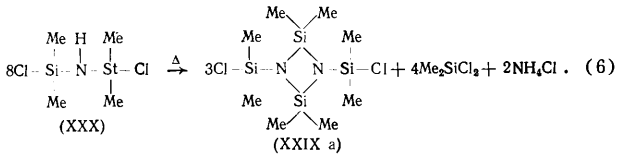
The properties of symmetrical organocyclodisilazanes are listed in Table 1 and those of the asymmetric compounds are in Table 2.



2. α,ω-Bis(diorganohalogenosilyl)-Substituted Cyclodisilazanes

Reports[2,76–93] of the synthesis of α,ω-bis(dimethylchlorosilyl)-substituted monomeric and oligomeric cyclodisilazane (XXIX, a–f) with chlorodimethylsilyl groups at a nitrogen atom, which can be used for the synthesis of linear polymers with cyclodisilazane chain units, are appearing at an increasing frequency at the present time; in compounds (XXIX, a–f) *m* varies from 1 to 6 respectively.



(XXIX, a–f)

When doubly or triply metallated hexamethylcyclotrisilazane (or octamethylcyclotetrasilazane) is treated with an excess of dimethyldichlorosilane, the corresponding dimethyldichlorosilyl derivative is not formed; the reaction yielded 1,3-dichlorotetramethyldisilazane (XXX) and 1,3-bis(dimethylchlorosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXIXa).[77,79] The readily crystallisable compound (XXIXa) can be isolated in a yield of 75% or higher:

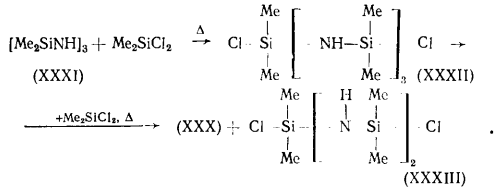
(XXIXa) (XXX)

1,3-Dichlorotetramethyldisilazane (XXX) can also be converted into compound (XXIXa) by prolonged refluxing. The temperature of the reaction mass then increases from 143 °C [the boiling point of compound (XXX)] to 235 °C [the boiling point of compound (XXIXa)]. According to the authors' hypothesis[79], the reaction proceeds via the formation of 1,5-dichlorohexamethyltrisilazane. The yield of the cyclodisilazane (XXIXa) is 70–75% of theoretical:

(XXX) (XXIX a)

(6)

In the presence of a tertiary amine, for example, triethylamine, compound (XXX) is also converted into compound (XXIXa):[79]



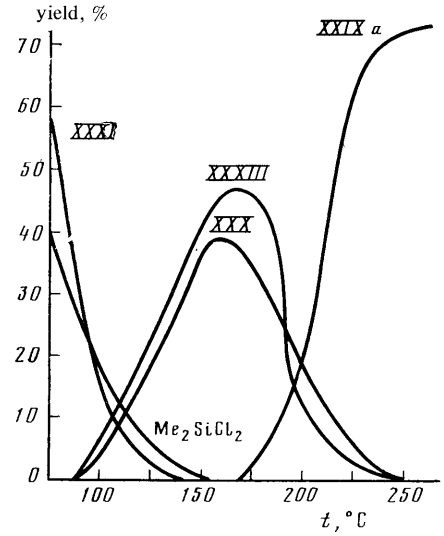
(7)

The optimum yield of compound (XXIXa) is obtained when the reaction is carried out under a low pressure at a temperature somewhat above 150 °C. Partly and fully phenylated substituted 1,3-dichlorotetraorganodisilazanes can be converted into the corresponding organocyclodisilazanes[79]. 1-Chloropentaorganodisilazane can be converted into 1,3-bis(triorganosilyl)-substituted cyclodisilazanes[79].

Hexamethylcyclotri- and octamethylcyclotetra-silazanes are cleaved by dimethyldichlorosilane with formation of compound (XXX) in 70–80% yield[2,78,86,94–97]:

The cleavage of hexamethylcyclotrisilazane (XXXI) by dimethyldichlorosilane has been investigated by quantitative gas chromatography[84,98]. It was established that hexamethylcyclotrisilazane (XXXI) is initially cleaved by dimethyldichlorosilane at a temperature below 100 °C with formation of 1,7-dichloro-octamethyltetrasilazane (XXXII); the latter reacts further with dimethyldichlorosilane to form 1,3-dichlorotetramethyldisilazane (XXX) and 1,5-dichlorohexamethyltrisilazane (XXXIII):

(XXXI) (XXXII) (XXXIII)



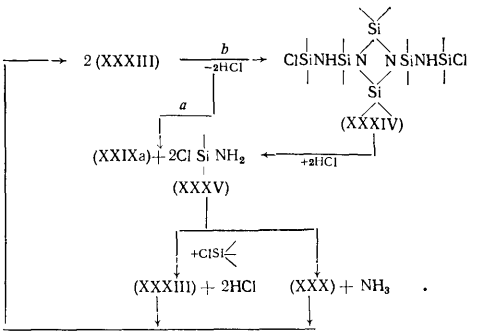


Figure 1. The interaction of hexamethylcyclotrisilazane with dimethyldichlorosilane (in proportions of 1 : 2); the yield with respect to silicon is indicated.

The content of compounds (XXX) and (XXXIII) in the mixture increases up to 160–170 °C, while at a higher temperature it falls and the formation of compound (XXIXa) begins at the same time (Fig.1).[79]

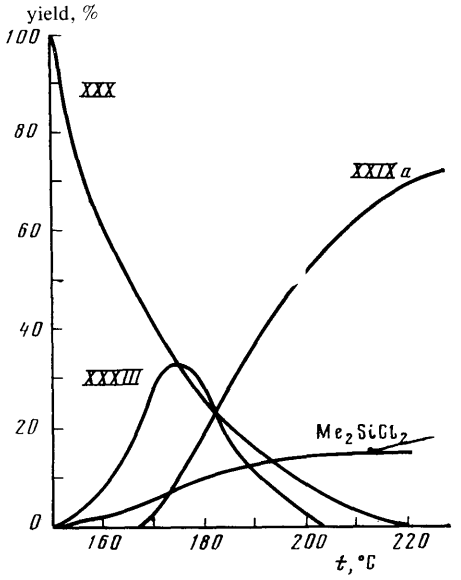
In a study of the pyrolysis of compound (XXX) it was found that dimethyldichlorosilane is evolved in the range 150–170 °C and compound (XXXIII) is formed (Fig.2). Compound (XXIXa) is not formed under these conditions, but even at 170–180 °C the content of compound (XXXIII) in the mixture diminishes and compound (XXIXa) appears[79].

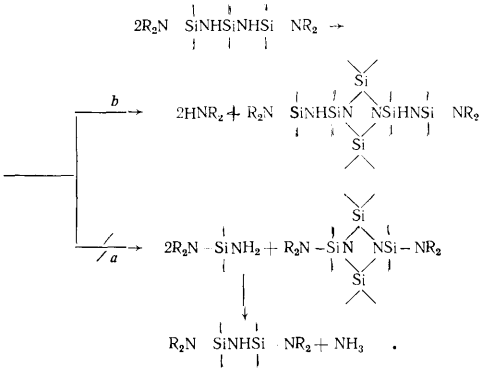
Compound (XXIXa) can be formed from compound (XXXIII) via two pathways: (*a*) via intermolecular migration of hydrogen; (*b*) via the elimination of hydrogen chloride with formation of the intermediate (XXXIV), which subsequently

interacts with hydrogen chloride:

(8)

In both cases the same desired product is obtained. The unstable compound (XXXV), formed via both reaction *a* and *b*, can evolve ammonia to form compound (XXX) or can react with dimethyldichlorosilane to form compound (XXXIII) and then compound (XXIXa).[79]





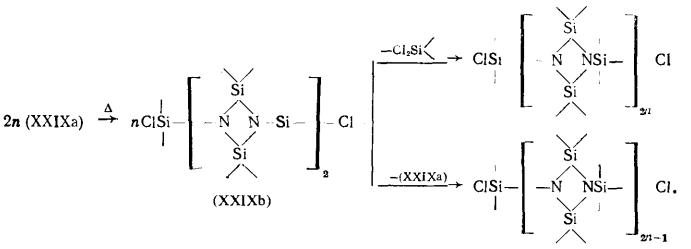


Figure 2. The pyrolysis of 1,3-dichlorotetramethyldisilazane; the yield with respect to silicon is indicated.

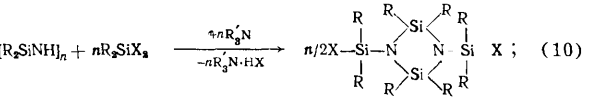
The probability of mechanism *b* is confirmed by the results of the pyrolysis of 1,5-bis(diethylamino)hexamethyltrisilazane [Eqn.(9)]. Diethylamine is then formed in amounts corresponding to the formation of hydrogen chloride by reaction (8) (mechanism *b*); ammonia, which can be formed via mechanism *a*, is not evolved[79]:



(9)

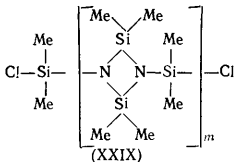
The final stage of the interaction of hexamethylcyclotrisilazane (XXXI) with dimethyldichlorosilane is the condensation of compound (XXIXa) to (XXIXb) [at the boiling point of compound (XXIXa)] and the subsequent formation of the oligomers (XXIXc)–(XXIXf) takes place fairly slowly at temperatures of the order of 300 °C with evolution of dimethyldichlorosilane and the possible elimination of compound (XXIXa):[79]

The author[79] notes that the mechanism of the formation of compound (XXIXa) and oligomers with a small number of cyclodisilazane units [compounds (XXIXb)–(XXIXf)] is not yet entirely clear.

Since compound (XXX) reacts subsequently with formation of compound (XXIXa), the simplest and most rational method for the synthesis of the cyclodisilazane (XXIXa) is direct interaction of six- and eight-membered methylcyclosilane respectively[2,76,78,79,86,87,93,97,99–101]. This reaction can be carried out between cyclic silazanes having substituents at a nitrogen atom and dimethyldichlorosilane[79,84,98], between cyclic silazanes $(R_2SiNH)_n$ and dihalogenodiorganosilanes R_2SiX_2, where R = hydrogen, fluorine, or a substituted or unsubstituted hydrocarbon, heterocyclic, or triorganosilyl group, while X = chlorine, bromine, or iodine[81,83,86], and also in the presence of the corresponding amount of a tertiary amine under an excess pressure[82], whereupon there is a sharp reduction of the reaction time, an increase of the yield of the desired product, and some decrease of the reaction temperature:

(10)

n = 3 or 4.



A study of the reaction of 1,3-dichlorotetramethyldisilazane (XXX) with a tertiary amine [Eqn.(7)] or of the interaction

of hexamethylcyclotrisilazane (XXXI) with dimethyldichlorosilane in an excess of a tertiary amine [Eqn.(10)] showed that even at elevated temperatures they are not fully converted into compound (XXIXa).[79] It was established that the optimum yields (89%) are reached when the reaction is carried out in the temperature range 170–190 °C.[79] At higher temperatures the yield of compound (XXIXa) decreases appreciably, since the rate of the reverse reaction increases and the equilibrium shifts towards the initial compound. On the other hand, when the reaction is carried out under an excess pressure (23–28 atm), the yield of compound (XXIXa) increases to 93–97%.[83]

If the reaction between hexamethylcyclotrisilazane (XXXI) and dimethyldichlorosilane is carried out in the absence of a tertiary amine, the maximum yield of compound (XXIXa) is reached for the ratio (XXXI) : dimethyldichlorosilane = 1 : 3 and the amount of oligomers formed is minimal.

On decrease of the amount of dimethyldichlorosilane by 1–2 moles, the yield of compound (XXIXa) falls and increasing amounts of α,ω-bis(dimethylchlorosilyl)-substituted cyclodisilazane oligomers are formed. For example, when compound (XXXI) is heated with dimethyldichlorosilane in proportions of 1 : 3 at 175 °C for 48–77 h, compound (XXIXa) is formed in 60–85% yield[76,85,87]; when the proportions are 1 : 2 (the reaction temperature increases), the yield of compound (XXIXa) falls somewhat and compound (XXIXb) [2,76–79,81–87]—the first member of the series of α,ω-bis(dimethylchlorosilyl)-substituted oligomeric cyclodisilazanes—is isolated on repeated fractionation from the oily material remaining after the removal of ammonium chloride and compound (XXIXa) (Table 3).

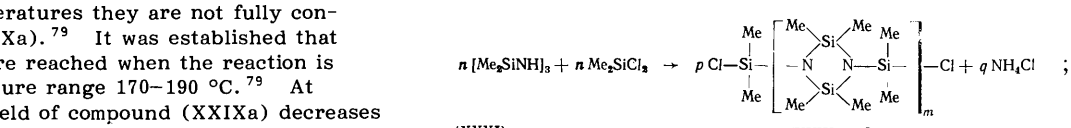


Table 3. The properties of α,ω-bis(dimethylchlorosilyl)-substituted cyclodisilazanes (XXIX) [79]

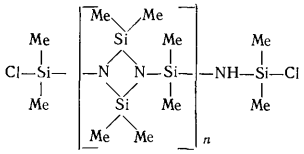
(XXIX)

Compound	*m*	B.p., °C/mmHg	M.p., °C
(XXIXa)	1	64/0.08	68–69
(XXIXb)	2	118/0.05	43.5
(XXIXc)	3	186/0.01	109–110
(XXIXd)	4	248/0.01	93
(XXIXe)	5	287/0.005	149–152
(XXIXf)	6	315/0.005	147

When a mixture of hexamethylcyclotrisilazane (XXXI) and dimethyldichlorosilane in proportions of 1 : 1 is heated, its temperature rapidly reaches 280 °C and then increases slowly to 330–340 °C. The resulting reaction mixture contains only 10–15% of compound (XXIXa) and 75–85% of oligomeric cyclodisilazanes in terms of the silicon introduced into the reaction; the oligomers (XXIXb)–(XXIXf) can be isolated in a pure form from this mixture[79]. It is of interest that the melting points or softening temperatures of the oligomers with an odd number of cyclodisilazane units in the chain are significantly higher than the corresponding temperatures of the compounds with an even number of units (Table 3):

(XXXI) $m = 1–6$.



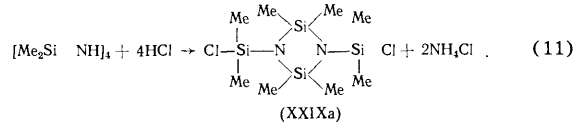
(XXIX, a–f)

The yield of oligomers (XXIX, b–f) depends on the reaction time and temperature (Table 4).[79] The isolation of individual compounds from the mixture by repeated fractionation is difficult.

Table 4. Dependence of the yield of oligomeric α,ω-bis-(dimethylchlorosilyl)-substituted cyclodisilazanes on temperature[79] .

Reaction time, h	Final temp., °C	Amount of NH_4Cl, g	Yield, %					
			(XXIXa)	(XXIXb)	(XXIXc)	(XXIXd)	(XXIXe)	(XXIXf)
6	285	32.8	32.5	35.3	10.8	12.6	5.7	1.5
11	292	36.9	29.0	34.5	12.7	12.4	7.3	2.1
18	314	39.3	16.2	29.4	17.0	14.3	12.7	6.5
45	334	42.5	10.9	18.3	17.8	16.1	13.3	8.5

Table 5. The properties of the cyclodisilazanes (XXXVI) [79]

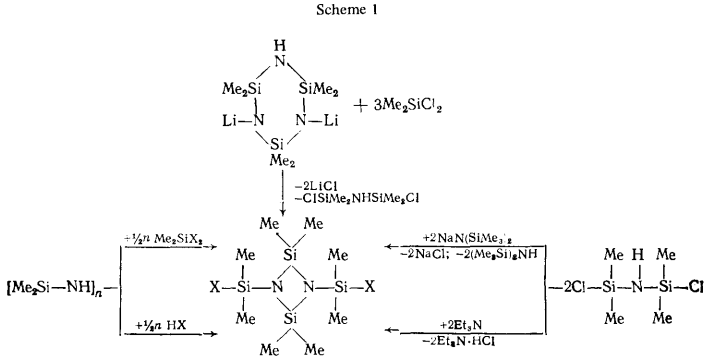


(XXXVI)

Compound	*n*	B.p., °C/mmHg	M.p., °C	n_D^{20}
(XXXVIa)	1	93/0.04	–	1.4598
(XXXVIb)	2	144/0.01	46	–
(XXXVIc)	3	209/0.005	–	–

Apart from compounds (XXIX, a–f), the oligomers (XXVI), containing NH groups in the side chain, are formed as side (or intermediate) products whatever the ratio of the initial reactants. The content of compounds of type (XXXVI) in the reaction mixture depends on the ratio of the initial reactants and on the reaction temperature; although these compounds are in most cases present only in insignificant amounts, they hinder to a large extent the isolation and purification of individual compounds of type (XXIX, a–f). If the reaction terminates at 200–240 °C, the main products are compounds of type (XXIXa) and (XXXVI).[79] Compound (XXXVIa) is formed in an amount of ~12% at a reaction temperature below 170 °C. The oligomers (XXXVI, a–c) are colourless compounds, which are very sensitive to moisture. The physical constants of compounds (XXXVI) are listed in Table 5.

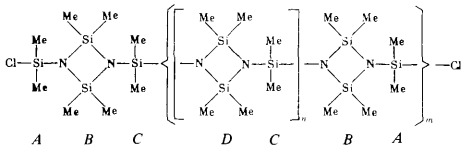
One of the ways of obtaining compound (XXIXa) involves the interaction of hexamethylcyclotrisilazane or octamethylcyclotetrasilazane with hydrogen chloride[2,86,95,96,99,102]:



(XXIXa)

Compound (XXIXa) is also obtained in a high yield (70%) by the interaction of compound (XXX) with sodium bis(trimethylsilyl)amide in petroleum ether[78].

Other *N,N'*bis(dimethylhalogenosilyl)-substituted cyclodisilazanes—1,3-bis(dimethylbromosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXXVII) and 1,3-bis(dimethyliodosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXXVIII)—are obtained analogously by reactions of types (6) and (11).[86,96,102]
The methods for the synthesis of 1,3-bis(dimethylhalogenosilyl)-2,2,4,4-tetramethylcyclodisilazanes can be represented by Scheme 1 below:



Scheme 1

n=3 or 4; X=Cl, Br, or I.

Tables 6 and 7. For compounds (XXXVII) and (XXXVIII), the spectra were recorded in 5% solution in cyclohexane[86]. For compound (XXXVII), the chemical shifts of the signals due to the protons in the exocyclic fragment XMe_2SiN and the cyclic fragment Me_2SiN_2 are respectively 9.41 and 9.57 p.p.m.; for compound (XXXVIII), $\tau = 9.32$ and 9.57 p.p.m. respectively. The study of the infrared spectra of α,ω-bis(dimethylhalogenosilyl)-substituted cyclodisilazanes showed that the absorption bands characteristic of the stretching vibrations of the cyclodisilazane fragment are in the ranges 880–890 and 1010–1040 cm^{-1}.[76,86,87,103,104] Table 8 presents the ν_1–ν_6 stretching vibrations characteristic of the Si_4N_2 fragment[86].

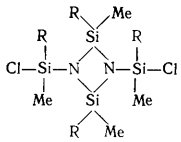
The characteristics of the mass-spectrometric fragmentation of cyclodisilazanes have been found[105] and used to determine the structure of the hydrolysis products—derivatives of compound (XXIXa).



Organocyclodisilazanes (XXXIX)–(XLII) (Table 9) with different organic groups can be obtained either by reactions (6) and (11) or by the reaction of 1,3-dichloro-1,1,3,3-tetraorganodisilazane with butyl-lithium:

R=Me, R′=$CF_3CH_2CH_2$, Ph, CH_2=CH, or Et.

Cooling is used in the treatment with butyl-lithium, while the condensation stage is carried out at elevated temperatures[100]. The principal conditions of the synthesis and the yields of organocyclodisilazanes (XXXIX)–(XLII) are presented in Table 10.

Table 9. The structure, properties, and infrared and ^1H NMR spectroscopic data for the organocyclodisilazanes (XXXIX)–(XLII) [100]

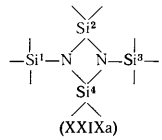
(XLII)	180	10	34			

Treatment of 1,3-bis(dimethylchlorosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXIXa) with diphenyldichlorosilane using different proportions of the initial reactants makes it possible to replace one, two, three, or all the dimethylsilyl groups, whereupon the dimethylchlorosilyl (exocyclic) and dimethylsilyl (endocyclic) groups are substituted almost equally readily by the diphenylchlorosilyl and diphenylsilyl groups respectively. It is noteworthy that the complete substitution of the dimethylsilyl groups requires comparatively high temperatures (~400 °C).[26] The compounds isolated as a result of these reactions are listed in Table 11.



Trans-silylation of compound (XXIXa) with diphenyldichlorosilane (1 : 1 ratio) yields two isomers (XLIIIa) and (XLIIIb) (with endocyclic and exocyclic diphenylsilyl groups) in proportions of 1 : 1 and with an overall yield of 80%.

Table 11. Organocyclodisilazanes obtained by the trans-silylation of 1,3-bis(dimethylchlorosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXIXa) with diphenyldichlorosilane or phenyltrichlorosilane[26]

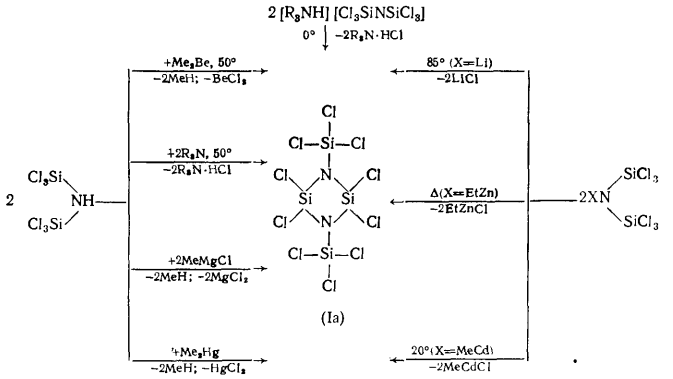
Si^4	9.45	9.77	9.83	9.92	9.78	—

When 2 moles of diphenyldichlorosilane per mole of compound (XXIXa) are used, there is a possibility of three isomeric products (XLIV)[(XLIVa) involving the substitution of one exocyclic and one endocyclic group, (XLIVb) involving the substitution of both exocyclic groups, and (XLIVc) involving the substitution of both endocyclic groups], but only two isomers, namely (XLIVa) and (XLIVb), were isolated. The high and approximately equal yields of the two isomers (86% overall) suggest that the third isomer is either not formed or is formed in a very small amount.

When the ratio of the initial components is 1 : 3, two isomers (XLV), having the same boiling point, are obtained. Isomers (XLVa) and (XLVb) are isolated by recrystallisation from petroleum ether.

Trans-silylation of compound (XXIXa) by treatment with 4 moles of diphenyldichlorosilane takes place very slowly (particularly the last stage). Compound (XLVI) is recrystallised from n-octane or from a mixture of hexane and benzene.



^{1}H NMR data (obtained in $CDCl_3$), confirming the structure of the isomers (XLIII)–(XLVI) obtained, are presented in Table 12.[26]

Other chlorosilanes behave similarly to diphenyldichlorosilanes; for example, phenyltrichlorosilane reacts with formation of compounds (XLVII)–(XLIX) [26] (Table 11).

As already stated, perchlorocyclodisilazanes were obtained as early as 1957 by the pyrolysis of a mixture of $SiCl_4$ and N_2,[14,15] but this synthesis was very complex and the yield of the desired product was extremely low. A new method of synthesis of 1,3-bis(trichlorosilyl)-2,2,4,4-tetrachlorocyclodisilazane (Ia) was proposed in 1967. It involves the interaction of hexachlorodisilazane with methyl-lithium in diethyl ether or with butyl-lithium in petroleum ether; the reaction takes place with cooling to −78 °C and subsequent condensation at 85 °C.[106]

A new more novel method of synthesis of compound (Ia), from lithium bis(trichlorosilyl)amide in the presence of $SiCl_4$, $SiBr_4$, $SiICl_3$, or $GeCl_4$ at 20 °C or by the condensation of tris(trichlorosilyl)amine at 50 °C, was proposed later[107].

The remaining methods of synthesis of perchlorocyclodisilazanes[107–110] are largely preparative and involve the use of organometallic derivatives. A clear idea about the syntheses of compound (Ia) is provided by the following scheme:

Numerous new studies of the formation of organocyclodisilazanes are being published nowadays, the attention of investigators being attracted to an increasing extent by the structure of these compounds, their reactivity, physical properties, and methods of analysis. The data obtained lead to the possibility of a wider practical employment of different types of organocyclodisilazanes, which can find the same applications in many branches of industry as siloxanes and it may be that they will be actually more effective.

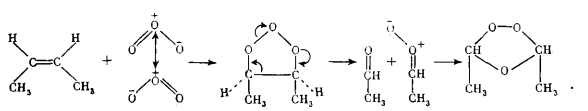
Kinetics and Mechanism of the Reaction of Ozone with Double Bonds

S.D.Razumovskii and G.E.Zaikov



Analysis of the results of recent studies has shown that the reaction of ozone with the double bonds of organic compounds apparently takes place not by a synchronous addition mechanism but through a reversible stage involving the formation of an intermediate complex of ozone with the double bond. The subsequent stages of the reaction involve the formation of a primary ozonide, its decomposition into two fragments, their combination, and a number of other transformations. The properties of the intermediate products, the relationship between the structure of the original alkenes and their reactivity towards ozone, the influence of the nature of the solvent on the direction and rate of the reaction, and the practical application of the reaction of ozone with double bonds in research and chemical technology have been examined. The bibliography contains 205 references.

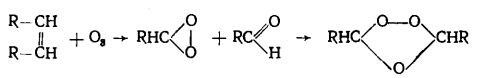
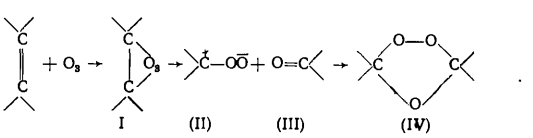
I. INTRODUCTION

The reaction of the double bond with ozone is one of the most specific reactions of unsaturated organic compounds. It is widely used in preparative synthesis, qualitative and quantitative analysis[1], and chemical technology[2,3]. At the start of the present century, this reaction was used to establish the structure of macromolecular compounds[4], and it is still often used to study the positions of C=C bonds in macromolecules[5,6]. A few years ago, it seemed that the mechanism of the reaction of ozone with a double bond had been fairly well established[2,3,7]. In monographs and reviews, this reaction is dealt with as a classical example of synchronous 1,3-dipolar addition[8-11]:



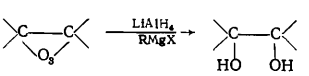
Recent studies have shown, however, that the reaction does not take place synchronously, but involves the reversible formation of an intermediate complex, which has been identified by kinetic and spectroscopic methods. The term 1,3-dipolar addition, introduced by Huisgen[8], is inappropriate when applied to ozone. Huisgen[8] assigned to ozone the structure $\overset{+}{O}-O=\overset{-}{O}$, which does not correspond to present-day views of the electronic structure of the ozone molecule[12-14]. Since in the ozone molecule the dipole moment vector is directed from the central oxygen atom to the terminal atoms  , there should be 1,2- and not 1,3-dipolar addition. However, the fact that most alkenes have zero dipole moment, the low value of the dipole moment of ozone (0.53 *D*), the insensitivity of the reaction to polar factors[15], and even, on the contrary, the decrease in the reaction rate with change in the electronegativity of one of the atoms at the double bond[16], indicate that the term "dipolar addition" does not correspond to the character of the reaction being considered.



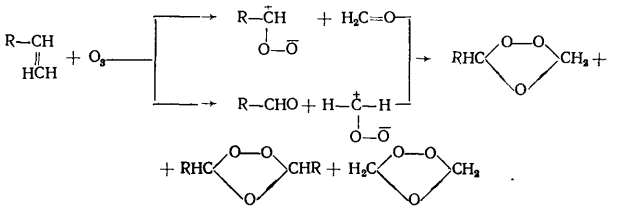
II. MECHANISM OF THE REACTION OF OZONE WITH DOUBLE BONDS

1. Development of Views of the Reaction Mechanism

At an early stage in the studies, Harries[17], Staudinger[18], and Rieche[19] suggested that the reaction involves the formation of a cyclic peroxide

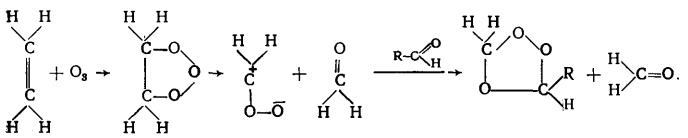


Later, Criegee[20,21] proposed a scheme showing better agreement with known facts about the reaction mechanism:

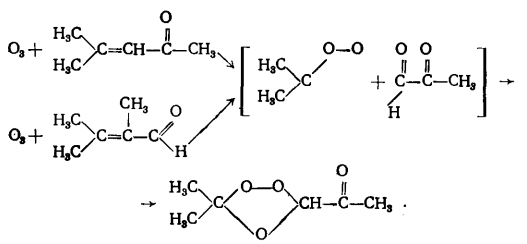


I (II) (III) (IV)

In this scheme, the primary product of the reaction is the so-called molozonide (I), which is unstable at ordinary temperatures and decomposes rapidly to the "zwitterion" (II) and a carbonyl compound (aldehyde or ketone (III)). These intermediate compounds can combine again (after preliminary rotation through 180°) and form a normal ozonide ("iso-ozonide" (IV)). By carrying out the reaction at low temperatures, it is possible to decrease the reaction rate at the molozonide stage, and to observe its transformation into other products[22], for example its reduction to the glycol[23]:

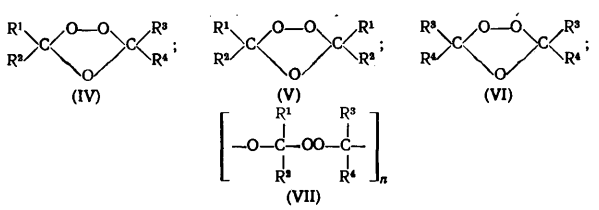


The conjugated formation of the zwitterion–carbonyl compound pair follows from many characteristic features of the reaction. In particular, it is known that the action of ozone



on unsymmetrical alkenes gives the crossed ozonides[24]:

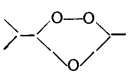
When introduced into a system in which an alkene and ozone are reacting, an aldehyde enters the molecule of the ozonide formed; simultaneously, a carbonyl-containing compound, which is a fragment of the intermediate molozonide, is detected in the system[25]:

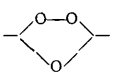


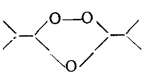
A very elegant confirmation of Criegee's mechanism is provided by the formation of a single final ozonide by the reaction of ozone with two different original alkenes—mesityl oxide and 2,3-dimethylcrotonaldehyde[26]:

Other schemes[24,27] have been proposed in addition to Criegee's scheme, but they have not been adequately confirmed[28,29].

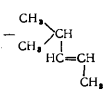
2. Reaction Products

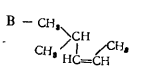






The products of the reaction of ozone with alkenes in solution (in an inert solvent) usually consist of a mixture of the normal ozonide (IV), the crossed ozonides (V) and (VI), and the polymeric ozonides (VII):

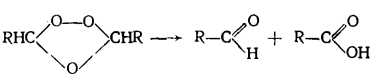




which in accordance with accepted nomenclature can be called 1,2,4-trioxolanes. The reaction mixture contains small quantities of alcohols[30], aldehydes and ketones[31], acids[32], and frequently alkenes oxides[33–36], the concentration of which may be high (up to 90%) in some cases.

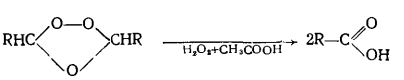
Gas chromatography has established the existence of the *cis*- and *trans*-isomers of the normal and crossed ozonides[37,38], which are fairly effectively separated on polyester phases (Table 1) and give different absorption bands in the infrared and PMR spectra[39]. The ratio of the *cis*- and *trans*-isomers in the reaction products is fairly sensitive to the nature of the solvent, the original concentration of the alkene, and the temperature of the experiment.

Table 1. Composition of ozonides, %, from gas–liquid chromatography[24].



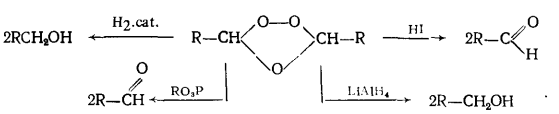
Ozonide	Formula	A	B
Normal			
cis-		32	4.2
trans-		34	4.4
Crossed			
cis-		2.3	5.19
trans-		3.7	6.1
Crossed			
cis-		5.5	12.5
trans-		5.5	6.5

Note: A—original alkene 

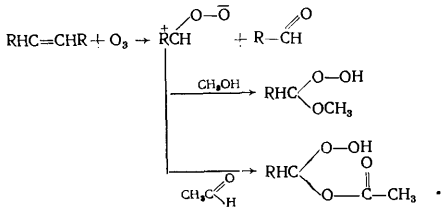


B – 

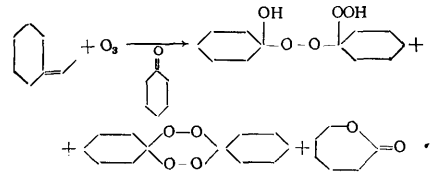
In early studies of the infrared spectra of ozonides, the maxima in the range 1705–1740 cm^{-1}, due to the absorption by the $>C=O$ group of the decomposition products, were erroneously assigned as characteristic bands of the trioxolane ring[40]. Most ozonides have characteristic absorption bands in the range 980–1100 cm^{-1}.[39,41–43].



The most typical reactions of ozonides are: thermal decomposition[44,45]

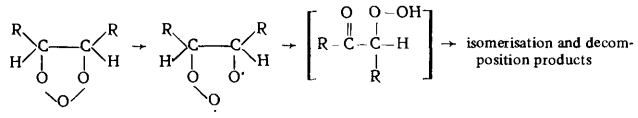


oxidation[46]

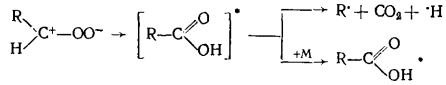


and reduction[46]

When the reaction is carried out in the presence of alcohols, acids, and various other compounds, the products are not ozonides but peroxo-compounds of different character[3,27,46]:



The composition of the peroxo-compounds obtained has not been studied in detail[52,53], but it is known that they are unstable, and capable of further reaction, for example with accompanying carbonyl compounds[54]. When the reaction was carried out in a ketone as solvent, the yield of ozonide decreased from 86.6% to 2.9%, and the chief products were peroxides and lactones[55]



3. Characteristic Features of the Reaction in the Gaseous Phase

The study of the reaction of ozone with alkenes in the gaseous phase has shown that ozonides, which are the chief products of the reaction in solution, are formed in very small quantities in the gaseous phase. The mixture containing CO, CO_2, H_2O, hydrocarbons, acids, and aldehydes, produced by the splitting of the alkene at the C=C bond and further decomposition of the fragments[56–59]. Mass spectrometry has shown that the reaction products contain compounds having mass numbers up to five original molecular units (in particular, for butenes, $M \geq 200$).[60] In the case of halogen-substituted alkenes, the formation of oxides as chief reaction products has been noted[36]. Matrix isolation techniques have shown that the products of the reaction of ozone with ethylene contain not only CO, CO_2, H_2O, CH_2O, HCOOH, CH_3OH, CH_3CHO, and also $\overline{CH_2OCH_2}$, but also the unstable formaldehyde and glyoxal[61]. The reaction is accompanied by chemiluminescence[62], so that it rapidly found practical application in apparatus for determining the concentration of ozone in samples of atmospheric air[63]. The luminescence is due to the presence of the excited species H_2CO (^1A) and OH ($X^2\Pi_i$; $v \leq 9$ and $A^2\Sigma^+$).[64,65]

In the proposed reaction schemes, the change in the composition of the products and the formation of excited intermediate species are attributed to radical processes, which begin with the homolytic rupture of the O–O bond of the molozonide[56,66–68]

or as a result of the isomerisation of the zwitterion[44]:

The stoichiometry of the alkene + ozone reaction varies from 1 : 1.4 to 1 : 2, depending on the conditions; when these prevent secondary reactions, the observed stoichiometric ratio is close to 1 : 1.

III. KINETICS OF THE REACTION OF OZONE WITH UNSATURATED COMPOUNDS

1. Gaseous Phase

The reaction of ozone with alkenes takes place readily at all temperatures studied, from −180 °C [43,69] to 300 °C.[70] Its rate is generally limited by the rate of supply of reagents to the reaction site. The elementary reaction of ozone with the double bond of an alkene obeys a bimolecular law[71], whereas the overall process may be described by more complex relationships. In particular, in the gaseous phase there is difference between the kinetics of the reaction in the presence and absence of oxygen[56,58,59,72]. Thus for example, the kinetics of the reaction of ozone with tetrafluoroethylene are described by the relationship[73]:

$$d[O_3]/d\tau = k_1[O_3][C_2F_4] + k_2[O_3]^2[C_2F_4],$$

where

$$\lg k_1 = (8.2 \pm 0.5) - (9500 \pm 700)/2.3\,RT;$$
$$\lg k_2 = (14.6 \pm 0.4) - (10100 \pm 600)/2.3\,RT$$

(k_1 and k_2 in litre mole^{-1} s^{-1} units), and the reaction of ozone with allene is described by the relationship[74]:

$$d[O_3]/d\tau = k'_1[O_3][C_3H_4] + k'_2[C_3H_4][O_3]^2/[O_3]_0,$$

where

$$\lg k'_1 = (6.0 \pm 0.7) - (5500 \pm 1000)/2.3\,RT;$$
$$\lg k'_2 = (6.9 \pm 0.7) - (6200 \pm 800)/2.3\,RT.$$

In both cases the second term takes account of the reaction of the intermediate products with ozone, responsible for its chain decomposition.

Table 2. Rate constants (10^{-3} k, litre mole^{-1} s^{-1}) for the reaction of ozone with alkenes in the gaseous phase at 25 °C.[56,57,71,74–80]

Alkene	Data from Ref.75	Data from Ref.76	Data from Refs.56,57,77–79	Alkene	Data from Refs.57,71, 77, 80
Ethylene	1.6±0.2	1.8	1.6[77]; 0.8[78]; 1.02[57]	Propene	7.1[57]
But-1-ene	6.2	3.9	—	Allene	0.09[74]
trans-But-2-ene	260±40	3	29[78]	Butadiene	4.5[57]
cis-But-2-ene	200	17	63[56]	1,1-Dichloroethylene	0.0022[71]
Isobutene	14±2	3.6	3.7[78]; 0.49[79]; 5.4[56]	1,2-Dichloroethylene	0.24[79]
2-Methylbut-2-ene	450	—	—	Tetrafluoroethylene	31[80]
Trimethylethylene	—	12	—	Hexafluoropropene	1.3[80]
Cyclopentene	—	4.6	61[77,78]	Octafluorobutene	1.6[80]
Pent-1-ene	—	3.9	3.2[77]; 4.5[78]		

Table 2 gives the rate constants for the reaction of ozone with alkenes having different structures. The data in Table 2 do not make it possible to establish a relationship between

the structure of an alkene and the rate of its reaction with ozone; moreover, the data given by different authors sometimes differ considerably (for example for *cis*- and *trans*-but-2-ene). The temperature dependence of the reaction rate has been used to find the activation energies of the process and the pre-exponential factors for a number of alkenes (Table 3). The high rate constants and low activation energies readily explain why the unsaturated components of a contaminated atmosphere are decomposed to the extent of more than 50% by atmospheric ozone, despite the fact that both the ozone and the unsaturated hydrocarbons are present in the atmosphere in small quantities[61,83]. This reaction, together with the reaction of ozone with SO_2 and NO_x, facilitates the formation of photochemical smog in large cities, and usually appears as one of the key reactions in the overall model describing the dynamics of the urban atmosphere[84,85].

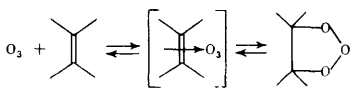


Table 3. Parameters of the Arrhenius equation for the reaction of ozone with alkenes in the gaseous phase*.

Alkene	$10^{-5}A_0$, litre mole^{-1} s^{-1}	E, kcal mole^{-1}
Ethylene	0.0016[77]; 16[75]; 54[81]; 3.2[79]	4.2±0.4[77]; 4.0±0.4[75]; 2.6[81]; 4.9[79]
Propene	0.00037[81]; 2.9[79]	1.9[81]; 3.9[79]
Butene	18	1.7
trans-But-2-ene	3.6[75]; 2.6[79]; 35	0.2±0.3[75]; 2.3[79]; 1.1
cis-But-2-ene	19	0.96
Isobutene	14[75]; 19	2.8[75]; 1.7
2,3-Dimethylbut-2-ene	17	0.82
Hex-1-ene	0.061[77]	

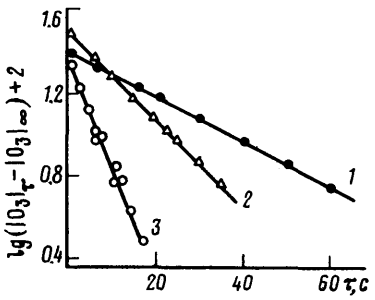
*The values without references are taken from Ref. 82.

2. Kinetics of the Reaction in Solution

In the examination of the reaction in the gaseous phase, it was noted that the reaction of ozone with a double bond is often complicated by side reactions. For the reaction in solution, in the case of simple alkenes, a stoichiometric reagent ratio of 1 : 1 is typical, and more than 95% of the products are formed by a single reaction path. This means that the rate of consumption of the starting materials characterises the reactivity of the ozone–alkene system. Experiments at low temperature, where the intermediate products can accumulate in large quantities and, after evaporation of the system, can regenerate the starting materials to be observed:

have shown that the contribution of the back reactions may be neglected. In a first approximation, the kinetics of the reaction in solution are described by a bimolecular law (Fig. 1).

The published reaction rate constants have been obtained by three methods: by measuring the relative rate of consumption of the alkene being studied, relative to a standard compound[86]; by measuring the rate of absorption of ozone from a gas stream[32]; and by the stopped-flow method[87]. The reaction rate constants in solution are more than an order of magnitude greater than those for the gaseous phase. This may be due to the experimental difficulty of measuring the rates of the rapid gas-phase reactions. Theory does not yet give an unambiguous answer to the question of the ratio of the rate constants in bimolecular reactions in the liquid and gaseous phases[88,89], although it can explain the decrease in the rate constant. For slow processes, such as, for example, the reactions of ozone with saturated hydrocarbons, the rate constants are similar for the solution and the gaseous phase[90].



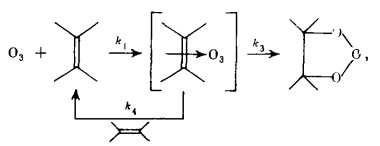


Figure 1. Kinetics of the reaction of ozone with vinylidene chloride in CCl_4 at 20 °C and different initial concentrations of vinylidene, M: *1*) 1×10^{-3}; *2*) 2×10^{-3}; *3*) 5×10^{-3}.

A study of the dependence of the reaction rate on the concentration of the alkenes over a wide concentration range showed that the kinetics of the reaction are described only approximately by the bimolecular law. The experimental data show best agreement with the scheme[3,91]:

in which a new reaction has been introduced—the reaction of the intermediate ozone–alkene complex with another alkene molecule, leading to decomposition of the complex to the starting materials. The observed rate constant k_{obs} is related to the rate constants of the first and subsequent stages by the equations ([Alkene] is the concentration of the alkene):

$$k_{obs} = k_1 k_3/(k_3 + k_4[\text{Alkene}])$$

or

$$1/k_{obs} = 1/k_1 + k_4[\text{Alkene}]/k_1 k_3.$$

Fig. 2 gives as an example the time dependence of the concentration of ozone in the gas stream at the outlet from a reaction vessel containing a solution of acrylic acid (AC), and the dependence of $1/k_{obs}$ on [AC], calculated from these data[32]. The values obtained are $k_1 = 4.2 \times 10^3$ litre mole^{-1} s^{-1} and $k_4/k_3 \doteq 8 \times 10^6$.

This characteristic feature of the reaction must be borne in mind when comparing the results of different studies or when examining the influence of the characteristic features of the structure of alkenes on their reactivity towards ozone.

The temperature dependence of the reaction rate in solution has been studied only for fumaric and maleic acids and maleic anhydride[91]; in the range 17–42 °C, the activation energies are 3, 6, and 6 kcal mole^{-1}, and the pre-exponential factors 1.6×10^6, 77.2×10^6, and 9.7×10^6 litre mole^{-1} s^{-1}

respectively. The rates of the reactions of non-substituted alkenes with ozone are greater by 2–3 orders of magnitude than that for fumaric acid, and the activation energies are 0.5–2 kcal mole^{-1}, which explains the weak influence of temperature on the reaction rate.

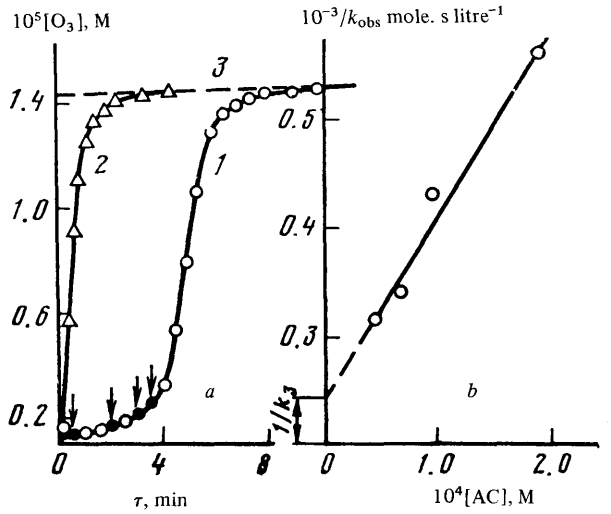

Figure 2. Time dependence of the concentration of ozone at the outlet from the reaction vessel (*a*) and plot of $1/k_{obs}$ against the concentration of acrylic acid (*b*): *1*) 2×10^{-4} M acrylic acid; *2*) CH_3COOH; *3*) concentration of ozone at the inlet to the reaction vessel, CH_3COOH, 20 °C. The arrows indicate the points used to calculate k_{obs}.

The experimental activation energies typical of the reactions of ozone with unsaturated compounds lie in a range which is not favourable for interpretation; their orders of magnitude do not differ greatly from those of many contributions which are usually difficult to incorporate and which are neglected at values of $E_{expt} \geq 10$ kcal mole^{-1} [92] (these contributions include the energy of reorientation of the solvation layers, the thermal energy of the molecules, etc.). Finally, in the range of these values it is in general difficult to expect that E_{expt} will be independent of temperature, since by definition, $E_{expt} = E_0 + 1/2RT$, where E_0 is the height of the potential barrier at 0 K.

Table 4 shows that low-molecular-weight alkenes having a terminal double bond (hex-1-ene, oct-1-ene, and octadec-1-ene) react with ozone at similar rates. On going to compounds having a C=C bond in the interior of the molecule (hex-2-ene, methyl oleate), there is a considerable increase in the reaction rate. Increase in the number of alkyl substituents on the carbon atoms at the double bond leads to an increase in the reaction rate (compare, for example, hex-1-ene and 2-methylpent-2-ene, acrylic and methacrylic acids, polybutadiene and polyisoprene). C_5–C_{12} cycloalkenes having one C=C bond react at similar rates, irrespective of the size of the ring, and, apparently, slightly less rapidly than a compound having a $\diagdown\!\!\diagup C{=}C \diagdown\!\!\diagup$ bond in an open chain (for cyclohexene, $k_1 = 4 \times 10^5$, compared with 1×10^6 for methyl oleate). The introduction of a phenyl substituent leads to an increase in the reaction rate, and not to a decrease, which might have been expected from the direction of the inductive effect of the phenyl ring. Increase in the number of phenyl groups (styrene–stilbene–1,1,4-tetraphenylbutadiene) has almost no influence on the reaction side.

Table 4. Rate constants for the reaction of ozone (litre mole^{-1} s^{-1}) with different unsaturated compounds in CCl_4 at 20 °C.[93]

Compound	$10^{-5}k_1$	Compound	$10^{-5}k_1$	Compound	k_1
Ethylene	0.4	Norbornene	5	Maleic acid	7.8
But-1-ene	1.3	Styrene	3	Fumaric acid	1.5
cis-But-2-ene	1.63	Stilbene	1.8	Maleic anhydride	14.1
Isobutene	0.97	1,4-Diphenylbutadiene	0.9	2,6-Dimethylhept-2-ene-carboxylic acid	2800
1,3-Butadiene	7.4	1,1,4,4-Tetraphenyl-butadiene	0.8	Vinyl chloride	1180
Pent-1-ene	1.4			Allyl chloride	8500
2-Methylbut-2-ene	5	Acenaphthene	2.2	Bis-1,2-dichloro-ethylene	35.7
Hex-1-ene	1.4	Acrylic acid	0.042		
Hex-2-ene	5	Methacrylic acid	0.078	Vinylidene chloride	22.1
2-Methylpent-2-ene	5	Methyl methacrylate	0.078	Trichloroethylene	3.6
Oct-1-ene	1.3	Oleic acid	10	Tetrachloroethylene	1.0
Octadec-1-ene	1.8	Methyl oleate	10	2-Bromopropene	2800
Cyclopentene	4	Polybutadiene	0.6	Acrylonitrile	100
Cyclohexene	4	Squalene	7.5	Tetracyanoethylene	0.4
Cyclododecene	4	Natural rubber	4.4	1,1,2-Triphenyl-2-nitroethylene	3.6
Cyclododeca-*trans*-1,5,9-triene	3.5	Gutta percha (*trans*-polyisoprene)	2.7		
		Polychloroprene	0.042	1,1-Diphenyl-2,2-dinitroethylene	0.7

The reaction of ozone with an unsaturated compound can be regarded as the reaction of an electrophile with a donor. Thus the introduction into the molecule of electronegative substituents such as Br, $Cl-C\overset{O}{\diagup\!\!\diagdown}OH$, and NO_2 decreases the electron density in the π-bond and leads to a significant decrease in the rate of the reaction with the corresponding compound. Comparison of macromolecular compounds with their low-molecular-weight analogues readily shows that the reaction rate constants of the polymeric products are lower (compare polybutadiene with methyl oleate and cyclododeca-*trans*-1,5,9-triene or polyisoprene with squalene and 2-methyl-2-ene).[94] A distinct difference is also observed between *cis*- and *trans*-isomers (maleic and fumaric acids, cyclohexene and cyclododeca-*trans*-1,5,9-triene, gutta percha and natural rubber).

The ozone molecule is small, so that steric factors do not play a significant role in the reaction. In only one of the cases in Table 4 is it possible to establish anomalies in the rate which might be attributed to steric effects. Comparison of the reaction rate constants of acrylic, methacrylic, and 2,6-dimethylhept-2-enecarboxylic acids (4.2×10^3, 7.8×10^3, and 2.8×10^3 litre mole^{-1} s^{-1} respectively) with allowance for the inductive effect of the substituents (the method for taking account of this effect is described below) shows that in the absence of steric hindrance, the reaction rate constant for 2,6-dimethylhept-2-enecarboxylic acid should be 7.8×10^3–1×10^4 litre mole^{-1} s^{-1}, whereas the experimental value is smaller by a factor of three.

3. Correlation Between the Structure of an Unsaturated Compound and the Rate of Its Reaction with Ozone

Table 4 shows that the rates of the reactions of ozone with alkenes have structures which differ considerably. For example, for oleic acid and tetracyanoethylene the values differ by more than six orders of magnitude. It is therefore very important to establish the quantitative relationship between the structure of an alkene and its reactivity to ozone, so that this relationship can be used for approximate estimates in work with new substances.

The first attempt in this direction was made by Cvetanovic and Williamson[86], who found a linear relationship between the logarithm of the rate constant and the ionisation potential of chlorinated ethylenes (Fig.3). In spite of the existence of a comparatively simple relationship, this approach cannot be regarded as successful, chiefly because a change in the potential by a small amount ($\lesssim$0.1 V) is accompanied by a change of several orders of magnitude in the reaction rate, and this makes the practical application of the observed relationship difficult. Moreover, the ionisation potential is a generalised characteristic of the molecule as a whole, and in the case of complex molecules, this relationship is not fulfilled in simple form. Distant parts of the molecule, which do not influence the reactivity of the C=C bond, make their contribution to the overall value of the potential.

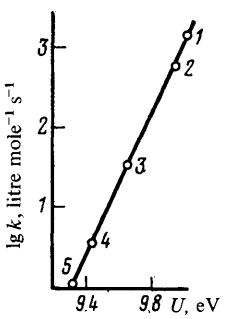

Figure 3. Plot of lg k against the ionisation potential for chlorinated ethylenes: *1*) C_2H_3Cl; *2*) *trans*-1,2-$C_2H_2Cl_2$; *3*) *cis*-1,2-$C_2H_2Cl_2$; *4*) C_2HCl_3; *5*) C_2Cl_4.

The rule that there is a linear relationship between the free energy changes, which establishes a semi-quantitative relationship between the rate constants and the inductive effects of a substituent at the reactive centre of molecules[95,96], is fulfilled for the decomposition of molozonides[97] and ozonides[98], and slightly less satisfactorily for the reaction of ozone with substituted alkenes[93]:

$$\lg(k_i/k_0) = \rho\sigma_{lit},$$

where k_0 and k_i are the rate constants for the reactions of ozone with the C=C bond of a compound taken as standard and the compound containing the substituent being studied, X_i; σ_{lit} is the inductive constant of the substituent, taken from published data, and ρ a proportionality coefficient, called the "sensitivity of the series". The standard compound chosen was ethylene, for which there are no substituents apart from hydrogen at the C=C bond. The plot of $\lg(k_i/k_0)$ against σ_{lit}, constructed from the data in Table 4, is given in Fig.4. In the set of compounds given, a significant deviation from the overall linear relationship is shown by the compounds containing phenyl substituents (styrene, stilbene), and maleic and fumaric acids. Since the rates of the reactions of ozone with acids and their methyl esters are identical (oleic acid and methyl oleate, methacrylic acid and methyl methacrylate), the values of σ_{lit} for the methyl esters were taken as equal to σ_{lit} for the acids (0.265).

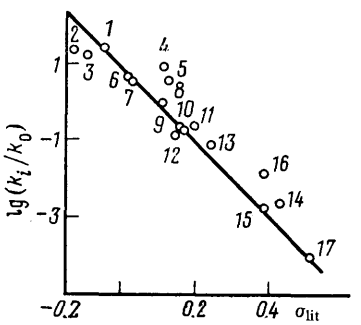

Figure 4. Plot of $\lg(k_i/k_0)$ against the inductive constant of the substituent[93]: *1*) methyl oleate, *2*) methylpent-2-ene, *3*) hex-2-ene, *4*) styrene, *5*) stilbene, *6*) hex-1-ene, *7*) octadec-1-ene, *8*) ethylene, *9*) methyl methacrylate, *10*) methacrylic acid, *11*) allyl chloride, *12*) 2-bromopropene, *13*) acrylic acid, *14*) acrylonitrile, *15*) maleic acid, *16*) fumaric acid, *17*) 1,1,2-triphenyl-2-nitroethylene.

Allowance for the spatial arrangement of the substituents and for electrostatic interactions might apparently improve the agreement between experiment and the model, but even as a first approximation it can be seen that the published values of σ_{lit} can be used to estimate the probable rates of the reactions of ozone with different unsaturated compounds. A negative sign for the coefficient ρ indicates that the reaction of ozone with the C=C bond is electrophilic.

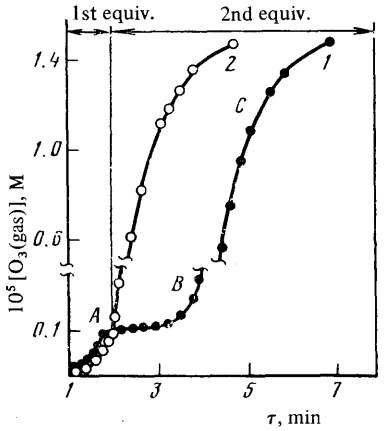
An interesting and as yet insufficiently clear question is the relationship between the reactivities of different groups in a molecule and the degree of deformation of the valence bonds. This deformation may be due to different factors (mechanical forces, steric factors, etc.). The alkenes given in Table 4 include compounds in which the C=C bond is strained for some reason. These include cycloalkenes having large rings (cyclododecene and cyclododecatriene), various norbornenes, and acenaphthene, and unsaturated compounds having bulky substituents at the C=C bond, for example 2,6-dimethylhept-2-enecarboxylic acid in Table 4. Compounds having strained bonds are more reactive than alkenes having an unstrained bond[99]. This is revealed, for example, in the fact that they readily react with diazomethane, whereas alkenes having unstrained C=C bonds do not react in this way. The decrease in the strain in the series of cycloalkenes $C_4 > C_5 > C_6$ coincides with the decrease in the yields of the corresponding pyrazolines[100].

Table 5 gives the published[101] rate constants for the reactions of C_5–C_{12} *cis*-cycloalkenes with ozone. There is a clear relationship between the size of the ring and the rate of the reaction of the compound with ozone. As expected, the reactivity shows a better correlation not with the excess energy of the molecule as a whole but with that fraction of

the strain corresponding to the double bond[101]. Analysis showed[101] that the chief contribution to the change in the reactivity on going from one ring to another is made by the steric factor, determined by the difference between the hybridisation of the carbon atoms at the double bond in the original state and in the activated complex.

Table 5. Rate constants for the reaction of O_3 with *cis*-cycloalkenes (0 °C, CCl_4) and the excess strain of the cycloalkene and the double bond, kcal mole^{-1}.

Ring	$10^{-5}k$, litre mole^{-1} s^{-1}	Cycloalkene	C=C
C_5	4.1	5.9	+2.3
C_6	0.96	0	0
C_7	2.5	5.2	+0.7
C_8	6.0	5.8	−1.6
C_9	3.1	9.4	−0.6
C_{10}	0.73	6.6	−0.7
C_{12}	0.59	—	



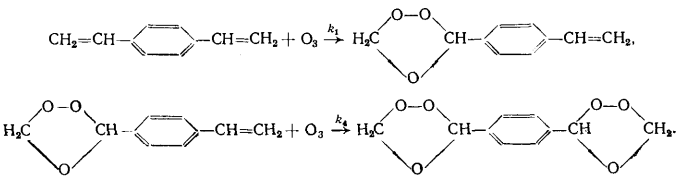


Figure 5. Plot of $[O_3(gas)]$ against reaction time for *p*-divinylbenzene (*1*) and styrene (*2*); *1*) 6×10^{-5} M, *2*) 1×10^{-4} M, CCl_4, 20 °C.

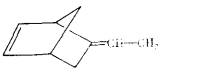
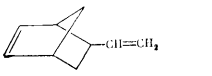
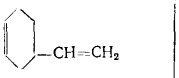
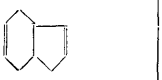
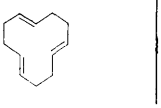
If the alkene molecule contains not one but several C=C bonds, the C=C bonds at a sufficient distance from one another react as independent kinetic units, and the addition of ozone at one of them has little influence on the reactivity of its neighbours. The inductive effect of a substituent usually decreases by a factor of 2.7 through each carbon atom of a saturated hydrocarbon chain[102], so that these influences are of little significance after only 3–4 carbon atoms. In the case of conjugated C=C bonds (1,3-dienes, *p*-divinylbenzenes, etc.), the difference in reactivities due to the structure of the original alkene may be increased by the positive inductive effect of the ozonide formed at a neighbouring group. This can be clearly seen for the case of divinylbenzene (DVB):











The fact that the reaction takes place in two stages is reflected in the form of the plot of $[O_3(gas)]$ against τ in a bubbler reaction vessel, shown in Fig.5; typical curves for styrene and divinylbenzene are given for comparison. The relationships obtained can be used to calculate rate constants. The rate constant for the reaction of the second double bond of DVB with ozone, k_4, is calculated along section AB using the equation:

$$k_4 = \frac{\omega([O_3]_0 - [O_3(g)]}{\alpha[DVB]''[O_3(g)]}$$

where $[O_3]_0$ and $[O_3(gas)]$ are the concentrations of ozone in the gas flow at the inlet and outlet of the reaction vessel; α the solubility coefficient of ozone; [DVB]" the current concentration of double bonds in the solution; and ω the specific rate of supply of the gas mixture.

Table 6. Rate constants for the reaction of ozone with di- and trialkenes in CCl_4 at 20 °C, litre mole^{-1} s^{-1}.

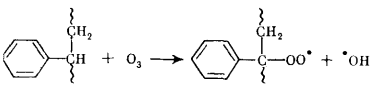
Compound	Formula	$10^{-5}k_1$	$10^{-5}k_4$
Divinylbenzene		2.1	0.22
Ethylidenenorbornene		3.6	2
Vinylnorbornene		3.3	0.82
Vinylcyclohexene		1.4	0.8
Tetrahydroindene		1.4	1.4
Cyclododeca-1,5,9-triene		3.5	3.5

The values of k_1 are found from the equation

$$k_1 = \frac{\omega([O_3]_0 - [O_3(g)]) - \alpha k_4[O_3(g)][DVB]_0}{\alpha[DVB]'[O_3(g)]},$$

where $[DVB]_0$ is the initial concentration of divinylbenzene, and [DVB]' the current concentration of DVB molecules having two double bonds. The calculations are possible when k_1 and k_4 differ significantly, and this is the case for divinylbenzene and many other alkenes (Table 6).

For divinylbenzene it is easily possible to follow the change in the reaction rate constant after the addition of one ozone molecule and to show how this change agrees with the general principles of the theory. The rate constant for the reaction of ozone with one C=C bond of the original divinylbenzene, because of the conjugation of the bonds, should be lower than that for styrene, as observed experimentally. When ozone attacks the first bond, the conjugation is broken, so that it might seem that the subsequent stage of the reaction should proceed at a rate close to that observed for styrene (3×10^5 litre mole^{-1} s^{-1}), but the products of the addition of ozone, that is the ozonides, have an appreciable inductive influence on the reaction, so that the second stage is much slower than the first.



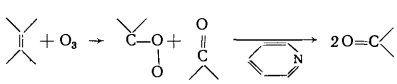
Comparison of the rate constants for the reactions of ozone with ethylidene- and vinylnorbornenes indicates that the initial attack is directed at the double bond in the side chain, since changes in its structure influence k_1, whereas the values of k_4 for the two isomers are identical. The separation of the bonds from one another, and the identical configurations of the immediate environments, make the C=C bonds in cyclododeca-1,5,9-triene equivalent, as shown by the fact that the rate constants for all three stages are identical.

The study of the kinetics of the reactions of ozone with macromolecular compounds is of exceptional interest, since this reaction is the chief cause of the cracking of rubber articles[103]. At the same time, the study of the kinetics of the reactions of ozone with the C=C bonds in macromolecules may give valuable information on the specific influence of the polymeric state on the course of chemical reactions. This question has been attracting considerable attention in recent years[104,105]. Flory[106] put forward the principle that the reactivity of the terminal group or any other group of a polymeric molecule is independent of its length. It is known, however, that certain reactions of polymers take place much more slowly than the reactions of the low-molecular-weight analogues (for example, catalytic hydrogenation), whereas a number of enzyme reactions take place extremely rapidly, but are not shown by the low-molecular-weight compounds[107].

In polymers, approach of the functional groups is possible, and this has a considerable influence on the kinetics of the reactions of these groups[104]. The coiled or straight forms of the macromolecule may create different conditions for the encounter between the reagent and the reacting parts of the macromolecule[108]. The applications of Flory's principle to reactions in which there is no specific interaction between the groups which have approached one another, or hindrance caused by diffusion, have been refined[109]. One of the greatest difficulties in this field is that there are no simple reactions which might serve as models for the study of the specific properties of a macromolecule. In this respect, the reaction of ozone with C=C bonds is exceptionally convenient: it takes place over a wide temperature range, the nature of the solvent has no influence on the reaction rate, and the mechanism of the reaction has been well studied and is the same for low-molecular-weight and macromolecular compounds.

Table 4 gives the rate constants for the reactions of ozone with polymeric compounds and their low-molecular-weight analogues. A good correlation is observed between the reactivities of the monomer and the polymer. In the macromolecular series, the reactivity decreases with change in the inductive effects of the substituents from electronegative to electropositive. It is well known that polychloroprene rubbers are more stable to ozone ageing than butadiene or polyisoprene rubbers. Attempts have been made to relate this increase in stability to a lower reaction rate; the imperfect methods used, however, did not make it possible to detect differences in the rates[110]. The data given in Table 4 show that high stability does in fact correspond to a lower reactivity.

As in the case of the low-molecular-weight alkenes, the *cis*-isomers (natural rubbers) react more rapidly than the *trans*-isomers (gutta percha). The effects associated with change in the length of the macromolecule or the extent to which it is coiled are apparently small, and could not be detected[111,112]. A noteworthy feature is that in all cases the reaction rate constant is smaller by a factor of 1.5–3 than that for the corresponding low-molecular-weight analogue. This characteristic feature cannot be attributed to the specific features of the electrophilic addition of ozone to the C=C bond. The reactions of ozone with the saturated polymers polystyrene and polyisobutene (which take place by a free-radical mechanism[111]):



are also slower than those of the low-molecular-weight analogues. The accuracy of the experiment does not make it possible to determine whether the decrease in the rate constant is due to the pre-exponential factor or to the exponential term of the Arrhenius equation (by putting $A_{mon} = A_{pol}$ for $k_{mon}/k_{pol} = 2$, we should have obtained the difference $E_{mon} - E_{pol} = 0.5$ kcal mole^{-1}); simple examination shows, however, that the reacting part of the polymer chain should have a lower mobility, since it is joined to extremely long chains. This may decrease the probability of a favourable orientation at the moment of encounter with the reagent.

4. Influence of Solvent on the Mechanism and Kinetics of the Addition of Ozone to the C–C Bond

Many compounds, for example alcohols and acids, can react with the intermediate species, chiefly the zwitterion, altering the direction of the reaction[27,46].

As noted above, in the presence of alcohols and acids, hydroxyalkyl- and hydroxyacylhydroperoxides are formed instead of ozonides[26,113]. When pyridine is used[114], reduction of the zwitterion to the corresponding carbonyl derivative probably takes place:

Saturated hydrocarbons, chloroform, and other halogen derivatives, used as solvents, apparently do not take part in the intermediate stages of the process, although it has been reported that they influence the yield of monomeric and polymeric ozonides[115,116].

An increase in the yield of acids when ozonisation is carried out in esters has been noted[117]. The chemical and physical properties of the system can be altered, sometimes radically, by using a suitable solvent. For example, in the presence of organic acids, gels are not formed in the ozonisation of cyclic alkenes, and the peroxide products of the ozonisation more readily undergo further transformation. In spite of their obvious importance, however, the problems of the influence of the solvent on the mechanisms of the reactions taking place have as yet been little studied, the published data are only preliminary, and the nature of the peroxide compounds and their interconversion, which has been observed by thin-layer chromatography[54], have not been established.

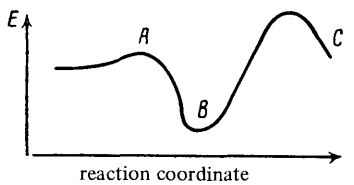
There are particularly few data on the influence of the medium on the rate of the reaction of ozone with alkenes. Only two papers have been published[15,87], giving different results. Razumovskii and Berezova[15] compared the influence of CCl_4, $C_{10}H_{22}$, CH_3COOH, H_2O, and a $CH_3COOH-H_2O$ binary mixture on the rate of the reaction of ozone with acrylic acid; the dielectric constant ranged from 2 to 80; in all cases the reaction rate constant was independent of the nature of the solvent. Henry and coworkers[87] studied the rate of the reaction of ozone with substituted stilbenes in solvents of different polarity (from CCl_4 to CH_3CN); in all cases, the reaction rate increases by a factor of 2–3 on going from CCl_4 ($\varepsilon = 2.24$) to CH_3CN ($\varepsilon = 37.4$). Since Razumovskii and Berezova[15] studied a wider range of ε and used a relatively unreactive alkene (which reduced the experimental difficulties), and since for the closest analogue of the reaction—the reaction of ozone with a C≡C bond—it has also been found that the polarity of the medium has no influence on the reaction rate[118], it may be assumed that the reaction rate depends little or not at all on the solvent.

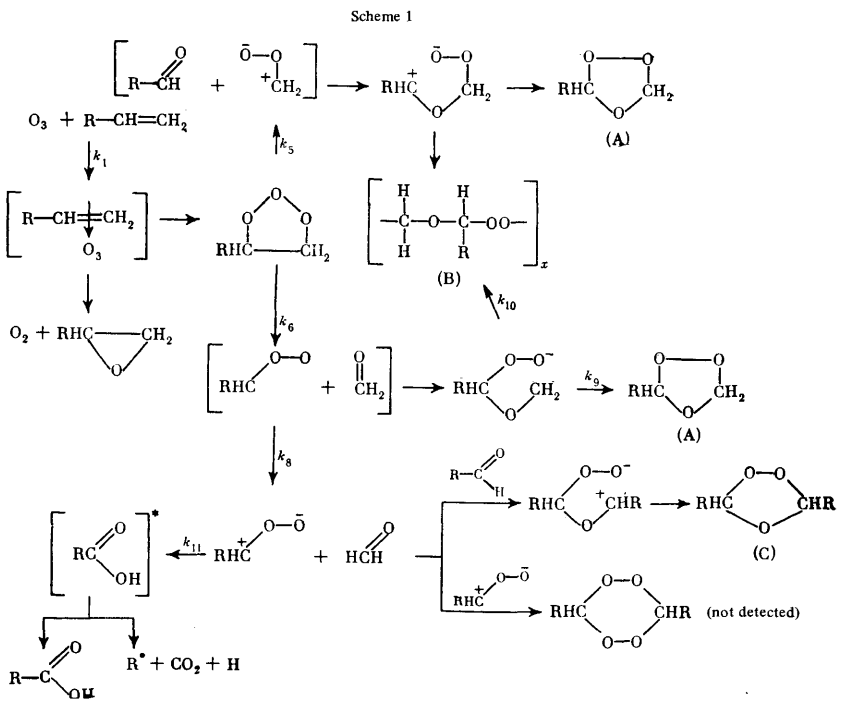
The fact that the polarity of the solvent has no influence on the reaction rate is in good agreement with the suggestion that the reaction involves a weak intermediate complex in which there is no appreciable transfer of electron density from one partner to the other, so that there is no significant rearrangement of the solvation layer.

IV. INTERMEDIATE STAGES IN THE ADDITION OF OZONE TO ALKENES

The intermediate stages of the reaction of ozone with unsaturated compounds, and the properties and structure of the labile intermediate products, are being studied intensively[28,29,32,119–127]. It still cannot be said that all the characteristic stages of the process are known, but the key reactions have been determined.

This section will examine the qualitative and quantitative characteristics of the stages of the scheme[1] given below. In the reaction of ozone with alkenes in solution, the first stage of the reaction is apparently the formation of a complex of ozone with the C=C bond of the alkene[28,91]. Its formation has been detected from the colour of the solution[7,28], the kinetic characteristics of the reaction[3,91], and the PMR and infrared spectra[43]. In the complex, both partners retain character and can be separated by decomposing the complex. At a low temperature, the reaction can be held at the stage of complex formation, appreciable quantitaties of which can be accumulated[7,119]. This means that the principal activation barrier to the reaction lies on the reaction coordinate after complex formation, as represented schematically in Fig.6. The complex has characteristic adsorption bands in the range 700–1000 cm^{-1}, which disappear rapidly with increase in temperature[119,120].





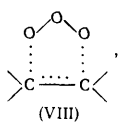


Figure 6. Change in the potential energy of the system in the transformation of the original reagents into the primary ozonide; *B* corresponds to the formation of the complex.

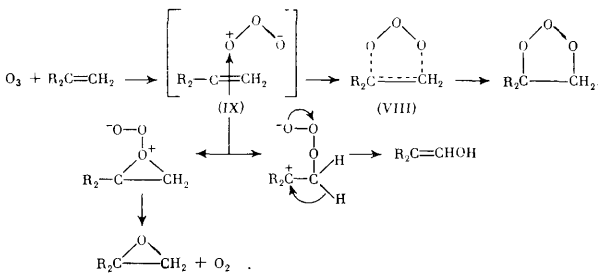
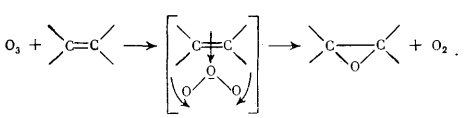
Scheme 1



Only tentative conclusions can be reached about the structure of the complex formed. There are serious objections to structure (VIII)

(VIII)

which would correspond to the idea of synchronous 1,3-dipolar addition. It does not explain the mechanism of formation of ozides and vinyl alcohols by the action of ozone on branched alkenes[128]. A scheme including the intermediate formation of a π-complex with a terminal oxygen atom in ozone (IX) has been proposed:



The qualitative character of the data makes it impossible to determine whether (VIII) is formed from (IX) or whether they accumulate in parallel, as suggested by Hull and coworkers[129]. Moreover, the polar structure assigned to (IX) contradicts the above conclusion that the medium does not influence the reaction rate[15]. The kinetic data indicate that in the transition state *A* (Fig.6) and the first intermediate complex, which has a similar structure (corresponding to the minimum *B* in Fig.6), the displacement of charges is slight, so that the solvation does not differ significantly for the original state and the transition state. Quantum-mechanical calculations also show that the formation of open complexes of type (IX) is unfavourable[127]. If it is assumed that the occupied molecular orbitals of ozone in the ground state $^1A_1$ have the configuration

$$O_3[(\text{core})(4b_2)^2(6a_1)^2(1a_2)^2],$$

and that the lowest unoccupied molecular orbital is $2b_1$,[12] it is found that in electrophilic reactions the largest coefficient of the AO corresponds to the central oxygen atom. In other words, electrostatic and polarisation factors favour the formation of a complex in which the optimum overlap of the π-orbital of the alkene and the lowest unoccupied molecular orbital of ozone corresponds to the crossed structure of the complex (Fig.7).

The formation of both the molozonide (for transverse displacements of the original components) and other products from the crossed complex can readily be represented. In particular, the deformation vibrations of the terminal oxygen atoms can probably lead to the formation of oxides:

The next intermediate product in order of relative stability is the molozonide, which can be accumulated in the system and studied. In most cases, the molozonide retains the stereoisomerism of the original alkene[130,131]. The *trans*-ozonide is much more stable than the *cis*-molozonide: the former can be observed in the system as far as −60 °C, whereas the second decomposes rapidly even at −130 °C;[38,119] the *cis*- and *trans*-isomers also differ in various other properties. Table 7 gives as an example the PMR spectra of the isomeric molozonides obtained from different alkenes.

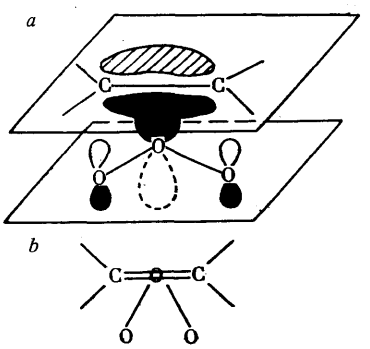


Figure 7. Schematic representation of the ozone–alkene complex: *a*) in the axonometric projection, *b*) view from above.

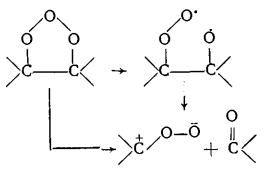
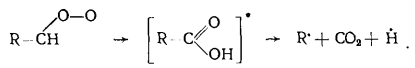
Table 7. Characteristic absorption bands in the PMR spectra (σ, p.p.m.) of the *cis*- and *trans*-molozonides and normal ozonides from the *cis*- and *trans*-molozonides in CF_2Cl_2 at −130 °C.[131]



Original alkene	Molozonide	Ozonide
cis-But-2-ene	4.52 (u)*	5.05 (q)*
trans-But-2-ene	4.12 (q)	5.00 (q)
cis-Pent-2-ene	4.35 (m)*	4.93 (m)*
trans-Pent-2-ene	4.08 (m)	4.95 (u)
trans-Hex-3-ene	4.07 (t)	—

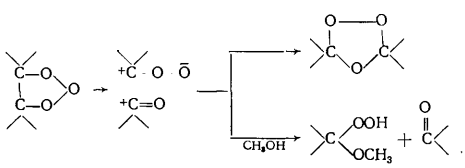
Symbols: q = quartet, m = multiplet, u = unresolved, t = triplet; the asterisks mark the data for the *cis*-molozonides.



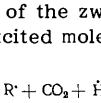
The molozonides have characteristic absorption bands in the range 700–1000 cm^{-1}, which are observed at low temperatures (between −175 °C and −100 °C),[119,121] but which disappear rapidly with increase in temperature to values between −80 °C and −60 °C. The strength of the C–O bond in the molozonide has been estimated as 45 kcal $mole^{-1}$.[132] The molozonides can be reduced to the corresponding diols by the action of an alkylmagnesium bromide or other reducing agents on the products of the reaction of ozone with the alkene at low temperature[123,133]. The first proof that the reaction involves the formation of molozonides involved this reaction.

The molozonide is unstable, and readily decomposes to give two fragments—the zwitterion and a carbonyl compound. It may be assumed that the reaction involves the intermediate rupture of one of the O–O bonds and the formation of a

biradical

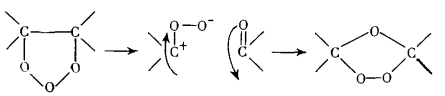


which decomposes rapidly to give the zwitterion and the carbonyl compound. This scheme has been used[66] to explain the high concentrations of free radicals in the reaction of ozone with alkenes in the gaseous phase. Although it has been reported that free radicals have been detected in the reaction of ozone with branched alkenes in solution[134], the accumulated experience in the study of this reaction nevertheless suggests that its principal direction is the direct conversion of the molozonide into two fragments without detectable radical states. The most probable route for the formation of radicals in solution is the isomerisation of the zwitterion and the subsequent decomposition of the excited molecules[44]:



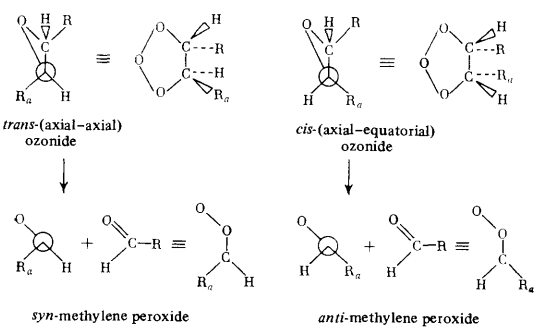
Since conditions in the gaseous phase are not more favourable than those in solution for the stabilisation of free radicals, yet the rates of the processes of energy dissipation are nevertheless greatly reduced, it is more logical to attribute the increase in the concentration of radicals in the gaseous phase to transformation of the zwitterion and to assume that the mechanism of the decomposition of the molozonide is the same for the liquid and gaseous phases, and involves a non-radical route.

The kinetics of the decomposition of the molozonide have been studied in solution by a chemical method[22] and by PMR spectroscopy[135]. In the chemical method, specimens removed at measured time intervals were mixed with alcohol. The molozonide which had not reacted at this moment was converted to the methoxyhydroperoxide in the presence of alcohol:



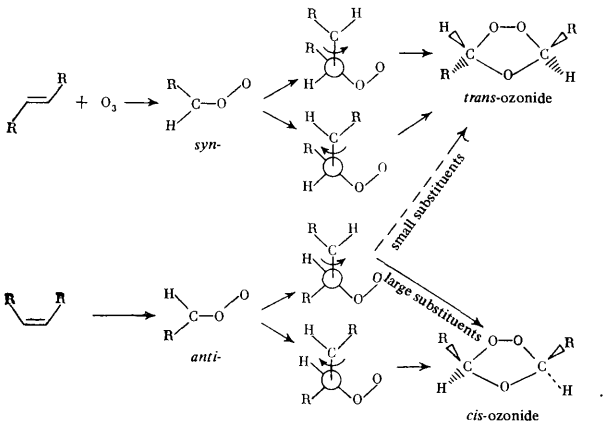
The concentration of the methoxyhydroperoxide in the reaction products gave a measure of the concentration of the molozonide.

The results obtained by the two methods showed good agreement: at -100 °C, the rate constant of the monomolecular decomposition ($k_5 \cong k_6$, see scheme 1) is equal to ~0.1 s^{-1}; the activation energy of the reaction is ~7–8 kcal $mole^{-1}$. The value of the activation energy can be used for a rough estimation of the energy of the O–O bond in the molozonide, which should differ from the activation energy by the difference in the free energies of solvation of the original molozonide and the transition state ($D_{O-O} \cong E$ + 5–10 ≅ 12–17 kcal $mole^{-1}$). The zwitterion formed as a result of the decomposition is an extremely reactive compound, about which very little is known; it can be represented as an aldehyde oxide[38] or as a methylene peroxide[136]. The description of the structure of this intermediate species in the usual symbols presents certain difficulties. It is isoelectronic with ozone, and is apparently a valence-saturated compound, although it is strongly polarised, in view of the difference in the electronegativities of oxygen and carbon.



Quantum-mechanical calculations show that the cyclic structure of the zwitterion is energetically more favourable than the open structure[137]. This brings the discussion back to Harries' ideas[17], but at a different qualitative level. A recent study of the reaction of ozone with ethylene in the gaseous phase detected species having a mass number of 46, but the position of their peak did not coincide with that for formic acid[138]. The microwave spectra of this system showed bands at 29.938 GHz and 30.872 GHz, assigned to dioxiran H_2C-OO.[139] For alkenes unsymmetrical with respect to the C=C bond, conditions can be created for the preferential formation of the zwitterion at one of the carbon atoms, depending on the nature of the substituents. In particular, substituents having a positive inductive effect (CH_3, RCH_2, etc.) increase the probability of formation of the zwitterion at the given carbon atom[140], whereas substituents having a negative inductive effect (Cl,  , etc.) decrease it. The ratio of the probabilities is described by a relationship of the Hammett type[140]. When both carbon atoms have substituents, the probability of the addition of two oxygen atoms depends on the difference in the inductive constants of the substituents.

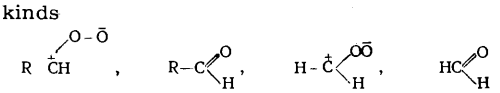
The pair (zwitterion and carbonyl compound) formed by the decomposition of the molozonide can combine again extremely rapidly, forming the ozonide (the arrows show the directions of the rotations of the fragments):



The formation of this compound is preceded by a change in the relative orientation of the fragments (rotation through 180°).

The composition of the final products usually carries valuable information on the processes preceding their formation. Thus analysis of the ratio of the *cis*- and *trans*-isomers in the ozonisation products showed that the zwitterion as it were "remembers" the structure of the original alkene. In spite of the free rotation at the stage of carbonyl formation, the preservation of the structure of the original alkene by the final ozonides is preferred[24,38,141]. This is attributed to the high barrier to rotation in the zwitterion (~29 kcal [136]), which fixes the *syn*- or *anti*-form of the zwitterion:

In the subsequent addition of the carbonyl, a difference betwen the structures of the substituents, together with the *syn*- or *anti*-form of the zwitterion, leads to the formation of *cis*- or *trans*-ozonides[136]:



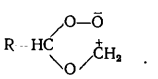
The recently detected influence of complex-forming species on the stereospecificity of the formation of ozonides was explained similarly[126]. A large amount of data has been published on the composition of ozonides[3,7,27,142–149], but only a few papers give a material balance of the principal components[32,41]. Table 8 gives the compositions of the reaction mixtures for several simple alkenes. Judging from the reaction products, most of the zwitterions are able to react with "their own" carbonyl compounds, with which they were formed from the molozonide, that is a clearly defined cage effect is observed[20,144].

Table 8. Composition of the reaction mixture after the ozonisation of the alkenes[32].

Component	Propene	Pent-1-ene	Hex-1-ene	Hex-1-ene
	−78° C			0° C
Normal ozonide (a)	73	67	70	75
Polymeric ozonide (B)	7	8	7	3
Crossed ozonide (C)	20	25	23	22
including:				
macromolecular ozonide	10	15	11	12
ethylene ozonide	10	10	12	10

Note; A, B, and C correspond to the final products of scheme 1, page 1171.

The decomposition of an unsymmetrical alkene gives species of four kinds

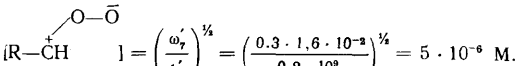


(X) (XI) (XII) (XIII)

in approximately equal proportions (allowance for the inductive effect of the substituent makes it possible to define this more accurately[140]). All the cages of the combination of (X) with (XIII) and of (XI) with (XII), giving A (scheme 1), and of (X) with (XI) and of (XII) with (XIII), giving C, are equally probable. The ratio ([A] + [B] − 0.5[C])/1.5 characterises the fraction of the transformation in the cage, which for all alkenes is close to 0.7. This indicates that the rate of reaction (7) in scheme 1 is comparable with the rate at which the particles leave the "cage". The duration of the existence of the pair of particles in the "cage" can be estimated from Einstein's equation[145,146] $\tau = \frac{1}{6}r^2/D$. For small molecules, $r = 4 \times 10^{-8}$ cm, $D = 10^{-5}$ cm s^{-1}; if it is assumed that the molecules can collide 10–100 times before moving apart, then $\tau = 10^{-11}$–10^{-10} s. For the present case, in the selection of the values of τ, it is also necessary to take account of the fact that an appreciable proportion of the zwitterions reacted outside the cage, forming crossed ozonides. This makes it possible to assume that the value of τ is close to the lower limit of the lifetime of the cage or even lower (10^{-9} s), so that

$$k_7 = 1/\tau = 1 \cdot 10^9 \ s^{-1}.$$

The activation energy of reaction (7) is low, since the cage effect was observed at all temperatures studied (from 30 °C to −78 °C), and the concentrations of the carbonyl compounds and bipolar ions were very low in all cases. Approximately 30% of the total quantity of molozonide decomposition products are able to leave the cage before the start of the reaction; an appreciable proportion leave with an unclosed ring:



(XIV)

These reactive species move freely in the solution, and are subsequently converted into crossed and polymeric ozonides.

A certain concentration of alkenes and carbonyl compounds is established in the solution. Estimation of this concentration (from the quantity of formaldehyde carried away by the bubbline gas) showed that it is much lower than 10^{-3} M. It can be estimated from the following: $k_8 = 0.3 \times 10^9$; $k_7 = 0.3 \times 10^9$. Since ω_8 is the rate of diffusion, in this case it is possible to use the regular features of diffusion kinetics[147]. The published experimental data[32] then give

$$k_8 k_7/(k_8 + k_7) = k_7', \text{ from which } k_7' = 0.2 \cdot 10^8 s^{-1},$$

and

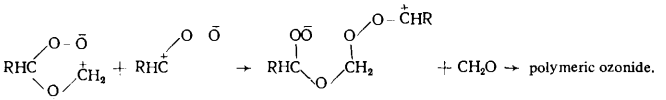
The nature of the substituents at the carbonyl group has a significant influence on the rate of its reaction with the zwitterion. The direction of the influence is the opposite of that observed in the reaction of ozone with the double bond or in the decomposition of the molozonide. Electron-donor substituents decrease the reaction rate, and electron-acceptor substituents increase it. Thus in the series of compounds

the rate of the reaction with the zwitterion increases[3]; the reaction rate constants in the cage, k_7, are 0.3×10^9, 1.0×10^9, and 4.2×10^9 s^{-1} respectively. The zwitterion in solution may react not only with the carbonyl group but also with another zwitterion[7].

In a number of cases, ozonide formation has not been observed at all, and dimeric peroxides and ketones have been obtained[55]. Dimeric peroxides have not yet been detected, however, in the ozonisation products of simple alkenes having an open chain. The formation of polymeric ozonides can be represented as follows: the primary association of the

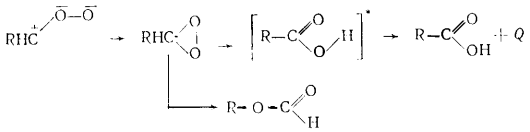
zwitterion with the carbonyl compound takes place at high rates and without a significant heat change, whereas ring closure is associated with a considerable increase in the order of the system and hence with a decrease in its entropy. The rate of this process is apparently lower than that of the preceding process, and several of these unclosed rings are able to combine with one another before the ring closes. The polymeric ozonides are cyclic formations including an average of about three monomeric units in the case of alkenes having a normal structure[41,148]. The action of ozone on cycloalkenes gives macromolecular three-dimensional products, exhibiting typical properties of polymers[148].

To estimate the probable values of k_9 and k_{10} (see scheme 1), it is possible to make three assumptions: 1) $k_9 \geq k_7$; in this case, k_{10} takes a value $\geq 1 \times 10^{12}$ litre mole^{-1} s^{-1}, which is unlikely; 2) $k_{10} \cong k_7$; in this case,



$$[\mathrm{XIV}] \simeq \left(\frac{1.6 \cdot 10^{-2} \cdot 0.1}{10^9}\right)^{1/2} \simeq 1.3 \cdot 10^{-6}\ \mathrm{M},$$

$$k_9 \simeq 1.6 \cdot 10^{-2}/1.3 \cdot 10^{-6} \simeq 10^{-4}\ c^{-1},$$

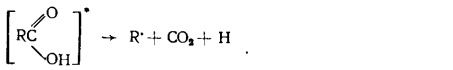


which is quite probable; and 3) both k_9 and k_{10} differ considerably from k_7; in this case it can be established from the experimental data that for −78 °C

$$k_{10}[(\mathrm{XIV})]/k_9 = 0{,}1.$$

The kinetic scheme shows that a decrease in the reaction temperature, an increase in the reaction rate, and the use of polar solvents facilitating an increase in the concentration of (XIV) should increase the formation of the polymeric ozonide. The zwitterion and the carbonyl compound leaving the cage and passing into the solution may also be involved in the formation of polymeric ozonides:

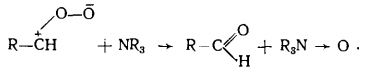
The zwitterion undergoes isomerisation comparatively readily. This reaction provides the principal channel for the formation of acids in the thermal decomposition of ozonides[44]. The isomerisation probably takes place via the cyclic form of the zwitterion:



The quantity of free acids formed in the reaction of ozone with the alkene can be used as a measure of the contribution of this reaction to the transformation balance[32].

The unimolecular rate constant for the isomerisation of the zwitterion can be found from the relationship

$$k_{11} = [\mathrm{Acid}]k_7^{1/2}/[\mathrm{Ozonide}]^{1/2}.$$

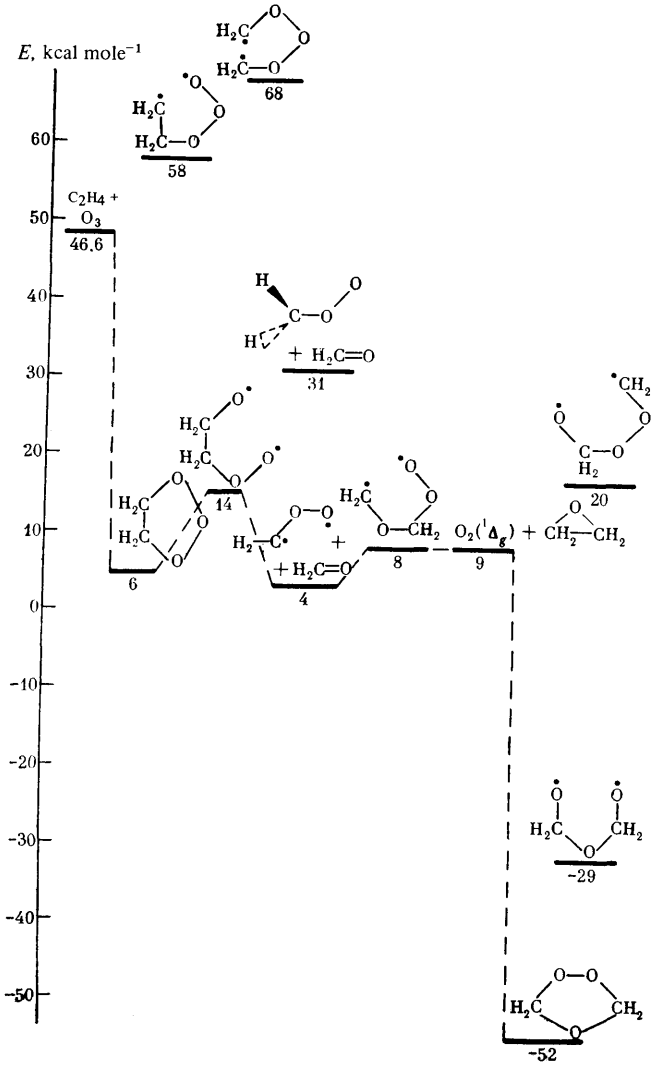


According to published data[32], $k_{11} = (1 \pm 0.8) \times 10^7 \exp\left[\frac{(-6600 \pm 800)}{RT}\right]$ s^{-1}.

The isomerisation of the zwitterions is accompanied by the liberation of 60–80 kcal of energy, which initially is concentrated in the newly formed bonds. The acid molecule is therefore in an excited state (marked by an asterisk in scheme 1) and can decompose relatively easily, for example[44]:

The decomposition takes place more rapidly under conditions in which the dissipation of the energy and the thermalisation of the "hot" molecules are hindered. Thus in the gaseous phase, this process becomes predominant[56–60], whereas in solution at room temperature or lower temperatures, its contribution usually does not exceed 1–3%.[32]

The reaction in the second direction—the splitting of the C–C bond with the formation of esters of formic acid—is slower by about three orders of magnitude, and is observed in the reaction of ozone with branched alkenes[149]. The zwitterion may react with added ammonia, pyridine, or tetracyanoethylene[150]:



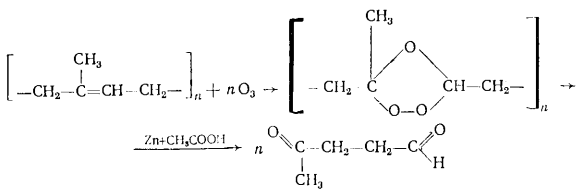


Figure 8. Thermochemistry of ozonisation.

Fig.8 gives the results of thermochemical calculations which make it possible to show the positions of the intermediate species on the reaction coordinate (marked by the broken line relative to the initial and final stages)[136]. In addition to the labile intermediate products mentioned in the text, the diagram shows species whose possible formation has been discussed in the literature. Unfortunately, Fig.8 does not give the complex of ozone with the alkene, for which thermochemical data are not yet available.

V. THE USE OF THE REACTION OF OZONE WITH UNSATURATED COMPOUNDS IN RESEARCH AND TECHNOLOGY

Comparison of the rate of the reaction of ozone with the double bond and with the $-CH_2-$ group of the saturated parts of the alkene molecule shows that they differ by 4–8 orders of magnitude[151]. This makes it possible to use ozone in analysis to determine the number of double bonds and their position in the molecule of an organic compound. Mention must first be made of the classical work of Harries, who determined the structure of various natural polymers, in particular natural rubber[4]:

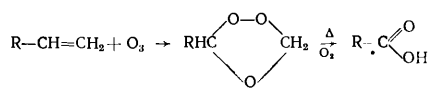
Subsequently, the rupture of a double bond by ozone has been used repeatedly in the study of the structure of various new polymers and copolymers[5,152–158]. This question has been the subject of several reviews[4,46,104].

The use of ozone to study the processes associated with the formation of unstable products, for example keto–enol tautomerism, has proved extremely effective[1,159].

In the early nineteen-thirties, a process for obtaining high-octane petrol by the dimerisation of propene and butenes was widely developed; the positions of the double bonds in the isomeric dimers were determined from the composition of the ozonisation products[160]. This method proved extremely useful in the study of the structure of lipids, fats, steroids, and other natural compounds[53,161,162].

The combination of ozonisation methods with gas–liquid chromatography increased considerably the possible use of ozone in determining the structure of unsaturated compounds, since it became possible to analyse ultramicro-quantities of the products (~10^{-3}–10^{-6} M). The procedure for these determinations has been described by a number of authors[163,164].

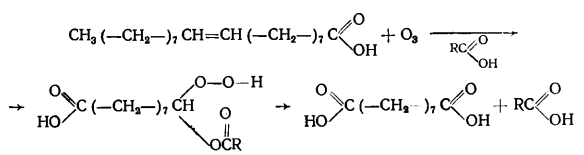
The determination of the position of a C=C bond in the molecule of an organic compound is now well established. It is often necessary to determine the positions of several C=C bonds present together (for example, the 1,2- and 1,4-structures in polybutadienes) and the nature of the terminal groups of the macromolecules of synthetic polymers, to distinguish double and triple bonds, etc. In these cases it is necessary to make a more complete study of the composition of the reaction products or to combine the results of the study of the composition of the reaction products with kinetic data[5].



A large proportion of present-day processes in organic synthesis, petroleum chemistry, and polymer chemistry are based on various transformations of compounds containing a double bond. The use of ozone has made it possible to develop control systems which are very rapid and have a very high sensitivity (as far as 10^{-8} M double bonds in the specimen)[165]. They have proved to be particularly effective in the determination of the quality of new saturated copolymers containing small quantities of added dienes, for example the ethylene–propene–diene copolymer (SKEPT), in which the concentration of unsaturated units in the molecule is 0.5–2%, which lies at the limit of the sensitivity of the methods previously used.

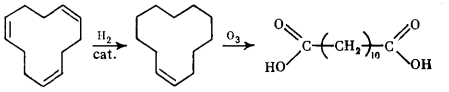
In the analysis of the products of the incomplete hydrogenation of fats (margarines), compounds containing halogen atoms or aromatic rings at a double bond, and new polymeric materials such as acrylates or urethanes, the usual iodometric or infrared spectroscopic methods are ineffective, whereas the use of ozone gives good results[151,166,167].

The concentration of ozone in the layers of the atmosphere close to the earth's surface is usually low (10^{-10}–10^{-9} M), but it increases considerably in industrial centres. Ozone plays an important role in the production of photochemical smog, so that the monitoring of atmospheric ozone is included in all ecological programmes[85]. Various methods have been proposed for determining ozone in air[3,168–171]. One of the best methods is that based on the measurement of the intensity of the chemiluminescence produced when ethylene is mixed with a portion of the air being studied[62,63].



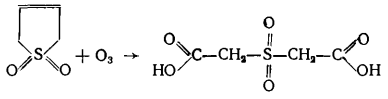
The reaction of ozone with double bonds has also found application in the preparation of many oxygen-containing compounds[26,172–175]. According to published data, a number of technological assemblies are now operating, and new ones are being devloped[26,174,176,177]. The principal direction in this work at present involves the preparation of expensive products from scarce raw material. In these processes, the high selectivity of the reactions of ozone has made it possible to achieve maximum yields.

Ozonisation provides the simplest method of obtaining various acids[178–180]:

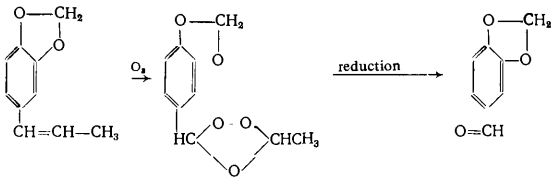


The demand for organic acids is extremely large; they are obtained from plant and animal products or by oxidising saturated petroleum hydrocarbons. The last reaction gives acids containing considerable quantities of undesirable functional groups (keto- and hydroxyacids, lactones, etc.) and having a wide fractional composition. The quality of the acids obtained by ozonisation is much better, and their composition is determined by the original alkene[180,181].

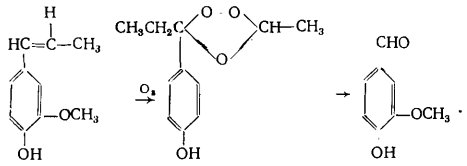
Several methods have been published for preparing adipic[182–184], azelaic[26,185–187], and other dicarboxylic acids[188–191]. The industrial production of azelaic acid is based on the treatment of oleic acid with ozone in nonanoic acid:



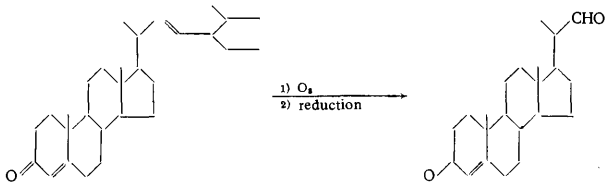
The development of methods for the cyclo-oligomerisation of divinyl[192] and the selective hydrogenation of dimers and



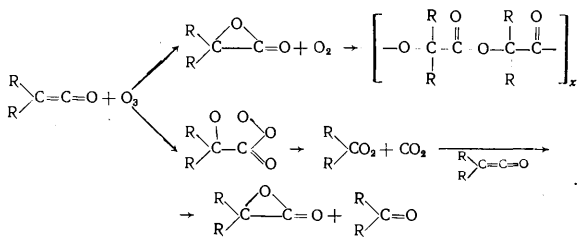
trimers to monocycloalkenes[193,194] makes promising the synthesis of octane dicarboxylic and dodecanedicarboxylic acids[113]:



The synthesis of dicarboxylic acids containing heteroatoms in the molecule has been reported[195,196]:



Various aromatic aldehydes have been obtained in good yields, for example heliotropine, used in perfumery and cosmetics[197]:



and of vanillin from isoeugenol[198]:

Various steroids in which the double bond in the ring is stabilised by substituents having an appreciable electron affinity give good yields (up to 94%) of aldehydes as a result of bond rupture in the side chain[26,174,199]:

The reaction of ozone with ketenes giving α-lactones, which polymerise spontaneously to give complex polyesters[200,201]. The mechanism of the reactions taking place can be represented by the following scheme:

The synthesis of biologically active compounds, for example glutamic acid from cyclopentadiene[202], various hormones such as cortisone and progesterone from ergosterol (protovitamin D),[203] keto steroids[204], steroids containing heteroatoms[205], and intermediate α,ω-dialdehydes of given stereoisomeric form in the synthesis of tellergons[91], has been described.

Internuclear Distances in Carbaboranes

V.S.Mastryukov, O.V.Dorofeeva, and L.V.Vilkov

Structural data for different carbaboranes, investigated in the solid and gas phases, have been compiled and arranged systematically. The subdivision of bonds into polyhedral and exopolyhedral, proposed previously, is illustrated by additional examples. It is shown that the concept of the coordination number helps to discover the rules governing the variation of the polyhedral C - C and B - C distances. Since this approach proved to be relatively ineffective in relation to B - B bonds, an attempt was made to estimate the influence of electronic factors on these distances on the basis of a modified inductive rule. This has shown that the polyhedral and exopolyhedral C - X and B - X distances in carbaboranes obey different rules.
The bibliography includes 66 references.

I. INTRODUCTION

Vigorous studies in the field of boron hydrides led at the end of the 1950s and the beginning of 1960 to the discovery of a new class of organic derivatives of boron—carbaboranes. The structural basis of carbaboranes consists of fragments of polyhedral boranes incorporating carbon atoms as an intrinsic component of the skeleton, in contrast, for example, to alkylboranes, in which carbon is a substituent. After a short time, this field of chemistry developed so actively that the possibilities for the synthesis of new compounds now appear almost unlimited. Interest in carbaboranes is to a large extent due to the fact that, both experimentally and theoretically, they occupy a strategically important position at the junction of many fields of chemistry: those of boron hydrides, organoelemental compounds, transition metal complexes, and metallic clusters. These common features were manifested particularly strikingly in the middle of the 1960s when metallocarbaboranes were discovered.

closo-Carbaboranes, forming closed polyhedral structures, were initially investigated in greatest detail. The inclusion of carbon atoms in the boron hydride skeleton is accompanied by the disappearance of hydrogen bridge atoms and greatly increases the thermal and chemical stabilities of the initial systems. The majority of studies were carried out on $C_2B_{10}H_{12}$ and $C_2B_5H_7$ and were designed to synthesise thermostable polymers. However, other ways of using carbaboranes were also found. Even before the polyhedral structure of carbaboranes was demonstrated by direct structural methods, their structure had been correctly predicted on the basis of indirect considerations. Both certain experimental methods (infrared spectroscopy, NMR, and mass spectrometry) and theoretical ideas, to a large extent developed by the American investigator Lipscomb†, played an important role here. In particular, one of the simple fundamental ideas was the observed analogy between the structures of *closo*-carbaboranes $C_2B_{n-2}H_n$ and the isoelectronic $B_nH_n^{2-}$ ions, for example, $C_2B_4H_6$ and $B_6H_6^{2-}$, etc. The vigorous development of the chemistry of carbaboranes would have been impossible without the exact knowledge of their structure. The majority of structural results for substituted carbaboranes were obtained by single crystal X-ray diffraction. The structure of volatile lower carbaboranes was established mainly by gas electron diffraction and microwave spectroscopy.

Data on the structure of carbaboranes are usually included in reviews on their chemical properties. As a result, extensive structural data have accumulated, the compilation and systematic arrangement of which are both urgently required and desirable. Furthermore, there is a possibility of surveying these experimental data and examining them from a single standpoint, for example in terms of coordination numbers (C.N.).

The stereochemistry of carbon with C.N. = 2, 3, and 4 has been studied in detail in relation to organic compounds. An expansion of the coordinating capacity of carbon has been observed in carbaboranes, where C.N. = 4, 5, and 6 are encountered. In the present review we attempted to compare these two ranges of C.N. on the basis of carbaborane data obtained in the gas and crystalline phases. The polyhedral and exopolyhedral bonds formed by carbon are considered separately; next, bonds involving boron atoms are analysed by analogy. The classification of exopolyhedral distances as an independent group, which we proposed on the basis of geometrical considerations[1], has been confirmed independently in the study of the photoelectron spectra of carbaboranes[2].

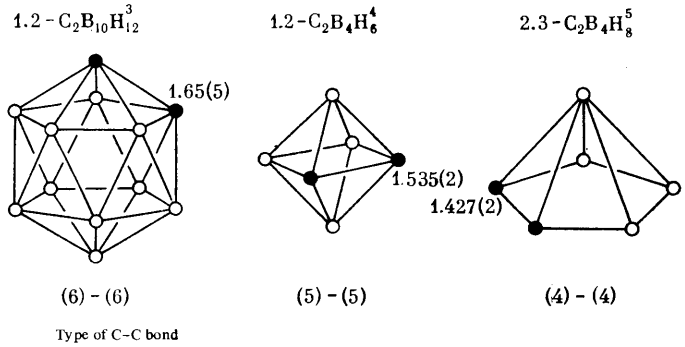
One cannot assume *a priori* that a fairly formal characteristic of the atom such as its coordination number will exert a unique or even a decisive influence on the lengths of all the bonds involving the given atom. In particular, this applies to systems with a considerable delocalisation of electrons, to which carbaboranes belong. Such cases may require an additional allowance for electronic factors.

II. C–C BONDS

Stoichev's rule, expressing the dependence of the C–C bond length on the number of bonds or atoms attached to

†Lipscomb also played an important role in the experimental determination of the structures of numerous boron hydrides and carbaboranes by X-ray diffraction. His work in this field was recognised by the award of the Nobel prize in 1976.

it, is well known in the stereochemistry of organic compounds:



$$r(C-C) = 1.299 + 0.040\,n(\text{Å});\ n = 2-6, \qquad (1)$$

where n is equal to the sum of the C.N. of the atoms forming the bond minus two.

This equation reproduces satisfactorily the C–C bond lengths in diacetylene ($n = 2$), vinylacetylene ($n = 3$), butadiene ($n = 4$), propene ($n = 5$), and ethane ($n = 6$), constituting a convincing illustration of the usefulness of the concept of the coordination number. Numerous attempts have been made at a theoretical justification of Stoichev's rule (these include the theory of orbital hybridisation, allowance for the influence of the delocalisation of electrons, steric effects, electronegativity, amount of ionic character of the bond, etc), but as yet there is no unanimous view on this subject.

The problem arises of the possibility of extrapolating Stoichev's equation to higher C.N. for carbon atoms, characteristic of carbaboranes. We have shown[1] that, for the C–C bond of the type (6)–(6) (the C.N. of the carbon atoms are indicated in brackets), Eqn.(1) leads to 1.699 Å, which agrees, within the limits of the errors of the individual measurements, with the value 1.655 Å found for 1,2-$C_2B_{10}H_{12}$ (Bohn and Bohn[3]) and its derivatives.

Analogous treatment yields 1.619 and 1.539 Å for bonds of the type (5)–(5) and (4)–(4) respectively, which differ appreciably from the experimental data quoted below:

Such a marked discrepancy led us to compile additional literature data for the structures of carbaboranes, which are listed in the Table. The coordination numbers for all the bonds, with the exception of those of the (6)–(6) type, are indicated here as superscripts; for C–B bonds, the C.N. of the carbon atoms is given first. Additional alphabetic subscripts are used only for B–B bonds and correspond to their classification in relation to carbon atoms (see below).

The majority of the compounds investigated are *closo*-carbaboranes; the letters (*n*) and (*a*) denote *nido*- and *arachno*-carbaboranes respectively. Carbaboranes with heteroatoms (1-$CH_3GaC_2B_4H_6$, 1,12-$CHPB_{10}H_{10}$, etc.) are not included in the Table.

The results for C–C bonds are presented in a graphical form in Fig.1. Inspection of this figure permits the following observations.

1. The length of polyhedral C–C bonds in *closo*- and *nido*-carbaboranes varies linearly with the C.N. of the carbon atoms, which is described by the empirical equation

$$r(C-C) = 1.074 + 0.058\,n(\text{Å});\ n = 6, 8, 9, 10. \qquad (2)$$

Evidently the observed relation for carbaboranes lies below that for hydrocarbons and the straight lines corresponding to Eqns.(1) and (2) diverge appreciably in the region of low C.N., which also accounts for the unsatisfactory estimates of the lengths of bonds of the type (4)–(4) and (5)–(5) in carbaboranes by Eqn.(1).

2. Extrapolation of Eqn.(2) to the region of small C.N., shown by a dashed line, yields satisfactory estimates of the lengths of the C=C and C≡C multiple bonds. This phenomenon is especially interesting in the light of the fact that a considerable amount of double-bond character has been postulated for the (4)–(4) bond in $C_2B_4H_8$ and $C_4B_2H_6$.[7,8,50]

3. The exopolyhedral C–C_e bonds form a special group of distances, depending little on the immediate environment, which is described by the empirical equation

$$r(C-C_e) = 1.510 + 0.002\,n(\text{Å});\ n = 6, 7, 8, 10. \qquad (3)$$

These distances vary on average from 1.52 to 1.53 Å with increase of n from 6 to 10, i.e. they are almost constant and intersect the bond corresponding to Eqn.(2) in the region of bonds of the type (6)–(4).

Overall, the data for the exopolyhedral C–X distances in carbaboranes are few and are in essence limited to C–C distances. However, for X = I or Si, the substituent is seen to exert a considerable influence, since the C–I bonds in 1,7-$C_2I_2B_{10}H_{10}$ [51] and 1,12-$C_2I_2B_{10}H_{10}$ [28] are much shorter and the C–Si bond in 1,2-$C_2(CH_3)[Si(CH_3)_3]B_{10}H_{10}$ [37] is much longer than might have been expected on the basis of stereochemical analogies. The structural data for C–H bonds are not very accurate and are therefore not discussed here. One should only note that the high vibration frequencies of the C–H bonds, characteristic of ethylenic and aromatic compounds, are also characteristic of carbaboranes: with increase of the C.N. of the carbon atom, the frequencies diminish[52].

III. POLYHEDRAL C–B BONDS

In the most symmetrical *closo*-carbaboranes the polyhedral C–B bonds depend only on the C.N. of the carbon atom n_C (Mastryukov et al.[1]):

$$r(C-B) = 1.249 + 0.077\,n_C(\text{Å});\ n_C = 4, 5, 6. \qquad (4)$$

When data for 1,10-$C_2B_8H_{10}$ were published[23], it became possible to estimate the influence of the C.N. of the boron atom for a constant C.N. of the carbon atom. The C–B bond lengths are indicated below for symmetrical *closo*-carbaboranes having C_2B_4, C_2B_8, and C_2B_{10} skeletons with an indication of the C.N. of the atoms forming the bond:

C(5)–B(5)	C(5)–B(6)	C(6)–B(6)
1.634 (4)[12]	1.602 (2)[23]	1.710 (11)[3]

This comparison shows that, when the C.N. of the boron atom is altered, there is a smaller change in the C–B bond lengths than after the alteration of the C.N. of the carbon atom. This justifies the choice of n_C as the variable quantity in Eqn.(4). On the other hand, when one employs the atomic radii of boron proposed by Brown and Lipscomb[53], then the C–B(6) bond should be longer by 0.070 Å than the C–B(5) bond.

A more complex picture arises for the C–B bonds when account is taken of less symmetrical *closo*-carbaboranes and data for *nido*-carbaboranes are included (see Table). It then becomes clear that Eqn.(4) is applicable only to the most symmetrical *closo*-carbaboranes. It can be assumed that the wide variety of C–B bonds is best characterised by the simplest relation in the form of Eqn.(4), taking into account

The bond lengths in carbaboranes (in Å).

Remarks: Research techniques used: E = electron diffraction; X = X-ray diffraction; M = microwave spectroscopy.

*An electron diffraction study of $C_4B_2(CH_3)_6$ has also been carried out[9]. These data are unreliable, since they differ markedly from the results for the unsubstituted molecule.

**The 2-Cl-1,6-$C_2B_4H_5$ molecule has been investigated by the microwave method[13]. These results have not been included in the Table because of their low accuracy.

***The values for two types of C–B bonds in *ortho*-carbaborane and its derivatives (Nos.23–40) are presented: C(1)–B(3) and C(1)–B(4) (the atoms are always numbered in accordance with Bohn and Bohn[3]) or average values are given. The values for seven types of B–B bonds are quoted: B(3)–B(4)(g); B(4)–B(5)(d); B(3)–B(8)(c); B(4)–B(8)(b); B(4)–B(9)(b); B(8)–B(9)(a); B(9)–B(12)(a); otherwise the average values for some of them are given.

****The values for three types of C–B bonds in *meta*-carbaborane and its derivatives (Nos.41–49) are quoted: C(1)–B(2), C(1)–B(4), and C(1)–B(5), or their average values are given. Seven types of B–B bonds are quoted: B(2)–B(3)(i); B(2)–B(6)(h); B(4)–B(5)(d); B(4)–B(8)(f); B(4)–B(9)(b); B(5)–B(9)(b); B(9)–B(10)(a); otherwise the average values of some of them are given.

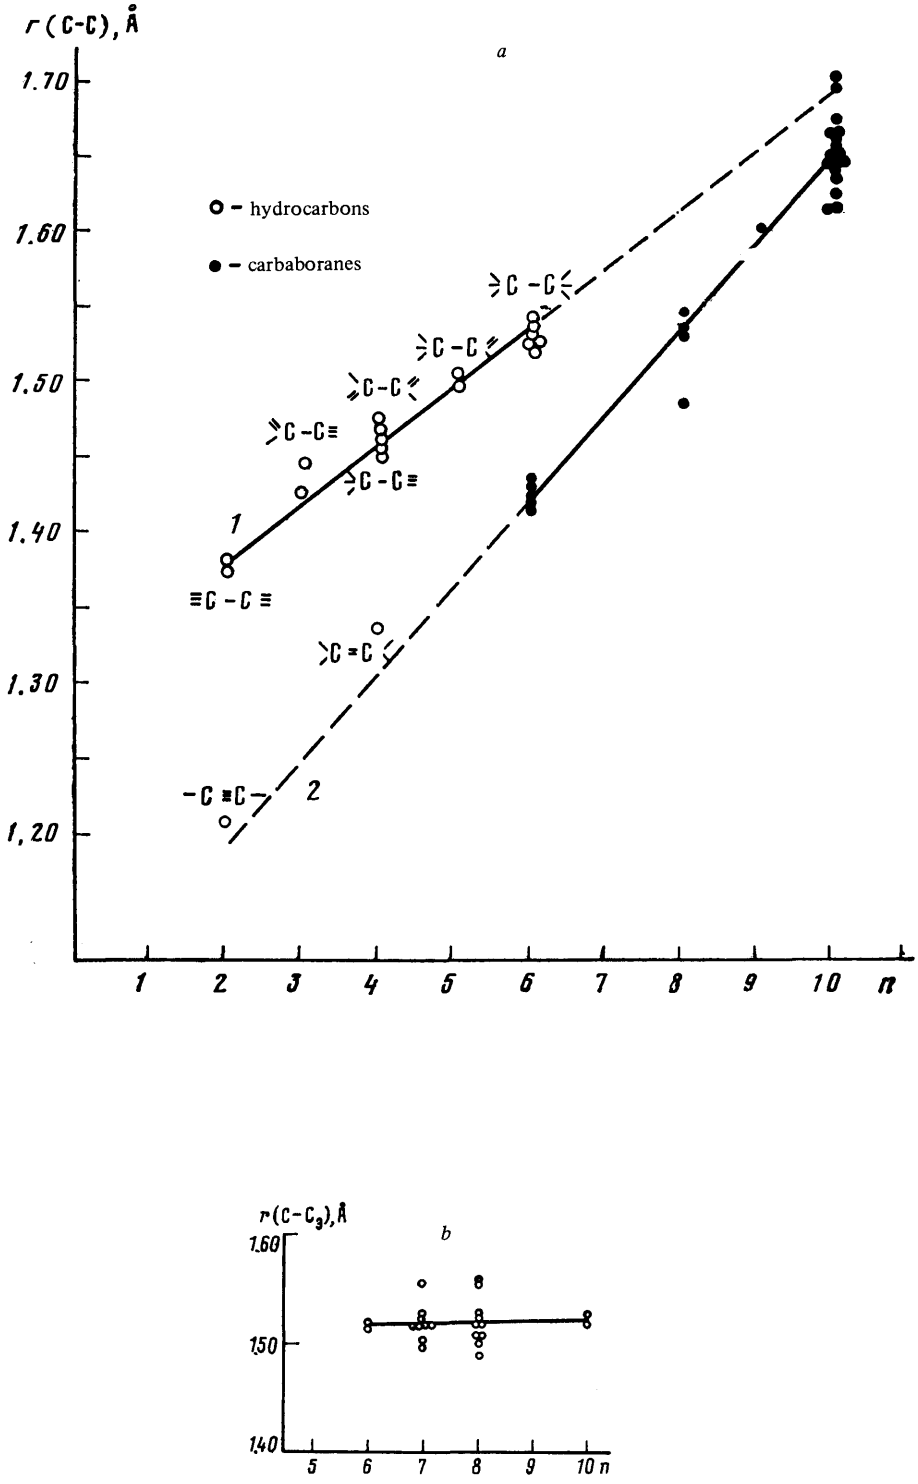

Figure 1. Variation of the C–C bond lengths in carbaboranes and hydrocarbons with the number n of neighbouring bonds: *a*) continuous line *1* corresponds to the variation of the bond lengths in hydrocarbons [see Eqn.(1)] and line *2* corresponds to the variation of the polyhedral distances in carbaboranes [see Eqn.(2)]; the dashed line represents the extrapolation of Eqn.(1) to the region of high C.N. of the carbon atom and the extrapolation of Eqn.(2) to the region of low C.N. of the carbon atom; *b*) variation of the exopolyhedral distances in carbaboranes [see Eqn.(3)].

the deviations from the latter, which in the case of *closo*-carbaboranes are indicated in Fig.2.

IV. POLYHEDRAL B–B BONDS

The uncertain role of the C.N. of the boron atom in C–B bonds becomes still more appreciable on passing to B–B bonds even in the simplest *closo*-carbaboranes with the following skeletons:

C_2B_3	C_2B_4	C_2B_5		C_2B_8	C_2B_{10}
(5) — (5)	(5) — (5)	(5) — (5)	(5) — (6)	(6) — (6)	(6) — (6)
1.853 (2)	1.724 (9)	1.659 (10)	1.772 (11)	1.850 (5)	1.792 (7)
			1.852 (11)	1.829 (4)	1.772 (13)

(for the corresponding references, see Table). The B–B bond lengths apparently depend to a large extent on electronic factors which are weakly related (or not related at all) to the C.N. One may note, by analogy, that in the stereochemistry of organic compounds not all the changes in C–C bond lengths depend on the C.N.: the most evident exceptions are cyclic hydrocarbons and sterically hindered molecules[54].

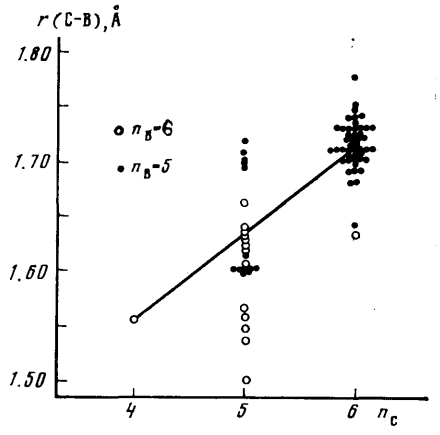

Figure 2. Variation of the C–B bond lengths in *closo*-carbaboranes with the C.N. of the carbon atom n_C. Different designations have been used for different C.N. of the boron atom (n_B). The straight line corresponds to Eqn.(4).

The anomalously long B–B bond in 1,5-$C_2B_3H_5$ [6] agrees with the quantum-chemical description of this molecule[55], which is represented as a bicyclic system consisting of three C–B–C bonds and without B–B bonds. For the remaining cases, a gradual increase of the B–B distances with increasing C.N. of the boron atoms can be seen. This agrees qualitatively with the proposed[53] atomic radii of boron with different coordination, but quantitative estimates are relatively inaccurate even in those cases where the geometry has been optimised[55,56].

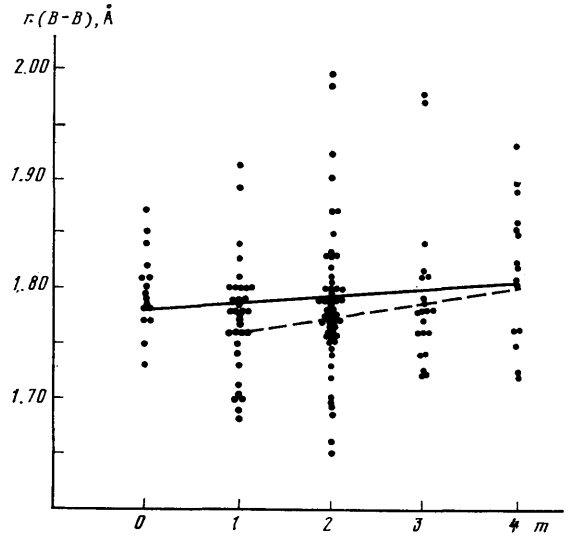
As a result of structural studies on carbaboranes, attempts have been made to specify the rules concerning the B–B distances.

1. In molecules of *p*-carbaborane 1,1,2-$C_2B_{10}H_{12}$ and its derivatives[3,27,28] and also in 1,10-$C_2B_8H_{10}$ [23] the B–B bonds at the bases of the pyramids are longer than the equatorial bonds.

2. The B–B distance included between two carbon atoms is longest in the molecules of certain small carbaboranes[15–17,22] and also in *m*-carbaborane 1,7-$C_2B_{10}H_{12}$ and its derivatives[3,42,44,45].

3. In the molecules of *o*-carbaborane 1,2-$C_2B_{10}H_{12}$ and its derivatives[3] there is a tendency towards an increase in the length of the B–B bonds near carbon atoms.

Although the proposed rules are not general (exceptions are known[18,19,34,46,48,49]), they are of considerable interest. They can be related to the distribution of charges on the boron and carbon atoms, which obey the so-called inductive rule[57]. According to this rule, boron atoms become electropositive when they are linked to carbon atoms. The inductive rule acquires a geometrical aspect when account is taken of the fact that the bond between two electropositive boron atoms should be weak and long and that an increase of the negative charge on the atoms should be accompanied by a strengthening and shortening of the bonds. Hence it follows that the longest B–B bonds are to be expected in the vicinity of carbon atoms and that the shortest B–B bonds are those at the maximum remove from them.



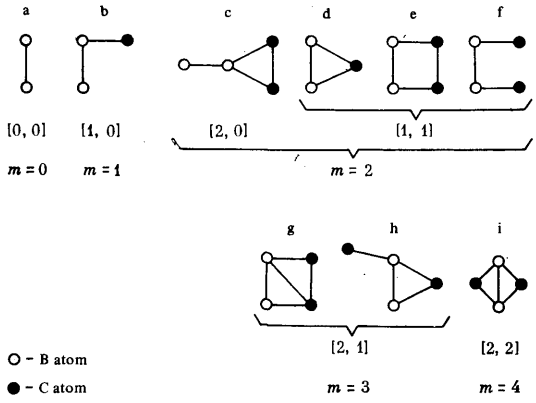


Figure 3. Variation of the B–B bond lengths in *closo*-carbaboranes with the overall number *n* of attached carbon atoms. The continuous line corresponds to Eqn.(5). The dashed line represents the corresponding relation for unsubstituted carbaboranes $C_2B_nH_{n+2}$.

As a result of this approach, it becomes clear that the empirical relations noted above are a direct consequence of a modified inductive rule. Furthermore, there is a possibility of a more detailed quantitative test of the applicability of this rule to the carbaboranes investigated. For this purpose, all the B–B bonds listed in the Table have been classified in terms of the [*k*, *l*[types; the numerals in square brackets show to how many carbon atoms each boron atom is linked.

The comparison of different B–B bonds is based on the overall characteristic $m = k + l$:

The results of a quantitative treatment of data for *closo*-carbaboranes alone are presented in Fig.3 and are described by the equation

$$r(\text{B—B}) = 1.780 + 0.006\,m(\text{Å});\ m = 0,\ 1,\ 2,\ 3,\ 4. \qquad (5)$$

For each type of B–B bond, there is a considerable scatter of values, but the average bond length is in all cases close to 1.80 Å. In order to eliminate the possible influence of substituents on the distribution of electron density in the skeleton, a calculation was performed taking into account only data for unsubstituted carbaboranes $C_2B_nH_{n+2}$. The final relation changed insignificantly, as shown by the dashed line in Fig.3.

Thus the analysis showed that the modified inductive rule is of limited applicability, being valid only for some molecules. In the remaining cases there are appreciable infringements of this rule, as a result of which the average B–B distances are almost independent of the distance from the carbon atoms in the molecules of *closo*-carbaboranes.

V. EXOPOLYHEDRAL B–X BONDS

The B–Hal bonds proved to be most thoroughly investigated among the exopolyhedral bonds formed by boron atoms in carbaboranes. Compared with, for example, the C–I bond mentioned above, their specific features consist in the fact that all the B–Hal distances in the carbaboranes investigated[13,30,32–34,42,43–48], where Hal = Cl, Br, or I, are greater by 0.01–0.1 Å than the corresponding distances in the simplest compounds of the type $BHal_3$.[58]# This is consistent with the fact that the electron-accepting properties of the C_2B_{10} carbaborane nucleus are manifested much more weakly in relation to the substituents attached to the boron atoms than in relation to the substituents at the carbon atoms[59]. It is also of interest to note that, in contrast to the C–H bonds (see above), the B–Cl vibration frequencies in carbaboranes are lower than in the B_2Cl_4 and BCl_3 molecules[60].

#The only exception is the B–Cl distance in the $1,7\text{-}C_2H_2B_{10}H_7CH_3ClI$ molecule (1.69 Å),[44] which is somewhat smaller than in BCl_3.

The B–C distances in the four carbaboranes investigated[25,36,39] are 1.55–1.60 Å, which is close to the B–C distances in the $B(CH_3)_3$ (1.578 Å)[61] and $1\text{-}CH_3B_5H_9$ (1.595 Å)[62] molecules and to values expected on the basis of Eqn.(4) (Fig.2) for the polyhedral C–B bonds with $n_C = 4$. For $1,2\text{-}C_2B_{10}$. $.(CH_3)_4H_8$, this distance is significantly longer (1.68 Å).[44]

The B–B distance between the two carbaboranyl systems in $(1,2\text{-}C_2B_{10}H_{11})_2$ is 1.660 Å,[27] which is appreciably smaller than the polyhedral distances of the same type, but is close to the corresponding distance (1.686 Å)[63] between the *closo*-borane fragments in $10,10'\text{-}\{B_{10}H_8[S(CH_3)_2]\}_2$ and to the distance (1.678 Å)[64] in its analogue $2,2'\text{-}(1\text{-}B_9H_8S)_2$.

---o0o---

It is seen from the foregoing that individual aspects of the geometrical structures of carbaboranes have now been investigated in fair detail. This applies primarily to the structure of *closo*-carbaboranes and especially to the structure of the icosahedral carbaboranes with the C_2B_{10} skeleton. The accumulated data permit a classification of the internuclear distances and make it possible to discover certain rules in the variation of the polyhedral bonds in carbaboranes. The exopolyhedral C–X and B–X bonds have been studied much less, although they undoubtedly merit a special systematic investigation.

During the preparation of this article, two reviews devoted to the chemistry of carbaboranes were published[65,66], which demonstrates yet again the vigorous development of this field of chemistry.

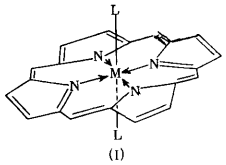
The Formation, Structure, and Properties of the Extracomplexes of Porphyrins

B.D.Berezin and O.I.Koifman



The results of studies on the extracomplexes of metalloporphyrins namely the conditions of their formation, structure, spectroscopy, kinetics, and thermodynamics, are considered.
The bibliography includes 245 references.

I. INTRODUCTION

Extracoordination in metalloporphyrins is one of the most important properties of compounds of this class[1]. Extracoordination is understood as additional coordination by a stable planar complex species (for example, a metalloporphyrin) or ligands occupying the fifth, sixth, etc. coordination sites in the inner coordination sphere of the metal and located above and below the plane of the initial stable complex; this results in the formation of the extracomplex (I)

(I)

If the extraligands in (I), i.e. the additional ligands, add to the fifth and sixth coordination sites along the z axis perpendicular to the plane of the molecule of the complex, the resulting complex has come to be referred to in coordination chemistry as an axial complex and the ligands are referred to as axial ligands. Numerous extracomplexes of porphyrins in which the ligands are not axial have now been obtained; consequently, the concepts of the "extracomplex" and "extracoordination" are wider than those of the "axial complex" and "axial coordination".

Depending on the nature of the metalloporphyrin (MP) and the nature and concentration of the extraligand, monoligand (LMP) or biligand (L_2MP) extracomplexes of metalloporphyrins are formed as a rule:

$$MP + L \rightleftharpoons LMP + L \rightleftharpoons L_2MP. \quad (1)$$

The molecules of water, organic solvents, nitrogen-containing heterocycles, aliphatic and aromatic amines, polypeptides, and proteins are most frequently used as the extraligands, while the acido-ligands are halide, acetate and other carboxylate, CN^-, OH^-, O^{2-}, HO_2^-, etc. ions.

Much attention is being devoted nowadays to experimental and theoretical studies to extracomplexes and the phenomenon of extracoordination to metalloporphyrins. The great interest in the extracomplexes of porphyrins is due to the fact that the most important biological functions of metalloporphyrins such as photosynthesis, the fixation and transport of oxygen by blood haemoglobin, and other enzymatic processes are associated primarily with the extracoordination of H_2O, O_2, H_2O_2, nitrogen-containing heterocycles, proteins, and other molecules. It is most likely that the catalytic activity of MP in both enzyme and chemical catalysis is due to the possibility of the formation of mono- and bi-ligand extracomplexes. Extracoordination ensures that the reacting molecules in the extracomplex are linked to one another. The ready reversibility of the formation of the extracomplex, and the possibility of chemical and photochemical oxidation-reduction reactions involving the complex.

It has been established[2] that chlorophyll strongly coordinates one water molecule to form an aquo-extracomplex. In combination with a protein molecule, which can also be part of the extracomplex, this complex is involved in the first (photophysical) stage of photosynthesis (and possibly also in the photochemical water oxidation stage).

The physical chemistry of extracoordination has been investigated for a long time, starting with the first studies by Williams[3]. However, until the 1970's the majority of the investigations were not systematic. From the 1970's the number of investigations of the extracomplexes of porphyrins (of their structure, spectroscopy, the thermodynamics of their formation, etc.) increased sharply. This review represents an attempt to survey the extensive data on extracomplexes which have accumulated hitherto: the conditions of their formation, structure, spectroscopy, kinetics, and thermodynamics; it deals only with the most fundamental studies.

II. GENERAL PRINCIPLES OF THE FORMATION OF EXTRACOMPLEXES OF METALLOPORPHYRINS

Depending on the strength of the metal–porphyrin coordination interaction, which is determined by the degree of covalence of the N–N dative bonds, i.e. the electronic structure of the porphyrin, the structure and charge of the cation, as well as steric factors, metalloporphyrins can be divided into coordination-saturated and coordination-unsaturated[1]. The former have a 2+ charge on the metal ion and form extremely stable covalent dsp^2-hybrid complexes (Cu^{2+}, Pt^{2+}, Pd^{2+}). Ions forming part of the coordination-saturated MP do not have low-energy non-bonding orbitals; their effective charge is low and they show little tendency to combine with extraligands regardless of the nature of the porphyrin molecule and the solvent. Naturally in the gas phase

the addition of extraligands to them takes place nevertheless[4], because the absolute coordination saturation of atomic-molecular species is virtually impossible. There are data[5] indicating the formation of very unstable monoligand extracomplexes by the porphyrin complexes of copper and nickel in solution.

Coordination-unsaturated porphyrin complexes contain ions which, having a formal 2+ charge, do not tend to undergo dsp^2-hybridisation (Zn^{2+}, Fe^{2+}, Cr^{2+}, Mn^{2+}), have unstable oxidation states (Co^{2+}, Re^{2+}), form predominantly ionic complexes with a weakly neutralised charge (Be^{2+}, Mg^{2+}, Cd^{2+}, Hg^{2+}, Ca^{2+}, Ga^{2+}), and all have a formal charge greater than two (Co^{3+}, Ru^{3+}, Al^{3+}, Ga^{3+}, Fe^{3+}, Mn^{3+}, Os^{4+}, Sn^{4+}, Ti^{4+}, VO_2^{2+}, UO_2^{2+}).[1] The subdivision of the central atoms in the MP into two groups—with coordination numbers of 5 and 6—of the kind carried out by Falk[6] cannot be regarded as desirable. The point is that, as a result of the strong saturation of the chemical affinity of the metal by the porphyrin molecule in the case of Mn^{2+} and in addition by the counterion in the case of Mn^{3+} the energy of subsequent coordination of extraligands usually proves to be so low that the degree of the overall extrainteraction cannot be measured and assessed quantitatively by the existing spectroscopic and thermodynamic methods. The nature of the extraligand plays a considerable role in the coordination of extracomplexes; extraligands containing N, O, P, and S atoms, and, as already mentioned, acido-ligands as the electron-donating species are mainly investigated nowadays. The formation of extracomplexes is naturally regulated by the thermodynamics of their formation.

1. Synthesis of Extracomplexes

The synthesis of extracomplexes of porphyrins and phthalocyanines has been described in many studies. The formation of extracomplexes of iron[7-31], cobalt[32-38], manganese[39,40], rhenium and technetium[41-43], rhodium[43-46], ruthenium[43,47,48], iridium[49], osmium[49], chromium[37], yttrium, lutetium, and thorium[50,51], and almost all the lanthanides except cerium and promethium[52] has been studied. Fairly detailed information about the extracomplexes synthesised and isolated in a crystalline state has been given in a review[53].

The formation of anionic extracomplexes of porphyrins, incorporating cations with a charge greater than two, takes place spontaneously in the synthesis of metalloporphyrins from porphyrin (H_2P) and a salt:

$$H_2P + MX_{(n+2)} \rightarrow (X)_nMP + 2HX \qquad (2)$$

($n = 1,2,3,4$; X = any singly charged anion). The anion X can then be substituted by any other anion on treatment of the extracomplex $(X)_nMP$ with solutions of salts or acids[20,36,37,54]. In the presence of water there is a possibility of hydrolysis:

$$MP \quad MP \qquad (3)$$

In many instances there is a possibility of the formation of a μ-oxo-dimer:

$$2OHMP \rightleftharpoons MPO\text{-}MP + H_2O \qquad (4)$$

or an oxo-extracomplex:

$$(OH)_2MP \rightleftharpoons O = MP + H_2O. \qquad (5)$$

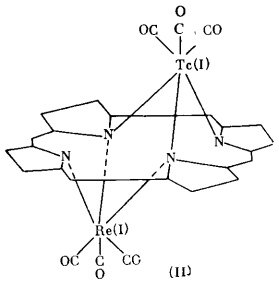
Complexes of Al^{3+}, Ga^{3+}, Cr^{3+}, Sn^{4+}, Si^{4+}, and Ge^{4+} are formed readily in reaction (3).[53] Reaction (4) is preferred for Sc^{3+}, Fe^{3+}, and In^{3+}, which is attributed[55] to the ease of displacement of the metal atom from the plane of the porphyrin molecule (see Section III), but the metals in the first list are also capable of forming μ-oxo-dimers. Complexes of Ti^{4+}, V^{4+}, Nb^{5+}, Mo^{5+}, W^{5+}, Re^{5+}, and Os^{6+} are formed via reaction (5).[53]

If a coordination-unsaturated MP and an extraligand are the initial reactants, the extracomplex is formed in a homogeneous phase when solutions of the metalloporphyrin and the extraligand in a weakly coordinating solvent are mixed; the concentration of the extraligand should usually greatly exceed that of the MP. Depending on the nature of the MP and the extraligand, the equilibration time varies from several minutes to several days. The extracomplexes of metalloporphyrins containing a readily oxidisable metal atom are obtained in an inert gas; the solvent is slowly evaporated in order to obtain solid complexes—in some cases *in vacuo*[23,24]. Thus, in order to obtain $L_2Fe^{+}PP$ (H_2PP = protoporphyrin) with a series of substituted imidazoles as the extraligands L, a suspension of protohaemin in a solution of the extraligand is shaken for 50 h.[10] The extracomplexes of iron-phthalocyanine FePc with amines[13], LCoPc, and L_2CoPc (L = pyridine or 4-methylpyridine) have been obtained similarly[32,33].

The extraligand can also be introduced into the complex in a chromatographic process. The presence of water in chromatography on Al_2O_3 or silica gel frequently leads to the substitution of the extraligand or to hydrolysis with subsequent reactions (3), (4), and (5).[53]

The extraligands and solvents employed must be carefully purified. It has been noted[53] that the most suitable solvents are methylene chloride and chloroform, which should be freed from alcohols and hydrochloric acid (otherwise alkoxo- and chloro-extracomplexes are formed). It has been observed[56,57] that *ortho*-substituted pyridines form extracomplexes only in the presence of negligible amounts of sterically unhindered pyridines as impurities.

The addition of gaseous NO as extraligand to ClFeTPP (H_2TPP = tetraphenylporphin) has been described[9,12]. A convenient method has been developed for the synthesis of porphyrin extracomplexes from metal acetylacetonates and octaethylporphin in quinoline and in imidazole and phenol melts[37]. The yield of extracomplexes varies from 55 to 85%, phenol constituting the most favourable reaction medium. The synthesis of Cr^{3+} complexes in diethylene glycol led to the formation of extracomplexes with unidentified extraligands, which forced the authors[37] to recrystallise the extracomplex. We may note that crystallisation is sometimes used as a method of obtaining extracomplexes[58].

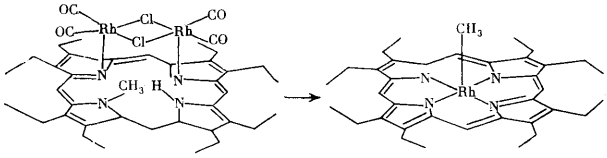


Complexes with tetra-arylporphyrins in which β-diketones serve as the extraligands have been obtained from lanthanide β-diketonates[52].

Metal carbonyls were used for the first time to synthesise extracomplexes of metalloporphyrins by Tsutsui et al.[59] The development of these methods is an important achievement in the synthetic chemistry of MP and their extracomplexes. New metalloporphyrins with chromium, molybdenum, technetium, ruthenium, rhodium, rhenium, and iridium have been obtained by the reaction of metal carbonyls and metal carbonyl halides with porphyrins[42,46,48,49,60-77]. With the exception of chromium and molybdenum complexes, the carbonyl groups used as extraligands are firmly retained at the central atom[43] and the number of carbonyl groups located on one side of the plane of the MP molecule varies from one for Ru and Ir to two for Rh [44,45] and three for Tc and Re.

Unusual extracomplexes of metalloporphyrins have been obtained[41] by heating $Re_2(CO)_{10}$ and $Tc_2(CO)_{10}$ in decalin†;[41]

† The term "axial complexes" cannot be applied to these complexes of metalloporphyrins as well as many others.



they have the structure

(II)

Formally these MP cannot be called extracomplexes. Their structure resembles that of the intermediate formed in many instances in the coordination of porphyrins to certain metal salts[78].

The synthesis of compound (III) from *N*-methyloctaethylporphin and $[Rh(CO_2)Cl]$, the product being converted on slight heating in chloroform or in the course of chromatography on silica gel into methylrhodium-octaethylporphin (IV),

(III) (IV)

i.e. a compound which is not an extracomplex of rhodium but combines the properties of a complex and an organometallic compound, has been described[46]. Numerous similar instances are now known. In conclusion we should note that the extracomplexes of iron- and cobalt-porphyrins merits particular attention in view of their catalytic activity, which is undoubtedly associated with extracoordination. These complexes have been examined in fair detail[53].

III. STEREOCHEMISTRY OF THE EXTRACOMPLEXES OF METALLOPORPHYRINS

The influence of the nature of the central atom as well as the structure of the porphyrin molecule and the extraligand on the M–extraligand bond length and on the position of the metal atom relative to the plane of the coordinating nitrogen atoms of the porphyrin molecule is examined below. These structural factors determine the physicochemical properties of the extracomplexes of metalloporphyrins.

The structure of many complexes has been determined by X-ray diffraction (Table 1). Table 1 lists the M–extraligand bond lengths for certain monoligand (tetragonal pyramid) and biligand (distorted octahedron) extracomplexes of porphyrins (Fig. 1).

It is known that the central atoms in MP capable of existing without an extraligand are located in the plane of the molecule (for example, Ni, Cu, and Pd). On the other hand, the formation of monoligand extracomplexes[33,39,79–94] leads to the displacement of the metal atoms from the plane of the porphyrin molecule, the deformation of the porphyrin skeleton, and in many instances the non-equivalence of the $M-N_{porph}$ bonds (where N_{porph} is a porphyrin nitrogen atom) in the solid phase. Depending on the nature of the complex, the metal atom is displaced from the plane of the porphyrin ring by 0.2–0.6 Å. It is noteworthy that, despite the apparent abundance of the results listed in Table 2, the dependence of the displacement of the metal atom from the molecular plane on the nature of the porphyrin, the central atom, and the extraligand virtually cannot be described in general terms in view of the lack of data in which only one of the above factors is varied.

** Here δ is the degree of displacement of the metal atom from the plane of the four nitrogen atoms.

The displacement of the central atom from the molecular plane has been attributed[91,94] to the considerable resistance of the porphyrin ligand to external deforming influences, the incomplete charge transfer from the porphyrin to the central atom, and the repulsion of the electron shells of the extraligands and the nitrogen atoms of the macroring.

From the standpoint of the chemistry of coordination compounds, the displacement of the central atom in the extracomplexes of metalloporphyrins under the influence of the extraligand can be due to three main causes: (1) the stepwise nature of the complex formation, (2) the interaction of the force fields of the metal and the first extraligand entering the complex, and (3) the repulsion of the electron shells of the extraligand and the π-electron cloud of the porphyrin macroring. The contributions of these individual factors to the geometry of the extracomplex can vary markedly as a function of the configuration of the porphyrin molecule and the nature of charge of the metal and the extraligand.

It has been suggested[91] that large extraligands, resembling the chloride ion, always cause a marked breakdown of the planarity of the coordination unit of the metalloporphyrin; small extraligands may not distort significantly the planar configuration of the MP. This postulate is valid for ClMnTPP and ClFePP, but it does not hold for ClCoTPP, in which the displacement of Co from the molecular plane is very slight. The latter can be explained by the fact that the cobalt ion in the complex is of the low-spin type and therefore has a comparatively small effective radius. On the other hand, the iron complex is of the high-spin type; its antibonding molecular orbitals, formed with participation of the d_{z^2} and $d_{x^2-y^2}$ orbitals of the metal, are filled, which leads to an increase of the effective radius and to the displacement of the central atom from the plane of the porphyrin[95].

The most significant displacement from the molecular plane is caused by the entry (substitution) of the first extraligand. The entry (substitution) of the second extraligand either diminishes the displacement from the molecular plane[27,96-99] or, as a rule, reduces it to zero[8,41,47,100,101-111] when both extraligands are of the same type (Table 2).

On the basis of ideas concerning the radius of the central cavity of the porphyrin, which determines the distance between each nitrogen atom and the centre of the molecule (Ct) (Fig. 1), Hoard[112] concluded that the metal can be located in the plane formed by the four nitrogen atoms, provided that the metal–nitrogen bond length is equal to the Ct–N distance (it amounts to $\leq 2.015 \pm 0.007$ Å). For example, according to Rifkind[113], the high-spin iron complexes (the Fe–N bond length is 2.061 ± 0.012 Å) cannot be planar, while the low-spin complexes (Fe–N = 1.91 Å) can be planar. However, the Fe–N bond length in the complex $Cl(pip)_2$FeTPP is 2.127 Å (Table 2), which does not lead to the displacement of the Fe from the plane of the ring[96].

Data for complexes of iron-containing porphyrins with proteins and other bioligands have been analysed in two reviews[113,114].

IV. PHYSICAL PROPERTIES OF THE EXTRACOMPLEXES

The typical electronic absorption spectra of porphyrins and metallo-porphyrins are their most important characteristics. Absorption spectroscopy is most widely used in the study of processes associated with extracoordination[5,9,14,25,45,47,81,82,91,114-137], due to the considerable possibilities of the method. Absorption spectroscopy is most frequently used to follow the formation of extracomplexes in solutions, to determine the number of extraligands combined, and to measure the stability of the extracomplexes.

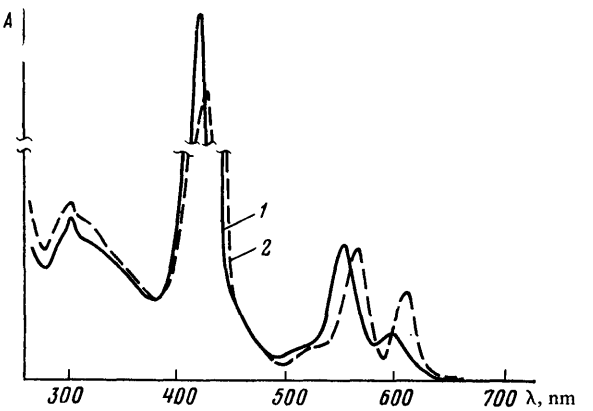

Figure 2. Electronic absorption spectra of ZnTPP (curve *1*) and its extracomplex (DMSO)ZnTPP (curve *2*) in CCl_4 at 25 °C.

A theoretical discussion of the absorption spectra of porphyrins and metalloporphyrins has been described in a monograph[138] and partially by Berezin[1]. However, the spectroscopy of the extracomplexes of porphyrins have been hardly discussed in the above publications. There have been a number of studies specially devoted to the electronic spectra

of the extracomplexes of porphyrins and phthalocyanines[14,36,91,139,140]. The positions and intensities of the absorption bands have been published[37,114] for a large number of extracomplexes of octaethylporphin.

The absorption spectra of metalloporphyrins in the range 350–750 nm consists as a rule of three bands[138]: the Soret band located in the near ultraviolet and two bands in the visible part of the spectrum (Fig. 2). The absorption bands of the MP are due to the $\pi-\pi^*$ transitions in the porphyrin molecule, which are described satisfactorily in terms of the four-orbital Simpson–Platt–Gouterman model[141,142]. The addition of extraligands is accompanied by a 5–35 nm shift of the absorption bands (Fig. 2). The magnitude of the shift and its direction (bathochromic or hypsochromic) depend on the nature of the central atom of the MP, the extraligand, and the structure of the porphyrin.

It is interesting to reproduce the essential feature of a brief analysis of the bathochromic and hypsochromic shifts of the absorption bands of the extracomplexes based on Berezin's data[1]. The extracomplexes of metalloporphyrins constitute one of the groups of mixed complexes. The characteristics of the formation of complexes with a mixed coordination sphere and the characteristics of the compatibility of the ligands in these complexes have been analysed in detail[143]. In the inner coordination sphere ligands of a similar electronic type (for example, σ-donor, π-acceptor, and electrostatic) are most compatible. It is therefore to be expected that π-ligands such as pyridine, imidazole, CN^-, dimethyl sulphoxide (DMSO), CO, O_2, and others of a similar type with both σ-donor and π-acceptor properties will enter more readily the coordination spheres of porphyrin complexes.

Allowance for only the electronic interaction of the extraligand with the MP makes it possible to use the concept of the electronic effects of coordination in planar macrocyclic complexes developed by Berezin[1,144] and to achieve a simpler treatment of the changes in the properties of MP on extracoordination of ligands; this approach is justified in many instances. According to it, for metals with an unfilled d shell the extraligands with suitable π orbitals can enter into a competitive interaction with the dxy, dxz, and dyz orbitals of the metals. As a result, the $d_\pi-p_\pi$ metal–porphyrin interaction is weakened due to the $d_\pi-p_\pi$ interaction of the metal with the extraligands and the role of the metal–porphyrin σ-interaction increases. The coordination of π-acceptor ligands should therefore result in a hypsochromic shift of the first band in the electronic spectra of MP, provided that the extraligands are indeed involved in the π-interaction with the metal atom[3]. The changes in the electronic spectra show that there is not only an electrostatic MP–ligand interaction but also a donor–acceptor interaction between the ligand and the metal atom[138].

In those cases where the central metal atom in the porphyrin complex has closed stable electronic orbitals (the overall orbital moment and the spin are zero), the formation of dative metal–ligand π-bonds becomes virtually impossible. Such cases occur in the metalloporphyrins of Mg^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, etc., where the interaction is limited to the σ-binding of the extraligand by the d^2sp^3 orbitals or ion–dipole attraction. In both cases the extraligand increases the electron density at the metal atom and decreases the degree of its σ-interaction with the porphyrin, so that one should expect a bathochromic shift of the first band in the electronic absorption spectrum of the complex.

The above interpretation of the spectra does not conflict with experiment, provided that the geometrical parameters of the coordination centre of the MP, particularly the coordinates of the metal and the nitrogen atoms linked to it, are not altered. If a displacement of the metal from the plane of the N atoms or the opposite movement is observed in extracoordination, an unambiguous solution of the problem of the nature of the spectroscopic changes in the extracoordination is still difficult. Thus examples of both hypsochromic[125] and bathochormic[122] shifts of the first band in the spectra of cobalt complexes of porphyrin are known. A hypsochromic shift of the first band has been observed for the iron complexes[137].

Despite numerous studies devoted to extracoordination to porphyrins, there are still no systematic studies of the dependence of the absorption spectra of extracomplexes on the nature of the central atom, the extraligand, and the porphyrin under comparable conditions. It is therefore at present difficult to establish rigorous correlations between the M–N bond lengths, the band shifts in the electronic absorption spectra, and the thermodynamic parameters of the extracoordination reaction.

A number of studies by other spectroscopic methods have appeared recently in the literature. EPR has been used for the extracomplexes of cobalt-, iron-, and manganese-porphyrins. Problems associated with the determination of the stoichiometry of the mono- or bi-ligand complexes formed[32,145] and of the spin state of the central atom[82,146–148] have been solved mainly by EPR, which also proved to be an effective method for the detection of cobalt-oxygen complexes[32,121,145,147].

It has been shown by EPR [121] that at −45 °C in air in the presence of imidazole or benzimidazole, CoPP forms a 1:1 complex of the type $(L)(O_2)(CoPP)$, which rapidly decomposes at room temperature with formation of $(L)CoP(O_2)PCo(L)$. It is believed[121] that bridged complexes should be characteristic of cobalt extracomplexes. On the basis of a study of the EPR spectra of CoPP in dimethylformamide (DMF), Stynes and Ibers[149] concluded that the greater the basicity of the extraligand the smaller the capacity of cobalt for oxidation. This conclusion is probably not general[145].

NMR has been used to determine the thermodynamic and kinetic parameters of the extracoordination reaction (see Sections V and VI), to determine the structure of the extracomplex[41,47,150], and to investigate the exchange of extraligands[151]. It has been correctly stated[152,153] that the calculation of K_{st} from NMR data is complicated by the solvent–solute interaction. In general a change in the nature of the extraligands is reflected to a greater extent in the chemical shifts of the protons of the methyl and α-methylene groups and of the meso-protons of the paramagnetic complexes. These data do not allow a distinction to be made between contact and pseudocontact shifts, which hinders the estimation of the effects of extracoordination and association[114]. It has been suggested[114] that the resulting contact shifts depend on the degree of type of interaction between iron and the nitrogen atoms of porphyrins, which depend in their turn on the differences in the binding of the central atom to the extraligands.

Infrared spectra have been used mainly to identify extracomplexes and extraligands. Analysis of the infrared spectra of haemins have led to the conclusion[114] that the nitrogen atom is displaced from the plane of the porphyrin ring by 0.5 Å or more.

Lack of space precludes a detailed examination of all the spectroscopic data for the extracomplexes of porphyrins. Numerous EPR [32,35,82,121,131,135,146–149,154–160], NMR [20,23,38,41,47–49,52,114,150,151,161–171], infrared spectroscopic[9–13,137,172–177], Raman spectroscopic[178–180], and Mössbauer spectroscopic[21,30,82,114,181–186] studies as well as studies based on magnetic circular dichroism spectra[187–189] have been made on porphyrin extracomplexes. The spectroscopic methods yield much useful information about porphyrins, but the lack of

systematic specific investigations hinders a general survey of these data.

The magnetic properties of metalloporphyrins and their extracomplexes are of considerable interest, since they make it possible to determine directly the oxidation state of the central metal atom. Magnetic properties depend significantly on the presence of extraligands in the molecule. Table 2 lists the magnetic properties of certain metalloporphyrins. The results of magnetic measurements have been discussed in detail in the literature[152,153].

V. KINETICS OF THE FORMATION OF THE EXTRACOMPLEXES

Information about the state of extraligands and the nature of their bonds with the metal atom in the extracomplex can be obtained by studying the kinetics of the formation and dissociation of these complexes. Several tens of studies on the kinetics of the formation of extracomplexes of metalloporphyrins and phthalocyanines have been published recently.

Blyumenfel'd[190] established for the first time (on the basis of the rate of substitution of one protein by another in a *gem*-protein complex saturated with O_2 and CO) that the rate of elimination of globin from the oxygenated protohaem (O_2). .FePP is limited by the rate of elimination of O_2, i.e. by the rate of the reaction

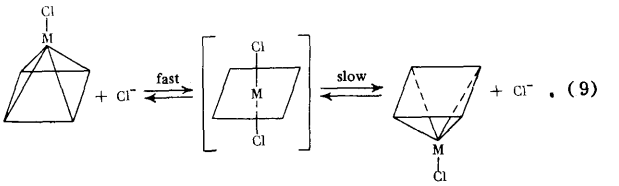
$$(O_2)\text{FePP} \rightleftharpoons O_2 + \text{FePP}. \qquad (6)$$

The rate constant for the reaction proved to be $k_V = (5 \pm 2) \times 10^5\ s^{-1}$; such a high rate is evidence for a low strength of the Fe–O_2 covalent bond. The activation energy for the reaction

$$(\text{globin})\text{FePP} + O_2 \rightarrow (\text{globin})O_2\text{FePP} \qquad (7)$$

is close to zero.

On the other hand, for the reverse reaction, it is 21 ± 1.5 kcal mol^{-1}, which is due to the simultaneous abstraction of O_2 and protein imidazole residue from the Fe atom. The considerable possibilities of the kinetic method for the investigation of phenomena based on extracoordination were demonstrated in the same study[190].



The imidazole exchange in low-spin iron(II) complexes of porphyrins (tetraphenylporphyrin, octaethylporphyrin, and protoporphyrin) has been studied[151] by ^1H NMR. Depending on the nature of the porphyrin, the rate of the exchange reaction

$$(\text{N–CH}_3\text{im})_2\text{FeTPP} + \text{N–CH}_3\text{im}^* \underset{\tau_{-1}}{\overset{\tau_1}{\rightleftarrows}} (\text{N–CH}_3\text{im})^*(\text{N–CH}_3\text{im})^*\text{FeTPP} + \text{N–CH}_3\text{im} \qquad (8)$$

can vary by an order of magnitude, which proves that the binding of imidazole to FePP is covalent.

It has been observed[191] that, under the influence of the extraligand, the metalloporphyrins ClFeTPP(p-CH_3)$_4$ and ClFeOEP undergo inversion with the rate constants of 15×10^2 and 60 s^{-1} respectively. It follows from these data that the rate of inversion determines the strength of the extracoordination of the second extraligand: as a result of the reduced effective charge on FeOEP compared with FeTPP, the strength of the binding of Cl^- to the former is smaller, the fraction of $(Cl)_2$FeOEP is small, and the rate of inversion is low.

An S_N2 mechanism has been proposed for the process

(9)

The rate of inversion was investigated later[20] and the activation parameters were calculated for a series of porphyrins; the data presented in Table 3 indicate the presence of solution of mono- and bi-ligand extracomplexes and show that their stabilities are different. Evidently the inversion reactions are virtually isentropic and the differences between their rates are caused mainly by the differences between the activation enthalpies for the inversion process, i.e. are associated with the stability of the extracomplexes. It is noteworthy that studies similar to that described above[20] can prove useful for the understanding of the detailed mechanisms of the formation and dissociation of porphyrin complexes, particularly with metals such as iron, cobalt, and manganese.

Table 3. Activation parameters for the inversion reaction (6).[20]

Extracomplex	extra-ligand	k^{298}, $m^{-1}\ s^{-4}$	$\Delta G^{\neq}$, kcal mol^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$-\Delta S^{\neq}$, e.u.
(Cl)FeTPP(p-CH_3)$_4$	Cl	$(5.6\pm1.4)\cdot10^2$	14.2±1.2	9.1±0.8	17±4
(I)FeTPP(p-CH_3)$_4$	I	$(5.9\pm1.2)\cdot10^3$	12.2±0.6	6.5±0.3	19±2
(Cl)FeOAEP	Cl	$(5.8\pm1.2)\cdot10$	15.0±1.0	8.8±0.5	21±2
(I)FeOAEP	I	$(9.0\pm1.6)\cdot10^2$	13.2±0.4	7.2±0.2	20±2

The self-reduction of Fe^{3+} to Fe^{2+} has been observed in the interaction with ClFeTPP with piperidine in $CDCl_3$.[192] In the presence of the cyanide ion and oxygen, continuous oxidation-reduction of iron takes place.

The kinetics and thermodynamics of the substitution of O_2 as an extraligand by an excess of the main extraligand in $(L)(O_2)$FeTPP, where L = pyridine piperidine, or 1-methylimidazole, have been investigated[193]:

$$(L)(O_2)\text{FeTPP} \xrightarrow[k_V]{\text{slow}} (L)\text{FeTPP} + O_2\ , \qquad (10)$$

$$(L)\text{FeTPP} + L \xrightarrow{\text{fast}} (L)_2\text{FeTPP}. \qquad (11)$$

For the extraligands enumerated, reaction (10) is characterised by the following rate constants respectively: $k_V = 4.3 \times 10^{-3}$, 2.3×10^{-3}, and $0.17 \times 10^{-3}\ s^{-1}$. The corresponding sequence based on the variation of the rate constants for the elimination of O_2 is due to the decrease of the π-donor activity of the central Fe(II) atom, which takes place under the influence of the change in the type and strength of the Fe–L bond and the effective charge on the iron atom. It also follows from the above data[193] that the strength of the binding of O_2 is determined not only by the π-acceptor but also by the σ-donor properties of extraligands.

In a study of the kinetics and thermodynamics of the binding of CO and O_2 to $(L)_2$FeTPP, Weschler et al.[19] used the same extraligands as in the previous study[193]. The reaction

proceeds in accordance with the equations

$$(L)_2FeTPP \rightleftharpoons (L)FeTPP + L; \quad (12)$$

$$(L)FeTPP + O_2 \rightleftharpoons (L)(O_2)FeTPP; \quad (13)$$

$$(L)FeTPP + CO \rightleftharpoons (L)(CO)FeTPP. \quad (14)$$

The study of the rate of the process as a function of the O_2 and CO concentrations Weschler et al.[19] to suggest a dissociative mechanism with formation of the extracomplex L(Fe). TPP. The rate of formation of the complexes with O_2 and CO decreases in the sequence pyridine > piperidine > 1-methylimidazole due to the increasing strength of σ- and π-binding of the extraligands.

It follows from the above data[19,193] that the strengthening of the π-donor properties of the extraligand in processes similar to reactions (10)–(14) leads to a decrease of the strength of the M–O_2 bond in the extracomplex. However, in a study of the interaction of O_2 with FePP in the presence of 2-picoline, 2-methylimidazole, and t-butyl alcohol, Wagner and Kassner[116] concluded that the coordinating properties of the extraligands are insignificant for the binding of O_2 and that ligands of the type of imidazole are not unique extraligands in this process. This conclusion is probably erroneous, since it has been shown in a number of studies[1,194] that π-binding determines the competition between the extraligands for *d* electrons (the *trans*-influence discovered by Chernyaev[195] plays a significant role here).

The electronic nature of the *trans*-influence, examined from modern standpoints in a number of studies, for example by Bersuker[196], can serve as the basis of the treatment of extracoordination to iron-porphyrins[1]. Comparison of the properties of imidazole with those of other nitrogen-containing protein residues led to the conclusion[194] that none of the latter creates more favourable conditions for the addition of O_2 than imidazole.

The reaction of $(pip)_2FePP$ with CO has also been studied by other workers[197,198], but fundamentally new information was not obtained. The substitution of water in diaquoiron(III)- and diaquocobalt(II)-haematoporphyrins by CN^- and SCN^- ions has been described[151,153,199]. The kinetics of the binding of CN^- and imidazole by haemin in micelles have been investigated[200]. A polarographic study has been made[201] of ClFePP in the presence of nitrogen-containing bases (4-cyanopyridine, 4-acetylpyridine, pyridine, 4-phenylpyridine, 4-aminopyridine, piperidine, pyrazole, benzimidazole, 5,6-dimethylimidazole, and imidazole). This study is interesting in connection with the observed linear relation between the pK_B of the nitrogen-containing bases and the rate of electron transfer. The correlation has been explained by the change of ligand environment and the spin state of iron.

Several interesting studies have been made on iron-phthalocyanines[202–206]. The kinetics of the reaction

$$(DMSO)_2FePc + 2im \rightleftharpoons (im)_2FePc + 2DMSO \quad (15)$$

have been studied. It was observed that the substitution of the first DMSO molecule is the rate-limiting stage and that even at a high imidazole concentration the reaction is of second order[205].

The reactions of FePc with tri-n-butyl phosphite [$P(OBu)_3$] and tri-n-butylphosphine (PBu_3) have been reported[206]. The reaction products are low-spin bi-ligand extracomplexes. The kinetics of the substitution reaction

$$[\{P(OBu)_3\}_2FePc] + 2PBu_3 \rightarrow (PBu_3)_2FePc + 2P(OBu)_3 \quad (16)$$

have been investigated. The rate of elimination of $P(OBu)_3$ from $[P(OBu)_3]_2FePc$ is 5000 times greater than the rate of elimination of imidazole from $(im)_2FePc$. Schweigart[206] attributes this finding to the greater *trans*-effect of $P(OBu)_3$ compared with imidazole on the grounds that the substitution of $P(OBu)_3$ by imidazole leads to $[P(OBu)_3](im)FePc$.

The kinetics of the substitution of chlorine by the OH^- group in dichlorosilicon-phthalocyanine have been investigated[207]:

$$Cl_2SiPc(solid) + 2OH^- \rightarrow (HO)_2SiPc(solid). \quad (17)$$

The rate constant for the substitution reaction in 0.1M NaOH solution is 6×10^{-6} s^{-1}, $E = 15.6$ kcal mol^{-1}, and $\Delta S = -19$ e.u. It is suggested that the low rates of substitution of chlorine in the extracomplex of silicon-phthalocyanine are due to the sharp decrease of the positive charge on the silicon atom owing to the strong coordinate σ-bond and the reverse dative Si ← N π-bond. The latter is formed by filling the vacant d_π orbital of silicon with the p_z electrons of chlorine, which reduces sharply the tendency of the Si atom towards nucleophilic substitution reactions.

There have been several studies on the kinetics of the substitution of extraligands in extracomplexes of cobalt[124,208,209]. The conclusions reached do not differ fundamentally from those described above. Reactions involving the substitution of extraligands in extracomplexes of manganese have been described in detail in Boucher's review[210].

Thus the above data show that numerous studies, usually isolated and scattered, have been devoted to the kinetics of the substitution of extraligands in extracomplexes of porphyrins. Large-scale systematic investigations are as yet lacking; the need for such investigations is entirely evident.

VI. THERMODYNAMICS OF THE EXTRACOORDINATION REACTION

The extracoordination reaction in solution

$$MP + L_n \rightleftarrows (L)_n MP \quad (18)$$

is as a rule investigated by electronic absorption and emission spectroscopy. It is readily reversible, which makes it possible to displace the equilibrium in the required direction by a moderate alteration of the concentration of the extraligand, the nature of the solvent, and temperature. Studies on stability are usually carried out by the isothermal saturation method. There have been investigations[211,212] in which the thermodynamic parameters of reaction (18) were determined calorimetrically.

The methods for the calculation of the constants do not differ from those generally adopted for the determination of the stepwise stability constants of the usual complexes[213]. The method proposed by Miller and Dorough[130] is most frequently used. The number of added ligands is found as described by Bent and French[214] and from the decrease of weight on heating the extracomplex *in vacuo*[129]. The latter method is suitable only for porphyrin molecules resistant to thermal degradation. There exist data for the thermodynamic parameters of reaction (18) for the Fe^{2+}, Fe^{3+}, Co^{2+}, Co^{3+}, Zn^{2+}, Ni^{2+}, Hg^{2+}, Cd^{2+}, Cu^{2+}, Mn^{2+}, Mg^{2+}, and VO^{2+} complexes of porphyrins with a large number of extraligands of different types.

One of the first studies[130] was devoted to pyridine complexes in benzene. The stability of pyridine complexes of metalloporphyrins is due to a number of factors, which have been examined[1]. According to the published[130] stability constants K_S, the monoligand extracomplexes of porphyrins can be arranged in the sequence Zn > Cd > Hg > VO. The pyridine complex of VO-porphyrin with H_2TPP has also been

included in this sequence[153], but we were unable to find its stability constant K_S in the literature. It follows from the above data[130] that the hydrogenation of the porphyrin ring leads to appreciable stabilisation of the pyridine complexes of Mg- and Zn-porphyrins; only Mg-porphyrins form a relatively stable dipyridine complex[130]. It has been shown that zinc also forms bi-ligand extracomplexes of a similar type with certain extraligands[215,216]. Baker et al.[5] observed the formation of a dipiperidine complex of Ni-mesoporphyrin and a monopiperidine copper complex. The influence of the nature of the extraligand on the stability of the extracomplexes has been examined in several studies[6,125,129,217-218].

Table 4 presents the logarithms of the stability constants of the monoligand extracomplex of chlorophyll a (MgChl) in benzene[6]. The constants were estimated from the fluorescence intensity, which increases as the extraligand is added to the chlorophyll solution in absolutely dry benzene. The stability of the extracomplexes is associated with the increase of the electron-donating capacity of the ligand. It is noteworthy that the data in Table 4 do not reflect the true stability constants, since the development of fluorescence need not be caused solely by the deaggregation of the associated chlorophyll species due to extracoordination. However, these data do reflect correctly the sequence in the variation of stability. The complexity of the phenomenon may be caused by the operation of several mechanisms of the formation and decomposition of the MgChl associated species[1]. Table 6 shows that the Mg atom in MgChl coordinates oxygen and nitrogen-containing ligands equally effectively.

Table 4. The stability constants of monoligand extracomplexes of chlorophyll *a* in benzene (6).

Extraligand	$\lg K_S$	Extraligand	$\lg K_S$
Dimethylaniline	1.0	Quinoline	4.1
Phenol	1.2	Benzylamine	4.4
Aniline	1.7	Water	4.5
n-Octyl alcohol	3.7	n-Heptylamine	5.2
Benzyl alcohol	3.5		

The formation of complexes of various substituted pyridines with Fe-porphyrins has been investigated[6]. It has been pointed out[129] that the stability constants K_S vary in inverse proportion to the basicity of the extraligand. It has been observed that there is only a tendency towards an increase of stability with decrease of the basicity of the extraligand, but a rigorous correlation has not been found. This complex dependence reflects the fact that the stability of the extracomplexes of iron-porphyrins is determined both by σ- and π-binding of the ligands. The data obtained have been discussed by Falk[6], who notes, in particular, the influence of steric factors on the binding of certain substituted pyridines by the central atom, which may be non-axial.

The stability constants K_S of 4-substituted pyridine complexes of MgDP have been published[129] and a correlation has been observed between the basicity of the substituted pyridine and the stability of the extracomplex. Analogous relations have been observed for ZnTPP, CdTPP, and HgTPP [217] as well as ZnTPP and NiTPP in $CHCl_3$ and benzene[218]. A correlation was observed in the above studies between K_S and the Hammett constants. This type of correlation has also been established for CoPP.[125]

An attempt has been made[129] to find a relation between the stability of the pyridine extracomplexes of Mg-porphyrin and the structure of the porphyrin molecule (Table 5). Table 5 lists the thermodynamic parameters of the reaction

$$(py)MgP + py \rightleftharpoons (py)_2MgP. \quad (19)$$

A difference has been observed between the equilibrium constants, but nothing definite has been established concerning the problem of the influence of the structure of the porphyrin molecule on extracoordination. The estimate of the error of the thermodynamic parameters obtained, quoted by Storm et al.[129], shows that the values of ΔH and ΔS for reaction (19), involving different porphyrins, are probably within the limits of experimental error. The influence of the porphyrin structure on the addition of the second extraligand is slight, owing to the weakness of the LMP—L coordination interaction. It is seen in relation to 2,4-dinitrodeuteroporphyrin[129] that even the introduction of two nitro-groups causes little change in K_2 and ΔH.

Table 5. Thermodynamic parameters of reaction (9) in 2,6-lutidine.

Deuteroporphyrin IX d.m.e.	0.228	0.85	3.89	16

* Here d.m.e. = dimethyl ester [and m.m.e. = monomethyl ester].

A weak dependence of the thermodynamic parameters of extracoordination to zinc-porphyrins on the porphyrin structure has been observed in a study of the equilibrium in the extracoordination of DMSO [215,216,219]. The addition of DMSO to the zinc complexes takes place stepwise:

$$ZnP + DMSO \rightleftharpoons (DMSO)ZnP; \quad (20)$$

$$(DMSO)ZnP + DMSO \rightleftharpoons (DMSO)_2ZnP. \quad (21)$$

The nature of the plots of the absorbance A against c_0^L (the concentration of the extraligand) (Fig.3) is the same for all the complexes investigated. The first DMSO molecule adds in the DMSO concentration range up to 1.3×10^{-3} M and the second molecule adds on further increase of the ligand concentration. The number of added extraligands (n) in solution has been determined by the Bent—French method[214].

However, one should note that $n = 1$ has been found in a series of studies[130,218,220-221] of the extracoordination to Zn-porphyrins using several extraligands; this is probably due to the inadequate number of experimental points over a wide range of concentrations.

The influence of the structure of the porphyrin molecule on the thermodynamic parameters of the extracoordination reaction has been investigated by Walker et al.[222], who published data for a series of Ni^{2+} and VO^{2+} complexes of *p*- and

m-derivatives of tetraphenylporphin; unfortunately, complete thermodynamic characteristics have been published only for two porphyrins. The second equilibrium constants in the reaction of piperidine with nickel-tetraphenylporphyrin[222] indicate a significant influence of the substituents in the phenyl residues of tetraphenylporphin on the K_S for the extracomplexes of the Ni^{2+} compound. The authors[222] note that the extent of this influence depends on the d_π electrons in the central atom: it is greater for $Ni^{2+}(d^8)$ than for $VO^{2+}(d^1)$. The observation of a correlation between K_S and the Hammett and Taft constants led the authors[222] to the conclusion that there exists a moderate conjugation between the phenyl residues and the macroring. They believe that the roles of the conjugation and inductive effects for *para*-substituted tetraphenylporphins are approximately the same; for *meta*-substituted tetraphenylporphins, the inductive effect predominates.

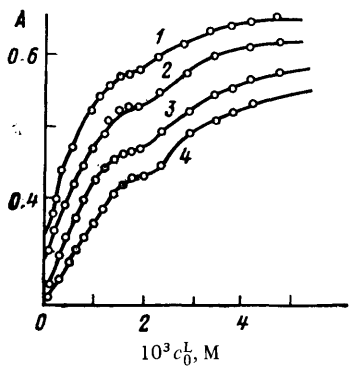

Figure 3. Dependence of A on c_0^L for (DMSO)ZnTPP at different temperatures (°C): *1*) 15; *2*) 25; *3*) 35; *4*) 45.

It is noteworthy that the conclusion that there is conjugation between the macroring and the benzene rings in tetraphenylporphyrins is based on shaky foundations. It can be regarded as premature, since it has not been confirmed by either spectroscopic or kinetic data[1]. The increase of the equilibrium constant K_2 for the binding of piperidine by nickel-tetraphenylporphyrins with enhancement of the electron-accepting properties of *para*-substituents ($NO_2 > CN > OCOCH_3 > Cl$—Table 10) can be readily accounted for by the increase of the effective charge on the nickel atom as a result of the weakening of the σ-donor properties of the corresponding tetraphenylporphin derivatives, which is caused by the inductive effect of the $-C_6H_4X$ groups in the molecule.

One must note that well-founded conclusions concerning the influence of the molecular structure of metalloporphyrins on the nature of their interaction with extraligands and other types of mutual influence of atoms in metalloporphyrins cannot be reached on the basis of the constants for the addition (particularly the second constants!) of extraligands in the absence of reliable numerical data for the entropies and enthalpies of extracoordination.

In their reaction with piperidine, the VO^{2+} complexes are less sensitive to the nature of the substituent in the benzene ring of the tetraphenylporphin[222]. They form only "monoligand" extracomplexes. The location of the vanadium atom outside the molecular plane leads to a change in the degree of overlap of its *d* orbitals with the π orbitals of the porphyrin, which the authors[223] believe to cause a decrease of the "sensitivity" of vanadium-porphyrins to the nature of the substituents in the benzene rings. Furthermore, nickel is capable of back π-bonding (interaction of d_π orbitals with the π^* orbitals of the porphyrin). On the other hand, in the case of V^{4+} its single *d* electron is located in the d_{xy} orbital[224,225] and cannot form a stable bond with the π^* orbitals of the porphyrin ring.

The hypothesis of the authors of an interesting and on the whole useful study[222] concerning the identical degrees of solvation of the complex in the extracoordination process appears doubtful; for example, the quantitative data obtained in our laboratory reveal a significant dependent of ΔH_{solv} on the structure of the porphyrin[219].

The thermodynamic parameters of the formation of extracomplexes of ZnTPP with tetramethylthiourea, tetramethylurea, and triphenylphosphine in benzene have been determined[221]. The increase of ΔH (kcal mol^{-1}) has been observed in the sequence S (−5.6) > O(−6.5) > P(−7.7). The methods of calculation of the equilibrium constant for the extracoordination reaction were critically analysed in the same study[221] and preference was given to the method of Rose and Drago[226].

The equilibrium constants for the coordination of the vanadyl group VO to porphyrins of different structure have been published[223,227,228] (Table 6). Unfortunately the lack of thermodynamic parameters hinders the analysis of the data obtained, which are of considerable interest.

Table 6. The stability constants of monopyridine extracomplexes at 25 °C in $CHCl_3$.

* Solvent—dioxan.

The use of vanadyl complexes of porphyrins is of interest in connection with the presence of the =O group in a single extraposition and also in connection with the possibility of the formation of the "monoligand" complex only. The dependence of K_S on the nature of functional substituents can be clearly traced in a series of porphyrins (Table 6). Electron-donating substituents (in H_2AEP and H_2MP) increase the electron density of the vanadyl ion and K_S is reduced compared with H_2DP. Electron-accepting substituents (in H_2PP, H_2HP, H_2TpyP, $H_2DP(Br)_2$, etc.) lead to an increase of K_S owing to the decrease of the electron density at the vanadyl ion.

Several studies have been published in recent years on the thermodynamics of extracoordination (Table 7) to various Co-porphyrins[121,123,125,161,209,229-231]. A sharp increase of the number of similar studies is apparently to be expected in the immediate future in connection with the extremely interesting ability of the cobalt complexes to combine reversibly with oxygen when the molecule contains another, particularly polymeric, extraligand. The main difficulty arising in the joint examination of these studies is in the first place the different reaction conditions. The marked dependence of the results of the measurements on the nature of the solvent

observed in a number of investigations[117,149,211,218] necessitates caution in comparing data obtained in different solvents.

The results of a study of cobalt-protoporphyrin are of considerable interest[121,125]. The extracoordination of eight extraligands to CoPP was investigated[125] (Table 12). It was established that there is no simple correlation between any thermodynamic parameter and the basicity of the ligand. The thermodynamic parameters of the addition of the second extraligand were not obtained, because the authors[125] were quite rightly afraid of introducing large amounts of extraligand capable of altering the structure of the solvent; the accompanying effects can lead to an erroneous interpretation of the results. The data obtained[125] showed that DMF is a "poore" extraligand for Co-porphyrins and can be used as a "neutral" solvent for the investigation of the extracoordination. The substitution of an alkyl in pyridine has only a slight influence on the complex-forming capacity of the latter, while the CN group causes a sharp decrease of this capacity. A similar behaviour was observed for imidazole, which is a somewhat weaker extraligand for the cobalt complex than pyridine. The identical complex-forming properties of pyridine and piperidine clearly indicate a major role of both σ- and π-binding in extracoordination to cobalt-porphyrins.

The interaction of CoTPP(p-CH_3)$_4$ with a series of π-acceptors and π-donors has been investigated by NMR in $CDCl_3$ (Table 7).[161] Thermodynamic parameters have been found for trinitrobenzene as an extraligand. The virtually complete identity of the K_S for acceptors and donors indicates, according to La Mar and Viscio[150], the ability of the metalloporphyrin to exhibit the properties of a π-acceptor or a π-donor, depending on the conditions. However, this claim does not appear convincing in the absence of fundamental thermodynamic characteristics of the extracoordination reaction.

It has been found[123] for phosphorus-, sulphur-, and arsenic-containing extraligands that the coordinating capacity diminishes in the sequence (Table 11) $P(C_4H_9)_3 \gg P(OCH_3)_3 > P(C_6H_5)_3 > S(CH_3)_2 > As(C_6H_5)_3$, while the K_S are correlated with the pK_B of the ligands. These results led the authors to the conclusion that σ-binding plays a dominant role for the above extraligands, i.e. the role of the d_π–d_π interaction between cobalt and the above ligands is small.

The formation of complexes by CoTPP and CoTPP(p-OCH_3)$_4$ with DMSO in CCl_4 has been investigated by a spectroscopic method[230]. It was established that two DMSO molecules are added in steps (Table 7). CoTPP and CoTPP(p-OCH_3)$_4$ were found to exhibit a significant difference in the extracoordination reaction with DMSO. The introduction of p-OCH_3 groups into the benzene rings alters significantly the enthalpy (increases it by 6 kcal) and entropy (increases it by 17 e.u.) of coordination. The stability constant then decreases almost by a factor of 2.5 (Table 7); the authors[230] attributed its decrease to the increase of the electron density in the porphyrin macroring and at the cobalt atom as a consequence of the greater electron-donating capacity of the $C_6H_4OCH_3$ group compared with the phenyl residue. However, this conclusion was reached without taking into account solvation and steric factors and cannot be regarded as well-founded. It is seen from the data in Table 7 how much the entropy can change in isotypical extracoordination reactions.

Interesting data on the extracoordination of nitrogen-containing heterocycles to ethoxycarbonyl derivatives of porphin (ECP complexes of Co^{2+} and Cu^{2+}) were obtained by Ginzburg et al.[231] Extracoordination is accompanied by a decrease of entropy from −7 to −12 e.u. (for pyridine), depending on the number of ethoxycarbonyl groups (Table 7). The enthalpy then decreases from −7 to −9 kcal mol^{-1}. Somewhat greater values of ΔH, ΔS, and stability constants are characteristic of the extracoordination of piperidine. Overall, the extracoordination to the ECP complexes of cobalt resembles that for CoTPP.

In contrast to the cobalt complexes, the copper complexes of ethoxycarbonylporphyrins coordinate pyridine and piperidine with greater difficulty (the values of lgK_S decrease from 0.2 to −0.8) and with smaller entropy changes (−ΔS changes from 16 to 24 e.u. for piperidine).[231] There is virtually no dependence on the number of ethoxycarbonyl groups.

The most numerous data on extracoordination have been obtained for iron-porphyrins. Studies on iron-porphyrins have been carried out for more than three decades. The first extensive investigations of the interaction of ferrous

and ferric protoporphyrins with hydroxide and cyanide ions as well as pyridine were carried out by Schak and Clark[232] in 1947.

The iron atom in porphyrin complexes has an especially high affinity of anions of the type of CN^-. The oxidation state of the initial iron atom plays a significant role in this. Thus the overall equilibrium constant for the addition of ligands in the extracomplexes $[(CN)_2FePP]^-$ is $K_{1,2} = 1.4 \times 10^{12}$, while the constant for $[(CN)_2FePP]^{2-}$ is $K_{1,2} = 8 \times 10^9$. At the same time the equilibrium constants for the dipyridine complex are $K_1 = 0.8$ and $K_2 = 5 \times 10^7$. The relative affinities of different types of ligands for Fe^{3+}-porphyrins vary in the sequence $CN^- \gg$ imidazoles $\gg$ pyridine[233], which indicates a significant role for π-binding of the extraligands by the iron-porphyrin. The accumulation of the negative charge in the porphyrin macroring then leads to destabilisation of the system. Anionic complexes are therefore more stable for Fe^{3+}-porphyrins and less stable for Fe^{2+}-porphyrins[1].

Since the mobility of *d* electrons diminishes with increase of the positive charge on the central atom, ferric porphyrins become less capable, relative to ferrous porphyrins, of the extracoordination of molecules (of the type of pyridine and oxygen) tending to form dative π-bonds. This ability is restored when one of the extraligands is a powerful electron pair donor. Mixed complexes of Fe^{3+}-porphyrins with cyano- and pyridine groups are therefore more stable than the corresponding Fe^{2+}-porphyrins {$K_{1,2} = 3.6 \times 10^{12}$ for (CN)(py)FePP and $K_{1,2} = 8 \times 10^{10}$ for $[(CN)(py)FePP]^-$ have been found}. Mixed π-ligands then entail a significant gain of the free energy ΔG compared with homogeneous ligands (2py, $2CN^-$).[1]

The central atoms in ferric and ferrous porphyrins exhibit a high affinity also in relation to other nitrogen-containing molecules as well as oxygen containing ligands (H_2O, OH^-, H_2O_2, CO, O_2). The study of the extracomplexes with H_2O and OH^- in an alkaline medium is greatly complicated by the dimerisation and greater degree of aggregation of metalloporphyrins, which makes the measurement of the thermodynamic parameters of extracoordination significantly more difficult[1]. This can probably explain the fact that only the values of K_S have been determined in the majority of studies on extracoordination equilibria[28,29,116,162,234].

An interesting study[117] was devoted to the thermodynamics of the extracoordination of pyridine and its substituted derivatives to the Fe^{2+}-porphyrins of the protoporphyrin group in benzene:

$$FeP + 2L \rightleftharpoons (L)_2FeP. \qquad (22)$$

The authors investigated the dependence of the thermodynamic parameters obtained from spectroscopic data on the nature of the extraligand and the structure of the porphyrin.

Thermodynamic parameters for the iron(II) and iron(III) complexes of 2,4-dicysteine-substituted mesoporphyrin have been determined spectrophotometrically[235] in aqueous solutions. In contrast to other ligands, extracoordination takes place stepwise in this instance. In terms of the changes in ΔH for the Fe^{3+}- and Fe^{2+}-porphyrins, the extraligands investigated can be arranged in the following sequences: CN^- > histidine > imidazole > pyridine; CN^- > pyridine > histidine > imidazole > *N*-acetyl-DL-methionine. The thermodynamic parameters of extracoordination obtained have been attributed[235] to changes in the degree of solvation of iron-porphyrin in a hydrophobic cavity within the haemoprotein and to the influence of the conformational changes in the aminoacid residues. This hypothesis has been confirmed by the values of ΔH and ΔS obtained for ferric cytochrome *c*.[236,237]

The stability of haemin in the extracoordination of histidine and imidazole to a series of peptides has been studied[28,29]. The values of $\lg K$ varied with the nature of the atomic environment of histidine in the range from 7.41 to 8.32. The authors[28] arrived at the interesting conclusion that the stability of the extracomplexes depends to a large extent on steric factors, i.e. on the bulk of the groups adjoining histidine. It has also been established[29] that the stability of the extracomplexes and the strength of the coordinate bond depend on the nature of the porphyrin system (on the basicity of the porphyrin) and the length and degree of branching of the extraligand chain. Table 8 indicates the limits of the variation of $\lg K_S$ for Fe-porphyrins with a series of histidine-containing ligands. Regrettably, these interesting communications[28,29] do not contain complete thermodynamic data.

Table 8. The limits of variation of $\lg K_S$ for the extracoordination of histidine-containing extraligands to Fe-porphyrins in chloroform[28,29].

MP	$\overset{+}{F}$eAEP(III)	$\overset{+}{F}$eMP d.m.e.	$\overset{+}{F}$eDP	$\overset{+}{F}$ePP d.m.e.	$\overset{+}{F}$ePP
$\lg K_S$	6.0—6.08	6.2—6.84	6.70—7.10	7.08—7.32	8.25—8.54

Among studies devoted to Fe-porphyrins, mention should also be made of that of Anusiem and Lumry[212], primarily because of the choice of the method of investigation: the thermodynamic parameters of the extracoordination of the azide ion to ferric haemoglobin were determined calorimetrically in water over a wide range of pH. The electrochemical reduction of the iron(III) complexes of a series of porphyrins has been investigated by cyclic voltammetry in the presence of substituted bipyridyls[238], forming extracomplexes with $K_S = 1 \times 10^{-3}$ for $\overset{+}{F}$eOAEP and 1.8×10^4 for $\overset{+}{F}$eTPP.

The influence of trinitrobenzene as a π-acceptor on the thermodynamics of the extracoordination of *N*-methylimidazole to (Cl)FeTPP was studied by ^1H NMR;[163] the authors suggest that trinitrobenzene can interact with the central atom and can reduce the affinity of the complex for a second *N*-methylimidazole molecule. The stability constants K_{S2} for the reaction of Fe-tetra-arylporphyrins with substituted imidazole and pyridine were determined by NMR [164] and the formation of a biligand extracomplex was discovered. Comparison of the observed values with the K_S obtained previously from electronic spectra led the authors[164] to the conclusion that the NMR method is suitable (subject to some limitations) for the determination of the stability constants and the stoichiometry of the formation of extracomplexes. It is noteworthy that, in the determination of the temperature variation of K_S by NMR, a large error is introduced due to the characteristics of the method, in the first place and high concentration of the metalloporphyrin, which causes its association.

It follows from Table 9 [164] that the influence of substituents in the *para*-position of the benzene rings of FeTPP on the values of K_{S2} is very insignificant. The nature of the halogen in the porphyrin complex has a significant influence on the values of K_{S2}; here K_{S2} varies in the sequence I > Br $\gg$ Cl. The dependence of K_{S2} on the nature of the extraligand is not correlated with pK_B. The authors[164] obtained the approximate value $\Delta H \approx -26$ kcal mol^{-1} for 1-methylimidazole and $\Delta H = -15$ kcal mol^{-1} for 1-methylbenzimidazole. The

authors explain the difference between the ΔH by steric factors preventing extracoordination, i.e.the maximum overlap of the iron and nitrogen orbitals in the case of 1-methylbenzimidazole.

Table 9. The influence of the structure of the porphyrin and of the halogen on the K_{S2} of the iron-porphyrin complexes with 1-methylimidazole in $CDCl_3$ at 25 °C.[164]

Complex	K_{S2}
(Cl)FeTPP(*p*-OCH_3)	$(4.0\pm0.6)\cdot10^3$
(Cl)FeTPP(*p*-CH_3)	$(3.0\pm0.4)\cdot10^3$
(Cl)FeTPP	$(1.4\pm0.7)\cdot10^3$
(Cl)FeTPP(*p*-Cl)	$(0.65\pm0.10)\cdot10^3$
(Br)FeTPP(*p*-CH_3)	$\gtrsim10^6$
(I)FeTPP(*p*-CH_3)	$>10^6$
(Cl)FeOAEP	$(0.66\pm0.13)\cdot10^3$
(Cl)FeTPP*	25 ± 5
(Br)FeTPP(*p*-CH_3)	$(2.4\pm0.5)\cdot10^3$

*Temperature—45 °C; extraligand—1-methylbenzimidazole.

Analysis of the thermodynamic parameters of the extracoordination reactions is frequently difficult, because the values of K_S, ΔH, and ΔS were obtained under non-standard conditions. The choice of solvent exerts an extremely powerful influence on the parameters of the extracoordination reaction, which has been shown in relation to Fe-porphyrins[211,239] and Cu-porphyrins[231].

Cole et al.[211] justly assumed that, when account is taken of the solvation, the extracoordination equation must be written as follows:

$$Fe^{2+}PP\,(solv)_{n_1} + 2\,L\,(solv)_{n_2} \rightleftarrows (L)_2Fe^{2+}PP\,(solv)_{n_3} + n\,(solv)\ . \qquad (23)$$

It follows from Eqn.(23) that the nature of the interaction of the metalloporphyrin can be significantly different in solvents of different types. It has been shown for the reaction of FePP with pyridine and its substituted derivatives in various solvents that the changes in ΔH and ΔS on changing the solvent can be significantly greater than the changes introduced by the structure of the porphyrin and the nature of the extraligand. Depending on the nature of the solvent, the entropies vary by up to 50 e.u. and the ΔH by up to 17 kcal mol^{-1}.

Cole et al.[211] examined the possible energy contributions to ΔH: (1) the formation of a π-complex; (2) the formation of a charge-transfer complex; (3) hydrophobic interaction; (4) dipole orientation forces; (5) dispersion interaction; (6) hydrogen bonding. The postulated contributions to ΔS are due to the following factors: (1) hindered rotation of the molecule owing to the attachment of a second ligand; (2) restricted rotation due to the π-bonding of iron to the extraligand; (3) the formation of a solvate complex, etc. Analogous results have been obtained[231] for copper complexes of ethoxycarbonylporphyrins in reactions with nitrogen-containing heterocycles.

In a study of the interaction of (Cl)FeTPP with imidazole, Kedderis et al.[239] obtained virtually identical values of all the thermodynamic parameters for a series of solvents (acetone, chloroform, methylene chloride, and ethyl acetate). The errors quoted for the values of ΔH are puzzling; whereas the errors in ΔS are consistent with the accuracy of the method, those for ΔH are too low (for the spectrophotometric method) at least by a factor of 10. The authors[239] were unable to explain the discrepancy with the results of Cole et al., but they attempted to relate it to the different charges on Fe in the systems investigated[211,239].

Comparison of the data in Table 9 [239] leads to the conclusion that the free energies of extracoordination reactions involving iron-porphyrins and their enthalpy and entropy components depend markedly on the structure of the porphyrin and the nature of the extraligand and the solvent. Low values of ΔH show that they include the effects of the solvation of the reactant in extracoordination to Fe-porphyrins, which can be inferred from the very low entropies. These data demonstrate clearly the important role of the π-bonding of extraligands to $Fe^{2+}P$.

The data presented for the thermodynamics of extracoordination demonstrate a series of interesting and practically important relations for the metalloporphyrins of certain metals. However, the lack of systematic studies (in which one or several variables are varied, while keeping a number of factors constant) rules out the possibility of wider generalisations and conclusions necessary for the solution of problems of technical and enzyme catalysis on metalloporphyrins.

---oOo---

It follows from the data presented that there exist factors favouring the formation of stable extracomplexes of metalloporphyrins. They include the following: (1) the increase of the effective positive charge on the central metal atom; the σ-electron-donating and π-electron-accepting capacities of the ligands; the latter is important in extracoordination to low-spin metal complexes whose *d* orbital is more than half-filled; (3) the weakening of the solvation and acid–base interaction of the extraligands with the medium; (4) the decrease of the steric hindrance to extracoordination from the side of the extraligand. The last condition is particularly significant for the formation of biligand extracomplexes of porphyrins.

Polyimides Based on Heterocyclic Monomers

A.L.Rusanov and I.Batirov

Data concerning polyimide macromolecules, containing various heterocyclic fragments in their main chains, which are obtained using monomers incorporating the required heterocyclic systems as well as groups capable of giving rise to such systems, are discussed.
The bibliography includes 189 references.

I. INTRODUCTION

The vigorous development of new branches of engineering, aviation, cosmonautics, electronics, etc. has imposed increasingly stringent requirements on the polymers employed in these fields. In particular, increasing operating temperatures of polymeric materials are needed—polymeric materials capable of being used at temperatures of 300 °C and above are nowadays of considerable interest. The solution of the problem of synthesising such materials is related directly to the development of new thermostable polymers.

Studies during the last 20 years in the USSR and abroad led to the creation of a series of polymers with high thermal and deformation-strengths[1-9]. In the various examples of new thermostable polymers polyheteroarylenes—polymers containing aromatic heterocycles in the main chains of the macromolecules—are most widely used[1-15]. Despite the great structural variety of the polyheteroarylenes synthesised, only a few of them have emerged from the area of academic research and have acquired industrial importance. Such polyheteroarylenes include in the first place aromatic polyimides—the product of the interaction of aromatic diamines with aromatic tetracarboxylic acid dianhydrides[16,17]:

Polyimides are usually synthesised by a two-stage process involving the interaction of the initial compounds in polar organic solvents, the conversion of the resulting pre-polymers [polyamidoacids (PAA), also referred to as poly(*o*-carboxy)amides] into articles, and thermal cyclisation of the PAA resulting in the formation of articles made of insoluble and infusible polyimides which do not require additional treatment. This method of synthesis of polyimides, which permits the formation of articles from polymers of different structure, has become very common and is nowadays used widely to make polyimide films, fibres, binders, adhesives, varnish coatings, plastics, etc.[16,17].

The majority of the polyimides known at present have been obtained from carbocyclic aromatic monomers, but in recent years polyimides based on heterocyclic monomers have attracted the attention of investigators to an increasing extent.

The great variety of the known heterocycles led to the possibility of formulating completely different projects designed to modify the properties of polyimides:

1. The introduction of highly condensed heterocyclic fragments permitted an increase in the thermal stability and heat resistance of the polyimides.

2. Heterocycles containing bulky side groups have been introduced in order to make polyimides soluble in organic solvents[18-21].

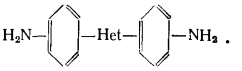
3. The high resistance of the majority of aromatic heterocycles to hydrolysis and the action of nucleophiles compared with imide rings has made it possible to use heterocyclic monomers with a comparatively high molecular weight, which reduced the content of imide rings per unit molecular weight of the polymer, increasing the hydrolytic stability of the polyimides.

Naturally, not every task enumerated above was solved to an equal extent, because all the approaches indicated are formal; nevertheless, definite successes have been achieved in the solution of these problems.

Heterocycles can be introduced into polyimides by employing monomers containing the required heterocycles and also monomers containing groups capable of giving rise to the required heterocyclic systems. Each of these methods has a number of advantages and disadvantages and merits separate consideration.

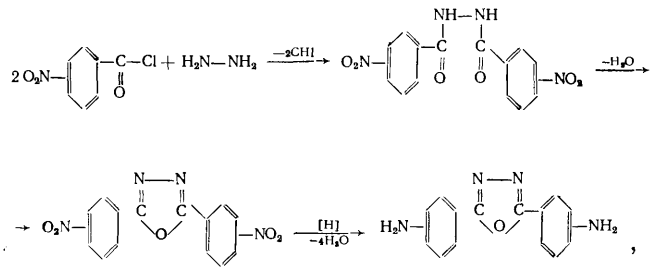
II. POLYIMIDES BASED ON MONOMERS CONTAINING THE REQUIRED HETEROCYCLIC SYSTEMS

The synthesis of polyimides using monomers containing particular aromatic heterocycles has a significant advantage over the synthesis based on monomers containing groups capable of giving rise to the corresponding heterocyclic systems, which arises because imidisation processes, i.e. cyclisation processes with formation of an imide ring, proceed under milder conditions than the processes leading to the formation of other heterocyclic systems. As a result, this procedure can yield polymers with a higher degree of cyclisation[22,23], i.e. with a less heterounit structure[24-28], which makes it possible to achieve more fully the properties designed into polymers of this type.



The heterocyclic monomers employed in most studies are isotypical products obtained as a result of complex reactions. This is true also of heterocyclic diamines, particularly of diamines containing azole and benzazole rings, which are synthesised by reactions widely used in the chemistry of polyazoles and polybenzazoles[29-34].

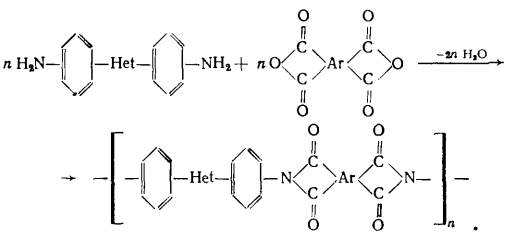
The simplest diamines containing azole rings are of the type



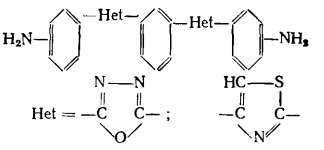
$$H_2N—Het—NH_2 ,$$

some of which (Het = 1,3,4-oxazole, 1,2,4-triazole, 1,3,4-thiadiazole, etc.) have attracted the attention of investigators[35,36] because of the possibility of synthesising from them (by reaction with the dianhydride of pyrazine-2,3,5,6-tetracarboxylic acid) polyimides without hydrogen atoms and possessing as a result an increased thermal stability[37-39]. However, according to some workers[35,36], the low basicity of diamines of this type and the tendency of pyrazine-2,3,5,6-tetracarboxylic acid to decarboxylate precluded the realisation of this possibility. The polyimides obtained had low molecular weights and contained a considerable number of amide fragments formed as a result of the decarboxylation of the PAA; it is noteworthy that these data[35,36] conflict with others[37-39].

More unambiguous results were obtained using azole-containing diamines of the type

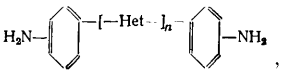


In the series of compounds of this kind the isomeric 2,5-(diaminophenyl)-1,3,4-oxadiazoles[40-47] and 3,5-(diaminophenyl)-4-phenyl-1,3,4-triazoles[41-45,47] are the most common. The former, obtained in accordance with the scheme



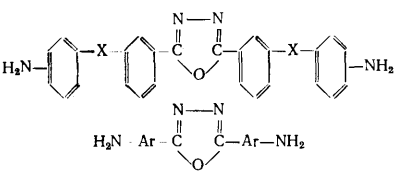
have been most widely used because of their availability.

Poly(*o*-carboxy)amides, the thermal cyclodehydration of which led to polyimides containing 1,3,4-oxadiazole rings, have been synthesised by the reaction of the above diamines with the dianhydrides of aromatic tetracarboxylic acids[41-49]:



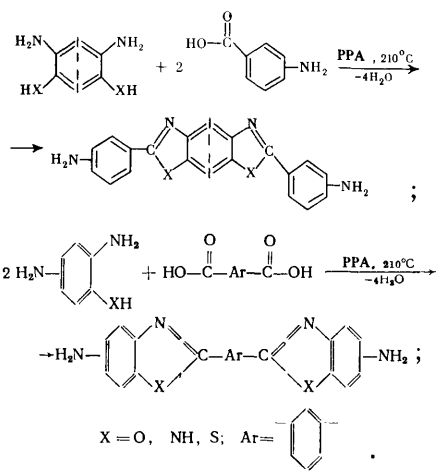
The authors of the above studies do not present data on the basicity of the diamines employed, but the viscosities of the fore-polymers ($\eta_{log} = 1.0-2.0$) indicate a high reactivity of the compounds used. The high molecular weights of the resulting PAA made it possible to obtain from them strong films and fibres, the thermal imidisation of which led to products insoluble in organic solvents and having melting points (485–520 °C) close to the temperatures of the onset of the degradation of these polymers (500–520°).

Polymers of analogous structure, characterised by the same set of properties, have been obtained by a number of other workers[50-52]. The same group of investigators achieved the synthesis of aromatic diamines containing 1,3,4-oxadiazole[51] and thiazole rings[4,45,47] and having the general formula

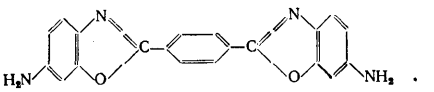


as well as polyimides based on them. Since such diamines are less readily available than di(aminophenyl)-1,3,4-oxadiazoles and the polymers based on them do not have appreciable advantages over the polyimides based on 2,5-(diaminophenyl)-1,3,4-oxadiazoles, these studies were not developed further.

Various modifications of the structure of diamines containing 1,3,4-oxadiazole rings have been carried out in studies[50-52] in which diamines of the following type were synthesised:



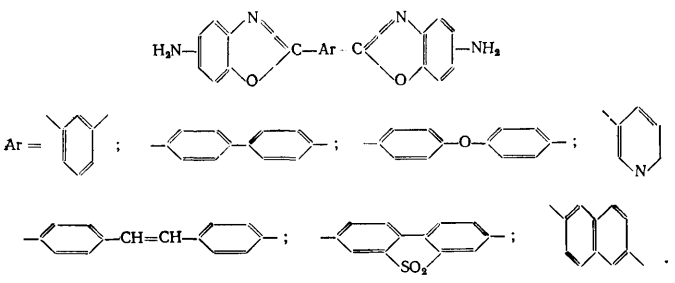
where $n = 2$ or 3 and Het = 1,3,4-oxadiazole or another heterocycle and



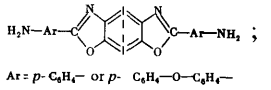
where Ar = naphthyl or a substituted phenyl group and X = O, S, or CH_2. Polyimides based on these diamines were also obtained.

A number of diamines containing benzazole rings were synthesised together with the azole-containing diamines with a symmetrical structure enumerated above. Among these compounds, symmetrical diamines formed in accordance with one

of the following schemes[40,53-59] in polyphosphoric acid (PPA) have come to be most widely used:

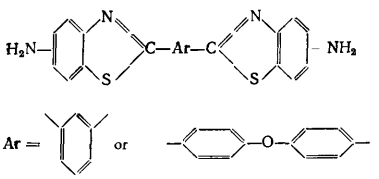


These reactions are employed successfully for the synthesis of diamines containing all three types of the most common benzazole rings—benzoxazole, benzimidazole, and benzothiazole, but, in the series of monomers synthesised, only 2,2-phenylenebis(5-aminobenzoxazole) is promising according to a number of investigators[60]:



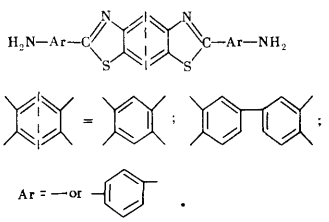
The interaction of this diamine with tetracarboxylic acid dianhydrides under the conditions of a two-phase process yielded high-molecular-weight (the viscosity of the solution of the fore-polymers was $\eta_{log} = 1.24-1.50$) polybenzoxoxazole imides, which can be made into strong elastic films and fibres, best results being obtained when the dianhydride of benzophenone-3,3',4,4'-tetracarboxylic acid is used[22,46,61]. The polymers obtained had high melting points (560–570 °C) and high temperatures for the onset of degradation in the range 560–595 °C (DTGA†, N_2, $\Delta T = 15$ K min^{-1}).

Polymers having comparable thermal characteristics have been obtained on the basis of a series of other benzoxazole-containing diamines having the general formula



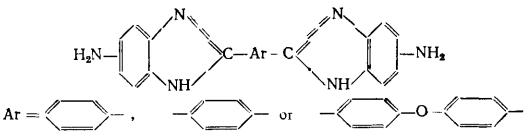
† DTGA = differential thermogravimetric analysis (Ed. of Translation).

Symmetrical benzoxazole-containing diamines derived from bis(*o*-aminophenols) and having the general formula

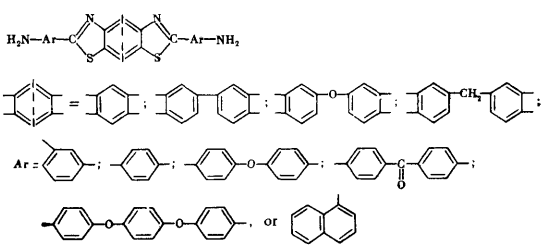


have been used successfully by a number of investigators[22,62-68] to obtain polyimides differing slightly in their characteristics from the polymers discussed above.

Compounds containing benzothiazole rings are much less readily available than the benzoxazole-containing diamines. Compounds of this type, having the general formula



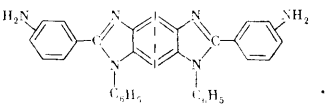
were used by Preston and coworkers[22,46,60] to obtain polyimides on the basis of pyromellitic and benzophenone-3,3',4,4'-tetracarboxylic acids. According to Korshak and Maksimov[69], an appreciable increase in the thermal stability of the systems under consideration might have been expected following the introduction of the benzothiazole ring into the main chains of the macromolecules, but the benzothiazole-containing polyimides did not in fact differ from their benzoxazole-containing analogues[22] and benzothiazole-containing diamines having the above structure have not therefore been widely used in the synthesis of polyimides.



All the above considerations are valid also for benzothiazole-containing diamines having the general formula[22,61,70]

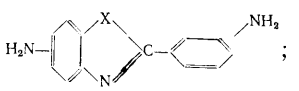
In the series of benzazole-containing aromatic diamines compounds containing benzimidazole rings have attracted most attention. Diamines having the general formula

have been comparatively little used[50], while products based on bis(*o*-phenylenediamines) and having the general formula



have been used to synthesise polyimides by a number of Soviet and foreign investigators[44,45,47,49,55,57-59,68,71-74].

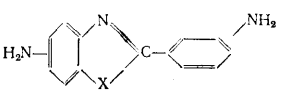
Detailed studies of polyimides based on benzimidazole-containing diamines[55] showed that, under the classical conditions of the two-stage synthesis of aromatic polyamides, i.e. when a solid dianhydride is added to a solution of the diamine, high-molecular-weight film-forming PAA are formed ($\eta_{log} = 0.48-3.3$). Thermal imidisation of the resulting films at 280–320 °C yielded polyimide films with comparatively high tensile strengths (1225–1900 kgf cm^{-2}), but giving rise to small elongations on rupture (1.5–3.8%).



The study of the thermal stability of the polyimides by the DTGA method (air, $\Delta T = 5$ K min^{-1}) showed that weight losses corresponding to 15% are observed in the temperature range 620–630 °C; however, one should note that such high values of the thermal characteristics of benzimidazole-containing polyimides conflict with the results of Preston and Black[45].

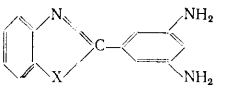
Korshak et al.[75] synthesised a series of symmetrical diamines containing *N*-phenylbenzimidazole rings:

The interaction of these diamines with the dianhydrides of aromatic tetracarboxylic acids under the conditions of one- and two-stage polycyclocondensation yielded polyimides containing *N*-phenylbenzimidazole rings[76–79]. In contrast to the polyimides examined above, which are obtained from diamines containing unsubstituted benzimidazole rings, these polymers are in most cases soluble in organic solvents, which makes it possible to make them into articles in the final stage. The polymers obtained in a number of investigations[76–79] exhibited high viscosities ($\eta_{int} = 0.2-2.00$), which makes it possible to convert them into films with interesting electrophysical properties[76]. The polyimides synthesised under the conditions of DTGA ($\Delta T = 5$ K min^{-1}, air) lost 10% of their weight at 520–550 °C and had softening temperatures between 300° and 540 °C depending on their structure.



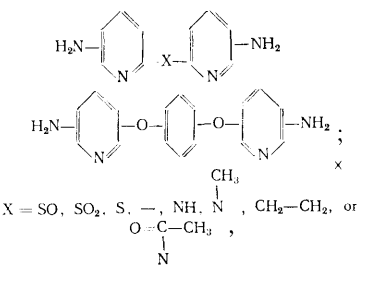
Together with symmetrical benzazole-containing diamines, asymmetric diamines containing benzoxazole, benzimidazole, and benzothiazole rings have attracted much attention[51,80,81]:

X = O; S; NH .



The interaction of asymmetric diamines with the dianhydrides of tetracarboxylic acids under the conditions of a two-stage process gave rise to benzazole-containing polyimides[51,74,80,82–86].

In contrast to the symmetrical diamines examined above, compounds having the general formula

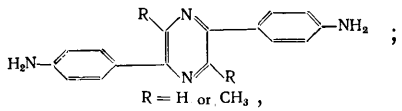


contain amino-groups with non-equivalent nucleophilic properties, which makes it possible to obtain from them polymers with a limited degree of order[82]; the few data available in the literature[87] indicate a comparatively low basicity of such compounds, which is nevertheless sufficient to obtain from them PAA with fairly high viscosity characteristics ($\eta_{log} = 0.6-2.5$). Despite their lack of order, the final structures—polyimides containing benzazole rings—hardly differ from polyimides obtained from symmetrical benzazole-containing diamines: their melting points are in the range 540–575 °C and the temperatures of the onset of their decomposition are in the range 525–575 °C (DTGA, N_2, $\Delta T = 15$ K min^{-1}).

Polyimides based on the benzazole-containing symmetrical and asymmetric diamines listed above contain benzazole heterocycles in the main macromolecular chains, which gives rise to the insolubility of the majority of these polyimides in organic solvents. When the benzazole ring is introduced as a side group into the macromolecular chains of polyimides, which is achieved by employing diamines with a specific structure[51,88]

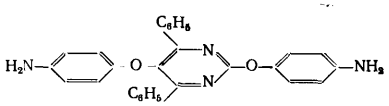
conditions are created for imparting solubility in organic solvents to polyimides, although information concerning the realisation of this possibility is not available in the literature.

Somewhat less systematic studies have been made on polyimides based on diamines containing six-membered aromatic heterocycles. The simplest diamine of this kind—2,6-diaminopyridine—attracted the attention of a number of research groups[35,36,89–91], but the weak nucleophilic properties of the second amino-group ($pK_{a2} = 1.67$) in this compound constituted a serious obstacle to the synthesis of high-molecular-weight polymers from it. Monomers of the bipyridyl series having the structural formulae



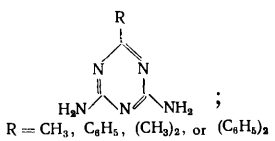
X = SO, SO_2, S, —, NH, N, CH_2—CH_2, or O=C—CH_3 ,
N

which are less readily available but are more nucleophilic compared with 2,6-diaminopyridine, have been used to synthesise polyimides[92,93]. Because of the relatively high nucleophilicities of diamines of this kind, they can interact with the dianhydrides of pyromellitic and benzophenone-3,3′,4,4′-tetracarboxylic acids under the conditions of low-temperature polycondensation in dimethyl sulphoxide (DMSO) to yield high-molecular-weight (η_{log} up to 2.26) film-forming PAA, whose cyclisation *in vacuo* at 190–200 °C for 2–2.5 h yielded polyimides.



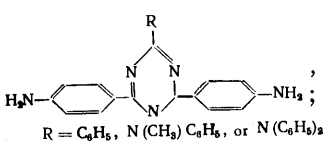
It is of interest to note that, according to the data of Kurita and Williams[92], the introduction of heteroatoms into aromatic rings increases significantly the solubility of polyimides in organic solvents. Polyimides obtained from bipyridyl-containing diamines, incorporating as groups X sulphide, sulphoxide, or sulphone fragments, are readily soluble in dimethylacetamide (DMAA) and *m*-cresol. On the other hand, the thermal stability of polyimides of this kind is appreciably lower than that of their carbocyclic analogues. It may be that these properties of bipyridyl-containing polyimides are due to the unduly mild imidisation conditions, which do not lead to a high degree of completion of this process.

A series of pyrazine-containing diamines having the general formula



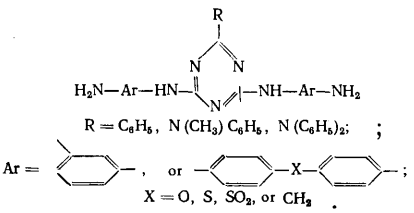
as well as isomeric compounds have been used[94] to obtain polyimides under the conditions of two-stage polycyclocondensation. PAA with logarithmic viscosities in the range 0.22–1.86 have been obtained in DMAA at 20 °C, those with highest molecular weights exhibiting film-forming properties. The thermal imidisation of these products at 250–270 °C led to the formation of polyimides soluble only in sulphuric and methanesulphonic acids and suffering a 5% weight loss (DTGA, N_2, $\Delta T = 5$ K min^{-1}) at 485–595 °C.

Polyimides soluble in amide solvents have been obtained[95] by the interaction of 2,5-bis(4-amino phenoxy)-4,6-diphenylpyrimidine



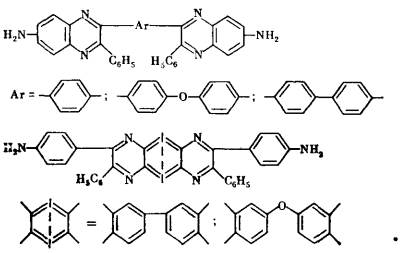
with a series of dianhydrides of aromatic tetracarboxylic acids. The polyimides synthesised exhibit an anomalous thermal stability—their decomposition temperatures do not exceed 310 °C.

Polyimides based on diamines containing symmetrical triazine rings have attracted much attention. The simplest compounds of this series—products having the general formula



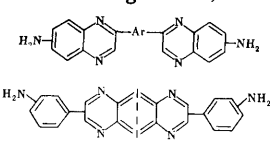
have a weakly nucleophilic second amino-group according to some data[35,36] ($pK_{a2} = 1.90$), which prevents the formation of polyamides with high molecular weights on the basis of these compounds[35,36,96,97]. Nevertheless, polyimides have been successfully synthesised as a result of the two-stage interaction of the above compounds with the dianhydrides of pyromellitic and benzophenone-3,3′,4,4′-tetracarboxylic acids, yielding polyimides which began to lose structure, according to DTGA data[96], at 390–420 °C in air and at 440–460 °C in N_2.

Triazine-containing diamines having the general formula



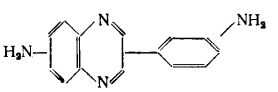
have been used[98,99] to obtain high-molecular-weight film-forming polyimides with high thermal stability and fire resistance.

Analogous results have been achieved by a number of investigators[100–103], who synthesised polyimides from diamines having the general formulae



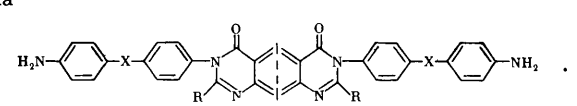
The presence of bulky side groups in the triazine-containing diamines discussed above makes it possible, in principle, to render the final polyimide soluble in organic solvents; however, only some of the investigators concerned have reported the realisation of this possibility[96,100,101].

A much more unambiguous influence of the introduction of a bulky substituent into the diamine molecule on the solubility of polyimides has been traced in the studies by Korshak and coworkers[104–107], who synthesised polyimides from diamines containing quinoxaline rings[107–109]:

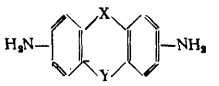


The large set of diamines makes it possible to vary the properties of the final polyamides[105], which combine a high thermal stability with solubility in *m*-cresol, *N*-methyl-2-pyrrolidinone, and the 3 : 1 tetrachloroethane–phenol mixture.

The decisive influence of the phenyl substituent on the solubility of polyimides has been confirmed by the finding that polyimides based on symmetrical diamines containing unsubstituted quinoxaline rings[110,111],



as well as asymmetric diamines having the general formula[77, 110–112]

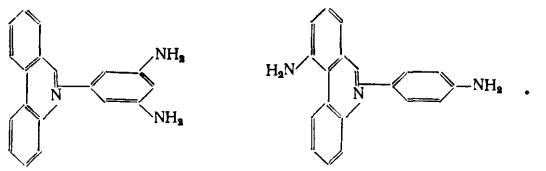


are insoluble in organic solvents.

Results confirming the increased solubility of the final polyimides under the influence of side groups in the diamines have been obtained also using as the starting compounds quinazolinone-containing diamines[113–115] having the general formula

The polyimides obtained from such diamines dissolved in *m*-cresol and exhibited thermal characteristics comparable to those of the usual polyamides.

In the series of diamines containing highly condensed heterocycles (tricyclic and tetracyclic systems) compounds having the general formula

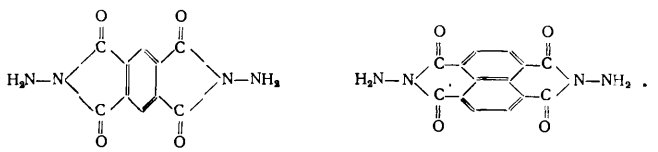


X = O, Y = S, SO_2, or CO; X = SO_2, Y = O, S, SO_2, or CH_2

have attracted most attention. The interaction of diaminophenoxathiine with the dianhydrides of aromatic tetracarboxylic acids yielded polyimides[116-118] with a higher thermal stability than that of polyimides based on di(4-aminophenyl) ether[118].

Polypyromellitimides[119], obtained using 2,7-diaminoxanthone as the initial compound, undergo an appreciable weight loss (under the conditions of DTGA) only at 500 °C.

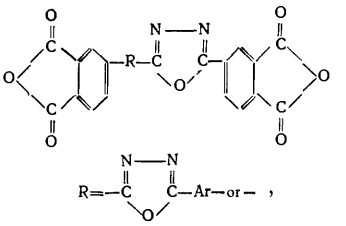
High-molecular-weight film-forming polyimides have been synthesised by the two-stage interaction of diaminocyclosulphones with the dianhydrides of aromatic tetracarboxylic acids[120].



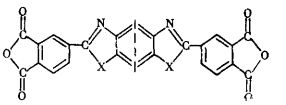
Polyimides based on aromatic diamines containing phenanthridine rings also exhibit high thermal characteristics[121-134]:

It is of interest to note that polyimides obtained from phenanthridine-containing diamines did not dissolve in organic solvents regardless of the location of the heterocycle (in the main chain or as a side group) and of the method of imidisation.

The attempts to employ 3,9-acridine as the monomer[91] did not lead to high-molecular-weight polymers as a consequence of the weak nucleophilic properties of this monomer.

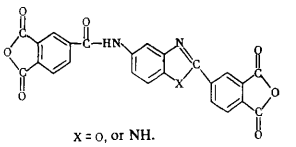


In the series of heterocyclic diamines monomers containing imide rings were of special interest, since one may hope to obtain, by an appropriate selection of those compounds, macromolecules consisting of imide rings only. An attempt to create such structures was undertaken by Dine-Hart[125], who used *N,N'*-diamino(pyromellitimide) and *N,N'*-diamino-(tetracarboxynaphthalene diimide):



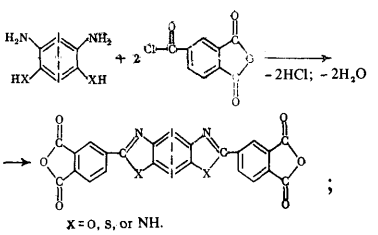
The attempt to synthesise high-molecular-weight polyimides was unsuccessful. Even the feasibility of the above solution of the problem of synthesising high-molecular-weight polymers of this type, capable of being worked, is controversial in view of the weakness of the N–N bonds in the main macromolecular chains.

The structural set of dianhydrides of heterocyclic aromatic tetracarboxylic acids, used to synthesise polyimides, is much smaller than the set of heterocyclic diamines discussed above. In the series of dianhydrides of the tetracarboxylic acids derived from the simplest aromatic heterocycles the dianhydrides of furan-2,3,4,5-tetracarboxylic[126] and thiophen-2,3,4,5-tetracarboxylic acids[100,126,132] attracted attention, but the properties of polyimides based on these monomers have not been studied in detail.



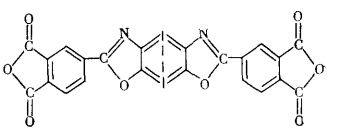
In the series of azole-containing dianhydrides of tetracarboxylic acids only 1,3,4-oxadiazole-containing compounds having the formula[44,133-135]

and in the series of benzazole-containing dianhydrides compounds having the general formulae[136-139]



X = O, S, or NH;

X = O, or NH.



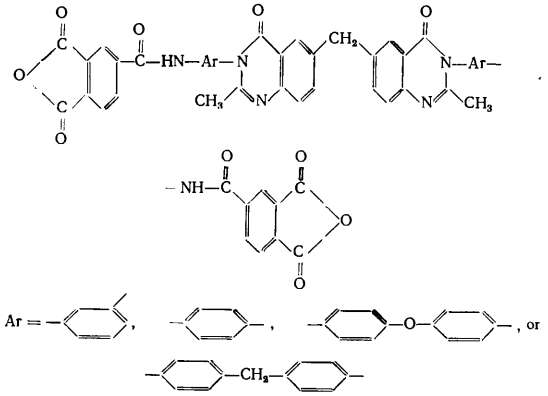
have been widely used.

In most cases, the dianhydrides of tetracarboxylic acids containing azole and benzazole heterocycles can be obtained by the interaction of tetra- or tri-functional nucleophiles with the 4-chloroformyl derivatives of phthalic anhydride[140]:

X = O, S, or NH.

Dianhydrides containing benzoxazole rings[140], particularly compounds having the formula

have been most widely used. Their interactions with di(4-aminophenyl) ether under the conditions of low-temperature polycondensation yielded PAA with $\eta_{log} \geq 0.4$; poly(benzoxazole-imides), obtained by the heat treatment of PAA at 200–380 °C *in vacuo* for 1 h, exhibited high thermal characteristics.

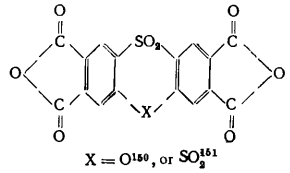


Poly(benzoxazole-imide) films are very strong and last for a long time at 300 °C. The study of the resistance of poly(benzoxazole-imides) to alkalis showed that, on being boiled for 30 min in 10% aqueous solutions of sodium hydroxide, the films hardly changed, their chemical stability being much superior to that of the usual polyimide films.

In the series of dianhydrides of aromatic heterocyclic tetracarboxylic acids containing six-membered heterocycles detailed studies have been made of the dianhydrides of pyridine-2,3,5,6-tetracarboxylic[126,141] and pyrazine-2,3,5,6-tetracarboxylic acids[35-39,90,100,126,127-131,142-146]. The second

dianhydride attracted the attention of numerous investigators in view of the possibility, in principle, of using it to synthesise hydrogen-free polyimides, although, as stated previously, the problem of applying this idea in practice remains open.

The dianhydrides of tetracarboxylic acids containing substituted symmetrical triazine rings[99,147,148] have been used, by analogy with diamines containing identical fragments, to synthesise polyimides soluble in organic solvents[99,147,148].



The interaction of the dianhydrides of tetracarboxylic acids containing substituted quinazolinone rings and amide groups and having the general formula

with various aromatic diamines yielded polyimides incorporating amide and quinazolinone groups[149]; these polyimides are soluble in *m*-cresol, but their thermal stability is somewhat lower than that of polyimides obtained from quinazolinone-containing diamines[113-115].

A number of investigators[150,151] attempted to synthesise polyimides from the dianhydrides of tetracarboxylic acids containing highly condensed (tricyclic and polycyclic) heterocycles. The aim in introducing such fragments was usually to increase the thermal stability and heat resistance of the polyimides, which, however, is not achieved in all cases.

When initial compounds having the general formula

were used under the conditions of two-stage processes, polyimides giving rise to strong elastic films and stable up to 440 °C were obtained according to patent data[151].

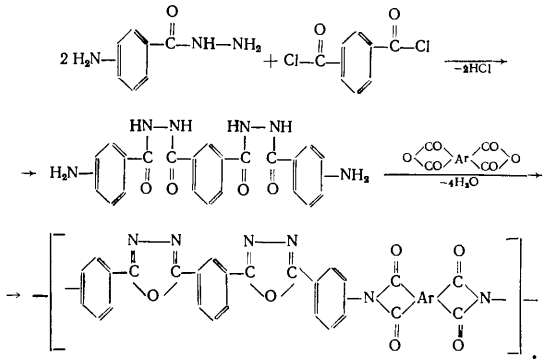
The syntheses of polymers based on monomers containing heterocyclic units discussed above have not only significant advantages (see above) but also suffer from considerable disadvantages. The latter include the following.

(1) An increased rigidity of the PAA containing certain (particularly highly condensed) heterocycles, which precludes a high solubility of these fore-polymers and a high capacity for being worked into articles.

(2) The reduced reactivity of certain monomers containing aromatic heterocyclic units, which precludes the synthesis of high-molecular-weight polymeric products from these compounds.

In view of the above disadvantages of the method, investigators became interested in monomers, containing groups leading to the final heterocyclic systems, as the initial compounds for the synthesis of polyimides.

III. POLYIMIDES BASED ON MONOMERS CONTAINING GROUPS CAPABLE OF GIVING RISE TO THE REQUIRED HETEROCYCLIC SYSTEMS

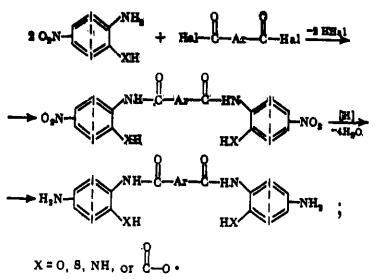


The simplest diamines of this type, containing groups capable of forming the 1,3,4-oxadiazole rings[51] (hydrazide fragments), have been obtained by the interaction of isomeric nitrobenzoic acid chlorides and hydrazides with subsequent mild reduction of the di(nitroaryl)hydrazides.

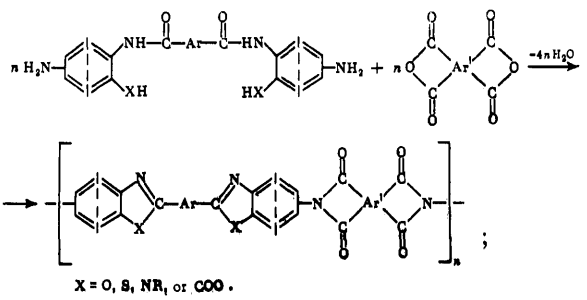
When the hydrazides of nitrobenzoic acids and the dichlorides of aromatic dicarboxylic acids were used as the comonomers (with subsequent reduction of the nitro-groups), diamines containing two hydrazide groups were obtained[51,152]. The reaction of these compounds with the dianhydrides of pyromellitic and benzophenone-3,3',4,4'-tetracarboxylic acids in DMAA led to the synthesis of PAA containing hydrazide groups, the heat treatment of which led to ordered copolyimido-1,3,4-oxadiazoles[51,152].

Solutions of PAA containing hydrazide fragments had fairly high viscosities ($\eta_{log} = 0.53-0.92$ dl g^{-1}), which made it possible to obtain strong and elastic films from them. Heating the polymers to 150 °C led to their imidisation and the formation of polyimidohydrazides, while heating to higher temperatures (up to 325 °C) resulted in the cyclisation of the hydrazide fragments to the 1,3,4-oxadiazole groups.

A study of the thermal stability of simple copoly(oxadiazole-imides) containing two imide groups per oxadiazole group showed that it is comparable to that of the best polyimide structures, while polymers with the same numbers of imide and oxadiazole rings proved to be less thermally stable[51].

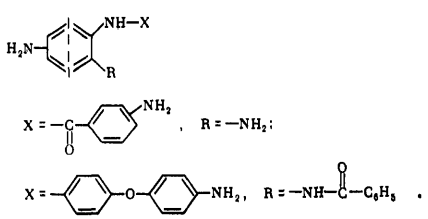


Preston chose a somewhat different approach to the synthesis of diamines containing hydrazide fragments[153,154] using the difference between the nucleophilic reactivities of the amino- and hydrazide groups of *p*-aminobenzohydrazide. The diamines obtained in this way, containing two hydrazide fragments, can be made to react directly with the dianhydride of a tetracarboxylic acid:



The structure of the resulting diamines is in this case less unambiguous than in the case where nitro-derivatives are used—apparently the interaction of the acid chloride groups can involve partially also the amino-group of the aminobenzohydrazide with formation of amide and amidoimide fragments in the final copolyimido-1,3,4-oxadiazoles, which have an unfavourable effect on various properties of these systems.

A general approach to the synthesis of symmetrical diamines incorporating groups capable of giving rise to benzazole and benzoxazinone rings has been proposed by Kurihara et al.,[155] who achieved the interaction of nitroamines containing various substituents with the dihalides of dicarboxylic acids and the



reduction of the resulting dinitro-compounds to the corresponding diamines:

The interaction of the resulting diamines with the dianhydrides of tetracarboxylic acids and subsequent heat treatment of the resulting pre-polymers led to the synthesis of polyimides containing benzoxazole, benzothiazole, benzimidazole, and benzoxazinone rings in the main chains of the macromolecules:

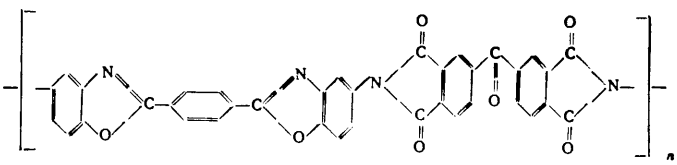
Asymmetric diamines containing groups capable of giving rise to benzimidazole and *N*-phenylbenzimidazole rings have been used[156-158] to synthesise film- and fibre-forming polyimides containing imidazole and *N*-phenylbenzimidazole rings:

A much larger number of studies were designed to synthesise polyimides from the dianhydrides of tetracarboxylic acids containing groups capable of giving rise to various, primarily azole and benzazole, heterocycles. The extensive development of such investigations was due mainly to the fact that the initial compounds can be obtained by a standard procedure involving the interaction of various tetrafunctional compounds, which have found applications in the chemistry of polyazoles[29-32], with the 4-chloroformyl derivatives of phthalic anhydride, which is a derivative of the readily available trimellitic acid[140].

Dianhydrides containing acylamidoxime fragments, capable of giving rise to 1,2,4-oxadiazole rings, have been obtained by the reaction of the bisamidoximes of dicarboxylic acids with the 4-chloroformyl derivatives of phthalic anhydride. The reaction of these compounds with aromatic diamines under the conditions of two-stage polycyclocondensation led to polyimides with 1,2,4-oxadiazole rings[135,160].

Polyimides containing isomeric 1,3,4-oxadiazole rings, whose thermal stability is higher than that of the compounds with 1,2,4-oxadiazole rings, have been obtained by the reaction of dicarboxylic acid dihydrazides with the 4-chloroformyl derivative of phthalic anhydride; the reaction of the dianhydrides containing hydrazide groups, obtained in this way, with diamines and the thermal cyclisation of the resulting copolyhydrazidoamidoacids[161] led to the synthesis of copolyimido-1,3,4-oxadiazoles.

A large series of studies were devoted to the synthesis of dianhydrides containing groups capable of giving rise to benzazole and benzoxazinone rings[162-166]. The interaction of these dianhydrides with aromatic diamines yielded high-molecular-weight (η_{log} up to 1.9) PAA containing groups capable of giving rise to benzazole and benzoxazinone rings; subsequent heat treatment at 250–400 °C converts these PAA into polyimides containing benzoxazole[137,162-175], benzothiazole[162-166,174], benzoxazinone[162-166,175], as well as unsubstituted[162-166,176,177] and *N*-substituted[178] benzimidazole rings.



The synthesis of poly(benzoxazoleimides) proceeds most smoothly owing to the ease of the selective acylation of bis(*o*-aminophenols) by the 4-chloroformyl derivative of phthalic anhydride, while the acylation of bis(*o*-phenylenediamines) and bis(*o*-aminothiophenols) by this compound is accompanied by side reactions and ultimately by gel formation. The more nearly ideal structure of poly(benzoxazoleimides) is responsible for their higher thermal characteristics compared with the remaining systems.

A number of studies were undertaken to synthesise copolymers from mixtures of traditional dianhydrides of aromatic tetracarboxylic acids with dianhydrides containing groups capable of giving rise to benzimidazole[179], benzothiazole[180], and benzoxazinone[181] rings.

The fact that almost all reactions using dianhydrides containing groups capable of forming azole, benzazole, and benzoxizinone rings have been carried out without isolating the dianhydrides from the reaction mixture merits attention; this approach is undoubtedly of considerable interest, since it makes it possible to eliminate the laborious and expensive processes involving the isolation and purification of the monomers and hence simplifies the technological synthesis of polymers and also reduces the cost of the latter. Evidently, this approach deserves the widest possible development, particularly in those cases where the syntheses of monomers proceed with a high selectivity and lead to homogeneous initial compounds and not mixtures of products containing various functional groups.

A critical examination of the foregoing data shows that the vast majority of studies on polyimides, obtained from heterocyclic monomers or monomers containing groups capable of giving rise to the required heterocycles, have been purely of their synthesis. Despite the large amount of evidence (particularly in patents) concerning the possibility of obtaining on the basis of polymers of this kind a wide range of materials for all purposes, specific data on the properties of the resulting articles are very few. The properties of materials obtained from polyimides containing azole and benzazole rings, introduced into these polymers as part of the initial diamines, have been examined in greatest detail. In particular, reinforced plastics, obtained using polyimides based on diamines containing 1,3,4-oxadiazole and benzimidazole rings, have been investigated in detail[182,183]. The properties of articles made from polyimides based on diamines and benzoxazole rings have been studied in even greater detail. In particular, fibres whose resistance to thermo-oxidative degradation is superior to that of the poly(*p,p'*-oxydiphenylenepyromellitimide) fibre[186] and the polypyromellitimide fibre based on 2,5-di(*p*-aminophenyl)-1,3,4-oxadiazole

have been obtained[184-189] from the polyimide

synthesised by the reaction of a benzoxazole-containing diamine with the dianhydride of benzophenone-3,3',4,4'-tetracarboxylic acid[187]; the copoly(benzoxazole-imide) fibres have a unique ability to retain acceptable strength characteristics up to temperatures of 500 °C.
